Metabolic Conversion of Fluorenone Oxime to Phenanthridinone by Hepatic Enzymes

YECHIEL GOLANDER and LARRY A. STERNSON ˣ

Received September 5, 1978, from the *Department of Pharmaceutical Chemistry, University of Kansas, Lawrence, KS 66045.* Accepted for publication December 18, 1978.

Abstract □ Fluorenone oxime is converted to phenanthridinone by enzymes present in rat liver homogenates. The reaction is analogous to the chemical Beckman rearrangement. The oxime–amide rearrangement enzyme is localized primarily in the microsomes, with some activity in the cytosol. The reaction requires reduced nicotinamide adenine dinucleotide phosphate and observes Michaelis–Menten kinetics. The reaction is relatively slow (V_{max} = 7.75 ± 2.01 nmoles of phenanthridinone formed/100 mg of liver/15 min), but the enzyme reaches maximum velocity at relatively low substrate concentrations (K_m = 3.90 ± 1.85 × 10^{-5} M). The reaction is strongly competitively inhibited by 1-decylimidazole (K_I = 3.75 ± 1.77 × 10^{-7} M) and inhibited to a lesser extent by the chelating agents bipyridyl (K_I = 1.33 ± 0.21 × 10^{-3} M) and ethylenediamine tetraacetate (K_I = 1.00 ± 0.28 × 10^{-3} M) and the sulfhydryl binding agent *p*-chloromercuribenzoate (K_I = 2.71 ± 0.07 × 10^{-4} M). Studies also suggest that the reaction mechanism does not involve initial enzymatic substrate esterification through acetylation, glucuronidation, phosphorylation, or sulfation.

Keyphrases □ Fluorenone oxime—metabolic conversion to phenanthridinone by hepatic enzymes, *in vitro*, kinetics □ Phenanthridinone—produced from fluorenone oxime by hepatic enzymes, *in vitro*, kinetics □ Enzymes, hepatic—conversion of fluorenone oxime to phenanthridinone, *in vitro*, kinetics

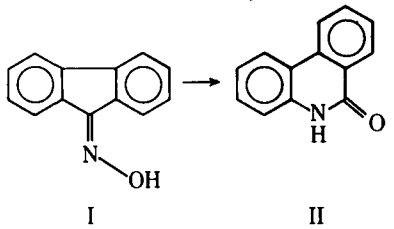
Oximes are metabolic products formed by liver microsomal oxidation of primary aliphatic amines (1, 2). Although these products were considered to be metabolically unreactive, they were susceptible to enzymatic reduction to the corresponding hydroxylamine and amine in several animal species (3, 4). Fluorenone oxime (I), when administered intravenously to rats, is converted (Scheme I) to phenanthridinone (II), which is subsequently excreted in the urine (5). The enzymes responsible for this transformation are localized primarily in the liver microsomes (6), with minor activity in the nuclear and mitochondrial fractions.

This report describes the enzymatic transformation kinetics and provides information to help characterize the oxime–amide rearrangement enzyme.

EXPERIMENTAL

Apparatus—High-performance liquid chromatography (HPLC) was performed on a component system[1], and analytes were detected with an absorbance detector operated at 254 nm.

Materials—Fluorenone oxime and phenanthridinone were synthesized by literature methods (7). Liver enzymes were prepared from male Sprague–Dawley rats, 200–250 g, as described previously (8).



I II

Scheme I

Enzymatic Assay—Incubation mixtures contained enzyme equivalent to 100 mg of liver, a reduced nicotinamide adenine dinucleotide phosphate (III)-generating system [nicotinamide adenine dinucleotide phosphate (1 μmole), glucose-6-phosphate (20 μmoles), glucose-6-phosphate dehydrogenase (1 unit), and magnesium chloride (100 μmoles)], fluorenone oxime, and phosphate buffer (0.05 M, pH 7.4) adjusted to a final volume of 5 ml.

Incubations were carried out for 15 min with agitation in a Dubnoff metabolic incubator at 37°. All reagents in the system used to generate III were in excess with respect to requirements for III during the entire incubation.

Analytical Methodology—Incubations were terminated by the addition of 10 ml of chloroform to the reaction mixture. The mixture was shaken for 20 min and centrifuged at 2500×*g*. The organic layer was recovered [extraction efficiency of II ≥98% (6)] and evaporated to dryness under nitrogen. The mixture was dissolved in 200 μl of dimethylformamide containing 20.8 nmoles of phenanthrene, present as an internal standard.

Aliquots (10 μl) of this mixture were analyzed by HPLC on a 4-mm o.d. × 30-cm column[2]. Components were separated using methanol–methylene chloride–water (60:5:35) as the mobile phase (flow rate of 2 ml/min). Under these conditions, the retention volumes (V_R) were: phenanthridinone, 7.1 ml; fluorenone oxime, 10.4 ml; and phenanthrene (added as internal standard), 26.7 ml. Quantitation of II was based on comparison of the peak height ratio (analyte–internal standard) with a standard curve prepared after analysis of liver homogenate samples containing known amounts of I and II in the 8.6 × 10^{-6}–1.4 × 10^{-4} M range. This response was related linearly to concentration, yielding the line $y = 0.05x - 0.005$ (zero-order correlation 0.99) after least-squares analysis.

Kinetic Measurement—The Michaelis constants (K_m) and the maximum velocity (V_{max}) for the conversion of I to II were determined from double-reciprocal (Lineweaver–Burk) plots of initial velocity against substrate concentration (9), which varied over the range of 62–1000 μM. The line of best fit was determined by least-squares regression analysis. In experiments to determine the effect of various chemicals on enzyme activity, the test compounds were added to the incubation mixture concurrently with the substrate (I). Microsomes isolated by centrifugation of the 9000×*g* supernate of liver homogenates at 105,000×*g* were not subjected to additional purification.

RESULTS AND DISCUSSION

A previous report (6) showed that the conversion of I to II in liver homogenates is an enzymatic process. Now it is shown that the major oxime–amide rearrangement enzyme responsible for the rearrangement of fluorenone oxime (present at concentrations of 10^{-4} M) is present in liver microsomes (6.04 ± 1.25 nmoles of phenanthridinone formed/100 mg of liver/15 min), with the cytosol exhibiting ~38% of this activity (2.32 ± 0.02 nmoles of phenanthridinone formed/100 mg of liver/15 min).

Minor activity was observed in nuclear and mitochondrial subcellular liver fractions. Repeated washings (six times) of the microsomal pellet (resuspending the pellet in the buffer and then centrifugating at 105,000×*g* for 45 min) caused no loss in enzyme activity, suggesting that the enzyme is bound relatively tightly to the membrane surface. Essentially no oxime–amide rearrangement was observed in the buffer used to wash the microsomal pellet.

Compound III was required as a cofactor for activity in both microsomes and cytosol (6). Neither oxidized nor reduced nicotinamide adenine dinucleotide nor oxidized nicotinamide adenine dinucleotide phosphate (NADP) was an effective cofactor for these enzymes. The role of III in

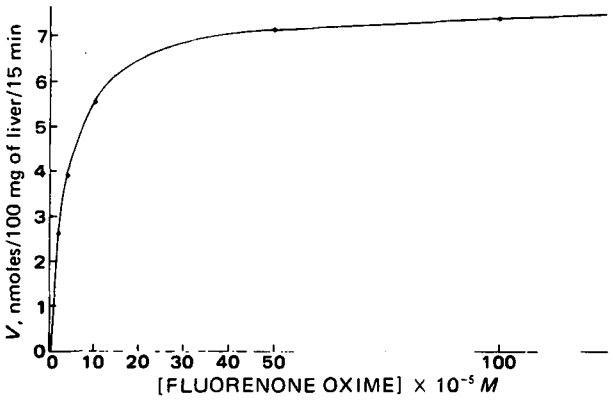

Figure 1—*Rate of fluorenone oxime rearrangement to phenanthridinone determined as a function of the substrate concentration.*

the transformation of I to II has not been elucidated. Conversion of I to II results in no net change in the oxidation state, so the involvement of III in a redox role is questionable.

Incubation of I with tritiated III resulted in the formation of II with no incorporation of tritium in the product. Compound III was consumed during both the microsomal- and cytosol-catalyzed rearrangement of I, as determined by monitoring the reaction spectrophotometrically at 340 nm. Although this result could suggest that the cofactor plays an electron-transfer role in the oxime–amide rearrangement enzyme-catalyzed reaction, the experiment was inconclusive because HPLC analysis of incubation mixtures showed that I was converted to products other than II (particularly in microsomes), and these transformations probably required III. This supposition is supported by the fact that III was consumed more rapidly than can be attributed solely to the enzymatic formation of II. Biotransformation of I occurred with III consumption, but its role in the reaction under study could not be segregated from the total substrate biodegradation.

Microsomal oxime–amide rearrangement enzyme-catalyzed reaction kinetics were determined by measuring the initial I–II conversion rate at substrate concentrations of 10^{-3}, 5×10^{-4}, 10^{-4}, 4×10^{-5}, and 2×10^{-5} *M*. Since microsomes were used without further purification, the observed K_m and K_i values may have been influenced by nonspecific substrate binding to proteins other than the oxime–amide rearrangement enzyme(s). Double-reciprocal plots of initial velocity data *versus* substrate concentration yielded the straight line $v^{-1} = 5.03 \times 10^{-6} S^{-1} + 0.13$ ($r = 0.99$). The plot linearity indicates Michaelis–Menten kinetics (10).

Values of K_m and V_{max} extracted from these plots were $3.90 \pm 1.85 \times 10^{-5}$ *M* and 7.75 ± 2.01 nmoles of II formed/100 mg of liver/15 min (for eight determinations), respectively. Therefore, the reaction was quite slow, but the enzyme reached maximum velocity at relatively low substrate concentrations. Figure 1 shows reaction rate as a function of substrate concentration.

The microsomal oxime–amide rearrangement enzyme system was further investigated by assessing the ability of certain compounds to inhibit the conversion of I to II. Three compounds that are structurally similar to I, carbazole, 2-nitrofluorene, and 9-aminofluorene, had no effect on the reaction in question when I was incubated with the microsomal system at a 10^{-4} *M* concentration and the potential inhibitors were present in a concentration of 10^{-7}, 10^{-6}, 10^{-5}, or 10^{-4} *M*. At substrate (I) concentrations of 10^{-4} *M*, ethyl 2,2-diphenylvalerate failed to inhibit the reaction when present at concentrations below 10^{-5} *M*; however, when this potential inhibitor was added at concentrations of 10^{-3} *M*, reaction was inhibited 62% during a 15-min incubation period.

N-Decylimidazole, a known inhibitor of microsomal mixed-function oxidases (11), was a potent competitive inhibitor of the microsomal oxime–amide rearrangement system (Table I), inhibiting the conversion of I to II by 77% when the substrate and inhibitor were present at concentrations of 10^{-4} and 10^{-3} *M*, respectively. However, cytochrome P-450 was not involved in the reaction since conversion of I to II was not effected by either carbon monoxide (6) or microsome preexposure to UV light. The imidazole inhibitory role in this reaction is, therefore, probably not that normally associated with this class of inhibitors.

Chelating agents bipyridyl and edetate sodium also inhibited the biotransformation of I to II (Table I), suggesting that metal ions may play a role in the enzymatic reaction. However, when the substrate was incubated with microsomes and III (*not* a reduced nicotinamide adenine dinucleotide phosphate-*generating* system but III itself), the rearrangement was not inhibited when magnesium ion was totally excluded from the incubation mixture. Thus, the observed inhibitory effects of chelating agents on the enzymatic I → II conversion apparently do not result from an inhibition of III formation (when an NADPH-generating system is used) due to complexation of the magnesium ion required for III formation.

Table I—Inhibition Constants for Various Compounds toward Microsomal Oxime–Amide Rearrangement Activity [a,b]

Inhibitor	Inhibitor Concentration, *M*	$K_I \pm SEM$[c], *M*
N-Decylimidazole	10^{-3}, 10^{-6}, 5×10^{-7}	$3.75 \pm 1.77 \times 10^{-7}$
Bipyridyl	10^{-3}	$1.33 \pm 0.21 \times 10^{-3}$
Edetate sodium	10^{-3}	$1.00 \pm 0.28 \times 10^{-3}$
p-Chloromercuribenzoate	10^{-3}	$2.71 \pm 0.07 \times 10^{-4}$

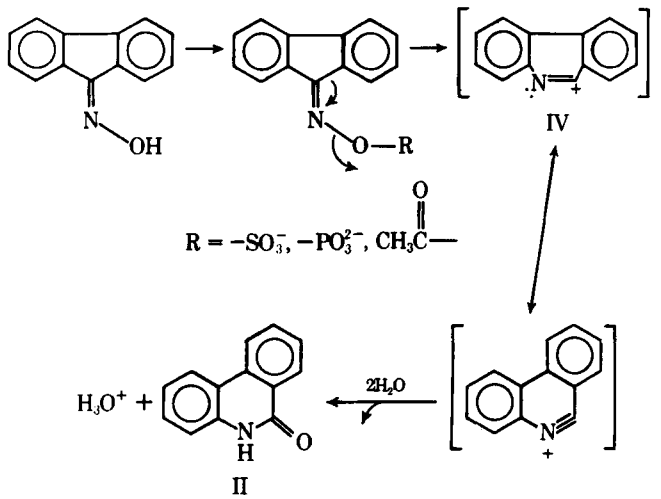
[a] Oxime–amide rearrangement activity assayed as described previously (6) using fluorenone oxime as the substrate. [b] Fluorenone oxime incubated at concentrations of 20, 40, 100, and 500 μ*M*. [c] Each inhibitor showed linear competitive kinetics, and inhibition constants were calculated from Lineweaver–Burke plots (9, 15).

Microsomal oxime–amide rearrangement enzymes also were sensitive to the sulfhydryl binding reagent *p*-chloromercuribenzoate; this reagent also competitively inhibited the rearrangement (Table I), suggesting the possible involvement of a thiol linkage in the transformation. Chelating agents and sulfhydryl binding agents rarely exhibit competitive kinetics with regard to reactions such as the one under investigation. No explanation is offered at this time for this observation.

Microsomal oxime–amide rearrangement activity also was studied as a function of pH. With a substrate concentration of 5×10^{-4} *M* ($13 K_m$), maximum activity was observed at pH 7.1 with diminished activity on either side of this maximum (Fig. 2) over the pH 6.0–8.2 range. All of the experiments in the study were carried out at pH 7.4 to compare oxime–amide rearrangement activity with other microsomal enzyme (mixed-function oxidase) processes acting on fluorenone oxime and to provide an environment for the microsomal suspension that was most similar to that encountered *in vivo*.

It was postulated (5, 6) that the role of the oxime–amide rearrangement enzyme may be to esterify the oxime, producing an intermediate with a high propensity for formation of a transitory nitrenium ion (IV), which undergoes facile rearrangement to yield the amide (II, Scheme II). This mechanism is identical with one that occurs during the Beckman rearrangement (12) of I to II. Four enzymatic esterifying systems were investigated as potential catalysts for the reaction: acetylation, glucuronidation, phosphorylation, and sulfation. Incubation of either microsomal or cytosol fractions with acetyl CoA (an acetylating substrate), uridinediphosphoglucuronic acid (a glucuronidation precursor), or adenosine triphosphate (a phosphorylating reagent) failed to facilitate the conversion of I to II.

The sulfation reaction was studied in greater detail because of its participation in the analogous enzymatic conversion of arylhydroxylamines to electrophilic intermediates (13). However, reaction of I (at levels of 10^{-4} *M*) with cytosol and/or microsomal homogenates to produce



Scheme II—Postulated mechanism for enzymatic transformation of fluorenone oxime to phenanthridinone.

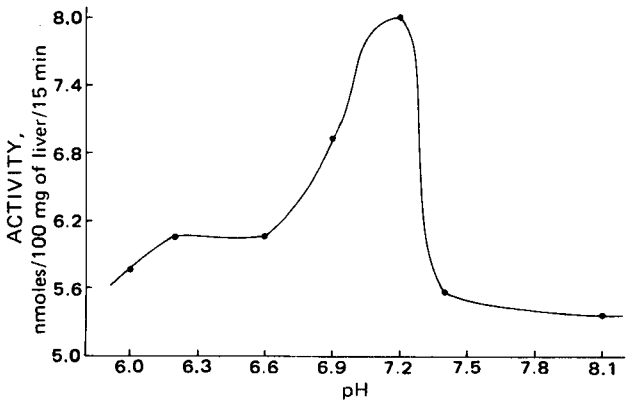


Figure 2—*Hepatic microsomal oxime-amide rearrangement enzyme activity toward fluorenone oxime determined as a function of pH. Each point is the average of six determinations.*

II was not stimulated by the addition of either inorganic sulfate (6.5×10^{-4} *M*) or adenosine triphosphate plus sulfate. Furthermore, the reaction was not inhibited by *p*-nitrophenol (1×10^{-4} *M*), a known consumer of sulfate (14) (and, therefore, a potential competitive inhibitor of the oxime-amide rearrangement system), or 3′,5′-adenosine diphosphate, another known sulfation inhibitor (14). These results suggest that enzymatic conversion of I to II does not involve oxime substrate esterification prior to rearrangement. The reaction mechanism remains a mystery but is being studied.

Stabilization of 5-Azacytidine by Nucleophilic Addition of Bisulfite Ion

DULAL C. CHATTERJI ˣ **and JOSEPH F. GALLELLI**

Received June 30, 1978, from the *Pharmaceutical Development Service, Pharmacy Department, The Clinical Center, National Institutes of Health, Bethesda, MD 20014.* Accepted for publication December 18, 1978.

Abstract □ 5-Azacytidine (I) stability was increased approximately 10-fold over its stability in water or lactated Ringer injection by the addition of excess sodium bisulfite and the maintenance of pH ~2.5. The increased stability in the presence of bisulfite at pH 2.5 was attributed to the addition of bisulfite across the 5–6 protonated imine bond of I, which prevented the hydrolytic attack on this labile double bond. However, above pH 4, bisulfite increased I degradation. At higher pH, the compound was no longer protonated and bisulfite did not form the stable addition product. The addition compound quickly decomposed above pH 6 to give back the parent compound and, thus, acted as a I prodrug. The intact drug remaining was assayed by high-pressure liquid chromatography (HPLC), and the reversibility of the bisulfite–I addition product above pH 6 was demonstrated by UV spectrophotometry and HPLC. The potential utility of the bisulfite–I addition product as a I prodrug in parenteral and possible oral dosage forms is discussed.

Keyphrases □ Azacytidine—prodrugs, sodium bisulfite, stabilization in aqueous solutions, effect of pH □ Sodium bisulfite—stabilization of azacytidine in aqueous solutions, effect of pH, prodrugs □ Prodrugs—azacytidine, stabilization by sodium bisulfite □ Antineoplastic agents—azacytidine, prodrugs, sodium bisulfite complex

The use of 5-azacytidine (I) in acute myelogenous leukemia (1–3) is often limited by severe and sometimes dose-limiting nausea and vomiting (4, 5). Although the GI toxicity can be controlled effectively by administering the drug as a slow infusion (6, 7), extreme drug instability (8–10) poses a serious problem. Even when I is infused in lactated Ringer injection, which provides optimum stability conditions for the drug at pH 6.4, ~10% of I is lost in 2 hr at room temperature (8).

BACKGROUND

Systematic kinetic studies on the I hydrolysis (8–10) revealed that hydrolysis proceeds by the classical acid-catalyzed hydration of the 5–6 imine double bond (Scheme I), followed by deamination to yield the formyl derivative, *N*-(formylamidino)-*N*-β-D-ribofuranosylurea (II).

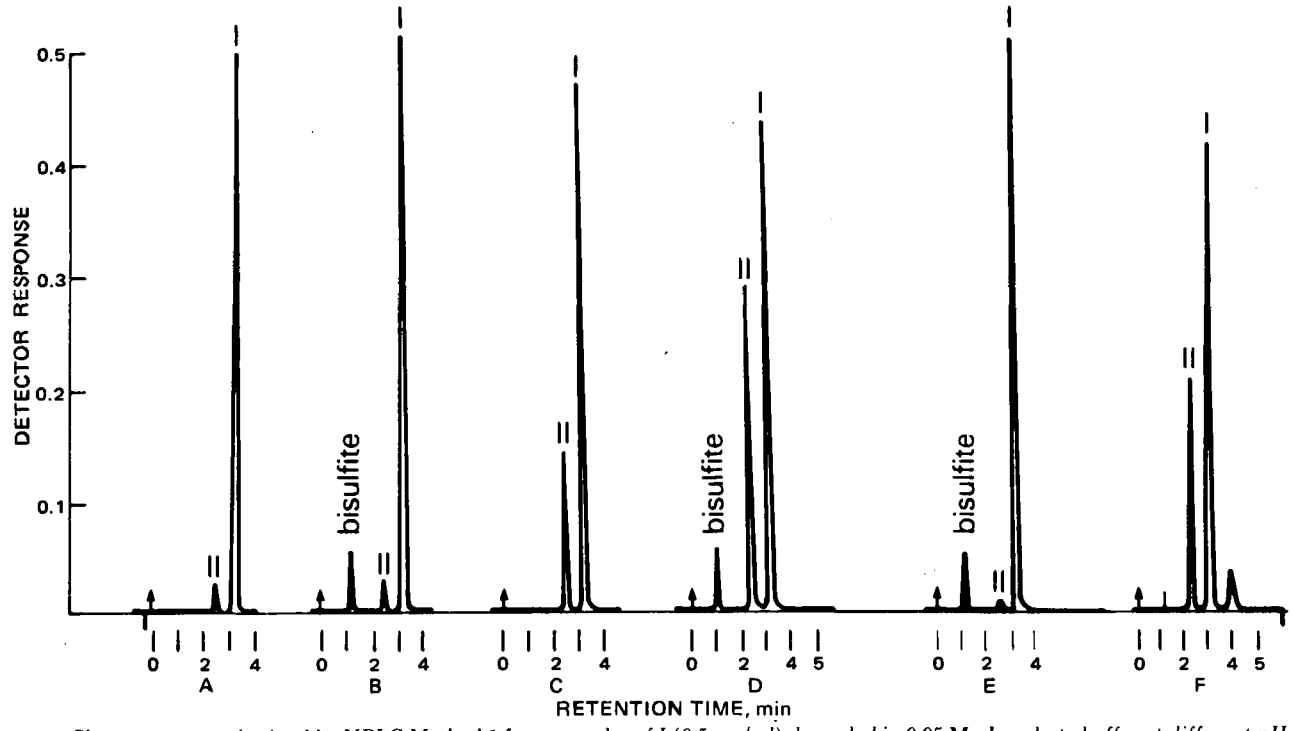

Figure 1—*Chromatograms obtained by HPLC Method 1 from samples of I (0.5 mg/ml) degraded in 0.05 M phosphate buffer at different pH values and room temperatures. Key: A, freshly prepared solutions of I in pH 7.0 phosphate; B, freshly prepared solution of I in pH 7.0 or 2.5 buffer containing 5 mg of sodium bisulfite/ml; C, sample in 1A after 70 min; D, sample in 1B with pH 7.0 buffer after 70 min; E, sample in 1B with pH 2.5 buffer after 70 min; and F, solution of I in pH 2.5 buffer in the absence of bisulfite after 70 min.*

The formyl derivative, II, can either reverse back to I or degrade subsequently (8–10).

The I hydrolysis rate, which is dictated by the pH dependence of hydration and deamination steps, is slowest around pH 6.5–7.0. However, even at this pH of maximum stability, drug degradation is too fast. Therefore, a different approach to improve I stability was needed.

The key to the instability of I is its 5–6 double bond, and saturating this double bond could improve drug stability. Synthesis of one such stable compound, 5,6-dihydro-5-azacytidine, was reported (11). Although the stability of this dihydro compound is excellent, approximately 20 times the dose of I is needed to yield an equivalent antitumor activity in experimental animals (11, 12).

Another approach to render the 5–6 double bond of I stable to water attack would be to add a stronger nucleophile capable of attacking the 5–6 double bond preferentially over water. Such a nucleophile should assure that the addition product does not undergo subsequent deamination; it should be stable in the infusion solution and, most important, it should quickly convert back to I under physiological conditions. The nucleophile should also be physiologically compatible.

Sodium bisulfite is a strong nucleophile and a common antioxidant additive in various pharmaceutical preparations. The nucleophilic addition of the bisulfite ion across the 5–6 double bond of I was demonstrated (9), but no attempt was made to study the results of this reaction or the stabilizing effect of sodium bisulfite on I. This paper reports the effect of sodium bisulfite on I stability in aqueous solutions.

EXPERIMENTAL

Materials—5-Azacytidine for injection (100 mg) was used as received[1]. Water was double distilled in an all-glass apparatus. All other chemicals were reagent grade.

Equipment—A high-pressure liquid chromatograph[2] equipped with a fixed-volume loop-type injection valve[3] and a variable-wavelength detector with a wavelength drive[4] attached to a computing integrator[5] were used. The columns used were a 250-mm × 4.6-mm i.d. reversed-phase column[6] and a 250-mm × 3.2-mm i.d. strong cation-exchange column[7]. Spectrophotometric analyses were carried out on a recording spectrophotometer[8]. All pH measurements[9] were taken at room temperature.

Degradation Studies—Solutions of I (0.5 mg/ml unless otherwise specified) were made by accurately weighing ~10 mg of I in a 20-ml screw-capped vial and adding 20.0 ml of the required buffer. Sodium bisulfite, when required, was incorporated into the buffer before adjustment of its final pH. The solutions were stored at room temperature (22–26°) and at refrigeration temperature (2–6°). The amount of intact I remaining at various time intervals was assayed by high-pressure liquid chromatography (HPLC) as described under *HPLC Method 1*. The time for 10% I degradation was obtained by extrapolation from the amount of intact I remaining at various time intervals.

UV Spectrum—The bisulfite–I mixture[10] was diluted 25-fold with pH 2.5 and 6.5 buffers (0.05 *M* phosphate), and their respective UV spectra using appropriate blanks were recorded[8]. UV spectra of I alone in pH 2.5 and 6.5 buffers were also recorded after appropriate dilution.

Assay and Identification Methods—*HPLC Method 1*—A reversed-phase column[6] with the mobile phase (0.02 *M* phosphate buffer, pH 6.5) at a flow rate of 2.0 ml/min was used to assay I. A 10-μl full loop sample volume was injected quantitatively, and the recorder was set at 0.64 full scale (254-nm detector). The area of the peak due to I was used to calculate the amount of intact I remaining in the sample. Typical run times were less than 6 min. The UV spectrum of the peaks were recorded when needed for identification by stopping the flow at the maximum of the peak and scanning them from 300 to 220 nm using the wavelength drive of the detector[4].

HPLC Method 2—A strong cation-exchange column[7] was used for separation of I from the I–sodium bisulfite addition product. The mobile phase consisted of 0.01 *M* NaCl with 0.01 *M* HCl in water (pH 2), and it was pumped at 1.25 ml/min. A 10-μl full loop sample volume was injected, and the recorder was set at 0.32 full scale (254-nm detector).

[10] Unless otherwise specified, the bisulfite–I mixture was 0.5 mg of I and 5 mg of sodium bisulfite/ml of 0.05 *M* phosphate with the pH adjusted to 2.5.

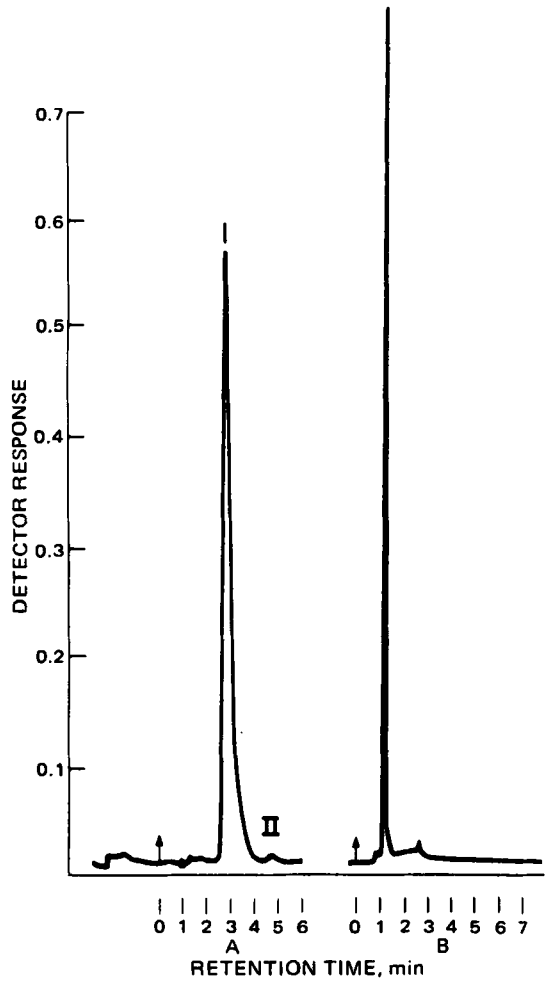

Figure 2—*Chromatograms obtained by HPLC Method 2 from samples of I (0.5 mg/ml) in 0.05 M phosphate buffers at different pH values and room temperature. Key: A, freshly prepared solution of I in pH 7.0 buffer; and B, freshly prepared solution of I in pH 2.5 buffer containing 5 mg of sodium bisulfite/ml.*

RESULTS AND DISCUSSION

HPLC Method 1 was similar in principle to the reversed-phase HPLC method used previously (8) to separate I and II. However, a different reversed-phase column[6] and mobile phase were used. A pH 6.5 buffer (0.02 *M* phosphate) was chosen as the mobile phase to prevent the retention time of I from changing when samples in concentrated buffers at low pH (2.5) were analyzed. Also, as discussed later, the maintenance of a high pH (>6) of the mobile phase was essential for the instant decomposition of the bisulfite–I addition product to yield I during the HPLC analysis.

As seen in Fig. 1F, the column[6] clearly separated the major degradation product, II (retention time of 150 sec), and an unidentified reaction product (retention time of 245 sec) from the peak due to I (retention time of 190 sec). Peak areas of I increased linearly with concentration from 0.3 to 0.5 mg/ml and were used for the calculation of intact I present in the samples.

Figure 1A shows the chromatogram of a freshly prepared solution of I in pH 7.0 buffer using HPLC Method 1. In addition to the major peak (I), a small peak (II) was present. Figure 1C is a chromatogram of the sample in Fig. 1A after 70 min at room temperature. Loss of I (~7%) was accompanied by an increase in peak II. Figure 1F shows the chromatogram of a I solution at pH 2.5 after standing for 70 min at room temperature. As is evident, I was less stable at pH 2.5 than at pH 7.0.

The chromatograms of freshly prepared solutions of I with bisulfite in either pH 2.5 or 7.0 buffer were identical (Fig. 1B). Peak I had the same retention time in all samples shown in Fig. 1. However, after 70 min at room temperature, the sample kept at pH 7.0 degraded almost 15% (Fig. 1D) whereas the same sample (Fig. 1B) kept at pH 2.5 showed little degradation (Fig. 1E). This finding indicates that bisulfite has a strong stabilizing effect on I hydrolysis at pH 2.5 (compare Figs. 1C–1E). This effect is more evident when the chromatogram of the I sample at pH 2.5 in the absence of bisulfite (Fig. 1F) is compared with that in Fig. 1E.

Table I—Time for I to Reach 90% of Its Original Concentration (0.5 mg/ml) in Buffer Solutions at Room Temperature (23–26°)

pH	Buffer	Time to Reach 90%, hr With Bisulfite[a]	Time to Reach 90%, hr Without Bisulfite
6.3	Lactated Ringer injection	—	2.3
7.0	0.05 *M* phosphate	0.8	2.6
6.5	0.05 *M* phosphate	1.2	2.3
6.0	0.05 *M* phosphate	1.0	1.5
4.0	0.05 *M* acetate	1.3	1.4
3.2	0.05 *M* phosphate	8.7	1.2
2.5	0.05 *M* phosphate	20	1.1
2.5	0.05 *M* phosphate	18[b]	—
2.5	0.05 *M* phosphate	6[c]	—
2.5	0.05 *M* phosphate	96[d]	—

[a] Sodium bisulfite, 5 mg/ml, unless specified otherwise. [b] Sodium bisulfite, 3 mg/ml. [c] Sodium bisulfite, 1 mg/ml. [d] Refrigeration temperature (2–6°).

Table I summarizes the effect of bisulfite on I stability at various pH values. Bisulfite increased the I degradation rate when the solution pH was maintained above 4.0. However, below pH 4.0, bisulfite slowed I degradation; the stabilization was more pronounced as the solution pH approached 2.5. Furthermore, at pH 2.5, increasing the amount of bisulfite increased the stabilization. At pH 2.5 in the presence of a 10-fold excess of bisulfite (5 mg of sodium bisulfite/ml with 0.5 mg of I/ml), ~20 hr was required for 10% I degradation at room temperature. This represents almost one order of magnitude improvement over the stability of I in the presently used clinical formulation of drug in lactated Ringer injection.

The large increase in I stability by bisulfite at acidic pH cannot be attributed to the effects of ionic strength but must be attributed to the protection of I by some direct interaction. To confirm that the peaks at 190 sec (Figs. 1B and 1E) (pH 2.5 sample) were due to I and not to the bisulfite–I product (III), the UV spectra of all peaks at 190 sec (Figs. 1A–1E) were recorded and found to be identical to those obtained from pure I. This finding demonstrates that whatever the stabilization mechanism, the addition product (III) eluted as I during HPLC Method 1. However, when the mobile phase had a pH of 2 (HPLC Method 2), the peak corresponding to I was missing in the chromatogram of the bisulfite–I mixture (Figs. 2A and 2B). The chromatogram in Fig. 2A was obtained from the sample represented in Fig. 1A; the chromatogram in Fig. 2B, which shows the absence of peak I, was obtained from the pH 2.5 sample represented in Fig. 1B. Therefore, in spite of high dilution during the HPLC procedure, when the mobile phase of low pH (pH 2) was used, III remained intact and did not elute as a peak corresponding to I. However, at pH 6.5, III rapidly reverted back to I; therefore, the peak resulting from III corresponds to I alone.

Another indication of the reversibility of III to I at pH 6.5 was obtained when equimolar (based on molar concentration of I) concentrations of I and the bisulfite–I mixture gave similar UV spectra (Fig. 3) at pH 6.5 (both I and the bisulfite–I mixture had λ_{max} of 239 nm, ϵ = 6800). However, at pH 2.5, the spectrum (Fig. 3) obtained from the bisulfite–I mixture was much less intense and different from that obtained with I (at pH 2.5, I had λ_{max} at 241, ϵ = 3700, and the bisulfite–I mixture had λ_{max} at 243, ϵ = 1900). Since the loss of absorption at 240 nm reflects the loss of the 5–6 double bond (8, 9), it is reasonable to suggest that the lower ϵ value at pH 2.5 of the bisulfite–I mixture was due to addition of bisulfite across this bond.

Stabilization Mechanism—The results of the present study indicate that bisulfite forms an addition product with I across the 5–6 double bond that is stable at low pH (*i.e.*, 2.5) and thus prevents the hydrolytic attack on the 5-azacytosine ring. The addition reaction at pH 2.5 is reversible and requires excess bisulfite to maintain the equilibrium in favor of the addition product. As seen in Table I, at pH 2.5, when the bisulfite concentration decreased, I stability also decreased. Based on these observations and in accordance with the hydrolysis mechanism proposed for I (9), it appears that the major reaction responsible for stabilization of I is as shown in Scheme II.

The formation of III proceeds through the protonation of N-5, similar to the protonation that usually precedes the nucleophilic attack on imine bonds (13) and as suggested for I hydrolysis (9). Therefore, formation of III (and, hence, stabilization of I against hydrolysis) is expected to increase as the pH is lowered and more I is protonated. If the pKa of I is assumed to be of the order of 2–3 from the reported pKa of the related

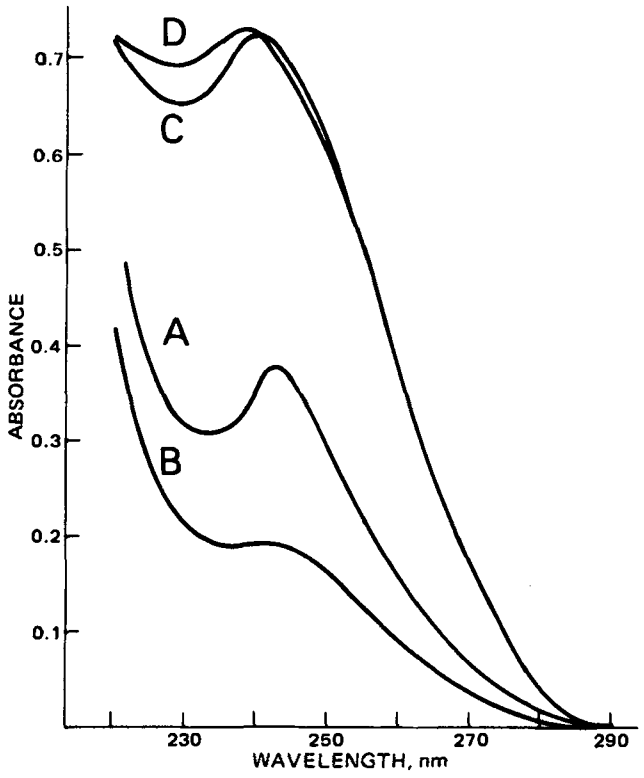

Figure 3—*UV spectrum of I and the bisulfite–I mixture in 0.05* M *phosphate buffer at different pH values. Concentration of I (or its equivalent) in the spectrophotometer cell was 30 μg/ml. Key: A, I in pH 2.5 buffer; B, bisulfite–I mixture in pH 2.5 buffer; C, I in pH 6.5 buffer; and D, bisulfite–I mixture in pH 6.5 buffer.*

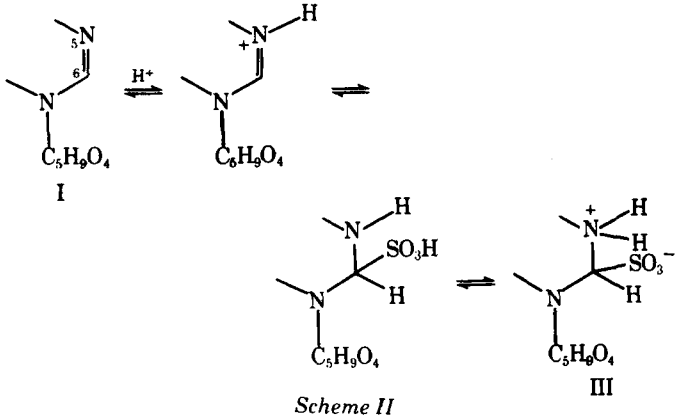

Scheme II

compound 5-azacytosine (9), the stabilization would be expected to increase as the pH is lowered below 4, provided the concentration of reactive nucleophile, bisulfite anion (HSO_3^-), is constant.

A substantial portion of sulfurous acid species would exist as the bisulfite anion up to pH 1.5 (pK_1 of sulfurous acid is 1.7), and increased I stability was observed up to pH 1.5. However, in strongly acidic solutions (*i.e.*, 1 *N* HCl), although I is expected to be completely protonated, the fraction of reactive nucleophile, bisulfite anion, is extremely small. Therefore, at very low pH, the addition reaction is expected to be slower. This was the case when a mixture of I and sodium bisulfite in 1 *N* HCl showed almost 90% free I after 1 min and 40% free I after 8 min (HPLC Method 2) whereas a mixture of the same concentrations of I and sodium bisulfite adjusted to pH 2 showed no free I (HPLC Method 2) even after 30 sec. This finding shows that the III formation rate is very fast at pH 2 but relatively slower in 1 *N* HCl.

To demonstrate that this slower rate is not due to an increase in the rate of reverse (desulfonation) reaction at this low pH, the bisulfite–I mixture[10] (where almost all I existed as III, Fig. 2B) was diluted with an equal volume of 2 *N* HCl and the resulting solution was analyzed by HPLC Method 2. The peak height due to I was 3, 20, and 40% of the theoretical amount of I after 0.5, 8, and 20 min, respectively. This finding

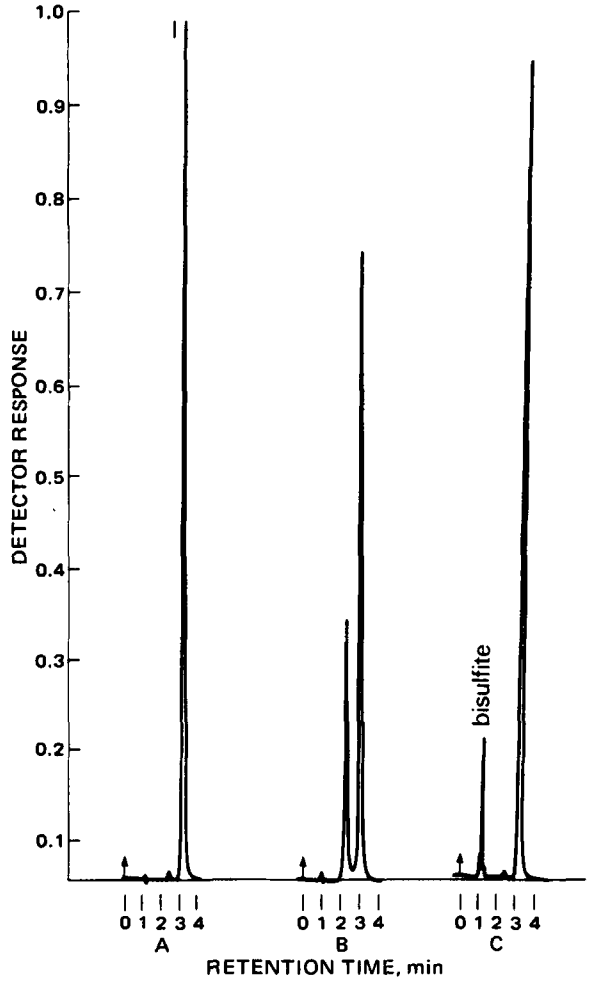

Figure 4—*Chromatograms obtained by HPLC Method 1 from samples of I (0.5 mg/ml). Key: A, freshly prepared solution of I in water; B, freshly prepared solution of I in 0.01* N *HCl; and C, sample in 4B after addition of sodium bisulfite (5.0 mg/ml).*

demonstrates that III does not decompose to I instantly in acidic solutions.

The degree of stabilization would also be influenced by the reverse reaction rate. The data presented in this paper indicate that the desulfonation rate of III to I is relatively slow at acidic pH whereas desulfonation is instantaneous at pH 6.5. It is unlikely that this fast reaction above pH 6 would be due to a direct replacement of bisulfite by hydroxyl ion followed by dehydration to yield I because (*a*) the hydroxyl-ion concentration is too small at pH 6.5 to compete effectively with bisulfite ion and (*b*) the product formed by the attack of hydroxyl ion would be expected to deaminate very fast at pH 6.5 (13). A more likely explanation is that, above pH 6, the cationic nitrogen of III would lose the proton and the resulting lone pair of electrons in N-5 would help in the desulfonation of III to I. At low pH (*i.e.*, pH ~2), the N-5 still would be protonated and desulfonation would be relatively slow. No further studies of this reaction were performed.

Catalysis of I Hydrolysis by Bisulfite at Neutral pH—The described stabilization mechanism of I by bisulfite does not explain why the I degradation rate above pH 4 is increased in the presence of bisulfite compared to buffer alone (Table I). As seen in Figs. 1C and 1D, the degradation product in the presence or absence of bisulfite at pH 7.0 is the same, *i.e.*, II. Therefore, the sulfurous acid species present at these pH values (pH 4–7) apparently does not form any other reaction product but catalyses I hydrolysis. Furthermore, the sulfite dianion appears to be a stronger catalyst than the bisulfite anion because bisulfite decreased I stability by a factor of 3 at pH 7 whereas the stability decrease was only 15% at pH 6, even though the total sulfurous acid concentration was the same (Table I). Since the pK_2 of sulfurous acid is ~6.7, it is reasonable to assume that faster degradation of I at pH 7.0 in bisulfite compared to that at pH 6.0 is due to the presence of a higher fraction of sulfurous acid species in the sulfite dianion form. No attempts were made to elucidate

further the mechanism of bisulfite-ion catalysis of I degradation.

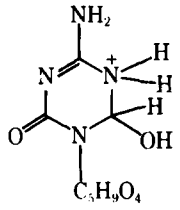
Pharmaceutical Significance—*Parenteral Route*—The results of this study indicate that if the solution in I is maintained at pH 2.5 and if a five- to 10-fold excess of sodium bisulfite (relative to the concentration of I) is provided, I is stable (<10% degradation) for 20 hr at room temperature and for ~4 days at refrigeration temperature. This conclusion represents a substantial improvement in the stability of I in solutions. Further, the ready reversibility of the bisulfite–I addition product (III) to yield I at neutral pH values indicates that III will quickly convert to I in the body and thus act as a I prodrug. Such increased stability will assure better control over the preparation of the I infusion solutions and over the dose being administered.

The results of this study also indicate that 1–2 g of sodium bisulfite would be necessary to provide a stable solution of 200 mg of I[11] to be infused over 24 hr. Infusions of similar amounts of sodium bisulfite in commercial amino acid solution are used routinely, so it appears unlikely that addition of bisulfite would add significantly to the drug toxicity.

Oral Route—The mixture of I with bisulfite also holds promise as an oral dosage form. The administration of I alone is not practicable because of its relatively short stability at 37° over the pH range of the stomach and intestine. Furthermore, at the highly acidic stomach pH, a substantial portion of I would be in the hydrated form (IV) and, as suggested (9), the bioreversibility of IV to I at physiological pH may not be complete. Above pH 6.0, a significant portion of IV probably would deaminate to II and subsequent degradation products, and conversion of IV to I may not be quantitative.

This argument is supported by comparing the chromatogram of a solution of I in 0.01 *N* HCl (Fig. 4B) with that of the same concentrations of I in water (Fig. 4A) using HPLC Method 1. There was a 25% decrease in peak I and an increase in peak II immediately after dissolving I in 0.01 *N* HCl. After further storage, there was a more gradual decrease in peak I in Fig. 4B (an additional 10% decrease in peak I after 20 min at room temperature). Based on the stability studies of I at acidic pH (9), it is unlikely that a 25% loss of I would occur instantly at pH 2 (0.01 *N* HCl); therefore, it must be attributed to the decomposition of IV during HPLC with pH 6.5 buffer as the mobile phase. This conclusion is substantiated by the fact that when bisulfite was added to the solution of I in 0.01 *N* HCl (Fig. 4B), the chromatogram showed complete loss of peak II and an increase in peak I to approximately the original height of peak I in Fig. 4A (Fig. 4C). If II were already present in the sample of Fig. 4B in 0.01 *N* HCl, it is unlikely that it would cyclize immediately and yield I upon addition of the bisulfite. Therefore, in the presence of bisulfite in acidic pH, IV apparently is converted to III, which then elutes as I in HPLC Method 1 as discussed earlier.

This discussion indicates that a significant portion of IV resulting from dissolving I in acidic pH in the absence of bisulfite does not reverse back to I on reaching physiological pH. However, a mixture of I and sodium bisulfite would quickly form a relatively stable compound (III) in the acidic pH of the stomach and then rapidly revert back to I above pH 6. Thus, drug absorbed in the stomach probably would quickly release I on reaching the higher pH (7.4) of blood. Although the stability of the bisulfite–I mixture at the higher pH of the ileum is uncertain, a mixture of I with bisulfite as an oral preparation holds promise as a stabilized dosage form during its passage through the stomach and warrants further investigation by the oral route. The toxicity and efficacy of III and its application in developing suitable dosage forms of I are presently being investigated.



IV

[11] Usual daily dose of I is 100–200 mg/ml.

In Vitro Nitrosation of Methapyrilene

WILLIAM J. MERGENS *x, FLOIE M. VANE *, STEVEN R. TANNENBAUM ‡, LAURA GREEN ‡, and PAUL L. SKIPPER ‡

Received October 5, 1978, from **Hoffmann-La Roche Inc., Nutley, NJ 07110*, and the ‡*Massachusetts Institute of Technology, Cambridge, MA 02139.* Accepted for publication December 18, 1978.

Abstract □ The reactions of sodium nitrite and methapyrilene were studied in aqueous solution at neutral pH and under simulated gastric fluid conditions. Reaction product formation was much more complex than nitrosation of the parent molecule dimethylamino moiety to form nitrosodimethylamine. Several new nitroso compounds were formed under the reaction conditions studied. The simultaneous incorporation of 2 moles of ascorbic acid/mole of nitrite ion prevented any destruction of methapyrilene under all conditions studied. The implications of these observations with respect to nitrosation theory, the general carcinogenicity of nitroso compounds, and methapyrilene dosage formulation are discussed.

Keyphrases □ Methapyrilene—nitrosation, *in vitro*, with sodium nitrite, nitrosodimethylamine formation, effect of pH, prevented by ascorbic acid □ Ascorbic acid—methapyrilene nitrosation, prevention of nitrosodimethylamine formation, *in vitro* □ Nitrosodimethylamine—formation from methapyrilene, prevention by ascorbic acid, *in vitro* □ Carcinogens—nitrosodimethylamine, formation from methapyrilene, prevention by ascorbic acid, *in vitro*

The formation of *N*-nitroso compounds by interaction of nitrite or other nitrosating agents such as gaseous nitrogen dioxide or dinitrogen trioxide with susceptible amines has received much attention over the past few years (1). A recent survey showed that of 100 nitrosamines studied, 80% were carcinogenic in animal studies (2).

BACKGROUND

No animal species has proved immune so far to the carcinogenicity of *N*-nitroso compounds (3, 4). Dimethylnitrosamine, the simplest dialkyl nitrosamine, is carcinogenic in a wide variety of species including the mouse, hamster, mink, rat, guinea pig, rabbit, and rainbow trout. Dimethylnitrosamine is carcinogenic in the mink at the lowest dose tested in rodents, 50 μg/kg, given twice per week in the diet (5). In addition, the carcinogenicity of *N*-nitrosamines is organospecific. In the rat, for example, dimethylnitrosamine is a liver carcinogen regardless of the administration route (6).

These results are of particular concern to humans, because many of these suceptible amines are commonly ingested as pharmaceuticals, pesticide residues, and normal components of food. Additionally, nitrite is produced by microbiological nitrate reduction in the mouth and is ingested from exogenous sources such as cured meat products and many vegetables.

Ascorbic acid inhibits this reaction, as was first demonstrated in an *in vitro* study (7) in 1972. This protective effect of ascorbic acid was extended to *in vivo* studies (8), which demonstrated that aminopyrine–nitrite-induced hepatotoxicity in rats could be completely abolished by the concomitant feeding of sodium ascorbate.

The mechanism of this protective effect by ascorbic acid is currently believed to be due to the ability of ascorbic acid to compete successfully with susceptible amines for the available nitrite (nitrosating species) ion. This premise is based on detailed studies (9) of the anaerobic oxidation of ascorbic acid by nitrous acid. The initial attack by the nitrosating species on the 3-hydroxy group of ascorbic acid forms the nitrite ester, which subsequently decomposes to yield the semiquinone. Further reaction of the semiquinone with an additional mole of nitrosating species completes ascorbate oxidation to dehydroascorbic acid. This work was extended (10) to aerobic systems, and a kinetic model was developed that predicted the amount of ascorbate required to inhibit completely nitrosation of an amine in the presence of ascorbic acid.

Since that time, the conditions required for ascorbic acid to prevent nitrite-induced reactions involving many different amine substrates have needed evaluation. The subject of the present study is methapyrilene, a tertiary pharmaceutical amine found in many over-the-counter antihistamine and sleep aid products. A significant incidence of liver tumors and other liver lesions was reported in rats fed an aqueous solution of methapyrilene plus sodium nitrite (11). The authors presumed that this hepatotoxicity was due to dimethylnitrosamine formation in the stomach of the test animals. The present study was undertaken to investigate the methapyrilene reaction with nitrite and the potential utility of ascorbic acid in protection of methapyrilene from such reactions.

EXPERIMENTAL

Materials and Methods—Methapyrilene hydrochloride[1] was commercial grade. Sodium nitrite[2] and isopentyl nitrite[3] were used as sources of nitrosating intermediates. Redistilled methylene chloride was used for all sample extractions and workups.

Nitrosated Standards—*Nitrosation of* N-(*2-Pyridyl*)-N′-*dimethylethylenediamine* (*VIII*)—The amine was purified by dissolving it in hydrochloric acid, extracting with methylene chloride, basifying the aqueous phase, and extracting the amine with ether.

The amine (165 mg, 1 mmole) was dissolved in 4 ml of ether and treated with 1 ml of isopentyl nitrite. After standing overnight, a gummy residue precipitated. The ether solution was decanted and heated to evaporate the solvent. Alcohol (7 ml) was added, and the resultant solution was evaporated by boiling and then under a nitrogen stream. The product (IX) was obtained as a reddish oil, pure by TLC.

Nitrosation of 2-(2-Thienylmethylamino)pyridine (*V*)—The recrystallized amine had a sharp melting point and dissolved cleanly in ether. One millimole (190 mg) was treated with 1.5 ml of isopentyl nitrite in 4 ml of ether for 2 days. The product (VI) was worked as for IX and yielded a reddish oil, pure by TLC. Both products were confirmed as nitrosamines by the use of UV photolysis and Griess reagent on their chromatograms.

Analyses—Methapyrilene determinations were performed by GLC[4] on an instrument equipped with a flame-ionization detector. The column, a 1.83-m × 0.635-cm o.d. 8% methyl silicone gum rubber[5] glass U-tube, was operated isothermally at 240° with a helium flow rate of 50 ml/min. Samples were injected as the free base after the reaction mixture had been rendered alkaline with sodium hydroxide and the compound had been extracted into distilled methylene chloride.

The reaction products of methapyrilene with sodium nitrite were extracted as outlined and analyzed by a combined GLC–mass spectrometer[6] system interfaced with a data dystem[7]. Methane was used as the GLC carrier gas and as the chemical-ionization reagent gas. A 1.02-m × 0.32-cm o.d. 3% methyl silicone gum rubber[5] column was used at an initial temperature of 140° and a programmed rate increase of 10°/min. The mass range of *m/e* 60–460 was scanned in 2 sec.

Electron-ionization mass spectrometry of the nitrosated standards of *N*-(2-pyridyl)-*N*′-dimethylethylenediamine and 2-(2-thienylmethylamino)pyridine were obtained by mass spectrometry[8] using a chamber voltage of 70 (standard ionizing voltage). Several columns were tried for GLC–electron-ionization mass spectrometry, with terephthalic acid-treated polyethylene glycol[9] proving the most useful. Injector temperatures of 150–200° and lower were compared.

TLC studies were performed using precoated 15-cm silica plates with and without the fluorescent additive for visualizing UV-absorbing compounds, as required. The solvent system was hexane–ether–meth-

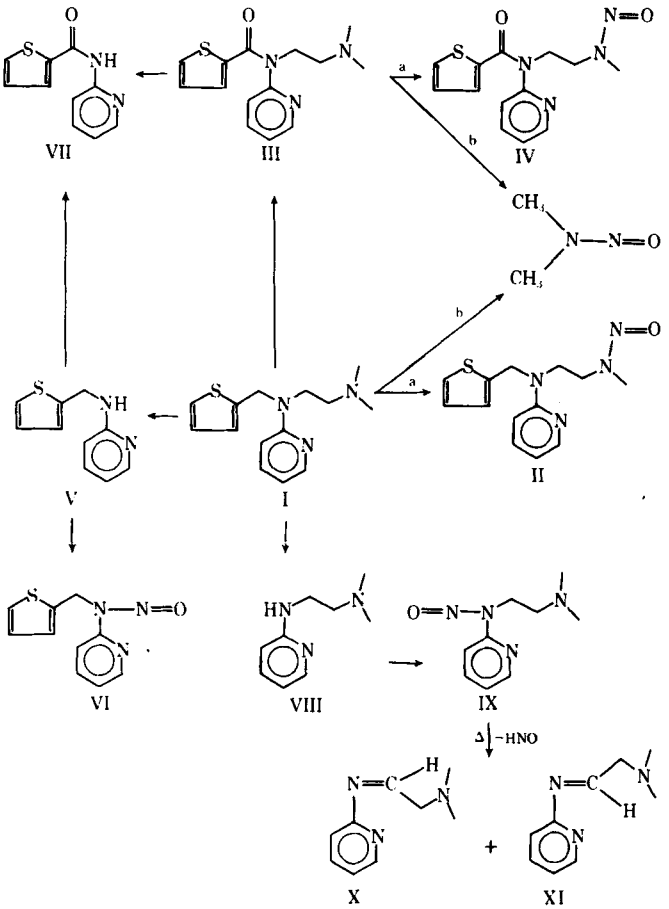
Table I—TLC R_f Values for Methapyrilene and Some Reaction Products on Silica Gel G

Compound	R_f Value	Reaction to Spray Reagent		
		Iodoplatinate	Griess	Isatin
I	0.5	+	−	+
III	0.4	+	−	+
VIII	0.25	+	−	−
IX	0.55	+	+	−

ylene chloride–methanol–concentrated ammonium hydroxide (40:15:20:10:0.25).

All compounds were visualized by UV on fluorescent plates. Nitrosamines were further identified by spraying the plate with Griess reagent followed by exposure to longwave UV light, which caused them to appear as pink spots. Basic nitrogen compounds were differentiated by spraying with iodoplatinate reagent, and thienyl compounds were detected by isatin reagent (12). The R_f values were not highly reproducible (probably because some components of the solvent system are very volatile). The compounds, in order of increasing R_f values, were VIII, I, IX, V, and VI (Scheme I and Table I).

Nitrosamine analyses are most conveniently and quite specifically performed using a thermal energy analyzer (13). This detector can be coupled with either a gas or liquid chromatograph. The nitrogen–nitrogen bond of the nitrosamine (nitrosamide) is thermally split in a pyrolysis chamber. The resulting reaction products, parent amine (or amide) plus the liberated nitric oxide radical, and any other components that emerge from the pyrolysis oven are then swept through a cold trap. The nitric oxide radical, one of the few substances that will not be trapped, passes into the reaction chamber where it is oxidized with ozone to yield an excited nitrogen dioxide molecule. As this molecule relaxes to the ground



Scheme I—Proposed reaction products of methapyrilene with sodium nitrite. The reaction products of I and III arise through nitrosative attack on the dimethylamino group. When the leaving group is $-CH_3$, the resulting product is the unsymmetrical dialkylnitrosamine (path a). When the leaving group is the substituted ethyl, both I and III yield nitrosodimethylamine (path b).

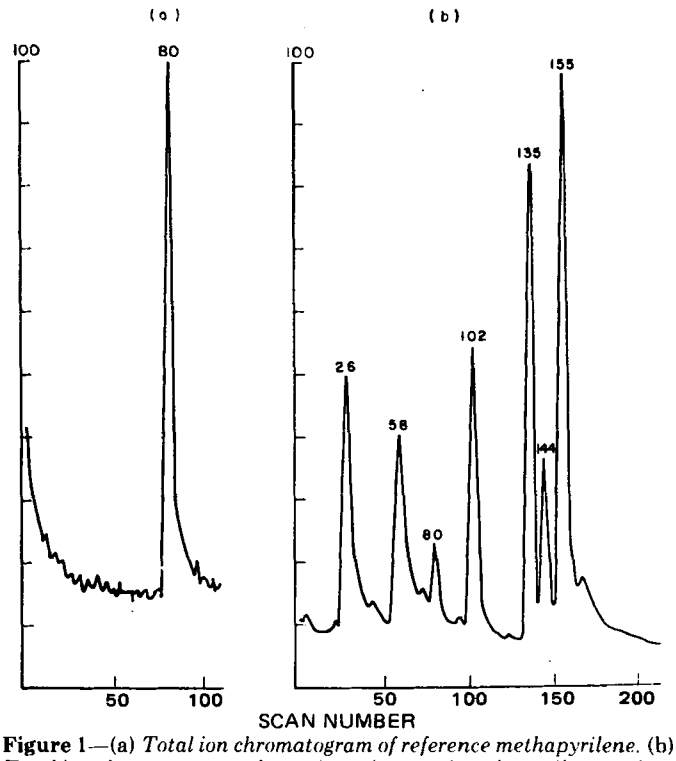


Figure 1—(a) *Total ion chromatogram of reference methapyrilene.* (b) *Total ion chromatogram of reaction mixture of methapyrilene and nitrite.*

state, it emits a characteristic energy (in the near IR), which is detected using a photomultiplier tube.

Nitrosodimethylamine analyses were performed by a GLC–thermal energy analyzer using a column of polyethylene glycol[10] on a potassium hydroxide-treated support. Methylene chloride solutions were generally analyzed isothermally at 145° and an attenuation of 0.1. Some analyses were performed using a temperature program between 100 and 180° at an attenuation of 0.1, when solvent tailing under isothermal conditions presented an analytical problem.

Compounds VI, IX, nitrosodimethylamine, and the reaction products of methapyrilene and nitrite at 37° were examined using a high-pressure liquid chromatography (HPLC)–thermal energy analyzer. These studies employed a prepacked column[11] and a mobile phase of 95% isooctane/5% acetone at a flow rate of 2 ml/min. The thermal energy analyzer detector was operated with an oven temperature of 450° and a reaction chamber pressure of 2 torr. The cold trap was held in a dry ice–isopropyl alcohol bath.

Reactivity of Methapyrilene with Nitrite as a Function of Temperature—Methapyrilene solutions (1 mg/ml) were prepared in pH 3.7 acetate buffer. Mole ratios of sodium nitrite to methapyrilene were adjusted by adding solid sodium nitrite to the solution to yield 8.6, 4.3, 1.0, and 0.5 mole ratios. Reactions were carried out by sealing 10-ml aliquots of the reaction mixtures in 20-ml amber all-glass ampuls. Reaction temperatures of 90, 70, 50, and 37° were maintained by immersion of the samples in constant-temperature water baths. Reaction time was 4 hr. Samples were stored under refrigeration pending analyses. In this particular study, nitrosodimethylamine determinations were performed by GLC using an electrolytic conductivity detector[12] operated in the reductive mode without a catalyst (14).

Mild Reaction Conditions—Studies were performed under simulated gastric fluid conditions at 37° and pH 3.7 for 4 hr in glass-stoppered vessels. The methapyrilene concentration was 1 mg/ml, and the sodium nitrite concentration was 2 mg/ml.

For a similar experiment involving the production of nitrosodimethylamine over 1–5 days under room temperature conditions at pH 6.2, the following sample workup was used. During storage, the samples were shielded from light. Afterwards, each sample was extracted with 3 × 100 ml of methylene chloride, dried over sodium sulfate, and con-

Table II—Reaction of Methapyrilene with Nitrite as a Function of Temperature and Mole Ratio [a]

Nitrite–Methapyrilene Mole Ratio	Methapyrilene Analysis, % retention				Nitrosodimethylamine at 90°, % of theory
	90°	70°	50°	37°	
8.6:1	2	50	97	99	12
4.3:1	7	59	96	99	8
1:1	47	67	98	99	0.1
0.5:1	75	82	98	100	<0.04

[a] Reaction time was 4 hr using pH 3.7 acetate buffer. Methapyrilene = 1 mg/ml.

centrated to 10 ml in an apparatus[13]. Heptane, 1 ml, was added, and the sample was further concentrated to 1 ml with nitrogen. Samples were then quantitatively vacuum transferred to remove nonvolatile material and analyzed by the GLC–thermal energy analyzer on a polyethylene glycol[10]–potassium hydroxide-treated column at 100°.

Ascorbic Acid Influence—The influence of ascorbic acid on the nitrite–methapyrilene reaction was evaluated by incorporating 0–2 moles of ascorbic acid/mole of sodium nitrite present. In all cases, the reaction mixture pH was adjusted to compensate for the acid addition.

RESULTS AND DISCUSSION

Methapyrilene Reaction Products—The methapyrilene molecule contains a dimethylamine moiety, which could be a potential source of nitrosodimethylamine. Tertiary amines have been reported to undergo nitrosative dealkylation to form a nitrosamine in the presence of a nitrosating intermediate (15, 16). The optimum condition for many aqueous nitrosations is usually about pH 3.4, the pKa for nitrous acid. This pH generally reflects the mutual optimization of the two reactive species: (*a*) the formation of the nitrosating intermediate, which increases with increasing acid concentration, and (*b*) the concentration of the unprotonated, more electrophilic form of the amine, which is, of course, dependent on the pKa of the specific base.

Reaction Products of Methapyrilene and Nitrite—Methapyrilene nitrosation at pH 3.7 was investigated as a function of temperature and mole ratio of nitrite (Table II). At 90° with an 8.6 mole excess of nitrite, the parent amine almost completely disappeared. As the temperature and mole ratios decreased, the stability of methapyrilene substantially increased.

GLC-Chemical-Ionization Mass Spectrometric Analysis—These analyses were performed to identify the reaction products at 90° and the highest mole ratio of nitrite. The total ion chromatograms for the reference standard (methapyrilene base) and a sample containing a mixture of the methylene chloride-extractable reaction products obtained under different reaction conditions are reproduced in Fig. 1. Proposed structures for the individual reaction products can be found in Scheme I and Table III. No definite structure could be made for scan 144. The presence of a carbonyl function in III, IV, and VII was confirmed by GLC coupled to an IR detection system[14].

At 90°, the major reaction product appeared to be III, in which the methylene bridge between the ethylenediamine and thienyl moieties had been oxidized to a keto group. One possible mechanism for the formation of such an amide structure would involve attack of the nitrosyl ion on this group to form a C-nitroso compound, which could rearrange to the corresponding oxime. Hydrolysis of the oxime would subsequently yield the amide plus hydroxylamine.

One interesting aspect of this experiment can be seen in Table II. At 90°, a definite break in both methapyrilene retention and nitrosodimethylamine formation occurred at nitrite–methapyrilene mole ratios at and below 1:1 compared to the higher ratios. Not only was the retention of the parent compound improved, but the conversion of methapyrilene to nitrosodimethylamine was almost negligible. One interpretation of this observation would indicate that the parent amine consumes 1 mole of nitrite prior to attack of the dimethylamino function. This idea is supported by the fact that III was the principal oxidation product under these conditions. Moreover, the dealkylation products observed at 90° involved cleavage of the parent molecule in the ethylenediamine portion of the molecule and not in the thienyl moiety (*viz.*, V and VII).

[14] RS1, Norcon Inc., Norwalk, Conn.

Room Temperature Storage—Based on these findings, the system was reexamined using considerably less stringent reaction conditions to identify the initial reaction products. Solutions of 1 mg of methapyrilene/ml of distilled water were stored at room temperature in the presence of 2 mg of sodium nitrite/ml. The pH of this mixture was 6.6. Under these conditions, substantial conversion (~1%/day) of the parent compound into *N*-(2-pyridyl)-*N'*-dimethylethylenediamine (VIII) was observed (Table IV). In the absence of nitrite, on the other hand, no deterioration of the parent compound was observed under identical storage periods. The appearance of this particular secondary amine is not unusual because its synthesis involves a cleavage of the activated methapyrilene methylene bond. One can only speculate as to why it was not observed at 90°.

Compound VIII was isolated by TLC at R_f 0.25 (Table I), and its identity was confirmed by GLC–mass spectrometric analysis of both the free amine and its trimethylsilyl derivative. Furthermore, it behaved identically to a known standard in all tests performed. The nitrosation of VIII was studied in simulated gastric fluid (pH 1.3) and acetate buffer (pH 3.7) using the same amine and nitrite-ion concentrations described for methapyrilene. After 4 hr of reaction, both samples were more than 90% converted to the corresponding nitrosamine. After 24 hr, the reaction was essentially complete in both cases as estimated by TLC.

The nitrosamine was separated from the reaction mix with methylene chloride and isolated by solvent evaporation. IR spectrophotometry confirmed the presence of a nitroso group and indicated a structure compatible with IX. The fact that VIII reacted more readily with nitrite than methapyrilene is understandable since it is a secondary amine. Secondary amines classically are the most readily nitrosated amines, with the exception of the tertiary amine aminopyrine (17).

Further confirmation of the structure of the nitroso derivative of VIII by direct mass spectrometry was attempted. The compound yielded a fairly clean spectrum in which the highest *m/e* was 163, corresponding to M − 31 for the *N*-nitroso derivative of VIII (inlet temperature of 160°). When the inlet temperature was lowered to 65°, a similar spectrum was obtained, but with additional peaks at *m/e* 164 and 179, presumably M − 30 and M − 15, respectively. In neither case was the molecular ion observed, so the resulting spectra, while consistent with the structure of IX, cannot be considered firm evidence that the desired product was obtained. GLC–mass spectrometry on terephthalic acid-treated polyethylene glycol[9] yielded complex chromatograms with injector temperatures at 150–200°. Lower injector temperatures gave simpler chromatograms, but this result may have been due either to less decomposition or simply to fewer components being flash evaporated.

Useful mass spectra were obtained for only two of these components. Both gave an apparent molecular ion at *m/e* 163 and probably correspond to the isomeric imines formed by HNO elimination of the parent nitrosamine during GLC (X and XI, Scheme I).

Similarly prepared samples were also analyzed for nitrosodimethyl-

Estimation of VII was based on a methapyrilene standard.

amine with the GLC–thermal energy analyzer after 1- and 5-day periods. The 1-day sample contained 0.33 ppm and the 5-day contained 0.104 ppm of nitrosodimethylamine. These values correspond to 16.5 and 5.2 μg of nitrosodimethylamine/50 mg of methapyrilene. The nitrosodimethylamine loss between Days 1 and 5 was due to chemical–physical factors that caused aqueous solutions of this nitrosamine to be unstable over long periods. The fact remains, however, that some production of nitrosodimethylamine can take place even under such mild conditions.

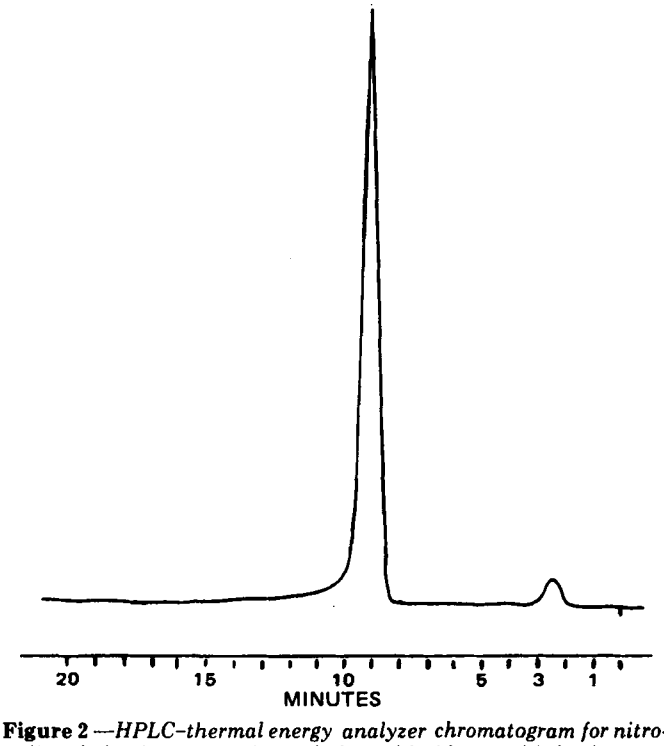

Figure 2—*HPLC–thermal energy analyzer chromatogram for nitrosodimethylamine, 5 ppm in methylene chloride, 10-μl injection, and attenuation 128×.*

Gastric Fluid Conditions—The potential for nitrosamine formation between an amine and nitrite is greatly enhanced under gastric fluid conditions as compared to the neutral solution. This situation directly relates to the hydrogen-ion influence on the nitrosating intermediate formation through the nitrite–nitrous acid equilibria (Schemes II and III):

$$NO_2^- + H^+ \rightleftharpoons HONO$$

Scheme II

$$2HONO \rightleftharpoons N_2O_3 + H_2O$$

Scheme III

The studies performed here for the methapyrilene system after 4 hr under simulated conditions yielded the following results. Conversion of methapyrilene to nitrosodimethylamine was 150 ng/ml from a maximum theoretical yield of 250 μg/ml, which represents a 0.06% conversion by GLC–thermal energy analyzer analysis. In addition to nitrosodimethylamine, several other peaks appeared in the HPLC–thermal energy analyzer chromatogram. The first peak in all HPLC–thermal energy analyzer chromatograms, appearing at 3 min after injection, was a solvent front response; it did not correspond to an *N*-nitroso compound, and its magnitude was unimportant. The remaining peaks corresponded to the same peaks derived from the nitroso derivative of V and the nitroso derivative of VIII standards, although not all peaks could be accounted for in this manner. Nitroso V represented yet another nitrosamine derivative, which could be formed from methapyrilene (Figs. 2–4).

These observations have important implications with respect to the experimental handling of methapyrilene–nitrite solutions, especially in animal feeding experiments such as those described previously (11). The present results indicate that the experimental protocol of mixing methapyrilene and sodium nitrite in drinking water prior to ingestion by test animals could lead to preformed nitrosodimethylamine in quantities (0.1–0.3 ppm in drinking water) comparable to those formed by incubation under simulated gastric fluid conditions for 4 hr. In addition, the substantial conversion of the parent amine to VIII complicates the scheme by introducing a secondary amine that has been shown to nitrosate much more rapidly than the parent amine under simulated gastric fluid conditions at 37°. For this and other reasons, caution should

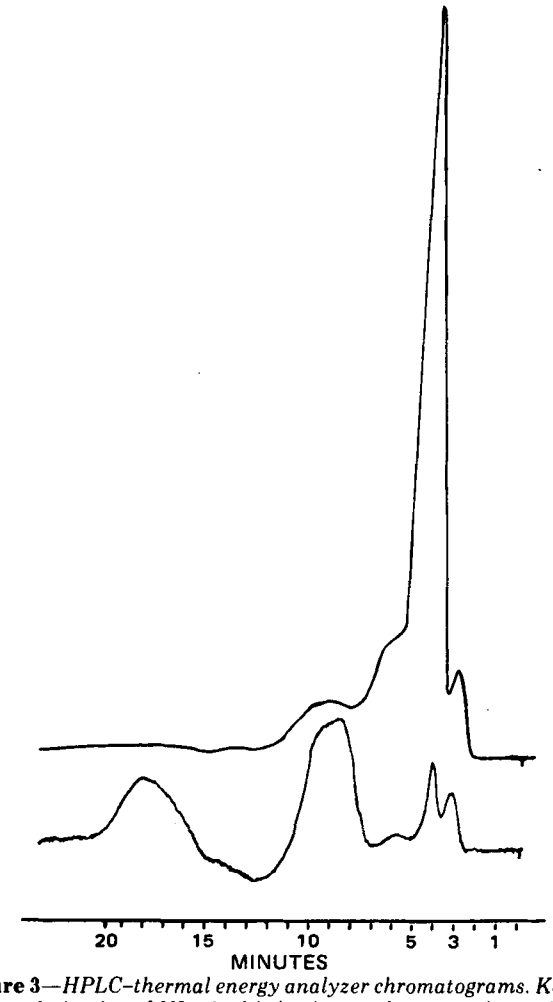

Figure 3—*HPLC–thermal energy analyzer chromatograms. Key: top, nitroso derivative of VI, 10-μl injection, and attenuation 128×; and bottom, nitroso derivative of IX, 10-μl injection, and attenuation 32×.*

be used in the interpretation of carcinogenicity experiments as solely the result of *in vivo* nitrosation of the parent amine.

Ascorbic Acid Effect—Ascorbic acid was applied successfully as a nitrosamine inhibitor in a number of *in vivo* (8, 18) and *in vitro* (7) systems involving drug nitrosation. Table V summarizes the results for the application of various mole ratios of ascorbic acid to nitrite ion for two different concentrations of nitrite and methapyrilene under different reaction conditions. As predicted (10), the presence of 2 moles of ascorbic acid/mole of nitrite was effective in preventing oxidative and nitrosative damage to the methapyrilene molecule. This result was true for all reaction conditions (Table V). Results not reported in Table V indicate that ascorbic acid is just as effective a protective agent at 90°. Although TLC results can be considered encouraging, this procedure lacks the sensitivity and specificity afforded by the thermal energy analyzer.

Analyses of methapyrilene–nitrite mixtures containing 2 moles of ascorbic acid/mole of nitrite were performed with the thermal energy analyzer. The reaction conditions were the same as those described under *Experimental* for 5 days at room temperature and 4 hr in simulated gastric fluid at 37°. No thermal energy analyzer responsive peaks were detected in either sample (Fig. 5). Based on the lowest detectable limit for nitrosodimethylamine under the conditions of analysis, a maximum of 0.0001% of nitrosodimethylamine could be present in the ascorbic acid-containing samples in contrast to 0.06 and 0.03% of this nitrosamine found in the gastric fluid and 1-day room temperature samples, respectively. These results indicate that ascorbic acid is an extremely effective agent in protecting against methapyrilene nitrosation. Hence, it follows that susceptible pharmaceutical amines could be safeguarded against *in vivo* nitrosation if they were compounded with ascorbic acid.

This suggestion has already been made (7). Technologically, however, other considerations come into play. If the nitrosation rate of the amine is sufficiently slower than the ascorbate and nitrite reaction, one can safely conclude that *in vivo* nitrosation of the amine will be halted successfully. Aside from kinetic considerations, this would presume that the ascorbic acid solution rate is comparable to or better than that for the susceptible amine. One formulation approach to assure this could be a T-T tablet with ascorbic acid comprising the outer tablet.

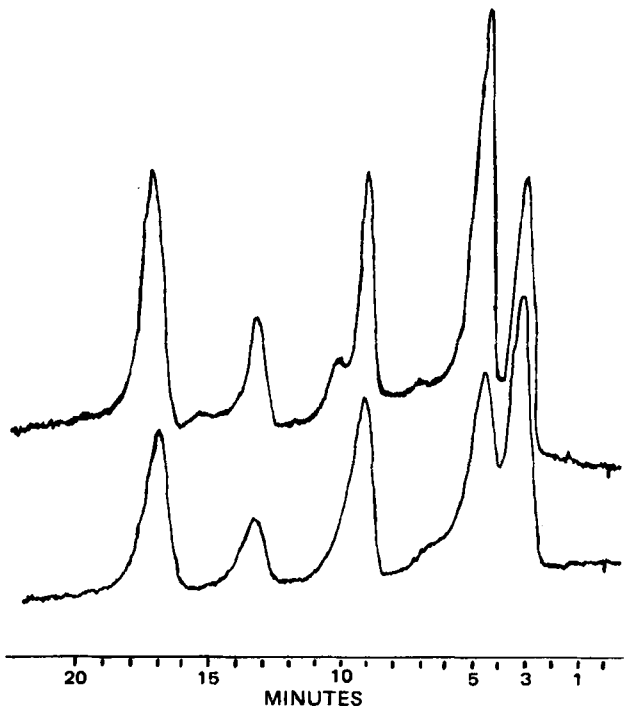

Figure 4—*HPLC–thermal energy analyzer chromatograms. Key: top, methapyrilene dissolved in sterile distilled water and immediately reacted with nitrite for 4 hr at 37°, 10-μl injection of methylene chloride extract, and attenuation 16×; and bottom, methapyrilene incubated at room temperature in sterile distilled water for 7 days and then reacted with nitrite for 4 hr at 37°, 10-μl injection of methylene chloride extract, and attenuation 32×.*

Recent experimental work has shown that yet another precaution must be taken. Aminopyrine is a popular headache remedy on the European market. It is also a tertiary amine, which nitrosates extremely rapidly in

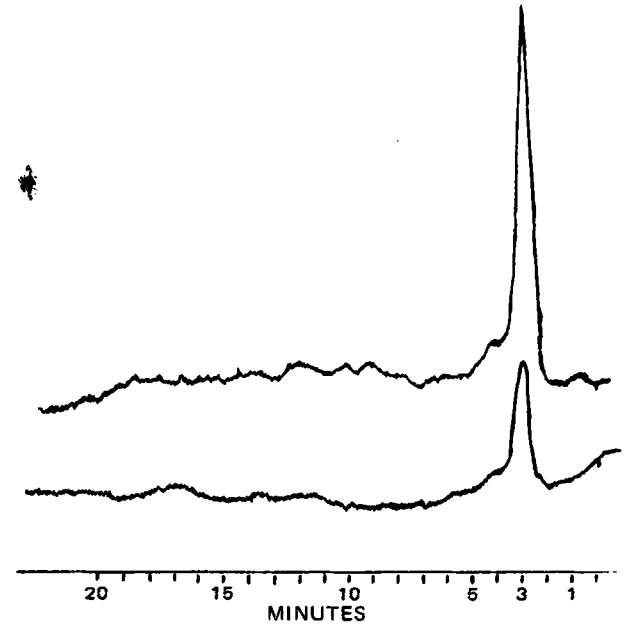

Figure 5—*HPLC–thermal energy analyzer chromatograms. Key: top, same as Fig. 4 (top) with twice molar ascorbic acid added with nitrite, 10-μl injection of methylene chloride extract, and attenuation 16×; and bottom, same as Fig. 4 (bottom) with twice molar ascorbic acid, 10-μl injection of methylene chloride extract, and attenuation 16×.*

the presence of nitrite to yield nitrosodimethylamine (20). Eisenbrand *et al.* (21) showed that tablets containing 300 mg of aminopyrine and protected with 160 mg of ascorbic acid contained 88, 89, and 57 μg/kg of nitrosodimethylamine as purchased. These same tablets, when exposed for about 12 hr to a continuous air flow containing 1 ppm of nitrogen dioxide, comparable to many urban atmospheres (chamber volume of 50 m^3, air flow of 50 m^3/hr), were found to contain 5090 μg/kg of nitrosodimethylamine. Obviously, the heterogeneous admixture of aminopyrine and ascorbic acid in a tablet of this nature is less than effective in protecting the aminopyrine crystals from attack by nitrogen dioxide molecules.

Aminopyrine is unusual in being a tertiary amine that is more rapidly nitrosated than most secondary amines. This fact is at least justified under aqueous nitrosation conditions if one considers that its pKa is 5.04. Whether or not the same aberrant behavior extends to its ability to be directly nitrosated by gaseous nitrogen dioxide as compared to other amines is not known.

Successful tablet formulations containing ascorbic acid to protect against the nitrosation of a susceptible amine should preclude the possibility of direct gas phase exposure of the amine to nitrogen dioxide or contain suitable experimental assurances that this nitrosation route is not possible. Protection of this type of susceptible amine would probably involve encapsulation of the amine crystals or possibly the entire tablet with a suitable barrier.

SUMMARY AND CONCLUSIONS

Methapyrilene contains a dimethylamine moiety, which, on the basis of previous studies (8, 15), was suspected of reacting with a nitrosating intermediate to form nitrosodimethylamine, a potent animal carcinogen. The present studies demonstrated that very small yields of nitrosodimethylamine are obtained in neutral solutions at room temperature after 1 day and also under conditions simulating gastric digestion (*i.e.*, 4 hr at 37° at pH 3.7). Severe reaction conditions (4 hr at 90° at pH 3.7) are required to obtain high yields (over 20%) in the reaction of methapyrilene with nitrite.

In near neutral solution at room temperature and under conditions simulating the environment of the stomach, the major pathway for the reaction of methapyrilene and nitrite is completely different than that leading to nitrosodimethylamine formation. One observed reaction is the formation of the secondary amine *N*-(2-pyridyl)-*N'*-dimethylethylenediamine (VIII) through nitrite oxidation of the thiophene-activated methylene bridge of the parent amine. A recent report (22) indicating that methapyrilene is metabolized *in vivo* to nonsulfur-containing metabolites tends to support this finding. Another secondary amine can be formed by removal of the side chain on the central nitrogen in the molecule leading to 2-(2-thienylmethylamino)pyridine. Evidence suggests that the formation of these secondary amines could lead to the generation of the corresponding nitrosamines under the acid conditions of the stomach.

Ascorbic acid, when present in a 2:1 molar ratio to nitrite ion, was completely effective in preventing the oxidative and nitrosative damage of the methapyrilene molecule in all systems studied.

The production of small, but toxicologically significant, amounts of nitrosodimethylamine and ~1%/day of VIII from methapyrilene under neutral aqueous conditions in the presence of nitrite indicates that caution should be exercised in any experimental protocol involving solution storage for the following reasons. Animal feeding studies cannot preclude the presence of preformed nitrosamines (*e.g.*, nitrosodimethylamine). In addition, ~1%/day of VIII, a secondary amine that has been shown to nitrosate much more rapidly than methapyrilene under simulated gastric fluid conditions, is formed.

The concept of protecting susceptible pharmaceutical amines from nitrosation by using ascorbic acid, either as its acid or salt form, is probably a viable goal. However, consideration must be given not only to aqueous sources of nitrosating intermediates but also to gaseous ones.

Prostaglandin Prodrugs I: Stabilization of Dinoprostone (Prostaglandin E_2) in Solid State through Formation of Crystalline C_1-Phenyl Esters

W. MOROZOWICH ˣ, T. O. OESTERLING, W. L. MILLER, C. F. LAWSON, J. R. WEEKS, R. G. STEHLE, and S. L. DOUGLAS

Received September 15, 1975, from the *Research Laboratories, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication December 28, 1978.

Abstract □ Dinoprostone *para*-substituted phenyl esters were synthesized in attempt to improve the solid-state stability of the parent prostaglandin. A phenol series covering a wide melting-point range was employed, and a linear relationship was observed between the phenol melting points and the resulting prostaglandin C_1-ester melting points. The crystalline esters showed improved solid-state stability over the parent compound, and many esters were biologically active.

Keyphrases □ Prostaglandins—dinoprostone, prodrugs, stabilization in solid state of crystalline C_1-phenyl esters, biological activity □ Prodrugs—dinoprostone, stabilization in solid state of crystalline C_1-phenyl esters, biological activity

Prostaglandins are naturally occurring long chain substituted carboxylic acids with various biological effects *in vivo* (1–3). These compounds are undergoing extensive molecular modification in attempts to increase potency and specificity and to improve pharmaceutical and biological properties. Chemical programs aimed at increasing potency or specificity involve the creation of analogs through substituent synthesis or skeletal modification, whereas biopharmaceutical properties are modified *via* prodrugs.

BACKGROUND

Following the identification of several highly active prostaglandin analogs (4–7), attention has been directed toward improving pharmaceutical or biological properties through the *in vivo* reversible modification known as the prodrug (8). Many highly active prostaglandin analogs do not have optimal pharmaceutical properties such as solubility, stability, and crystallinity nor optimal biological properties such as absorption and duration of action (9). These problems may be solved through prodrug synthesis.

Two pressing problems with prostaglandins are E-series prostaglandin instability and difficulty in handling many prostaglandins that occur as liquids (9). This report focuses on the utility of crystalline C_1-esters in improving the solid-state stability of dinoprostone (I).

Dinoprostone (I) instability is due to the 9,11β-ketol system in which the activated C_{11}-hydroxyl undergoes facile elimination to give prostaglandin A_2 (10). Attempts to stabilize this prostaglandin have included solvent stabilization (11), complex formation (12, 13), and bisulfite formation at C_9 (14).

Crystalline high-melting C_1-esters were synthesized to improve the solid-state stability of I based on the following reasoning. Compound I is a crystalline solid (mp 63°) stable at room temperature for short periods but liquefies and decomposes rapidly after a few months. High melting I C_1-esters might maintain crystal integrity and improve the solid-state stability. Prediction of the ester melting points was not possible *a priori* from structural formula inspection, but, intuitively, phenols capable of strong intermolecular interaction were expected to provide high melting esters. The melting point of the parent phenol used in ester formation reflects the intermolecular interaction strength; therefore, higher melting phenols would be expected to give higher melting esters.

This work describes the synthesis of various I C_1-esters using a phenol series covering a wide melting-point range in an attempt to explore the: (*a*) relationship between the phenol and corresponding prostaglandin ester melting points, (*b*) utility of crystalline dinoprostone esters in improving the parent prostaglandin solid-state stability, and (*c*) influence of esterification on bioactivity.

RESULTS AND DISCUSSION

Synthesis—Prostaglandin C_1-esters have been synthesized by numerous routes including the *N,N*-dicyclohexylcarbodiimide procedure (15), carboxyl activation with pivaloyl chloride (16), and carboxyl activation with sulfonyl halides (17). In this work the isobutyl chlorocarbonate carboxyl activation route widely used in peptide synthesis (18) was chosen.

Reaction of I with isobutyl chlorocarbonate (II) gave the acylisobutylcarbonate mixed anhydride (III); upon reaction with 1.5–4 mole equivalents of the appropriate phenol in pyridine at room temperature, III gave the desired C_1-esters (V) (Scheme I). The use of a small excess (0.1–0.5 mole equivalents) of II generally gave quantitative I esterification in less than 15 min; for convenience, the reactions were allowed to stand at room temperature for up to 3 hr before workup.

The esters were purified by silica gel column chromatography and, upon recrystallization, they were shown to be pure by silica gel TLC. The structures were verified by combustion analyses (Table I) and, in some cases, by mass spectral analyses.

[a] Prostaglandin E = 1. [b] Reference compound. [c] Minimal effective dose (MED_{100}) for 100% inhibition of pregnancy. [d] Relative potency and 95% confidence interval in parenthesis. [e] Amount equivalent to 200 μg of I.

Melting Points—Plotting the I C_1-ester melting points *versus* the starting phenol[1] melting points (Fig. 1) showed that higher melting phenols generally gave higher melting esters. The lowest melting ester on the plot was that of 5-indanol (19).

The least-squares line is shown without the most deviant point (V*f*, the *p*-tritylphenyl ester). The correlation coefficient was 0.937 (slope, 0.57; intercept, 10.1°). Inclusion of V*f* decreased the correlation coefficient to 0.780 (slope, 0.43; intercept, 31.1°). The reason for the large deviation of V*f* is not clear but could be the isolation of an unusually low melting polymorph or a different crystal packing arrangement caused by exceptional ester bulkiness.

Structurally, the amido-substituted phenyl esters provided higher melting points than the acyl- or aromatic-substituted phenyl esters, presumably due to strong amido moiety hydrogen bonding (20). The melting points increased progressively from the *p*-acetamidophenyl ester (V*g*) to the *p,p'*-acetamidobenzamidophenyl ester (V*n*). The latter ester is remarkably effective in raising the melting point of I and is the highest melting ester (173.2–176.2°) recorded to date.

Stability—Storage of crystalline esters V*c*–V*e*, V*g*–V*l*, and V*n* at room temperature for 23–30 months resulted in no detectable degradation as shown by silica gel TLC; the esters remained as white solids. The free acid I, on the other hand, underwent 44–59% degradation in 12 months at room temperature with partial liquefaction. Since the liquid esters V*a* and V*b* underwent decomposition as well as discoloration upon storage at room temperature, the improved solid-state stability of the crystalline esters apparently is due to the stabilization by the crystal lattice.

Biological Activity—The ester biological activities in three test screening systems are summarized in Table II. Significant activity was observed in the antifertility assay for all compounds except V*d*, V*m*, and V*n*. Full activity was attained with V*c*. Some esters were nearly as active as I in the gerbil colon assay, but all compounds were less active than I in the rat blood pressure assay.

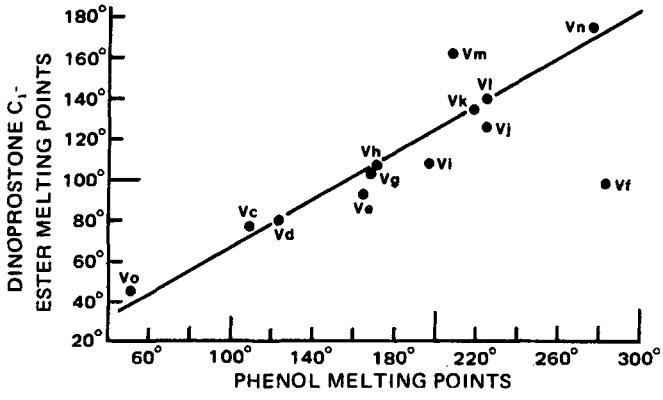

Figure 1—*Plot of the melting points of starting phenols* versus *the melting points of resulting dinoprostone C_1-esters. The least-squares line is shown omitting ester V*f.

[1] The melting-point range midpoint was used.

EXPERIMENTAL

Materials and Methods—Compound I[2] (mp 63°) purity was verified by silica gel TLC using ethyl acetate–acetic acid (97:3). The phenols, except those synthesized below, were obtained commercially[3]. Pyridine (analytical reagent) was dried over molecular sieves[4] for 1 week before use. All other solvents were glass-distilled quality[5]. Acetone and tetrahydrofuran were dried by stirring 100 ml of the solvent with 50 g of alumina[6] for 15 min followed by filtration under nitrogen.

Column chromatography was conducted on 0.063–0.2-mm silica gel[7]. In most cases, the support was deactivated by stirring 1 kg of silica gel with 4 liters of ethyl acetate containing 30 ml of water. After the slurry settled for about 2 min, the supernate was decanted and the remaining thick slurry was poured into glass columns. Silica gel TLC was conducted on 250-μm layer plates[8]. The compounds were visualized by spraying the developed plates with aqueous 15% ammonium sulfate followed by charring on a hot plate.

Synthesis—p-*Benzamidophenol*—A solution of 20 g of *p*-aminophenol in 200 ml of dry pyridine was treated with 20 g of benzoic anhydride. After 4 hr at room temperature, the solvent was removed under vacuum at 45°, and the residue was dissolved in 200 ml of hot methanol. Dilution with 300 ml of water gave 22 g of tan crystals. An 11.2-g portion of the product was recrystallized from 350 ml of hot acetonitrile, affording 8.5 g of white crystals, mp 218.0–218.5°. The product was soluble in alkali, indicative of a phenol, and the mass spectrum revealed a molecular ion at *m/e* 213.

Anal.—Calc. for $C_{13}H_{11}NO_2$: C, 73.22; H, 5.20; N, 6.56. Found: C, 73.49; H, 5.30; N, 6.47.

p,p'-*Acetamidobenzamidophenol*—A solution of 12.5 g of *p*-acetamidobenzoic acid in 250 ml of dry tetrahydrofuran was treated with 11.1 ml of triethylamine, and partial crystallization of the triethylammonium salt occurred. Isobutyl chlorocarbonate (10.4 ml) was added to the suspension with stirring, and a voluminous precipitate occurred. After 5 min of stirring at room temperature, a solution of 13.3 g of *p*-aminophenol in 80 ml of dry pyridine was added. The suspension was stirred for 40 min and then diluted with 2 liters of water, affording 14.3 g of a brown solid. Then the product was dissolved in 500 ml of hot methanol. After partial decolorization with 1 g of charcoal, the solution was diluted with 300 ml of water, giving 5.9 g of white crystals, mp 275.0–277.0°.

Anal.—Calc. for $C_{15}H_{14}N_2O_3$: C, 66.69; H, 5.18; N, 10.36. Found (corrected for 3.87% H_2O): C, 66.08; H, 5.36; N, 10.33.

The compound was rendered anhydrous by drying under vacuum at 110° overnight.

p-*Benzamidophenyl Ester of Dinoprostone* (*Vk*)—A solution of 260 mg (0.74 mmole) of I in 20 ml of dry acetone was treated with 0.206 ml (1.48 mmoles) of triethylamine. While under a positive nitrogen atmosphere, the solution was cooled to −5°, and 0.194 ml (1.47 mmoles) of isobutyl chlorocarbonate was added. Rapid crystallization of triethylamine hydrochloride occurred. After 3 min at −5°, a solution of 0.8 g (3.76 mmoles) of *p*-benzamidophenol in 8 ml of dry pyridine was added.

After 3 hr at room temperature, the solvent was removed under vacuum at 45°, and the resulting oily residue was purified by column chromatography on 80 g of silica gel. Elution was achieved with 150 ml of ethyl acetate followed by acetonitrile. TLC showed the product was in tubes 25–30 (15 ml each); upon solvent removal under vacuum at 45°, a white solid was obtained. The product was dissolved in 20 ml of tetrahydrofuran and diluted with 20 ml of hexane, affording 269 mg of white crystals, mp 132.8–135.0°, after drying under vacuum at 50°. The product was pure by silica gel TLC with ethyl acetate as the developing solvent.

Anal.—Calc. for $C_{33}H_{41}NO_6$: C, 72.37; H, 7.55; N, 2.56. Found: C, 71.95; H, 7.34; N, 2.55.

Mass spectral analysis showed a peak at *m/e* 529 corresponding to $M^+ - H_2O$, and the fragmentation pattern supported the structure.

The other I C_1-esters were synthesized by similar methods.

Biological Assays—*Hamster Antifertility*—The esters were evaluated for their ability to inhibit pregnancy in adult female hamsters, as reported previously (21). The compounds were administered subcutaneously in 0.5 ml of a vehicle containing 30% ethanol and 70% physiological saline. (In some cases, the ethanol concentration was increased slightly to achieve dissolution.) The solutions were stored at −30° until used. The ester doses were equivalent to 200 μg of I/animal unless otherwise indicated. The minimum I dose giving 100% pregnancy inhibition was 200 μg. The percentage inhibition of pregnancy was determined from the number of animals pregnant in a six to 12 animal group.

Isolated Gerbil Colon—The male gerbil ascending colon was used to evaluate smooth muscle stimulating activity, as previously described (21). Generally, two colons were used for each test. The response to 3.2 and 10 ng/ml of prostaglandin E_1 was obtained, and increasing ester concentrations were tested until a response was obtained between the two standard concentrations. The standard concentration to test concentration ratio was calculated, and the activity was expressed as the range of these two ratios.

Rat Blood Pressure—Direct blood pressure measurement was made from a common carotid artery of anesthetized, mature female rats as described previously (21). Generally, only one rat was used for each test. The depressor response of 1 and 3.2 μg/kg of prostaglandin E_1 was determined following intravenous administration, and increasing test compound doses were administered intravenously until a response was obtained between the two standard doses. Activity was expressed as indicated for the gerbil colon.

Prostaglandin Prodrugs II: New Method for Synthesizing Prostaglandin C_1-Aliphatic Esters

W. MOROZOWICH ˣ, T. O. OESTERLING, W. L. MILLER, and S. L. DOUGLAS

Received September 15, 1975, from the *Research Laboratories, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication December 28, 1978.

Abstract □ A new method for synthesizing C_1-aliphatic esters of dinoprost and dinoprostone without using hydroxyl protective groups is described. Reaction of the prostaglandin with an alkyl halide in the presence of the sterically hindered amine *N,N*-diisopropylethylamine proceeds smoothly to give C_1-esters in various solvents at ambient or slightly elevated temperatures. Polar solvents were strongly catalytic, and even the hindered *tert*-butyl esters were synthesized by employing solvents such as dimethylformamide or dimethyl sulfoxide. Biological evaluation in the hamster antifertility assay showed that some esters maintained high bioactivity.

Keyphrases □ Prostaglandins—prodrugs, dinoprost, dinoprostone, C_1-aliphatic esters, synthesis, biological activity □ Prodrugs–dinoprost and dinoprostone, C_1-aliphatic esters, synthesis, biological activity □ Dinoprost—prodrugs, C_1-aliphatic esters, synthesis □ Dinoprostone—prodrugs, C_1-aliphatic esters, synthesis

The conversion of prostaglandins to C_1-methyl esters has resulted in increased or more rapid intestinal absorption (1, 2), as well as in greater potency following intravenous administration (3). Since few prostaglandin C_1-aliphatic esters have been reported, various aliphatic esters of dinoprost (I) and dinoprostone (II) were synthesized for evaluation of their utility as prodrugs in continuation of our effort on prostaglandin prodrugs (4).

The S_N2 reaction of inorganic metal salts of carboxylic acids and alkyl halides produces C_1-alkyl esters (5), but the

[a] Conducted on the trimethylsilyl derivatives of the II esters and on the trimethylsilyl–methoxime derivatives of the IV esters unless otherwise indicated. [b] The minimum effective doses for 100% pregnancy inhibition are 100 μg of I/animal and 200 μg of II/animal. The dose is stated as the equivalent amount of the parent prostaglandin. [c] Characterized by silica gel TLC and GLC as identical to authentic I methyl ester prepared by diazomethane (13). [d] Compound crystallized upon storage in a freezer. [e] Mass spectral analysis was conducted on nonderivatized ester. Key fragmentation pattern: m/e 476 ($M^+ - 18$), 458 ($M^+ - 36$), and 405 ($M^+ - 18 - 71$). [f] Prepared previously by the diazoalkane route (8). [g] Administered in 95% ethanol. Compound was inactive in the standard vehicle.

reaction generally is slow due to the use of a heterogeneous medium. A recent communication reported that prostaglandins could be converted rapidly to C_1-*p*-nitrophenacyl esters by reaction of the prostaglandin with *p*-nitrophenacyl bromide in the presence of a small excess of the sterically hindered amine *N,N*-diisopropylethylamine (6). The competing quaternary ammonium side reaction between this sterically hindered amine and the phenacyl halide was slower than the esterification reaction, thereby allowing successful phenacyl ester formation.

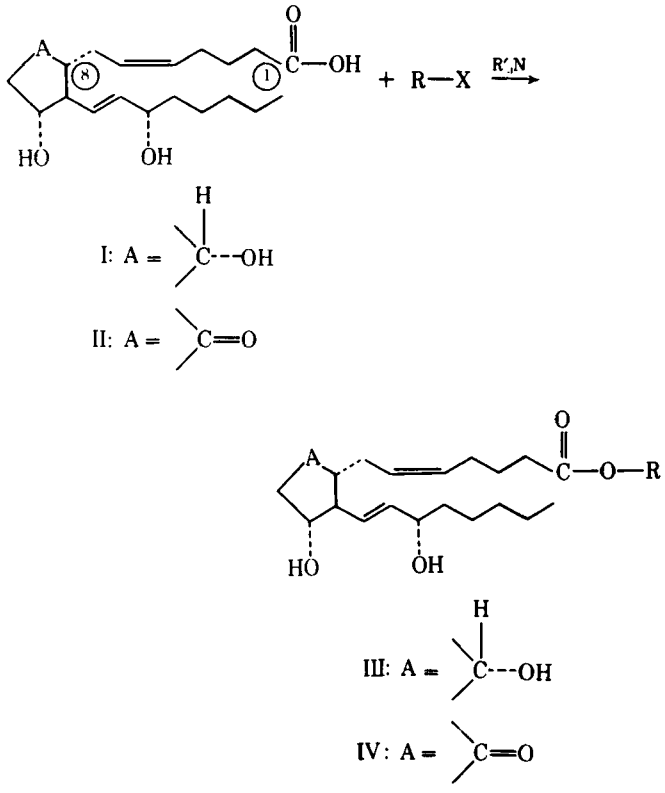
This report shows that prostaglandin C_1-aliphatic esters can be synthesized rapidly at ambient or slightly elevated temperatures using the prostaglandin, *N,N*-diisopropylethylamine, and an alkyl halide in a suitable solvent.

RESULTS AND DISCUSSION

Synthesis—The general method for synthesizing the aliphatic I and II C_1-esters involved reaction of the parent prostaglandin in a suitable solvent with a 3–10-mole alkyl halide excess in the presence of a 2–4-mole *N,N*-diisopropylethylamine excess (Scheme I).

The reaction was monitored by silica gel TLC, and greater than 90% esterification generally occurred with the linear alkyl halides in 1–24 hr at room temperature; in some cases, mildly elevated temperatures (40–50°) were employed. Polar solvents showed a remarkable catalytic effect as illustrated by the facile synthesis of the *tert*-butyl II ester. Reaction of II in dimethyl sulfoxide with *tert*-butyl iodide and *N,N*-diisopropylethylamine gave about 70% of the *tert*-butyl ester in 3 hr at 40°, as evidenced by silica gel TLC; in acetonitrile, about a 10% reaction occurred in the same time period.

Esterification of II in polar solvents generally gave a small amount (<10%) of a side product slightly less polar than the desired C_1-ester (IV). The by-product subsequently was removed by column chromatography and was identified tentatively as the II 8-iso C_1-ester since the II 8-isomer is slightly less polar than II by silica gel TLC. Previously, it was shown that prostaglandin E_1 undergoes isomerization at C_8 under mildly basic conditions (7). Presumably, the excess amine in the esterification medium was responsible for isomerization of either II or the resulting C_1-ester. Indeed, in the absence of an alkyl halide, treatment of II with a 3–20-mole excess of *N,N*-diisopropylethylamine in dimethyl sulfoxide or dimethylformamide gave about 5% of the II 8-isomer in 24 hr at room tempera-



Scheme I

ture. The II 8-isomer was identified by TLC in comparison with the authentic compound.

No II isomerization occurred in acetonitrile under the same conditions, in accord with similar observations reported previously (6).

Excepting the branched esters, the crude ester yield as shown by TLC generally was quantitative with I and about 90% with II due to formation of by-products. The esters were purified by conventional column chromatography using silica gel, and purity was verified by TLC. Table I lists the esters synthesized along with some of the mass spectral fragment ions observed. The only esters isolated as crystalline solids were the *n*-decyl esters (IV*g* and III*j*), the pentafluorobenzyl ester (IV*h*), and the *p*-nitrobenzyl ester (IV*i*).

The simplicity of the alkyl halide esterification method makes it an attractive alternative to previous methods that employed diazoalkanes (8), *N,N*-dicyclohexylcarbodiimide (9), dimethylsulfate (10), and acid chloride–carboxyl activation (11).

Biological—Preliminary prostaglandin C_1-ester screening in the subcutaneous hamster antifertility assay showed that all compounds were active in the range of 50–1000 μg (weight basis)/animal (Table I). Some of the esters, such as the isopropyl ester (III*d*), appeared to be more active than I, for which the minimal effective dose for 100% inhibition of pregnancy was 100 μg/animal.

Initial evaluation of orally administered ethyl ester (III*b*) and propyl ester (III*c*) in hamsters showed that both esters gave 33% inhibition of pregnancy at 500 μg/animal, but I was ineffective in inhibiting pregnancy at this dose. The results indicate improved oral absorption.

EXPERIMENTAL

Materials and Methods—The purity of I[1] and II[1] was verified by silica gel TLC using ethyl acetate–acetic acid (97:3). The alkyl halides were obtained commercially[2]. All solvents were glass-distilled quality[3].

Column chromatography was conducted on 0.063–0.2-mm silica gel[4]. Silica gel TLC was conducted on 250-μm layer plates[5], and visualization was achieved by spraying the developed plates with aqueous 15% ammonium sulfate followed by charring on a hot plate. The mass spectra[6] of the I esters were obtained after conversion to the trimethylsilyl derivatives using a mixture of bis(trimethylsilyl)acetamide–trimethylchlorosilane–hexamethyldisilazane–pyridine (1:1:1:3). The II esters were converted initially to the C_9-methoxime derivatives by reaction of ~1 mg of the ester with 0.2 ml of a saturated solution of hydroxylamine hydrochloride in pyridine for 6 hr at 50°. The methoxination reaction mixture was treated with 0.5–1 ml of the silylating mixture followed by mass spectral analysis.

Ester Synthesis—Representative examples of the methods for synthesizing C_1-esters are given here. All other esters were synthesized by similar procedures.

Dinoprostone Ethyl Ester (IV*a*)—A solution of 181 mg of II in a mixture of 2 ml of dimethyl sulfoxide, 0.2 ml of *N,N*-diisopropylethylamine, and 1 ml of ethyl iodide was allowed to stand at room temperature for 3 hr. Silica gel TLC (ethyl acetate–acetic acid, 97:3) showed greater than 95% conversion of II to the less polar ester. The solution was diluted with 100 ml of ethyl acetate and extracted with 100 ml of aqueous 3% citric acid, and the organic phase was dried with sodium sulfate. After solvent removal at 40° under vacuum, the brown oily residue was chromatographed over 50 g of silica gel with ethyl acetate–methanol (99:1) as the eluant. The product fractions were identified by silica gel TLC. After solvent removal, 75 mg of a colorless oil was isolated.

Dinoprost Benzyl Ester (III*k*)—A solution of 116 mg of I in a mixture of 0.2 ml of *N,N*-diisopropylethylamine, 0.3 ml of benzyl bromide, and 3 ml of acetonitrile was stored at room temperature overnight. Silica gel TLC (ethyl acetate–acetic acid, 97:3) showed quantitative esterification. After extraction and column chromatography as for IV*a*, 85 mg of a colorless oil was isolated.

Biological: Hamster Antifertility Assay—The esters were evaluated for their ability to inhibit pregnancy following subcutaneous injection in adult female hamsters in estrus as reported previously (4, 12) using an ethanol–physiological saline (3:7) vehicle.

Molecular Topology and Aqueous Solubility of Aliphatic Alcohols

ARTHUR CAMMARATA

Received August 31, 1978, from the *School of Pharmacy, Temple University, Philadelphia, PA 19140.* Accepted for publication December 28, 1978.

Abstract □ A physically based method for arriving at topological indexes is described. The derived indexes correlate with molecular surface areas and with the molecular connectivity index. The newly derived index seems to account better for the expected distinctions among primary, secondary, and tertiary alcohol aqueous solubilities. This study suggests that the Del Re method for calculating molecular charges and dipole moments also may be used, without appreciable change, to provide estimates of molecular refraction.

Keyphrases □ Alcohols, aliphatic—molecular topology, aqueous solubility, structure–activity relationships □ Topological indexes—aliphatic alcohols, molecular surface area, molecular connectivity, aqueous solubility, structure–activity relationships □ Solubility, aqueous—aliphatic alcohols, molecular topology, structure–activity relationships □ Structure–activity relationships—aliphatic alcohols, molecular topology, aqueous solubility

About 3 years ago, an approach was presented (1) for assigning a numerical index to acyclic hydrocarbons and for ranking them according to their degree of branching. To each atom (vertex) of a molecular structure (graph) was assigned a value $1/\nu^{1/2}$, where ν is the vertex valency. The valency may be taken as the number of valence electrons less the number of hydrogens associated with an atom. Each molecular bond (edge) was characterized by the product of associated atom values: $1/(\nu_i\nu_j)^{1/2}$. The branching index was obtained by summing all bond values appropriate to a molecule. Reciprocal values were used to distinguish bond types since the branching indexes thus derived parallel the ordering for branched structures arrived at from a binary representation of their connectivity (bonding or topological) matrixes.

BACKGROUND

This approach has been extended considerably (2). In particular, the treatment of cyclic aliphatics, alkenes, aromatics, and heteroatomic substances was left unspecified previously (1). The definition for ν [also termed δ (2)] was extended to include first row atoms of the periodic table (C, N, and O) irrespective of the nature of the bonding; valency values for the halogens and for sulfur were established empirically; and an adjustment to the branching index (termed χ), which is appropriate to cyclic aliphatics, was provided (2).

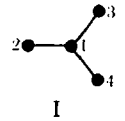
No physical definition for the branching index exists, although it appears to be related to molecular refraction or to molecular volume by the nature of its construction. The physical properties of branched aliphatic substances frequently differ from those of corresponding n-aliphatic substances. Hence, a graph of a physical property (or its logarithm) against an integer (1, 2, . . .) representing the number of carbon atoms in a side chain generally will be linear for the n-aliphatic substances, but considerable departures from this line most often will be noted for branched aliphatic substances. An index such as that described, which allows both n-aliphatic and branched aliphatic substances to lie on a line when graphed against a physical property, reflects a change due to branching in molecular refraction or to molecular volume, because these are the principal physical attributes of n-aliphatic substances.

In a sense, the derivation of branching indexes by the described approach corresponds to the determination of a molecular refraction value using bond refractions adjusted according to the nature of the immediate molecular environment. That is, molecular refractions, which are usually considered to be additive–constitutive properties, are in reality only approximately additive–constitutive; more accurate estimates require consideration of the perturbations induced by differing atomic environments. Such a perturbational approach has been taken (3, 4) for molecular dipole calculation. Bond dipoles are vectorially additive, but the effect of differing atomic environments has to be taken into account for more accurate molecular dipole estimates.

In this study, the perturbational approach described previously (3–5) was applied topologically to arrive at numerical indexes appropriate to a given molecule. The indexes obtained for a hydrocarbon series have the same general attributes as the molecular connectivity index. The indexes obtained for a series of 51 aliphatic alcohols correlate with their aqueous solubilities similarly to the correlations reported when their molecular surface areas (6) or connectivity indexes (7) were used. These results suggest that the perturbational approach may provide a means of arriving at topographically consistent molecular refraction and charge estimates.

EXPERIMENTAL

Isolated atoms, when bonded, have their properties changed. The electron affinity toward an isolated atom differs from the electron affinity for a bonded atom. Hence, depending on the bonding about an atom, the electronegativity and, consequently, the charge and polarizability characteristics of the atom will vary. For a molecule such as isobutane (I) (hydrogen atoms suppressed for simplicity), a given atomic property for a bonded atom, δ_i, may be said to be perturbed from the isolated atom value, δ_i^0, in a linear manner with respect to each similar atomic property for its immediate neighbors. Thus, a set of equations may be written (one equation for each atom of the molecule) that represents the existing perturbations within a molecule (Eqs. 1*a*–1*d*):



I

$$\delta_1 = \delta_1^0 + \gamma_{12}\delta_2 + \gamma_{13}\delta_3 + \gamma_{14}\delta_4 \quad \text{(Eq. 1}a\text{)}$$

$$\delta_2 = \delta_2^0 + \gamma_{21}\delta_1 \quad \text{(Eq. 1}b\text{)}$$

$$\delta_3 = \delta_3^0 + \gamma_{31}\delta_1 \quad \text{(Eq. 1}c\text{)}$$

$$\delta_4 = \delta_4^0 + \gamma_{41}\delta_1 \quad \text{(Eq. 1}d\text{)}$$

The coefficients γ_{ij} provide a measure of the influence of bonded atom i on bonded atom j. With numerical values for γ_{ij} and δ_i^0, one can solve the simultaneous equations represented by Eq. 2 so as to estimate the atomic properties, δ_i, appropriate to the atoms in a given molecule:

$$\begin{vmatrix} 1 & -\gamma_{12} & -\gamma_{13} & -\gamma_{14} \\ -\gamma_{21} & 1 & 0 & 0 \\ -\gamma_{31} & 0 & 1 & 0 \\ -\gamma_{41} & 0 & 0 & 1 \end{vmatrix} \begin{vmatrix} \delta_1 \\ \delta_2 \\ \delta_3 \\ \delta_4 \end{vmatrix} = \begin{vmatrix} \delta_1^0 \\ \delta_2^0 \\ \delta_3^0 \\ \delta_4^0 \end{vmatrix} \quad \text{(Eq. 2)}$$

Inspection of Eq. 2 shows that the matrix of the γ_{ij} coefficients has the form of a bonding or topological matrix. Therefore, a consistently applied set of arbitrary values for δ_i^0 and γ_{ij} may be used to arrive at topographically meaningful indexes for the atoms of a molecule. The sum of the atom indexes would then provide a branching index. In this work, the following conditions were applied: (*a*) molecular structures were represented with the hydrogen atoms suppressed; (*b*) δ_i^0 values were chosen to correspond to the number of valence electrons on an atom ($\delta_C^0 = 4$; $\delta_O^0 = 6$); and (*c*) the value of γ_{ij} ($\gamma_{ij} = \gamma_{ji}$) was taken as 0.1 for C–C and C–O bonds because such a value provides computed atom indexes, δ_i, that are all positive.

RESULTS AND DISCUSSION

The 51 aliphatic alcohols listed in Table I were the subject of a study correlating molecular surface area with aqueous solubility (6). The same alcohols were included in an investigation correlating aqueous solubility with the molecular connectivity index, χ (7). These compounds represent a variety of *n*-aliphatic and branched aliphatic alcohols and constitute a good series for testing the relation between the newly derived branching index, M', and the molecular connectivity index. Linear regression performed on the indexes leads to the correlation equation:

$$\chi = 0.0990(\pm 0.0031)M' - 0.3981(\pm 0.1292) \qquad \text{(Eq. 3)}$$
$$n = 51 \quad s = 0.175 \quad r = 0.976 \quad F(1,49) = 982.7$$

where n is the total number of compounds, s is the standard error of the estimate, r is the correlation coefficient, and F is the computed F ratio for the correlation. The values in parentheses beside each regression coefficient are the standard errors for the regression coefficient estimates. The correlation between the two indexes is highly significant ($p < 0.01$).

A comparison of atom indexes for select molecules is instructive. In the surface area approach (6) and the molecular connectivity approach (2), hydrogen atoms bonded to carbon are taken into account either explicitly in terms of their contribution to a van der Waals radius or implicitly as the difference between the valence electron number and the number of hydrogens bonded to an atom. In the present approach, hydrogen atoms are not considered either explicitly or implicitly; a molecule is viewed as a linked chain of C and O atoms and with no other distinction.

Table II compares indexes for the methyl and methylene groups in 1-nonanol. The surface area approach shows that the terminal methyl group differs from the methylene groups and that the methylene groups nearest the terminal points of the chain differ from those more central in the chain. A similar pattern is noted for the atom indexes obtained in this work but not for the bond indexes obtained from the molecular connectivity approach. The molecular connectivity approach distinguishes a terminal methyl group from internal methyl groups since the product $(1/v_i^{1/2}v_j^{1/2})$ differs in each instance; but the methylene groups in the chain necessarily are identical as in this instance the product $(1/v_i^{1/2}v_j^{1/2})$ is the same. Since the results of this work are purely topographical in origin, methyl and methylene group distinctions apparently are a necessary consequence of both molecular topography (geometry) and atomic valency. The perturbational approach described in this work can be extended to include hydrogens. In principle, both topographical and valency effects can be taken into account.

Molecular branching or cyclization can affect the molecular physical properties by reducing the surface exposed to an external environmental influence. For example, neopentane as opposed to pentane has the central carbon atom effectively shielded from external influences by the methyl groups bonded to it. Cyclohexane as opposed to *n*-hexane has the inner

CH_2(5)	31.82	4.99	0.707
CH_2(6)	31.82	4.99	0.707
CH_2(7)	31.82	4.99	0.707
CH_2(8)	42.75	4.94	0.707
CH_3(9)	84.92	4.49	1.000

[a] From Ref. 6. [b] These atom indexes are used to derive a bond index, which is the basis of the approach in Ref. 1.

surfaces of the ring atoms shielded from external influences to a greater extent than the outer surfaces of the ring atoms. Branched or cyclic substances will be expected to have lower surface areas, molecular refractions, and molecular volumes when compared with isomeric straight-chain substances. A branching index, irrespective of its origin, seeks to mirror this expectation.

Table III compares the total surface area, the perturbationally derived index M', and the connectivity index χ for these illustrative compounds. The connectivity index for the acyclic hydrocarbons mirrors the order of their computed total surface areas, but a comparison of cyclic and straight-chain isomers shows that the order is reversed. Since the molecular connectivity approach is bond centered and cyclic hydrocarbons contain one more bond than their acyclic counterparts, an amount corresponding to the additional bond contribution should be subtracted from the computed χ value for cyclic hydrocarbons when making such comparisons (2). This adjustment properly orders χ with respect to total surface area in a comparison of cyclic with noncyclic hydrocarbons.

Since the perturbationally derived index is atom centered rather than bond centered, no adjustment for cyclic hydrocarbon indexes seems necessary. However, a comparison of M' with the total surface areas for the molecules in Table III shows that in each case the order is the reverse of that expected. This result can be traced to the fact that in the perturbational approach the more highly substituted atoms have higher derived atom indexes. Hence, atoms that are more shielded from external environmental influences are weighted more heavily in M' ($\equiv \Sigma\, \delta_i$).

An index that would weight shielded atoms less than those that are more external would be more physically realistic. For simplicity, one may make the definition $A' = \Sigma\, (1/\delta_i)$, although such a definition still will tend to overweight heavily shielded atoms. This index provides the expected surface area ordering for the compounds of Table III. When compared to the χ index, the A' index is slightly less satisfactory than M', as a statistical comparison for Eqs. 3 and 4 shows:

$$\chi = 2.573(\pm 0.088)A' - 0.317(\pm 0.138) \qquad \text{(Eq. 4)}$$
$$n = 51 \quad s = 0.197 \quad r = 0.972 \quad F(1,49) = 841.2$$

The correlation coefficients and calculated F ratios for Eqs. 5 and 6 show that the χ index has a slight statistical edge over A' in correlating the total surface areas (TSA) for the alcohols in Table I:

$$A' = 0.0060(\pm 0.0003)\text{TSA} - 0.515(\pm 0.103) \qquad \text{(Eq. 5)}$$
$$n = 51 \quad s = 0.105 \quad r = 0.943 \quad F(1,49) = 394.4$$

$$\chi = 0.0162(\pm 0.0006)\text{TSA} - 1.883(\pm 0.230) \qquad \text{(Eq. 6)}$$
$$n = 51 \quad s = 0.234 \quad r = 0.960 \quad F(1,49) = 579.7$$

The alcohol aqueous solubilities (Table I) have been correlated with total surface area (6) and with the χ index (7). There are four fewer alcohols in Table I than in the total surface area study (6); the four alcohols not considered are all long chain n-aliphatic alcohols and are equivalent to those in the study involving χ. The solubilities can be correlated by the respective indexes (Eqs. 7–9):

$$-\log X_2 = 0.0185(\pm 0.0006)\text{TSA} - 3.309(\pm 0.220) \qquad \text{(Eq. 7)}$$
$$n = 51 \quad s = 0.224 \quad r = 0.972 \quad F(1,49) = 832.8$$

$$-\log X_2 = 2.833(\pm 0.140)A' - 1.337(\pm 0.218) \qquad \text{(Eq. 8)}$$
$$n = 51 \quad s = 0.311 \quad r = 0.945 \quad F(1,49) = 408.2$$

Table III—Accessible Area Distinctions between Select Molecules

Compound	Structure	Molecular Index: Total Surface Area[a]	M'	χ	A'
n-Pentane		287.0	23.84	2.414	1.048
Neopentane		270.1	24.15	2.000	1.043
n-Hexane		319	28.84	2.914	1.248
Cyclohexane		279.1	29.94	3.000	1.200

[a] Reference 6.

$$-\log X_2 = 1.093(\pm 0.042)\chi - 0.961(\pm 0.155) \qquad \text{(Eq. 9)}$$
$$n = 51 \quad s = 0.248 \quad r = 0.965 \quad F(1,49) = 673.5$$

The computed correlation coefficients and F ratios for these correlations indicate that total surface area provides a better fit and A' a poorer fit of the data than does χ. All fits, however, are highly significant.

For any isomeric aliphatic alcohol series, the aqueous solubility increases in the order: primary < secondary < tertiary. The increase in solubility tends to parallel the carbonium-ion stability and suggests a distinction in the C–O bond character among primary, secondary, and tertiary alcohols. Such isomeric alcohols can be distinguished using the indexes described in the following way: (*a*) surface areas—separate the hydroxyl surface area (OHSA) from the total surface area to provide a hydrocarbon residue surface area (HYSA); (*b*) molecular connectivity—separate the C–O bond contribution (C_{CO}) from χ to provide the residual hydrocarbon index χ_R; and (*c*) perturbational—sum the atom indexes for a C–O bond (A'_{CO}) and separate the result from A' to provide the residual hydrocarbon index A'_R. A regression analysis of the alcohol solubilities using the respective hydroxyl and hydrocarbon residue indexes leads to:

$$-\log X_2 = 0.0265(\pm 0.0028)\text{OHSA} + 0.0184(\pm 0.0006)\text{HYSA} - 3.6227(\pm 0.2332) \qquad \text{(Eq. 10)}$$
$$n = 51 \quad s = 0.209 \quad r = 0.976 \quad F(2,48) = 480.7$$

$$-\log X_2 = 25.62(\pm 2.59)A'_{CO} + 2.91(\pm 0.11)A'_R - 8.94(\pm 0.88) \qquad \text{(Eq. 11)}$$
$$n = 51 \quad s = 0.230 \quad r = 0.971 \quad F(2,48) = 394.5$$

$$-\log X_2 = 3.060(\pm 0.444)C_{CO} + 1.064(\pm 0.043)\chi_R - 2.074(\pm 0.304) \qquad \text{(Eq. 12)}$$
$$n = 51 \quad s = 0.253 \quad r = 0.965 \quad F(2,48) = 323.4$$

For this analysis, the surface area values provide only slightly better correlation than do the corresponding perturbational indexes. These correlations are somewhat more significant than the correlation using molecular connectivity indexes.

A comparison of the correlation coefficients for the single-parameter and two-parameter relations (Eqs. 7–9 *versus* Eqs. 10–12) is instructive. No appreciable increase in the correlation coefficient is noted for the relations involving either the surface area index or the molecular connectivity index. However, for the correlations involving the perturbational index, the correlation coefficient is improved. Apparently, the expected hydroxyl group influence in primary, secondary, and tertiary alcohols on aqueous solubility is reflected better by the perturbational approach than by either the surface area or molecular connectivity approach.

CONCLUSIONS

The perturbational approach described previously (3–5) for the calculation of molecular charges and dipole moments contains the essential features for arriving at a topographical index[1]. The original parameterization given for the calculation of molecular charges probably can be maintained unchanged and the calculations can provide a topographical index related to molecular refraction and volume as well as charges. A

[1] Molecular connectivity indexes were derived for atoms, and these indexes were shown to correlate with CNDO/2 calculated electronic charges in alkanes. See L. H. Hall and L. B. Kier, *Tetrahedron*, 33, 1953 (1977).

combination of charge and molecular refraction indexes could extend greatly the applicability range of solubility-related correlation analyses such as have been reported for aromatic substances (8, 9). Since this approach is atom centered rather than bond centered, it appears highly suitable for arriving at molecular descriptors for pattern recognition studies (10, 11).

Rheological and Drug Release Properties of Oil Gels Containing Colloidal Silicon Dioxide

M. SHERRIFF * **and R. P. ENEVER** ˣ

Received July 25, 1978, from the *Department of Pharmaceutics, School of Pharmacy, University of London, London WC1N 1AX, England.* Accepted for publication December 27, 1978. *Present address: Department of Pharmaceutical Chemistry, School of Pharmacy, University of London, London WC1N 1AX, England.

Abstract □ The rheological properties of oil gels prepared by dispersing colloidal silica in *n*-dodecane and 1-dodecanol were examined. The differences in gel strength using these two media were accounted for by the difference in the extent of hydrogen bond formation between the silanol groups on the silica surface. The incorporation of methyl salicylate further modified the rheological properties of the gels. The drug was capable of hydrogen bonding with silanol groups in the *n*-dodecane gels, which increase gel strength at low concentrations; at high concentrations, the drug acted as a plasticizer. In 1-dodecanol systems, the drug acted solely as a plasticizer. Adsorption studies showed that methyl salicylate was adsorbed only on the silica particles in the *n*-dodecane medium. Interaction of the drug with the silanol groups in the *n*-dodecane systems did not appear to effect methyl salicylate release from the gels.

Colloidal silicon dioxide (fumed silica), produced by the vapor-phase hydrolysis of silicon tetrachloride, is used widely in the pharmaceutical industry as a binder and glidant in tablets and as a suspending agent and viscosity modifier in suspensions, ointments, and suppositories. Its use as a viscosity modifier is largely attributable to the ability of the very small silica particles to form a network structure throughout the medium by interparticle hydrogen bonding *via* the silanol groups on the silica surface. In addition to these particle interactions, there is possible bonding between the silanol groups and other components that are also capable of hydrogen bond formation. A detailed investigation of this type of interaction was published (1).

Modification of the magnitude of the interparticle interactions and production of ointment bases of different consistencies are possible by selecting, as dispersion media, oils that differ from each other in hydrogen bonding ability. Incorporation of a drug capable of hydrogen bonding into such bases might be expected to influence not only their rheological characteristics but also their drug release properties.

The object of this work was to quantify some of these phenomena by incorporating methyl salicylate into model gel systems prepared by dispersing fumed silica in the nonhydrogen bonding *n*-dodecane and the hydrogen bonding analog 1-dodecanol. The influences of silica and drug concentration on rheological and release properties are reported.

EXPERIMENTAL

Materials—Specially pure (99%) 1-dodecanol[1], laboratory reagent grade *n*-dodecane[1] and BP quality methyl salicylate[2] were used as received. Colloidal silicon dioxide[3] was dried for 1 hr at 150° and stored in a desiccator prior to use.

Gel Preparation—The requisite amount of continuous phase, containing drug where appropriate, was added to the silica, and the system was sonicated[4] for 30 sec to obtain a uniform dispersion. The gel was transferred to a glass container, sealed, and stored at 40°.

Rheological Properties—Dynamic rheological properties were measured using a modified Weissenberg rheogoniometer[5] in conjunction with a digital transfer function analyzer[6]. This rheogoniometer is one of the few commercially available instruments with facilities for both oscillatory (dynamic) and continuous shear measurements. The viscoelastic properties of materials may be evaluated using the oscillatory technique, and its application to pharmaceutical semisolid systems was described previously (2, 3).

Parallel plate geometry (platen radius of 3.75 cm) was used, and all gels were tested over the frequency range of 0.01–25.0 Hz using two torsion strips (Nos. 6 and 7) to minimize problems associated with natural resonance (4). The measurement temperature, as monitored by a thermocouple system[7] embedded in the top platen, was 37 ± 0.5°. Samples were

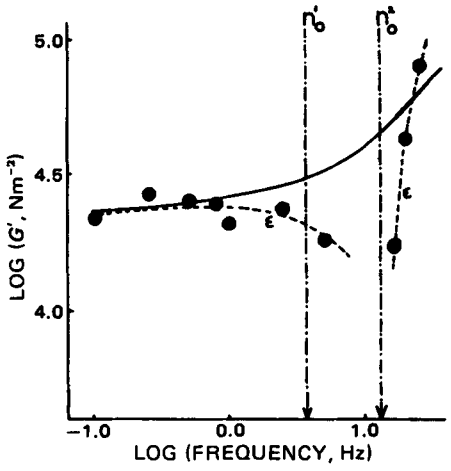

Figure 1—*Frequency dependence of log G′ for n-dodecane gel containing 8% (w/w) silica at 37°. The lines labeled ϵ represent the lower bounds of error due to the discontinuity in the data produced as the test frequency passed through the natural frequency of the rheogoniometer; n_0^1 is the resonance frequency for torsion strip No. 6, and n_0^2 is that for torsion strip No. 7.*

equilibrated for 30 min between the platens prior to measurement. For the 1-dodecanol gels, the gap width between platens was maintained at 0.05 ± 0.002 cm.

The analysis of Walters and Kemp (5) was used to evaluate the inertia parameter, α^2. The inertia parameter of the system is related to the complex dynamic viscosity of the test material, η^*, in the following manner:

$$\alpha^2 = \frac{-i\omega\rho}{\eta^*} \qquad \text{(Eq. 1)}$$

where i is the square root of -1, ω is the frequency of sinusoidal oscillation, and ρ is the density of the test sample.

For a linear viscoelastic system undergoing small amplitude oscillations, η^* is expressed as a combination of real and imaginary parts:

$$\eta^* = \eta^1 - \frac{iG'}{\omega} \qquad \text{(Eq. 2)}$$

where η^1 is the dynamic viscosity and G' is termed the real component of the complex shear modulus, G^*.

Once the inertia parameter has been determined, all test material parameters can be evaluated. Equation 2 can be transformed to give:

$$G^* = G' + iG'' \qquad \text{(Eq. 3)}$$

since the imaginary component, G'', of the complex shear modulus is given by:

$$G'' = \eta^1\omega \qquad \text{(Eq. 4)}$$

and G', the real component, describes the elastic properties of the system, and G'', the imaginary component, describes the viscous properties.

With parallel plate geometry, the upper platen is constrained by the torsion strip and the lower platen is oscillated with a frequency of ω Hz

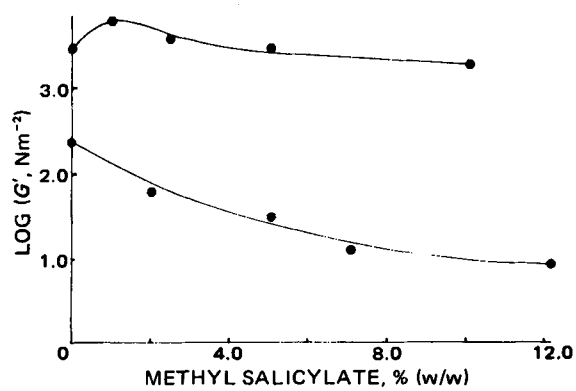

Figure 2—*Variation of G′ with methyl salicylate concentration for gels containing 8% (w/w) silica at 37°. Oscillation frequency was 0.25 Hz. Key: ●, n-dodecane; and ●, 1-dodecanol.*

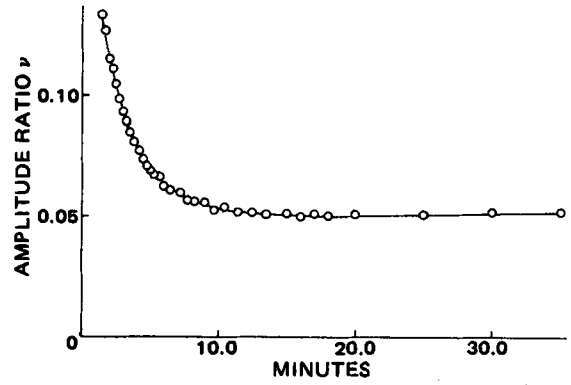

Figure 3—*Variation of amplitude ratio, ν, with time for 8% (w/w) silica in 1-dodecanol containing 12% (w/w) methyl salicylate at 37°. Oscillation frequency was 0.25 Hz.*

and amplitude θ_2. The platens are coupled through the sample under test; its rheological properties result in a phase lag, C, between the constrained and driven platens. In addition, the constrained platen oscillates with an amplitude of θ_1. The experimentally measured parameters for the sample were thus the amplitude ratio, ν, (θ_1/θ_2), and the phase lag, C, which were used to calculate α^2 using an iterative procedure, since:

$$\frac{\exp(iC)}{\nu} = \cos\alpha h + S\alpha h \sin\alpha h \qquad \text{(Eq. 5)}$$

where h was the gap between the platens and S was defined by the test geometry.

Subsequently, α was used to calculate G' and G'' using Eqs. 1–3.

Methyl Salicylate Adsorption—Methyl salicylate solutions ranging in concentration from 0.008 to 0.04 mg/ml were prepared in *n*-dodecane and 1-dodecanol. Ten milliliters of each solution was equilibrated with 0.1 g of silica in glass-stoppered vessels for 24 hr at 37°. The supernatant solutions were subsequently centrifuged[8] to remove the residual silica and assayed for equilibrium methyl salicylate content by UV spectrophotometry[9] using the 308-nm absorption maximum.

Drug Release from Gels—Approximately 10 ml of each gel was placed in a Perspex holder and covered with a cellophane membrane[10] so that there was complete contact between the gel and the 20.43 cm² of membrane area. The holder was placed at the bottom of a 1-liter, flat-bottom, glass reaction vessel containing 500 ml of pH 2.0 Clark and Lub buffer (6) at 37°. A stainless steel paddle stirrer was placed in the surface of the medium and rotated at 75 rpm. Aliquots were removed at 5-min intervals and assayed spectrophotometrically[9] for methyl salicylate with the absorption maximum at 238 nm.

Methyl Salicylate Partition Coefficients—Five-milliliter volumes of 1-mg/ml solutions of methyl salicylate in *n*-dodecane and 1-dodecanol were equilibrated with 5-ml volumes of pH 2.0 buffer at 37° for 1 week. Drug concentrations in organic and aqueous phases were determined spectrophotometrically[9] with the absorption maximum at 308 nm. The mean values of four determinations were used to calculate the partition coefficient (organic phase–pH 2.0 buffer).

RESULTS AND DISCUSSION

Preliminary experiments established that the gel properties were critically dependent on the preparation method; for this reason, the dispersion technique using an ultrasonic bath was used.

The *n*-dodecane gels exhibited a linear viscoelastic response under the test conditions. At any given silica concentration, G' increased slightly with frequency. Specimen data for a gel containing 8% (w/w) silica are shown in Fig. 1. The discontinuity was due to the test frequency passing through the natural frequency range of the rheogoniometer, n_0 (7). At any given frequency, G' increased as the silica concentration increased from 6 to 11% (w/w); G'' was lower than G' under all experimental conditions. These results are characteristic of the plateau region of viscoelastic response where there is reversible elastic deformation of the gel structure. Figure 2 shows the influence of methyl salicylate concentration on G' for *n*-dodecane gels containing 8% (w/w) silica. There was an initial

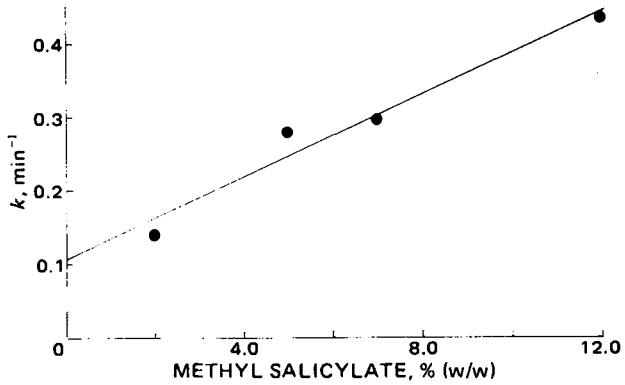

Figure 4—*Variation of first-order rate constant for gel breakdown, k, with methyl salicylate concentration for 1-dodecanol gels containing 8% (w/w) silica at 37°. Oscillation frequency was 0.25 Hz.*

increase in G' with drug concentration to a maximum of ~2% (w/w) methyl salicylate, followed by a progressive decline thereafter.

In contrast, the 1-dodecanol gels exhibited nonlinear viscoelastic behavior to the extent that there was a progressive decrease in ν during the time of the rheological measurement. This behavior (Fig. 3) indicates irreversible shear breakdown of the gel network. Analysis of the ν-time data using Guggenheim's method (8) showed that the breakdown obeyed first-order kinetics. The irreversibility of the process was evident from the fact that a sheared sample left between the plates of the rheogoniometer for 15 hr only recovered to ~5% of its original ν value on reshearing. The 1-dodecanol systems also exhibited syneresis when placed in the rheogoniometer at narrow gap widths.

To minimize this problem and to obtain comparative data, all samples were tested using the 0.05-cm gap. As a consequence of this behavior, it must be emphasized that G' data for the 8% (w/w) silica in 1-dodecanol gels (Fig. 2) have no absolute meaning since they are values calculated 1 min after shear. Nevertheless, the plot demonstrates that there was a progressive decrease in G' with increasing methyl salicylate concentration and no evidence of a maximum in the relationship.

The 1-dodecanol systems contained such an excess of hydroxyl groups relative to silanol groups that the probability of silanol–1-dodecanol interactions was higher than that of silanol–silanol interactions. This fact accounts for the much weaker network structure exhibited by these gels when compared with the n-dodecane systems. Methyl salicylate incorporated into the 1-dodecanol gels would act solely as a plasticizer and would reduce G', since it is not likely that any silanol groups would be available for hydrogen bond formation with the drug. The efficiency of the methyl salicylate molecule as a plasticizer is demonstrated by examining its effect on the kinetics of breakdown of the 1-dodecanol gel. The influence of the drug concentration on the first-order rate constant, k (Fig. 4), clearly demonstrates the disruptive effect of the drug on the interparticulate network structure.

In the n-dodecane systems, since there is no possibility of hydrogen bonding between silanol groups and the continuous phase, all silanol groups are available for interparticle or drug–particle interactions. Therefore, the initial increase in G' with methyl salicylate concentration

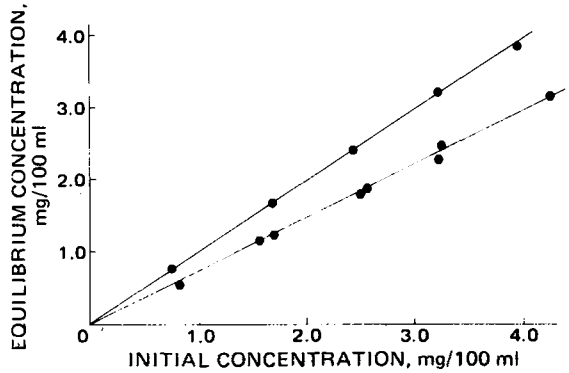

Figure 5—*Relation between initial and equilibrium methyl salicylate concentrations for systems containing 0.1 g of silica in 10 ml of* n-*dodecane (●) or 1-dodecanol (●) at 37°.*

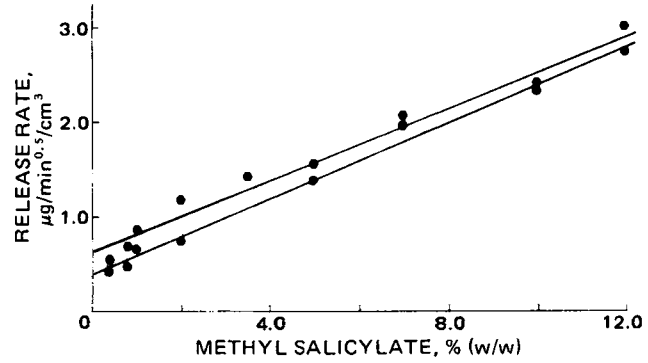

Figure 6—*Influence of continuous phase and methyl salicylate concentration on the release rate from gels containing 8% (w/w) silica at 37°. Key: ●, n-dodecane; and ●, 1-dodecanol.*

(Fig. 2) can be attributed to the drug acting as a cross-linking agent, *via* hydrogen bonds, and extending the network structure. Since there is a finite number of silanol groups in the gels, a point will be reached where they will all be involved in particle–particle or drug–particle interactions; upon further addition, methyl salicylate will act as a plasticizer and will reduce G' in a similar manner to that seen with the 1-dodecanol gels. A crude estimate of the drug concentration needed to produce saturation of the available silanol groups can be made from a knowledge of the specific surface area of the silica, its concentration in the gel, and the number of silanol groups in a given surface area.

According to the manufacturer's data (9), on average there are three silanol groups/100 Å^2 of silica surface. For this silica sample, the specific surface calculated using the Brunauer, Emmett, and Teller equation for adsorption (10) was 300 m^2/g. If the gross assumptions are made that all silanol groups are available and that each methyl salicylate molecule can react with a silanol group, then all groups will have interacted when approximately 2% (w/w) methyl salicylate is present. In practice, the correspondence ratio between methyl salicylate and silanol groups would probably be less than 1:1, and this would reduce the saturation concentration. Despite the crudity of the calculation, the result is in agreement with the experimentally observed maximum in G'.

The ability of methyl salicylate to bond to silanol groups in n-dodecane gels but not in 1-dodecanol systems also was demonstrated by the results of the adsorption studies (Fig. 5). If no bonding occurred, there would be a linear relation between initial and equilibrium methyl salicylate concentrations with a slope of unity. Bond formation, with consequent absorption, would result in an initial linear relation of a slope less than unity. Least-squares regression analysis gave slope values of 0.986 for 1-dodecanol systems and 0.744 for n-dodecane systems.

The differing effects on gel structure produced by addition of methyl salicylate to the two systems should be reflected in the drug release data. Preliminary work showed no significant drug adsorption to the cellophane membrane in the drug release experiments. Linear relations were obtained on plotting amounts released per unit area against (time)$^{0.5}$ after steady-state conditions had been attained.

Figure 6 shows the relation between the slope values for such plots and drug concentrations for the two systems. The experimental scatter reflects the difficulty in obtaining high quality data in this particular experiment. For this reason, no attempt was made to calculate effective diffusion coefficients. Statistically, there was no significant difference in the slopes of the two lines (p = 0.05), and this result parallels the similarity of the oil–pH 2.0 buffer partition coefficients for the two oily media (193.3 for n-dodecane and 184.4 for 1-dodecanol).

The conclusion to be drawn is that the amount of methyl salicylate bound in the n-dodecane gels is small with respect to the total drug concentration in the gels available for diffusion. Nevertheless, if the drug incorporated had been of high potency, its ability to bond to the silanol groups might seriously have reduced its availability. Further work is in progress on such systems; the continuous phase hydrogen bonding capability will be varied in a systematic manner to permit an investigation of the interaction thermodynamics.

Quinazolines and 1,4-Benzodiazepines LXXXIX: Haptens Useful in Benzodiazepine Immunoassay Development

JAMES V. EARLEY, R. IAN FRYER ˣ, and ROBERT Y. NING

Received September 22, 1978, from the *Department of Chemical Research, Hoffmann-La Roche Inc., Nutley, NJ 07110.* Accepted for publication January 5, 1979.

Abstract □ The syntheses of some 1,4-benzodiazepines potentially useful as haptens are reported. These compounds are related to chlordiazepoxide, diazepam, nitrazepam, clonazepam, and some of their metabolites. The chemistry reported here is intended to support specific immunoassay development for these drugs.

Keyphrases □ Benzodiazepines—chemical synthesis, potentially useful haptens □ Tranquilizers—benzodiazepines, various, chemical synthesis, potentially useful haptens □ Haptens—benzodiazepines, chemical synthesis

Immunoassay (1, 2) is a powerful method for measuring drug levels in biological fluids. The extensive clinical use (3, 4) and continued development (4, 5) of benzodiazepines as a drug class make immunoassays for these compounds desirable. This paper reports some benzodiazepine hapten[1] syntheses. Many haptens reported here have been utilized (6–8) in the immunoassay development for clinically important benzodiazepines and their metabolites.

The synthetic compounds are presented in three groups. Where possible, the numerical sequence reflects the synthetic sequence. The end-products, XII–XXIV, in Group A are related to diazepam and metabolites of diazepam and chlordiazepoxide. Compounds XXXI–XXXVI in Group B are related to chlordiazepoxide. Group C contains compounds derived from nitrazepam, clonazepam, and their metabolites.

The synthetic methods are known either in the general art or in the special benzodiazepine chemistry described elsewhere (5, 9, 10). 5-Chloro-3-(4-hydroxyphenyl)-2,1-benzisoxazole (I) (11) and the corresponding 3-(4-aminophenyl) analog II (12–14) were the crucial starting materials for compounds in Groups A and B. All other compounds reported are new except for the following: IV (11, 15), VII (16), XXIV (6), XXV (17), XXXVIII (18), XXXVII (19), and XL (20). The preparation of VII, XXIV, and XL, however, is reported for the first time.

[1] Haptens are defined (1) as antigens that are coupled to larger molecules, usually proteins, to provoke an antibody response.

EXPERIMENTAL[2]

3-(4-Aminophenyl)-5-chloroanthranil (II) (12–14)—To a mixture of 100 g (0.662 mole) of *o*-nitrobenzaldehyde and 160 g (1.05 mole) of phosphorus oxychloride was added dropwise, with stirring, 100 g (1.08 moles) of aniline while the temperature was kept below 30°. After 3 hr at room temperature, the solution was heated at 75° for 18 hr and at 90° for 3 hr. (The reaction becomes exothermic when heated.)

The mixture was cooled, 200 ml of ethanol and 200 ml of concentrated hydrochloric acid were added, and the solution was heated to reflux for 3 hr with stirring. On cooling, the precipitate was collected and washed with acetone, resuspended in dilute ammonium hydroxide for 1 hr, and collected again. After crystallization from ethanol, 70 g (86%) of II was obtained. Recrystallization from ethanol gave orange rods, mp 208–211°.

4′-(5-Chloro-3-anthranilyl)-2,2,2-trifluoroacetanilide (III)—A mixture of 70 g (0.286 mole) of II, 75 g (0.357 mole) of trifluoroacetic anhydride, and 1 liter of tetrahydrofuran was heated to reflux for 30 min. After concentration to a small volume, ether (300 ml) was added. The solution was filtered to give 60 g of product and then was concentrated to give an additional 5 g. The filtrate was evaporated, and the residue was stirred with cold aqueous potassium carbonate solution and filtered.

The solid thus collected was dissolved in tetrahydrofuran and treated with charcoal. After filtration and concentration to a small volume, ether was added. A 10-g precipitate of III was collected to give a total yield of 75 g (77%). A sample recrystallized from tetrahydrofuran–hexane gave pale-yellow rods, mp 251–254°; IR (KBr): 3310 (NH) and 1705 (C=O) cm^{-1}.

Anal.—Calc. for $C_{15}H_8ClF_3N_2O_2$: C, 52.88; H, 2.37; N, 8.22. Found: C, 52.85; H, 2.32; N, 8.27.

2-Amino-5-chloro-4′-hydroxybenzophenone (IV) (11, 15)—To a solution of 83.7 g (0.34 mole) of 5-chloro-3-(4-hydroxyphenyl)-2,1-benzisoxazole (I) (11) in 1500 ml of acetic acid was added 45 g of iron filings. The mixture was stirred and heated on the steam bath for 20 min. Every 30 min, an additional 20 g of iron filings and 100 ml of water were added for 2.5 hr. After 30 min more, the reaction mixture was filtered while hot.

The collected precipitate was heated with acetic acid and filtered. The combined filtrates were diluted with ice water to precipitate 39.8 g (47%) of IV, mp 170–175°. Recrystallization from methanol–water gave yellow rods, mp 173–178°.

2-Amino -5- chloro-4′-(2,2,2-trifluoroacetamido)benzophenone

(V)—Following the procedure described for IV, III afforded V in an 88% yield. A sample was recrystallized from methanol to give yellow needles, which crystallized as a methanolate, mp 65–75°, reset 148–149°; IR ($CHCl_3$): 3500, 3420 (NH_2), 1740, and 1634 (2 C=O) cm^{-1}.

Anal.—Calc. for $C_{15}H_{10}ClF_3N_2O_2 \cdot CH_3OH$: C, 51.28; H, 3.77; N, 7.48. Found: C, 51.19; H, 3.71; N, 7.35.

2-[4-(2-Amino-5-chlorobenzoyl)phenoxy]acetic Acid (VI)—A solution of 30 g (0.12 mole) of IV in 75 ml of dry dimethylformamide under nitrogen was cooled in an ice bath, and 5.5 g (1.3 moles) of 57% sodium hydride in mineral oil was added with stirring. After 20 min, 24.5 g (0.16 mole) of methyl bromoacetate was added dropwise. The reaction mixture was allowed to stand at room temperature for 18 hr and then was poured into ice water. The precipitate was collected, dried, and recrystallized from methylene chloride–hexane to give VI as yellow needles (25.1 g, 65%), mp 144–147°; IR ($CHCl_3$): 3500, 3375 (NH_2), 1760, and 1638 (2 C=O) cm^{-1}.

Anal.—Calc. for $C_{16}H_{14}ClNO_4$: C, 60.10; H, 4.41; N, 4.38; Found: C, 60.03; H, 4.38; N, 4.28.

5-Chloro-4'-hydroxy-2-methylaminobenzophenone (VII) (16)—The 4.5 g of the XV–XVI mixture described under XV was heated on a steam bath for 2 hr with 70 ml of 48% hydrobromic acid and then at reflux for 1 hr. The reaction mixture was cooled, made basic with 3 *N* NaOH, and washed with 100 ml of ether. The water layer was acidified with hydrochloric acid and extracted with methylene chloride (2 × 100 ml). The methylene chloride extract was dried and evaporated. The residue was crystallized and recrystallized from aqueous methanol to give 2.9 g of VII as yellow rods, mp 163–164°.

Anal.—Calc. for $C_{14}H_{12}ClNO_2$: C, 64.25; H, 4.62; Cl, 13.55. Found: C, 64.03; H, 4.37; Cl, 13.50.

2-Bromo-4'-chloro-2'-(4-hydroxybenzoyl)acetanilide (VIII)[3]—A solution of 41 g (0.165 mole) of IV in 800 ml of ether and 200 ml of water was cooled to 5°. The mixture was stirred while 20 ml (0.277 mole) of bromoacetyl bromide and a 20% solution of sodium carbonate were added alternately, keeping the solution slightly basic. After 20 min, the reaction mixture was filtered to collect 60 g (~100%) of VIII, mp 201–202°. Recrystallization from ethanol gave colorless prisms, mp 201–203°.

Anal.—Calc. for $C_{15}H_{11}BrClNO_3$: C, 48.87; H, 3.01, total halides, 31.30. Found: C, 49.17; H, 3.34; total halides, 30.84.

2-(Bromoacetamido) - 5-chloro-4'-(2,2,2-trifluoroacetamido)-benzophenone (IX)—Following the procedure described for VIII but with sodium bicarbonate instead of sodium carbonate, V afforded IX in a 96% yield. Recrystallization of IX from methylene chloride–methanol–petroleum ether gave off-white rods, mp 198–201°; IR (KBr): 1750, 1663, and 1640 (3 C=O) cm^{-1}.

Anal.—Calc. for $C_{17}H_{11}BrClF_3N_2O_3$: C, 44.03; H, 2.39; N, 6.04. Found: C, 44.22; H, 2.56; N, 6.03.

2-Bromo - 4'-chloro-2'-(4-methoxycarbonylmethoxybenzoyl)-acetanilide (X)—To a stirring solution of 16 g (0.05 mole) of VI in 350 ml of methylene chloride was added 6.3 g (0.075 mole) of sodium bicarbonate, followed dropwise by 12.1 g (0.06 mole) of bromoacetyl bromide. After 18 hr, 125 ml of water was added; the organic layer was separated, dried, and evaporated. Crystallization of the residue from methylene chloride–methanol afforded 19 g (86%) of X as colorless needles, mp 124–126°; IR ($CHCl_3$): 3300 (NH), 1760, 1682, and 1640 (3 C=O) cm^{-1}.

Anal.—Calc. for $C_{18}H_{15}BrClNO_5$: C, 49.06; H, 3.43; N, 3.18. Found: C, 48.96; H, 3.31; N, 3.05.

2-Bromo-4'-chloro-2'-(*p*-hydroxybenzoyl)-*N*-methylacetanilide (XI)[3]—To a solution of 2.9 g (0.011 mole) of VII in 100 ml of methylene chloride were added 2.4 g (0.012 mole) of bromoacetyl bromide, 1 g (0.012 mole) of sodium bicarbonate, and 25 ml of water. The reaction was stirred for 18 hr. The water layer was separated and extracted with 50 ml of methylene chloride. The combined organic layers were dried and evaporated. Crystallization of the residue from methanol and recrystallization from acetone–hexane gave 2.2 g (52%) of XI as colorless prisms, mp 187–189°.

[3] This compound was first prepared by Dr. A. Stempel of these laboratories.

Anal.—Calc. for $C_{16}H_{13}BrClNO_3$: C, 50.22; H, 3.42. Found: C, 50.09; H, 3.73.

7-Chloro - 1,3-dihydro-5-(4-hydroxyphenyl)-2*H*-1,4-benzodiazepin-2-one (XII)—To 350 ml of liquid ammonia was added 60 g (0.163 mole) of VIII. After refluxing for 3 hr, the ammonia was allowed to evaporate. The residue was heated to reflux in 400 ml of ethanol for 3 hr. Ethanol was evaporated, and 800 ml of acetone was added. This suspension was heated and filtered to remove inorganic salts. Concentration of the acetone filtrate gave 31.5 g (67%) of XII, mp 271–272°.

Anal.—Calc. for $C_{15}H_{11}ClN_2O_2$: C, 62.84; H, 3.87; N, 9.77. Found: C, 62.52; H, 4.13; N, 9.92.

7-Chloro - 1,3-dihydro-5-[4-(2,2,2-trifluoroacetamidophenyl)]-2*H*-1,4-benzodiazepin-2-one (XIII)—A solution of 90 g (0.194 mole) of IX in a mixture of 900 ml of tetrahydrofuran and 900 ml of ethyl acetate was stirred in an ice bath and saturated with a stream of ammonia gas over 1 hr. The mixture was allowed to stand overnight at room temperature and then filtered. The filtrate was evaporated, and the residue was partitioned between methylene chloride and water.

The product mixture from evaporation of the methylene chloride layer was heated to reflux in 400 ml of ethanol for 3 hr. The solution was concentrated, cooled, and filtered to give 32 g (43%) of XIII. A sample was recrystallized from methylene chloride–ether to give colorless prisms, which reset on heating to form needles, mp 273–276°; IR (KBr): 1730 and 1678 (2 C=O) cm^{-1}.

Anal.—Calc. for $C_{17}H_{11}ClF_3N_3O_2$: C, 53.49; H, 2.90; N, 11.00. Found: C, 53.63; H, 2.92; N, 10.85.

7-Chloro - 1,3-dihydro-5-(4-methoxycarbonylmethoxyphenyl)-2*H*-1,4-benzodiazepin-2-one (XIV) and 5-(4-Carbamoylmethoxyphenyl) -7- chloro -1,3- dihydro-2*H*-1,4-benzodiazepin -2- one (XVII)—A solution of 14.3 g (32.5 mmoles) of X in 100 ml of dioxane and 150 ml of methanol was added to 150 ml of a saturated solution of ammonia in methanol. After 5 hr, the reaction mixture was neutralized with acetic acid and evaporated to dryness. The residue was partitioned between 150 ml of methylene chloride and 100 ml of dilute ammonium hydroxide. After a few minutes, filtration gave 4.5 g (41%) of XVII. A sample was recrystallized from chloroform–ethanol to give off-white prisms, mp 272–275°; IR (KBr): 3440, 3210 (NH_2), and 1695 (2 C=O) cm^{-1}.

Anal.—Calc. for $C_{17}H_{14}ClN_3O_3$: C, 59.40; H, 4.11; N, 12.22. Found: C, 59.06; H, 3.99; N, 11.89.

The methylene chloride layer was separated, dried, and filtered through activated magnesium silicate. Elution with ether and then ethyl acetate and recrystallization of these two fractions gave 2.2 g (19%) of XIV as pale-yellow prisms, mp 235–243°; IR (KBr): 1762 and 1680 (2 C=O) cm^{-1}.

Anal.—Calc. for $C_{18}H_{15}ClN_2O_4$: C, 60.26; H, 4.21; N, 7.81. Found: C, 60.39; H, 4.36; N, 7.83.

7-Chloro - 1,3-dihydro-5-(4-hydroxyphenyl)-1-methyl-2*H*-1,4-benzodiazepin-2-one (XV)[3] and 7-Chloro-1,3-dihydro-5-(4-methoxyphenyl)-1-methyl-2*H*-1,4-benzodiazepin-2-one (XVI)—To a solution of 6.5 g (0.022 mole) of XII in 40 ml of dimethylformamide was added 11.6 ml (0.055 mole) of 4.74 *M* sodium methoxide in methanol. After 90 min, the mixture was cooled in an ice bath and 9.4 g (0.066 mole) of methyl iodide was added dropwise with stirring. After 18 hr at room temperature, the reaction mixture was acidified with acetic acid and partitioned between 100 ml of methylene chloride and 100 ml of water.

The water layer was extracted once more with methylene chloride. The combined extracts were evaporated to dryness. The residual product mixture was separated on an activated magnesium silicate column. The column was eluted with methylene chloride, ether, and then ethyl acetate. The ethyl acetate fraction was evaporated and crystallized from methanol to give 0.40 g (6%) of XV as colorless prisms, mp 255–259°.

Anal.—Calc. for $C_{16}H_{13}ClN_2O_2$: C, 63.90; H, 4.35; N, 9.31. Found: C, 63.89; H, 4.29; N, 9.46.

The filtrates and the other fractions from the column were combined and evaporated to give 4.5 g of a XV–XVI mixture.

Compound XV from XI—A solution of 2.2 g (5.7 mmoles) of XI in a mixture of 90 ml of methylene chloride and 20 ml of tetrahydrofuran was added to 175 ml of liquid ammonia. After 18 hr, 100 ml of methylene chloride was added and the reaction mixture was dried and evaporated to dryness. The residual oil was crystallized from methanol to give 1.45 g (85%) of XV as colorless prisms, mp 254–260°.

7-Chloro -1,3- dihydro -5- (4-hydrazinocarbonylmethoxyphenyl)-2*H*-1,4-benzodiazepin-2-one Hemitetrahydrofuranate (XVIII)—To a solution of 0.50 g (1.3 mmoles) of XIV in a mixture of 25 ml of methanol and 30 ml of tetrahydrofuran was added 5 ml of hydrazine hydrate (85% in water). After 1 hr, the solution was evaporated under reduced pressure and 25 ml of methylene chloride and 20 ml of water were added. After standing overnight, the solution was filtered and the solid was recrystallized from tetrahydrofuran–hexane to give 0.30 g (59%) of colorless prisms, mp 180–185°, resets 210–220°; IR (KBr): 1700 and 1680 (C=O) cm^{-1}.

Anal.—Calc. for $C_{17}H_{15}ClN_4O_3 \cdot 0.5\ C_4H_8O$: C, 57.80; H, 4.88; N, 14.19. Found: C, 57.59; H, 4.79; N, 14.10.

7-Chloro - 1,3-dihydro-5-[4-(2,2,2-trifluoroacetamido)phenyl]-2*H*-1,4-benzodiazepin-2-one 4-Oxide (XIX)—To a mixture of 31.5 g (0.0825 mole) of XIII in 1.8 liters of methylene chloride was added, with stirring, 30 g (0.147 mole) of 85% *m*-chloroperbenzoic acid. After 18 hr, 500 ml of cold water was added and the solution was made basic with ammonium hydroxide. The crystalline XIX was collected on a filter. The

synthetic sequences

XXXVII, XXXVIII, XXXIX; XL, XLI, and XLII

methylene chloride was concentrated for a second crop, giving a total yield of 21.5 g (66%). Recrystallization from methylene chloride–methanol gave off-white rods, mp 295–297° dec.; IR (KBr): 1698 (broad 2 C=O) cm^{-1}.

Anal.—Calc. for $C_{17}H_{11}ClF_3N_3O_3$: C, 51.33; H, 2.79; N, 10.57. Found: C, 51.32; H, 2.57; N, 10.44.

5-(4-Aminophenyl) - 7-chloro-1,3-dihydro-2*H*-1,4-benzodiazepin-2-one 4-Oxide (XX)—To a solution of 1.0 g (2.51 mmoles) of XIX in 25 ml of methanol was added 20 ml (20 mmoles) of 1 *N* NaOH. After 15 min, 20 ml of water was added. The reaction mixture was allowed to stand for 3 hr and was then acidified with acetic acid; methanol was removed *in vacuo*. The mixture was made basic with ammonium hydroxide and filtered. Recrystallization from tetrahydrofuran–methanol gave 0.30 g (39%) of pale-yellow rods, mp 256–258°; IR (KBr): 3415, 3350, 3245 (NH_2, NH), and 1700 (C=O) cm^{-1}; mass spectrum: *m/e* 301 (M^+).

Anal.—Calc. for $C_{15}H_{12}ClN_3O_2$: C, 59.71; H, 4.10; N, 13.93. Found: C, 59.52; H, 4.02; N, 13.73.

3-Acetoxy - 7-chloro-1,3-dihydro-5-[4-(2,2,2-trifluoroacetamido)phenyl]-2*H*-1,4-benzodiazepin-2-one (XXI)—A mixture of 14 g (0.0352 mole) of XIX in 200 ml of tetrahydrofuran and 400 ml of acetic anhydride was heated on the steam bath for 2 hr. The mixture was evaporated under reduced pressure. Crystallization of the residue from methanol afforded 8.3 g of XXI. A second crop of 5.3 g was obtained from ether–hexane, giving a total yield of 13.5 g (87.7%).

Recrystallization from a mixture of tetrahydrofuran, methylene chloride, and hexane gave white prisms, mp 257–262°; IR (KBr): 1740, 1720, and 1688 (3 C=O) cm^{-1}; mass spectrum: *m/e* 439 (M^+).

Anal.—Calc. for $C_{19}H_{13}ClF_3N_3O_4$: C, 51.89; H, 2.98; N, 9.56. Found: C, 51.36; H, 2.99; N, 9.23.

5-(4-Aminophenyl) -7- chloro-1,3-dihydro -3- hydroxy-2*H*-1,4-benzodiazepin-2-one (XXII)—To a solution of 0.60 g (1.3 mmoles) of XXI in 25 ml of methanol was added 20 ml of 1 *N* NaOH, followed by the addition of 20 ml of water after 1 hr. The reaction mixture was filtered after 3 hr. The filtrate was acidified with acetic acid and then made slightly basic with ammonium hydroxide. It was extracted with methylene chloride (2 × 100 ml), which was dried and concentrated to a small volume.

Compound XXII, which crystallized, was collected. Recrystallization from tetrahydrofuran–methanol afforded 0.20 g (50%) of yellow prisms, mp >350°; IR (KBr): 3455, 3375 (NH_2, NH), 3225, 3160 (OH), 1713, and 1698 (split C=O) cm^{-1}; NMR (dimethyl sulfoxide-d_6): δ 10.60 (s, 1H, NH), 6.02 (d, 1H, OH), 5.58 (s, 2H, NH_2), and 4.64 (d, 1H, CH); mass spectrum: *m/e* 301 (M^+).

Anal.—Calc. for $C_{15}H_{12}ClN_3O_2$: C, 59.71; H, 4.00; N, 13.93. Found: C, 59.33; H, 4.46; N, 14.03.

5-[3-(4-Acetamidophenylazo)-4 - hydroxyphenyl]-7-chloro-1,3-dihydro-1-methyl-2*H*-1,4-benzodiazepin-2-one (XXIII)—To a mixture of 1.2 ml (15 mmoles) of concentrated hydrochloric acid and 5 g of ice was added 0.90 g (6 mmoles) of *p*-aminoacetanilide, followed by the dropwise addition of a solution of 0.45 g (6.2 mmoles) of sodium nitrite in 5 ml of water. To a separate solution of 0.5 g (1.67 mmoles) of XV in 25 ml of tetrahydrofuran were added 1 ml (12 mmoles) of 1 *N* NaOH and 20 g of ice. The diazonium salt solution was added rapidly with stirring to the basic solution.

The mixture was refrigerated at 5° for 2.5 days. The precipitate was collected and recrystallized from methylene chloride–methanol to give 0.60 g (70%) of XXIII as red prisms. Recrystallization from methylene chloride–petroleum ether gave yellow rods, mp 276–278°; IR (KBr): broad 1700 (2 C=O) cm^{-1}.

Anal.—Calc. for $C_{24}H_{20}ClN_5O_3$: C, 62.41; H, 4.36; N, 15.16. Found: C, 62.24; H, 4.31; N, 14.97.

5-[3-(4-Aminophenylazo)-4-hydroxyphenyl]-7-chloro-1,3-dihydro-1-methyl-2*H*-1,4-benzodiazepin-2-one (XXIV)—A solution of 0.60 g (1.3 mmoles) of XXIII in 50 ml of methanol and 10 ml of concentrated hydrochloric acid was heated for 10 min on a steam bath. After 2 hr at room temperature, the methanol was evaporated. The solution was made basic with ammonium hydroxide and extracted with 50 ml of methylene chloride. The organic layer was dried and evaporated. Crystallization of the residue from methanol and recrystallization from methylene chloride–methanol gave 0.25 g (45%) of brown prisms, mp 262–268°; IR (KBr): 3450, 3350 (NH_2), and 1682 (C=O) cm^{-1}.

Anal.—Calc. for $C_{22}H_{18}ClN_5O_2$: C, 62.93; H, 4.32; N, 16.68. Found: C, 62.96; H, 4.49; N, 16.47.

2-Amino-5-chloro-4'-hydroxybenzophenone Oxime (XXV)—The preparation of XXV from IV was described in Ref. 17.

2-Amino-5-chloro-4'-(2,2,2-trifluoroacetamido)benzophenone Oxime (XXVI)—A mixture of 3.1 g (8.27 mmoles) of V and 2.5 g (36 mmoles) of hydroxylamine hydrochloride in 100 ml of ethanol was heated under reflux for 66 hr and then concentrated. The residue was partitioned between 100 ml of methylene chloride and 75 ml of water. The organic layer was concentrated, cooled, and filtered to give 1.0 g of XXVI. An additional 0.6 g was obtained from the filtrates for a yield of 1.6 g (53%). Recrystallization from methylene chloride–hexane gave off-white prisms, mp 179–183°; IR (KBr): 3440, 3340, and 3280 (NH, NH_2, OH) cm^{-1}.

Anal.—Calc. for $C_{15}H_{11}ClF_3N_3O_2$: C, 50.37; H, 3.10; N, 11.75. Found: C, 50.31; H, 2.93; N, 11.72.

2,4' - Dichloro-2' - (4-hydroxybenzoyl)acetanilide Oxide (XXVII)—See Ref. 17.

2,4' - Dichloro-2'-(4-trifluoroacetamido-α-hydroxyiminobenzyl)acetanilide (XXVIII)—To a solution of 1.6 g (4.4 mmoles) of XXVI in 50 ml of ether was added 20 ml of water. The mixture was cooled to 5°, and 0.54 g (4.8 mmoles) of chloroacetyl chloride and a 5% solution of sodium bicarbonate were added alternately, keeping the solution slightly basic. After 1 hr, the ether layer was separated and the water layer was extracted with 50 ml of ether.

The combined ether layers were dried and evaporated. The residue was crystallized from methylene chloride–hexane to give 1.8 g (95%) of colorless prisms. A sample recrystallized for analysis from ether–methylene chloride melted at 210–214°; IR (KBr): 3420, 3300, 3200 (NH, OH), and 1700 (2 C=O) cm^{-1}.

Anal.—Calc. for $C_{17}H_{12}Cl_2F_3N_3O_3$: C, 47.03; H, 2.78; N, 9.58. Found: C, 46.94; H, 2.70; N, 9.48.

6-Chloro-2-chloromethyl-4-(4-hydroxyphenyl)quinazoline 3-Oxide (XXIX)[3]—A solution of 40.5 g (0.12 mole) of XXVII in 750 ml of dry dioxane and 40.5 ml (0.329 mole) of boron trifluoride etherate was heated to reflux. After 5 hr, it was cooled and 200 ml of water was added. The dioxane was removed by distillation, and the reaction mixture was made basic with a 5% sodium bicarbonate solution. The solid was collected, heated in methanol at reflux for a few minutes, cooled, and collected to give, in two crops, 21.3 g (56%) of XXIX. An analytical sample recrystallized from methanol melted at 226–227° dec.

Anal.—Calc. for $C_{15}H_{10}Cl_2N_2O_2$: C, 56.10; H, 3.14; N, 8.72. Found: C, 56.26; H, 2.81; N, 9.02.

6-Chloro - 2-chloromethyl-4-[4-(2,2,2-trifluoroacetamido)phenyl]quinazoline 3-Oxide (XXX)—Following the procedure described for XXIX, XXVIII was isolated by methylene chloride extraction. The residue from evaporation was crystallized from methanol and recrystallized from methylene chloride–methanol to give 1.0 g (62%) of pale-yellow rods, mp 244–248°. A good elemental analysis could not be obtained because of solvents in the crystals; IR (KBr): 1730 (C=O) cm^{-1}; mass spectrum: *m/e* 415 (M^+).

7-Chloro - 5-(4-hydroxyphenyl)-2-methylamino-3*H*-1,4-benzodiazepine 4-Oxide (XXXI)[3]—To a saturated methylamine solution in 600 ml of methanol in an ice bath was added 19.2 g (0.60 mole) of XXIX. The solution was stirred for 7 hr in an ice bath and for 10 hr at room temperature and then was evaporated under reduced pressure. The residue was acidified with dilute acetic acid, stirred with ether, and filtered to give 19 g of product. Recrystallization for analysis from ethyl acetate gave colorless plates, mp 278–279° dec.

Anal.—Calc. for $C_{16}H_{14}ClN_3O_2$: C, 60.86; H, 4.47; N, 13.30. Found: C, 61.23; H, 4.74; N, 13.14.

5-(4-Aminophenyl)-7 - chloro-2-methylamino-3*H*-1,4-benzodiazepine 4-Oxide (XXXII)—To 100 ml of methanol saturated with methylamine in an ice bath was added 1.6 g (3.8 mmoles) of XXX. After 18 hr at room temperature, the solution was evaporated to dryness. Crystallization of the residue from methanol followed by recrystallization from methylene chloride–methanol gave yellow prisms, mp 180–185°, reset 288–290°.

The filtrates were partitioned between 1 *N* HCl and ether. The acid layer was made basic with sodium hydroxide and filtered. The solids collected were recrystallized from methylene chloride–methanol to give 0.60 g (50%) of XXXII. A good elemental analysis was not obtained due to occlusion of solvents in the crystal; IR (KBr): 3250 (broad) and 1625 cm^{-1}; mass spectrum: *m/e* 314 (M^+).

7-Chloro - 5-(*p*-methoxycarbonylmethoxyphenyl)-2-methylamino-3*H*-1,4-benzodiazepine 4-Oxide (XXXIII)—A solution of 5.00 g (0.0158 mole) of XXXI in 25 ml of dry dimethylformamide under nitrogen was stirred and cooled in an ice bath. To the reaction was added 0.75 g (0.0174 mole) of 57% sodium hydride in mineral oil; after 45 min, 3.0 g (0.205 mole) of methyl bromoacetate was added dropwise. After 64 hr at room temperature, the mixture was poured into ice water.

The precipitate was collected and dissolved in 150 ml of methylene chloride, which was washed with water, dried, and evaporated. Crystal-

lization from methylene chloride–hexane gave 3.6 g (59%) of colorless prisms, mp 106–110°; IR ($CHCl_3$): 3460 (NH) and 1760 (C=O) cm^{-1}. An additional 1.6 g of crude XXXIII was obtained from the filtrates.

Anal.—Calc. for $C_{19}H_{18}ClN_3O_4$: C, 58.84; H, 4.68; N, 10.84. Found: C, 58.61; H, 4.56; N, 10.96.

7-Chloro - 5-(4-hydrazinocarbonylmethoxyphenyl)-2-methylamino-3*H*-1,4-benzodiazepine 4-Oxide (XXXIV)—A solution of 1.0 g (2.6 mmoles) of XXXIII in 125 ml of methanol was treated with 6 ml of 85% hydrazine hydrate. After stirring for 2 hr, the solution was concentrated to a small volume under reduced pressure and cooled. The precipitate was collected, triturated with ethanol, filtered, and recrystallized from dimethylformamide–methanol–water to give 0.90 g (90%) of colorless prisms, mp 254–256°; IR (KBr): 3300, 3240 (NH, NH_2), 1668 (C=O), 1635 (C=N), and 1250 (ether) cm^{-1}.

Anal.—Calc. for $C_{18}H_{18}ClN_5O_3$: C, 55.75; H, 4.68; N, 18.06. Found: C, 55.62; H, 4.58; N, 18.28.

7-Chloro -2- methylamino-5-[4-[(3-benzyloxycarbonylamino)-propoxy]phenyl]-3*H*-1,4-benzodiazepine 4-Oxide (XXXV)—A solution of 0.50 g (1.58 mmoles) of XXXI in 5 ml of dry dimethylformamide under nitrogen was treated with 0.080 g (1.9 mmoles) of 54.7% sodium hydride in mineral oil. After 20 min, 0.54 g (2 mmoles) of *N*-carbobenzyloxy-3-bromopropylamine and 0.10 g (0.29 mmole) of tetrabutylammonium hydrogen sulfate were added with stirring. After 18 hr, the reaction mixture was stirred with ice water, which was then decanted.

The remaining oil was dissolved in 25 ml of methylene chloride, washed with 15 ml of water, dried, and filtered over a pad of activated magnesium silicate. The pad was eluted with methylene chloride, ether, and then ethyl acetate. The ethyl acetate fraction was evaporated and purified by preparative TLC using five silica gel plates (20 cm × 20 cm × 1.5 mm), which were developed in benzene–acetone (1:1). The material having R_f 0.4–0.5 was eluted from the silica gel with methanol. Crystallization from methylene chloride–ether gave 0.15 g (19%) of colorless prisms, mp 103–106°; IR ($CHCl_3$): 3460 (NH) and 1720 (C=O) cm^{-1}; mass spectrum: *m/e* 506 (M^+).

Anal.—Calc. for $C_{27}H_{27}ClN_4O_4$: C, 63.97; H, 5.37; N, 11.05. Found: C, 63.87; H, 5.42; N, 10.80.

7-Chloro - 2-methylamino-5-[4-(3-amino)propoxy]phenyl-3*H*-1,4-benzodiazepine 4-Oxide Dihydrochloride (XXXVI)—To a stirring solution of 4 ml of 30% hydrogen bromide in acetic acid was added 0.10 g (0.197 mmole) of XXXV. After 40 min, 20 ml of ether was added. The precipitate was collected and partitioned between 30 ml of methylene chloride and 10 ml of dilute ammonium hydroxide. The organic layer was dried and evaporated, and excess ethanolic hydrogen chloride was added. After concentration, the oil was crystallized from isopropanol and recrystallized from a mixture of methanol and isopropanol to give 70 mg (80%) of colorless prisms, mp 211–215° dec.; IR (KBr): 3400 (broad NH, NH_2) and 1688 (C=O) cm^{-1}.

Anal.—Calc. for $C_{19}H_{21}ClN_4O_2 \cdot 2HCl$: C, 51.19; H, 5.20; N, 12.57. Found: C, 50.85; H, 5.49; N, 12.24.

1,3-Dihydro-3-hemisuccinyloxy - 7-nitro-5-phenyl-2*H*-1,4-benzodiazepin-2-one (XXXVIII) (18)—To a suspension of 6.60 g (22 mmoles) of 1,3-dihydro-3-hydroxy-7-nitro-5-phenyl-2*H*-1,4-benzodiazepin-2-one (XXXVII) (19) in 400 ml of tetrahydrofuran (dried by passing over a bed of activated alumina) was added 1.2 g of a 50% suspension of sodium hydride in mineral oil (27 mmoles hydride). After stirring for 0.5 hr at room temperature under a nitrogen atmosphere, a clear solution formed. Succinic anhydride (3.35 g, 33 mmoles) was added in one portion, and stirring was continued. After 1 hr, tetrahydrofuran was evaporated *in vacuo*.

The residual mixture was slurried with 200 ml of water, acidified with acetic acid, and extracted with 300 ml of methylene chloride. The acidification and extraction were performed rapidly enough so that the product did not crystallize out of solution. After drying over anhydrous sodium sulfate, the solution was concentrated to half of its volume. Hexane addition afforded 8.3 g of XXXVIII, mp 187–190° dec. After recrystallization from tetrahydrofuran–methylene chloride–hexane, 5.6 g (64%) of colorless needles was obtained, mp 183–185° dec.

An analytical sample obtained from recrystallization with methylene chloride–hexane melted at 187–190° dec.; IR (KBr): unresolved carbonyl bands at 1690–1760 cm^{-1}; UV λ_{max} (2-propanol): 219 (ε 24,500), 264 (17,100), and 305 (10,900) nm; NMR (dimethyl sulfoxide-d_6): δ 2.51–2.65 (m, 2, CH_2), 2.69–2.83 (m, 2, CH_2), 5.89 (s, 1, 3-H), 7.45–7.62 (m, 6, C_6H_5 and 9-H), 8.06 (d, *J* = 2.5 Hz, 1,6-H), and 8.48 (q, *J* = 2.5 and 9.0 Hz, 1, 8-H) ppm.

Anal.—Calc. for $C_{19}H_{15}N_3O_7$: C, 57.43; H, 3.81; N, 10.58. Found: C, 57.47; H, 3.87; N, 10.30.

7-Amino-1,3-dihydro-3-hemisuccinyloxy-5-phenyl-2*H*-1,4-benzodiazepin-2-one (XXXIX)—A solution of 397 mg (1.0 mmole) of XXXVIII in 25 ml of tetrahydrofuran containing 500 mg of Raney nickel was hydrogenated under a hydrogen atmosphere at room temperature for 2 hr. Removal of the catalyst and solvent followed by recyrstallizations from tetrahydrofuran–methylene chloride–hexane afforded 175 mg (48%) of XXXIX as yellow microprisms, melting point indefinite, gradually shrinking above 190°; UV λ_{max} (2-propanol): 243 (ε 31,100) and 354 (2700) nm; NMR (dimethylsulfoxide-d_6): δ 6.44 (d, *J* = 2.5 Hz, 1, 6-H), 6.80 (dd, *J* = 2.5 and 9.0 Hz, 1,8-H), and 6.94 (d, *J* = 9.0 Hz, 1,9-H) ppm.

Anal.—Calc. for $C_{19}H_{17}N_3O_5$: C, 62.12; H, 4.66; N, 11.44. Found: C, 62.20; H, 4.96; N, 11.17.

5-(2-Chlorophenyl)-1,3-dihydro-3-hydroxy - 7-nitro-2*H*-1,4-benzodiazepin-2-one (XL) (20)—A solution of 27 g (81 mmoles) of 5-(2-chlorophenyl)-1,3-dihydro-7-nitro-2*H*-1,4-benzodiazepin-2-one 4-oxide [prepared in 64% from clonazepam (V), the desoxy precursor, by oxidation with *m*-chloroperbenzoic acid and obtained from ethanol as colorless flakes, mp 254° dec.] in 300 ml of acetic anhydride was heated on a steam bath for 2 hr. After acetic anhydride was removed *in vacuo*, the residue was crystallized from benzene to afford 14 g of 3-acetoxy-5-(2-chlorophenyl)-1,3-dihydro-7-nitro-2*H*-1,4-benzodiazepin-2-one, mp 279–281°.

To a solution of the 3-acetoxy compound (14 g) in 400 ml of dioxane was added 160 ml of 1 *N* NaOH. The mixture was stirred at room temperature for 0.5 hr and then neutralized with 1 *N* HCl. Water (2 liters) was added, and the mixture was extracted with methylene chloride. The organic layer was washed with water, dried, and evaporated to dryness. Crystallization from acetone afforded XL, which, on recrystallization from acetone, yielded 8.7 g (30% overall) of a hemiacetonate of XL as colorless prisms, mp 159–160°; IR (KBr): 3200, 3140, 1700 (broad), 1530, and 1345 cm^{-1}.

Anal.—Calc. for $C_{15}H_{10}ClN_3O_4 \cdot 0.5C_3H_6O$: C, 54.93; H, 3.63; N, 11.65. Found: C, 55.14; H, 3.70; N, 11.47.

5-(2-Chlorophenyl)-1,3-dihydro-3 - hemisuccinyloxy-7-nitro-2*H*-1,4-benzodiazepin-2-one (XLI)—The 3-hydroxy compound (XL) was succinylated, as in the preparation of XXXVIII, in a 67% yield. Colorless prisms (tetrahydrofuran–methylene chloride–heptane) were obtained, mp 172–180° dec.; IR (KBr): 1770–1700 (strong unresolved), 1530, and 1350 cm^{-1}; UV λ_{max} (2-propanol): 215 (ε 32,800), 248 (16,500), and 308 (12,000) nm.

Anal.—Calc. for $C_{19}H_{14}ClN_3O_7$: C, 52.75; H, 3.08; N, 9.75. Found: C, 52.85; H, 3.27; N, 9.73.

7-Amino-5-(2-chlorophenyl)-1,3-dihydro - 3-hemisuccinyloxy-2*H*-1,4-benzodiazepin-2-one (XLII)—Catalytic hydrogenation of XLI in the manner described in the preparation of XXXIX afforded XLII in a 70% yield as a light-yellow amorphous solid from tetrahydrofuran–methylene chloride–hexane, melting point indefinite, beginning at 130°; IR (KBr): 3500–2800 and 1680–1760 (unresolved), 1620, 1505, and 1160 cm^{-1}.

Anal.—Calc. for $C_{19}H_{16}ClN_3O_5$: C, 56.80; H, 4.01; Cl, 8.82. Found: C, 57.06; H, 4.34; Cl, 8.54.

Benoxaprofen, a New Anti-Inflammatory Agent: Particle-Size Effect on Dissolution Rate and Oral Absorption in Humans

A. S. RIDOLFO ˣ, L. THOMPKINS, L. D. BECHTOL, and R. H. CARMICHAEL

Received September 7, 1978, from the *Lilly Laboratory for Clinical Research, Lilly Research Laboratories, and Dry Products Development, Indianapolis, IN 46202.* Accepted for publication December 28, 1978.

Abstract □ The particle-size effect of benoxaprofen, a new nonsteroidal anti-inflammatory agent, on the *in vitro* dissolution rate and oral absorption in humans was evaluated. Ten normal subjects participated in a randomized crossover-designed absorption study with two sieved particle-size formulations: one with crystals larger than 60 mesh (mean equivalent spherical diameter = 640 μm) and the other with crystals smaller than 100 mesh (mean equivalent spherical diameter = 67 μm). Plasma drug concentrations and urinary drug excretion were used to determine the relative absorption of the two formulations. The standard USP procedure was used for the dissolution study. Particle size had a dramatic effect on both the *in vitro* drug dissolution and its oral absorption in humans. *In vitro*, the smaller crystals dissolved more rapidly and more efficiently than the larger crystals. *In vivo*, the smaller crystals produced higher plasma concentrations, more rapid peak concentration attainment, and more drug excreted in the urine.

Keyphrases □ Benoxaprofen—effect of particle size on dissolution rate and oral absorption in humans □ Dissolution rate—benoxaprofen, effect of particle size □ Absorption, oral—benoxaprofen, effect of particle size □ Anti-inflammatory agents—benoxaprofen, effect of particle size on dissolution rate and oral absorption in humans

The particle size of sparingly soluble drugs (drugs that are practically insoluble in aqueous fluids at physiological pH) can affect their dissolution rate *in vitro* (1–7). Similarly, the rate and extent of drug absorption can be reduced *in vivo* when dissolution in GI fluids is limited by particle size (2, 8–11). In several cases, rank correlations were obtained between sparingly soluble drug dissolution *in vitro* and absorption *in vivo* (12). In several instances, drug dissolution improved when particle size was reduced, probably because an increased surface area was available for dissolution.

Certain physicochemical properties of the experimental anti-inflammatory compound benoxaprofen, *dl*-2-(4-chlorophenyl)-α-methyl-5-benzoxazoleacetic acid, indicate that its dissolution *in vitro* and its absorption *in vivo* might be affected by altering its crystal particle size. It is a crystalline solid at room temperature. The pKa in 66% dimethylformamide is 6.9, and its solubilities at 25° in phosphate buffer at pH 5.0, 6.0, 7.0, and 7.6 are 4.4, 21, 207, and 835 μg/ml, respectively[1].

Because of benoxaprofen's low aqueous solubility and its largely unionized, lipoid-soluble form in the GI tract, a rate-limiting step in oral absorption could be drug dissolution in the GI fluids. This report describes the relationship between drug particle sizes and dissolution rates *in vitro* and the effect of particle sizes on oral bioavailability in humans.

EXPERIMENTAL

Dosage Preparation—GLC showed benoxaprofen[2] to be 99.9% pure. Two particle-size fractions were isolated using U.S. standard mesh sieves. One fraction contained particles larger than 60 mesh (mean diameter = 640 μm), and one contained particles less than 100 mesh (mean diameter = 67 μm). The individual fractions were mixed with corn starch USP in a laboratory blender[3]. The blends were hand filled into size 2 gelatin capsules, each containing 100 mg of benoxaprofen and 180 mg of starch.

Dissolution Study—The assembly and conditions used to study the dissolution rate and extent of the two drug particle sizes are described in USP XIX (13). The dissolution assembly consisted of four variable-speed stirring motors attached to four basket and shaft assemblies with a three-blade stainless steel propeller mounted on each basket shaft immediately above each basket, four 3-liter beakers, and a water bath at 37 ± 0.5°. The dissolution medium for each determination was 2 liters of pH 7.6 phosphate buffer. One capsule was placed in each basket and rotated at 100 rpm. Four capsules from each formulation were tested.

Five-milliliter aliquots were withdrawn at 20, 60, and 120 min using a pipet fitted with a suitable filter. Aliquots withdrawn were not replaced with corresponding volumes of the dissolution medium[4]. After the 120-min sample withdrawal, the basket contents were quantitatively transferred to the remaining dissolution medium, a stirring bar was added, and the mixture was magnetically stirred (at >500 rpm) for ~1 hr. A final aliquot was then taken. The benoxaprofen content in each specimen was measured spectrophotometrically.

Clinical Study—In humans, the benoxaprofen availability from the dosage forms containing the two different particle sizes was compared on the basis of plasma unchanged drug concentration and of urinary excretion of the unchanged drug and its glucuronide conjugate.

Twelve healthy males participated in the study after being informed of the objectives, potential risks, and procedures. The subjects were 21–33 years and within an acceptable weight range (14). According to a randomized crossover design, each subject received a single oral 100-mg drug capsule. Two weeks elapsed between the single doses of the two parti-

[a] $p < 0.05$. [b] $p < 0.01$.

cle-size formulations. This period represents about 10–12 plasma disappearance half-lives of the unchanged drug.

All subjects fasted overnight (at least 8 hr) before dosing. No food or liquid, except water, was permitted for at least 2 hr after the study dose, when a standard light meal was offered. Water, *ad libitum*, was permitted during this period. All doses were taken with 180 ml of water. After dosing, subjects remained ambulatory or sitting for at least 2 hr.

Blood samples (10 ml) were obtained by venipuncture at 0, 0.5, 1, 1.5, 2, 3, 6, 9, 12, 24, 48, 72, and 96 hr after dosing. The samples were heparinized and centrifuged; the plasma was collected and frozen until assayed. Total urine samples were collected every 6 hr for 24 hr and then daily through Day 4; the volume was measured and aliquots were frozen until assayed.

The plasma benoxaprofen concentration was determined by GLC after extraction and derivatization. Fifty micrograms of the mass internal standard, 2-(3,5-dichlorophenyl)-α-methyl-5-benzoxazoleacetic acid, in 1 ml of 0.01 *M* NaOH was added to 1 ml of plasma. The plasma proteins were precipitated with 2 ml of 10% trichloroacetic acid, and the mixture was extracted with 9 ml of 20% (v/v) hexane in ethyl acetate. The organic phase containing the drug and the internal standard was back-extracted into 5 ml of 0.3 *M* Na_3PO_4. The aqueous phase was recovered, made acidic with 2 ml of 1 *M* HCl, and reextracted with 5 ml of methylene chloride.

The organic phase was recovered and evaporated to dryness at 50° under a nitrogen stream, and the residue was treated with diazomethane in methylene chloride containing 10% (v/v) methanol. After evaporation, the derivatized material was dissolved in a small volume of methanol and analyzed by GLC using a 0.61-m × 3-mm i.d. glass column of 80–100-mesh Chromosorb W-HP coated with 2% OV-7. Chromatographic conditions were: injection temperature, 250°; column oven temperature, 235°; and flame-ionization detector temperature, 275°. Quantitation was by electronic integration.

The urine benoxaprofen concentration was measured as the sum of the unchanged free form plus the amount resulting from glucuronide conjugate hydrolysis (15). The analytical technique was the same as for plasma, except that the urine plus the added internal standard was treated with β-glucuronidase[5] before extraction to hydrolyze the glucuronide metabolite to the free drug and glucuronic acid.

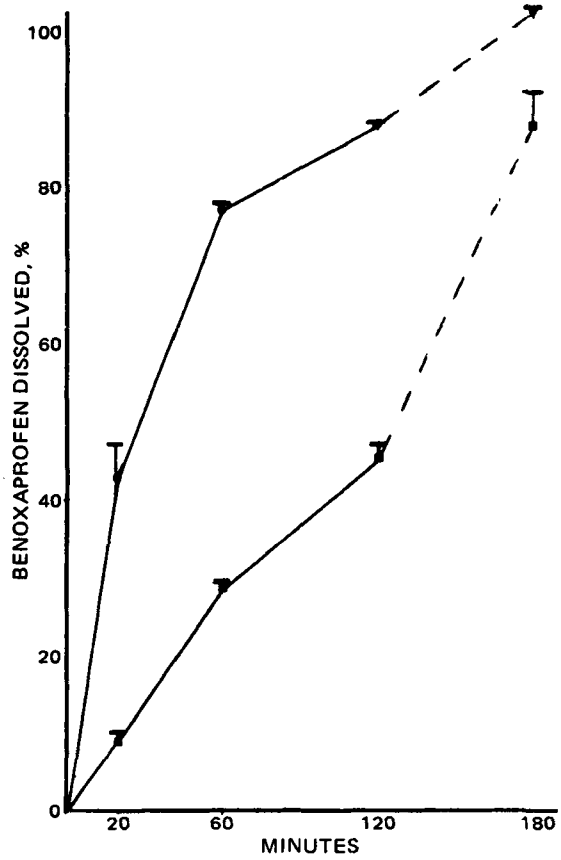

Figure 1—*Dissolution of two benoxaprofen particle-size formulations using the standard (USP XIX) 2-hr* in vitro *procedure. Key:* ■, *crystals larger than 60 mesh;* ●, *crystals smaller than 100 mesh; and* - - -, *results of vigorous magnetic stirring for an additional 1 hr. Each data point represents the mean of four assays with standard error.*

RESULTS AND DISCUSSION

The *in vitro* dissolution of the two benoxaprofen particle sizes is illustrated in Fig. 1. Twice as much benoxaprofen dissolved from the small particle formulation at each sampling time as from the large particle formulation, except the final sampling after an additional hour of vigorous stirring (>500 rpm with stirring bar). Since the medium would be only 6% of saturation if the 100 mg of drug dissolved, it was expected that both particle sizes would dissolve completely during this additional period of vigorous stirring. Instead, even under these relatively extreme conditions, the large particles dissolved relatively poorly.

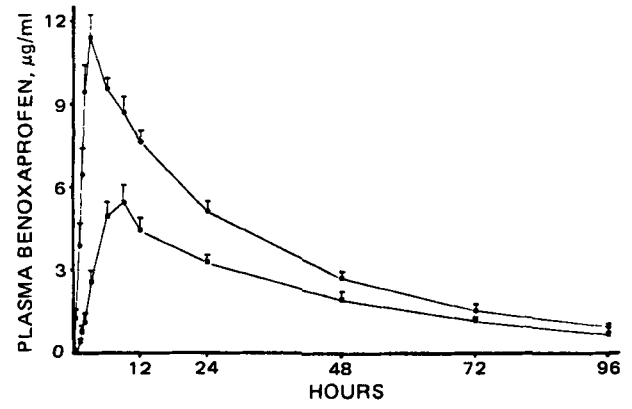

Figure 2—*Plasma unchanged benoxaprofen concentrations after oral dosing with 100 mg of two particle-size formulations. Key:* ■, *crystals larger than 60 mesh; and* ●, *crystals smaller than 100 mesh. Each data point represents the mean of 10 subjects with standard error.*

[5] Ketodase, General Diagnostics, Morris Plains, N.J.

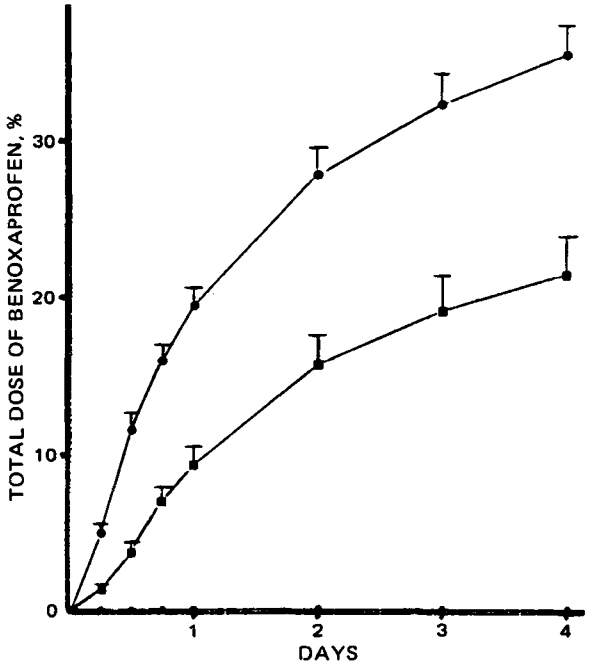

Figure 3—*Cumulative urinary benoxaprofen excretion (unchanged plus glucuronide metabolite) after oral dosing with 100 mg of two particle-size formulations. Key: ■, crystals larger than 60 mesh; and ●, crystals smaller than 100 mesh. Each data point represents the mean of 10 subjects with standard error.*

The average large particle dissolution after vigorous stirring was 87% of the drug in the capsules; the corresponding value for the small particles was 102%. Large particle dissolution also was more variable than dissolution of the small particles. Relative standard deviations for the average 20-, 60-, and 120-min large particle dissolution values were 26.7, 9.0, and 9.4, respectively; the corresponding determinations for the small particles were 25.6, 4.1, and 1.8.

These *in vitro* studies show that the dissolution of the two sieved benoxaprofen fractions containing particles with an ~10-fold difference in mean diameter was significantly different.

In the clinical study, two subjects withdrew after one dose for reasons other than those relating to drug dosing. The plasma data from the 10 subjects who completed the study are depicted in Fig. 2. Particle size dramatically affected both the rate and extent of GI benoxaprofen absorption. The calculated mean peak plasma concentration (12.0 μg/ml) for the small particle sizes was twice that for the large ones (5.5 μg/ml). Differences were also reflected in the calculated mean time to peak, 3.2 *versus* 6.2 hr, and the area under the mean plasma concentration–time curve, 357 *versus* 213 μg/hr/ml (0–96 hr).

The difference in benoxaprofen absorption from the two formulations also was reflected in the urinary drug and metabolite excretion (Fig. 3). An average of ~20% of the drug in the small particle formulation was excreted in the first 24 hr as the free plus glucuronide form compared to about 9% with the large particle formulation. Total drug excreted in the urine during the 96-hr collection averaged 35 and 21 mg, respectively.

That the differences in absorption noted were due to particle size is supported by analyses of variance (Table I) on the timed plasma levels, peak values, time to peak, area under plasma concentration–time curve, and total urinary drug excretion. The p value was <0.01 for all variables except the 0.5-, 72-, and 96-hr plasma levels.

Interaction of Streptonigrin with Metals and with DNA

KOPPAKA V. RAO

Received August 28, 1978, from the *Department of Pharmaceutical Chemistry, College of Pharmacy, J. Hillis Miller Health Center, University of Florida, Gainesville, FL 32610.* Accepted for publication January 10, 1979.

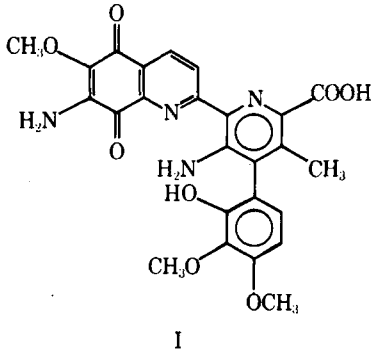
Abstract □ The antitumor antibiotic, streptonigrin, interacted with zinc, copper, and manganese but not with calcium or magnesium, as indicated by spectral shifts and difference spectra. The titration data showed the formation of 1:1 complexes, and further titration continued to show spectral shifts until a molar ratio for zinc to streptonigrin of 5–10 to 1 was reached. Streptonigrin interacted with DNA only in the presence of a metal ion such as zinc. Streptonigrin titration with DNA at varying zinc molar equivalents revealed that one antibiotic molecule required 5–7 moles of zinc and 20–25 moles of DNA-phosphorus for complexation. Similar values were obtained from gel permeation chromatography.

Keyphrases □ Streptonigrin–interaction with metals and with DNA, complexation, spectrophotometry, gel permeation chromatography □ Antibiotics—streptonigrin, interaction with metals and with DNA □ Antineoplastic agents—streptonigrin, interaction with metals and with DNA □ DNA—interaction with streptonigrin and with metals □ Metals—complexation with streptonigrin and with DNA

Streptonigrin (I), an antitumor antibiotic and a *Streptomyces flocculus* metabolite (1, 2), shows high activity against various experimental neoplasms (3–5). Extensive clinical trials showed that it was active against certain lymphomas (6), and a double-blind comparison with chlorambucil showed comparable activity, with I being slightly more toxic in the GI tract (7).

Strong streptonigrin involvement in DNA metabolism in various cellular systems manifests itself in chromosomal aberration and fragmentation and in drug absorption by nuclear fractions (8–10). Mizuno and Gilboe (11), who studied the *in vitro* interaction of I and DNA, showed that two complexes were formed, one unstable to dialysis and the other stable, with a stoichiometry of 1:2000 for streptonigrin–DNA nucleotides. However, a sedimentation behavior, melting-profile, and gel permeation chromatography study (12) indicated that no complex was formed between streptonigrin and DNA. In that study, I showed no inhibition of DNA-dependent RNA polymerase, unlike other DNA-interacting antibiotics such as actinomycin or daunomycin. Thus, streptonigrin binding to DNA is controversial; this behavior would be somewhat unusual in view of its demonstrated involvement in DNA metabolism.

The complexing ability of streptonigrin toward certain metal ions was explored in this laboratory. Preliminary spectrophotometric studies showed that I readily formed complexes with ions such as Zn^{2+}, Cu^{2+}, and Mn^{2+} but not with Ca^{2+} or Mg^{2+}. Streptonigrin–metal complexes readily interacted with DNA to form clearly demonstrable and relatively stable complexes. This paper describes some characteristics of the interaction of I with metals such as Zn^{2+} and of the complexes such as streptonigrin–zinc with DNA.



I

EXPERIMENTAL

Tromethamine buffer (0.01 *M*) of appropriate pH was used. Streptonigrin was dissolved in dioxane, approximately three equivalents of sodium bicarbonate were added, and the solution was diluted with water to $2–5 \times 10^{-4}$ *M*. Since I solutions made in tromethamine buffer (pH 7) decomposed gradually, the experiment was completed within 1 hr after the dilution with tromethamine.

Calf thymus DNA (sodium salt, highly polymerized, 8% phosphorus) was purchased[1]. A weighed sample was dissolved in water by gentle stirring with a magnetic stirrer at room temperature for 2–3 hr and was diluted to $1.0–1.5 \times 10^{-2}$ *M* solutions, based on DNA–phosphorus. The solutions were dispensed in 2–4-ml portions in test tubes and kept frozen until use.

The complexation was followed by a recording spectrophotometer[2] with silica cells of 1-cm path length. Metal complexes were studied in alcoholic and in aqueous solutions. For obtaining a Job plot, various molar mixtures of I and the metal ion with constant total molarity were prepared and their spectra were recorded. Corresponding reference solutions with I, but without the metal, also were prepared and their spectra were recorded. The difference in the absorbance between the two at the λ_{max} was plotted against the mole fraction.

Titrations were carried out by adding the metal-ion solution from a microburet[3] to the sample taken in the cell containing a magnetic stirring bar. The spectra were recorded against a distilled water (or alcohol) blank. In an alternative procedure, a I solution was taken in both the reference and sample cells, and the sample cell was titrated with the metal-ion solution. The spectra so obtained were the "difference spectra." Correction for the volume change was made by the addition of an identical volume of water to the reference cell.

DNA complexation was studied in aqueous solution with or without a buffer. Both titration methods, using either water or streptonigrin–Zn^{2+} solution as reference, were employed for measuring complexation.

Complex formation also was demonstrated through gel permeation chromatography by direct mixture chromatography and by an adaptation of the Hummel–Dreyer method (13). A cross-linked dextran[4] column (8 × 600 mm) was prepared and equilibrated with the streptonigrin–Zn^{2+} solution (4×10^{-5} *M* with respect to I and 4×10^{-4} *M* with respect to Zn^{2+}). The DNA sample (6.4×10^{-3} *M*, DNA–phosphorus) was diluted with the appropriate amount of the ligand–metal solution and applied to the column, which was then developed by more of the same solution. Fractions (3 ml) were collected, and their absorbance was read at 385 nm.

RESULTS AND DISCUSSION

In Fig. 1, curve A is a portion of the spectrum (300–450 nm) of 4×10^{-5} *M* I in 0.01 *M* tromethamine buffer, pH 7.5, with λ_{max} 363 nm and ϵ = 15,000. Curve B shows the shift of the λ_{max} to 385 nm (ϵ = 17,000) in the presence of 4×10^{-4} *M* Zn^{2+}. Curve C is the spectrum of a solution of I (4×10^{-5} *M*), Zn^{2+} (4×10^{-4} *M*), and DNA (3.2×10^{-3} *M*) with λ_{max} 410 nm and ϵ = 16,300. An identical solution, but without Zn^{2+}, gave curve

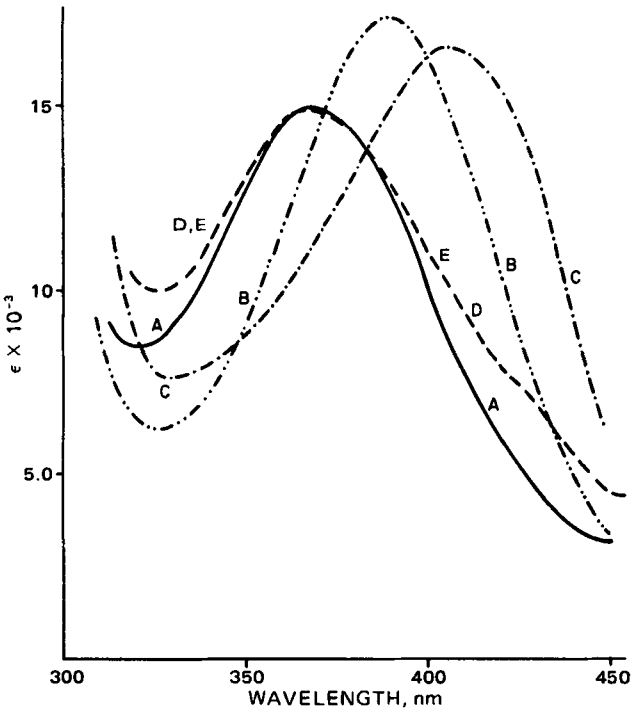

Figure 1—*Effects of Zn^{2+} and DNA on the absorption spectrum of I. Key: A, spectrum of I (4×10^{-5} M) in 0.01 M tromethamine buffer, pH 7.5; B, A + Zn^{2+} (4×10^{-4} M); C, A + B + DNA (3.2×10^{-3} M); D, A + DNA (3.2×10^{-3} M); and E, C + edetate sodium.*

D with λ_{max} and ϵ values essentially the same as those of I. To demonstrate that Zn^{2+} was essential for the I complexation with DNA, the solution that gave curve C was treated with edetate sodium, which produced a spectrum similar to that of D. Without zinc, DNA caused a slight spectral shift in the 410–450-nm region.

The complexation could be observed in two other ways. The reddish-brown I solutions essentially remained unchanged when treated with either Zn^{2+} or DNA separately; but when both were present, the color changed to brownish yellow. Addition of edetate sodium to this solution brought back the original reddish-brown color. In the second method, ethanol addition (5–6 volumes) to a I-DNA solution gave a white stringy DNA precipitate. Similar addition to streptonigrin-Zn^{2+}-DNA gave a dark-brown stringy precipitate even with 2–3 volumes of ethanol. The precipitate, after being washed with the solvent, gave the characteristic complex spectrum (curve C).

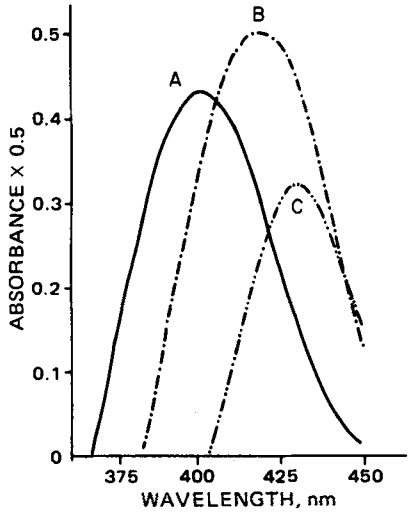

Figure 2—*Difference spectra. Key: A, spectrum of streptonigrin-Zn^{2+} complex read against a reference of streptonigrin; B, streptonigrin-Zn^{2+}-DNA complex read against a reference of streptonigrin-DNA; and C, streptonigrin-Zn^{2+}-DNA complex read against a reference of streptonigrin-Zn^{2+}.*

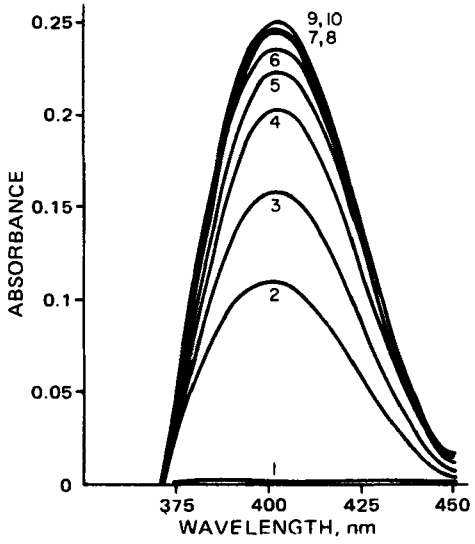

Figure 3—*Difference spectra similar to Fig. 2A resulting from titration of I with Zn^{2+}. The numbers 1–10 represent the zinc-streptonigrin molar ratios.*

Figure 2 shows the difference spectra.

Results with Cu^{2+} and Mn^{2+} were similar to those with Zn^{2+}. No spectral shifts were observed when I solutions were treated with Mg^{2+} or Ca^{2+} ions or when DNA was added in the presence of these ions in the pH 6.0–8.0 range.

Metal Complexation—I titration with Zn^{2+} solution, in the presence or absence of a buffer, gave difference spectra of increasing intensity (Fig. 3). A plot of the difference spectrum intensity against the I mole fraction is shown in Fig. 4. The slope change occurring at mole fraction 0.5 shows the existence of a 1:1 complex. The same result was obtained with the continuous variation (Job) method (Fig. 5). The experiments with Zn^{2+}, Cu^{2+}, and Mn^{2+} were carried out in aqueous as well as in ethanolic solutions with the same results shown in Fig. 3. Values from these experiments were used to calculate the formation constants for the complexation reaction shown in Table I according to Scheme I:

$$\text{streptonigrin} + Zn^{2+} \rightleftharpoons \text{streptonigrin-}Zn^{2+}$$

Scheme I

where the formation constant K = [streptonigrin-Zn^{2+}]/([streptonigrin]/[Zn^{2+}]). The concentration of each component was obtained from the spectrophotometric data according to the relationship:

$$K = \frac{(\epsilon_l - \epsilon_c)}{C_M(\epsilon_c - \epsilon_l) - (A - \epsilon_c C_l)} \qquad \text{(Eq. 1)}$$

where ϵ_c and ϵ_l were the absorptivities of the complex (which was the absorptivity at very high DNA/streptonigrin-Zn^{2+} ratios) and of the ligand, respectively; C_M and C_l were the total initial Zn^{2+} and streptonigrin

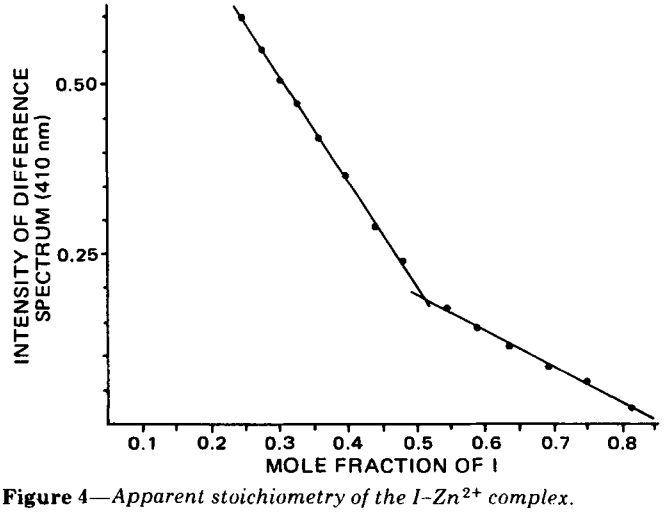

Figure 4—*Apparent stoichiometry of the I-Zn^{2+} complex.*

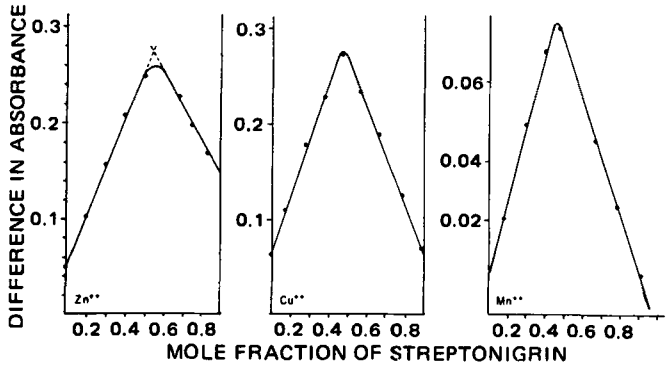

Figure 5—*Job plots of streptonigrin–metal complexes. The ordinates represent the difference between the absorbance of streptonigrin and that of the complex at the mole fraction value represented in the abscissa. The total molarity (ligand plus metal) was constant.*

concentrations, respectively; and A was the observed absorbance value.

Although a 1:1 complex could be demonstrated readily in the preceding experiments, further I titration with Zn^{2+} showed progressive increases in the difference spectrum intensity. The increase rate showed a slope change at a 5–10-mole ratio for Zn^{2+} to streptonigrin. This continued until a 20–25-mole ratio was reached, beyond which point it remained constant. This unusual metal to ligand ratio is difficult to rationalize merely on the basis of the streptonigrin structure. To assess the ionic strength influence on the metal complexation, a titration was carried out in the presence of sodium chloride (0.1 M). This lowered the end-point, with the constant value being obtained at a mole ratio of 10–15:1 for Zn^{2+} to streptonigrin.

The streptonigrin structure has many potential sites for complexation with zinc: the picolinic acid system, the 2,2-pyridylquinoline system, the aminoquinone system, the 2-(3-amino-2-pyridyl)quinoline system, and the amino and phenolic functions of rings C and D. The strongest are probably the first two. However, they cannot all be involved in complexation at the same time because some atoms or functions taking part in complexation are common to several systems. Also, after one proton has been displaced to form a complex, additional proton removal is a more difficult operation. A more likely explanation for the observed large metal–ligand ratios is in terms of mass action; *i.e.*, a sufficiently large metal ion excess must be present to form a relatively stable complex involving more than one metal atom. The term "apparent stoichiometry" is used in expressing this relationship until a more detailed picture of the interactions emerges.

DNA Complexation—Although the necessity for zinc was clearly demonstrated for streptonigrin binding with DNA, stoichiometry determination must consider the variable metal to ligand ratios indicated. For this reason, I titration with DNA was carried out at various Zn^{2+} to streptonigrin ratios (Fig. 6A). In the absence of Zn^{2+}, the difference spectrum was nonexistent. In the presence of varying Zn^{2+}, spectrophotometric titrations with DNA could be carried out to stable end-

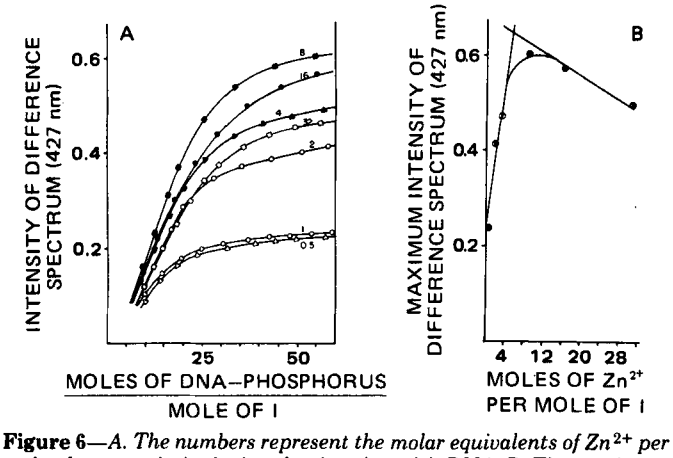

Figure 6—*A. The numbers represent the molar equivalents of Zn^{2+} per mole of streptonigrin during the titration with DNA. B. The maximum intensity values from Fig. 6A are plotted against the molar ratio of Zn^{2+}-streptonigrin.*

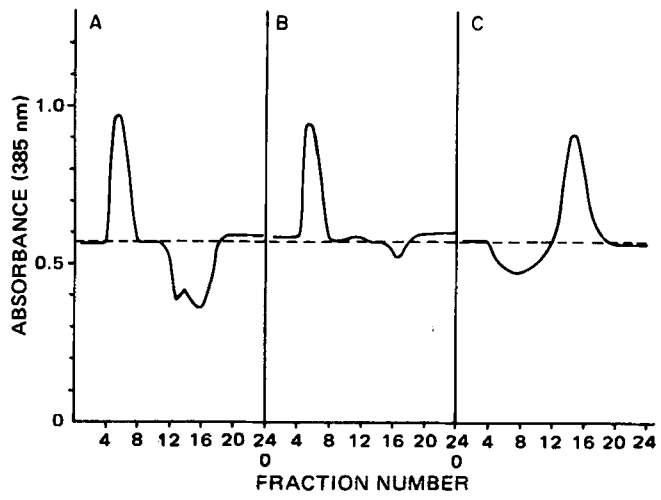

Figure 7—*Gel-chromatography of I-DNA in the presence (A and B) and absence (C) of Zn^{2+}. A. The column was equilibrated with streptonigrin–zinc (4×10^{-5} M and 4×10^{-4} M, respectively) and the DNA sample (6.4×10^{-3} M of DNA-phosphorus) was added. Elution was with the same streptonigrin–Zn^{2+} solution. B. Same as A but the DNA sample contained 3.2×10^{-4} M of streptonigrin. C. Same as A but without Zn^{2+}.*

points. At Zn^{2+} to streptonigrin ratios of 0.5:1 and 1:1, the curves were of the same order of magnitude. They showed that complexation took place between DNA and 1:1 streptonigrin–Zn^{2+}. At higher metal to ligand ratios, the difference spectrum intensity increased progressively until a maximum was reached at a zinc to streptonigrin ratio of 8:1. At still higher ratios, the difference spectrum intensity began to decrease.

In Fig. 6B, the maximum difference spectrum intensity was plotted against the Zn^{2+} to streptonigrin ratio. Extrapolation of the linear portions gave an intersection point that corresponded to a ratio of 6–7:1 for Zn^{2+} and streptonigrin. This value gave the maximum difference spectrum intensity change, suggesting that at this ratio of Zn^{2+} to streptonigrin, complexation with DNA was at the maximum. Titration of I with DNA at what appears to be an optimum Zn^{2+}-streptonigrin ratio of 7:1 showed the pattern commonly seen during complex formation, and titration could be performed to a relatively stable end-point. From several titrations, a value of 20–25 was obtained for the apparent stoichiometry, *i.e.*, 1 mole of streptonigrin/20–25 moles of DNA-phosphorus in the presence of 7 moles of Zn^{2+}. Thus, the interaction of I and DNA in the presence of Zn^{2+} parallels that of I and Zn^{2+}, where several moles of metal ion per mole of I were required for maximum interaction, as judged by the spectral shifts and intensity changes.

The streptonigrin–Zn^{2+}–DNA complex prepared in a 1:7:25 ratio could be diluted up to 10-fold without appreciable dissociation (as shown by the Beer's law plot). The complex was stable to dialysis for 4 days at 5°. The presence of Zn^{2+} in the complex was readily demonstrable by the λ_{max} (405–410 nm), as well as through the shift induced by edetate sodium to 365 nm.

Gel permeation chromatography was used for further characterization. When a I-DNA mixture was chromatographed on a cross-linked dextran column, the two appeared as sharp bands at their appropriate elution volumes. In the presence of Zn^{2+} (10 molar excess), two bands representing bound and free I could be seen during initial column development. However, as the elution progressed, they emerged as a very broad band. This behavior was not unexpected because of the continuous equilibrium alteration during elution.

The existence of the complex between streptonigrin and Zn^{2+} and DNA could be seen more clearly by the chromatographic procedure described previously (13) (Fig. 7A). As the DNA emerged from the column, the peak represented not only DNA but also the apparent stoichiometric amount of streptonigrin–Zn^{2+}. Since the introduced sample did not have the

Table I—I-Metal Complex Formation Constants

Complex	K at 22°
I-Zn^{2+}	$1.45 \pm 0.5 \times 10^5\ M^{-1}$
I-Cu^{2+}	$1.27 \pm 0.5 \times 10^5\ M^{-1}$
I-Mn^{2+}	$2.03 \pm 0.5 \times 10^4\ M^{-1}$

required ligand–metal complex concentration, it must have been taken up by the DNA from the surrounding solution. The negative peak that followed the DNA peak represented the ligand–metal complex removed from the solution. The two peak areas were equal.

Figure 7B shows the behavior when an additional 20 equivalents of streptonigrin–Zn^{2+} were introduced with the DNA sample. The negative peak was nearly absent, although the positive peak height due to the complex was the same as before. The apparent stoichiometry determined from several such elution curves, in which the negative peak was nearly absent, was 1 mole of streptonigrin/20–25 moles of DNA–phosphorus in the presence of 7 *M* equivalents of Zn^{2+}.

The column behavior in the absence of Zn^{2+} is shown in Fig. 7C. The initial negative peak suggested that the DNA displaced I from its position on the column and emerged first. The displaced streptonigrin appeared as the subsequent positive peak. This finding further indicates that complexation did not occur in the absence of Zn^{2+}.

3-Quinuclidinyl Benzilate Hydrolysis in Dilute Aqueous Solution

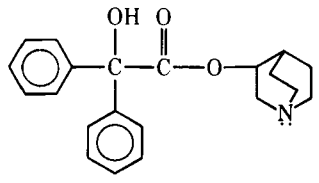
LARRY A. HULL, DAVID H. ROSENBLATT, and JOSEPH EPSTEIN ˣ

Received March 9, 1977, from the *Environmental Research Division, Chemical Systems Laboratory, Department of the Army, Aberdeen Proving Ground, MD 21010.* Accepted for publication January 9, 1979.

Abstract □ The hydrolysis kinetics of 3-quinuclidinyl benzilate were determined over the pH 0–14 range at different temperatures in solutions buffered to a constant pH. Analysis of data extrapolated to zero buffer concentrations permitted construction of an overall rate expression for pH 0–14 and 0–100°. Reaction mechanisms are discussed.

Keyphrases □ Quinuclidinyl benzilate—hydrolysis in dilute aqueous solution, kinetics, pH, temperature □ Aminoalcohol esters—quinuclidinyl benzilate, hydrolysis in dilute aqueous solution, kinetics □ Hydrolysis kinetics—quinuclidinyl benzilate in dilute aqueous solution, pH, temperature

3-Quinuclidinyl benzilate (I), like atropine, is a muscarinic cholinergic antagonist of considerable pharmacological interest (1). Among the properties of greatest pharmaceutical significance is its hydrolytic behavior in dilute aqueous solution. In the present research, sufficient information was gained to permit hydrolysis rate prediction in the absence of high general base or salt concentrations at any desired temperature (0–100°) or pH (0–14).



I

EXPERIMENTAL

Reagents and Materials—Technical grade I was dissolved in chloroform, decolorized with charcoal, and extracted into aqueous hydrochloric acid. The acidic solution was made slightly basic and back-extracted with chloroform. Solvent evaporation left a solid residue, which was recrystallized twice from ethyl acetate to give a product of at least 98% purity.

Anal.—Calc. for: C, 74.75; H, 6.87; N, 4.15; O, 14.23. Found: C, 74.6; H, 7.1; N, 4.3; O, 14.4.

Compound I-HCl was prepared by addition of hydrogen chloride-saturated ether to a chloroform solution of I; the crystalline precipitate was dried carefully. All solutions were made with carbon dioxide-free distilled water. Commercial grade buffers were used without additional purification. Ether was purified of peroxide by filtration through an alumina column.

Instrumentation—A spectrophotometer[1] with 1-cm quartz cells or 10-cm silica cells was used for absorptiometric determinations. The pH was determined with a pH meter[2]. Solvent contamination with stopcock grease was avoided through the use of separators with polytef stopcocks for liquid–liquid extractions. The reaction solutions were kept at a constant temperature with water baths[3], or, in some cases, the reacting mixtures were sealed in glass vials immersed in appropriate refluxing solvents that kept the temperature constant.

Procedure—Products were isolated from a pH 11.5 reaction mixture that was kept 4 hr at 60°. Only benzilic acid and 3-quinuclidinol were found; these compounds were identical to authentic samples according to IR and melting-point analyses.

3-Quinuclidinyl Benzilate Hydrolysis in Dilute Aqueous Solution

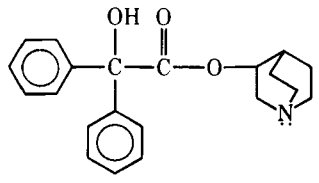
LARRY A. HULL, DAVID H. ROSENBLATT, and JOSEPH EPSTEIN ˣ

Received March 9, 1977, from the *Environmental Research Division, Chemical Systems Laboratory, Department of the Army, Aberdeen Proving Ground, MD 21010.* Accepted for publication January 9, 1979.

Abstract □ The hydrolysis kinetics of 3-quinuclidinyl benzilate were determined over the pH 0–14 range at different temperatures in solutions buffered to a constant pH. Analysis of data extrapolated to zero buffer concentrations permitted construction of an overall rate expression for pH 0–14 and 0–100°. Reaction mechanisms are discussed.

Keyphrases □ Quinuclidinyl benzilate—hydrolysis in dilute aqueous solution, kinetics, pH, temperature □ Aminoalcohol esters—quinuclidinyl benzilate, hydrolysis in dilute aqueous solution, kinetics □ Hydrolysis kinetics—quinuclidinyl benzilate in dilute aqueous solution, pH, temperature

3-Quinuclidinyl benzilate (I), like atropine, is a muscarinic cholinergic antagonist of considerable pharmacological interest (1). Among the properties of greatest pharmaceutical significance is its hydrolytic behavior in dilute aqueous solution. In the present research, sufficient information was gained to permit hydrolysis rate prediction in the absence of high general base or salt concentrations at any desired temperature (0–100°) or pH (0–14).



I

EXPERIMENTAL

Reagents and Materials—Technical grade I was dissolved in chloroform, decolorized with charcoal, and extracted into aqueous hydrochloric acid. The acidic solution was made slightly basic and back-extracted with chloroform. Solvent evaporation left a solid residue, which was recrystallized twice from ethyl acetate to give a product of at least 98% purity.

Anal.—Calc. for: C, 74.75; H, 6.87; N, 4.15; O, 14.23. Found: C, 74.6; H, 7.1; N, 4.3; O, 14.4.

Compound I-HCl was prepared by addition of hydrogen chloride-saturated ether to a chloroform solution of I; the crystalline precipitate was dried carefully. All solutions were made with carbon dioxide-free distilled water. Commercial grade buffers were used without additional purification. Ether was purified of peroxide by filtration through an alumina column.

Instrumentation—A spectrophotometer[1] with 1-cm quartz cells or 10-cm silica cells was used for absorptiometric determinations. The pH was determined with a pH meter[2]. Solvent contamination with stopcock grease was avoided through the use of separators with polytef stopcocks for liquid–liquid extractions. The reaction solutions were kept at a constant temperature with water baths[3], or, in some cases, the reacting mixtures were sealed in glass vials immersed in appropriate refluxing solvents that kept the temperature constant.

Procedure—Products were isolated from a pH 11.5 reaction mixture that was kept 4 hr at 60°. Only benzilic acid and 3-quinuclidinol were found; these compounds were identical to authentic samples according to IR and melting-point analyses.

To determine the I hydrolysis rates, concentration analyses were made at appropriate intervals. The reaction solutions were buffered to a constant pH, adjusted to 0.055 ionic strength with sodium chloride, and thermostated to within ±2°. Kinetic experiments above pH 9 were performed under a nitrogen atmosphere to reduce carbon dioxide absorption.

Because of the limited solubility of I at high pH, two analytical procedures were employed. Each reaction mixture for studies below pH 7 was at an initial I-HCl concentration of 0.0023 *M*. Ten-milliliter aliquots of the reaction mixture were taken at appropriate intervals, mixed with 2 ml of 1.3 *M* H_2SO_4, and extracted with 10 ml of ether to remove benzilic acid. The aqueous extraction layer was collected and analyzed spectrophotometrically for I (as the protonated species, $I{\cdot}H^+$) at 258 nm using a 1-cm light path cell.

For kinetic studies above pH 9, initial concentrations of 0.00026 *M* I-HCl were used. Forty-milliliter aliquots of the reaction mixtures were extracted with mixtures of 40 ml of ether and 8 ml of 1.3 *M* H_2SO_4. Aqueous layers were analyzed spectrophotometrically as already described with 10-cm light path silica cells.

No appreciable error was introduced in the analyses due to I hydrolysis after extraction of the acidified mixtures since the molar absorptivities of I and benzilic acid were not significantly different. The molar absorptivities at 258 nm were 479 and 481, respectively. Also, the hydrolysis reaction in acid at 25° was extremely slow. There was a slight shift in the spectrum when benzilic acid was converted to the benzilate ion, but this shift was not noticeable at 258 nm.

Data Analysis—The linearity of semilogarithmic I absorbance plots (and, hence, of concentration) invariably indicated first-order kinetics. The pseudo-first-order rate constants, k_{obs}, were calculated from these lines by a least-squares treatment. The k_{obs} values determined at three different buffer concentrations were extrapolated back to zero buffer concentration to eliminate buffer effects and to obtain the first-order rate constants for the water species, *i.e.*, H_3O^+, OH^-, and H_2O. The intercept of each plot was designated k_0. The kinetic runs gave pseudo-first-order reactions with respect to the I disappearance rate because of the large excess or constancy of the water species, whether OH^-, H_3O^+, or H_2O.

Initial data inspection led to the assumption, later confirmed by theoretical curves, that the important reactions were analogous to those observed by Hussain and Schurman (2) with 2-dimethylaminoethanethiol propionate, *i.e.*:

$$I{\cdot}H^+ + H_3O^+ \xrightarrow{k_1} \text{products}$$

Scheme I

$$\text{rate} = k_1[I{\cdot}H^+][H_3O^+] \qquad \text{(Eq. 1)}$$

$$I{\cdot}H^+ + H_2O \xrightarrow{k_2} \text{products}$$

Scheme II

$$\text{rate} = k_2[I{\cdot}H^+][H_2O] \qquad \text{(Eq. 2)}$$

$$I{\cdot}H^+ + OH^- \xrightarrow{k_3} \text{products}$$

Scheme III

$$\text{rate} = k_3[I{\cdot}H^+][OH^-] \qquad \text{(Eq. 3}a\text{)}$$

or:

$$I + H_2O \xrightarrow{k_{3'}} \text{products}$$

Scheme IV

$$\text{rate} = k_{3'}[I][H_2O] \qquad \text{(Eq. 3}b\text{)}$$

and:

$$I + OH^- \xrightarrow{k_4} \text{products}$$

Scheme V

$$\text{rate} = k_4[I][OH^-] \qquad \text{(Eq. 4)}$$

Although Eqs. 3*a* and 3*b* are kinetically equivalent, Eq. 3*b* was ruled out effectively by several authors for related reactions (2–5). The rigid structure of I cannot be contorted to give the intermediate required by Bruice and Mautner (6), who would favor Eq. 3*b*. Equation 3*a* represents the important reaction in the present instance. Also, since the hydrogen-ion concentration is quite low in the region where the free base form (I) is significant, the following reaction was not considered:

$$I \xrightarrow{H^+} \text{products}$$

Scheme VI

The dissociation constant for $I{\cdot}H^+$, $K_a = [I][H_3O^+]/[I{\cdot}H^+]$, and the protolysis constant for water, $K_w = [H^+][OH^-]$, were utilized in an overall rate expression:

$$k_0 = \frac{k_3K_w + k_4K_aK_w/[H_3O^+] + k_1[H_3O^+]^2 + k_2[H_2O][H_3O^+]}{[H_3O^+] + K_a} \qquad \text{(Eq. 5)}$$

Values of K_w at 0.055 ionic strength were calculated according to the equations of Harned and Owen (7), assuming the electrolyte to be sodium chloride, where $K_{w0.055} = K_{w0.0}\,(\alpha_{H_2O}/\gamma_{H^+}\gamma_{OH^-})$. Values of k_4 were obtained from experiments above pH 11, where $k_4 = k_0/[OH^-]$. The individual values of k_4 were fitted to an Arrhenius equation by a least-squares plot.

The value of K_a could not be determined directly by potentiometric titration owing to solubility problems and to hydrolysis during titration. Therefore, at 25°, a least-squares data plot for pH 6.8, 8.1, and 9.05 was used to calculate k_3 and K_a. The resulting equation derived from Eq. 5, with omission of terms in k_1 and k_2, was:

$$k_0[H_3O^+] = k_3K_w + \{(k_4K_w/[H_3O^+]) - k_0\}K_a \qquad \text{(Eq. 6)}$$

The ordinate $k_0[H_3O^+]$ was plotted against the abscissa $(k_4K_w/[H_3O^+]) - k_0$ to give K_a as the slope and k_3K_w as the intercept. In this calculation, the average k_4 value at 25°, 155 M^{-1} hr^{-1}, was used.

Approximate k_3 values were calculated from 45 and 87° data at pH 6.86, which were used along with the 25° value for an initial Arrhenius plot of k_3. The Arrhenius plot values were used to calculate K_a at four temperatures; in turn, these values were used to correct the preliminary values of k_3, *i.e.*:

$$k_3 = \left\{k_0/[OH^-] - k_4\left(\frac{K_a}{[H_3O^+] + K_a}\right)\right\}\left(\frac{[H_3O^+] + K_a}{[H_3O^+]}\right) \qquad \text{(Eq. 7)}$$

The corrections were small. The final Arrhenius plot of k_3 (25, 45, and 87°) provided the necessary input for refined K_a calculations.

The reaction of $I{\cdot}H^+$ with water at 25° in the pH range of minimum reaction, ~pH 3.6, was too slow for a direct rate determination. Therefore, the value for k_2 was estimated by means of a Bronsted plot (8) of log k_B/q *versus* log $(p/q)K_a$, where k_B is the catalytic constant of the base and K_a is the dissociation constant of the aminomethane, HPO_4^{2-}, and acetate. This plot was extrapolated to the log of $(p/q)K_a$ for water (9), *i.e.*, 1.744, to obtain k_2, which is also k_B for water.

Values of k_B for each base were determined as follows. First, values of k_{Bi} for three of the bases that had been used to establish the k_0 values ($H_2BO_3^-$, tromethamine, and HPO_4^{2-}) were calculated from the slopes of:

$$k_{obs} = k_{Bi}[\text{buffer base}] + k_0 \qquad \text{(Eq. 8)}$$

where the buffer base concentration was taken as one-half of the total buffer concentration since the acid to base ratio was always 1:1. Then, k_B was calculated from k_{Bi} by correcting for the dissociation of $I{\cdot}H^+$ to I and assuming that the reactivity of I was 1/29 (*i.e.*, $k_3 = 29k_4$) as great as that of $I{\cdot}H^+$. (See *Appendix* for details.) The value of k_B for hydroxide ion was taken as equal to k_3, and the dissociation constant for water, the conjugate acid of hydroxide ion, was taken as 1.8×10^{-16}.

To obtain k_B for acetate ion, which was run at pH = pKa of acetic acid, the calculation required that the water reaction be included:

$$k_B = \frac{k_{obs} - k_3[OH^-] - k_2[H_2O]}{[\text{acetate ion}]} \qquad \text{(Eq. 9)}$$

Thus, on the first round, k_2 was considered to be zero in the calculation of acetate k_B, which was used in determining an approximate value of k_2. This value, in turn, was used to refine the acetate k_B and so on in a rapidly convergent iterative process.

For determining k_2 at 100°, an aqueous $I{\cdot}H^+$ solution was adjusted with hydrochloric acid to pH 3.6 and ionic strength 0.055. From the relative densities of water at 25 and 100° and the molar water concentration at 25°, the molar water concentration at 100° is 53.4. The value of k_{obs} was corrected by subtraction of $k_3[OH^-]$ to obtain k_0. The rate was then:

$$k_2 = k_0/[H_2O] = k_0/53.4 \qquad \text{(Eq. 10)}$$

At the pH in question, correcting k_2 for $k_1[H_3O^+]$ was unnecessary.

From the values of k_2 at 25 and 100°, an Arrhenius equation was derived.

The calculation of k_1 involved the assumption that ionic strength has little effect. [This assumption was necessary because the reaction rate at 0.055 ionic strength, *i.e.*, 0.055 *N* HCl, and 25 or 45° is so low. From data for 1 and 0.5 *N* HCl at 25°, one may estimate that the rate increase due to the ionic strength of 1 *N* HCl over the rate at ionic strength 0.055

[a] Buffers other than NaOH and HCl consisted of equal concentrations of the buffer base and its conjugate acid. [b] Calculated k_0 for buffer concentration. [c] Ionic strength same as molar concentration. [d] The pH for these experiments was estimated from the pKa of the buffer at the given temperature. [H. W. Robinson, *J. Biol. Chem.*, **82**, 775 (1969). R. G. Bates, "Electronic pH Determinations," Wiley, New York, N.Y., 1954, p. 86. R. P. Bell, "Acid-Base Catalysis," Oxford University Press, London, England, 1941, pp. 11-35.]

is about 12%. According to Aksnes and Prue (10), it might have been higher.] The calculation was:

$$k_1 = k_{obs} - k_2[H_2O] \qquad \text{(Eq. 11)}$$

The values of k_1 at 25 and 45° were incorporated in an Arrhenius equation.

RESULTS AND DISCUSSION

Kinetic Rate Data and Equilibria—Kinetic rate data and associated pH values are summarized in Table I. Data used for the Bronsted plot to estimate k_2 at 25° are shown in Table II. A plot of log $k_{B/q}$ *versus* log $(p/q)K_a$ using the values in Table II was linear ($r = 0.9996$) with a slope of 0.58, supporting the contention that I hydrolysis is subject to general base catalysis.

Table II—General Base Catalysis Data for Hydrolysis of 3-Quinuclidinyl Benzilate (Protonated Species)

Base	p/q	K_a	k_B[a]
Water	1/1	55.5	2.94×10^{-7}
Acetate	1/2	2.399×10^{-5}	0.00272
Phosphate	2/3	1.585×10^{-5}	0.0460
Tromethamine	1/1	7.943×10^{-9}	0.1257
Borate	3/1	8.913×10^{-10}	1.0036
Hydroxide	1/1	1.80×10^{-16}	4514

[a] k_B calculated from:

$$k_B = \frac{k_{obs} - k_0}{[\text{buffer base}]} \left[\frac{[H_3O^+] + K_a}{[H_3O^+] + K_a/29} \right]$$

The temperature-related equations for the hydrolysis rate constants in units of M^{-1} hr^{-1} and the acid dissociation constant of I are:

$$\log_{10} k_1 = (-3388.2/T) + 8.2477 \qquad \text{(Eq. 12)}$$

$$\log_{10} k_2 = (-2717.5/T) + 2.5827 \qquad \text{(Eq. 13)}$$

$$\log_{10} k_3 = (-2379.6/T) + 11.5558 \qquad \text{(Eq. 14)}$$

$$\log_{10} k_4 = (-2531.6/T) + 10.6599 \qquad \text{(Eq. 15)}$$

and:

$$\log_{10} K_a = (-2455.8/T) - 1.0647 \qquad \text{(Eq. 16)}$$

where T is in °K.

In Table III, the values of k_0 for nine experiments are compared with those obtained by use of Eq. 5 with the constants calculated from Eqs. 12–16. The predicted values were generally within 35% of the experimental values.

The pH of maximum stability in water at 25° containing little or no basic anions is 3.64 (11). From Eq. 5, the observed rate at this pH is 1.66×10^{-5} hr^{-1}. The water reaction accounts for ~98% of the reaction at this pH. At pH 3, the rate is only 1.71×10^{-5} hr^{-1}, with the water reaction accounting for 95% of the overall reaction. At pH 4.5, the water reaction accounts for 93% of the total reaction.

Thus, the left side of the pH profile of I hydrolysis (Fig. 1) shows a decreasing rate with increasing pH; the change of the rate initially is 10-fold per pH unit but diminishes as the pH nears 3. The rate over pH

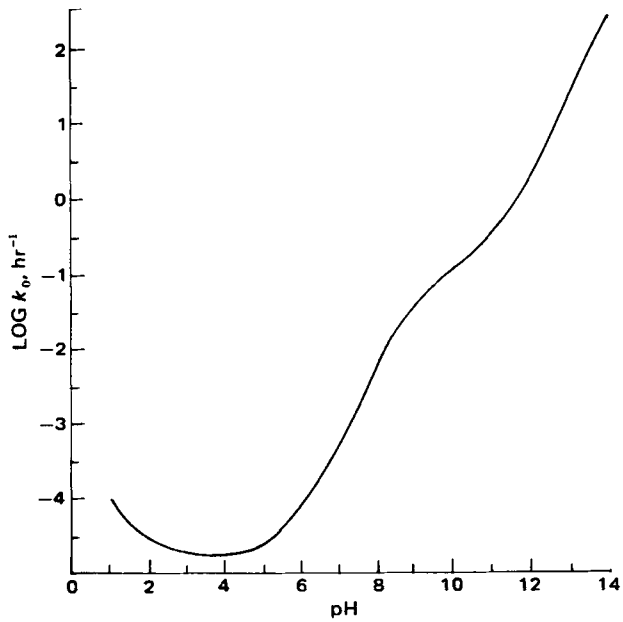

Figure 1—*Hydrolysis rates of 3-quinuclidinyl benzilate from pH 1–14 at t = 25° and μ = 0.055.*

Table III—Calculated *versus* Experimental k_0 Values for 3-Quinuclidinyl Benzilate (I) Hydrolysis in Buffer Solutions

Temperature	pH	k_0[a], hr^{-1} Calculated	Found
15°	9.15	0.0142	0.0143
25°	6.80	0.000356	0.000377
25°	8.10	0.00677	0.00890
25°	9.05	0.0428	0.0380
35°	8.90	0.102	0.132

45°	8.83	0.253	0.273
65.5°	8.94	1.428	1.178
87°	6.86	0.522	0.363

[a] Values of k_0 calculated from:

$$k_0 = \frac{k_3K_w + K_4K_aK_w/[H_3O^+] + k_1[H_3O^+]^2 + k_2[H_2O][H_3O^+]}{[H_3O^+] + K_a}$$

3–4.5 is, to all intents, constant and is due to the reaction of $I{\cdot}H^+$ with water molecules. Above pH 4.5, the rate increases in the manner shown in Fig. 1.

The hydrolysis of I in the absence of buffers lowers the aqueous solution pH since hydrolysis produces benzilic acid. Thus, an unbuffered I solution that is initially slightly basic (the pKa of $I{\cdot}H^+$ is 9.3) will hydrolyze at a rate calculable from Eq. 5 but will produce acid, lower the pH, and thus produce an environment where the hydrolysis rate is less than it was initially.

Comparison with Hydrolysis of Related Compounds—The hydrolysis kinetics of amino alcohol (and amino mercaptan) esters in which the nitrogen is separated from the alcohol oxygen by two or three carbons was studied as early as 1950 (12). In general, reactivity with hydroxide ion is in the order: protonated tertiary amine > quaternary ammonium > tertiary amine. Values of k_4 (the hydroxide-ion rate constant with the unprotonated species) tend to remain fairly close to one another under a given set of conditions (4, 13–15), as well as to values for esters containing no nitrogen (4, 14, 15). Nitrogen proximity to the carbonyl carbon is unimportant (4, 13, 15).

Nitrogen quaternization by alkylation inductively increases these rate constants up to 32-fold (2, 4, 6, 12, 13, 15). Protonation, however, increases the reactivity up to 40,000-fold (2, 4, 6, 13, 14, 16). The higher increase, therefore, cannot be ascribed only to an inductive effect of the positive charge. The large increases are found in cases where the proton can participate in intramolecular hydrogen bonds with the acyl carbonyl oxygens (4, 17). When rigidity prevents intramolecular hydrogen bonding, the protonated species are not much more reactive than the quaternized species. Thus, in the case of 3-quinuclidinyl acetate, the factor is less than 2 (13, 18). The k_3/k_4 ratio of 29 in this work appears entirely reasonable.

Significance of Present Study—Amino alcohol ester hydrolytic stability has been of concern in the pharmaceutical field, and several pH profile determinations are on record (2–6, 16, 19, 20). These usually have ignored both the water reaction (k_2), which is generally slow enough to present experimental difficulties, and the acid-catalyzed hydrolysis (k_1). The present study provides the means for calculating the hydrolysis rate over wide temperature and pH ranges with all four rate-determining reactions considered.

APPENDIX

For the calculations of K_B from K_{Bi}:

$$k_{Bi} = \frac{[I{\cdot}H^+]k_B}{[I] + [I{\cdot}H^+]} + \frac{[I]k_B}{29([I] + [I{\cdot}H^+])} \qquad \text{(Eq. A1)}$$

Since:

$$\frac{[I{\cdot}H^+]}{[I] + [I{\cdot}H^+]} = \frac{[H_3O^+]}{[H_3O^+] + K_a} \qquad \text{(Eq. A2)}$$

and:

$$\frac{[I]}{[I] + [I{\cdot}H^+]} = \frac{K_a}{[H_3O^+] + K_a} \qquad \text{(Eq. A3)}$$

it follows that:

$$k_B = k_{Bi} \div \left(\frac{[H_3O^+]}{[H_3O^+] + K_a} + \frac{K_a/29}{[H_3O^+] + K_a}\right) \qquad \text{(Eq. A4)}$$

or:

$$k_B = k_{Bi}\left(\frac{[H_3O^+] + K_a}{[H_3O^+] + K_a/29}\right) \qquad \text{(Eq. A5)}$$

Controlled Drug Dissolution by Radiation-Induced Polymerization in the Presence of Dimethylaminoethyl Methacrylate–Methyl Methacrylate Copolymer or Methacrylic Acid–Methyl Acrylate Copolymer

MASARU YOSHIDA, MINORU KUMAKURA, and ISAO KAETSU ˣ

Received July 24, 1978, from the *Takasaki Radiation Chemistry Research Establishment, Japan Atomic Energy Research Institute, Takasaki, Gunma, Japan.* Accepted for publication January 11, 1979.

Abstract □ Polymer-containing tablet preparation was studied using radiation-induced polymerization of glass-forming monomers at low temperatures in the presence of dimethylaminoethyl methacrylate–methyl methacrylate copolymer or methyl acrylate–methacrylic acid copolymer. Drug dissolution from tablets was in the pH 3.0–8.0 range. A copolymer contained in the tablets dissolved in the dissolution medium at a specific pH. Drug dissolution from tablets took place rapidly at pH >6.0 in the presence of methyl acrylate–methacrylic acid copolymer and at pH <5.0 in the presence of dimethylaminoethyl methacrylate–methyl methacrylate copolymer. The polymers had fibrous or capillary pore structures in contrast to the spherical pore structures formed in the presence of polyethylene glycol 600.

Keyphrases □ Dosage forms—controlled-release delivery devices, radiation-induced polymerization of glass-forming monomers, low temperature, in the presence of dimethylaminoethyl methacrylate–methyl methacrylate or methacrylic acid–methyl acrylate copolymers, for various drugs, dissolution rate from tablets □ Tablets—drug dissolution rate, radiation-induced polymerization of glass-forming monomers in the presence of dimethylaminoethyl methacrylate–methyl methacrylate or methacrylic acid–methyl acrylate copolymers, various drugs □ Copolymers—anionic and cationic, controlled-release tablets, dissolution rate, various drugs □ Dissolution rates—various drugs, tablets containing radiation-induced polymers of glass-forming monomers in the presence of cationic and anionic copolymers

Recent studies reported enzyme immobilization by polymer entrapment (1–3). Controlled drug dissolution by polymer entrapment is attractive due to durable and moderately controlled pharmaceutical effects (4–6).

Radiation-induced polymerization using glass-forming monomers (7) at low temperatures for the preparation of polymer matrixes containing biofunctional substances (8–10) such as enzymes, microbial cells, and drugs has been reported. Glass-forming monomers are a suitable entrapping matrix because they supercool to highly viscous liquids or amorphous solid at low temperatures and because they polymerize even at low temperatures. The polymer matrixes produced by this method were characteristic in porous structure due to crystallized solvent or crystallized water in the matrix at low temperatures; this porous structure facilitates substrate or drug diffusion in and out of the matrix.

However, controlled drug dissolution often requires dissolution of a drug in a solvent within a specific pH range. The entrapping method permits the mixing of various additives with drugs and polymer in the matrix. This paper describes drug dissolution from solid tablets prepared by radiation-induced polymerization in the presence of dimethylaminoethyl methacrylate–methyl methacrylate copolymer or methacrylic acid–methyl acrylate copolymer for controlled dissolution at pH 3.0–8.0.

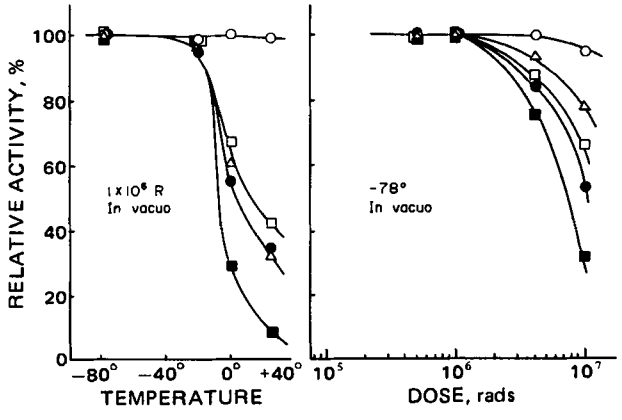

Figure 1—*Effect of irradiation conditions on native drug activity. Drug was dissolved in distilled water (pH 6.0) and put into a glass ampul. The ampul was sealed under a vacuum of 10^{-3} mm Hg. Irradiation was carried out at 1 × 10^6 rads (R)/hr* in vacuo. *The native drug activity was taken ds 100%. Key (drug concentration): ○, 60 μg of potassium chloride/ml; □, 25 μg of salicylic acid/ml; △, 8 μg of sulfanilamide/ml; ●, 60 μg of aspirin/ml; and ■, 20 μg of colchicine/ml.*

EXPERIMENTAL

Monomers—2-Hydroxyethyl methacrylate[1], hydroxyethyl acrylate[1], and glycidyl methacrylate[1] were used.

Drugs—Aspirin[2], sulfanilamide[3], salicylic acid[3], colchicine[3], and potassium chloride[4] were used.

Copolymers—Copolymer[5] of dimethylaminoethyl methacrylate–methyl methacrylate (cation-type copolymer) and copolymer[6] of methacrylic acid–methyl acrylate (anion-type copolymer) were used. The cation-type copolymer was dissolved only in a medium corresponding to the gastric juice at pH <5.0; the anion-type copolymer was dissolved in a medium corresponding to the intestinal juice at pH >6.0.

Porous Polymer–Drug Tablet Preparation—Polymer tablets containing drugs were made as follows. Drug, 600 mg, was put in a flat-bottom glass ampul, 14 mm i.d., and then 0.5 ml of the copolymers–glass-forming monomer mixture was added. Powdered copolymers, such as anion- and cation-type copolymers, completely dissolved at 30–80° in glass-forming monomers such as 2-hydroxyethyl methacrylate, hydroxyethyl acrylate, and glycidyl methacrylate. The ampul was sealed under a vacuum of 10^{-3} mm Hg at −196° (liquid nitrogen) and was irradiated for 2 hr at 5 × 10^5 rads/hr at −78° with γ-rays from a ^{60}Co source. After irradiation, the polymer–drug matrix was obtained as a homogeneous tablet, 14 mm in diameter and 4 mm thick.

Drug Dissolution from Tablets—The dissolution test was made with the dissolution apparatus[7] at 37° at a rate of 100 rpm according to USP XIX. The basket containing the tablet was immersed in 1000 ml of dissolution medium at various pH values. At time intervals over 480 min, 5 ml of the dissolution medium was sampled. The dissolved drug was

Table I—Parameters for Drug Dissolution from Polymer Tablets, 14 mm in Diameter and 4 mm Thick, in the Presence of Anion-Type Copolymer

Sample	Composition, wt. % Anion-Type Copolymer	Monomer	Drug (mol. wt.)	W, %	k, $\times 10^{-3}$ min^{-1}
1	—	100% Hydroxyethyl methacrylate	Aspirin (180.16)	31.2	0.89
2	5	95% Hydroxyethyl methacrylate	Aspirin (180.16)	34.9	1.24
3	10	90% Hydroxyethyl methacrylate	Aspirin (180.16)	39.3	1.99
4	20	80% Hydroxyethyl methacrylate	Aspirin (180.16)	47.4	3.41
5	10	90% Hydroxyethyl acrylate	Aspirin (180.16)	57.9	7.26
6	10	90% Glycidyl methacrylate	Aspirin (180.16)	7.2	0.50
7	10	90% Hydroxyethyl methacrylate	Potassium chloride (74.55)	37.6	4.31
8	10	90% Hydroxyethyl methacrylate	Salicylic acid (138.12)	40.1	2.88
9	10	90% Hydroxyethyl methacrylate	Sulfanilamide (172.21)	37.2	2.36
10	10	90% Hydroxyethyl methacrylate	Colchicine (399.45)	38.6	1.00

assayed spectrophotometrically[8] at 460 nm by a mercury thiocyanate method for potassium chloride (11), at 258 nm for sulfanilamide, at 296 nm for salicylic acid, at 273 nm for aspirin, and at 353 nm for colchicine.

Measurement of Tablet Porosity—Polymer–drug matrix porosity was observed by scanning electron microscopy[9].

The polymer–drug matrix water content (W) was defined as:

$$W\ (\%) = \frac{W_w}{W_p + W_w} \times 100 \qquad \text{(Eq. 1)}$$

where W_w and W_p are the weights of water absorbed in the polymer and of dried polymer, respectively.

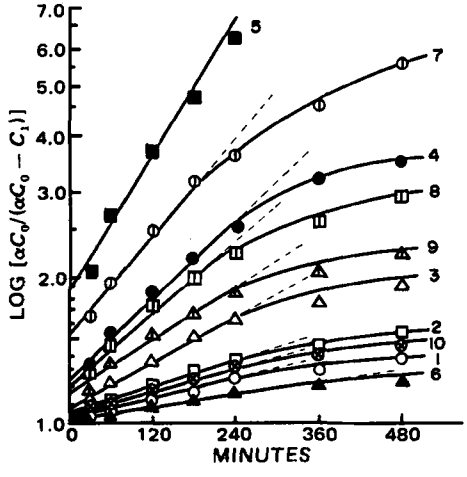

Figure 2—*Semilogarithmic relationship between $\alpha C_0/(\alpha C_0 - C_1)$ and dissolution time for polymer tablets in the presence of an anion-type copolymer. Sample number refers to compositions in Table I. The dissolution medium was at pH 8.0. Key (tablet system and drug): ○, 100% hydroxyethyl methacrylate (aspirin); □, 95% hydroxyethyl methacrylate–5% anion-type copolymer (aspirin); △, 90% hydroxyethyl methacrylate–10% anion-type copolymer (aspirin); ●, 80% hydroxyethyl methacrylate–20% anion-type copolymer (aspirin); ■, 90% hydroxyethyl acrylate–10% anion-type copolymer (aspirin); ▲, 90% glycidyl methacrylate–10% anion-type copolymer (aspirin); ⊙, 90% hydroxyethyl methacrylate–10% anion-type copolymer (potassium chloride); ⊡, 90% hydroxyethyl methacrylate–10% anion-type copolymer (salicylic acid); ◭, 90% hydroxyethyl methacrylate–10% anion-type copolymer (sulfanilamide); and ⊗, 90% hydroxyethyl methacrylate–10% anion-type copolymer (colchicine).*

RESULTS AND DISCUSSION

Effect of Irradiation on Drugs—It was necessary to know the irradiation effect on drug activity before polymer tablet preparation. The relation between native drug relative activity and the irradiation conditions used in experimental tablet preparation is shown in Fig. 1. Under the present experimental temperature, energy, and irradiation duration, there was no detectable drug decomposition. Since drug radiation damage is enhanced in the presence of oxygen, the irradiation in a vacuum is desirable.

Drug Dissolution–Time Curves of Tablets in Presence of Anion-Type Copolymer—Potassium chloride, salicylic acid, sulfanilamide, aspirin, or colchicine was entrapped in the polymer matrix by radiation-induced polymerization of a glass-forming monomer at low temperature in the presence of an anion-type copolymer. The dissolved drug in the dissolution medium at pH 8.0 was measured at certain time intervals.

First-order drug dissolution kinetics were investigated using the Noyes–Whitney equation (12, 13). The rate constant for dissolution (k) and the drug concentration at time t were expressed as:

$$kt = \ln \frac{\alpha C_0}{(\alpha C_0 - C_1)} \qquad \text{(Eq. 2)}$$

where α represents V/V_0, V and V_0 are the volumes of tablet per unit weight and medium used for dissolution, C_1 is the drug concentration in the dissolution medium, C_0 is the initial drug concentration in the tablet, and k is the dissolution rate constant.

The relation between t and $\alpha C_0/(\alpha C_0 - C_1)$ in tablets of various anion-type copolymer concentrations and various polymer matrixes and drug components is shown in Fig. 2. The dissolution rate constant (k) was calculated from the initial slope of linear graphs (Table I).

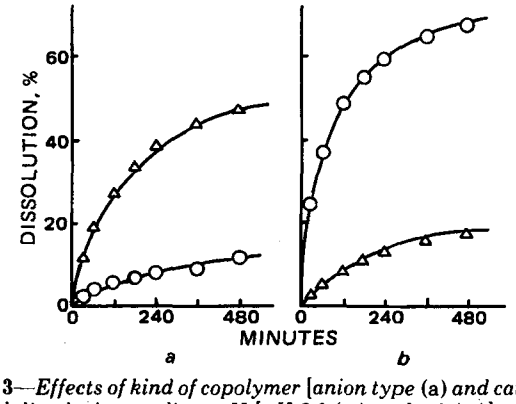

Figure 3—*Effects of kind of copolymer [anion type (a) and cation type (b)] and dissolution medium pH [pH 3.0 (○) and 8.0 (△)] on aspirin dissolution from polyhydroxyethyl methacrylate tablet. Tablet composition was 90% hydroxyethyl methacrylate–10% copolymer.*

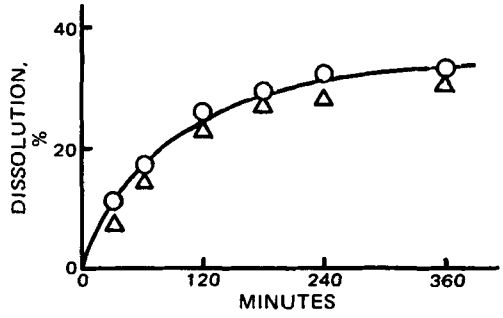

Figure 4—*Effect of dissolution medium pH [pH 3.0 (○) and 8.0 (△)] on aspirin dissolution from polyhydroxyethyl methacrylate tablet in the presence of polyethylene glycol 600.*

For Samples 1–4 (Fig. 2), aspirin dissolution from the tablet increased with anion-type copolymer concentration. This increase was attributed to anion-type copolymer dissolution in the tablet at pH 8.0, although the copolymer barely dissolved in 2-hydroxyethyl methacrylate monomer at concentrations above 30%. The results for Samples 3, 5, and 6 in Fig. 2, showing aspirin dissolution from various polymer tablets, depended on the kind of glass-forming monomer or matrix. This dissolution was related to the hydrophilic property of the matrix, which is indicated in Table I in relation to the polymer matrix water content (W).

Drug dissolution from tablets in the presence of a 10% anion-type copolymer is shown for Samples 3 and 7–10 in Fig. 2. Dissolution decreased in the order potassium chloride, salicylic acid, sulfanilamide, aspirin, and colchicine, perhaps due to differences in drug molecular weights (Table I). The larger the molecular weight of the trapped substances, the smaller was the dissolution rate from the matrix.

The intersections of the straight lines and the axis of the ordinates show values higher than unity (Fig. 2). This deviation was probably due to the rapid dissolution of drugs and anion- or cation-type copolymers trapped on the matrix surface by polymer swelling.

Effect of Medium pH on Aspirin Dissolution from Polyhydroxyethyl Methacrylate Tablet—The anion-type copolymer dissolved in the medium only at pH >6.0, while the cation-type copolymer dissolved only at pH <5.0. Aspirin dissolution from tablets containing various copolymers was investigated for dissolution media at various pH values (14, 15) (Fig. 3). The dissolution rate at pH 8.0 was larger than that at pH 3.0 for anion-type copolymer tablets, while the pH dependency of dissolution in the presence of the cation-type copolymer was the opposite to that in the presence of the anion-type copolymer. Therefore, dissolution of the formulation was markedly influenced by pH in the presence of a copolymer.

Aspirin dissolution from a porous polyhydroxyethyl methacrylate tablet prepared with polyethylene glycol 600 instead of with a copolymer also was investigated. Dissolution of the formulation was hardly influenced by dissolution medium pH (Fig. 4).

Porous Structure—Polymer tablet structure was observed by scanning electron microscopy after complete removal of additives such as aspirin, polyethylene glycol 600, and copolymers (Fig. 5). Since the porous structure is hardly observable in Fig. 5*a*, it must have been a consequence of the dissolution of copolymers or polyethylene glycol 600. The porous polymer matrix obtained in the presence of a copolymer is shown in Figs. 5*b* and 5*c*, and the porous polymer matrix obtained in the presence of polyethylene glycol 600 is shown in Fig. 5*d*. The porous structures in Figs. 5*b* and 5*c* are quite similar but are different from the structure in Fig. 5*d*. The reason may be the difference in dispersion form of those additives (copolymer and polyethylene glycol 600) in hydroxyethyl methacrylate monomer before polymerization. That is, the anion- or cation-type copolymer may be dispersed in the monomer in the fibrous molecular form, and the pore structure forms in the polymer after polymerization as shown in Figs. 5*b* and 5*c*. On the other hand, polyethylene glycol 600 may be dispersed in the monomer in the spherical form owing to its crystallization at low temperatures, and then the pore structure in Fig. 5*d* forms. Consequently, porous structure in the tablets can be controlled by varying the kinds of additives and their concentrations.

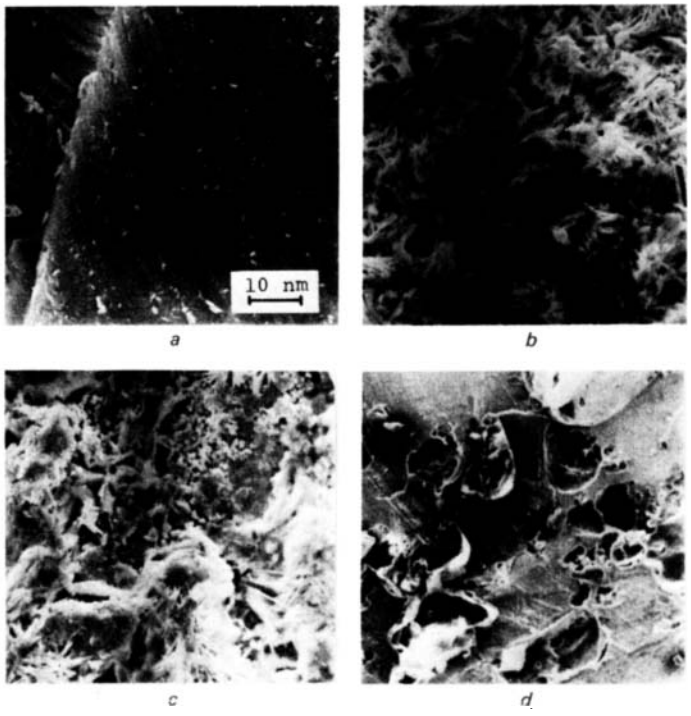

Figure 5—*Scanning electron microphotographs of porous structure of polyhydroxyethyl methacrylate tablets containing aspirin in the presence of various additives. The specimens were dried for 4 days at room temperature* in vacuo *(10^{-4} mm Hg) and then fractured at room temperature. The fractured surface was coated by gold in a vacuum evaporator. Cefoxitin Sodium: Solution and Solid-State Chemical Stability Studies

EARL R. OBERHOLTZER and GERALD S. BRENNER ˣ

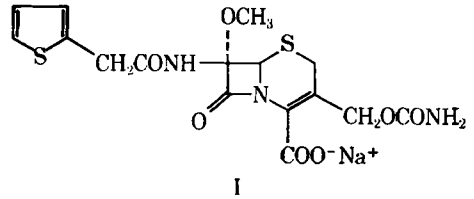
Received July 31, 1978, from *Merck Sharp & Dohme Research Laboratories, West Point, PA 19486.* Accepted for publication January 16, 1979.

Abstract □ Studies were undertaken to provide the basic physicochemical information necessary for preparing a suitable parenteral formulation of cefoxitin sodium. Emphasis was placed on the physicochemical properties of the compound in solution and in the solid state. Cefoxitin sodium is very soluble in water and exhibits apparent first-order decomposition in this medium at pH 3–9. Maximum stability in water is at pH 5–7. Under these pH conditions, cefoxitin sodium loses about 10% of its activity in 2 days at 25°. Thermal decomposition rates for amorphous and crystalline cefoxitin sodium samples were determined. Amorphous cefoxitin sodium was considerably less stable than its corresponding crystalline form. Solid-state decomposition plots are biphasic, displaying initial rapid losses followed by a slower decay period. The extent of loss in the crystalline solid at the end of the more rapid initial phase can be correlated with the water content of the solid.

Keyphrases □ Cefoxitin sodium—chemical stability, amorphous and crystalline solids, water content □ Antibiotics—cefoxitin sodium, chemical stability, amorphous and crystalline solids, water content □ Stability—cefoxitin sodium, amorphous and crystalline solids, water content

Cefoxitin sodium[1] (I), the sodium salt of 3-(hydroxymethyl)-7α-methoxy-8-oxo-7-[2-(2-thienyl)acetamido] -5- thia-1-azabicyclo[4.2.0]oct-2-ene-2-carboxylate carbamate (ester), is a semisynthetic derivative of a new class of β-lactam antibiotics, the cephamycins. It is chemically unique in that the cephem nucleus is substituted with a 7α-methoxy and 3-carbamoyloxymethyl group. Cefoxitin is active against Gram-positive and Gram-negative bacteria (1) and is therapeutically important because of its resistance to destruction by bacterial β-lactamase (2, 3).

This paper describes preformulation studies undertaken to provide the basic physicochemical information necessary for preparing a suitable parenteral formulation of this antibiotic. Emphasis was placed on the physicochemical properties of the compound in solution and in the solid state. Findings from these preformulation studies are reported herein.



I

EXPERIMENTAL

Materials—Amorphous and crystalline cefoxitin sodium samples were laboratory samples[2] used as received. A selected lot of cefoxitin free acid was used as a reference standard. All other chemicals and solvents were reagent grade and were used without further purification.

Kinetic Procedures—*Solution Studies*—Buffer solutions for kinetic studies were prepared by adding 1.0 *N* NaOH sufficient to attain the desired pH to 50 ml of solutions 0.5 *M* each in acetic, phosphoric, and boric acids and diluting to 250 ml with water (modified Britton–Robinson buffer). In this manner, buffers were prepared at pH 3, 5, 7, or 9, 0.1 *M* in each of the previously named acids.

Aliquots of an aqueous stock solution (5% w/v) of cefoxitin sodium were diluted with sufficient buffer to make 0.5 or 1% solutions. These solutions were stored at 25.0 ± 0.5° in glass-stoppered volumetric flasks, and aliquots were withdrawn periodically for analysis. Aliquots of reaction solutions and reference standard cefoxitin acid were diluted for UV spectrophotometric assay with 1% pH 6.0 phosphate buffer prepared as directed in the USP (4). Each aliquot was diluted to a nominal concentration of 40 μg/ml with 1% pH 6.0 phosphate buffer. For the standard solution, cefoxitin acid was dissolved in 1% pH 6.0 phosphate buffer and diluted to about 40 μg/ml. Absorbances of sample and standard solutions were determined at 262 nm. The true absorbance at 262 nm was obtained by applying a suitable baseline correction.

The reaction solution pH was checked initially and at the end of the 10-day period and did not change significantly during that time.

Solid-State Studies—Individual samples of about 50 mg each of amorphous and crystalline cefoxitin sodium were stored in tightly closed glass vials in constant-temperature ovens. Separate individual samples were removed periodically for each assay point.

Characterization of Crystalline Form—The primary tool for the differentiation of amorphous and crystalline cefoxitin sodium was a commercial X-ray powder diffractometer[3] supplying CuKα radiation. Solid-state IR spectroscopy, differential scanning calorimetry, and optical

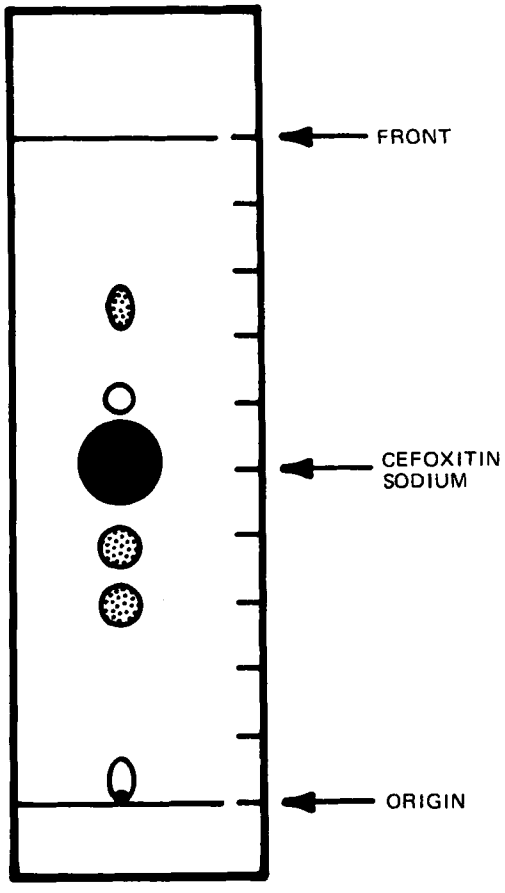

Figure 2—*Thin-layer chromatogram of a 1% solution of cefoxitin sodium following storage at 25° for 72 hr.*

microscopy with polarized light were also employed to determine crystallinity.

Analytical Procedures—Cefoxitin sodium stability studies in solution and in the solid state were monitored by UV spectrophotometry, iodometric titration, microbiological assay, high-performance liquid chromatography (HPLC), and TLC.

UV Spectrophotometry—Intact cefoxitin sodium exhibits a UV absorption band near 262 nm attributed to the O=CNC=C linkage in the molecule. β-Lactam ring opening leads to disappearance of this absorption band. Periodic monitoring of UV spectra of stability samples was carried out to follow the extent of this transformation. This UV spectrophotometric method, with appropriate baseline corrections, yielded assay values essentially identical to those obtained by HPLC and iodometric methods.

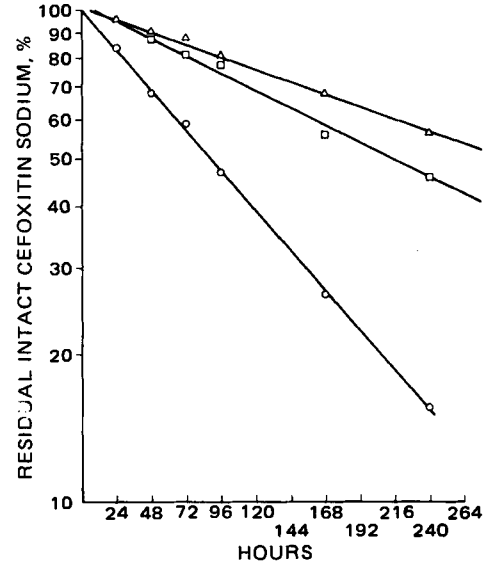

Figure 3—*Apparent first-order plots followed by UV spectrophotometry for decomposition of 0.5 and 1% solutions of cefoxitin sodium at 25° and various pH values. Key: △, pH 5 and 7; □, pH 3; and ○, pH 9.*

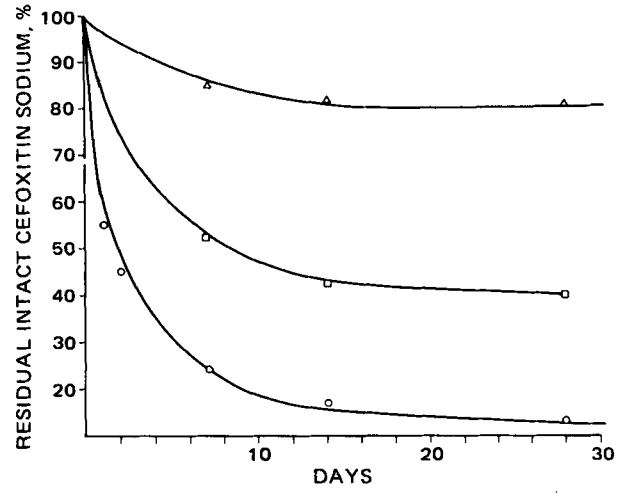

Figure 4—*Typical plots of solid-state decomposition of amorphous cefoxitin sodium at various temperatures. Key: △, 40°; □, 60°; and ○, 80°.*

Spectral changes as a function of time for the decomposition of a cefoxitin sodium solution at pH 9 are illustrated in Fig. 1.

Iodometric Titration—The well-established iodometric titration for β-lactam antibiotics is applicable to the determination of the integrity of the β-lactam moiety in cefoxitin sodium. The procedure used in these studies is a modification of the "Code of Federal Regulations" method (5).

Microbiological Assay—Cefoxitin sodium potency was determined by an agar-diffusion (plate) assay with *Staphylococcus aureus* (NRRL-B11034) as the test organism.

HPLC—HPLC was used to follow cefoxitin sodium decomposition. The liquid chromatograph[4] employed was equipped with a variable-wavelength UV detector[5] set at 254 nm; the separation was carried out on a 30-cm, 10-μm, microporous, octadecylsilane stationary phase[6] with an acetonitrile–water–acetic acid (20:80:1) mobile phase. The column pressure was 800–900 psig, and the column temperature was controlled at 25°. The sample load on the column was 10 μl of a 1-mg/ml solution.

TLC—Solution and solid degraded samples (100 μg) were evaluated qualitatively by TLC. Cefoxitin sodium was chromatographed using butanol–acetic acid–water (4:1:1) with precoated silica gel plates containing a fluorescent indicator[7]. Visualization was accomplished by fluorescence quenching under shortwave UV light or by iodine staining.

RESULTS AND DISCUSSION

The results of experimental studies with cefoxitin indicated that crystalline cefoxitin sodium has properties that make it a suitable chemical and physical form of the antibiotic for use as a sterile powder for reconstitution prior to parenteral administration.

Physical Properties—Crystalline and amorphous cefoxitin sodium forms are colorless to off-white solids with a slight characteristic odor. The compound is optically active and, as a 1% solution in methanol, exhibits a specific rotation of $[\alpha]^{25°}_{589\,nm}$ +210°, calculated on a water and solvent-free basis. The UV spectrum in pH 7.0 phosphate buffer is characterized by maxima at 235 and 262 nm with approximate log ε values of 4.17 and 3.97, respectively.

Solution Properties—*Aqueous Solubility*—Cefoxitin sodium is soluble in water in excess of 1000 mg/ml. This value more than satisfies

Table I—Apparent First-Order Constants, $T_{10\%}$, and $T_{50\%}$ for 0.5 and 1.0% Solutions of Cefoxitin Sodium at 25° and Various pH Values

pH	$K_{obs} \times 10^3$, hr^{-1}	$T_{10\%}$, hr	$T_{50\%}$, hr
3.0	3.42	40	212
5.0	2.44	50	291
7.0	2.46	49	288
9.0	7.83	14	89

the required solubility for use in injection products based on the intended dose and desired volumes for administration.

Solution Stability—The β-lactam ring of cefoxitin sodium undergoes cleavage in water. Subsequent fragmentation of the β-lactam hydrolysis product yields a complex product mixture, as evidenced by the TLC hydrolysis product pattern (Fig. 2).

As with other β-lactam antibiotics, long-term solution stability at 25° is not sufficient at pH 3–9 to permit formulation of cefoxitin sodium as a preconstituted solution (Table I). However, these studies established the viability of a formulation consisting of a readily soluble sterile solid for the extemporaneous preparation of a solution for injection. As the data indicate, such solutions, under proper pH control, exhibit about a 10% loss ($T_{10\%}$) in potency when maintained at 25° for 48 hr.

The studies summarized in Table I and Fig. 3 establish the pH–rate profile for cefoxitin sodium at 25°. The semilogarithmic data plots obtained at various pH values were reasonably linear (Fig. 3), indicating that cefoxitin sodium degradation follows first-order kinetics. The apparent first-order rate constants, K_{obs} (Table I), were calculated from the slopes of log percent remaining cefoxitin sodium concentration–time data by means of a computer-programmed least-squares regression analysis. The β-lactam hydrolysis rate was nearly identical at pH 5.0 and 7.0. Under these pH conditions, the time for 10% loss ($T_{10\%}$) was approximately 50 hr at 25° and the half-life ($T_{50\%}$) was about 290 hr. Reactivity of the β-lactam was significantly greater under basic conditions. At pH 9.0, the half-life was approximately 89 hr. Sensitivity to acid was less pronounced than to base, as evidenced by the degradation rate at pH 3.0 which was not dramatically greater than the rate in the pH 5.0–7.0 range.

No adverse physical changes, other than some yellowing, were observed in the solutions employed for solution stability studies. All solutions remained free of precipitates during the study.

Solid-State Properties—*Physical Forms*—An amorphous and a crystalline form of cefoxitin sodium were evaluated during preformulation studies. The amorphous material was the first form investigated during preclinical and initial clinical studies. As solid-state stability deficiencies in the amorphous material became apparent, attention was directed toward preparation of a more highly ordered structure, a crystalline solid. When this goal was accomplished, the properties of the crystalline solid were investigated and compared to the amorphous materials.

The amorphous form is a white to off-white solid and does not exhibit any well-defined thermal transitions by differential scanning calorimetry below 350°. Gradual solid decomposition is observed by differential scanning calorimetry as temperatures increase over 150°. The amorphous form shows no distinct X-ray powder diffraction pattern and is nonbirefringent when examined microscopically under polarized light.

Crystalline cefoxitin sodium is a white to off-white solid and exhibits a characteristic X-ray powder diffraction pattern and a decomposition exotherm by differential scanning calorimetry at approximately 190–200°. The solid is birefringent when examined microscopically under polarized light.

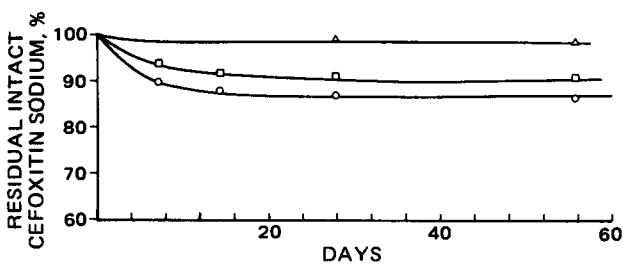

Figure 5—*Typical plots of solid-state decomposition of crystalline cefoxitin sodium at various temperatures. Key: △, 40°; □, 60°; and ○, 80°.*

Solid-State Stability—Accelerated chemical and physical stability testing of amorphous and crystalline cefoxitin sodium solids was carried out as part of a screening program to guide selection of the proper physical form for use in a formulation. Both solid forms, when exposed to elevated temperature and subsequently examined qualitatively by TLC, revealed degradation to a complex mixture of decomposition products. The complexity of the degradation pattern also was reflected in quantitative studies. Typical data plots from these studies used to determine reaction order indicate that degradation did not follow a simple kinetic relationship. A rough reaction order screening was carried out by data plotting. If the amount of intact cefoxitin is plotted as a function of time, a straight line does not result for zero- or first-order plots.

The amount of intact cefoxitin sodium in the two different solid forms as a function of time and temperature is depicted graphically in Figs. 4 and 5. Both solids exhibited a biphasic decomposition pattern typified by an initial accelerated decomposition period followed by a slower decay period. This trend suggests that cefoxitin sodium exhibits two or more parallel decomposition pathways, one or more of which is rapid and the others slower. The initial more rapid degradation rate of crystalline material at elevated temperature and of amorphous material at low temperatures to a level of ~85–90% of the initial concentration is consistent with partial solid hydrolysis; the hydrolysis apparently is limited only by the concentration of water, an exhaustible solid constituent. Thermal degradation reactions occurring at a slower rate most likely account for the additional losses in the subsequent slow decay period.

In cefoxitin sodium decomposition by hydrolysis, water is consumed when the β-lactam, R-CO-N-R′R″, is opened to RCOOH + HNR′R″. Since the cefoxitin sodium samples studied contained about 0.5% water, which corresponded to approximately 12 mole % water, about 12% of the drug could be expected to decompose by hydrolysis. In fact, as the data in Fig. 5 indicate, crystalline cefoxitin sodium subjected to 60 and 80° thermal stress suffered drug loss to that extent in the initial more rapid phase of its decomposition. Drug loss to that extent also occurred in crystalline material at 40° when the study was extended to periods beyond those shown in Fig. 5 and to samples of amorphous solid maintained at 40° as indicated in Fig. 4. The fact that the loss in the initial phase of accelerated studies on the amorphous solid at 60 and 80° is more extensive suggests that the decomposition pathway for this material is not the same as for the crystalline solid at higher temperatures and that the observed rates must reflect a substantial contribution from nonhydrolytic reactions. The activation energy for these thermal, nonhydrolytic processes is most likely considerably less for amorphous materials than for their corresponding crystalline forms.

A comparison of the thermal decomposition data for amorphous and crystalline cefoxitin sodium demonstrates that crystalline material is more stable. While an increasing water content generally increased the net decomposition rate of both forms, it could be shown by maintaining equivalent water levels that stability differences between the two forms did not reflect differences in water content. The data in Figs. 4 and 5 were obtained for samples of approximately equal water content (0.5%).

It is concluded that the stability differences noted between the solids relate to differences in the degree of crystallinity. Stability differences between crystalline and amorphous solids have been the subject of prior publications. Among β-lactam antibiotics, amorphous forms of penicillin potassium (6), epicillin (7), and a number of cephalosporins (8, 9) are less stable chemically than their crystalline counterparts.

In addition to chemical stability differences between amorphous and crystalline forms of cefoxitin sodium solids, physical stability differences have been noted. Upon aging, amorphous cefoxitin sodium develops considerably more color than its crystalline counterparts, as reflected in both solid-state and solution color measurements.

Crystalline cefoxitin sodium is thus both chemically and physically more stable than the amorphous form.

Synthesis and Evaluation of Benzylfluorenyl and 1-Arylethyl Quaternary Ammonium Salts for Antimicrobial and Antineoplastic Activities

J. R. DIMMOCK *x, P. J. SMITH ‡, and S. K. TSUI ‡

Received September 11, 1978, from the **College of Pharmacy and the* ‡*Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan, S7N 0W0, Canada.* Accepted for publication January 18, 1979.

Abstract □ A number of substituted benzyldimethyl-9-fluorenylammonium bromides (II) and 9-benzylfluorenyl-9-trimethylammonium bromides (IV) were synthesized and examined for antimicrobial and anticancer activities. Series IV showed greater antimicrobial activity than Series II while some corresponding acyclic fluorene analogs were bereft of antimicrobial activities. Significant antineoplastic activity was not found in Series II and IV. Representative fluorenes subjected to a preliminary screen for various pharmacological activities revealed marked anti-inflammatory and analgesic properties coupled with some antihistaminic activities. The acyclic quaternary ammonium compounds demonstrated substantial pressor activities.

Keyphrases □ Benzylfluorene—quaternary ammonium derivatives, synthesis, antimicrobial and antineoplastic activity, structure-activity relationships □ Arylethylamines—quaternary ammonium derivatives, synthesis, antimicrobial and antineoplastic activity, structure-activity relationships □ Antimicrobial agents—benzylfluorene, arylethylamines, quaternary ammonium derivatives □ Antineoplastic agents—benzylfluorene, arylethylamines, quaternary ammonium derivatives

As a continuation of studies on new antimicrobial (1–4) and antineoplastic (5–8) agents, it was decided to examine the biological activities of some novel substituted fluorenes, representatives of which have demonstrated antimicrobial (9–11) and anticancer (12–14) activities. Since quaternary ammonium compounds are known to possess antiseptic properties, especially when bulkyl groups are attached to the quadrivalent nitrogen center, which may reduce adsorption onto serum proteins (15), the preparation of fluorenes attached to a quaternary nitrogen atom was contemplated.

The reactivity of benzylic derivatives is documented clearly (16); in the two planned structural isomer series (Scheme I), a benzyl group was attached either to a quaternary nitrogen atom (II) or directly to the fluorene ring (IV). In both cases, facile proton loss from the benzylic methylene group may occur. Furthermore, in Series II, the 9-fluorenyl proton may be considered labile. Thus, both II and IV have the potential for forming carbanions, which would be available for electrophilic attack by biological macromolecules.

In addition, it was proposed to synthesize some fluorene II and IV analogs so that structural requirements for bioactivities might be discerned. In the case of V, which is similar in structure to antifungal 9-fluorenol (9), both the benzyl and quaternary ammonium groups were removed. The quaternary ammonium compound VI was an analog of IV with the benzyl function replaced by a methyl group. Previous investigations compared the antimicrobial activities of flexible acyclic analogs of more rigid cyclic structures with the corresponding cyclic compounds (1–4). For this reason, the synthesis of several quaternary ammonium compounds derived from 1-arylethylamines (VII and VIII) was contemplated.

Synthesis and Evaluation of Benzylfluorenyl and 1-Arylethyl Quaternary Ammonium Salts for Antimicrobial and Antineoplastic Activities

J. R. DIMMOCK *x, P. J. SMITH ‡, and S. K. TSUI ‡

Received September 11, 1978, from the **College of Pharmacy and the* ‡*Department of Chemistry and Chemical Engineering, University of Saskatchewan, Saskatoon, Saskatchewan, S7N 0W0, Canada.* Accepted for publication January 18, 1979.

Abstract □ A number of substituted benzyldimethyl-9-fluorenylammonium bromides (II) and 9-benzylfluorenyl-9-trimethylammonium bromides (IV) were synthesized and examined for antimicrobial and anticancer activities. Series IV showed greater antimicrobial activity than Series II while some corresponding acyclic fluorene analogs were bereft of antimicrobial activities. Significant antineoplastic activity was not found in Series II and IV. Representative fluorenes subjected to a preliminary screen for various pharmacological activities revealed marked anti-inflammatory and analgesic properties coupled with some antihistaminic activities. The acyclic quaternary ammonium compounds demonstrated substantial pressor activities.

Keyphrases □ Benzylfluorene—quaternary ammonium derivatives, synthesis, antimicrobial and antineoplastic activity, structure-activity relationships □ Arylethylamines—quaternary ammonium derivatives, synthesis, antimicrobial and antineoplastic activity, structure-activity relationships □ Antimicrobial agents—benzylfluorene, arylethylamines, quaternary ammonium derivatives □ Antineoplastic agents—benzylfluorene, arylethylamines, quaternary ammonium derivatives

As a continuation of studies on new antimicrobial (1–4) and antineoplastic (5–8) agents, it was decided to examine the biological activities of some novel substituted fluorenes, representatives of which have demonstrated antimicrobial (9–11) and anticancer (12–14) activities. Since quaternary ammonium compounds are known to possess antiseptic properties, especially when bulkyl groups are attached to the quadrivalent nitrogen center, which may reduce adsorption onto serum proteins (15), the preparation of fluorenes attached to a quaternary nitrogen atom was contemplated.

The reactivity of benzylic derivatives is documented clearly (16); in the two planned structural isomer series (Scheme I), a benzyl group was attached either to a quaternary nitrogen atom (II) or directly to the fluorene ring (IV). In both cases, facile proton loss from the benzylic methylene group may occur. Furthermore, in Series II, the 9-fluorenyl proton may be considered labile. Thus, both II and IV have the potential for forming carbanions, which would be available for electrophilic attack by biological macromolecules.

In addition, it was proposed to synthesize some fluorene II and IV analogs so that structural requirements for bioactivities might be discerned. In the case of V, which is similar in structure to antifungal 9-fluorenol (9), both the benzyl and quaternary ammonium groups were removed. The quaternary ammonium compound VI was an analog of IV with the benzyl function replaced by a methyl group. Previous investigations compared the antimicrobial activities of flexible acyclic analogs of more rigid cyclic structures with the corresponding cyclic compounds (1–4). For this reason, the synthesis of several quaternary ammonium compounds derived from 1-arylethylamines (VII and VIII) was contemplated.

VIII

mofluorene (I), which was prepared by reduction of the appropriate 9-fluorenone followed by bromination. The quaternary ammonium salts II, having acidic hydrogen atoms alpha to the positively charged nitrogen atoms, underwent the Stevens rearrangement to the *N,N*-dimethyl-9-benzylfluorenylamines (III). The amines III were quaternized readily with bromomethane to produce the required salts IV.

Compound VI was prepared by a synthetic route in which methyl magnesium iodide was reacted with 9-fluorenone, and the resultant 9-fluorenol was brominated and treated with trimethylamine. The acyclic quaternary ammonium compounds VII were prepared by the action of methyl magnesium iodide on the substituted benzaldehyde, and the resultant carbinol was brominated and treated with trimethylamine.

The antimicrobial screening results are summarized in Table I. The quaternary ammonium compounds in Series II and IV showed the best activities; the tertiary amines III*a* and III*i*, the fluorenol V, and the 9-methylfluorene VI were either bereft of antimicrobial activity or possessed only marginal potencies. In Series II, with the exception of II*h*, the compounds had approximately the same activity. In Series IV, the halogenated compounds had higher potencies than the unsubstituted compound, which, in turn, was more active than IV*f* and IV*g*, which have electron-repelling groups in the phenyl ring. The average antimicrobial activity in Series IV was 175 compared to 120 in Series II.

The open chain quaternary ammonium compounds VII, which like Series II have one carbon atom separating the substituted phenyl ring from the quaternary nitrogen, were devoid of antimicrobial activity at the highest concentration examined (500 μg/ml). Furthermore, VIII, which may be regarded as an open chain IV*a* analog, was similarly devoid of antimicrobial activity.

The most susceptible bacteria to the compounds were species of *Staphylococci* and *Streptococci* as well as *Bacillus subtilis*. Approximately half of the compounds demonstrated low antifungal activity against *Microsporum gypseum* and *Saccharomyces uvarum*. With the exception of II*c*, II*d*, and IV*d*, all compounds in Table I were inactive at 10 μg/ml against the protozoan *Entamoeba histolytica*. Against *Trichomonas foetus*, the compounds listed in Table I, except II*c*, IV*e*–IV*g*, and VI, were devoid of antiprotozoal activity at the maximum concentration employed, 50 μg/ml.

All compounds listed in Table I plus III*h* were assessed for anticancer activity, except IV*e*–IV*g* and VI. The animal tumor model was the L-1210 lymphoid leukemia system in mice except for II*d* and IV*h*. In those two cases, the screen was conducted *versus* murine P-388 lymphocytic leukemia. No compounds achieved the criterion for activity, namely a 25% increase in mean survival time. The quaternary ammonium compounds II and IV showed murine toxicity at 100 mg/kg (either zero or one survivor out of six after 5 days of injections), but there were no mortalities on Day 5 when the dose was reduced to 50 mg/kg. The only exception to this observation was II*a;* in a screen *versus* Sarcoma 180 in mice, II*a* showed murine toxicity at 2 mg/kg, and there were no mortalities when the dose was reduced to 0.50 mg/kg.

The tertiary amines III*h* and III*i* showed no toxicity at 400 mg/kg, while III*a* showed marginal toxicity at 225 mg/kg (four out of six survivors on Day 5), which disappeared at 200 mg/kg. The *in vitro* KB screen conducted on II*h*, II*c*, III*h*, IV*a*, and IV*i* showed 50% inhibition of human nasopharyngeal epidermoid carcinoma at 25, 44, 100, 9.7, and 15 ppm, respectively, and thus fell short of the 4-ppm established criterion for activity.

The primary screen permitted the assessment of representative compounds for various pharmacological activities (Table II). Since the

[a] The doses in all screens are in milligrams per kilogram except for the antihistaminic screen in which the dose is in milligrams per milliliter. [b] The + indicates an increase in blood pressure or heart rate, and the − indicates a fall in either blood pressure or heart rate. [c] At these dose levels, IV*a* and IV*f* increased the number of writhes by 22 and 19%, respectively. [d] Compounds IV*a* and IV*g* increased the wheal formation by 20% in both compounds at the dose levels indicated. [e] Compound VII*d* increased the contractile force of the isolated guinea pig ileum preparation by 6%. [f] The reference compounds for the analgesic, anti-inflammatory, antianaphylactic, antihistaminic, and antidepressant screens were aspirin, indomethacin, disodium chromoglycate, diphenhydramine, and tranylcypromine sulfate, respectively. The criteria for activity in the analgesic, anti-inflammatory, antianaphylactic, and antihistaminic screens were changes of 50, 50, 50, and 20%, respectively; in the antidepressant screen, a compound had to show 30% protection at the end of 1.5 hr and 10% protection after 3 hr for it to be considered active. [g] In addition to increasing the blood pressure and heart rate by 30%, a compound should exert its action considerably in excess of 5 min.

compounds were screened at various dose levels and ED_{50} values were not obtained, a potency comparison was not possible. However, the fluorenes that demonstrated analgesia had marked anti-inflammatory activities, with the exception of VI. Antihistaminic potency as well as a small, but perceptible, heart rate elevation coupled with a decrease in blood pressure was found with the fluorenes. The cardiovascular effects were generally of less than 5-min duration, and in no case was action over 10 min observed. No noteworthy effects were seen by the fluorenes in the antianaphylactic and antidepressant screens.

The acyclic quaternary ammonium compounds VII and VIII were subjected to the primary screens. Analgesic activity was found with VII*a* and VII*c* but, in contrast to the fluorenes, there was an absence of anti-inflammatory activity. The cardiovascular screen showed that all compounds had marked pressor activity; VII*c* showed the maximum activity at the 1.0-mg/kg dose level. The duration of action was generally less than 5 min, and none of the compounds displayed an effect on blood pressure or heart rate for greater than 10 min. No compounds in Table II displayed hypoglycemic activity at 100 mg/kg.

In conclusion, the study showed that some fluorenes with a quaternary ammonium group at position 9 have antibacterial activities against three species of *Streptococcus* and also against *Staphylococcus aureus* and *B. subtilis*, coupled with moderate potency against two fungi. Some related open chain analogs displayed a complete absence of antimicrobial activity. While several useful anticancer drugs were chemically reactive, the quaternary ammonium compounds II and IV displayed murine toxicity but did not produce noteworthy increased mean survival times in mice with leukemia. Preliminary pharmacological tests showed anti-inflammatory analgesia as well as some effect in the cardiovascular screen to be present with a number of the fluorenes in contrast to the open chain analogs VII and VIII, which were devoid of anti-inflammatory and analgesic properties but had potent pressor activities.

EXPERIMENTAL[1]

Melting points and boiling points are uncorrected. Organic extracts were washed with water and dried over anhydrous sodium sulfate. The solvent was removed using a water aspirator. The 60-Hz NMR spectra[2] were determined in deuterochloroform with tetramethylsilane as the internal standard.

Substituted 9-Bromofluorenes (I) and 2-Chloro-9-fluorenol (V)—9-Bromofluorene[3] (I*a*) was used without further purification. 9-Bromo-2-chlorofluorene (I*b*) was prepared as follows. Reaction of 9-fluorenone[3] with *N*-chlorosuccinimide according to a literature method (17) gave 2-chloro-9-fluorenone in a 44% yield, mp 121–122° [lit. (17) mp 122°], which was reduced with lithium aluminum hydride by a reported procedure (18) to give 2-chloro-9-fluorenol (V) in a 50% yield, mp 140–141° [lit. (18) mp 140–141°]. Treatment of V with acetyl bromide using a literature method (19) gave I*b* in a 57% yield, mp 125–127° [lit. (19) mp 126–128°].

[1] Elemental analyses were carried out by Mr. R. E. Teed, Department of Chemistry and Chemical Engineering, University of Saskatchewan, and by Galbraith Laboratories Inc., Knoxville, Tenn.

[2] Varian T 60 spectrophotometer, Varian Associates of Canada Ltd., Georgetown, Ontario, L7G 2J4, Canada.

[3] Aldrich Chemical Co., Milwaukee, WI 53233.

2,9-Dibromofluorene (Ic) was prepared in an 80% yield by the reaction of 2-bromofluorene[3] with *N*-bromosuccinimide using a reported procedure (20). It had a melting point of 127–128° [lit. (20) mp 127°].

Benzyldimethyl-9-fluorenyl Ammonium Bromides (II)—The benzyldimethylamines were prepared as follows. Four of the required substituted benzylamines were treated with formic acid and formalin using a literature method (21) to give *p*-fluorobenzyldimethylamine in an 80% yield, bp 50–51°/2 mm [lit. (22) bp 61–62°/6.5 mm], *p*-chlorobenzyldimethylamine in a 79% yield, bp 100–105°/12 mm [lit. (23) bp 90–95°/9–11 mm], *p*-methylbenzyldimethylamine in an 82% yield, bp 197–198°/750 mm [lit. (23) bp 196–197°/760 mm], and *p*-methoxybenzyldimethylamine in an 80% yield, bp 104–106°/12 mm [lit. (23) bp 105–119°/10 mm].

p-Trifluoromethylbenzyl bromide, bp 93–94°/20 mm [lit. (24) bp 65–66°/5 mm], was prepared in a 61% yield from *p*-trifluoromethyl benzoic acid[3] using a literature synthetic sequence (24). A solution of *p*-trifluoromethylbenzyl bromide (0.05 mole) and anhydrous dimethylamine (0.10 mole) in nitromethane (50 ml) stood at room temperature for 4 hr and then was poured into water (100 ml). The reaction mixture was extracted with ether (2 × 50 ml), and removal of the solvent *in vacuo* gave an oil. On distillation, this oil afforded *p*-trifluoromethylbenzyldimethylamine, bp 107–110°/61 mm, in a 68% yield; the NMR spectrum was in accordance with the proposed structure. *p*-Bromobenzyldimethylamine, bp 130–132°/22 mm [lit. (25) bp 121–122°/20 mm], was prepared similarly from *p*-bromobenzyl bromide[3]. Benzyldimethylamine was obtained commercially[3].

A 0.1 *M* solution of Ia or of the 2-substituted bromofluorenes (Ib or Ic) in nitromethane (10 ml) was added to the appropriate benzyldimethylamine (0.2 mole), and the mixture was stirred at room temperature overnight. The product was precipitated by ether and purified by recrystallization from ether–ethanol. The melting points and yields of the benzyldimethyl-9-fluorenyl ammonium bromides were: II*a*, 154–156° [lit. (20) mp 155–156°], 88%; II*b*, 148–150°, 82%; II*c*, 153°, 84%; II*d*, 148°, 80%; II*e*, 153–154°, 85%; II*f*, 158°, 60%; II*h*, 149°, 50%; and II*i*, 155–156°, 85%. NMR spectra of the benzyldimethyl-9-fluorenyl ammonium bromides were consistent with the structures proposed. In the case of II*g*, ether failed to precipitate the compound from the reaction mixture and it was extracted with water (20 ml). The water was removed to give the crude product, which was not purified further.

9-Benzylfluorenyl-9-dimethylamines (III)—The appropriate benzyldimethyl-9-fluorenyl ammonium bromide (2.0 g) was dissolved in sodium methoxide solution, which was prepared by dissolving sodium (0.5 g) in methanol (7 ml). The reaction mixture stood at room temperature overnight with occasional shaking, and then water (100 ml) was added. The reaction mixture was extracted with ether (60 ml), and removal of the ether gave the crude amine III. With III*a*, III*b*, III*i*, and III*h*, the compounds were recrystallized from nitromethane unless otherwise stated.

9-Benzylfluorenyl-9-dimethylamine (III*a*) was prepared in an 81% yield, mp 98–99° [lit. (26) mp 98.5–99°]. The NMR spectrum of III*a* was consistent with the proposed structure. 9-(*p*-Fluorobenzyl)-fluorenyl-9-dimethylamine (III*b*), mp 55°, was recrystallized from petroleum ether (bp 100°).

Anal.—Calc. for $C_{22}H_{20}FN$: C, 83.24; H, 6.35; N, 4.41. Found: C, 84.00; H, 6.43; N, 4.38.

2-Chloro-9-benzylfluorenyl-9-dimethylamine (III*h*) melted at 108–109°.

Anal.—Calc. for $C_{22}H_{20}ClN$: C, 79.15; H, 6.04; N, 4.20. Found: C, 78.48; H, 6.00; N, 4.19.

2-Bromo-9-benzylfluorenyl-9-dimethylamine (III*i*) melted at 129°.

Anal.—Calc. for $C_{22}H_{20}BrN$: C, 69.84; H, 5.33; N, 3.70. Found: C, 69.71; H, 5.17; N, 3.63.

The remaining derivatives (III*c*–III*g*) were isolated as oils that could not be induced to crystallize. TLC of the products on silica gel with benzene as the solvent showed a single spot, and further purification was not undertaken.

9-Benzylfluorenyl-9-trimethylammonium Bromides (IV)—The 9-benzylfluorenyl-9-dimethylamine (0.01 mole) was dissolved in nitromethane (10 ml) containing bromomethane (0.065 mole), and the resultant solution stood at room temperature overnight. The product, obtained from the reaction mixture by the addition of ether, was recrystallized from ether–ethanol. The physical data for the salts (IV) are summarized in Table III.

9-Methylfluorenyl-9-trimethylammonium Bromide (VI)—A solution of 9-fluorenone[3] (0.035 mole) in anhydrous ether (100 ml) was added slowly to methyl magnesium iodide (0.035 mole), prepared from magnesium (0.85 g) and methyl iodide (5.0 g) in anhydrous ether (50 ml).

Table III—9-Benzylfluorenyl-9-trimethylammonium Bromides (IV)

[a] Lit. (26) mp 175°.

The resultant mixture stood at room temperature overnight and then was poured onto a mixture of crushed ice (100 g) and 10% HCl (100 ml). The aqueous phase was extracted with ether. Solvent evaporation gave the crude product, which on recrystallization from benzene gave 9-methyl-9-fluorenol in a 58% yield, mp 176° [lit. (27) mp 176–177°].

Acetyl bromide (0.035 mole) was added to a solution of 9-methyl-9-fluorenol (0.025 mole) in chloroform (20 ml), and the reaction mixture was shaken. After the vigorous reaction had subsided, acetic acid and chloroform were removed under reduced pressure. The crude bromide was dissolved in nitromethane (20 ml) and added to a solution of trimethylamine in nitromethane (10%). The reaction mixture was kept at 0° for 2 days, and the separated product was recrystallized from absolute ethanol to give VI in a 20% yield, mp 170°.

Anal.—Calc. for $C_{17}H_{20}BrN$: C, 64.15; H, 6.33; N, 4.40. Found: C, 63.63; H, 6.55; N, 4.40.

1-Phenylethyltrimethylammonium Bromides (VII and VIII)—The following three-step synthesis was used for VII. A solution of the appropriate *para*-substituted benzaldehyde (0.03 mole) in anhydrous ether (25 ml) was added slowly to methyl magnesium iodide (0.035 mole), prepared from magnesium (1.0 g) and methyl iodide (5.0 g) in anhydrous ether (50 ml). The reaction mixture stood at room temperature overnight and, after being poured onto a mixture of crushed ice (100 g) and hydrochloric acid (10% v/v, 100 ml), was then extracted with ether. The solvent was removed and the required 1-phenylethanols were purified by distillation to give the *p*-chloro derivative in an 88% yield, bp 130–132°/15 mm [lit. (28) bp 110–120°/9 mm], the *p*-trifluoromethyl derivative in a 90% yield, bp 116–118°/20 mm [lit. (29) bp 106–107°/18 mm], and the *p*-methoxy derivative in an 85% yield, bp 130–132°/20 mm [lit. (30) bp 104°/3 mm].

Acetyl bromide (0.034 mole) was added quickly to the appropriate 1-phenylethanol (0.025 mole). After the vigorous reaction had subsided, acetic acid and acetyl bromide excess were removed under reduced pressure. The residue was dissolved in benzene (50 ml) and shaken with aqueous sodium bicarbonate solution (10% w/v). Solvent removal gave the crude 1-phenylethyl bromide as a pale-red oil. A crude bromide solution (0.016 mole) in nitromethane (10 ml) was added to a trimethylamine solution in nitromethane (10% w/v, 20 ml) at room temperature, and the reaction mixture was left overnight. Ether addition gave the required 1-phenylethyltrimethylammonium bromides, which were recrystallized from ether–ethanol. 1-Phenylethyltrimethylammonium bromide (VII*a*), mp 197–198° [lit. (31) mp 198–200°], was obtained in a 60% yield. 1-(*p*-Chlorophenyl)ethyltrimethylammonium bromide (VII*b*), mp 199°, was obtained in an 80% yield.

Anal.—Calc. for $C_{11}H_{17}BrClN$: C, 47.41; H, 6.15; N, 5.03. Found: C, 47.78; H, 6.53; N, 4.91.

1-(*p*-Methoxyphenyl)ethyltrimethylammonium bromide (VII*d*), mp 165–166°, was prepared in a 60% yield.

Anal.—Calc. for $C_{12}H_{20}BrNO$: C, 52.56; H, 7.35; N, 5.11. Found: C, 52.80; H, 7.58; N, 5.10.

1-(*p*-Trifluoromethylphenyl)ethyltrimethylammonium bromide (VII*c*) was prepared as follows. 1-(*p*-Trifluoromethylphenyl)ethanol (0.067 mole) was added to phosphorus bromide (0.067 mole). After standing at room temperature overnight, the reaction mixture was poured onto ice and extracted with benzene. The organic extracts were washed with aqueous sodium bicarbonate solution (10% w/v), and solvent removal gave the crude bromide. A solution of the crude bromide (3.2 g) in methanol (10 ml) was added to a triethylamine solution in absolute alcohol (10% v/v, 20 ml) to yield VII*c*, mp 218–219°, in a 58% yield.

Anal.—Calc. for $C_{12}H_{17}BrF_3N$: C, 46.17; H, 5.49; N, 4.49. Found: C, 45.47; H, 5.48; N, 4.48.

2-Phenylethyltrimethylammonium bromide (VIII) was prepared by the method described previously (32).

Screening[4] of Compounds—In the antimicrobial screen, the compounds were dissolved in water or dimethyl sulfoxide and diluted serially to various concentrations. The stock solutions were prepared in such a way that when 0.5 ml was added to 15 ml of agar, the desired final concentrations were obtained. The bacterial growth medium was trypticase soy agar with 5% defibrinated rabbit blood added for the growth of *Haemophilus influenzae*, *Streptococcus pyogenes*, and *Streptococcus pneumonia*. Modified Sabouraud agar was employed for the fungi.

The test organisms were grown previously for 2 days at 35° for bacteria and yeasts and for 1 week at 24° for fungi on slants of the media mentioned above. The agar plates were streaked with a loopful of cell suspension, which had been washed off from the slants and diluted to approximately 10^5 organisms/ml. The plates were incubated for 2–14 days at 24° for fungi and at 35° for bacteria. The results (Table I) indicated the minimal inhibitory concentration of the compound that prevented visible growth in the media.

The antiprotozoal screen utilized the tube dilution technique previously described (33). The test organisms were *E. histolytica* (ATCC 30015) grown in a TP-S-1 monophasic medium devised by Diamond (34) and *T. foetus* (ATCC 30003) grown in modified TYM basal media (34). Activity was defined as the minimal concentration that inhibited 90% of the protozoal growth at 10 and 50 μg/ml for *E. histolytica* and *T. foetus*, respectively.

Unless otherwise stated, the same numbers of animals were used as controls and for the evaluation of various pharmacological activities. The screen for examining analgesic activity was the phenylquinone writhing test (35). Five male Swiss albino mice, 18–22 g, were used for each compound except IV*g*, IV*e* (at the 64-mg/kg dose level), VII*a*, and VII*c*, in which cases 10 animals were used.

The anti-inflammatory screen measured the antagonism of the test compound to carrageenan-induced rat paw edema (36). Six female Sprague–Dawley rats, 120–160 g, were used for each compound, and the edema volume was recorded at the end of 3 and 5 hr.

The antianaphylactic screen measured passive cutaneous anaphylaxis inhibition in rats (37). Four female Sprague–Dawley rats were used for each compound except IV*f*, VII*c*, and disodium chromoglycate, in which cases eight rats were employed. Two rats were used for VIII at both dose levels.

The compounds were examined for antihistaminic activity using two guinea pig ileum preparations (38), except in the cases of IV*a*, IV*b*, and IV*f* where three preparations were used and VII*d* where one preparation was used.

The antidepressant screen measured the antagonism of tetrabenazine-induced ptosis in mice (39, 40). Six male Swiss albino mice were used for each compound.

In the cardiovascular screen, a Sprague–Dawley rat of either sex, 250–400 g, was anesthetized by intraperitoneal urethan (1.9 g/kg). After femoral vein cannulation, the blood pressure was monitored *via* a pressure transducer[5] connected to a cannula in the left carotid artery. The arterial blood pressure and heart rate were recorded on a polygraph[6]. After the preparation had stabilized, the test compound was dissolved in saline and/or polysorbate 80[7] (1%) and administered in a volume of 0.01–0.05 ml. The changes recorded in blood pressure and heart rate were expressed as percentage differences between the pre- and postdrug values. Two determinations at each dose level using one rat were made for each compound.

The screen for hypoglycemic activity involved the measurement of blood glucose in rats (41). Four male Sprague–Dawley rats were used for each compound at a dose of 100 mg/kg. A 20% decrease in blood glucose concentration was required for a compound to be considered active.

The anticancer screening was carried out by the Drug Research and Development Division of the National Cancer Institute according to their protocols (42). The compounds were administered to $B_6D_2F_1$ or CD_2F_1 mice by intraperitoneal injection either daily or every 4 days, except in the case of II*a versus* Sarcoma 180 in Swiss mice where injections were made twice daily for a total of 14 injections. The compound showed no activity.

[4] All screens, except for the assessment for anticancer activities, were carried out by Bio-Research Laboratories Ltd., Montreal, Quebec, Canada.

The authors thank Dr. H. B. Wood, Jr., for arranging for some compounds to be assessed for antineoplastic activities and also Bio-Research Laboratories which undertook the remainder of the screening.

Separation and Determination of Testosterone and Testosterone Esters in Selected Pharmaceutical Formulations

R. E. GRAHAM *x, E. R. BIEHL ‡, and C. T. KENNER ‡

Received October 20, 1978, from the **Food and Drug Administration, Dallas, TX 75204*, and the ‡*Department of Chemistry, Southern Methodist University, Dallas, TX 75275.* Accepted for publication January 26, 1979.

Abstract □ A rapid quantitative procedure is presented for the separation of testosterone esters from their hydrolysis products through the use of the acetonitrile–infusorial earth column. The method was applied to testosterone cypionate, testosterone enanthate, and testosterone propionate. Recovery and replication of reference standard testosterone and its three esters through the proposed method ranged from 99.1 to 100.3%, and the percent relative standard deviation ranged from 0.6 to 1.0%. Two samples can be separated into testosterone and testosterone ester fractions in about 1.5 hr. The analyses of 20 injectable and one buccal tablet formulations made by 12 different manufacturers are reported.

Keyphrases □ Chromatography, column—analysis, testosterone and testosterone esters, various pharmaceuticals, acetonitrile–infusorial earth column □ Testosterone—analysis, acetonitrile–infusorial earth column chromatography, separation from testosterone esters, various pharmaceuticals □ Testosterone esters—analysis, acetonitrile–infusorial earth column chromatography, separation from testosterone esters, various pharmaceuticals

The "American Drug Index" (1) lists 57 different drug products that contain testosterone esters; they are mostly injectables and are made by 27 different manufacturers. The active ingredients are testosterone cypionate in 11 formulations, testosterone enanthate in 34, testosterone ketolaurate in one, and testosterone propionate in 11.

The official assay procedure in the USP (2) for testosterone drug substance and injection requires GLC analysis. Cleanup of testosterone propionate oil injectables by reversed-phase chromatography has been described (3), and this method is the basis for the modified cleanup procedure in USP XIX (4) for testosterone cypionate and testosterone propionate injectables. These USP procedures measure total testosterone plus esters. The final determinative step for these two compounds is spectrophotometric measurement of their isoniazid hydrazones, a procedure that is slightly altered from that originally described (5).

The USP–NF (6) presents a high-pressure liquid chromatographic (HPLC) method for testosterone propionate tablets. Other steroid separation methods include column adsorption chromatography (7), GLC (8, 9), TLC (10), paper chromatography (11), HPLC (4), column partition chromatography (12), and use of an acetonitrile–infusorial earth column (13).

This paper reports a relatively rapid quantitative analytical procedure for the separation of testosterone from its cypionate, enanthate, and propionate esters using an acetonitrile–infusorial earth column. The final determinative step compares the standard and sample isoniazid hydrazones. The proposed procedure was applied to the analysis of 21 pharmaceutical formulations made by 12 different manufacturers.

EXPERIMENTAL

Apparatus—The following were used: UV–visible recording spectrophotometers[1] with 1-cm stoppered quartz cells, a high-pressure liquid chromatograph[2] (sensitivity of 0.005 absorbance unit full scale with a 254-nm UV detector[3] and a reversed phase column[4]), glass chromatographic columns for partition chromatography (2.2 × 25 cm, constricted at one end to 0.4 × 5 cm), an aluminum tamping rod, an electrobalance[5], and TLC[6] equipment. Volumetric flasks and pipets were either NBS calibrated or Class A glassware.

Materials—Alcohol USP, distilled-in-glass grade[7] acetonitrile, chloroform, *n*-heptane, absolute methanol, and reagent grade acetic acid were used along with acid-washed infusorial earth[8]. Also used were USP reference standard testosterone cypionate, testosterone enanthate, and testosterone propionate and NF reference standard testosterone.

Reagents—Mutually saturated acetonitrile–*n*-heptane was prepared as follows. Acetonitrile, 30 ml, was mixed with 500 ml of *n*-heptane (sufficient for two determinations) in a separator, agitated vigorously for 2 min, and allowed to stand until both layers were clear. These mutually saturated solutions were used whenever acetonitrile or *n*-heptane was called for in these directions.

Sample Preparation—*Tablets*—Twenty tablets were weighed,

The authors thank Dr. H. B. Wood, Jr., for arranging for some compounds to be assessed for antineoplastic activities and also Bio-Research Laboratories which undertook the remainder of the screening.

Separation and Determination of Testosterone and Testosterone Esters in Selected Pharmaceutical Formulations

R. E. GRAHAM *x, E. R. BIEHL ‡, and C. T. KENNER ‡

Received October 20, 1978, from the **Food and Drug Administration, Dallas, TX 75204*, and the ‡*Department of Chemistry, Southern Methodist University, Dallas, TX 75275.* Accepted for publication January 26, 1979.

Abstract □ A rapid quantitative procedure is presented for the separation of testosterone esters from their hydrolysis products through the use of the acetonitrile–infusorial earth column. The method was applied to testosterone cypionate, testosterone enanthate, and testosterone propionate. Recovery and replication of reference standard testosterone and its three esters through the proposed method ranged from 99.1 to 100.3%, and the percent relative standard deviation ranged from 0.6 to 1.0%. Two samples can be separated into testosterone and testosterone ester fractions in about 1.5 hr. The analyses of 20 injectable and one buccal tablet formulations made by 12 different manufacturers are reported.

Keyphrases □ Chromatography, column—analysis, testosterone and testosterone esters, various pharmaceuticals, acetonitrile–infusorial earth column □ Testosterone—analysis, acetonitrile–infusorial earth column chromatography, separation from testosterone esters, various pharmaceuticals □ Testosterone esters—analysis, acetonitrile–infusorial earth column chromatography, separation from testosterone esters, various pharmaceuticals

The "American Drug Index" (1) lists 57 different drug products that contain testosterone esters; they are mostly injectables and are made by 27 different manufacturers. The active ingredients are testosterone cypionate in 11 formulations, testosterone enanthate in 34, testosterone ketolaurate in one, and testosterone propionate in 11.

The official assay procedure in the USP (2) for testosterone drug substance and injection requires GLC analysis. Cleanup of testosterone propionate oil injectables by reversed-phase chromatography has been described (3), and this method is the basis for the modified cleanup procedure in USP XIX (4) for testosterone cypionate and testosterone propionate injectables. These USP procedures measure total testosterone plus esters. The final determinative step for these two compounds is spectrophotometric measurement of their isoniazid hydrazones, a procedure that is slightly altered from that originally described (5).

The USP–NF (6) presents a high-pressure liquid chromatographic (HPLC) method for testosterone propionate tablets. Other steroid separation methods include column adsorption chromatography (7), GLC (8, 9), TLC (10), paper chromatography (11), HPLC (4), column partition chromatography (12), and use of an acetonitrile–infusorial earth column (13).

This paper reports a relatively rapid quantitative analytical procedure for the separation of testosterone from its cypionate, enanthate, and propionate esters using an acetonitrile–infusorial earth column. The final determinative step compares the standard and sample isoniazid hydrazones. The proposed procedure was applied to the analysis of 21 pharmaceutical formulations made by 12 different manufacturers.

EXPERIMENTAL

Apparatus—The following were used: UV–visible recording spectrophotometers[1] with 1-cm stoppered quartz cells, a high-pressure liquid chromatograph[2] (sensitivity of 0.005 absorbance unit full scale with a 254-nm UV detector[3] and a reversed phase column[4]), glass chromatographic columns for partition chromatography (2.2 × 25 cm, constricted at one end to 0.4 × 5 cm), an aluminum tamping rod, an electrobalance[5], and TLC[6] equipment. Volumetric flasks and pipets were either NBS calibrated or Class A glassware.

Materials—Alcohol USP, distilled-in-glass grade[7] acetonitrile, chloroform, *n*-heptane, absolute methanol, and reagent grade acetic acid were used along with acid-washed infusorial earth[8]. Also used were USP reference standard testosterone cypionate, testosterone enanthate, and testosterone propionate and NF reference standard testosterone.

Reagents—Mutually saturated acetonitrile–*n*-heptane was prepared as follows. Acetonitrile, 30 ml, was mixed with 500 ml of *n*-heptane (sufficient for two determinations) in a separator, agitated vigorously for 2 min, and allowed to stand until both layers were clear. These mutually saturated solutions were used whenever acetonitrile or *n*-heptane was called for in these directions.

ground to pass through a 60-mesh sieve, and mixed thoroughly. Then a sample containing ~12.5 mg of steroid was accurately weighed and transferred to a 50-ml volumetric flask, diluted to volume with methanol, and mixed. Two 5-ml aliquots, each containing ~1.25 mg of steroid, were evaporated just to dryness. The sample residues were dissolved in 1.5 ml each of acetonitrile and *n*-heptane for cleanup as directed under *Column Preparation*.

Injectables—The contents of several containers were well mixed, and duplicate 2.0-ml sample portions were diluted accurately with chloroform so that aliquots of the final sample solution containing ~1.25 mg of testosterone ester could be evaporated just to dryness on the steam bath. The sample residues were dissolved in 1.5 ml each of acetonitrile and *n*-heptane for cleanup as directed under *Column Preparation*.

Column Preparation—A glass wool plug was inserted in the bottom of a chromatographic column. Then a 4-g portion of infusorial earth, thoroughly mixed with 4 ml of acetonitrile, was transferred to the column and packed firmly with a tamping rod.

The sample solution, prepared as directed, was mixed thoroughly with 3 g of infusorial earth to yield a light fluffy mixture. This mixture was transferred to the column above the acetonitrile layer and packed firmly. The sample beaker, tamping rod, spatula, and funnel were dry washed with about 1 g of infusorial earth, which was added to the column. The same equipment was dry washed with glass wool, which was placed on top of the sample layer plus washings and packed firmly.

Column Elution of Steroids—The sample beaker was washed with 250 ml of *n*-heptane in small portions, which were transferred to the column to maintain a liquid head approximately 12 cm above the column bed. About 60 ml of *n*-heptane eluate was collected in the first fraction, the beakers were changed, and about 190 ml was collected in the second fraction. The last wash was allowed to drain completely from the column, the tip was rinsed with alcohol, and both effluents were saved for further analysis.

The first 60-ml *n*-heptane fraction was diluted accurately to volume with chloroform to give a final concentration of ~0.012 mg of steroid ester/ml. This solution was allowed to come to room temperature and was readjusted to volume before further dilution or taking of aliquots. The second 190-ml *n*-heptane fraction was carefully evaporated just to dryness on the steam bath. The residues were dissolved and diluted accurately to a volume with absolute methanol to yield a concentration of ~0.012 mg of steroid/ml. In every case, aliquots were taken carefully just to dryness for the isoniazid determination.

Isoniazid Method—The procedure of Umberger (5) was used, except that the hydrochloric acid concentration was doubled to increase the sensitivity.

UV Method—Aliquots of testosterone fractions 1 and 2 were taken carefully to dryness on the steam bath. The residues were dissolved and diluted with methanol to ~0.010 mg of testosterone/ml or 0.012 mg of testosterone esters/ml and scanned spectrophotometrically from 360 to 220 nm *versus* the same solvent. They were compared with a reference standard solution of steroid of about the same concentration.

Completeness of Testosterone Elution—After column elution with 250 ml of *n*-heptane in accordance with the proposed method, an additional step was employed to check the completeness of testosterone elution in all method development studies. The sample beaker was washed with 125 ml of chloroform in several portions, which were added to the column to maintain the liquid level close to the column top. The last portion was allowed to drain completely, the tip was rinsed with alcohol, and the eluate was taken carefully just to dryness. When dissolved and reacted with 4 ml of isoniazid, the residues gave no visible color.

Elution Studies—Approximately 2 mg, accurately weighed, of reference standard testosterone and each of the three testosterone esters were dissolved in 1.5 ml each of acetonitrile and *n*-heptane and placed on the column as described. These compounds were eluted at a rate of ~7 ml/min with 300 ml of *n*-heptane and collected in 15-ml portions for analysis. A second determination was made of testosterone with the rate of elution set at about 1 ml/min. Each 15-ml portion of the eluate was taken carefully just to dryness. Each residue was dissolved in and diluted with methanol and spectrophotometrically scanned in the UV region. Elution curves were plotted for each experiment.

Replication Studies of Recoveries of Testosterone and Its Esters—Reference standard testosterone and its esters, equivalent to ~10 mg (accurately weighed) of testosterone, were dissolved and diluted to 50 ml with methanol. Nine 5-ml aliquots of each steroid were taken carefully just to dryness. The residues were dissolved in 1.5 ml each of *n*-heptane and acetonitrile, placed on the column, and eluted according to the described procedure.

For testosterone esters, the 60-ml fraction of *n*-heptane was diluted to 100 ml with chloroform, and 5-ml aliquots were evaporated carefully

to dryness and used for the isoniazid determination. The 190-ml *n*-heptane fraction containing testosterone was evaporated to a small volume, made up to 100 ml with chloroform, and mixed; then 5-ml aliquots were taken carefully just to dryness for the isoniazid reaction. Results of this study (Table I) ranged from 99.1 to 100.3% recovery, and the relative standard deviations calculated from the range (14) were 0.6–1.0%.

Recovery and Replication Studies of Testosterone and Testosterone Ester Separation—About 10 mg of testosterone standard (accurately weighed) and the equivalent weight of its cypionate, enanthate, and propionate ester standards were dissolved and diluted to 50 ml with chloroform. Several 10-ml aliquots were taken carefully just to dryness on the steam bath. The residues were dissolved in 1.5 ml each of acetonitrile and *n*-heptane, placed on the column, and separated using the procedure described.

The first and second *n*-heptane fractions were taken carefully just to dryness on the steam bath. In some cases, the column was eluted with 60 ml of *n*-heptane and 125 ml of chloroform (instead of 190 ml of *n*-heptane), and the chloroform fraction was taken carefully just to dryness. All residues were dissolved in absolute methanol and diluted to 100 ml. Selected samples were determined by UV spectrophotometry, and 5-ml aliquots of all samples were evaporated just to dryness for colorimetric determination by isoniazid.

Results of this study (Table II) showed that recoveries ranged from 94.5 to 103.7% for testosterone and from 97.1 to 101.1% for its esters and that the values obtained by the UV and isoniazid methods compared favorably. Relative standard deviations of separated steroids calculated from the range were 0.8–2.5%.

TLC and HPLC determinations of Samples 5–8 (Table III) for the separation of testosterone and testosterone cypionate showed no cross-contamination. An 80:20 acetonitrile–water mixture was used to elute testosterone cypionate in 10.5 min, and a 40:60 acetonitrile–water system was used to elute testosterone by HPLC. TLC of testosterone and its cypionate on silica gel G with chloroform gave R_f values of 0.35 and 0.7, respectively.

Recovery Study of Large Quantities of Testosterone Esters—Three accurately weighed portions of each testosterone ester standard, ranging from 2 to 6 mg, were dissolved in 1.5-ml aliquots of acetonitrile and *n*-heptane and placed on columns using the procedure described. The first fractions from several columns were taken carefully to dryness on the steam bath. The residues were dissolved and diluted with absolute methanol to obtain a concentration of ~0.012 mg/ml for UV and isoniazid determinations.

For other selected samples, the first fraction was diluted to 100 ml with chloroform, and appropriate aliquots were taken just to dryness by evaporation for UV and isoniazid determinations. Each residue was treated with 4 ml of isoniazid reagent to develop the color. The results (Table III) showed that as much as 5.6 mg of testosterone esters could be recovered satisfactorily in fraction 1.

Solvent Volatility Study—About 1.25 mg, accurately weighed, of each testosterone ester was dissolved and diluted to 100 ml with methanol. Five-milliliter aliquots were placed in 100-ml beakers and evaporated just to dryness on the steam bath. Replicate residues were left on the steam bath for selected periods after dryness. The residues were dissolved and diluted to volume, and aliquots were taken for the isoniazid reaction.

The experiment was repeated with replicate aliquots of testosterone and its esters but with the beakers placed over the openings on the steam bath to allow heating by live steam for 40 and 60 min. The residues were dissolved and diluted to volume with methanol for determination by isoniazid. Table IV shows that significant testosterone and testosterone propionate losses occurred when they were exposed to steam temperatures for extended periods after solvent volatilization.

Base Degradation Study—About 12.5 mg, accurately weighed, of each testosterone ester was dissolved in ~25 ml of methanol. Then 0.5 ml of 10% aqueous tetramethylammonium hydroxide was added. The mixture was diluted to 50 ml with methanol and mixed. At selected times, 5-ml aliquots were removed and 0.5 ml of acetic acid was added to each aliquot. The acidified methanol aliquots were evaporated carefully just to dryness on the steam bath.

Each residue was dissolved in 1.5 ml each of acetonitrile and *n*-heptane, and the mixture was placed on the column and treated as already described. The results (Table V) showed that testosterone ester hydrolysis by tetramethylammonium hydroxide in methanol proceeded at a fairly

rapid rate at room temperature and that the undecomposed steroid ester and testosterone could be separated and recovered by the proposed method.

RESULTS AND DISCUSSION

The effects of various hydrocarbon solvents and flow rates on testosterone elution from acetonitrile–infusorial earth columns have been studied (13). *n*-Heptane was selected as a solvent for use in the column chromatography because it gives optimum separation of testosterone from its esters. Symmetrical elution curves for testosterone and the three esters studied showed that testosterone enanthate required 20 ml, testosterone cypionate required 23 ml, and testosterone propionate required 45 ml of *n*-heptane for complete elution.

A 7-ml/min normal flow rate of *n*-heptane eluted 2 mg of testosterone from the acetonitrile column in a band between 88 and 195 ml. A 1-ml/min flow rate of *n*-heptane eluted the same amount of testosterone in a band between 105 and 184 ml. While the faster elution rate resulted in band broadening, adequate separations between testosterone and its esters were obtained. Testosterone propionate elution was completed at 45 ml of *n*-heptane, and elution of testosterone from the column did not occur before 88 ml. The recommended cut-off volume at 60 ml of *n*-heptane provided an adequate safety factor and resulted in pure fractions.

The values reported for all determinations represent an average of two isoniazid color developments.

Table I shows 0.3–1.3% hydrolysis of the testosterone ester reference standards. TLC confirmed the presence of testosterone in the second *n*-heptane fraction of all three esters. Both HPLC and TLC of portions of the final diluted solutions after separation on the acetonitrile column showed no testosterone cross-contamination with its esters in either *n*-heptane fraction. The agreement between the results obtained by the UV and isoniazid methods (Table II) was well within the expected range and recoveries obtained for testosterone by eluting the column with an additional 190 ml of *n*-heptane or with 125 ml of chloroform. Fewer manipulations were required if chloroform was used to elute testosterone from the acetonitrile column, but less sample interference resulted from elution with 190 ml of *n*-heptane.

Table III shows that up to 5.6 mg of the three testosterone esters could be eluted completely in the first 60 ml of *n*-heptane collected from the acetonitrile column. It also shows that the results of chloroform dilution of the first *n*-heptane fraction and evaporation of small aliquots to dryness were in agreement with the results obtained by evaporating the *n*-heptane (fraction 1) carefully just to dryness, dissolving the residue in absolute methanol for UV measurement, and carrying subsequent aliquots to dryness for isoniazid determination.

The solvent volatility study (Table IV) showed that when the samples were evaporated carefully just to dryness under air on the steam bath, no steroid loss occurred. However, significant losses of 10–30% of testosterone and testosterone propionate resulted when the sample residues were left on the steam bath for extended periods after the solvent had been volatilized.

The rate of testosterone ester hydrolysis by tetramethylammonium hydroxide (Table V) was faster for testosterone cypionate than for testosterone enanthate and fastest for testosterone propionate. At 8 hr, the hydrolysis rate for testosterone enanthate was ~0.8%/hr; for testosterone cypionate, it was ~1.3%/hr; and for testosterone propionate, it was ~2.1%/hr. TLC and IR spectrophotometry confirmed the presence of enanthic acid in the chloroform fraction from the acetonitrile column.

Analyses of typical pharmaceutical formulations, mostly injectables, by the proposed method are reported in Table VI. Good replication of sample analysis was obtained. The amount of testosterone found varied from 0.1 to 13.5% of the declared amount of testosterone ester, with only three of the 21 products analyzed showing more than 2.0%. Sample 14, analyzed in duplicate by direct dilution and the isoniazid method, gave 123.8 and 125.1%, while Sample 15 gave 121.6 and 120.0% of the declared amount. These results, when compared with those shown in Table VI, showed that a 20–25% interference was removed by the proposed cleanup procedure. Apparently the cleanup procedure is applicable to injectables containing a wide variety of excipients (Table VI) including cottonseed and sesame oils.

The samples that contained benzyl alcohol could not be cleaned up by the proposed procedure for determination by UV spectrophotometry since it eluted in the first *n*-heptane fraction along with the testosterone esters. While benzyl alcohol interfered with the UV spectrum of the testosterone esters, there was no interference when isoniazid was used as the final determinative step.

Samples 22 and 23 (Table VI) for testosterone suspensions are included to show the versatility of the acetonitrile column.

The proposed procedure is relatively rapid and is specific for testosterone ester determination. Two samples can be prepared for analysis, placed on separate columns, and separated into two fractions containing testosterone ester and testosterone in 1.5 hr. The results of the duplicate analyses of 21 different pharmaceutical formulations showed that the proposed procedure provided adequate sample cleanup with satisfactory accuracy and replication of the analytical data. This method can be used to assess hydrolytic degradation of testosterone esters in pharmaceutical formulations by measuring intact testosterone ester and/or testosterone present in the sample.

Application of Thermochromism in Spectrophotometric Analysis: Selective Determination of Berberine in Pharmaceuticals by Solvent Extraction

TADAO SAKAI

Received May 3, 1978, from the *Department of Chemistry, Gifu College of Dentistry, Gifu, Japan.* Accepted for publication January 19, 1979.

Abstract □ A solvent extraction and spectrophotometric method for selective determination of berberine in pharmaceuticals is proposed. Berberine forms an ion associate with tetrabromophenolphthalein ethyl ester, which is extracted into ethylene dichloride. Secondary and tertiary amines and alkaloids are coextracted with the berberine and complicate the berberine determination. The absorbance of the secondary and tertiary amines and alkaloids into ethylene dichloride, however, decreases nearly to zero when the temperature is elevated from 25 to 60°. Thus, berberine can be determined successfully in the presence of the secondary and tertiary amines and alkaloids by using thermochromism.

Keyphrases □ Berberine—analysis, solvent extraction, spectrophotometric method using thermochromism, various pharmaceuticals □ Thermochromism—analysis, berberine in various pharmaceuticals, solvent extraction, spectrophotometry □ Spectrophotometry, solvent extraction—analysis, berberine in various pharmaceuticals, using thermochromism □ Antibacterial agents—berberine, analysis in various pharmaceuticals, solvent extraction, spectrometry, using thermochromism

Bromthymol blue, bromcresol green, and bromphenol blue usually are used for the solvent extraction and spectrophotometric determination of thiamine (1), quaternary ammonium compounds (2), and quinine ethylcarbonate (3), respectively. These dyes are diprotic acids with a narrow optimum pH range and poor extractability of the ion associates into organic solvents.

Tetrabromophenolphthalein ethyl ester anion (I) is a monoprotic acid and can form ion associates (II) with quaternary ammonium cations (III) and charge transfer complexes (IV) with amines (V), which are effectively extracted into organic solvents through a wide pH range (4). Tetrabromophenolphthalein ethyl ester shows a high sensitivity for quaternary ammonium cations and amines, but the absorption spectra overlap each other. Thus, it is difficult to determine spectrophotometrically the quaternary ammonium salts and amines separately when they coexist. An attempt was made to separate the amine procaine from the quaternary ammonium salt benzethonium by solvent extraction, but it was difficult to remove the amine completely (5).

The author found, however, that the color of the charge transfer complex in ethylene dichloride reversibly disappeared with the elevation of temperature. Even at 60°, the red complex was rarely found while the absorbance of the ion associate at 610 nm was unchanged at 60°. Thus, a quaternary ammonium salt could be determined spectrophotometrically at 60° without the disturbance of amines.

This paper describes the extraction and spectrophotometric determination of berberine in pharmaceuticals after the temperature is increased to 60° to eliminate the effect of the coexisting amines.

EXPERIMENTAL

Apparatus—A double-beam spectrophotometer[1] attached to a temperature-controlled cell holder was used to measure absorbances at a constant temperature using quartz 1-cm cells with stoppers. An x–y recorder[2] was used for the spectra. Constant cell temperature was maintained by circulating constant-temperature water through the temperature-controlled cell holder by means of a temperature-controlled circulator[3]. The solvent temperature in the cell was checked by dipping a thermoelement of a thermometer[4] in the solvent. A pH meter, a shaker, and a centrifuge were also used.

Reagents—*Standard Berberine Solution*—A stock solution of 1×10^{-3} M berberine was prepared by dissolving 0.4075 g of berberine hydrochloride[5] (dried at 105°) in distilled water and diluting to 1 liter with distilled water. The stock solution was standardized by the official method (6). The solution was used after accurate dilution.

Tetrabromophenolphthalein Ethyl Ester Solution—A 2.0×10^{-3} M solution of tetrabromophenolphthalein ethyl ester was prepared by dissolving 0.1400 g of tetrabromophenolphthalein ethyl ester potassium salt[6] in ethanol to give a 100-ml solution.

Buffer Solution (pH 8.5)—The borate–phosphate buffer was prepared by adding 1 N H_2SO_4 or 1 N NaOH to the 0.3 M potassium dihydrogen phosphate containing 0.1 M sodium borate.

Procaine[7], ephedrine[8], quinine[9], papaverine[9], eserine[10], and emetine[5] were used as the hydrochloride and the sulfate. Ethylene dichloride was used as the extractant. All chemicals were reagent grade.

	1:0.5	128	106

[a] The berberine taken was 1×10^{-6} *M*, the wavelength was 610 nm, and the pH was 8.5.

Recommended Procedure—Berberine solution, 0.5–5 ml (2.5×10^{-5} *M*), 2 ml of tetrabromophenolphthalein ethyl ester (2×10^{-3} *M*), and 5 ml of borate–phosphate buffer (pH 8.5) were pipetted into a 100-ml separator. The mixture was diluted with water to 50 ml and shaken with 10 ml of ethylene dichloride for 5 min mechanically.

The organic layer was transferred into a stoppered test tube and centrifuged to remove water droplets. The absorbance (610 nm) of the organic phase was measured at 25° in the temperature-controlled cell holder against the reagent blank. The temperature was raised to 60° with the cell remaining in the holder, and the absorbance of the same phase was measured.

The calibration curves were straight, starting at the origin, over 0.25–2.5 $\times 10^{-6}$ *M* berberine aqueous solution. The molar absorptivities at 25 and 60° in ethylene dichloride were 9.80×10^4 and 9.24×10^4 mole^{-1} cm^{-1} liter, respectively. The precision was checked by 10 measurements, and the variation coefficient was ±1% at each temperature.

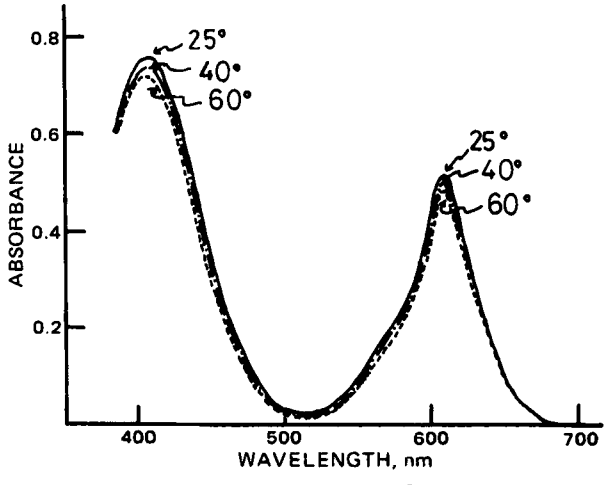

Figure 1—*Absorption spectra of 6.4 × 10^{-6} M tetrabromophenolphthalein ethyl ester–1 × 10^{-6} M berberine at different temperatures and pH 8.5. The shaking time was 5 min, and the reference was water.*

Table II—Berberine Analysis in Practical Samples

Sample	Amount Manifested, mg	Amount Found, mg 25°	60°
1[a]	75	81	76
2[b]	50	53.5	51
3[c]	100	105	101

[a] Also contained thiamine hydrochloride (5 mg), diphenhydramine hydrochloride (10 mg), and methylephedrine hydrochloride (15 mg). [b] Also contained diphenhydramine hydrochloride (10 mg), papaverine hydrochloride (5 mg), and thiamine hydrochloride (5 mg). [c] Also contained chlorpheniramine maleate (15 mg), thiamine hydrochloride (10 mg), and papaverine hydrochloride (20 mg).

RESULTS AND DISCUSSION

Extraction Mechanism with Tetrabromophenolphthalein Ethyl Ester—Tetrabromophenolphthalein ethyl ester anion (I) reacted with quaternary ammonium salts such as berberine, tetraethylammonium, benzethonium (7), and sparteine to form blue-color ion associates, which were extracted into ethylene dichloride. Secondary and tertiary amines such as ephedrine, quinine (4), papaverine, procaine (5), and emetine also reacted with I to form reddish complexes, which were extracted into ethylene dichloride. The ratio of I to the compounds of both the blue ion associates and the reddish complexes in ethylene dichloride was 1:1, as determined by the continuous variation method.

The electric conductivities of the dye molecule (VI), of the ion associate with berberine, and of the complex with procaine in ethylene dichloride were measured. The solutions containing 10^{-4} *M* VI and its charge transfer complex with procaine did not show conductivity when measured at various temperatures from 20 to 50°. The solutions containing 10^{-4} *M* of the ion associate with berberine showed some small conductivity (micro-ohms per centimeter): 20°, 6.14; 30°, 6.78; 40°, 7.29; and 50°, 8.0.

Accordingly, the following extraction scheme is presented. The subscripts *o* and *w* refer to the organic and aqueous phases, respectively.

$$\underset{\text{blue}}{I_w} + H_w^+ \rightleftarrows \underset{\text{yellow } (\lambda_{max} = 410 \text{ nm})}{VI_0}$$

Scheme I—Extraction of tetrabromophenolphthalein ethyl ester

$$I_w + III_w \rightleftarrows \underset{\text{blue}}{I\text{-}III_0(II)} \rightleftarrows \underset{\text{blue } (\lambda_{max} = 610 \text{ nm})}{I_0 + III_0}$$

Scheme II—Extraction of ion associate

$$I_w + H_w^+ + V_w \rightleftarrows \underset{\text{red } (\lambda_{max} = 545 - 585 \text{ nm})}{I\text{-}H\text{-}V_0(IV_0)}$$

Scheme III—Extraction of charge transfer complex

Thermochromism of Ion Associate and Charge Transfer Complex with I—The absorption spectra of the I–berberine ion associate and the

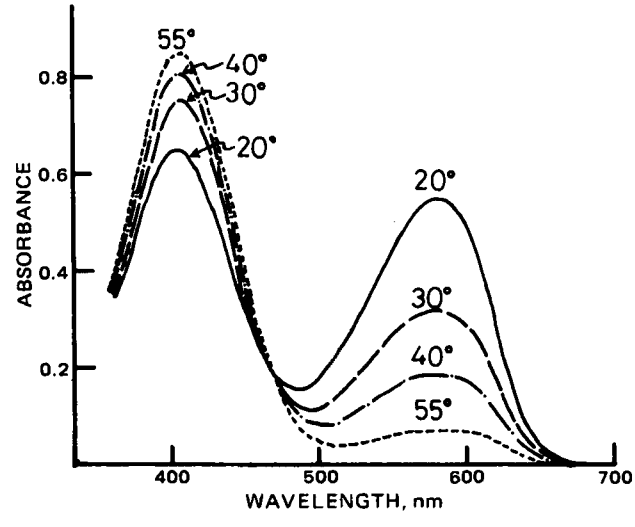

Figure 2—*Changes in absorption spectra of the charge transfer complex by thermochromism. The amine was 2.5 × 10^{-5} M procaine with 1.28 × 10^{-5} M tetrabromophenolphthalein ethyl ester at pH 8.5. The reference was water.*

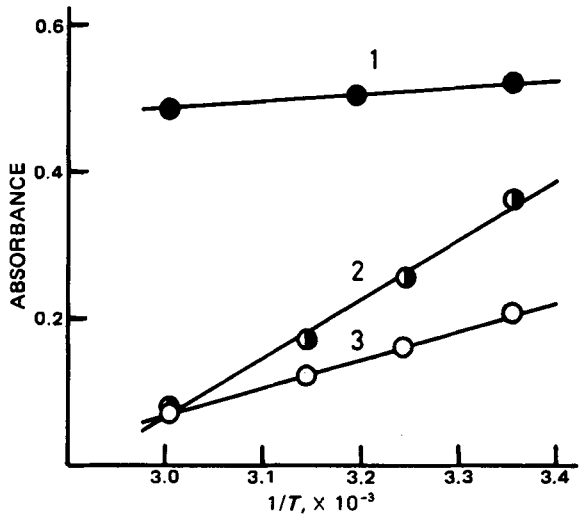

Figure 3—*Effect of temperature on tetrabromophenolphthalein ethyl ester–berberine and amines. Key: 1, 1 × 10⁻⁶ M berberine with 8 × 10⁻⁵ M tetrabromophenolphthalein ethyl ester at 610 nm; 2, 2.0 × 10⁻⁵ M papaverine with 1.6 × 10⁻⁴ M tetrabromophenolphthalein ethyl ester at 572 nm; and 3, 1.0 × 10⁻⁶ M procaine with 1.6 × 10⁻⁴ M tetrabromophenolphthalein ethyl ester. The reference was water.*

VI–procaine complex in ethylene dichloride at various temperatures are shown in Figs. 1 and 2, respectively. The absorption spectrum of the I–berberine ion associate was scarcely affected by the temperature change. The slight decrease in absorbance with a rise in temperature depended on the expansion of ethylene dichloride.

On the other hand, the VI–procaine complex absorption spectrum in ethylene dichloride was greatly influenced by temperature. When the temperature was elevated, the absorbance at 585 nm decreased and the absorbance at 410 nm increased. The isosbestic point in this absorption spectrum was 465 nm.

Thus, Scheme IV is presented.

$$\underset{\text{red}}{IV_0} \underset{\text{cool}}{\overset{\text{warm}}{\rightleftharpoons}} \underset{\text{yellow}}{VI_0} + \underset{\text{colorless}}{V_0}$$

Scheme IV

The absorbances of the I–berberine ion associate at 610 nm, of the VI–procaine complex at 585 nm, and of the VI–papaverine complex at 572 nm were plotted against $1/T$(T = absolute temperature) (Fig. 3). The absorbance change of the I–berberine ion associate is attributed to solvent expansion, and the absorbance decreases of the VI–papaverine and the VI–procaine complexes with increased temperature are due to complex dissociation according to Scheme IV. At 60°, the absorbances of the VI–procaine complex at 585 nm and of the VI–papaverine complex at 572 nm were almost the same as the reagent blank.

When berberine (1×10^{-6} M) was extracted into ethylene dichloride with I, the absorbance at 610 nm was 0.520 at 25° and 0.484 at 60°, with water as a reference. When berberine (1×10^{-6} M) and eserine (1×10^{-6} M) coexisted, the absorbance at 610 nm was 0.577 at 25° and 0.485 at 60°. When the eserine concentration was doubled, the absorbance was 0.655 at 25° and 0.493 at 60°. Therefore, the berberine concentration can be determined successfully at 60° without hindrance from coexisting amines. The other amines such as emetine, papaverine, procaine, and pilocarpine were tested, with the same results as eserine.

Effect of Foreign Substances—Various foreign substances were added to a solution containing 1×10^{-6} M berberine, and their influences were examined by the recommended procedure (Table I). Glucose, lactose, and inorganic ions such as ammonium, calcium, sodium, chloride, and sulfate did not interfere with the determination of berberine. Quaternary ammonium salts such as benzethonium and neostigmine severely affected the determination, with positive errors even at 60°. Amines such as emetine, papaverine, pilocarpine, and eserine interfered with the determination at 25° but not at 60°.

Analysis of Practical Samples—Commercial samples were analyzed according to the proposed method (Table II). Of the coexisting substances, diphenhydramine, methylephedrine, and chlorophenylamine gave some interference at 25°; at the elevated temperature, their influences were suppressed by thermochromism. As a result, this thermochromism method is more selective, sensitive, and accurate than the official methods of determining berberine in pharmaceuticals.

High-Pressure Liquid Chromatographic Determination of Saccharin in Artificial Sweeteners and Pharmaceuticals

PHILIP J. PALERMO ˣ **and PETER SHI-FU TSAI**

Received January 20, 1978, from *Norwich-Eaton Pharmaceuticals, Norwich, NY 13815.* Accepted for publication January 22, 1979.

Abstract □ A high-pressure liquid chromatographic procedure is presented for determining saccharin in various formulations. The method is fast, precise, and accurate and is specific for saccharin in the presence of its most likely impurities and degradation products. Reversed-phase chromatography on a micro-C_{18} column is utilized with an internal standard, and detection is by UV absorption at 280 nm.

Keyphrases □ High-pressure liquid chromatography—analysis, saccharin in various artificial sweeteners and pharmaceuticals, stability indicating □ Saccharin—analysis, high-pressure liquid chromatographic, in various artificial sweeteners and pharmaceuticals, stability indicating □ Stability—saccharin, various artificial sweeteners and pharmaceuticals, high-pressure liquid chromatography

Current literature is abundant in techniques for saccharin determination. Spectrophotometry (1, 2), gravimetry (3, 4), polarography (5), partitioning (6), and specific ion electrode (7, 8) techniques are available but lack the specificity needed for a stability-indicating assay. TLC techniques (9, 10) have a limited and unknown specificity and accuracy. GLC techniques (11–15) require isolation of the saccharin in the dry state and derivatization as either the methyl or trimethylsilyl derivative, and their specificity usually is not stated.

A liquid chromatographic procedure using an ion-exchange column has been described (16). This method was applied to soft drinks and foods, but its specificity for saccharin is unknown. Another liquid chromatographic procedure (17) using a μBondapak C_{18} column and aqueous acetic acid was not applied to pharmaceuticals. Its specificity for saccharin and, therefore, its use as a stability-indicating assay are questionable.

This paper describes the development of a high-pressure liquid chromatographic procedure for saccharin or saccharin sodium determination in artificial sweeteners. With modifications in sample handling, this procedure is applicable to a wide range of pharmaceutical preparations containing saccharin. The specificity and speed of this method allow its use as both a stability-indicating and a quality control assay.

EXPERIMENTAL

Apparatus—The high-pressure liquid chromatograph was equipped with a 280-nm absorbance detector. A 30-cm × 3.9-mm μBondapak C_{18} column of 10-μm average particle size was used with an eluent flow rate of 1.5 ml/min. Peak areas were determined by a computerized laboratory data system, but calculations may be performed using peak heights if desired.

Materials and Reagents—Saccharin and saccharin sodium equivalent to USP specifications and theophylline[1] of USP purity were used. All other reagents and chemicals were ACS reagent grade or equivalent.

Mobile Phase Preparation—Ten milliliters of acetic acid was added to 600 ml of methanol and diluted to 2 liters with distilled water. The eluent was filtered through a 0.5-μm cellulose acetate filter and degassed prior to use.

Internal Standard Solution—Theophylline, 0.35 ± 0.05 g, was dissolved in ~250 ml of eluent.

Saccharin Standard Solution—About 0.7 g of reference standard saccharin sodium or 0.6 g of reference standard saccharin was weighed accurately and diluted to 100.0 ml with 50% methanol–water.

Standard Solution for Injection—Ten milliliters of internal standard solution was combined with 10.0 ml of saccharin solution, and about 30 ml of eluent was added.

Procedure for Artificial Sweetener—Depending on the dosage level, the amount of ground sample equivalent to ~50 mg of saccharin was weighed into a flask. Ten milliliters of internal standard and ~40 ml of eluent were added. After dissolution and filtration, the sample was ready for injection.

General Procedure for Other Pharmaceutical Preparations—A sample size equivalent to 1–10 mg of saccharin was reacted with 50 ml of 5% HCl. The solution was extracted with a total of 100 ml of ether in several portions. The ether portions were combined and taken to near dryness with heat and a nitrogen stream. An aliquot of internal standard solution was added commensurate to the saccharin level in the sample. This solution was injected without further dilution.

TLC—Solution volumes of standards and samples corresponding to ~200 μg of saccharin were spotted onto 20 × 20-cm fluorescent silica gel (0.25 mm) plates. After drying, the plates were developed in chloroform–methanol–ammonia (70:30:0.5 v/v) to about a 15-cm solvent migration. The saccharin spots were excised with the aid of UV light and taken up in 4 ml of 2% ammonia in methanol. After centrifugation, the UV absorbances were measured at 269 nm.

RESULTS

Individual stock solutions of saccharin and theophylline were prepared, and aliquots of each were combined in different ratios for injection to determine the response linearity. Thus, for this experiment, both the saccharin and theophylline contents were varied simultaneously. The response ratios (both areas and peak heights) were plotted *versus* the weight ratios injected over 0–4 μg of saccharin and 0–1.6 μg of theophylline injected. The results of the least-squares linear regression analysis (Table I) indicated very good linearity by both peak height and area measurements. A typical chromatogram is shown in Fig. 1. The amounts injected were 2.9 μg of saccharin and 0.6 μg of theophylline.

Laboratory-prepared synthetic samples of the artificial sweetener were assayed to determine the accuracy of the method. Three groups of five samples each in which the placebo was held constant while the sodium saccharin was varied at 80, 100, and 125% of label were assayed by the procedure (Table II). The data indicated no bias in the method and statistically no difference in the groups by F and t tests. The calculation is:

$$\text{mg of saccharin sodium/g of sample} = \frac{R_{\text{sample}}}{R_{\text{standard}}} \times \frac{\text{mg of saccharin sodium standard}}{\text{sample weight}} \quad \text{(Eq. 1)}$$

where the R's are the saccharin to theophylline response ratios. The method was validated for peak height and area ratios.

A manufactured sample was assayed 15 times, varying the sample weights from 80 to 120% recommended. The relative standard deviation of the assay was ±0.3%. The solutions for injection were stable for many weeks as demonstrated by a lack of change in the response ratios.

The method was challenged directly by the presence of seven possible impurities and degradation products documented in the literature (1, 18–20). Figure 2 shows a chromatogram of a typical saccharin and theophylline sample solution after quantities of seven of these compounds, each equal to the amount of saccharin present, were added. The identities of the peaks are: 1, 1,5-naphthalenedisulfonic acid; 2, ammonium-*o*-sulfobenzoate; 3, 2-(aminosulfonyl)benzoic acid; 4, *p*-carboxyben-

zenesulfonamide; 5, salicylic acid; and 6, *o*- and *p*-toluenesulfonamides. All of the peaks were well resolved from both saccharin and theophylline, and none of these compounds at reasonable levels interfered in the method.

The artificial sweetener was subjected to stress conditions for an attempted forced degradation study. The samples showed no measurable degradation at 100° for 1 month and also were unaffected by 2 weeks of exposure to strong fluorescent and incandescent light. However, a sample stored at 75° at very high humidity gave a low assay and the formation of a new peak in the chromatogram. The assay value by the liquid chromatographic procedure was 44.9% of initial. This new peak had a retention time corresponding to 2-(aminosulfonyl)benzoic acid, the alkaline hydrolysis product, which was suspected to be the most likely first degradation product. This sample was assayed by TLC, and the result was 42.8% of initial.

DISCUSSION

The artificial sweetener consists of saccharin sodium and sodium bicarbonate. Acetic acid in the eluent neutralizes both. Acetic acid in the eluent increases the retention (capacity factor) of saccharin by suppressing ionization and also results in a much sharper peak. If saccharin is allowed to elute in its ionic form, very little retention occurs and little use is made of the separating capabilities of the column.

Before an assay can be considered qualified for a stability-indicating program, its specificity characteristics must be proven. Specificity in this method is provided mainly by the liquid chromatographic column. It is clearly not proper to assume specificity simply because a chromatographic process is involved. For this study, the proposed method was challenged in three ways.

First, a literature search was conducted to determine the documented impurities and degradation products of the active drug saccharin. These compounds were subjected to the column under the assay conditions and were all innocuous to the assay. These compounds must be added directly to the sample solution so that possible matrix effects are eliminated.

Second, a forced degraded sample of the actual product was assayed for two reasons: (*a*) the actual decomposition products in the drug matrix may be different from those postulated in the literature and (*b*) interferences by degradation products of the excipients are possible. When the assay passes these conditions, it is more likely to prevail during the shelflife of the product.

Third, the forced degraded sample assay, whenever possible, should be compared with a completely independent assay based on different analytical principles. If possible, this reference method should be of demonstrated accuracy. When the results of the two methods agree within the expressed objectives, the method developer can be confident of the reliability of the new method. These three approaches are by no means completely rigorous but can be regarded as minimum criteria for a proposed stability-indicating method.

The general procedure given for other pharmaceutical preparations was applied to mouthwashes, analgesic liquids, and antidiarrhetics. Occasionally, such samples can be injected after dilution, addition of the internal standard, and clarification. Generally, however, ether extraction is required because of the low saccharin levels in the formulations. The ether extraction technique also is preferable because of the added selectivity of the extraction step and the extended column life resulting from injection of a cleaned-up sample solution.

Because of pharmaceutical formulation diversity, components other than saccharin are frequently extracted and the resulting chromatograms are less simple than those of the artificial sweetener. However, interferences often may be eliminated by proper pH and methanol adjustments in the eluent. The selectivity of the chromatographic process provides enough resolution so that the saccharin assay can be carried out in the presence of other ingredients such as salicylic acid and alkyl parabens. Injections can be made every 5 min, and about 30 samples of artificial sweetener can be analyzed per 8-hr day. Fewer samples of the other pharmaceutical formulations can be analyzed because of the lengthier sample-handling procedure, but this procedure is necessary for almost any technique.

In summary, this reversed-phase liquid chromatographic system provides a precise, accurate, and specific saccharin assay with high sample throughput. The procedure is applicable to a wide range of pharmaceuticals, especially for a stability-indicating program.

High-Performance Liquid Chromatographic Assay for the Anthelmintic Agent Mebendazole in Human Plasma

K. B. ALTON ˣ, J. E. PATRICK, and J. L. McGUIRE

Received June 30, 1976, from the *Drug Disposition Section, Ortho Pharmaceutical Corporation, Raritan, NJ 08869.* Accepted for publication January 16, 1979.

Abstract □ A rapid and specific high-performance liquid chromatographic (HPLC) assay for quantitative plasma mebendazole determination is described. After a simple extraction, the compound was analyzed by HPLC using a reversed-phase column and a UV detector (313 nm). Quantitation was accomplished using an internal standard; peak area ratios were determined with an integrating computer. The average mebendazole recovery over a concentration range of 0.01–0.20 μg/ml was 75.9 ± 3.8% *SD*, and the maximum assay sensitivity was ~10 ng/ml.

Keyphrases □ High-performance liquid chromatography—analysis, mebendazole in human plasma □ Mebendazole—analysis, high-performance liquid chromatography, in human plasma □ Anthelmintic agents—mebendazole, high-performance liquid chromatographic analysis in human plasma

Mebendazole[1] (I), methyl 5-benzoyl-2-benzimidazolecarbamate, is a broad spectrum anthelmintic agent (1–3). Initial absorption studies in humans (1) suggested that 6–10% of the radioactivity was recovered in the urine following 5–7 mg po of ^{14}C-mebendazole (18.5–22.7 μCi). Approximately 2.5% of this urinary radioactivity was unconjugated mebendazole, about 20% was the decarbamated metabolite, and 75% was of undetermined identity. Plasma radioactivity levels remained low throughout the study. There are no published methods sensitive enough to

measure plasma levels of the parent compound following oral administration of mebendazole tablets.

This report describes a simple and specific high-performance liquid chromatographic (HPLC) method for the rapid determination of plasma mebendazole. This assay may have the sensitivity (~0.01 μg/ml) and precision needed to measure unchanged drug levels after chronic high-dose administration of mebendazole to patients being treated for *Echinococcus multilocularis* cysts.

EXPERIMENTAL

Apparatus—Analyses were performed on a liquid chromatograph[2] operated at ambient temperature and equipped with a differential UV (313 nm) detector[3]. Separations were performed on a 300 × 3.0-mm (i.d.) reversed-phase column[4]. Samples were introduced onto the column through a septumless injector[5] with a 25-μl syringe[6]. Chromatograms were traced on a strip-chart recorder[7], and peak area integration was performed by an integrating computer[8] interfaced with the detector by an analog–digital converter[9]. Analog signal modification to reduce noise from the UV detector was achieved with an electronic filter[10].

Reagents and Solvents—Mebendazole (I), three known human urinary metabolites of mebendazole [2-amino-5-benzoylbenzimidazole (II), 5-benzoyl-2-hydroxybenzimidazole (III), and methyl 5-(α-hydroxybenzyl)-2-benzimidazolecarbamate (IV)], and the internal standard methyl 5-(4-fluorobenzoyl)-2-benzimidazolecarbamate (V, flubendazole) were used as received[11]. All chemicals and reagents except acetonitrile[12] were reagent grade.

Chromatographic Conditions—The mobile phase was 0.05 *M* KH_2PO_4–NaOH buffer (pH 6.0)–acetonitrile (73:27 v/v), and the flow rate was adjusted to 2.5 ml/min (~2500 psi). The solvent mixture was prepared daily and degassed under reduced pressure before use. A stainless steel precolumn[13] (3 × 0.32 cm o.d.) was used to minimize the detrimental effect of any irreversibly adsorbed plasma-extracted material on the performance of the microparticulate reversed-phase column.

0.025	0.0187	6	74.9 ± 5.1
0.050	0.0389	9	77.9 ± 1.9
0.100	0.0754	13	75.4 ± 1.4
0.200	0.151	6	75.4 ± 1.5
		$\bar{x}$	75.9 ± 3.8[b]

[a] $\bar{x} \pm SD$. [b] $\overline{CV}$ = 5.09%.

Extraction Procedure—Aliquots (2.0 ml) of plasma were transferred to 15-ml test tubes (16 × 125 mm) fitted with polytef-lined screw caps, diluted with 2.0 ml of 0.05 *M* KH_2PO_4–NaOH buffer (pH 7.0), and extracted with 7.0 ml of ethyl acetate. The mixture was shaken vigorously, and the phases were separated by centrifugation (2 min at ~1500×*g*). The organic layer was removed with a Pasteur pipet and transferred to another 15-ml screw-capped tube. A second extraction was performed similarly. The ethyl acetate layers were pooled for each sample and taken to dryness under a nitrogen stream in a water bath (55°). An aliquot (2.0 ml) of 0.001 *N* HCl was added to the ethyl acetate residue and mixed with a vortex mixer. The hydrochloric acid solution was then extracted twice with 6.0 ml of petroleum ether (bp 30–60°) and centrifuged to obtain a clear supernate, and the upper layers were discarded after aspiration. The remaining aqueous fraction was alkalinized with 2.0 ml of 0.01 *N* NaOH, and this mixture was extracted twice with ethyl acetate.

The final residues were transferred with ethyl acetate to 2.5-ml glass conical centrifuge tubes and concentrated with two ethyl acetate washings under a nitrogen stream in a water bath (55°). The resulting residue was dissolved in 60 μl of ethyl acetate, and aliquots (20 μl) were injected onto the chromatograph for analyses.

Extraction Efficiency—Venous blood from several untreated volunteers was drawn into heparinized containers[14] and centrifuged to generate a plasma pool. The efficiency of extracting the drug from plasma was established using the following procedure. Known amounts of mebendazole and of the internal standard, flubendazole, both of which were dissolved in methanol–formic acid (described later), were added to drug-free plasma samples (15–25 ml each) to achieve mebendazole concentrations of 0.01, 0.025, 0.05, 0.10, and 0.20 μg/ml and a constant flubendazole concentration of 0.15 μg/ml for each sample. Aliquots (2.0 ml) of each plasma sample were transferred to 15-ml test tubes and stored frozen (−20°) until extracted as described.

All samples ($n \geq 6$) at each concentration were analyzed in duplicate. Mebendazole quantitation was accomplished by use of the described internal standard method.

Calibration and Standard Preparation—Mebendazole (25.0 mg) was dissolved in ~10 ml of formic acid (98%) and diluted to volume with methanol in a 25.0-ml volumetric flask to yield a concentration of 1.0 μg/μl. Three additional standard solutions containing 0.10, 0.01, and 0.001 μg/μl of mebendazole were prepared by serial dilution of the 1.0-μg/μl stock solution with methanol. Standard solutions of flubendazole (1.0, 0.1, and 0.01 μg/μl) were prepared in the same manner.

The internal standard method contained in the software section of the computer is predicated on a linear relationship between micrograms of mebendazole injected and the peak area ratio of mebendazole to the internal standard. Calibration solutions were prepared in the following manner. Aliquots (100, 71, 50, 33, and 25 μl) of the 0.1-μg/μl internal standard solution were transferred to glass vials and taken to dryness. These samples were diluted with 1.0 ml of the mebendazole standard solution (0.001 μg/μl) so that a constant amount of flubendazole (0.05 μg) and 0.005, 0.007, 0.01, 0.015, and 0.02 μg of mebendazole were delivered in 5, 7, 10, 15, and 20 μl of solution. The linearity of the calibration curve was initially evaluated by repeated ($n \geq 5$) injections of each solution. Thereafter, an average calibration response factor was established by the computer following triplicate injections (15 μl) of a calibration

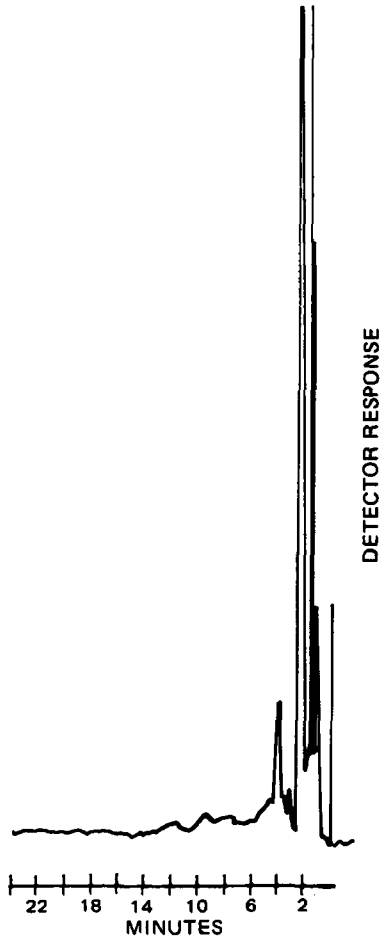

Figure 1—*Liquid chromatogram of an extract from drug-free plasma. The mobile phase consisted of 0.05 M KH_2PO_4–NaOH buffer (pH 6.0)–acetonitrile (73:27 v/v) with the flow rate adjusted to 2.5 ml/min.*

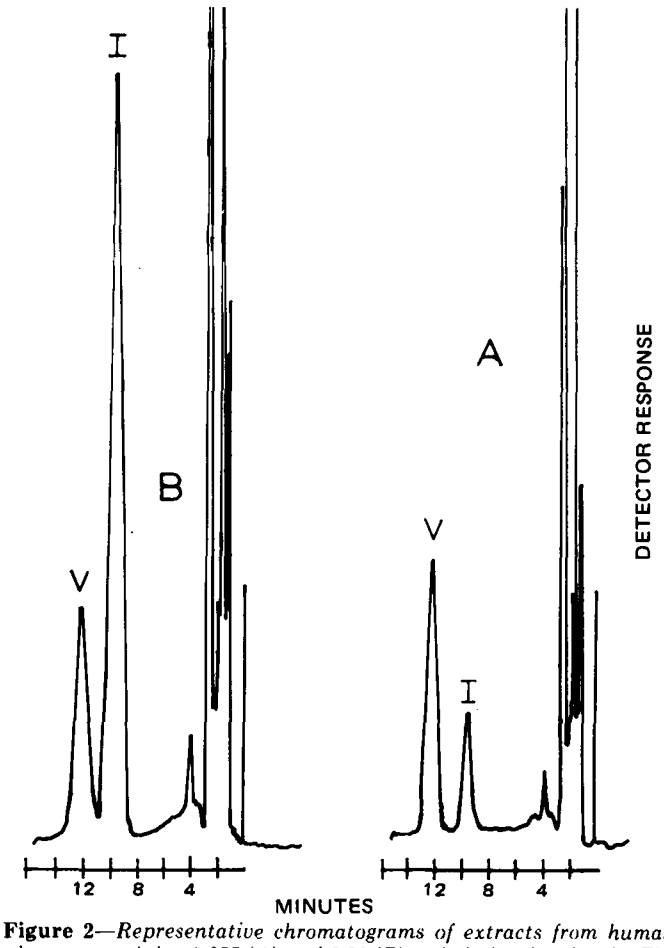

Figure 2—*Representative chromatograms of extracts from human plasma containing 0.025 (A) and 0.20 (B) μg/ml of mebendazole. The amount of the internal standard added to the plasma was 0.15 μg/ml. The detector response was at 0.005 aufs.*

solution containing 0.015 μg of mebendazole and 0.05 μg of the internal standard.

Specificity—Assay specificity was determined by injecting solutions of mebendazole (I) and its potential metabolites, II, III, and IV (~0.1 μg/μl in methanol), onto the HPLC column. A portion of an ethyl acetate extract (20 μl/60 μl) from a drug-free plasma sample also was chromatographically evaluated for the presence of any ethyl acetate-extractable, UV-absorbing (313 nm) material that might interfere with the measurement of mebendazole or flubendazole.

RESULTS AND DISCUSSION

The average drug recovery from plasma samples to which mebendazole had been added was 75.9 ± 3.8% *SD* (Table I) with an average precision (*CV*) of 5.09%. Linear regression analysis of percent recovery *versus* plasma concentration revealed no statistically significant ($p = 0.7143$) slope (β). One-way analysis of variance of the recovery data from each mebendazole concentration demonstrated no significant differences among the groups. These data suggest that extraction efficiencies are not concentration dependent over the investigated plasma drug range. The average internal standard recovery was 94.1 ± 2.88% *SD* with a coefficient of variation equal to 3.06%.

Even though the λ_{max} observed for mebendazole in methanol was 246 nm, detection at 313 nm was particularly advantageous since the ethyl acetate extracts from drug-free plasma were free of interfering UV-absorbing peaks (313 nm) (Fig. 1). Extraction of the acidified residue with petroleum ether aided in eliminating lipophilic material, which might otherwise become highly bound to the column and interfere with analyses.

Baseline resolution between mebendazole (I) and the internal standard, flubendazole (V), was achieved under the chromatographic conditions described. Compounds II, III, and IV, although not well separated from each other, were separated completely from I and V. The observed retention times (t_r) for I, II, III, IV, and V were 10.03, 5.61, 4.89, 4.89, and 12.64 min, respectively. Representative chromatograms of extracts from plasma containing 0.025 and 0.20 μg/ml of mebendazole are shown in Fig. 2.

Linear regression analysis of the curve described by plotting the area ratio (*y*-axis) of mebendazole over flubendazole *versus* micrograms of mebendazole injected (*x*-axis) demonstrated linearity ($r^2 = 0.9803$) over the concentration range evaluated (0.005–0.02 μg/injection). The slope of the line was calculated to be 21.908 μg^{-1}, and the *y*-intercept was calculated to be 0.021. The calculated *x*-intercept was equivalent to −0.96 ng of mebendazole/injection. This value was used as a background correction factor in mebendazole recovery calculations. Over a 2-month period of analyses, the slope of this line demonstrated little change ($CV = 4.8\%$, $n = 56$).

In summary, an assay was developed that can be used to measure plasma mebendazole levels as low as 0.01 μg/ml. The method is both rapid and specific, and its sensitivity indicates that it might be suitable for measuring unchanged drug levels after chronic administration of mebendazole tablets to patients being treated for *E. multilocularis* cysts.

Antitumor Agents XXXIV: Mechanism of Action of Bruceoside A and Brusatol on Nucleic Acid Metabolism of P-388 Lymphocytic Leukemia Cells

I. H. HALL ˣ, K. H. LEE, S. A. ElGEBALY, Y. IMAKURA, Y. SUMIDA, and R. Y. WU

Received October 13, 1978, from the *Division of Medicinal Chemistry, School of Pharmacy, University of North Carolina at Chapel Hill, Chapel Hill, NC 27514.* Accepted for publication January 8, 1979.

Abstract □ The quassinoids bruceantin, brucein D, brucein E, bruceoside A, and brusatol significantly inhibited P-388 lymphocytic leukemic cell RNA and protein synthesis in tissue culture. However, DNA synthesis inhibition seemed to correlate more directly with the antineoplastic activity of these compounds in the *in vivo* P-388 survival system. *In vitro*, brusatol and bruceoside A marginally inhibited 10-day P-388 lymphocytic leukemia DNA polymerase, RNA polymerase, thymidylate synthetase, dihydrofolate reductase, phosphoribosyl pyrophosphate aminotransferase, and cathepsin protease activities. *In vivo* studies demonstrated similar inhibition and elevated cyclic AMP levels, correlating positively with the antineoplastic activity of individual compounds. Purine synthesis was inhibited drastically by brusatol *in vivo*, and one key inhibition site in purine synthesis was at phosphoribosyl pyrophosphate aminotransferase, the regulatory enzyme. Histone phosphorylation and ribonucleotide reductase activity also were inhibited marginally by brusatol.

Keyphrases □ Antineoplastic agents—bruceoside A and brusatol, effect on cultured P-388 lymphocytic leukemia cell nucleic acid metabolism □ Quassinoids—antineoplastic activity, effect on cultured P-388 lymphocytic leukemia cell nucleic acid metabolism □ Leukemia, lymphocytic—*in vitro* P-388 cells, effect of quassinoids on nucleic acid metabolism □ Nucleic acid synthesis, tumor—effect of quassinoids on P-388 lymphocytic leukemia cells

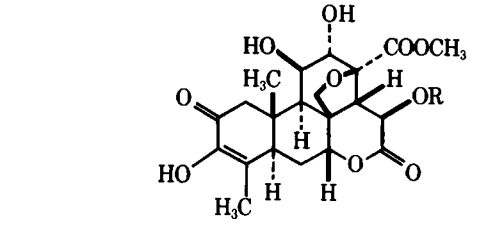
The structure of bruceantin (I), a quassinoid isolated from *Brucea antidysenterica*, was elucidated previously (1). Subsequently, bruceantin was active at 1 mg/kg/day against P-388 lymphocytic leukemia (T/C = 197) and at 2 mg/kg/day against B16 melanoma (T/C = 178) in mice. Brucein D (II), brucein E (III), and bruceoside A (IV) were isolated from *Brucea javanica* and characterized by Lee *et al.* (2)[1].

Studies with HeLa cells (3) demonstrated that bruceantin inhibited protein synthesis >90% at 2 μM, whereas DNA synthesis was only inhibited ~60%. RNA synthesis was marginally inhibited (~15%). Protein synthesis was blocked 79% in rabbit reticulocytes by bruceantin at 0.1 mM during the initiation events of translocation. In *Saccharomyces cereviseae*, bruceantin did not inhibit the initiation event but blocked peptide bond formation during chain elongation by binding to the free ribosome P site, resulting in 90% inhibition at 0.01 mM (4).

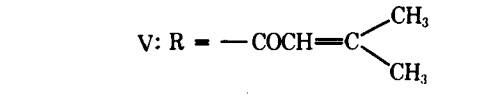
This paper reports the effects of brusatol and bruceoside A on P-388 lymphocytic leukemia cell metabolism.

EXPERIMENTAL

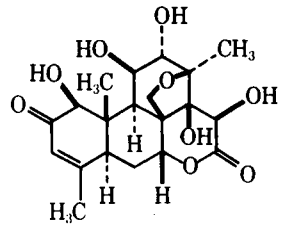
Materials—Bruceantin (I) was obtained in small quantities from the National Cancer Institute. Brucein D (II), brucein E (III), and bruceoside A (IV) were extracted from *B. javanica* according to the exact literature technique (2), and brusatol (V) was obtained by treating bruceoside A with 3 N H_2SO_4–methanol (1:1) to hydrolyze the glycosidic linkage (2).



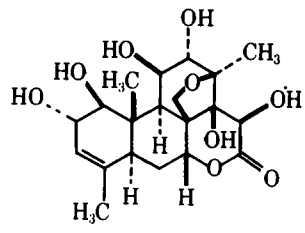
I: R = —COCH=C(CH$_3$)—CH(CH$_3$)$_2$



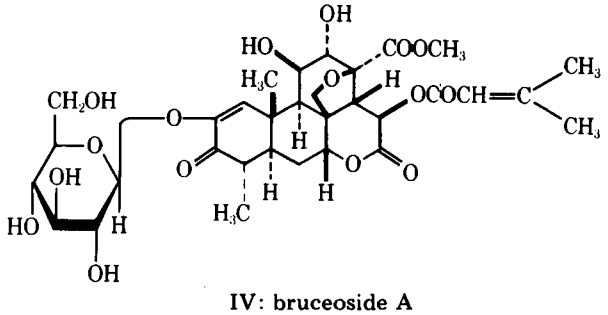
V: R = —COCH=C(CH$_3$)$_2$



II: brucein D



III: brucein E



IV: bruceoside A

P-388 Lymphocytic Leukemia Antitumor Screen—DBA/2 male mice (~25 g) were administered 10^6 P-388 lymphocytic leukemia cells intraperitoneally on Day 0. Test compounds were homogenized in 0.05% polysorbate 80 and administered on Days 1–14 intraperitoneally. The average days survived for each group was determined, and T/C (treated/control) values were calculated (5). Fluorouracil was used as a positive standard.

P-388 Lymphocytic Leukemia Cell Metabolism Studies—DBA/2 male mice were innoculated with 10^6 P-388 lymphocytic leukemia cells on Day 0. On Days 7, 8, and 9, brusatol, 100 μg/kg/day, or bruceoside A, at 5 mg/kg/day, was administered intraperitoneally. On Day 10, P-388 cells were harvested from the peritoneal cavity. The number of tumor cells per milliliter and the 0.4% trypan blue uptake were determined with a hemocytometer (6). Thymidine incorporation into DNA was determined by a literature method (7). One hour prior to the animal's sacrifice, 10 μCi of [^{14}C-*methyl*]-thymidine (47.5 mCi/mmole) was injected intraperitoneally.

[a] T/C ≥ 125 is required for significant activity. [b] Bruceantin was tested by the National Cancer Institute in CDF_1 mice. [c] Toxic at this dose.

The DNA was isolated, and the carbon-14 content was determined in two parts of toluene, one part of octoxynol, 0.4% 2,5-diphenyloxazole, and 0.01% 1,4-bis[2-(5-phenyloxazolyl)]benzene scintillation fluid and corrected for quenching. The DNA concentration was determined by UV spectrophotometry at 260 nm with calf thymus DNA as a standard. Uridine incorporation into RNA was determined in an analogous manner with 10 μCi of 5-^{3}H-uridine (24.2 Ci/mmole). RNA was extracted by a literature method (8). Leucine incorporation into protein was determined by the Sartorelli (9) method with 5 μCi of ^{14}C-leucine (54.4 Ci/mmole).

The P-388 tissue culture cells were maintained according to literature methods (10). Fetal calf serum (10%) was added to the medium 24 hr prior to studies. The P-388 cells were diluted to 1.6×10^6 cells/ml, and ^{14}C-thymidine (0.086 μCi), ^{3}H-uridine (0.08 μCi), or ^{14}C-leucine (0.0845 μCi) was added to 1 ml of cells (3). The synthesis rates, after 1 hr, of DNA, RNA, or protein were measured as the uptake of labeled precursors into cold trichloroacetic acid-insoluble material. DNA was collected on glass fiber paper (GF/F) by vacuum suction. RNA and protein were collected on nitrocellulose membrane filters.

The P-388 lymphocytic cells from 10-day DBA/2 mice also were collected for *in vitro* studies. The drug effects on the transport of precursor radiolabeled thymidine, uridine, or leucine across membranes were determined using whole cells and cell homogenates. Labeled macromolecules were collected on the appropriate filters after 1 hr of incubation (3).

In the *in vitro* studies, bruceantin and bruceoside A were present at 0.015 m*M* concentrations and brusatol was present at 0.015 and 0.005 m*M* final concentrations.

Emzymatic Studies—Nuclear DNA polymerase activity was determined on isolated P-388 lymphocytic leukemia cell nuclei (11). The incubation medium was that of Sawada *et al.* (12), except that 2-^{14}C-deoxyribothymidine triphosphate (45 mCi/mmole) was used; the insoluble nucleic acids were collected on glass fiber paper (GF/F). Messenger RNA polymerase activity was measured by literature methods (13, 14) with 5,6-^{3}H-uridine 5′-triphosphate (35 Ci/mmole). Insoluble RNA was collected on nitrocellulose filters.

Deoxythymidine kinase, deoxythymidylate monophosphate kinase, and deoxythymidylate diphosphate kinase activities were measured by a literature method (15) based on the disappearance of 0.1 μmole of reduced nadide (nicotinamide adenine dinucleotide) at 340 nm in 2 min. Thymidylate synthetase activity was assayed by a literature method (16), utilizing a postmitochondrial (9000×*g* for 10 min) supernate and 5 μCi of 5′-^{3}H-deoxyuridine monophosphate (11 Ci/mmole). Dihydrofolate reductase activity was determined by a literature method (17) based on the disappearance of 0.1 μmole of reduced nadide phosphate at 340 nm for 1 hr. *S*-Adenosylmethionine transferase activity was determined by a literature method (18) with 0.05 μCi of $^{14}CH_3$-*S*-adenosyl-L-methionine (53 mCi/mmole).

Ribonucleotide reductase activity was determined by the method of Moore and Hurlbert (19). Deoxyribonucleotides were separated from ribonucleotides by poly(ethyleneimine) cellulose TLC (20). ^{14}C-Formate incorporation into purines was measured by a reported method (21), using 0.5 μCi of ^{14}C-formic acid (4.95 mCi/mmole). Purine separation was carried out on silica gel TLC plates eluted with *n*-butanol–acetic acid–water (4:1:5). The plates were scraped and radioactivity was determined.

Table II—Relative Incorporation of Radiolabeled Precursors into P-388 Tissue Culture Cells during 1 hr with the Incubation Test Drugs (0.015 m*M*)

Compound	Percent Control (dpm)		
	^{14}C-Thymidine Incorporation into DNA	^{3}H-Uridine Incorporation into RNA	^{14}C-Leucine Incorporation into Protein
I (0.015 m*M*)	63 ± 7[a]	68 ± 9[b]	38 ± 5[a]
II (0.015 m*M*)	81 ± 5	45 ± 5[a]	26 ± 9[a]
III (0.015 m*M*)	76 ± 8	43 ± 3[a]	35 ± 13[a]
IV (0.015 m*M*)	67 ± 9[a]	45 ± 5[a]	35 ± 15[a]
V (0.015 m*M*)	16 ± 9[a]	38 ± 3[a]	14 ± 8[a]
0.05% Polysorbate 80	100 ± 7	100 ± 3	100 ± 14

[a] $p = 0.001$. [b] $p = 0.005$.

Phosphoribosyl pyrophosphate aminotransferase activity was determined by a method (22) based on the reduction of 0.6 μmole of nadide at 340 nm for 30 min.

Carbamyl phosphate synthetase activity was determined with ornithine and ornithine transcarbamylase present by the method of Kalman *et al.* (23). The colorimetric determination of citrulline was performed according to the Archibald method (24). Aspartate carbamyl transferase activity was carried out by a literature method (23) in the presence of aspartate transcarbamylase. The colorimetric determination of carbamyl aspartate was carried out according to a literature method (25).

To determine if purine synthesis inhibition was the reason for decreased ^{14}C-thymidine incorporation into DNA, P-388 lymphocytic leukemia cells were incubated *in vitro* with 0.05 μCi of [^{14}C-*methyl*]-thymidine and deoxyguanosine triphosphate, deoxycytosine triphosphate, and deoxyadenosine triphosphate in buffer for 1 hr. A second experiment was performed after dosing with brusatol on Days 7, 8, and 9 at 100 μg/kg/day to determine if the actual purine content had been altered *in vivo*. Purines were extracted (21) and determined by UV analysis at 258 nm.

Histone phosphorylation was determined by injecting intraperitoneally 10 μCi of γ-^{32}P-adenosine triphosphate (18.8 Ci/mmole). The nuclei were isolated 1 hr later, and the histone chromatin protein was extracted by a literature method (26). Nonhistone chromatin phosphorylation by nuclei protein kinase was determined on isolated nuclei (11), utilizing 2 nmoles of γ-^{32}P-adenosine triphosphate. Chromatin protein was collected on nitrocellulose membrane filters (27).

Cyclic AMP levels were determined by a literature method (28) with the ^{3}H(G)-adenosine 3′,5′-cyclic phosphate (39.8 Ci/mmole) radioimmunoassay. The drug effect on hydrolytic enzymatic activity was measured also. Deoxyribonuclease activity was measured at pH 5.0 by a modification of the deDuve method (29). Ribonuclease activity and acid cathepsin activity were determined at pH 5.0 by a literature method (30).

In vitro UV binding studies (6) were conducted with brusatol or bruceoside A (7.8 μg/ml) with DNA or deoxyguanosine monophosphate (38 μg/ml) in 0.1 *M* phosphate buffer, pH 7.2, over 200–340 nm for 24 hr. Protein concentration was determined by the method of Lowry *et al.* (31).

RESULTS

Bruceantin was active against the P-388 lymphocytic leukemia cell survival system in the 250–1000-μg/kg/day range. Brucein D and brucein E were inactive. Bruceoside A was active against the P-388 survival system at 6 mg/kg/day, and brusatol was active at 125–500 μg/kg/day (Table I). Incorporation of radiolabeled precursors into P-388 tissue culture cell macromolecules showed that thymidine, uridine, and leucine were incorporated at the rates of 5559, 3381, and 1646 dpm/10^6 cells, respectively, for the control.

All five compounds reduced protein and RNA syntheses significantly at 0.015 m*M* (Table II). Brusatol caused the highest inhibition, resulting in 86% suppression of protein synthesis and 62% suppression of RNA synthesis of P-388 lymphocytic leukemia tissue culture cells. DNA synthesis was inhibited 37% by bruceantin, 19% by brucein D, 24% by brucein E, 33% by bruceoside A, and 84% by brusatol at 0.15 m*M*. Since brucein D and brucein E were inactive in the P-388 lymphocytic leukemia survival system, it appeared that suppression of RNA and protein was not the critical event resulting in tumor cell death. DNA synthesis inhibition appeared to correlate more directly with antitumor activity. For this reason, it was decided to examine specific events in DNA synthesis.

Table III—*In Vitro* Effect of Brusatol (0.005 m*M*) and Bruceantin (0.015 m*M*) on Whole Cells and Homogenates of 10-Day P-388 Lymphocytic Leukemia Cells (n = 5)

Whole cells harvested from 10-day P-388 lymphocytic leukemia-bearing mice and cells homogenized four times showed that brusatol at 0.005 m*M* and bruceantin at 0.015 m*M* did not retard ^{14}C-thymidine transport across the tumor membrane. In fact, both brusatol and bruceantin were more effective inhibitors of protein and DNA syntheses in homogenates (Table III). Untreated 10-day P-388 lymphocytic leukemia cells demonstrated changes in absorbance of 0.500 optical density (O.D.) unit/min/mg of protein for thymidine kinase activity, of 0.489 O.D. unit/min/mg of protein for thymidylate monophosphate kinase activity, and of 0.566 O.D. unit/min/mg of protein for thymidylate diphosphate kinase activity. Compounds II–V at 0.015 m*M* had no effect on the nucleotide kinases tested (Table IV). DNA polymerase activity for 10-day P-388 cells was 27,368 dpm/mg of nuclear protein. Brusatol caused 21% inhibition of polymerase activity. Thymidylate synthetase activity in 10-day P-388 cells was 1,645,840 dpm/mg of protein, which brusatol reduced 32%. Dihydrofolate reductase activity for 10-day P-388 cells was 2192 O.D. units/hr/mg of protein. At 0.015 m*M*, dihydrofolate reductase activity was reduced 27% by brucein D, 25% by brucein E, 31% by bruceoside A, and 36% by brusatol. At 0.005 m*M*, brusatol and methotrexate reduced dihydrofolate reductase activity by 28 and 59%, respectively.

Hydrolytic enzymatic activity was not increased due to the drugs; therefore, increased hydrolytic activity of deoxyribonuclease, ribonuclease, or cathepsin protease could not account for the reduction of radiolabeled precursors into macromolecules of P-388 cells. Deoxyribonuclease activity for 10-day cells was 1.718 μg of DNA hydrolyzed/min/mg of protein. Brucein D reduced the activity by 19% and brucein E reduced it by 58%. Ribonuclease activity for 10-day P-388 cells was 7.236 μg of RNA hydrolyzed/min/mg of protein. Brucein D reduced the activity by 45%, brucein E by 37%, and brusatol by 27%. Cathepsin activity for 10-day P-388 cells was 65.7 μg of azocasein hydrolyzed/min/mg of protein, which was suppressed significantly by brusatol, bruceoside A, brucein D, and brucein E.

In vitro messenger RNA polymerase activity also was measured in 10-day P-388 cells and was 76,088 dpm/mg of protein. The presence of brucein E reduced RNA polymerase activity by 17%; bruceoside A and brusatol reduced it by 32 and 12%, respectively. Phosphoribosyl pyrophosphate aminotransferase was inhibited by brusatol by 39%.

In the *in vivo* experiments, DBA/2 mice were treated with brusatol and bruceoside A on Days 7, 8, and 9 and the cells were harvested on Day 10. ^{14}C-Thymidine incorporation into DNA for the control was 75,098 dpm/mg of DNA, which was reduced 77% by brusatol and 48% by bruceoside A (Table V). ^{3}H-Uridine incorporation into RNA for the control was 386,004 dpm/mg of RNA, which was reduced 68% by brusatol and 55% by bruceoside A. ^{14}C-Leucine incorporation for the control was 22,666 dpm/mg of protein, which was reduced 86% by brusatol and 41% by bruceoside A. The number of tumor cells at Day 10 for the control was 142 × 10^6 cells/ml, which was reduced 79% by brusatol and 65% by bruceoside A after 3 days of administration.

Cyclic AMP in the control animals was 1.01 pmoles/10^6 P-388 cells. *In vivo* brusatol treatment increased cyclic AMP to 12.69 pmoles/10^6 cells. A single dose of brusatol (100 μg/kg) on Day 10 increased cyclic AMP by 167% after 1 hr. Bruceoside A for 3 days increased cyclic AMP only to 2.74 pmoles/10^6 cells. Bruceantin caused an increase to 5.49 pmoles of cyclic AMP/10^6 cells. Histone phosphorylation by ATP for the 10-day P-388 cells was 241 cpm/mg of protein, which was reduced 36% by brusatol. Nonhistone phosphorylation for the 10-day P-388 cells was 6246 cpm/mg of protein, which was reduced 8% by brusatol.

^{14}C-Formate incorporation into purine for the 10-day P-388 cells was 19,807 dpm/mg of protein. Brusatol treatment reduced purine synthesis 50%, whereas bruceoside A reduced it only 4%. Phosphoribosyl pyrophosphate aminotransferase activity for the 10-day P-388 cells was 0.285 O.D. unit/min/mg of protein, which was reduced 43% by brusatol. Carbamyl phosphate synthetase activity for 10-day P-388 cells was 1.8 mg of carbamyl phosphate formed/hr/mg of protein, which was unaffected by brusatol. Aspartate carbamyl transferase activity for 10-day P-388 cells was 44.4 mg of carbamyl aspartate formed/hr/mg of protein, which was reduced 7% by brusatol.

In vivo dihydrofolate reductase activity was reduced 30% by brusatol. Ribonucleotide reductase activity of 10-day P-388 cells was 517,053 dpm/mg of protein, which was reduced 14% by brusatol. *S*-Adenosyl-L-methionine transferase activity of 10-day P-388 cells was 251 dpm/mg of protein, which was unaffected by brusatol. Purine and pyrimidine base concentration after 3 days of brusatol treatment was reduced 17%. *In vitro* incorporation of ^{14}C-thymidine into DNA of 10-day P-388 cells in the presence of deoxyguanosine triphosphate, deoxyadenosine triphosphate, deoxycytidine triphosphate, and 0.005 *M* brusatol was inhibited only 14% (Table III). *In vivo* DNA polymerase activity was inhibited 16% by brusatol.

UV spectral studies demonstrated that brusatol had absorption peaks at 219 and 279 nm. Bruceoside A had an absorption peak at 270 nm. DNA had absorption peaks at 260 and 220 nm. Deoxyguanosine monophosphate had absorption peaks at 270 and 253 nm. Since these spectra overlapped, it was difficult to determine if binding occurred between nucleotides and drugs. However, when the drug was present, the absorption was higher for DNA and for deoxyguanosine monophosphate than would be expected for two single species in solution. The areas under the curves indicated that a combination of brusatol and DNA resulted in a 29% higher absorption than the calculated absorbances of both species added together. Brusatol and deoxyguanosine monophosphate combinations resulted in a 40% higher absorbance than the calculated

Table V—*In Vivo* Effects of Brusatol and Bruceoside A on P-388 Lymphocytic Leukemia Cell Metabolism of DBA/2 Mice ($n = 6$)

	Control	Percent Control: Brutasol, 100 μg/kg/day	Percent Control: Bruceoside A, 5 mg/kg/day
^{14}C-Thymidine incorporation into DNA	100 ± 17	23 ± 15[a]	52 ± 7[a]
^{3}H-Uridine incorporation into RNA	100 ± 16	32 ± 11[a]	45 ± 10[a]

absorbances. With DNA and deoxyguanosine monophosphate, bruceoside A likewise showed 73 and 18% higher absorbances, respectively, than the calculated absorbances of both species added together.

The Student t test was used to calculate the probable (p) significant difference in Tables II–V. Data are expressed as percent of control of the average mean and standard deviation; n equals the number of animals per group.

DISCUSSION

The effects of five quassinoids on P-388 lymphocytic leukemia metabolism are diverse. Although bruceantin, brucein D, brucein E, bruceoside A, and brusatol cause drastic inhibition of protein and RNA synthesis of cultured P-388 leukemic cells, these effects could not be correlated directly with cell death. Of these agents, Liao *et al.* (3) observed that compounds that did not contain the quassinoid ester side chain caused less protein synthesis reduction in HeLa cells and rabbit reticulocytes. These investigators postulated that the ester side chain at C-15 was necessary for drug transport across the cell membrane. Studies with P-388 cells do not support this postulate; brucein D and brucein E both inhibited protein synthesis. Actually the P-388 tumor cell membrane appears to retard transport of brusatol and bruceantin into the cell.

The inhibition of DNA synthesis showed the strongest correlation with antitumor activity in the P-388 lymphocytic leukemia survival system. DNA template activity, as observed through DNA polymerase activity, both *in vitro* and *in vivo* and RNA polymerase activity *in vitro* were inhibited marginally by the quassinoids. The nucleotide UV spectral studies showed absorbance increases in the presence of brusatol or bruceoside A above the calculated absorbance of the two individual species in solution, which may reflect partial or limited drug binding to the template and suppression of polymerase template activity. *In vitro* thymidylate synthetase inhibition correlated with antitumor activity for the quassinoids. Dihydrofolate reductase also was inhibited marginally by the quassinoids, with brusatol having the most activity. However, brusatol was only one-half as active as methotrexate at the same concentration. The nucleotide kinases did not appear to be a site of metabolism inhibition by the quassinoids.

In vivo quassinoid effects on P-388 lymphocytic leukemia cells at Day 10 were similar to the effects on DNA, RNA, and protein syntheses after 3 days of dosing. Brusatol required a dose of 100 μg/kg/day to bring about the same magnitude of inhibition as an *in vitro* concentration of 0.015 mM, whereas bruceoside A required a dose of 5 mg/kg/day. The *in vivo* doses correlated positively with doses required for antineoplastic activity in the P-388 survival system. The observation that brusatol was more active *in vivo* than bruceoside A raised the question whether brusatol is bioactivated *in vivo* to the active species, which is not fully seen in the *in vitro* studies.

Elevated cyclic AMP levels correlated with antineoplastic activity, brusatol > bruceantin > bruceoside A. Elevated levels of cyclic AMP reverse malignant states to a more normal cell (33, 34) and are correlated with less phosphorylation of the regulatory H-1 histone fraction, thereby reducing cell proliferation (35). Brusatol treatment moderately reduced histone phosphorylation, whereas nonhistone phosphorylation was unaffected. Cancer cells are also known to have a high proteolytic activity on the membrane surface. The quassinoids effectively blocked P-388 cathepsin proteolytic activity. Purine synthesis was significantly inhibited by brusatol but not by bruceoside A. The regulatory enzyme of purine synthesis, phosphoribosyl pyrophosphate aminotransferase, was a major site of brusatol inhibition. The enzyme was less affected by brusatol *in vitro* at 0.015 mM, again possibly indicating *in vivo* drug bioactivation.

Early steps in pyrimidine synthesis were not affected by brusatol. One carbon transfer from *S*-adenosyl-L-methionine also was unaffected by brusatol. Purine in the P-388 cells after 3 days of treatment also was reduced. A drastic purine reduction was not seen, which may have been due to the salvage pathway of purine from already synthesized nucleic acid. When DNA polymerase was assayed in the presence of added triphosphate deoxyribonucleotide, only marginal inhibition by brusatol *in vitro* was observed. One means of determining if the lack of purine for DNA synthesis was the prime factor in inhibition of ^{14}C-thymidine incorporation was to add nucleotide to the medium. In the presence of ample purine and pyrimidine, thymidine incorporation was inhibited only 14%, which probably reflects brusatol inhibition of DNA polymerase. Lack of purine would also explain the reduction in RNA synthesis. The reduction of ribose to deoxyribose nucleotide also was marginally inhibited in brusatol.

From these studies, it can be concluded that brusatol and bruceoside A have multiple sites of action on P-388 lymphocytic cells. Brusatol appeared to be more potent and effectively blocked a number of metabolic sites necessary for nucleic acid synthesis. Quassinoid effects on protein synthesis are currently being investigated. Preliminary data support the observation of Fresno *et al.* (4) that the elongation process of protein synthesis is the site of brusatol and bruceoside A inhibition.

Abstract □ Brusatol, a quassinoid with potent antineoplastic activity against P-388 lymphocytic leukemia cell proliferation, significantly inhibited P-388 cell hexokinase, phosphofructokinase, malic dehydrogenase, and succinic dehydrogenase. Mitochondrial oxidative phosphorylation, basal, and adenosine diphosphate-stimulated respiration, utilizing succinate and α-ketoglutarate as the substrate, was suppressed significantly by *in vivo* treatment with brusatol. However, brusatol treatment had no effect on liver oxidative phosphorylation. Brusatol greatly increased P-388 cyclic AMP levels but had no effect on liver cyclic nucleotides. Similar inhibitory effects on P-388 cell oxidative phosphorylation were found *in vitro* with brusatol, bruceoside A, and bruceantin. Brusatol had no effect on adenosine triphosphatase activity or on uncoupling of oxidative phosphorylation. Rather, brusatol appeared to increase the concentration of reduced mitochondrial electron-transport cofactors, thereby blocking aerobic respiration. A proposed mechanism of action is discussed.

Keyphrases □ Antineoplastic agents—brusatol, bruceoside A, bruceantin, effect on cellular respiration of P-388 leukemia cells, *in vivo, in vitro* □ Quassinoids—antineoplastic activity, effect on cellular respiration of P-388 leukemia cells, *in vivo, in vitro* □ Leukemia, P-388—effect of quassinoids on cellular respiration, *in vivo, in vitro* □ Cellular respiration—P-388 leukemia cells, effect of various quassinoids

Numerous quassinoids have been isolated recently, *e.g.*, bruceantin (I) from *Brucea antidysenterica* (1), bruceoside A (II) from *Brucea javanica* (2), and its subsequent hydrolysis product brusatol (III). All three agents are active in the P-388 lymphocytic leukemia survival system. Bruceantin has a T/C = 197 at 1 mg/kg/day, bruceoside A has a T/C = 156 at 6 mg/kg/day, and brusatol has a T/C = 158 at 125 μg/kg/day (3). At a concentration of 0.015 m*M*,

all of these quassinoids significantly inhibited DNA, RNA, and protein syntheses in P-388 cells.

A positive correlation between aerobic respiration inhibition and antitumor–antimitotic activity has been observed for a number of nonrelated compounds, *e.g.*, a podophyllotoxin derivative, ellipticine, 4,6-diaminotriazines, methotrexate, naphthoquinone derivatives, tritylthioalanine, carminomycin, piperazinedione (4), 5-fluorinated pyrimidine-6-carboxyaldehydes (5), benzamalecene, triparanol (6), and sesquiterpene lactones (7). Sesquiterpene lactone antineoplastic agents also have been observed to suppress tumor cell glycolytic and Krebs cycle dehydrogenase activity enzymes (8). This paper reports the effect of quassinoids on P-388 lymphocytic leukemia aerobic and anaerobic cell metabolism.

EXPERIMENTAL

Materials—Bruceantin (I) was obtained in small quantities from the National Cancer Institute. Bruceoside A (II) was extracted from *B. javanica* according to the literature technique (2), and brusatol (III) was obtained by treating II with 3 *N* sulfuric acid–methanol (1:1) to hydrolyze the glycosidic linkage (2).

P-388 Lymphocytic Leukemia Cell Metabolism Studies—DBA/2 male mice (~25 g) were inoculated with 10^6 P-388 lymphocytic leukemia cells intraperitoneally on Day 0. For the *in vitro* studies, P-388 lymphocytic leukemia cells were harvested from the peritoneal cavity on Day 10. For the *in vivo* studies, the mice were treated on Days 7, 8, and 9 with 100 μg/kg/day ip of brusatol or 5 mg/kg/day ip of bruceoside A. Drugs were prepared by homogenization in 0.05% polysorbate 80 and water.

The number of tumor cells per milliliter and the 0.4% trypan blue uptake were determined with a hemocytometer (9). Phosphofructokinase activity of 10-day cells was determined by a literature method (10) based on the absorbance change of 1.125 μmoles of reduced nadide (nicotinamide adenine dinucleotide) at 340 nm. Hexokinase activity was assayed by a literature method (11) based on the absorbance change of 500 μmoles of nadide phosphate at 340 nm. Lactic dehydrogenase activity was determined by a literature method (12) based on absorbance changes of 0.12 μmole of reduced nadide at 340 nm.

Succinic dehydrogenase activity was determined by a literature method (13) based on the reduction of potassium ferric cyanide to the ferrous ion at 455 nm. Malic dehydrogenase activity was measured by a literature technique (14) based on absorption changes of 15 μmoles of reduced nadide. Protein concentrations were determined by the method of Lowry *et al.* (15).

In vitro respiration studies were carried out on 10-day P-388 lymphocytic leukemia cells. Oxygen consumption was measured with an electrode[1] connected to an oxygraph[2]. The reaction vessel typically contained 55 μmoles of sucrose, 22 μmoles of monobasic potassium phosphate, 22 μmoles of potassium chloride, 90 μmoles of succinate or 60 μmoles of α-ketoglutarate as the substrate, 22 μmoles of adenosine triphosphate, and 0.015 or 0.005 μmole of test drugs in a total volume of 1.8 ml at 37°. After the basal metabolic level (state 4) was obtained, 0.257 μmole of adenosine diphosphate was added to obtain the adenosine diphosphate-stimulated respiration rate (state 3) (7).

In vivo studies were conducted on 10-day cells after treatment of the DBA/2 mice. The method of Lindahl and Oberg (16) was used to determine if oxidative phosphorylation was uncoupled with 0.2 μmole of 2,4-dinitrophenol as an internal standard. The reaction medium contained, in 2 ml, 50 μmoles of phosphate buffer, 10 μmoles of magnesium chloride, 2 μmoles of diphosphate, 80 μmoles of glucose, excess hexokinase, 60 μmoles of pyruvate or succinate, and P-388 isolated mitochondria. Studies were carried out using the oxygraph. Measurement of individual electron-transport system components was carried out by a literature method (17) by recording differences in spectral absorption after incubating the P-388 lymphocytic leukemia mitochondrial suspensions (9000×*g* × 10 min) at pH 7.4 with 50 m*M* tromethamine hydrochloride, 50 m*M* potassium chloride, 50 m*M* sucrose, 10 m*M* inorganic phosphate, and either 4.2 m*M* glutarate plus 4.2 m*M* malate or 1.3 m*M* succinate as the substrate.

Nadide was measured at 340 and 374 nm, flavin adenine dinucleotide was measured at 455 and 500 nm, cytochrome b was measured at 410 and 430 nm, cytochrome c and c_1 was measured at 540 and 550 nm, and cytochrome oxidase was measured at 603 and 605 nm. The difference was obtained by calculating the difference between the reduced and oxidized cofactor forms, which was expressed as percent of the control. *In vitro* spectral studies were carried out by incubating 3.16 μmoles of nadide with 0.005 μmole of brusatol in phosphate buffer, pH 7.2, and measuring the appearance of the reduced form at 340 nm. Cytochrome c at 0.1 μmole was also incubated with brusatol, and the appearance of the reduced form was measured at 550 nm over 48 hr. Reduced nadide (6.5 μmoles) and brusatol (10 μmoles) were incubated at room temperature in 1 ml of 0.067 *M* phosphate buffer at pH 7.2 for 72 hr. The reaction medium was subjected to preparative TLC separation on silica gel plates eluted with chloroform–methanol (10:1). Spots were identified by UV absorption. Individual spots were scraped off the plate. An unknown spot was separated from the silica gel by column chromatography, which was eluted with acetone. Silica gel TLC showed a single spot at R_f 0.55 as compared to brusatol at R_f 0.64 whereas the cofactor remained at the origin.

Adenosine triphosphatase activity was measured in P-388 leukemia cells by the method of Suolinna *et al.* (18), and inorganic phosphate released was measured by the method of Chen *et al.* (19). Cyclic AMP levels were measured by a literature radioimmunoassay (20), using ^{3}H(G)-cyclic

AMP (39.8 Ci/mmole). Liver oxidative phosphorylation studies were carried out on nontumor-bearing DBA/2 male mice. The liver was excised, and a 10% homogenate in 0.25 *M* sucrose and 0.001 *M* edetic acid was prepared (21). Respiration was carried out on 0.1 ml of the homogenate in the reaction vessel. Cyclic AMP levels also were measured on the 10% homogenate.

RESULTS

Brusatol treatment of P-388 lymphocytic leukemia-bearing mice significantly reduced the activity of the glycolytic pathway regulatory enzymes of P-388 cells (Table I). Ten-day P-388 cells demonstrated a hexokinase activity as an absorbance change of 0.300 optical density (O.D.) unit/min/mg of protein, which brusatol reduced 38%. The phosphofructokinase activity for 10-day P-388 cells was 0.270 O.D. unit/min/mg of protein, which was reduced 46% by brusatol treatment. Krebs cycle dehydrogenase enzymes were also suppressed by brusatol. Malic dehydrogenase activity for control P-388 cells was 135.7 O.D. units/min/mg of protein, which brusatol reduced 57%. Succinic dehydrogenase activity for 10-day P-388 cells was 0.145 O.D. unit/min/mg of protein. Brusatol inhibited succinic dehydrogenase activity 75%.

In vitro oxidative phosphorylation studies showed that 0.015 μmole of bruceantin, bruceoside A, or brusatol at 0.015 and 0.005 μmole reduced states 3 and 4 respiration significantly (Table II). Basal respiration (state 4) with succinate as the substrate resulted in 11.44 μl of oxygen consumed/min/mg of protein. Adenosine diphosphate-stimulated respiration (state 3) with succinate was 20.76 μl of oxygen consumed/min/mg of protein. Basal respiration using α-ketoglutarate as the substrate resulted in 10.01 μl of oxygen consumed/min/mg of protein. State 3 consumption resulted in 19.17 μl of oxygen consumed/min/mg of protein.

Brusatol at 0.005 μmole *in vitro* caused a 50% inhibition of state 4 and state 3 with succinate as the substrate. Brusatol with α-ketoglutarate as the substrate caused a 41% inhibition of state 4 and a 39% inhibition of state 3. Both concentrations of brusatol, *i.e.*, 0.005 and 0.015 μmole, caused the same degree of suppression. Bruceoside A with succinate caused a 46% inhibition of state 4 and a 45% of inhibition of state 3. With α-ketoglutarate, bruceoside A caused a 42% inhibition of state 4 and a 34% inhibition of state 3. Bruceantin caused a 50% inhibition of state 4 and a 43% inhibition of state 3 with succinate and a 40% inhibition of state 4 and a 48% inhibition of state 3 with α-ketoglutarate.

At 100 μg/kg/day, brusatol suppressed *in vivo* state 4 basal respiration 78% and adenosine diphosphate respiration (state 3) 82% in the presence of succinate (Table I). α-Ketoglutarate basal respiration was suppressed 74% by brusatol treatment, and state 4 respiration was inhibited 71%. Bruceoside A treatment *in vivo* at 5 mg/kg/day caused a 7% inhibition of state 4 respiration and a 31% inhibition of state 3 with succinate. State 4 with α-ketoglutarate was inhibited 18% and state 3 was inhibited 25% by bruceoside A.

In vitro and *in vivo* studies with liver homogenates of nontumor-bearing animals demonstrated no changes in states 4 and 3 with either succinate or α-ketoglutarate as the substrate. *In vitro* state 3 studies with P-388 lymphocytic leukemia mitochondria with 0.005 μmole of brusatol showed that respiration was inhibited 29% with pyruvate and 49% with succinate as the substrate, respectively (Table II). 2,4-Dinitrophenol addition further suppressed state 3 respiration by 79% with pyruvate and 85% with succinate, indicating that oxidative phosphorylation was not uncoupled by brusatol. Adenosine triphosphatase activity after brusatol treatment was within normal limits (Table I).

Examination of the different spectra of cofactors of the electron-transport system showed that *in vivo* administration of brusatol increased the concentration of all reduced forms of the chain cofactors. Incubation with malate showed a 24% increase in reduced nadide, a 7% increase in reduced flavin adenine dinucleotide, a 13% increase in reduced cytochrome b, a 110% increase in reduced cytochrome c_1 and c, and a 100% increase in reduced cytochrome $\alpha_1 + \alpha_3$. Incubation with succinate resulted in a 198% increase in reduced flavin adenine dinucleotide, a 49% increase in reduced cytochrome b, a 216% increase in reduced cytochromes c_1 and c, and a 100% increase in reduced cytochrome $\alpha_1 + \alpha_3$.

In vitro studies showed the same trends but not as markedly. When brusatol was incubated with isolated nadide for 24 hr, there was a 26% increase in the reduced form; there was a 35% increase in reduced nadide after 40 hr, indicating that brusatol chemically reacted with the cofactor. When cytochrome c was incubated with brusatol, there was a 21% increase in reduced cytochrome c after 24 hr; after 48 hr, there was a 13% increase in reduced cytochrome c. Incubation of brusatol with reduced nadide demonstrated that the two agents chemically interacted to give a product that did not have the same R_f value as the two starting materials, suggesting the formation of an adduct between brusatol and the cofactor.

DISCUSSION

Brusatol treatment of P-388 lymphocytic leukemia-bearing mice significantly reduced the activities of enzymes of the Embden-Meyerhoff cycle and of the Krebs cycle. The key regulatory enzymes, hexokinase and phosphofructokinase, were significantly depressed by brusatol treatment. Krebs cycle dehydrogenase activities of malate and succinate were also significantly reduced. Succinate, which is a flavin adenine dinucleotide-linked dehydrogenase, was more severely depressed than malate dehydrogenase, which is a nadide-linked dehydrogenase. Oxidative phosphorylation processes of P-388 lymphocytic leukemia cells were significantly reduced by the quassinoids tested. With succinate as the substrate, both basal respiration (state 4) and adenosine diphosphate-stimulated respiration (state 3) were suppressed slightly more than with α-ketoglutarate as the substrate. Brusatol *in vivo* was more effective in reducing states 4 and 3 respiration with succinate or α-ketoglutarate.

Brusatol *in vivo*, however, did not affect normal liver respiration processes, nor did any of the quassinoids affect *in vitro* liver respiration at 0.015 μmole. The mitochondria studies showed that brusatol did not uncouple oxidative phosphorylation like 2,4-dinitrophenol does. Nor did brusatol treatment stimulate mitochondrial adenosine triphosphatase activity, which would facilitate the uncoupling of mitochondrial oxidative phosphorylation. Rather, brusatol appeared to act on the mitochondrial

electron-transport chain. *In vivo* studies showed drastic increases in the reduced forms of chain cofactors with either malate or succinate as the substrate. *In vivo* brusatol effects were more striking than *in vitro* effects on reducing cofactors, which may explain the observed increased effects of brusatol on *in vivo* states 4 and 3 respiration after 3 days of treatment as compared to *in vitro* effects. UV *in vitro* studies showed that brusatol chemically interacted with nadide increasing the reduced form absorbance at 340 nm. Cytochrome c, a heme, also was reduced in the presence of brusatol to the ferrous form with an increase in absorbance at 550 nm.

Although separation of the brusatol adduct and reduced nadide has not been achieved to date, incubation of the two agents showed that a possible reaction product existed. Nucleophilic attack of reduced nadide on the diosphenol ring A of brusatol may be postulated. If such an attack occurs, then complexation or alkylation of cofactor or functional groups of enzymes could account for the inhibitory effects of brusatol on P-388 lymphocytic leukemia cell metabolism with respect to the suppression of tumor cell anaerobic and aerobic respiration.

^{13}C-NMR Spectra of α-Adrenergic Blocking Agents

SHIVA P. SINGH *, SURENDRA S. PARMAR *x, SYLVIA A. FARNUM ‡, and VIRGIL I. STENBERG ‡

Received October 13, 1978, from the *Departments of *Physiology and ‡Chemistry, University of North Dakota, Grand Forks, ND 58202.* Accepted for publication January 17, 1979.

Abstract □ The natural abundance ^{13}C-NMR spectra of five α-adrenergic blocking agents, tolazoline, dibenamine, azapetine, phenoxybenzamine, and phentolamine, are reported. The chemical shifts of various carbon resonances were assigned on the basis of chemical shift theory, multiplicities observed in single-frequency off-resonance-decoupled spectra, relaxation times, and comparisons with the chemical shifts of model compounds.

Keyphrases □ NMR spectroscopy—analysis, tolazoline, dibenamine, azapetine, phenoxybenzamine, phentolamine □ α-Adrenergic blocking agents—analysis, NMR spectroscopy

Earlier studies reporting the ^{13}C-NMR spectra of antimalarials (1, 2), anti-inflammatory agents (3, 4), antipyretic analgesics (5), and central nervous system acting agents (6–10) prompted the assignments of the natural abundance ^{13}C-NMR chemical shifts of α-adrenergic blocking agents, 2-benzyl-2-imidazolone (I) (tolazoline), *N,N*-dibenzyl-β-chloroethylamine (II) (dibenamine), 6,7-dihydro-6-(2-propenyl)-5*H*-dibenz[*c,e*]azepine (III) (azapetine), *N*-(2-chloroethyl)-*N*-(1-methyl-2-phenoxyethyl)benzenemethanamine (IV) (phenoxybenzamine), and 3-[[(4,5-dihydro-1*H*-imidazol-2-yl)methyl](4-methylphenyl)amino]phenol (V) (phentolamine). The ^{13}C-NMR spectra of these therapeutic agents are of theoretical as well as of biological interest.

Both the proton noise-decoupled and single-frequency off-resonance-decoupled (SFORD) spectra of I–V were recorded using the Fourier transform technique. The proton noise-decoupled spectra of these compounds gave the chemical shifts of various carbon resonances, while the SFORD spectra provided the distinction of methyl, methylene, methine, and nonprotonated carbons. Furthermore, the relaxation time measurements differentiated nonprotonated carbons from protonated carbons.

The assignments of various carbon-13 signals were made on the basis of chemical shift theory (11), multiplicities observed in the SFORD spectra, percent integration of the signals in the proton noise-decoupled spectra, relaxation times, and chemical shifts of the corresponding carbons of model compounds (12).

I II III IV V

EXPERIMENTAL

The ^{13}C-NMR spectra of I–V were obtained on a spectrometer[1] operating at 15.00 kHz with tetramethylsilane as a reference. The samples were run in a 10-mm tube with deuterochloroform (30% w/v) as an internal lock and solvent for I–IV and deuterated dimethyl sulfoxide (30% w/v) as an internal lock and solvent for V. The spectrometer settings were: spectral width, 4 kHz; pulse width, 12 μsec (60°); and data points, 4 K. Relaxation time (T_1) measurements of all compounds were carried out in undegassed solutions and were calculated automatically by the computer by least-squares analysis (13) of the plot of ln $(I - I_t)$ *versus* T.

Azapetine phosphate and the hydrochlorides of tolazoline, dibenamine, phenoxybenzamine, and phentolamine, were converted into the corresponding free bases prior to the determination of their ^{13}C-NMR spectra.

RESULTS AND DISCUSSION

Tolazoline (I)—The chemical shifts and relaxation times of various I carbon resonances are recorded in Table I. The SFORD spectrum of I showed two singlets, two doublets, and two triplets. The two singlets farthest downfield having longer relaxation time are due to C-2 and C-7. Since the methyl substituent in the benzene nucleus causes an 8.9-ppm downfield shift to the *ipso*-carbon (11), the singlets at 136.1 and 166.5 ppm are assigned to C-7 and C-2, respectively.

The C-10 chemical shift could be differentiated from the C-8 and C-9 chemical shifts by its shorter relaxation time (T_1). In I, C-10 is *para* to the methylene substituent of the benzene nucleus. It should have a shorter T_1 value compared to C-8 and C-9 due to the anisotropic motion along the preferred long molecular axis, *i.e.*, from C-6 to C-10, where C-8 and C-9 show more motion, resulting in longer T_1 values due to less favorable dipole–dipole interaction (11). Also, methyl substituents in the benzene ring produce 0.1- and 2.9-ppm upfield shifts to *meta*- and *para*-carbons, respectively, and a 0.7-ppm downfield shift to the *ortho*-carbon (11). On this basis and the percent integration of signals, the doublet centered at 126.7 ppm is assigned to C-10 and the doublet at 128.5 ppm is assigned to both C-8 and C-9. These assignments compare well with their calculated values.

Table I—^{13}C-Chemical Shifts of Tolazoline

Assignment[a]	Multiplicity[b]	Relaxation Time[c]	Chemical Shift[d]
C-2	s	15.20	166.5
C-7	s	26.10	136.1
C-8, C-9	d	3.21	128.5
C-10	d	1.68	126.7
C-4, C-5	t	1.02	49.5
C-6	t	2.40	35.7

[a] Numbering of the carbons is shown in the structure. [b] Signal multiplicity obtained from SFORD spectrum; s = singlet, d = doublet, t = triplet, and q = quartet. [c] Relaxation time was measured in undegassed solution. [d] Chemical shifts are expressed in parts per million relative to tetramethylsilane.

[1] Jeol FX 60.

Table II—^{13}C-Chemical Shifts of Dibenamine

Assignment[a]	Multiplicity[b]	Relaxation Time[c]	Chemical Shift[d]
C-4	s	7.68	138.9
C-5[e]	d	1.02	128.5
C-6[e]	d	1.03	128.1
C-7	d	0.75	126.9
C-3	t	0.60	58.3
C-2	t	0.60	55.1
C-1	t	0.98	41.6

[a–d] See Table I. [e] May be interchanged.

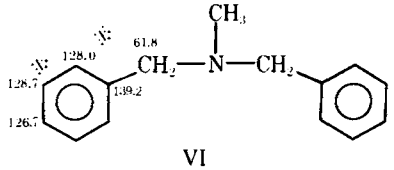
The C-4 and C-5 of the I imidazole ring are directly attached to the nitrogen atom and are in the same environment, so the signals due to these carbons should be observed at the same place. On this basis and the percent integration of the signals, the triplet centered at 35.7 ppm is assigned to C-6 and the triplet at 49.5 ppm is assigned to both C-4 and C-5.

Dibenamine (II)—As is evident from Table II, one singlet and three doublets in the downfield region and three triplets in the upfield region are observed in the ^{13}C-NMR spectrum of II; these signals account for all 16 carbon resonances. The four signals in the downfield region represent the 12 aromatic carbon resonances due to the plane of symmetry. The farthest downfield singlet at 138.9 ppm having a longer relaxation time is attributed to C-4. Considering the effect of a methyl substituent on the benzene nucleus (11) and the relaxation times of C-5, C-6, and C-7, where C-7 should have a shorter T_1 value compared to C-5 and C-6 (11), the doublets centered at 128.5, 128.1, and 126.9 ppm are assigned to C-5, C-6, and C-7, respectively. The assignments of C-5 and C-6 could be interchanged. Furthermore, these assignments compare well with the chemical shifts of the corresponding carbons of I and VI (12).

Previous studies reported that the amino group in aliphatic amines exhibits 20- and 2-ppm downfield shifts to α- and β-carbons, respectively (11). Also, chlorine in alkyl chlorides causes 23- and 2-ppm downfield shifts to α- and β-carbons, respectively (11). Both α- and β-carbons cause an ~9-ppm downfield shift while the γ-carbon produces a 2-ppm upfield shift (11). The chemical shift of the methyl group carbon resonance in toluene is 21.2 ppm (12). The C-3 is directly attached to the nitrogen atom and has two β- and one γ-carbons. Thus, the triplet centered at 58.3 ppm is best assigned to C-3. The C-1 has one α-chlorine, one α- and two γ-carbons, and one β-nitrogen; C-2 has one α- and two β-carbons, one α-nitrogen, and one β-chlorine. Considering these effects on the base peak of ethane (11), the triplets centered at 55.1 and 41.6 ppm are attributed to C-2 and C-1, respectively.

Azapetine (III)—The chemical shifts of the carbon resonances of III obtained from its ^{13}C-NMR spectrum and their relaxation times are recorded in Table III. The structure of III indicates that there is a plane of symmetry that reduces half of the aromatic carbon resonances. The signals at 140.9 and 134.4 ppm, observed as singlets in the SFORD spectrum of III and having longer relaxation times, must be due to C-5 and C-10. A phenyl substituent in the benzene ring produces a 13.1-ppm downfield shift to the *ipso*-carbon and a 1.1-ppm upfield shift to the *ortho*-carbon, and a methyl group causes 8.9- and 0.7-ppm downfield shifts to *ipso*- and *ortho*-carbons, respectively (11). The singlets at 140.9 and 134.3 ppm are assigned to C-10 and C-5, respectively.

The chemical shift of the ethylene carbon resonance is 123.3 ppm (11). The vinylic carbon C-2 has one α- and two γ-carbons and one β-nitrogen while C-1 has one α′- and two γ′-carbons and one β′-nitrogen. The α- and γ′-carbons cause 10.6- and 1.5-ppm downfield shifts, respectively, while γ and α′ produce 1.5- and 7.9-ppm upfield shifts, respectively, in alkenes (11). The β-nitrogen exhibits a 2-ppm downfield shift (11). On this basis, the doublet centered at 136.1 ppm and the triplet centered at 117.7 ppm



VI

Table III—^{13}C-Chemical Shifts of Azapetine

Assignment[a]	Multiplicity[b]	Relaxation Time[c]	Chemical Shift[d]
C-10	s	21.30	140.9
C-2	d	1.80	136.1
C-5	s	15.00	134.3
C-6	d	1.20	129.5
C-7[e]	—	0.87	127.7
C-8[e], C-9[e]	—	1.10	127.4
C-1	t	0.92	117.7
C-3	t	0.75	58.2
C-4	t	0.68	54.5

[a-d] See Table I. [e] See Table II.

are assigned to C-2 and C-1, respectively. The signals at 129.5 and 127.7 ppm are assigned to C-6 and C-7, respectively, and the signal at 127.4 ppm is assigned to both C-8 and C-9 on the basis of chemical shift theory and percent integration of the signals. The assignments of C-7, C-8, and C-9 may be interchanged.

The upfield triplets centered at 58.2 and 54.5 ppm are assigned to C-3 and C-4, respectively, on the basis of chemical shift theory and signal intensity observed in the proton noise-decoupled spectrum of III.

Phenoxybenzamine (IV)—The chemical shifts and relaxation times of the various carbon resonances of IV are recorded in Table IV. Thirteen separate signals in the proton noise-decoupled spectrum account for the 18 carbon resonances of IV. The carbon resonances of C-4 and C-10 could be easily separated from the others due to their longer relaxation times and multiplicities in the SFORD spectrum. Since methoxy and methyl substituents in the benzene nucleus exhibit 31.4- and 8.9-ppm downfield shifts to the *ipso*-carbon (11), respectively, the singlet at 158.7 ppm is assigned to C-10 and the singlet at 140.1 ppm is assigned to C-4. The benzene ring methoxy group causes a 1-ppm downfield shift to the *meta*-carbon and 14.4- and 7.7-ppm upfield shifts to *ortho*- and *para*-carbons, respectively (11). The chemical shift due to the methyl substituent in the benzene ring was already mentioned in the assignment of I carbon resonances. Thus, on the basis of signal intensities, multiplicities in the SFORD spectrum, and effects of methyl and methoxy substituents on the benzene ring, the doublets centered at 129.2, 128.2, 126.9, 120.5, and 114.3 ppm are attributed to C-12, both C-5 and C-6, C-7, C-13, and C-11, respectively. Furthermore, the assignments of C-4, C-5, C-6, and C-7 are in agreement with the corresponding carbon chemical shifts of II.

The farthest upfield quartet centered at 13.1 ppm could be easily assigned to C-14 on the basis of multiplicity and chemical shift theory. The signals at 42.9, 54.5, and 55.6 ppm are assigned to C-1, C-2, and C-3, respectively. These assignments are based on chemical shift theory and comparisons with the corresponding carbon chemical shifts of II. The chemical shift of C-3 is observed upfield compared to C-3 of II because C-3 of IV has two more γ-carbons, which produce about a 2-ppm upfield shift. The C-9 has one α-, one β-, and two γ-carbons, one α-oxygen, and one β-nitrogen while C-8 has two α-, two β-, and one γ-carbons, one α-nitrogen, and one β-oxygen. Considering the chemical shifts caused by carbon, nitrogen, and oxygen atoms (11), the triplet centered at 70.0 ppm is assigned to C-9 and the signal at 52.9 ppm is assigned to C-8.

Phentolamine (V)—The chemical shifts and relaxation times of the V various carbon resonances are shown in Table V. The SFORD spectrum gave five singlets, five doublets, two triplets, and one quartet. The singlets were confirmed by their longer relaxation times. The farthest downfield

Table IV—^{13}C-Chemical Shifts of Phenoxybenzamine

Assignment[a]	Multiplicity[b]	Relaxation Time[c]	Chemical Shift[d]
C-10	s	12.10	158.7

Table V—^{13}C-Chemical Shifts of Phentolamine

Assignment[a]	Multiplicity[b]	Relaxation Time[c]	Chemical Shift[d]
C-2	s	2.60	165.9
C-15	s	2.00	158.3
C-13	s	3.10	149.6
C-7	s	3.70	145.0
C-10	s	2.80	132.2
C-9, C-11, C-17	d	0.34	129.7
C-8, C-12	d	0.31	123.9
C-18	d	0.14	108.2
C-16	d	0.12	107.2
C-14	d	0.18	104.9
C-6	t	0.10	51.1
C-4, C-5	t	0.13	49.1
C-19	q	0.92	20.4

[a-d] See Table I.

singlet at 165.9 ppm is assigned to C-2 by comparing the chemical shift of C-2 in I. Considering the chemical shifts caused by amino, hydroxy, and methyl substituents on the benzene ring (11), the singlets at 158.3, 149.6, 145.0, and 132.2 ppm are assigned to C-15, C-13, C-7, and C-10, respectively. The doublet centered at 129.7 ppm is assigned to C-9, C-11, and C-17, and the doublet at 123.9 ppm is assigned to C-8 and C-12. The remaining doublets at 108.2, 107.2, and 104.9 ppm are assigned to C-18, C-16, and C-14, respectively. The assignments are made on the basis of chemical shift theory (11) and signal intensity.

The quartet centered at 20.4 ppm is attributed to C-19, which agrees well with the toluene methyl carbon chemical shift (12). The triplet centered at 49.1 ppm is assigned to C-4 and C-5 on the basis of signal intensity and chemical shift theory. Furthermore, this assignment is supported by the corresponding carbon chemical shifts of I. The remaining triplet centered at 51.1 ppm is assigned to C-6.

Synthesis of Phenyl-3- and Phenyl-5-acetamidosalicylates as Potential Analgesics

KHALID SABIH A. RAZZAK

Received April 24, 1978, from the *College of Pharmacy, University of Baghdad, Baghdad, Iraq.* Accepted for publication January 17, 1979.

Abstract □ Phenylsalicylate was nitrated to obtain two nitro isomers, which were separated and reduced to the corresponding amines followed by acetylation to give phenyl-5- or phenyl-3-acetamidosalicylate. Phenyl-5-acetamidosalicylate displayed analgesic activity comparable to that of aspirin and phenacetin at doses of 25–50 mg/kg sc and was much less toxic than the latter compounds. Phenyl-3-acetamidosalicylate, however, was ineffective at a similar dose range and caused restlessness at larger doses.

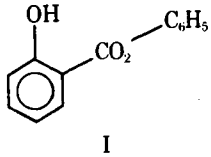
Keyphrases □ Phenylsalicylates—synthesis of phenyl-3- and phenyl-5-acetamidosalicylates, analgesic activity □ Analgesics—phenylsalicylates, derivatives, synthesis, tested for analgesic activity □ Antitubercular agents, potential—phenylsalicylates, synthesis, analgesic activity

Phenylsalicylate (I) has been used as an analgesic and as an enteric coating material for oral dosage forms (1). It also has several other industrial uses (2). However, it has been replaced by more potent and safer analgesic–antipyretic drugs such as aspirin and acetaminophen (II). Aminosalicylic acid (III), phenyl-*p*-aminosalicylate (IV), and their corresponding acetyl derivatives have been used for the treatment of tuberculosis (3–6) in conjunction with other antitubercular agents.

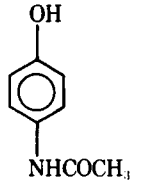
This report describes the synthesis of some new phenylsalicylate derivatives (V–X) as potential analgesic–antipyretic agents with possible antitubercular activity. Compound VIII is a combination of phenylsalicylate and acetaminophen in one molecule. Furthermore, VII–X are isomers of phenyl-4-amino- or phenyl-4-acetamidosalicylates, which are used as antitubercular agents.

EXPERIMENTAL[1]

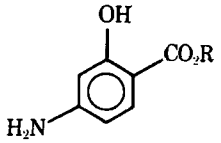
Phenyl-3- and Phenyl-5-nitrosalicylates (V and VI)—A solution of 40 g (0.184 mole) of phenylsalicylate[2] in acetic acid was treated with 50 ml of nitric acid (68%) in acetic acid (1:1) dropwise with stirring and cooling in an ice bath for 20 min. The temperature was raised to 30–35°



I

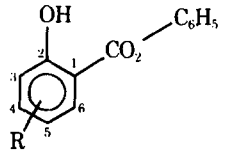


II



III: R = H
IV: R = C_6H_5

and maintained for 5–6 min, during which time the reaction mixture turned deep orange. The mixture was poured over 200 g of crushed ice. Upon stirring, an orange solid material separated. This material was filtered, washed with alcohol, and dried to give 45 g of nitrated salol.



V: R = 5-nitro
VI: R = 3-nitro
VII: R = 5-amino
VIII: R = 5-acetamido
IX: R = 3-amino
X: R = 3-acetamido

Compounds V and VI were separated by fractional crystallization from ethanol; V crystallized immediately from the hot alcoholic solution. Further recrystallization of this fraction from alcohol gave 20 g (0.078 mole, 42%) of white needle-like crystals, mp 148–150°. Compound VI was obtained upon standing and cooling of the alcoholic mother liquor to give colorless crystals, mp 87–89°. Further recrystallization of this fraction from alcohol gave 22 g (0.097 mole, 52%) of VI, mp 99–100°.

The mass spectra of V and VI showed identical molecular ions at *m/e* 259 ($C_{13}H_9NO_5$); IR of V ($CHCl_3$): ν_{max} 3250–3090, 3010, 1690, 1630, 1530, 1350, and 840 cm^{-1}; NMR of V ($CDCl_3$): δ 11.18 (1H, s), 9.04 (1H at C-6, d, J = 2.6 Hz), 8.42 (1H at C-4, dd, J = 9.4 and 2.6 Hz), 7.16 (1H at C-3, d, J = 9.6 Hz), and 7.6–7.18 (5H, complex m) (one replaceable proton); IR of VI ($CHCl_3$): ν_{max} 3250–3090, 3010, 1690, 1630, 1530, 1350, 900, 860, and 840 cm^{-1}; NMR of VI ($CDCl_3$): δ 11.71 (1H, s), 8.32 (1H at C-4, dd, J = 8 and 1.7 Hz), 8.22 (1H at C-6, dd, J = 8.2 and 1.7 Hz), and 7.6–7.01 (6H, complex m) (one replaceable proton).

Nitro Derivative Reduction—A sample of 13 g of V or VI (0.05 mole) was dissolved in a minimum amount of chloroform and mixed with 200 ml of methanol or ethanol, 0.3 g of platinum oxide or palladium, and 1–2 g of activated charcoal. The mixture was placed in a hydrogenator[3], and hydrogenation of the nitro derivatives was allowed to proceed until no more hydrogen was absorbed. The reduction yield was based on the amount of hydrogen absorbed by the nitro derivatives.

In both cases, complete reduction was obtained, as indicated by the absorption of 3.4 liters (3 equivalents) of hydrogen in each reduction process. The reduction mixture was filtered, and the residue was washed with ~50 ml of alcohol. The combined filtrate and washings were taken to dryness under vacuum, and the residue was dissolved in 5% HCl. The amine hydrochloride was used for the next step without further purification.

Amine Acetylation—The aqueous solution of the hydrochloride of VII or IX was heated to 50° and mixed with 60 ml of acetic anhydride. A freshly prepared solution of 100 g of sodium acetate in 100 ml of water was heated to 50° and added to the mixture with stirring and cooling in an ice bath for 30 min. The acetamido derivatives were filtered and purified by recrystallization from ethanol or ethanol–water. Compound VIII was obtained in an 84% yield, and X was obtained in an 80% yield. The physical constants of VIII and X are shown in Table I.

Compound VIII was white to slightly pink needle-like crystals, mp 174–177°. Its mass spectrum showed a molecular ion at *m/e* 271; IR ($CHCl_3$): ν_{max} 3430, 3250, 3010, 1680, 1670, 1610, 1360, 1270, and 1050 cm^{-1}; NMR ($CDCl_3$): δ 2.17 (3H, s), 6.98 (1H at C-3, d, J = 8.8 Hz), 7.12–7.54 (5H, complex m), 7.62 (1H at C-4, dd, J = 8.5 and 2.4 Hz), and 8.22 (1H at C-6, d, J = 2.6 Hz).

Compound X was white to slightly greenish flakes, mp 165–166°. Its mass spectrum showed a molecular ion at *m/e* 271; IR ($CHCl_3$): ν_{max} 3420, 3180, 3010, 1680, 1670, 1610, 1360, 1280, 1060, and 980 cm^{-1}; NMR ($CDCl_3$): δ 2.23 (3H, s), 6.98 (1H at C-5, t, J = 8 Hz), 7.15–7.58 (5H, complex m), 7.78 (1H at C-4, dd, J = 8 and 1.5 Hz), and 8.65 (1H at C-6, dd, J = 8 and 1.5 Hz).

[1] Melting points were determined using a Büchi apparatus and are uncorrected. The structures of all compounds were confirmed by IR, NMR, and mass spectra. IR spectra were recorded on IR-257 and IR-221 spectrophotometers (Perkin-Elmer). NMR spectra were determined as solutions in deuterochloroform, with tetramethylsilane as the internal standard, on a WH-90 instrument (Bruker). The WH-90 instrument was connected to a computer (model B-NC 12) with a FINMR V 51218 program.

Mass spectra were recorded by Morgan-Schaffer Corp., Montreal, Canada. The spectra of V, VI, and VIII were recorded on a Hitachi Perkin-Elmer mass spectrometer (model RMU-6D) by introducing the samples by direct probe at 40° with an ionization voltage of 70 ev. The mass spectra of VIII and X were recorded on a CH-5 mass spectrometer (Varian MAT) by direct probe at 110° and 70 ev. TLC was performed on 0.25-mm precoated silica gel plates (Merck silica gel 60 F-254 or silica gel F-254). Materials on plates were detected with a UV lamp. NMR data are expressed in δ. Microanalyses were performed by Dr. Daessle, Organic Micro-Analysis Laboratories, Montreal, Canada.

[a] Two R_f values are reported for each compound in different solvents. The first value represents the R_f on silica gel 60 F-254 (slow moving); the second value represents the R_f on silica gel F-254 (fast moving). [b] Lit. (7, 8) mp 150–151°. [c] Lit. (8) mp 101–102° for anhydrous. The compound was dried after analysis to give mp 99–100°. [d] The compound did not move.

Biological Testing of VIII and X—Solutions of VIII or X in dimethyl sulfoxide or propylene glycol or suspensions in 1% methylcellulose were administered to groups of six, eight, or 10 albino MRI female or male mice weighing 18–20 g. The doses were 25, 50, 100, 200, 300, 400, and 500 mg/kg. Twenty minutes later, the mice were given, intraperitoneally, 0.2 ml of a 0.02% solution of phenyl-*p*-quinone in water containing 5% alcohol.

The mice for each dose were placed in separate cages and observed for 20 min. Those that showed signs of writhing were removed from the cage. The ED_{50} data of VIII are shown in Table II. Compound X was ineffective at doses of 50 and 200 mg/kg.

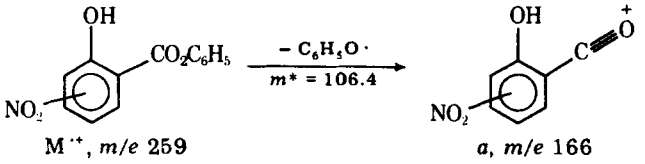
RESULTS AND DISCUSSION

Chemistry—Several nitro derivatives of phenylsalicylate have been made by treatment of nitrosalicylic acid and phenol with phosphorus oxychloride or by treatment of salicylic acid and nitrophenol with phosphorus oxychloride (7–9). Other investigators (10) nitrated salicylic acid and salicylamide by treatment of these compounds with nitric acid to obtain the corresponding 3- and 5-nitro derivatives. Our approach to the synthesis of V and VI also involved direct nitration of I with nitric acid. This procedure achieved almost complete conversion of I into V and VI.

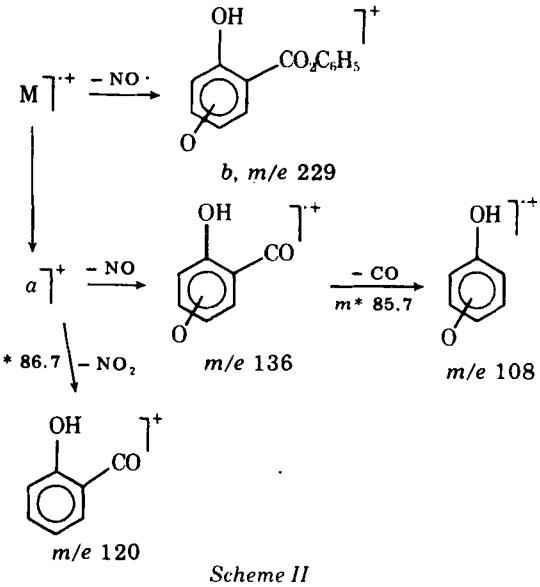
Evidence for structural identification of V and VI was obtained from mass spectral (Table III) and NMR studies. Both compounds had a molecular ion at *m/e* 259 with relative intensities of 95% for V and 76.5% for VI. These data indicate that one nitro group is introduced in both compounds and that the molecular ion of V is more stable than that of VI[4] (11). Isotopic analysis gave good agreement with the theoretical value for $C_{13}H_9NO_5$ (Table IV). The mass spectra of both compounds were similar except for the quantitative differences in the relative peak intensities.

Both V and VI showed peaks at *m/e* 166 (100%) upon electron impact. This peak may be represented by ion *a* (Scheme I), which indicated the introduction of the nitro group onto the salicylate ring of I.

The peak at *m/e* 229 may be represented by ion *b* (M − NO). This ion may result from the rearrangement of the nitro group prior to loss of the NO group (12–16). The intensity difference of this peak in the mass spectra of V and VI can be attributed to the differences in the nitro group position in the two molecules (12–16). Such rearrangement has been reported for several *para*- and *meta*-substituted nitrobenzene derivatives. The *ortho*-derivatives lack such rearrangement or show peaks of very low intensity corresponding to ions resulting from this rearrangement. This type of rearrangement was also observed for ion *a* (Scheme II and Table III).



Scheme I



Scheme II

The IR spectra of various V and VI concentrations also were studied to reveal the effect of the nitro group on hydrogen bonding in phenylsalicylate. Both compounds showed broad absorption bands at 3300–3090 cm^{-1} in concentrations ranging between 2.5 and 12.5% in chloroform. No shift was observed in the absorption band of the hydroxyl group in this region. This result may indicate that the nitro group position in the salicylate ring had no effect on the intramolecular hydrogen bond that exists in I (17–19) between the hydroxyl group and the carboxyl group.

The mass spectral data for V and VI suggest that the former compound may have a 1,2,5-substitution and that the latter may have a 1,2,3-substitution. NMR and decoupling studies confirmed this evidence. At the low field end of the aromatic region of the NMR spectrum of V, there was a doublet at δ 9.04 with splitting of 2.6 Hz. The chemical shift indicated the resonance of the proton at C-6 with the two *ortho*-positions occupied by electron-withdrawing groups. The *J* value indicated the presence of a *meta*-proton (20–23), indicating the presence of a proton at C-4 whose signal appeared as two doublets at 8.42 with splitting of 9.4 and 2.6 Hz. This finding indicated the presence of *meta*- (at C-6) and *ortho*- (at C-3) protons. The signal of the latter appeared as a doublet at 7.16 with

Table II—Biological Testing Data of VIII

Dose, mg/kg	Number of Mice	Percent Protection
25	8	37.50
50	6, 6, 8[a]	50.00
100	8, 8, 10[a]	66.60
200	6	83.30
300	6	83.30
500	6, 8[a]	100.00

[a] The experiment was repeated using the number of animals shown, and percent protection represents the average.

Table III—Mass Spectral Data of V and VI

m/e	Percent V	Percent VI
92	64.4	22.4
108	11.2	3.0
120	81.4	69.2
121	15.0	10.0
166	100.0	100.0
229	11.9	3.3
259	95.1	76.5
260	43.9	17.0
261	6.3	2.9

splitting of 9.6 Hz, which indicated the presence of an *ortho*-proton (at C-4). The decoupling study confirmed this assignment since irradiation of H-3 removed the *ortho*-coupling to H-4, which appeared as a doublet with *meta*-splitting. Irradiation of H-4 removed the *ortho*-coupling to H-3, which appeared as a singlet, and the *meta*-coupling to H-6, which also appeared as a singlet. Irradiation of H-6 removed the *meta*-coupling to H-4, which appeared as a doublet with *ortho*-splitting only. These data indicate that the salicylate ring protons in V have a 1,2,4-relationship.

The NMR spectrum of VI showed a two-doublet signal at δ 8.32 with splitting of 8 and 1.7 Hz, characteristic of *ortho*- and *meta*-splitting, respectively (20–23). This signal was assigned to the proton at C-4. The signal representing the C-6 proton of the salicylate ring also appeared as a doublet at δ 8.21 with splitting of 8.2 and 1.7, which indicated the presence of *ortho*- and *meta*-protons at C-5 and C-4, respectively. However, the signal representing C-5 proton was included in the complex multiplet at δ 7.60–7.01. The decoupling study confirmed this assignment since H-5 irradiation removed the *ortho*-splitting with H-4 and H-6 and both appeared as doublets with *meta*-splitting to each other. Irradiation of H-4 or H-6 removed the *meta*-splitting to each other, and their signals appeared as doublets with *ortho*-splitting. These data indicate that the nitro group occupies the 3-position and that the protons in VI have a 1,2,3-relationship.

Reduction of the isomeric nitro salols was achieved by simple catalytic hydrogenation in very high yields. The corresponding amines were acetylated by treatment of the amines with acetic anhydride to produce the corresponding acetamido derivatives (VIII and X) in high yields. In contrast to the IR spectra of V and VI, the IR spectra of VIII and X showed a clear difference in the hydroxyl group absorption band. The hydroxyl absorption band in the IR spectrum of X appeared at 3180 cm^{-1}; in the IR spectrum of VIII, it appeared at 3250 cm^{-1}. This difference may be based upon the different types of hydrogen bonding the molecules undergo.

The mass spectra of VIII and X also were similar (Table V), and the fragmentation pattern was comparable to that of the nitro derivatives. The appearance of a peak at *m/e* 178 (100%) may have arisen from the loss of a phenoxide radical from the molecular ion (*m/e* 271), as shown in Scheme III together with the other important fragmentations.

The NMR spectra of VIII and X and the decoupling study were consistent with the positional assignment of the acetamido group (Table VI).

Biological Testing and Toxicity—Compounds VIII and X were tested for analgesic activity in the writhing test (24). Compound VIII had comparable analgesic activity to that of aspirin and phenacetin. The ED_{50} of VIII under the experimental conditions was 56 mg/kg (27–122) when the writhing material was injected 20 min after treatment of the mice. However, X was ineffective at 50 mg/kg and caused restlessness at 200 mg/kg upon injection of the writhing material. Compound VIII was nontoxic at doses of 1 and 2 g/kg sc and caused 10% death of the mice at 3 g/kg ip during 24 hr.

Conductivity and Hardness Changes in Aged Compacts

RAJKUMAR P. BHATIA * and NICHOLAS G. LORDI ˣ

Received August 8, 1978, from the *College of Pharmacy, Rutgers—The State University, Piscataway, NJ 08854.* Accepted for publication January 28, 1979. *Present address: Alcon Laboratories, Fort Worth, TX 76133.

Abstract □ Batches of sodium, potassium, and ammonium chloride tablets containing no excipients and spray-dried lactose tablets containing 0.5% magnesium stearate were stored at 20 and 76% relative humidity. Electrical resistance and hardness measurements were made within 1 hr after compression and at intervals during a 45-day period. Hardness values of sodium, potassium, and ammonium chloride tablets stored at 20% relative humidity increased from 70 to 200% at 45 days, while conductances decreased 10-fold. Tablets stored at 76% relative humidity showed no increases or slight decreases in hardness with slight increases in conductance. Lactose tablets decreased slightly in hardness with corresponding increases in conductance.

Keyphrases □ Conductivity, electrical—effect of aging and humidity, various compressed tablets □ Hardness—effect of aging and humidity, various compressed tablets □ Tablets, compressed—effect of aging and humidity on electrical conductivity and hardness

The effect of aging on the physical characteristics of tablets has been discussed by several investigators. Increased hardness was reported in hydrochlorothiazide tablets formulated with acacia (1). Dibasic calcium phosphate dihydrate tablets displayed no significant changes in hardness over a 4-month period but showed significant increases in disintegration and dissolution times when stored at 25° and 50% relative humidity (RH) (2).

The crushing strength of sodium chloride compacts prepared from dried samples doubled 1 hr after compaction (3). No significant changes in crushing strength were observed when compacts were stored for longer periods at low humidities. This phenomenon was attributed to time-dependent relaxations, resulting in stress release within the compacts which increased interparticulate contact and bonding. Compacts with higher moisture content possessed low tensile strength compared to those with lower moisture content, which was attributed to weakening of interparticulate bonding by trace moisture (3).

Significant increases in hardness were observed in sodium chloride tablets stored for several days (4). These changes correlated with changes in electrical conductances calculated from measured dissipation factors.

The electrical conductance of a compact is determined in part by the number of interparticulate contact points and the effective internal surface area resulting from microscopic cracks and imperfections (5). Hardness changes in compacts should be associated with conductance changes that reflect changes in the contact area and internal surface. Increases in compact strength should be correlated with decreases in electrical conductance, measured under conditions in which there is no substantial increase in compact moisture content.

This study was designed to verify the expected relationship between conductance and hardness changes in compacts and to establish the role of moisture in affecting these changes in compacts of directly compressible salts.

EXPERIMENTAL

Materials—Since different lots of the same material show variations in electrical properties (6), single lots of USP grade sodium chloride, potassium chloride, ammonium chloride[1], and spray-dried lactose[2] were studied. Saturated solutions of sodium acetate (analytical reagent) and potassium acetate (analytical reagent) were used to maintain ~20 and 76% RH in 5-liter desiccators. The chloride salts were screened to isolate the 40–50-mesh fractions, which were dried at 65° for 24 hr before compaction.

Preparation and Treatment of Compacts—Batches of compacts were prepared from the 40–50-mesh fraction of unlubricated sodium, potassium, and ammonium chlorides and spray-dried lactose blended with 0.5% magnesium stearate. The latter was included as an example of a formulation that showed no significant hardness changes on aging. Tablets were compressed manually, using a 1.27-cm diameter punch and die assembly, on a single-punch tablet press[3].

Compacts of suitable weight, thickness, and hardness were produced and stored in the 20 and 76% humidity chambers. Resistance and hardness values were determined within 1 hr of compression and after 2, 7, 15, 30, and 45 days of storage. The 20 and 76% RH conditions were selected to observe the effect of drying and atmospheric moisture on compact conductance and hardness.

In some experiments, sodium chloride compacts were stored at 76% RH for 10 days and then transferred to 20% RH. Resistance and hardness values were measured at the time of transfer and after up to 45 days of storage at 20% RH.

A small batch of sodium chloride compacts was prepared using the 1.27-cm punch and die assembly on a hydraulic press[4] at 1800-, 2700-, and 3600-kg gauge pressures. Pressure was applied for at least 15 sec. Compacts were stored at 20% RH until subject to resistance and hardness measurements.

Conductance Measurements—The complete system for measurement of the electrical resistance of compacts was described previously (7). Compacts were placed on a grounded steel plate attached to the lower stage of the hydraulic press. A 2.5-cm diameter shielded tablet punch, which was fixed to the upper stage of the press through an insulating acrylic[5] block, served as the active electrode. A shielded cable connected the punch to an electrometer[6]. The lower stage of the press was raised until the tablet contacted the punch face.

A minimal pressure (<50 kg) was applied to minimize contact resistance. Stable resistance values were attained within 1 min and recorded. The thickness and weight of each compact were measured before testing for hardness. Specific conductances were calculated from the measured resistance and dimensions. This procedure was repeated on five different compacts to obtain each experimental point.

Hardness Measurements—A 1.27-cm diameter standard concave punch was fastened to the platform of a motorized linear drive[7] so that it was exactly centered beneath an indentation probe. The latter consisted

of an 0.4-cm diameter stainless steel ball bearing fixed to a threaded shaft, which was fastened to a 22.7-kg (50-lb) load cell[8]. The output of the load cell was amplified[9] and recorded[10]. The motorized drive was operated at a platform speed of 0.5 cm/min.

Compacts were placed on edge on the punch face, and the identation probe was driven diametrically into the compact, which split into two equal halves. Figure 1 shows a plot of measured force on the tablet as a function of time. Point A represents the onset of stress; point B represents the maximum stress the compact experienced prior to splitting, shown by line BC, which represents the sudden release in stress. In Fig. 1, AC represents the degree of indentation required to split the tablet. Hardness values were expressed in terms of the maximum force in kilograms required to split the compact.

RESULTS AND DISCUSSION

Tables I–III summarize observed conductance and hardness values of sodium, potassium, and ammonium chloride compacts stored at 20 and 76% RH for 45 days. Figure 2 shows relative changes in hardness compared to initial values as a function of time. Sodium and potassium chloride compacts stored at 20% RH exhibited marked increases in hardness along with significant decreases in specific conductance. Constant hardness and conductance values were observed after 15 days with

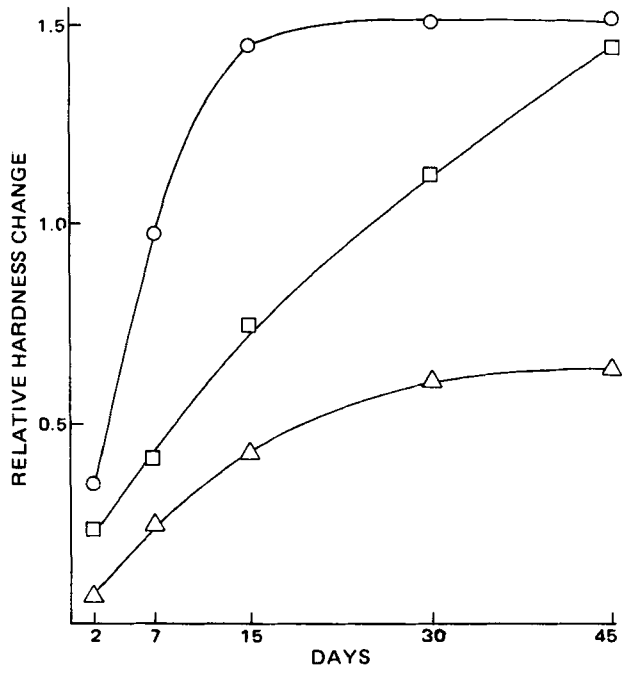

Figure 2—*Relative hardness changes observed in sodium (○), potassium (□), and ammonium chloride (△) compacts stored at 20% RH.*

sodium chloride and after 45 days with ammonium chloride. However, potassium chloride compacts continued to increase in hardness after 45 days. Measurements were made on compacts of equal density, as indicated by the constancy of the weight to thickness ratio.

No significant changes in hardness or conductance were observed in compacts stored at 76% RH, except for sodium chloride where hardness increased and conductance decreased slightly in the first 7 days of storage. Table IV summarizes observations made on sodium chloride compacts stored at 76% RH for 7 days before transfer to 20% RH. The same degree of conductance and hardness changes was observed as for compacts stored at 20% RH initially.

Table V summarizes conductance and hardness values for sodium chloride compacts prepared on the hydraulic press and stored at 20% RH. While the initial values varied as expected with the pressure used to form the compacts, essentially the same conductance and hardness values were observed after 30 days of storage. These data suggest that maximum bonding was attained in all three batches of sodium chloride compacts at the same time.

The observed significant increases in hardness of sodium, potassium, and ammonium chloride compacts when stored under low humidity is evidence of strong interparticulate bond formation during storage. Rees and Shotton (3) reported a doubling of the strength of sodium chloride compacts prepared from sodium chloride dried at 110° within 1 hr after compression with negligible changes after 140 hr. They also reported that exposure of salt compacts to 76% RH prevented the hardness increase. It was not possible to prepare satisfactory compacts from completely dried salts in the pressure ranges available on the single-punch press. The traces of moisture present in the materials used in this study contributed to the delayed hardening in contrast to Rees and Shotton's data, which may also reflect increased crystal defects owing to the higher temperatures required to dry the salt completely.

Not all of the potential bond strength developed immediately at the time of compression. Some of the bonded areas formed during compression might have broken during tablet elastic recovery when pressure was released. Sufficient bonding remained to permit the compacts to maintain their shape while new, stronger interparticulate bonding developed.

The data suggest that the principal mechanism of hardening occurs because of a loss of moisture traces at low humidities. This conclusion is supported by the observations summarized in Table IV since compacts stored at 76% RH increased in hardness when transferred to a significantly lower humidity. The amount of moisture involved did not significantly contribute to compact weight.

Rees and Shotton (3) also observed that sodium chloride compacts with a high moisture content had lower tensile strengths than those with a low moisture content. At high humidities, loss of moisture, which results in

the deposition of salt around existing contact regions, is inhibited. The differences observed between the different chloride salts is related to the different tendencies of the salts to pick up moisture at 76% RH, which is the critical deliquescence point for sodium chloride. Potassium and ammonium chlorides are more deliquescent at this humidity.

Compacts prepared from spray-dried lactose containing lubricant showed a slight decrease in hardness with an increase in conductance at 20% RH (Table VI). Previous investigators (8) suggested that consolidation in lactose occurs mainly by brittle fracture, in contrast to plastic deformation in sodium chloride. Compacts stored at reduced humidity lose traces of moisture; at a reduced moisture content, magnesium stearate decreases hardness.

The data in this study support the expected relationship between conductance and hardness changes. In all cases, increased hardness was accompanied by more than 10-fold decreases in conductance. Conductance values were stable if hardness was stable. These effects were most pronounced in ionic materials whose electrical resistance was directly measurable. Compacted spray-dried lactose represented the upper limit of resistance measurement with the equipment employed.

Cytotoxic Saponins from the Chinese Herbal Drug Yunnan Bai Yao

P. R. RAVIKUMAR, PAUL HAMMESFAHR, and CHARLES J. SIH ˣ

Received August 14, 1978, from the *School of Pharmacy, University of Wisconsin, Madison, WI 53706.* Accepted for publication January 19, 1979.

Abstract □ Two cytotoxic saponins were isolated from the acetone extracts of the herbal preparation "Yunnan Bai Yao" by column chromatography. They were identified as 3-{[α-L-rhamnopyranosyl(1_{Rha} → 2_{Glu})]-[α-L-arabinofuranosyl(1_{Ara} → 4_{Glu})]-β-D-glucopyranosyl}-25(*R*)-spirost-5-en-3β-ol (I) and 3-{[α-L-rhamnopyranosyl(1_{Rha} → 4_{Rha})-α-L-rhamnopyranosyl(1_{Rha} → 4_{Glu})]-[α-L-rhamnopyranosyl(1_{Rha} → 2_{Glu})]-β-D-glucopyranosyl}-25(*R*)-spirost-5-en-3β-ol (VI). Both saponins exhibited significant cytotoxicity in the standard P-388, L-1210, and 9KB tissue culture screens.

Keyphrases □ Folk medicine—Yunnan Bai Yao, Chinese herbal, cytotoxic activity of isolated saponins □ Yunnan Bai Yao—analysis, cytotoxic saponins, Chinese herbal □ Antineoplastic agents, potential—Yunnan Bai Yao, Chinese herbal, cytotoxic activity of isolated saponins □ Hemostatic agents—Yunnan Bai Yao, cytotoxic activity of isolated saponins, Chinese herbal

The Chinese herbal preparation "Yunnan Bai Yao" was formulated with indigenous medicinal plants about 50 years ago in the Yunnan province. This powdered herbal mixture has been used primarily as a hemostatic agent and gained wide acceptance during the Sino-Japanese War (1937–1945) (1). Claims regarding its efficacy in promoting wound healing and relieving pain also have been made.

In recent years, rumors have circulated among the overseas Chinese that Yunnan Bai Yao could be used in cancer therapy (2). Since extracts of Yunnan Bai Yao exhibited a confirmed level of activity (3–5) in the National Cancer Institute's P-388, L-1210, and 9KB tissue culture screens, the cytotoxic components of this herbal preparation were of interest.

EXPERIMENTAL

Melting points were determined in open capillary tubes[1] and are uncorrected. Optical rotations were measured with a polarimeter[2]. NMR spectra[3] were determined in deuterochloroform containing tetramethylsilane as the internal standard. Mass spectra[4] were recorded at an ionizing voltage of 70 ev. Descending paper chromatography was carried out on Whatman No. 1 paper, which was developed for 48 hr in *n*-butanol–ethanol–water (4:1:5, upper phase). Sugars were visualized with alkaline silver nitrate spray.

Silica gel[5] was used for column chromatography. A gas chromatograph[6], equipped with a 3.66-m column (2.16 mm i.d.) of 5% SE-30 on Chromosorb and operated at 190°, was used for the separation of trimethylsilyl ethers (6) of the sugars. The carrier nitrogen gas flow was 40 ml/min. For the separation of methylated and partially methylated methyl glycosides, a 1.83-m column of 15% butanediol succinate (7) on Chromosorb W-AW (2.16 mm i.d.) at 175° was used instead. Monoglucoside and maltoside of 25(*R*)-spirost-5-en-3β-ol (II) were prepared by known methods (8).

Yunnan Bai Yao was used. The preparation and its chemical constituents were described previously (2).

Fractionation and Isolation of I and VI (Scheme I)—A total of 1.3 kg of Yunnan Bai Yao was extracted successively with 10 liters of benzene for 24 hr, followed by 10 liters of acetone for 48 hr. After solvent evaporation *in vacuo*, 31 g of cytotoxic residue was obtained from the acetone extract. This residue (31 g) was chromatographed on a silica gel (2-kg) column (72 × 9.4 cm). The column was eluted with chloroform–methanol–water (65:25:10), and 900-ml fractions were collected. After solvent evaporation *in vacuo* from fractions 11–16, 5.15 g of a white solid was obtained. Crystallization from 95% ethanol afforded pure 3-{[α-L-rhamnopyranosyl(1_{Rha} → 2_{Glu})]-[α-L-arabinofuranosyl(1_{Ara} → 4_{Glu})]-β-D-glucopyranosyl}-25(*R*)-spirost-5-en-3β-ol (I), mp 242–248°; $[\alpha]_D^{25}$ −118.6° (c, 0.51, methanol); IR (KBr): 3550–3110, 981, 912, 894, and 862 cm^{-1}.

Anal.—Calc. for $C_{44}H_{70}O_{16}\cdot 2H_2O$: C, 59.32; H, 8.31. Found: C, 59.55; H, 8.39.

Fractions 24–33 were combined to afford 2.57 g of 3-{[α-L-rhamnopyranosyl(1_{Rha} → 4_{Rha})-α-L-rhamnopyranosyl(1_{Rha} → 4_{Glu})]-[α-L-rhamnopyranosyl(1_{Rha} → 2_{Glu})]-β-D-glucopyranosyl}-25(*R*)-spirost-5-en-3β-ol (VI), mp 203–210°; $[\alpha]_D^{25}$ −110° (c, 0.50, 95% ethanol); IR (KBr): 3600–3100, 976, 908, 890, and 860 cm^{-1}.

Anal.—Calc. for $C_{51}H_{82}O_{20}\cdot 4H_2O$: C, 56.35; H, 8.28. Found: C, 56.50; H, 8.42.

Hydrolysis of I—The saponin I (100 mg) was heated with 2 *N* H_2SO_4 (4 ml) and dioxane (2 ml) at 100° for 10 hr. It was then diluted with 75 ml of water, and the mixture was extracted with ethyl acetate (4 × 75 ml). The organic layer was washed successively with sodium bicarbonate solution and water. After drying over sodium sulfate, the solvent was evaporated *in vacuo* to give 42 mg of II, mp 205–206°; $[\alpha]_D^{25}$ −115.7° (c, 0.53, chloroform).

The aqueous portion of the hydrolysate was neutralized with anion-exchange resins (carbonate form). After filtration and evaporation, a syrup resulted (52 mg); paper chromatography demonstrated spots corresponding to D-glucose, L-arabinose, and L-rhamnose. The identification of these sugars was further confirmed by reacting 5 mg each of the sugars with hexamethyldisilazane (0.4 ml) and trimethylsilyl chloride (0.2 ml) in pyridine (0.5 ml). After removal of the pyridine *in vacuo*, a hexane solution of the silylated sugars was subjected to GLC analyses.

Methylation of I (9)—Sodium hydride (500 mg, washed three times with hexane) in 40 ml of dimethyl sulfoxide was heated at 70° for 30 min under nitrogen with stirring. A solution of 500 mg of I in 25 ml of dimethyl sulfoxide was added. After stirring for 30 min, methyliodide (10 ml) was added. After stirring for 60 min, the reaction mixture was diluted with 400 ml of water and extracted with ether (4 × 100 ml).

The ethereal extract was washed with water (6 × 100 ml), dried over sodium sulfate, and evaporated to dryness to yield 504 mg of crude III. This procedure was repeated three times to obtain 497 mg of III, mp 159–161°; $[\alpha]_D^{25}$ − 92.5° (c, 1.03, chloroform).

Methanolysis of III (7)—After 350 mg of III was refluxed with methanolic hydrogen chloride (3 *N*, 75 ml) for 10 hr, the mixture was kept overnight at 25° and then evaporated *in vacuo*. Anhydrous methanol (100 ml) was added and again evaporated. After the addition of 75 ml of water, the aqueous layer was neutralized with anion-exchange resin (carbonate form) and then evaporated to yield 170 g of mixed methyl glycosides, which was subjected to GLC.

The methyl glycosides also were separated by column (2 × 23.5 cm) chromatography on silica gel (20 g). The column was eluted with a gradient system consisting of 200 ml of chloroform–methanol (99.5:0.5) in the mixing flask and 200 ml of chloroform–methanol (98:2) in the reservoir flask, and 10-ml fractions were collected. Fractions 12–16 afforded 41 mg of methyl 2,3,4-tri-*O*-methyl-L-rhamnopyranoside (III*a*). Fractions 18–29 gave 36 mg of methyl 2,3,5-tri-*O*-methyl-L-arabinofuranoside (III*b*). Fractions 37–48 yielded 42 mg of methyl 3,6-di-*O*-methyl-D-glucopyranoside (III*c*). These methyl glycosides were identified by mass spectral analyses (10).

Partial Hydrolysis of I—After 250 mg of I was heated with 10 ml of dioxane and 20 ml of 2 *N* H_2SO_4 at 75° for 1 hr, the mixture was diluted with 30 ml of water and neutralized with anion-exchange resin (carbonate form). The mixture was then filtered through a bed of Dowex 1 × 4 resin (carbonate form). The resin was washed successively with 200 ml of methanol followed by 200 ml of methanol–chloroform (1:1).

The filtrate and the washings were combined and evaporated *in vacuo* to yield 246 mg of residue, which was chromatographed on a silica gel (65 g) column (2.2 × 36.5 cm). The column was eluted with chloroform–methanol–water (65:25:10, organic phase), and 4-ml fractions were collected. Fractions 22–27 afforded 28 mg of 3-[β-D-glucopyranosyl]-25(*R*)-spirost-5-en-3β-ol (IV), mp 246–251°, $[\alpha]_D^{25}$ −87.9° (c, 0.52, methanol). Fractions 43–61 gave 120 mg of the prosapogenin (IV), mp 215° dec.; $[\alpha]_D^{25}$ −98.4° (c, 0.51, methanol).

Table I—Calculated and Experimental Molecular Rotations of Glycosides

Glycoside	$[M]_D$ Found	$[M]_D$ Calc.
3-[β-D-Glucopyranosyl]-25(*R*)-spirost-5-en-3β-ol	−572	−656
3-[α-L-Rhamnopyranosyl(1 → 2)-β-D-glucopyranosyl]-25(*R*)-spirost-5-en-3β-ol	−889	−853
3-{[α-L-Rhamnopyranosyl(1 → 2)]-[α-L-arabinofuranosyl(1 → 4)]-β-D-glucopyranosyl}-25(*R*)-spirost-5-en-3β-ol	−1034	−1064

Permethylation of IV—With the same procedure as described for the methylation of I, 120 mg of IV afforded 123 mg of crude V. Purification by column chromatography yielded 8.6 mg of pure V, mp 97–100°; $[\alpha]_D^{25}$ −101.5° (c, 0.8, chloroform).

Methanolysis of V—After 70 mg of V was treated with 30 ml of 2 *N* methanolic hydrogen chloride, the procedure used was the same as that described for III. A total of 30 mg of methyl glycoside was obtained, which was chromatographed on a silica gel (3-g) column (0.5 × 16.5 cm). The column was eluted with benzene–ethyl acetate (7:3), and 3-ml fractions were collected. Fractions 27–29 gave 8 mg of III*a*, and fractions 49–56 afforded 7.6 mg of methyl 3,4,6-tri-*O*-methyl-D-glucopyranoside (V*a*).

Hydrolysis of VI—Hydrolysis of VI (100 mg), carried out in the same manner as for I, yielded 39 mg of II. The sugars were identified by paper chromatography as L-rhamnose and D-glucose.

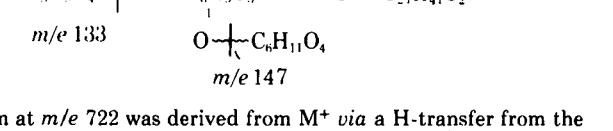
Methylation of VI—Following the methylation procedure for I, 750 mg of VI afforded 703 mg of VII, mp 116–118°; $[\alpha]_D^{25}$ −86° (c, 1.0, chloroform).

Methanolysis of VII—A mixture of 259 mg of methyl glycosides was obtained from methanolysis of 470 mg of VII. These glycosides were analyzed by GLC and further separated by column chromatography on silica gel with the same solvent system as described for the isolation of methyl glycosides from III. Fractions 13–19 gave 70 mg of III*a*, fractions 23–31 afforded 52 mg of methyl 2,3-di-*O*-methyl-L-rhamnopyranoside (VII*a*), and fractions 38–45 yielded 48 mg of III*c*.

Partial Hydrolysis of VII—After 190 mg of VII was refluxed with 0.5 *N* HCl in 40 ml of methanol for 3 hr, the mixture was evaporated, and 50 ml of water was added. The mixture was extracted with ethyl acetate (4 × 30 ml), and the ethyl acetate layer was washed with water, dried over sodium sulfate, and evaporated to yield 98 mg of residue. This residue was subjected to preparative TLC (20 × 20 cm, Kieselgel 60 F-256) using chloroform–acetone (85:15) as the solvent system. Compound VIII (R_f 0.46) was isolated and, upon methylation, yielded V.

RESULTS AND DISCUSSION

Acid hydrolysis of the saponin I afforded II, D-glucose, L-rhamnose, and L-arabinose. GLC analyses of the trimethylsilyl derivatives of these sugars revealed that they were present in a 1:1:1 ratio. The mass spectrum of I showed prominent peaks at *m/e* 133, 147, 414, 576, and 722. The peaks at *m/e* 133 and 147 correspond to arabinosyl and rhamnosyl ions, respectively, suggesting that these sugars are present in I as terminal units in branched chain fashion.



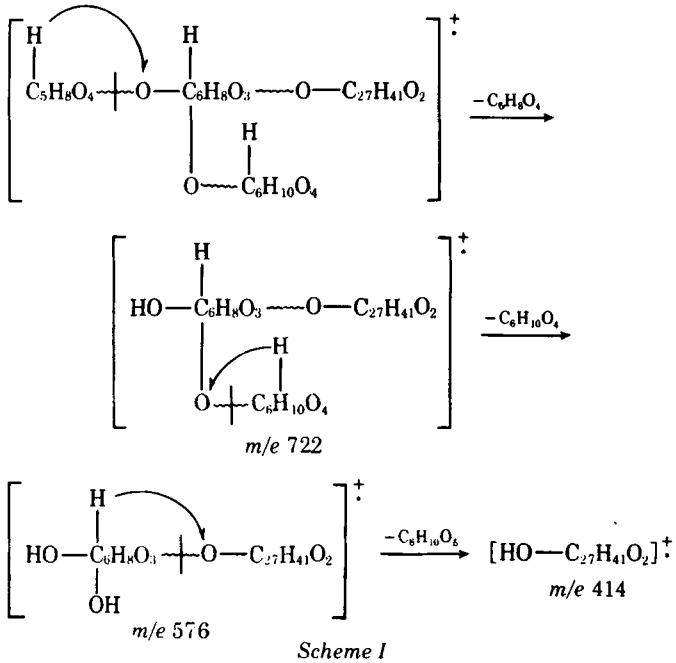
The ion at *m/e* 722 was derived from M^+ *via* a H-transfer from the arabinosyl group, accompanied by its concomitant elimination (Scheme I). In turn, the ion at *m/e* 576 originated from the ion at *m/e* 722 by a similar H-transfer from the terminal rhamnosyl group, accompanied by its elimination. The ion at *m/e* 414 was formed from the ion with *m/e* 576 by a H-transfer from the glucosyl group, followed by its elimination (11, 12), indicating that glucose was directly attached to the aglycone.

This proposed branched sugar sequence was further substantiated by the mass spectrum of the permethylated derivative (III), which gave prominent peaks at *m/e* 175 and 189, corresponding to terminal tri-*O*-methylarabinosyl and tri-*O*-methylrhamnosyl ions. The peak at *m/e* 435 may be rationalized by assuming that the terminal tri-*O*-methylrham-

Table II—Cytotoxic Activity of Natural and Synthetic Saponins [a]

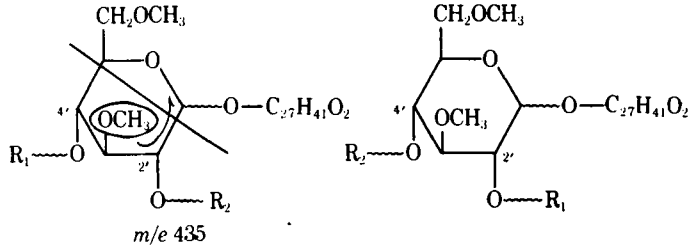
Glycoside	ED_{50}, μg/ml P-388	L-1210	KB
I	0.94	0.14	0.16
VI	0.22	0.43	0.029
Synthetic 3-[glucosyl]-25(*R*)-spirost-5-en-3β-ol	23.9	65.7	12
Synthetic 3-[maltosyl]-25(*R*)-spirost-5-en-3β-ol	30.8	58.9	29

[a] For the P-388 and L-1210 tissue cultures, 1-(2-chloroethyl)-3-(4-methylcyclohexyl)-1-nitrosourea (NSC 95441) was used as the positive control compound, tested at 10, 5, 2.5, 1.25, and 0.625 μg/ml. For synthetic compounds, an ED_{50} value of ≤ 4 μg/ml is considered to be significant cytotoxic activity. For the KB tissue culture test system, mercaptopurine monohydrate was used as the standard.



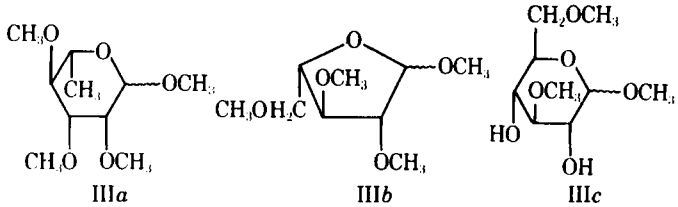
Scheme I

nosyl and tri-*O*-methylarabinosyl groups are attached to the C-2′ and C-4′ positions of the D-glucose moiety.

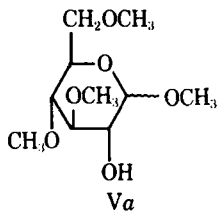


R_1 = tri-*O*-methyl-L-arabinosyl
R_2 = tri-*O*-methyl-L-rhamnosyl

The position of the sugar linkage was established by GLC analyses (7) of the methyl glycosides derived from methanolysis of III, which showed the presence of IIIa–IIIc. The identification of these methyl glycosides was made by comparison of their GLC retention times and mass spectra (10) with samples synthesized by published procedures (13, 14). These results were consistent with the supposition that rhamnose is attached to either the C-2′ or C-4′ position of glucose.



IIIa IIIb IIIc



Va

The exact locations of the sugar linkages in I were deduced by the partial acid hydrolysis of I, which afforded 3-[β-D-glucopyranosyl]-25(*R*)-spirost-5-en-3β-ol and the prosapogenin IV. Paper chromatographic analysis of the sugars in the acid hydrolysate of IV showed only D-glucose and L-rhamnose, indicating that L-arabinose had been cleaved off during the partial hydrolysis of I. Permethylation of IV afforded V. Methanolysis of V gave two methyl glycosides, which were separated by column chromatography and characterized as IIIa and, more importantly, Va. This identification was accomplished by comparison of GLC retention times and mass spectral data with synthetic samples prepared by published procedures (10).

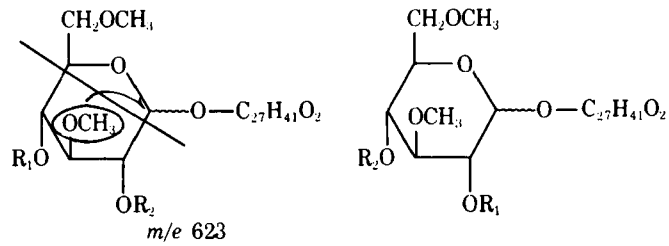
These experimental data can only be interpreted to mean that rhamnose is attached to the glucose C-2′ position. Hence, the arabinosyl unit must be attached to the glucose C-4′ in I.

With the sugar linkage sites established, the stereochemistry of the glycosidic linkages in I was then studied. The NMR spectrum of V showed signals at 4.26 (d, 1H, J = 7 Hz) and 5.15 (s, 1H) ppm. The former signal corresponds to the axial anomeric proton of the tri-*O*-methyl-D-glucopyranosyl moiety, and the latter corresponds to the equatorial anomeric proton of the tri-*O*-methyl-L-rhamnopyranosyl moiety. Thus, D-glucose is linked to II *via* a β-glycosidic bond, whereas L-rhamnose is linked to D-glucose *via* an α-glycosidic linkage.

The NMR spectrum of III exhibited signals at 4.36 (d, 1H, J = 7 Hz), 5.15 (s, 1H), and 5.18 (s, 1H) ppm. The signal at 5.15 ppm is characteristic of the equatorial anomeric proton in the tri-*O*-methyl-L-arabinosyl moiety, confirming that L-arabinose is attached to C-4′ of the D-glucose unit *via* an α-glycosidic linkage. The calculated and experimental molecular rotation values (16) for IV and I are in good agreement (Table I), further substantiating the stereochemical assignment.

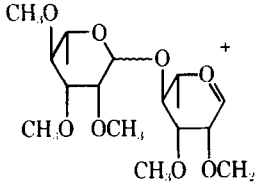
Hydrolysis of the saponin VI afforded II, D-glucose, and L-rhamnose. GLC analyses of the trimethylsilyl derivatives of these sugars revealed that D-glucose and L-rhamnose were present in a 1:3 ratio. The mass spectrum of VI showed prominent peaks at *m/e* 147, 414, 576, and 722. The ions at *m/e* 414 and 576 indicated that D-glucose was linked directly to II as 3L-rhamnose–D-glucose–II.

Methanolysis of the permethylated derivative VII gave three types of methyl sugars, which were identified as IIIa, methyl 2,3-di-*O*-methyl-L-rhamnopyranoside (VIIa), and IIIc. Thus, VII may be represented by one of the following structures.



R_1 = tri-*O*-methyl-L-rhamnopyranosyl
R_2 = tri-*O*-methyl-L-rhamnopyranosyl(1→4)-di-*O*-methyl-L-rhamnopyranosyl

The mass spectrum of VII gave prominent ions at *m/e* 189, 363, and 623, in accord with this assignment. The peak at *m/e* 189 may be rationalized in terms of the two terminal tri-*O*-methyl-L-rhamnopyranosyl units; the ion at *m/e* 363 corresponds to the tri-*O*-methyl-L-rhamnopyranosyl(1 → 4)-di-*O*-methyl-L-rhamnopyranosyl ion. The ion at *m/e* 623 strongly suggests C-2′ and C-4′ substitutions of the D-glucosyl unit.



m/e 363

Partial acid hydrolysis of VII afforded VIII, whose mass spectrum gave prominent ions at *m/e* 189, 379 and 796 (M^+), indicating that a tri-*O*-methyl-L-rhamnopyranosyl(1 → 4)-di-*O*-methyl-L-rhamnopyranosyl group was cleaved during hydrolysis. Since methylation of VIII afforded V, one may logically conclude that the L-rhamnopyranosyl(1 → 4)-L-rhamnopyranosyl group must be attached to C-4′ and that the L-rhamnopyranosyl group may be attached to C-2′ of the D-glucopyranosyl moiety of VII.

The NMR spectrum of VII showed a doublet at 4.4 ppm (1H, J = 7 Hz) and two broad singlets at 5.03 (1H) and 5.21 (2H) ppm. The doublet corresponds to the axial anomeric proton of D-glucose, and the singlets correspond to the equatorial anomeric protons of the three L-rhamnose units. Thus, the D-glucose unit is attached to II *via* a β-glycosidic linkage and to the three L-rhamnose residues *via* α-glycosidic bonds, and the chemical structure of this tetraglycoside is represented by VI.

The cytotoxic activities of I and VI are shown in Table II. Both saponins were quite effective against P-388, L-1210, and 9KB tissue culture systems. To demonstrate that this cytotoxic activity is not simply due to a detergent effect, glucoside and maltoside of II were prepared and evaluated in these test systems. Since both synthetic saponins were much less active, it appears that some unique structural features are required for optimal cytotoxic activity.

Extracts of *Dioscorea* have been widely used for the treatment of a variety of tumors in China, India, South America, and Southeast Asia (17). After completion of these studies, it was noted that I and VI had been isolated from the dried rhizomes of *Paris polyphylla* SM. obtained in a market of Katmandu, Nepal (18).

NOTES

Phosphodiesterase Inhibition by Succinic and Related Acid Biphenylalkyl Monoesters

M. E. ROGERS ˣ, S. G. BOOTS *, and M. R. BOOTS

Received September 22, 1978, from the *Department of Pharmaceutical Chemistry, School of Pharmacy, Virginia Commonwealth University, Richmond, VA 23298.* Accepted for publication December 7, 1978.

*Present address: Department of Chemistry, Stanford University, Stanford, Calif.

Abstract □ Biphenylalkyl monoesters of succinic and related acids represent a potent new class of cyclic AMP phosphodiesterase inhibitors. The biphenyl group is necessary for potent inhibition. The spatial relationship of the carboxyl and ester groups and alkyl chain length are important to inhibitory potency.

Keyphrases □ Succinic acid biphenylalkyl monoesters—phosphodiesterase inhibition, synthesis, structure–activity relationships □ Cyclic AMP phosphodiesterase—inhibitors, succinic acid biphenylalkyl monoesters, synthesis, structure–activity relationships □ Phosphodiesterase inhibitors—succinic acid biphenylalkyl monoesters, synthesis, structure–activity relationships

Tissue cyclic AMP levels appear to be regulated by two enzymes, adenylate cyclase and phosphodiesterase, and by cellular extrusion. Phosphodiesterase catalyzes the hydrolysis of cyclic AMP to 5′-AMP. Because phosphodiesterase inhibitors can increase tissue cyclic AMP levels, these compounds are of interest as biochemical tools and as potential therapeutic agents (1–3).

Most potent cyclic AMP phosphodiesterase inhibitors are nitrogen-containing heterocycles, *i.e.*, theophylline, 3-isobutyl-1-methylxanthine, papaverine, and 4-(3-butoxy-4-methoxyphenyl)-2-imidazolidinone[1], and most contain either a 6,5- or 6,6-fused heterocyclic ring (4–6). Only a few reports described the effects of organic acids on phosphodiesterase. Citrate at high concentrations (12 m*M*) inhibited the enzyme (7). Ethacrynic acid was reported to be one-half as potent as theophylline against the enzyme from beef heart (8). Recently, acidic anti-inflammatory agents were reported to inhibit phosphodiesterase (9–11). Enzyme activation by the lipoidal organic acid, stearic acid, was observed (12), as was inhibition by unsaturated fatty acids (13).

1-(4-Biphenylyl)pentyl hydrogen succinate is a hypo-

II

cholesterolemic agent previously reported to inhibit β-hydroxy-β-methylglutaryl coenzyme A reductase (14). The purpose of this investigation was to examine the phosphodiesterase inhibition by *Ib* and related acids.

RESULTS AND DISCUSSION

Compound *Ib* was a potent beef heart phosphodiesterase[2] inhibitor (Table I). Closely related *Ia*, *Ic*–*Ie*, and II were also examined for effects on the enzyme[3]. Lineweaver–Burke plots were obtained for *Ib*, *Id*, and *Ie* (Fig. 1). The I_{50} values were determined at substrate concentrations of 100 and 1 μ*M* for *Ia*–*Ie*. Most phosphodiesterase preparations, including bovine heart phosphodiesterase, contain both high and low affinity enzymes or enzyme forms (5, 6). The preparations could be assayed at a low cyclic AMP concentration to observe effects on the high affinity form and at high substrate concentrations (actually, this high concentration reflected total enzyme activity) to observe effects on the low affinity enzyme. Additionally, miscellaneous acids were examined for effects on phosphodiesterase to substantiate *Ib*–*Ie* specificity. Finally, structure–activity relationship analysis of *Ia*–*Ie* led to the synthesis of *If*, the most potent inhibitor yet uncovered in this series.

The discovery that *Ib* inhibited phosphodiesterase raised the following question: Would other organic acids, especially arylalkyl organic acids, in view of the known acidic anti-inflammatory agent effect, inhibit the enzymes? The failure of all eight diverse acids to inhibit phosphodiesterase indicated that this is not a general organic acid effect (Table I).

[2] Sigma Chemical Co.

[3] These results did not correlate with the potency of these compounds as inhibitors of β-hydroxy-β-methylglutaryl coenzyme A reductase (14, 15).

Table I—Phosphodiesterase Inhibition [a]

Compound [b]	I_{50}, μM	
	1 μM Cyclic AMP [c]	100 μM Cyclic AMP [c]
Ia	514 ± 56 [d]	1215 ± 103
Ib	64 ± 2	205 ± 6
Ic	49 ± 2	95 ± 7
Id	121 ± 15	402 ± 27
Ie	29 ± 2	93 ± 10
If	16 ± 2	25 ± 3
II	823 ± 68	>1000 [e]
Theophylline	306 ± 24	917 ± 25
3-Isobutyl-1-methyl-xanthine	10 ± 1	52 ± 1

[a] Bovine heart phosphodiesterase was used. [b] The following acids at 5×10^{-4} M, using 100 μM cyclic AMP, showed less than 5% enzyme inhibition: *p*-chlorophenoxyacetic, cinnamic, *p*-hydroxyphenylacetic, monomethyl adipate, α-naphthylacetic, α-phenylbutyric, phenylpropionic, and 2-pyridylacetic. [c] Substrate concentration. [d] Data are expressed as the mean ± *SE* of three determinations. [e] Sixteen-percent inhibition at 1000 μM; a solubility problem was encountered at higher concentrations.

Additional specificity evidence was indicated by the lack of succinate analog activity where biphenyl was replaced by phenyl (II) and where the *n*-butyl chain was replaced by methyl (Ia, Table I). Furthermore, if the inhibition was *via* an enzyme–inhibitor complex, there should be a variation in potency among stereoisomers. In fact, the fumarate (*trans*-isomer) analog Ie was four times as potent as the maleate (*cis*-isomer) analog Id, with the succinate Ib intermediate between the two.

Attempts to establish the inhibition type *via* Lineweaver–Burke plots were not definitive (Fig. 1). Beef heart phosphodiesterase inhibition by Ib appeared to be competitive or partially competitive at both low and high substrate concentrations. Replotting the data using Hofstee plots did not improve identification of the inhibition type. The inability to obtain definitive curves may have been due to assay error, enzyme preparation crudeness, or the presence of additional enzyme forms.

The most striking structure–activity relationships for this series (Table I) can be summarized as follows: the biphenyl moiety is necessary (Ib *versus* II), a *trans*-configuration of the carboxyl and ester groups is optimal (Ie > Ib > Id), and an increased alkyl chain length is advantageous (Ic > Ib > Ia). These results suggested the synthesis of If[4].

Compound If is almost equipotent with the very potent, standard phosphodiesterase inhibitor 3-isobutyl-1-methylxanthine against the high affinity enzyme and is more potent against the low affinity enzyme. The ability of these compounds to inhibit cyclic AMP phosphodiesterase should be considered when interpreting pharmacological studies.

EXPERIMENTAL

Chemistry[5]—Compounds Ia–Ic and II were prepared as previously described (15). Compounds Id and Ie were synthesized as previously described (14).

Compound If, mp 82–84°, was prepared using the method described for Ie (14); NMR: δ 0.60–2.20 [broad, 13H, $CH_3(CH_2)_5$], 5.90 (t, J = 6 Hz, 1H, HCO_2C–), 6.95 [s, 2H, —CH=CH—], 7.20–7.80 [m, 9H, aromatic], and 8.45 [s, 1H, CO_2H] ppm.

Anal.—Calc. for $C_{23}H_{26}O_4$: C, 75.4; H, 7.1. Found: C, 75.1; H, 7.4.

Enzyme Studies—The assay (16) was used as previously described (17) employing bovine heart phosphodiesterase[2].

[4] Further chain elongation would likely reduce solubility beyond workable limits.

[5] Melting points were determined with a Thomas–Hoover apparatus and are uncorrected. Elemental analyses were obtained from Atlantic Microlab Inc., Atlanta, Ga. NMR spectra were determined using a Perkin-Elmer R-24 spectrometer in deuterochloroform with tetramethylsilane as the internal reference.

Molecular Connectivity Analysis of Hallucinogenic Mescaline Analogs

R. A. GLENNON *x, **L. B. KIER** *, and **A. T. SHULGIN** ‡

Received June 9, 1978, from the *Department of Pharmaceutical Chemistry, School of Pharmacy, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA 23298, and ‡1483 Shulgin Road, Lafayette, CA 94549. Accepted for publication December 20, 1978.

Abstract □ The hallucinogenic (psychotomimetic) potency of 10 mescaline analogs was examined by molecular connectivity analysis. Potencies could be described by a two-term relating equation, which explained 94% of the variance in activity, on the basis of structural variation. 2,5-Dimethoxy substitution as well as the nature of the 4-position substituent played an important role in determining hallucinogenic potency. With the relating equation, reasonable potency predictions were made for six compounds not included in the initial investigation.

Keyphrases □ Mescaline analogs—hallucinogenic activity, structure—activity relationships, molecular connectivity analysis □ Hallucinogenic agents—mescaline, analogs, hallucinogenic activity, structure-activity relationships, molecular connectivity analysis □ Structure-activity relationships—mescaline analogs, molecular connectivity analysis

Molecular connectivity analysis was used recently in studies of the structure–activity relationships of hallucinogenic phenylisopropylamine (amphetamine) analogs (1). Hallucinogenic activity could be related to three structural descriptors (χ terms) by an equation that accounted for greater than 80% of the variance in hallucinogenic potency. The relating equation, generated from the amphetamine data, was used to predict the hallucinogenic potency of six phenethylamine derivatives (mescaline analogs) (1).

One χ term in the original equation encodes the presence of the α-methyl group of the amphetamine side chain. Being devoid of this α-methyl group, the phenethylamines were predicted correctly to be of lower hallucinogenic potency (1). The correct prediction of the six phenethylamine derivative activities may have been fortuitous since only one of these six compounds was experimentally more active than mescaline in humans.

Recently, data became available on additional phenethylamines with potency six to 35 times that of mescaline. In light of these findings and of the newly available active compounds, it was of interest to reexamine the phenethylamines as a separate hallucinogenic class.

EXPERIMENTAL

Molecular structures can be analyzed in terms of the number of atoms, kinds of atoms, bonding types, and adjacency environment by the molecular connectivity method (2). The method used in this investigation was described previously (2) and has given good results in correlating biological activity with the structures of, for example, hallucinogenic amphetamine derivatives (1) and lysergide analogs (3). Molecular connectivity indexes or descriptors (χ terms) have been computed for each compound in this study. A multivariable search of connectivity terms was conducted in a regression analysis using a program that considers all variable combinations. The number of terms employed was limited necessarily by the molecular size and the number of observations and was governed by statistical considerations.

Psychotomimetic or hallucinogenic activity measurement is necessarily only semiquantitative. Hallucinogenic agent potencies are measured relative to a total dose of 350 mg of mescaline. For example, the dose of V required to produce an effect similar to that of 350 mg of mescaline is 40–60 mg (4); thus, for an average 50-mg dose, V is calculated to have a potency seven times that of mescaline, or 7 mescaline units. The variance in mescaline-unit data has been estimated as ~25% (5). Therefore, although V might possess an activity of ~5–9 mescaline units, a value of 7 mescaline units was used to perform the regression analysis.

Compounds I and IX are reported to possess an activity of "less than" 1 and 5 mescaline units, respectively (5). Again, to perform the regression, certain assumptions must be made. Thus, activities midway between inactivity and the reported activity (*i.e.*, 0.5 and 2.5 mescaline units, respectively) were assumed for these compounds. Although II has an activity of less than 1 mescaline unit, one study (6) reported an activity of 0.2 mescaline unit, and this latter value was used in the regression analysis.

RESULTS AND DISCUSSION

The relative hallucinogenic potencies of the 10 phenethylamine derivatives can be described by:

$$\text{mescaline units} = 129\ {}^{3}\chi_c^{v} - 4.45\ {}^{4}\chi_p - 14.54 \qquad \text{(Eq. 1)}$$

$$n = 10 \quad s = 3.02 \quad r = 0.97$$

Although the correlation is significant and explains 94% of the variation in hallucinogenic activity, the variation in biological activity measurement should be called to attention again.

The two molecular connectivity indexes important in the equation are weighted counts of structural fragments. The ${}^{3}\chi_c^{v}$ index describes a structural feature of three bonds converging at one atom (cluster). The v denotes the index valence form; that is, the atom δ assignments are based on the atomic valence rather than on the simple degree of adjacency. The ${}^{4}\chi_p$ index describes a structural feature of four contiguous bonds in which the atom δ values are based on the degree of adjacency. Several detailed descriptions of the molecular connectivity method and the calculation of the indexes were published recently (2).

From the relating equation, several generalizations can be derived about the impact of structural variation on activity. The ${}^{3}\chi_c^{v}$ term suggests that increasing the number of nuclear substituents will generally increase potency; compare the activities of I and II with those of III and IV. This is in accord, biologically, with previous findings (7) that those phenethylamines with high methoxylation serve less well as substrates for enzymatic degradation. In addition, the presence of the ${}^{3}\chi_c^{v}$ term implies that the lower the δ^{v} in the substituent, the higher the potency; *i.e.*, Br > CH_3 > OCH_3 (compare III, VII, and VIII).

The ${}^{4}\chi_p$ term is related to the phenethylamine ring substitution pattern. Because the coefficient for this term in the relating equation is negative, the greater the value of the term, the lower is the potency of the compound. In the monosubstituted phenethylamines, an *ortho*-substituent contributes two additional terms and a *meta*-substituent contributes one additional term as compared to a *para*-substituent. Therefore, the position of the substituent would be expected to enhance activity in the order: *ortho* < *meta* < *para*.

For phenethylamines with more than one nuclear substituent, the ${}^{4}\chi_p$ term indicates that activity is enhanced when two substituents are *para* to one another (*para* > *meta* > *ortho*). Such substitution can only be realized, in disubstituted molecules for example, when the phenethylamine is 2,5-disubstituted.

These statements, which can be quantified using the χ terms, echo those structure–activity relationships that have evolved in a qualitative manner by inspection of a phenethylamine series. Shulgin (4) reported that if the *p*-methoxy group is replaced with another substituent (higher alkoxy, methyl, or halo), there is an unquestioned increase in potency. Shulgin (4) commented further that 2,4,5-orientation appears to be more effective than 3,4,5-orientation, although there are too few examples to establish this generality.

Investigations of structure–activity relationships can highlight those structural features that influence activity. However, because hallucino-

[a] Not used to derive the relating equation; activities were predicted using the equation. [b] Effective human intoxication levels have not been evaluated fully.

genic activity cannot be measured with great accuracy and because mescaline units do not reflect the route of administration, time of onset, and duration of action, one cannot expect to predict hallucinogenic potency confidently. Furthermore, the potencies used in the regression analysis span more than two orders of magnitude (from 0.2 mescaline unit for II to 35 mescaline units for VIII). In addition, several activities have been reported in uncertain terms, *i.e.*, "less than." This uncertainty is reflected by the standard deviations and results in broad ranges of predicted activity, particularly for compounds that are only weakly active. Conversely, compounds that are the most active and, subsequently, those from which the most information might be gleaned should be predicted rather well (*e.g.*, VII and VIII).

Application of the relating equation should, nevertheless, afford a relative prediction of activity. To test the relating equation, data from several compounds that have not yet been fully evaluated in humans and/or were not used in generating the relating equation were compared with their predicted potencies. Compounds XI and XII are relatively weak hallucinogenic agents with potencies similar to mescaline. Both compounds are predicted by the relating equation to possess low hallucinogenic activity.

Previous investigators (8), employing a modified Bovet-Gatti profile, found that 2,3,4,5,6-pentamethoxyphenethylamine (XIII) is behaviorally active in animal models with a potency about eight times that of mescaline. With the relating equation, XIII is predicted to have a potency of ~4.5 mescaline units. As another example, an iodinated derivative, 4-iodo-2,5-dimethoxyphenethylamine (XIV), recently was titrated in humans, but effective intoxication levels have not been explored fully. The iodo group, which is *para* to the side chain, possesses a δ^v that is even lower than that of a bromo group. In addition, this molecule possesses two methoxy groups *para* to one another (*i.e.*, 2,5-dimethoxy). On this basis, XIV is predicted by the relating equation to be ~42–48 times more active than mescaline. Shulgin[1] found that the threshold effects of XIV were clear at a total dose of 8 mg; this amount corresponds to an activity of ~44 mescaline units.

Compounds XV and XVI are an order of magnitude more potent than mescaline[1] but less active than XIV. Table I reveals that their activity was predicted reasonably well.

The indexes encode structural information about features contributing to hallucinogenic potency. When applied to several examples not included in the analysis, the relating equation gives reasonable predictions. The structural information derived from this analysis contributes to an understanding of structural influence on hallucinogenic potency.

High-Pressure Liquid Chromatographic Evaluation of Aqueous Vehicles for Preparation of Prednisolone and Prednisone Liquid Dosage Forms

V. DAS GUPTA

Received July 10, 1978, from the *Department of Pharmaceutics, College of Pharmacy, University of Houston, Houston, TX 77004.* Accepted for publication December 19, 1978.

Abstract □ A high-pressure liquid chromatographic method was developed that separates prednisolone from prednisone, prednisone from methylprednisolone succinate sodium, and hydrocortisone from hydrocortisone acetate or cortisone acetate. The common liquid dosage preservatives methylparaben, propylparaben, and sodium benzoate do not interfere with quantitative prednisolone, prednisone, and hydrocortisone determinations. The method was used to study prednisolone and prednisone stability in five aqueous vehicles (water, citrate buffer USP, 50% glycerin, 50% sorbitol, and 50% sucrose) containing 10% (v/v) ethanol. Prednisone crystallized out in all vehicles except glycerin, in which it appeared to be stable for at least 92 days. Prednisolone did not crystallize in any vehicle but decomposed quickly in citrate buffer. Sorbitol and glycerin appeared to be the best vehicles for prednisolone. The developed method was applied successfully to the quantitative determinations of prednisolone, prednisone, and hydrocortisone in commercial tablets.

Keyphrases □ Prednisolone—analysis, high-pressure liquid chromatography, liquid dosage forms, separation from prednisone □ Prednisone—analysis, high-pressure liquid chromatography, liquid dosage forms, separation from prednisolone □ High-pressure liquid chromatography—analysis, prednisolone and prednisone in liquid dosage forms □ Dosage forms, liquid—prednisolone and prednisone, separation by high-pressure liquid chromatography

A number of drugs are not available commercially in liquid dosage forms due to stability problems. However, physicians often prescribe some of these drugs for infants and small children who cannot swallow tablets or capsules. Furthermore, liquid dosage forms may be required for administration to adults through nasal gastric tubes.

BACKGROUND

The effect of some solid buffering agents, *e.g.*, antacids, aluminum hydroxide, calcium carbonate, magnesium carbonate, magnesium oxide, and magnesium trisilicate, on prednisolone stability in aqueous suspensions was reported previously (1). The steroid was adsorbed by magnesium trisilicate and decomposed in the presence of magnesium carbonate. The other antacids had no effect on the stability. A later article (2) on base-catalyzed prednisolone decomposition reported that the steroid exhibited first-order degradation kinetics. A kinetic study (3) on fluprednisolone acetate stability in aqueous solution (pH 7.2) also indicated that the steroid could not be stabilized in a neutral aqueous solution.

Prednisone may change to prednisolone on standing in an aqueous solution[1]. Before vehicle evaluation, therefore, it was important to develop an appropriate analytical method to separate prednisolone from prednisone. The previously developed high-pressure liquid chromatographic (HPLC) technique for hydrocortisone (4) was not suitable since it did not separate prednisolone from prednisone. In this procedure, a column of semipolar packing material consisting of a monomolecular layer of cyanopropylsilane permanently bonded to silica was used.

The purposes of this study were to develop an appropriate analytical procedure to separate prednisone from prednisolone and to evaluate the effect of some aqueous vehicles [ethanol, citrate buffer USP (5), 50% glycerin, 50% sorbitol, and 50% sucrose] on prednisone and prednisolone stability.

EXPERIMENTAL

Chemicals and Reagents—All chemicals and reagents were USP, NF, or ACS grade and were used without further purification. Prednisolone[2] (I), prednisone[2] (II), hydrocortisone[2], hydrocortisone acetate[3], and cortisone acetate[4] were used as received. Methylprednisolone succinate sodium[2] powder for injection USP also was used without further treatment.

Apparatus—The high-pressure liquid chromatograph[5] was equipped with a fixed wavelength (254 nm) detector, a recorder[6], and an integrator[7].

Column—The nonpolar prepacked column[8] consisted of a mono-

Figure 1—*Sample chromatograms. [a] Prednisone crystallized and, therefore, was not followed. [b] Done only to determine if II had changed to I (see Fig. 1D and *Discussion*).

molecular layer of octadecyltrichlorosilane permanently bonded to silica (30 cm and 4 mm i.d.).

Chromatographic Conditions—The solvent was 0.01 *M* KH_2PO_4 in water containing 50% (v/v) methanol. The temperature was ambient, the flow rate was 1.6 ml/min, and the chart speed was 30.5 cm/hr. The attenuation unit for full-scale deflection was 0.04.

Standard Solutions—The stock solution of each hormone was prepared by dissolving 100.0 mg of hormone in enough ethanol to make 100.0 ml. The standard solutions were prepared by diluting 2.0 ml of the stock solution to 100.0 ml with water. For tablet analysis, the standard solution was prepared by diluting with ethanol. A standard solution containing the four hormones, I, II, methylprednisolone succinate sodium, and hydrocortisone acetate, also was prepared by diluting with water.

Aqueous Solutions of I and II—Five aqueous solutions each of I and II were prepared. The stock solutions of I and II were prepared by dissolving 500.0 mg of drug in enough ethanol to make 100.0 ml. A 10.0-ml quantity of a stock solution was brought to volume (100.0 ml) either with water or with another appropriate solution, a 50% aqueous solution of glycerin (v/v), a 50% solution of sorbitol in water, a 50% solution of sucrose in water, or citrate buffer USP (5). The citrate buffer pH was 4.4. All solutions contained 0.1% sodium benzoate as a preservative.

Assay Solutions—A 2.0-ml quantity of the aqueous solution was diluted to 50.0 ml with water.

Assay Solutions from Commercial Tablets—Ten tablets were weighed and ground to a fine powder. A quantity of the powder representing 2.0 mg of the active ingredient was weighed accurately and transferred to a 150-ml beaker. Then 80 ml of ethanol was added, and the mixture was heated just to boiling. The mixture was cooled, brought to 100.0 ml with ethanol, and filtered. The first 20 ml of the filtrate was rejected, and then samples were collected for analysis.

After the initial assays using the method discussed below and the determination of pH values (after diluting 1:10 with water), the aqueous solutions of I and II were stored at room temperature. After appropriate storage periods, the aqueous solutions were assayed again and pH values also were determined.

Assay—Twenty microliters of the assay solution was injected into the chromatograph using the described conditions. For comparison, an identical volume of the standard solution was injected after the assay was eluted.

Since preliminary investigations on each hormone indicated that Beer's law was followed in the 0.2–2.5-μg range, the results were calculated as follows:

$$\frac{A_a}{A_s} \times 100 = \text{percent of label claim} \qquad \text{(Eq. 1)}$$

where A_a is the peak area of the assay solution and A_s is the peak area of the standard solution (Figs. 1 and 2 and Tables I and II).

Table II—Tablet Results

Tablet	Active Ingredient per Tablet	Color	Assay Results, % of claim HPLC Method	Blue Tetrazolium Method
1	5 mg of I	Yellow	100.5	295.3
2	5 mg of II	White	101.3	348.6
3	5 mg of hydrocortisone	White	99.8	>386

For comparison, the commercial tablets were also assayed (Table II) using the USP blue tetrazolium method (6). For this method, the same assay solution as already described was used.

DISCUSSION

The developed HPLC method separated I from II (Fig. 1A) efficiently. Other systems tried without success were[9]: (*a*) 0.01 *M* KH_2PO_4 in water containing 20% (v/v) methanol; (*b*) same as *a* with 2% (v/v) acetic acid (final pH 2.6); (*c*) same as *b* with 0.005 *M* heptanesulfonic acid sodium; (*d*) 0.01 *M* KH_2PO_4 in water containing 20% (v/v) ethanol (pH 7.8 adjusted with 1:100 phosphoric acid in water); (*e*) 0.005 *M* $(NH_4)_2HPO_4$ in 20% (v/v) ethanol in water; (*f*) 0.005 *M* tetrabutylammonium hydroxide in 20% (v/v) ethanol in water (pH 7.8 adjusted with 1:100 phosphoric acid in water); and (*g*) 0.005 *M* $(NH_4)_2HPO_4$ in water containing 10% (v/v) methanol, acetonitrile, or a combination of both (5% each).

The HPLC method separated I from its salt, methylprednisolone succinate sodium (Fig. 1A). It also separated hydrocortisone from hydrocortisone acetate and from cortisone acetate. Hydrocortisone did not separate from I, and hydrocortisone acetate did not separate from cortisone acetate. The common preservatives methylparaben, propylparaben, and sodium benzoate did not interfere with the determinations of I, II, and hydrocortisone. The relative percent standard deviations based on five injections of the standard solutions were 0.64, 0.84, and 1.8 for I, II, and hydrocortisone, respectively.

Due to the poor solubility of II, partial crystallization occurred in all of the vehicles except 50% (v/v) glycerin. In glycerin, there was no II decomposition (Table I) in 92 days. Chromatograms from a standard so-

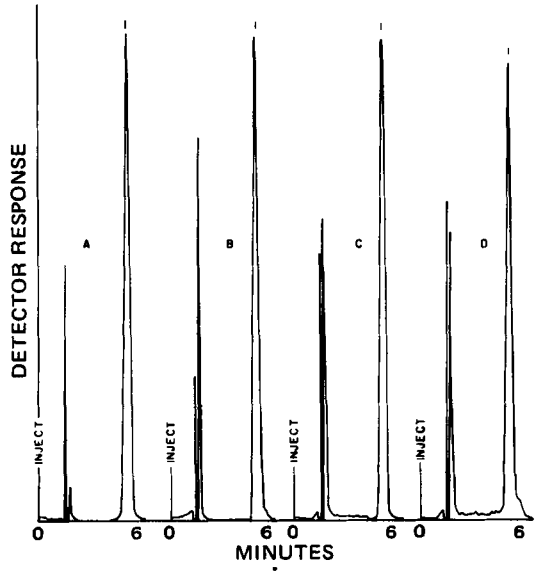

Figure 2—*Sample chromatograms from prednisolone. Key: peak 1 in A–D, prednisolone in a standard solution, in 50% glycerin, in 50% sorbitol, and in 50% sucrose, respectively; and B, C, and D, 92-day-old samples. For chromatographic conditions, see text.*

[9] Using Waters μBondapak/CN.

lution (Fig. 1B) and from a glycerin solution (Fig. 1C) were similar. In the presence of sugar, besides crystallization (Fig. 1B), II may be partially reduced to I (Figs. 1B and 1D).

Prednisolone did not crystallize in any vehicle investigated. It decomposed fast in the presence of citrate buffer. The percent retained after 92 days was 62.9 (Table I). Some decomposition also was recorded in water and in 50% aqueous sucrose (Table I and Fig. 2D). Both 50% (v/v) glycerin in water and 50% aqueous sorbitol appear to be excellent I vehicles (Table I). The peak obtained from a I solution in sorbitol (Fig. 2C) compared better with the standard (Fig. 1A) than did the peak from a glycerin solution (Fig. 2B), which had a slight shoulder, perhaps a sign of slight decomposition. All solutions studied contained 10% (v/v) ethanol and 0.1% sodium benzoate.

The developed method also was suitable for the quantitative determinations of I, II, and hydrocortisone in commercial tablets (Table II). The results obtained with the blue tetrazolium method were very high, presumably due to interference from some inactive ingredients. When the active ingredients were extracted with ethanol without heat, inconsistent and sometimes low results were obtained. Therefore, the mixture was heated to extract the active ingredient quantitatively.

Fluorometric Determination of Chlorzoxazone in Tablets and Biological Fluids

JAMES T. STEWART ˣ **and CHE W. CHAN**

Received December 4, 1978, from the *Department of Medicinal Chemistry, School of Pharmacy, University of Georgia, Athens, GA 30602.* Accepted for publication December 27, 1978.

Abstract □ A fluorometric determination for chlorzoxazone was developed based on the intrinsic drug fluorescence in chloroform using excitation and emission wavelengths of 286 and 310 nm, respectively. A calibration curve for chlorzoxazone in chloroform gave a linear working range of 0.027–2.3 μg/ml (r = 0.9999) with the minimum detectability at 27 ng/ml. The procedure was applied to chlorzoxazone analysis in spiked plasma and urine samples. Minimum detectable drug levels in these samples were 60 and 130 ng/ml, respectively. Data revealed that chlorzoxazone could be determined in plasma and urine even in the presence of 20-fold molar excesses of its major metabolite, 6-hydroxychlorzoxaxone, and acetaminophen. The method also was applicable to chlorzoxazone analysis in a commercial dosage form containing acetaminophen.

Keyphrases □ Chlorzoxazone—analysis, fluorometry, in commercial tablets and biological fluids, in presence of hydroxychlorzoxazone and acetaminophen □ Fluorometry—analysis, chlorzoxazone in commercial tablets and biological fluids, in presence of hydroxychlorzoxazone and acetaminophen □ Muscle relaxants—chlorzoxazone, fluorometric analysis in commercial tablets and biological fluids, in presence of hydroxychlorzoxazone and acetaminophen

Chlorzoxazone (I) is one of the most useful skeletal muscle relaxants in the treatment of painful muscle spasm, especially in combination with acetaminophen, a product that has been among the top 100 drug products in the United States in recent years. Studies of chlorzoxazone metabolism in humans have shown that its major metabolite is 6-hydroxychlorzoxazone (II) (1, 2). The drug is rapidly absorbed from the GI tract and essentially disappears from the blood in 7–8 hr. Less than 1% of the intact drug is excreted in the urine.

Among the analytical methods reported for I analysis have been spectrophotometry (1), titrimetry (3), and GLC and TLC (4–6). Direct application of many procedures to the determination of the drug in biological fluids is lacking. In other instances, parameters such as accuracy, linearity, sensitivity, and detection limit were not evaluated for the reported methodology.

In this paper, the intrinsic fluorescence of I is presented as a suitable analytical technique for the determination of the drug in biological fluids. The method also is useful for analysis of I in tablets. The method described is sensitive for I in the nanogram per milliliter range and is free from interference from II and acetaminophen. A previous report examined the analysis of I using derivatization with various fluorogenic reagents (7).

EXPERIMENTAL

Apparatus—Fluorescence measurements were made with a spectrophotofluorometer[1] equipped with a corrected spectra accessory. The following settings were used: excitation and emission slits, 10 nm; amplifier sensitivity coarse, 0.1; and measurement mode in true emission. Clear fused quartz cells (12.5 × 45 mm) were used as sample cells for dosage form analysis. Quartz microcells[2] (path length 5 mm) were used for the biological fluid assays.

Reagents and Chemicals—Chlorzoxazone[3], 6-hydroxychlorzoxazone[3], and acetaminophen[4] were obtained as pure powders and were used without further purification in the preparation of stock solutions. All other reagents and chemicals were commercially available and were used as received.

Determination of Chlorzoxazone in Dosage Form—A tablet[5] containing 250 mg of chlorzoxazone and 300 mg of acetaminophen was suspended in 15 ml of distilled water contained in a 50-ml centrifuge tube. After 25 ml of ethyl acetate was added, the solution was mixed[6] for 5 min. An aliquot of the ethyl acetate extract corresponding to 100 mg of chlorzoxazone was transferred to a 50-ml volumetric flask and diluted to volume with ethyl acetate. One milliliter of this solution was trans-

lution (Fig. 1B) and from a glycerin solution (Fig. 1C) were similar. In the presence of sugar, besides crystallization (Fig. 1B), II may be partially reduced to I (Figs. 1B and 1D).

Prednisolone did not crystallize in any vehicle investigated. It decomposed fast in the presence of citrate buffer. The percent retained after 92 days was 62.9 (Table I). Some decomposition also was recorded in water and in 50% aqueous sucrose (Table I and Fig. 2D). Both 50% (v/v) glycerin in water and 50% aqueous sorbitol appear to be excellent I vehicles (Table I). The peak obtained from a I solution in sorbitol (Fig. 2C) compared better with the standard (Fig. 1A) than did the peak from a glycerin solution (Fig. 2B), which had a slight shoulder, perhaps a sign of slight decomposition. All solutions studied contained 10% (v/v) ethanol and 0.1% sodium benzoate.

The developed method also was suitable for the quantitative determinations of I, II, and hydrocortisone in commercial tablets (Table II). The results obtained with the blue tetrazolium method were very high, presumably due to interference from some inactive ingredients. When the active ingredients were extracted with ethanol without heat, inconsistent and sometimes low results were obtained. Therefore, the mixture was heated to extract the active ingredient quantitatively.

Fluorometric Determination of Chlorzoxazone in Tablets and Biological Fluids

JAMES T. STEWART ˣ **and CHE W. CHAN**

Received December 4, 1978, from the *Department of Medicinal Chemistry, School of Pharmacy, University of Georgia, Athens, GA 30602.* Accepted for publication December 27, 1978.

Abstract □ A fluorometric determination for chlorzoxazone was developed based on the intrinsic drug fluorescence in chloroform using excitation and emission wavelengths of 286 and 310 nm, respectively. A calibration curve for chlorzoxazone in chloroform gave a linear working range of 0.027–2.3 μg/ml (r = 0.9999) with the minimum detectability at 27 ng/ml. The procedure was applied to chlorzoxazone analysis in spiked plasma and urine samples. Minimum detectable drug levels in these samples were 60 and 130 ng/ml, respectively. Data revealed that chlorzoxazone could be determined in plasma and urine even in the presence of 20-fold molar excesses of its major metabolite, 6-hydroxychlorzoxaxone, and acetaminophen. The method also was applicable to chlorzoxazone analysis in a commercial dosage form containing acetaminophen.

ferred to a 25-ml volumetric flask, and the solution was adjusted to volume with ethyl acetate.

Individual aliquots of 19.5, 39, and 78 μl were each transferred to 5-ml volumetric flasks and evaporated to dryness with nitrogen. Chloroform, 5 ml, was added to redissolve each residue, and the chloroform solution fluorescence was determined using excitation and emission wavelengths of 286 and 310 nm, respectively. A calibration curve for chlorzoxazone in the 0.1–1.50-μg/ml range was determined concurrently using dilutions obtained from a stock solution of chlorzoxazone in chloroform. Slope and intercept data from the calibration data regression analysis were used to solve for the drug concentration in individual aliquots: fluorescence = (slope × concentration) + intercept.

Assay of Chlorzoxazone in Plasma or Urine—One milliliter of plasma or urine containing chlorzoxazone was added to a 15-ml centrifuge tube containing 0.5 ml of pH 2.5 phosphate buffer. Six milliliters of petroleum ether containing 1.5% isoamyl alcohol was added, followed by mixing[6] for 2 min and centrifugation for 5 min at 2000 rpm. Five milliliters of the organic phase was transferred to a clean 15-ml centrifuge tube, followed by the addition of 2.25 ml of 0.5 *N* NaOH. After mixing[6] (1 min) and centrifugation (3 min), the organic phase was aspirated and 1.25 ml of 1 *N* HCl and 5 ml of chloroform were added. The solution was mixed[6] for 1 min, and the aqueous phase was aspirated.

Anhydrous sodium sulfate (1 g) was added to the chloroform layer, and the mixture was centrifuged for 3 min. The chloroform was decanted into a clear 15-ml centrifuge tube and evaporated to dryness with a nitrogen stream. Chloroform, 1 ml, was added to redissolve the residue. Fluorescence measurements were made using excitation and emission wavelengths of 286 and 310 nm, respectively. A calibration curve for chlorzoxazone was performed concurrently using spiked plasma or urine samples[7] in the 1–10-μg/ml concentration range. Slope and intercept data from regression analysis of the calibration data were used to solve for the drug concentration in each sample: fluorescence = (slope × concentration) + intercept.

RESULTS AND DISCUSSION

Fluorometric examination of I in water at pH 2–14 showed maximum fluorescence at pH < 6 using excitation and emission wavelengths of 286 and 310 nm, respectively. The fluorescence was essentially quenched at pH ≧ 10. A comparison of chlorzoxazone fluorescence in various organic solvents (water, ethanol, isobutanol, tetrahydrofuran, ethyl acetate, chloroform, carbon tetrachloride, and petroleum ether containing 1.5% isoamyl alcohol or 2% isobutanol) indicated that the drug was more fluorescent in the polar solvents. However, sensitivity was limited by the influence of Raman scatter of the various solvents, especially at low I concentrations.

Data showed that the chloroform Raman peak was less intense than those of the other solvents studied. Chloroform also gave less interference at the I emission wavelength while showing adequate solubility for the drug. Thus, chloroform was selected as the solvent for the fluorescence measurements. A calibration curve for I in chloroform showed a linear working range from 0.027 to 2.3 μg/ml (r = 0.9999) with minimum detection at 27 ng/ml (signal/noise = 2).

Chlorzoxazone was extracted from water samples using various organic solvents. The percent recovery of I from water using chloroform was 100.0 ± 4.4% (n = 6). Optimal extraction was at pH < 7. Other solvents such as ethyl acetate, isobutyl or isoamyl alcohol, ethyl acetate–isobutanol (3:2), and petroleum ether containing 1.5% isoamyl alcohol or 2% isobutanol also were useful extraction solvents. However, when these solvents were applied to chlorzoxazone extraction in plasma or urine samples, petroleum ether containing 1.5% isoamyl alcohol yielded the highest percent recovery in terms of chlorzoxazone fluorescence in chloroform.

Inclusion of isoamyl alcohol in petroleum ether serves two purposes: (*a*) it increases the solvent system polarity, and (*b*) it prevents drug adsorption on the glass walls of the containers (8). Increasing the isoamyl alcohol concentration in the petroleum ether from 1.5 to 10% or adding isobutanol (2–10%) did not significantly increase the percent recovery of I but gave higher blank readings. In general, higher blank readings were obtained for biological fluids extracted with polar solvents, probably due to extraction of endogenous plasma and urine components that absorb strongly at 280 nm in the vicinity of the I fluorescence excitation wavelength. Such substances also could reduce chlorzoxazone fluorescence, a phenomenon known as the inner-filter effect (9).

The petroleum ether–isoamyl alcohol extraction solvent minimized these interferences as well as those of II and acetaminophen, potentially interfering substances likely to be present with I in biological samples. Calculated percent recoveries of II and acetaminophen from aqueous solution using the solvent mix were 0.2 and 0.12%, respectively. Little or no interference in the chlorzoxazone assay in plasma or urine was observed even in the presence of a 20-fold excess of II and/or acetaminophen (Table II).

In the assay for I in biological fluids, chlorzoxazone extraction with

Table II—Typical Analysis of Chlorzoxazone at 1.7 μg/ml in Spiked Plasma and Urine Samples [a]

Mixture	Amount Found[b], μg/ml		Percent of Theory

[a] Samples were spiked by addition of microliter aliquots of stock chlorzoxazone, hydroxychlorzoxazone, and acetaminophen solutions in ethanol to 1.0-ml blank plasma or urine samples. [b] Based on quadruplicate samples. [c] Hydroxy metabolite was present in equimolar concentration to that of chlorzoxazone. [d] Hydroxy compound present in fourfold molar excess. [e] Compound present in 20-fold molar excess.

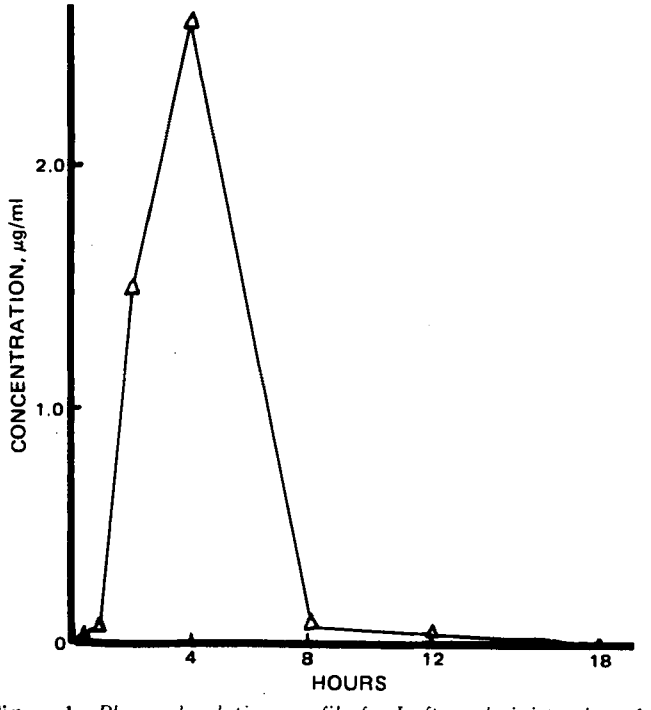

Figure 1—*Plasma level–time profile for I after administration of a single 300-mg oral dose to a healthy adult male.*

[7] Samples were spiked by addition of 2.5, 5.0, 10.0, and 20.0 μl of a 3.4-mg/10-ml ethanolic solution of I to 1.0 ml of blank plasma or urine samples.

petroleum ether–isoamyl alcohol is followed by a reextraction of the drug into aqueous sodium hydroxide, adjustment to pH 6.8 with acid, and extraction into chloroform for the final fluorometric measurement. With this procedure, percent recoveries of chlorzoxazone from plasma and urine compared to unextracted drug were 86.63 ± 1.66 (n = 8) and 95.37 ± 2.42 (n = 8), respectively. The linear working ranges for I in plasma and urine were 0.06–3.2 (r = 0.9993) and 0.13–3.0 (r = 0.9995) μg/ml, respectively, with minimum detectable levels at 60 and 130 ng/ml, respectively.

To demonstrate the application of the fluorometric I analysis, drug determinations in a commercial dosage form and in spiked plasma and urine samples were performed (Tables I and II). Plasma and urine data for spiked samples of I at 0.85, 3.4, and 6.8 μg/ml in the presence of varying concentrations of II and acetaminophen gave similar results. In addition, a plasma level–time profile for I (Fig. 1) illustrated the utility of the assay in determining plasma drug levels after oral administration of a single 300-mg dose to a healthy adult male. The peak plasma I level was obtained within 4 hr, with the drug essentially disappearing from plasma in 8 hr. Analysis of I in urine samples taken over 24 hr revealed that 116 μg of unchanged drug (<0.1% of administered dose) was excreted. These findings are comparable to those of previous metabolic studies (2).

Acetazolamide Binding to Two Carbonic Anhydrase Isoenzymes in Human Erythrocytes

W. F. BAYNE, L.-C. CHU, and F. THEEUWES ˣ

Received July 13, 1978, from *Alza Corporation, Palo Alto, CA 94304.* Accepted for publication August 18, 1978.

Abstract □ Acetazolamide binding to high activity and low activity carbonic anhydrase isoenzymes in red blood cells was studied. Inhibitory constants of 0.041 and 2.72 μ*M* and maximum binding capacities of 17.2 and 155 μ*M*, respectively, were found.

Keyphrases □ Acetazolamide—binding to two carbonic anhydrase isoenzymes, human erythrocytes, *in vitro* □ Carbonic anhydrase inhibitors—acetazolamide, binding to two carbonic anhydrase isoenzymes, human erythrocytes, *in vitro* □ Erythrocytes—acetazolamide binding to two carbonic anhydrase isoenzymes, *in vitro*

Acetazolamide, a carbonic anhydrase inhibitor widely used in the treatment of glaucoma, acts directly on the carbonic anhydrase in secretory cells of the ciliary body to reduce aqueous production and to lower intraocular pressure (1). The decrease in aqueous humor formation is thought to result from a decrease in bicarbonate flux from secretory cells (2, 3). Acetazolamide also acts indirectly to lower intraocular pressure by eliciting systemic acidosis (1). With the administration of therapeutic acetazolamide doses, renal carbonic anhydrase is inhibited, decreasing reabsorption of renally excreted bicarbonate (4).

BACKGROUND

Most carbonic anhydrase is in the red blood cells, with extravascular sources contributing an additional 10% or less (1). Two types of carbonic anhydrase have been identified: high activity type C and low activity type B (5). Extravascular carbonic anhydrase, including that found in the ciliary body, is generally the high activity type C isoenzyme (5). In humans, red blood cells are the major source of low activity type B isoenzyme (4). The ratio of low activity isoenzyme to high activity isoenzyme in human erythrocytes was reported as 6:1 (6).

Acetazolamide binding to human erythrocytes was studied previously (7). Intracellular and extracellular acetazolamide concentrations were determined by GLC following drug equilibration between the red blood cells and the external medium (either plasma or buffered saline). Rosenthal plots were constructed from the bound intracellular and extracellular concentrations to obtain the dissociation constants (inhibitory constant) of the enzyme–drug complex and the maximum binding capacity of the enzyme.

The inhibitory constant reported for the high activity isoenzyme was approximately an order of magnitude larger than that reported for the low activity isoenzyme (5, 6). Therefore, if *in vitro* binding studies are performed such that a wide range of intracellular acetazolamide concentrations is obtained, a definite curvature in the Rosenthal plot should be seen. Resolution of the curved plot into linear segments should permit the determination of maximum binding capacities and inhibitory constants for both isoenzymes.

Rosenthal plots constructed from *in vitro* equilibration studies performed in this laboratory exhibit a pronounced curvature. Inhibitory constants determined from the resolution of the curve were used as parameters in a nonlinear pharmacokinetic model for acetazolamide described previously (8).

EXPERIMENTAL

Human blood was drawn into heparinized tubes and immediately centrifuged to isolate the red blood cells. The cells were washed twice with two volumes of pH 7.4 buffered saline (0.15 *M* NaCl and 0.01 *M* phosphate), which were discarded. The cells were then suspended in the same buffered saline, and the hematocrit of the reconstituted red blood cell suspension was determined.

Acetazolamide was dissolved in methanol (0.5 μg/μl), and aliquots containing 1–200 μg of the drug were added to 20-ml disposable vials. Methanol was evaporated with a nitrogen stream. Red blood cell suspension was added to the vials (6 ml to vials containing <6 μg of acetazolamide and 3 ml to vials containing >6 μg of drug). The contents were incubated for 2 hr at 37° with gentle swirling in a reciprocating shaker. All incubations were performed using the suspension prepared from cells obtained from a single subject.

After incubation, the artificial blood medium was centrifuged. The acetazolamide concentration in 1–3-ml aliquots of the supernate was determined using a previously described high-pressure liquid chromatographic (HPLC) method (9).

The inhibitory constant reported for the high activity isoenzyme was approximately an order of magnitude larger than that reported for the low activity isoenzyme (5, 6). Therefore, if *in vitro* binding studies are performed such that a wide range of intracellular acetazolamide concentrations is obtained, a definite curvature in the Rosenthal plot should be seen. Resolution of the curved plot into linear segments should permit the determination of maximum binding capacities and inhibitory constants for both isoenzymes.

Rosenthal plots constructed from *in vitro* equilibration studies performed in this laboratory exhibit a pronounced curvature. Inhibitory constants determined from the resolution of the curve were used as parameters in a nonlinear pharmacokinetic model for acetazolamide described previously (8).

EXPERIMENTAL

Human blood was drawn into heparinized tubes and immediately centrifuged to isolate the red blood cells. The cells were washed twice with two volumes of pH 7.4 buffered saline (0.15 *M* NaCl and 0.01 *M* phosphate), which were discarded. The cells were then suspended in the same buffered saline, and the hematocrit of the reconstituted red blood cell suspension was determined.

Acetazolamide was dissolved in methanol (0.5 μg/μl), and aliquots containing 1–200 μg of the drug were added to 20-ml disposable vials. Methanol was evaporated with a nitrogen stream. Red blood cell suspension was added to the vials (6 ml to vials containing <6 μg of acetazolamide and 3 ml to vials containing >6 μg of drug). The contents were incubated for 2 hr at 37° with gentle swirling in a reciprocating shaker. All incubations were performed using the suspension prepared from cells obtained from a single subject.

After incubation, the artificial blood medium was centrifuged. The acetazolamide concentration in 1–3-ml aliquots of the supernate was determined using a previously described high-pressure liquid chromatographic (HPLC) method (9).

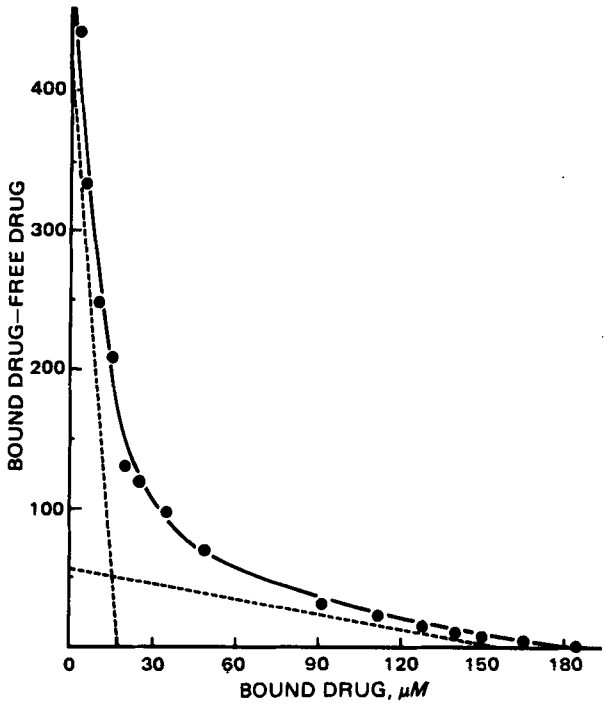

Figure 1—*Theoretical curve (—) that approximates the data points. The linear segment representing isoenzyme C has a negative reciprocal slope of 0.041 μM and an intercept on the abscissa of 17.2 μM; the linear segment representing isoenzyme B has a negative reciprocal slope of 2.71 μM and an intercept on the abscissa of 155 μM.*

The starting acetazolamide concentration in the artificial blood medium was assumed to be equivalent to the amount of acetazolamide added to each vial divided by the volume of the added suspension.

The total acetazolamide concentration in the red blood cells was calculated using:

$$C_{T,AB} = \frac{C_{AB} - (1-H)C_{ECF}}{H} \qquad \text{(Eq. 1)}$$

where C_{AB} is the concentration in the artificial blood, C_{ECF} is the concentration in the supernate or extracellular fluid, and H is the hematocrit.

RESULTS AND DISCUSSION

The acetazolamide concentration bound to carbonic anhydrase was calculated as the total intracellular concentration minus the product of the extracellular concentration times the cell water volume. The free drug concentration in the cell water was assumed to be equivalent to the extracellular concentration at equilibrium. The calculated bound drug concentration was expressed relative to the total cell volume, as was the measured total intracellular concentration.

A Rosenthal plot (Fig. 1) was constructed by plotting the ratio of the bound concentration to the intracellular free concentration *versus* the bound concentration. Except at bound concentrations that approached the total carbonic anhydrase concentration (intercept on abscissa), all intracellular drug essentially was bound (high bound to free ratio). The curvilinear plot was resolved into two linear segments by a graphic procedure (10). The negative reciprocal of the slope of each line is the inhibitory constant, and the intercept on the abscissa is the maximal binding capacity for the respective isoenzyme. The inhibitory constants were 0.041 and 2.72 μM and the maximum binding capacities were 17.2 and 155 μM for the high activity and low activity isoenzymes, respectively. Since there is one binding site per carbonic anhydrase molecule for the sulfonamides (11), the maximum binding capacity for a particular isoenzyme is the intracellular concentration of that isoenzyme.

The total carbonic anhydrase concentration in the human erythrocyte was reported to be 156 μM, of which 20 μM was the high activity isoenzyme and 136 μM was the low activity isoenzyme (6).

Previous studies (7) also showed that the carbonic anhydrase concentration (presumably type B) is variable in the human erythrocyte. Maren *et al.* (1) reported that the total carbonic anhydrase concentration is highly variable (range of 130–200 μM). Thus, the total carbonic anhydrase concentration in this study (172 μM) is within the range of previously reported values.

The inhibitory constant (2.72 μM) determined for the low activity isoenzyme in the present study agrees well with the inhibitory constant determined by previous investigators (7) (2 μM) using the *in vitro* equilibrium uptake technique. An inhibitory constant of 1 μM at 37° was reported for the low activity isoenzyme using kinetic measurements (6). The value reported at 37° in that study actually was extrapolated from measurements at lower temperatures.

Anions have been shown to inhibit carbonic anhydrase. For example, Maren *et al.* (5) showed that the low activity isoenzyme is much more sensitive to anion inhibition than the high activity isoenzyme (5). In particular, intracellular chloride and bicarbonate concentrations reduce the activity of the low activity isoenzyme to 8% of that in the absence of the anions. The intracellular chloride and bicarbonate anions probably compete with acetazolamide for binding sites in the uptake studies. Thus, the apparent inhibitory constant determined in studies may be larger than the true dissociation constant of the enzyme–drug complex in the absence of anions.

Intracellular red blood cell concentrations of chloride and bicarbonate are 85 and 15 mM, respectively (5). Chloride- and bicarbonate-ion concentrations that reduce the enzyme-catalyzed hydration of carbon dioxide by one-half (I_{50}) were reported to be 26 and 12 mM, respectively; these values approximate the inhibitory constants (5). Thus, the inhibitory constant of 2.72 μM, as determined in the present uptake study, becomes 0.18 μM in the absence of chloride and bicarbonate anions.

Maren *et al.* (1) reported an I_{50} value of 0.25 μM for acetazolamide using the low activity isoenzyme. These kinetic measurements were conducted using a barbital buffer to minimize carbonic anhydrase inhibition by anions in conventional buffer systems. Thus, there is agreement between the inhibitory constants determined by kinetic measurements and uptake studies if competition by intracellular anions is taken into account.

Since anions are present in the physiological situation, the inhibitory constants determined from uptake studies, rather than kinetic measurements, are more representative of the parameters to be used in describing drug disposition.

The I_{50} value reported for acetazolamide, using the high activity isoenzyme and the barbital buffer system, was 0.017 μM (1). This value compares favorably with the inhibitory constant (0.04 μM) determined from the uptake study. The similarity in these values is a manifestation of the negligible competition of intracellular anions with acetazolamide for the binding site on this isoenzyme. The negligible inhibition of the high activity isoenzyme by anions was demonstrated using kinetic measurements (5).

Modified Fluorometric Quantitation of Pancuronium Bromide and Metabolites in Human Maternal and Umbilical Serums

LEMUEL B. WINGARD, Jr. *‡x, EZZAT ABOULEISH ‡¶, DANIEL C. WEST *, and THOMAS J. GOEHL §

Received June 7, 1978, from the *Departments of *Pharmacology and ‡Anesthesiology, School of Medicine, and the §Department of Medicinal Chemistry, School of Pharmacy, University of Pittsburgh, Pittsburgh, PA 15261, and the ¶Magee-Women's Hospital, Pittsburgh, PA 15213.* Accepted for publication December 29, 1978.

Abstract □ The procedure for pancuronium bromide ion-pair extraction into chloroform using rose bengal and subsequent fluorometric measurement was modified by changing the extraction pH and eliminating phenol, ethanol, and acetone to give easier operation and enhanced fluorescence stability. Precision, accuracy, and sensitivity were evaluated over 0.14–0.82 μg/ml (CV = 14; relative error = 9%) and 0.05–0.17 μg/ml (CV = 19; relative error = 21%). Following a dose of 0.1 mg/kg for cesarean section in humans, the mean maternal arterial and umbilical venous serum concentrations of pancuronium bromide and metabolites were 0.52 and 0.12 μg/ml, respectively, at delivery (mean of 13 min after injection).

Keyphrases □ Muscle relaxants—pancuronium bromide, analysis, fluorometry, maternal arterial and umbilical venous serum □ Fluorometry—analysis, pancuronium bromide in maternal arterial and umbilical venous serum □ Pancuronium bromide—analysis, fluorometry, maternal arterial and umbilical venous serum, transplacental transfer □ Transplacental transfer—pancuronium bromide

Pancuronium bromide is used as a muscle relaxant during anesthesia for cesarean section (1). Therefore, the quantitation of maternal and fetal serum pancuronium bromide concentrations is important for evaluating transplacental drug transfer (2).

Pancuronium is a bisquaternary ammonium steroid that contains acetate ester groups at the 3- and 17-positions. Drug metabolism produces the 3-hydroxy, 17-hydroxy, and 3,17-dihydroxy derivatives through ester hydrolysis. A sensitive fluorometric quantitation procedure for pancuronium bromide and its metabolites in human plasma was described (3), and an initial modification to stabilize the fluorescence was reported (4). However, a higher intensity and more stable fluorescence signal was still desirable. In addition, a rigorous evaluation of the precision, accuracy, and sensitivity of the fluorometric plasma or serum pancuronium bromide determination has not appeared, although a minimum 0.02-μg/ml sensitivity, using 1 ml of plasma, was reported (3, 4).

Two reports on transplacental pancuronium bromide transfer have appeared (5, 6). In the earlier study (5), conclusions were based on the detection of pancuronium bromide and its metabolites in fetal urine using a limited sensitivity (0.6 μg/ml) spectrophotometric procedure. The second study (6) was based on maternal and umbilical cord blood samples taken during cesarean section delivery and assayed for pancuronium bromide using the fluorometric procedure; however, despite predosing with succinylcholine, no consideration was given to possible interferences in the pancuronium bromide assay due to succinylcholine or its metabolites.

In the present study, the fluorometric method was modified, and precision and accuracy were evaluated over the expected fetal and maternal concentration ranges. Serum, rather than plasma, was selected to facilitate the measurement of γ-globulin, to which pancuronium binds (7). The method was used to measure pancuronium bromide concentrations in maternal and umbilical cord blood samples obtained at cesarean section delivery.

EXPERIMENTAL

Chemicals and Reagents—Crystalline pancuronium bromide[1] was used as received. Rose bengal[2] was purified by washing six times with ethyl acetate[3] and three times with chloroform[4] and was desiccated (8). All other materials were reagent grade. All glassware was cleaned in 15% nitric acid. The centrifuge tubes were coated with dimethyldichlorosilane[5], rinsed with toluene[3], methanol[3], water, and acetone[3], and air dried. Pooled human serum[6] from normal subjects was used for the standard curves. The buffer was prepared by adding 0.2 M sodium bicarbonate to 0.2 M sodium carbonate until pH 10.5 was attained.

Previous Assay—To a 25-ml glass-stoppered centrifuge tube were added 7 ml of chloroform containing 2.5% phenol and 5% ethanol, 1 ml of serum, 1 ml of 0.1 M pH 7.8 phosphate buffer, and 0.5 ml of 0.2 mg of rose bengal/ml of 0.45 M dibasic potassium phosphate. The mixture was shaken 2 min on a vortex mixer followed by 30 min on a rotary mixer. The samples were centrifuged 10 min at 1500×g, and the aqueous layer was aspirated. An aliquot (0.5 ml) of the chloroform–phenol layer was added to 3.5 ml of acetone and vortexed. The relative fluorescence intensity was determined at 570 nm with excitation at 546 nm.

Modified Assay—To a 15-ml screw-capped (polytef-lined caps) centrifuge tube were added 1 ml of serum, 1 ml of 0.2 M sodium bicarbonate–carbonate buffer (pH 10.5), 0.5 ml of 0.5 mg of rose bengal/ml of 0.45 M dibasic potassium phosphate, and 7 ml of chloroform, with vortexing after each addition. After 30 min on a reciprocating horizontal shaker at 185 oscillations/min, the samples were centrifuged for 10 min at 1500×g; the aqueous layer was aspirated.

About 3 ml of the chloroform layer was transferred to a 1-cm silica cell. The relative fluorescence intensity was measured at 570 nm, with excitation at 546 nm, using a spectrofluorometer[7]. The instrument was adjusted daily to the same relative fluorescence intensity with 1 μg of quinine sulfate/ml of 0.1 N H_2SO_4 at 450 nm, with excitation at 350 nm. The blood samples were held for 2 hr at 0–4° and then centrifuged[8] for 10 min at 6000 rpm for serum preparation. All samples were assayed within 6 hr of blood sampling.

Standardization Procedure—To compensate for normal daily fluctuations in the spectrofluorometer xenon lamp output, a five-point linear least-squares fitted calibration curve was prepared each day using freshly prepared pancuronium bromide in serum over the range of 0–0.8 μg/ml. To establish precision, accuracy, and sensitivity, replicate pancuronium bromide samples in serum were prepared over the ranges of ~0.05–0.2 and 0.1–0.8 μg/ml. The resulting relative fluorescence intensity *versus* concentration data were fit by linear least squares; the coefficient of variation and the percentage deviation of each point (percent error) from the fitted line were calculated.

Human Study Protocol—Patients undergoing elective cesarean section delivery gave informed consent. The patients weighed 67 ± 10 (SD) kg and received 0.75 mg of hydroxyzine/kg im, 0.4 mg of atropine iv, 4 mg of thiamylal sodium/kg iv, 0.1 mg of pancuronium bromide/kg iv, and nitrous oxide–oxygen anesthesia. Blood samples included ma-

ternal predrug control, maternal arterial at delivery, and fetal venous from the clamped umbilical cord.

RESULTS AND DISCUSSION

A previous study in adults undergoing nonobstetric surgery showed that pancuronium concentrations ranged from 0.12 to 0.79 μg/ml during the 20-min interval after intravenous injection of ~0.1 mg/kg (9). Since pancuronium is a positively charged quaternary ammonium compound, its transfer rate across the placental membranes into the fetal blood would be slow; so fetal pancuronium concentrations would be much less than those in adults. For example, for the similar quaternary ammonium muscle relaxant metocurine, the human fetal plasma concentration was about one-tenth the maternal plasma concentration (10). Since the estimated fetal pancuronium bromide concentrations were near the lower limit for quantitation by the fluorometric method, its precision, accuracy, and sensitivity had to be evaluated.

In this laboratory, the relative fluorescence intensity varied by ±90% from the mean for four 1-μg/ml samples using the original (3) or modified (4) fluorometric assay. Since this variation was too great for the present study, the following changes were made: the extraction pH was increased from 7.8 to 10.5, phenol was eliminated from the extraction, and acetone and most of the ethanol were eliminated from the fluorescence measurement step.

The higher extraction pH increased the relative fluorescence from 0.27 ± 0.006 (*SD*) at pH 7.8 to 0.52 ± 0.03 (*SD*) at pH 10.5 for three samples of 0.5 μg of pancuronium bromide/ml of serum. The fluorescence decreased by 10% if the extraction was done at pH 12 instead of 10.5. This improvement could be expected if the rose bengal phenolic groups ionized to a greater extent at the higher pH. This would give a higher negative charge and improve complexation with the positively charged pancuronium ion. To obtain this desired pH change, a different buffer system (carbonate) was employed.

The phenol had been added in the extraction step to reduce emulsion formation during analysis (3, 8); however, there was still considerable emulsion formed. Unfortunately, the phenol also quenched the fluorescence (8). With the modifications, no advantage was observed from phenol addition; therefore, the phenol was omitted. Similarly, the ethanol used in the earlier procedures to stabilize the pancuronium–rose bengal complex fluorescence in acetone (3, 8) was omitted since the pancuronium–rose bengal–chloroform solutions without acetone showed only 3% change in fluorescence intensity over 30 min. The chloroform used in the present studies contained 0.75% ethanol as preservative; this amount was negligible compared with the 5% by volume in the chloroform–phenol solution used previously. Apparently, the combination of the higher pH, less alcohol, and no phenol minimized the emulsion formation by an unknown mechanism.

In these studies, the enhanced fluorescence obtained by mixing one volume of the pancuronium–rose bengal–chloroform solution with seven volumes of acetone was less than the loss in fluorescence due to dilution. For example, at 0.5 μg of pancuronium/ml, the relative fluorescence intensity was 0.52 ± 0.03 (*SD*) (n = 3) without acetone and only 0.19 ± 0.07 (*SD*) (n = 3) with acetone. Therefore, the acetone was omitted, which greatly helped to stabilize the fluorescence since the acetone fluorescence enhancement was transitory (4).

Precision and accuracy were evaluated by using serum to which known pancuronium bromide amounts were added. These samples were assayed as described. The standard curve was linear over the 0.14–0.82-μg/ml range, but some scatter was evident over the 0.05–0.17-μg/ml range. Representative results for the mean percent relative standard deviation (*CV*) and the mean relative error for each concentration range are shown in Table I. For the 0.05–0.14-μg/ml range, the validation was done on three separate groups (Table I). The averages of the *CV* for the high and low concentration ranges were 14 and 19, respectively; the averages of the mean relative error were 9% and 21% for the high and low ranges, respectively.

The mean fluorescence intensity at 0.05 μg/ml was three times the mean fluorescence intensity of the serum samples without added pancuronium bromide. Therefore, the minimum detectable level, defined as two times the blank fluorescence value, was less than 0.05 μg/ml. However, based on the *CV* values, the precision would be too poor to use at concentrations <0.05 μg/ml. Patient data with serum blanks that deviated more than 3 *SD* from the mean were omitted.

An evaluation to see if samples could be stored for later assay demonstrated that the fluorescence readings were significantly lower if the serum samples were not assayed promptly. In this evaluation, a solution of 0.5 μg of pancuronium bromide/ml of serum was prepared and divided into 15 1-ml aliquots. Three samples were assayed on the same day with a result of 0.49 μg/ml. The other samples were frozen. Three tubes were thawed and assayed after the days shown with the following results: 1 day, 0.42 μg/ml; 2 days, 0.41 μg/ml; 7 days, 0.28 μg/ml; and 13 days, 0.37 μg/ml. In addition, an umbilical cord sample assayed as described and again 24 hr later showed an apparent 30% decrease in pancuronium concentration.

Whether this change in fluorescence intensity was due to drug instability or to some other factor is not known. However, the results showed clearly that samples could not be stored and assayed later. Therefore, all samples were assayed within 4–6 hr after blood sampling. This finding raises an additional question concerning the data obtained in the previous placental transfer study of pancuronium using the fluorometric assay since the samples were frozen and assayed later (6). However, in that study, heparinized plasma rather than serum was used; pancuronium stability in heparinized plasma has not been reported.

The modified assay was utilized to determine the mean maternal arterial and umbilical vein concentrations in 15 patients undergoing elective cesarean section delivery. A preinduction maternal blood sample was used as a control. To test for possible interference in the pancuronium assay due to the other drugs used during cesarean section, the maximum maternal serum concentrations of the other drugs, except gaseous nitrous oxide, were estimated and added to samples of 0.5 μg of pancuronium bromide/ml of serum. The drugs, their concentrations, and the relative fluorescence following assay for pancuronium were: hydroxyzine hydrochloride, 50 μg/ml, 0.51 ± 0.04 (*SD*) (n = 3); atropine, 0.08 μg/ml, 0.49 ± 0.04 (*SD*) (n = 3); thiamylal sodium, 56 μg/ml, 0.44 ± 0.02 (*SD*) (n = 3); and control, 0.46 ± 0.05 (*SD*) (n = 9). It was concluded that no interference existed at the concentrations tested.

The mean maternal arterial and umbilical venous pancuronium concentrations were 0.52 ± 0.14 and 0.12 ± 0.04 μg/ml, respectively. All samples were obtained at delivery, which occurred at a mean time of 13 ± 4 min after the pancuronium injection. The resulting fetal to maternal ratio of the pancuronium concentrations at delivery was 0.23. This ratio was similar to the mean ratio of 0.24 reported earlier (6) for a smaller dose of pancuronium bromide but with a possible question concerning the absolute concentration values in the earlier study.

Table I—Representative Results for Precision and Accuracy Evaluation over Two Concentration Ranges [a]

Pancuronium Bromide Added, μg/ml	n	Calculated Experimental Mean (Range), μg/ml	*CV*	Relative Error, %
		Part 1: High Range		
0.14	4	0.14 (0.11–0.17)	24	17
0.38	3	0.40 (0.34–0.45)	15	12
0.82	4	0.81 (0.78–0.84)	3	3
		Part 2: Low Range		
0.05	3	0.04 (0.03–0.04)	15	18
0.06	6	0.06 (0.04–0.08)	22	22
0.07	4	0.11 (0.09–0.12)	11	47
0.12	5	0.10 (0.08–0.13)	22	20
0.14	5	0.14 (0.09–0.16)	20	13
0.15	3	0.13 (0.10–0.14)	16	16

[a] Unknown "test" and known "standard" samples of pancuronium in serum were prepared and assayed to give relative fluorescence values. All samples were randomized. The standard samples duplicated those used in preparing the daily reference curve and were used to plot a relative fluorescence intensity *versus* concentration reference curve. This curve was used to convert fluorescence intensity to concentration for the test samples. The results in this table are for the test samples.

Isolation and Identification of 3,3′,5,5′-Tetrabis(*tert*-butyl)stilbenequinone from Polyethylene Closures Containing Titanium Dioxide and Butylated Hydroxytoluene

I. JAGNANDAN *x, H. DAUN, T. J. AMBROSIO *, and S. G. GILBERT

Received October 3, 1977, from the *Department of Food Science, Rutgers—The State University, New Brunswick, NJ 08903.* Accepted for publication December 28, 1978. *Present address: Research and Development, Schering Corp., Bloomfield, NJ 07003.

Abstract □ A yellow compound was isolated from commercially available, discolored, polyethylene ophthalmic closures containing titanium dioxide and butylated hydroxytoluene (I). This compound was present at 7.46 ppm (w/w). It was identified by UV, IR, and mass spectra as 3,3′,5,5′-tetrabis(*tert*-butyl)stilbenequinone (II), a dimer of I. Further structural confirmation was obtained by NMR. Formation of II is catalyzed by titanium dioxide.

Keyphrases □ Tetrabis(*tert*-butyl)stilbenequinone—analysis, isolation from polyethylene closures, synthesis from butylated hydroxytoluene catalyzed by titanium dioxide □ Butylated hydroxytoluene—conversion to tetrabis(*tert*-butyl)stilbenequinone in polyethylene closures, catalyzed by titanium dioxide □ Polyethylene—drug packaging, discoloration, butylated hydroxytoluene conversion to tetrabis(*tert*-butyl)stilbenequinone catalyzed by titanium dioxide □ Titanium dioxide—in polyethylene closures, catalysis of butylated hydroxytoluene discoloration reaction

Polymers are widely used in industry as packaging materials for food and drugs. As they age, they undergo oxidation *via* a free radical mechanism initiated by heat, light, or radiation. One result is scission or branching in the polymer chain, leading to eventual degradation in the mechanical properties of the polymer.

Antioxidants are added to the polymer in small amounts to prevent degradation. These substances can inhibit free radical formation and may become degraded instead of the polymer. Some antioxidants can convert to colored substances.

The oxidation products of antioxidants have been linked to the discoloration of polyethylene (1). An oxidation product of I caused a marked yellow discoloration of clear polyethylene (2). This colored compound was 3,3′,5,5′-tetrabis(*tert*-butyl)stilbenequinone (II). It has been isolated from cooking oil to which I was added (3). The corresponding yellowing of pigmented polyethylene caused by I has not been reported. The pigment, titanium dioxide, is used extensively as an opacifier for food and drug packaging.

This work was undertaken to isolate and identify the yellow discoloration product in titanium dioxide-pigmented polyethylene in which I is the antioxidant and to evaluate the titanium dioxide role in the discoloration reaction.

EXPERIMENTAL

Closures—Commercially available, opaque, ophthalmic, 15-mm closures, consisting of polyethylene with 1.5% titanium dioxide as the pigment and I as the antioxidant, were used. Each closure weighed ~0.2922 g with a specific gravity of 0.931.

Extraction—Extraction was performed using a soxhlet extractor under defined reproducible conditions.

Separation and Purification of II—*Column Chromatography*—The silica gel column was purged with hexane, toluene, and chloroform. The yellow band was removed using hexane and concentrated by blowing nitrogen on it at room temperature.

TLC—Hexane–toluene (80:20, v/v) was used as the developing medium on silica gel 60 F 254, 25-mm glass plates. On separation, the yellow band was scraped off and reeluted for further purification.

Spectrophotometry—A spectrophotometer was used to determine spectra in the visible and UV regions. IR spectrophotometric analysis was performed with a beam condenser in conjunction with an ultramicro liquid cell.

Mass Spectrometry—A mass spectrometer with a single-focusing magnetic mass analyzer was used. Temperature programming was such that spectra were obtained rapidly at increasing temperatures. All samples were analyzed at 70 ev.

NMR—An NMR spectrometer analyzed the sample in deuterated chloroform with tetramethylsilane as the internal marker. The sample was run at ambient temperature at 100.1 MHz in the Fourier transfer mode using a computer. Chemical shift was expressed as δ (delta) in parts per million.

GLC—GLC analysis was at 200° using a 3.08-m column (0.64 cm in diameter) with 10% SE-30 on 90–100-mesh packing. Nitrogen was the carrier gas with a flow rate of 60 ml/min.

Quantification—The amount of I injected *versus* response was generated using the gas chromatograph. Twelve solutions of I in acetone ranging from 1.0×10^{-5} to 12.0×10^{-5} g were prepared by linear stepwise dilution to quantify I in the 250–500-ppm region. Chloroform was unsuitable because both spectral and analytical grades produced a response at the same retention time as I around or below 9.0×10^{-8} g. With identical extraction conditions, the amount of I extracted per hour from nondiscolored caps was determined.

RESULTS AND DISCUSSION

At room temperature, the yellow material was slightly soluble in chloroform. A total of 913 closures, weighing 266.7786 g, was placed in this solvent. After the extraction procedure, they weighed 265.0773 g, a difference of 1.7013 g. A 10-μl injection of the concentrated crude extract into the gas chromatograph revealed 29 distinct substances.

Spectrophotometric examination of an aliquot of the extract showed major absorption bands at 418 and 442 nm and two minor absorption bands at 396 and 218–233 nm.

Isolation and Identification of 3,3′,5,5′-Tetrabis(*tert*-butyl)stilbenequinone from Polyethylene Closures Containing Titanium Dioxide and Butylated Hydroxytoluene

I. JAGNANDAN *x, H. DAUN, T. J. AMBROSIO *, and S. G. GILBERT

Received October 3, 1977, from the *Department of Food Science, Rutgers—The State University, New Brunswick, NJ 08903.* Accepted for publication December 28, 1978. *Present address: Research and Development, Schering Corp., Bloomfield, NJ 07003.

Abstract □ A yellow compound was isolated from commercially available, discolored, polyethylene ophthalmic closures containing titanium dioxide and butylated hydroxytoluene (I). This compound was present at 7.46 ppm (w/w). It was identified by UV, IR, and mass spectra as 3,3′,5,5′-tetrabis(*tert*-butyl)stilbenequinone (II), a dimer of I. Further structural confirmation was obtained by NMR. Formation of II is catalyzed by titanium dioxide.

Keyphrases □ Tetrabis(*tert*-butyl)stilbenequinone—analysis, isolation from polyethylene closures, synthesis from butylated hydroxytoluene catalyzed by titanium dioxide □ Butylated hydroxytoluene—conversion to tetrabis(*tert*-butyl)stilbenequinone in polyethylene closures, catalyzed by titanium dioxide □ Polyethylene—drug packaging, discoloration, butylated hydroxytoluene conversion to tetrabis(*tert*-butyl)stilbenequinone catalyzed by titanium dioxide □ Titanium dioxide—in polyethylene closures, catalysis of butylated hydroxytoluene discoloration reaction

Polymers are widely used in industry as packaging materials for food and drugs. As they age, they undergo oxidation *via* a free radical mechanism initiated by heat, light, or radiation. One result is scission or branching in the polymer chain, leading to eventual degradation in the mechanical properties of the polymer.

Antioxidants are added to the polymer in small amounts to prevent degradation. These substances can inhibit free radical formation and may become degraded instead of the polymer. Some antioxidants can convert to colored substances.

The oxidation products of antioxidants have been linked to the discoloration of polyethylene (1). An oxidation product of I caused a marked yellow discoloration of clear polyethylene (2). This colored compound was 3,3′,5,5′-tetrabis(*tert*-butyl)stilbenequinone (II). It has been isolated from cooking oil to which I was added (3). The corresponding yellowing of pigmented polyethylene caused by I has not been reported. The pigment, titanium dioxide, is used extensively as an opacifier for food and drug packaging.

This work was undertaken to isolate and identify the yellow discoloration product in titanium dioxide-pigmented polyethylene in which I is the antioxidant and to evaluate the titanium dioxide role in the discoloration reaction.

EXPERIMENTAL

Closures—Commercially available, opaque, ophthalmic, 15-mm closures, consisting of polyethylene with 1.5% titanium dioxide as the pigment and I as the antioxidant, were used. Each closure weighed ~0.2922 g with a specific gravity of 0.931.

Extraction—Extraction was performed using a soxhlet extractor under defined reproducible conditions.

Separation and Purification of II—*Column Chromatography*—The silica gel column was purged with hexane, toluene, and chloroform. The yellow band was removed using hexane and concentrated by blowing nitrogen on it at room temperature.

TLC—Hexane–toluene (80:20, v/v) was used as the developing medium on silica gel 60 F 254, 25-mm glass plates. On separation, the yellow band was scraped off and reeluted for further purification.

Spectrophotometry—A spectrophotometer was used to determine spectra in the visible and UV regions. IR spectrophotometric analysis was performed with a beam condenser in conjunction with an ultramicro liquid cell.

Mass Spectrometry—A mass spectrometer with a single-focusing magnetic mass analyzer was used. Temperature programming was such that spectra were obtained rapidly at increasing temperatures. All samples were analyzed at 70 ev.

NMR—An NMR spectrometer analyzed the sample in deuterated chloroform with tetramethylsilane as the internal marker. The sample was run at ambient temperature at 100.1 MHz in the Fourier transfer mode using a computer. Chemical shift was expressed as δ (delta) in parts per million.

GLC—GLC analysis was at 200° using a 3.08-m column (0.64 cm in diameter) with 10% SE-30 on 90–100-mesh packing. Nitrogen was the carrier gas with a flow rate of 60 ml/min.

Quantification—The amount of I injected *versus* response was generated using the gas chromatograph. Twelve solutions of I in acetone ranging from 1.0×10^{-5} to 12.0×10^{-5} g were prepared by linear stepwise dilution to quantify I in the 250–500-ppm region. Chloroform was unsuitable because both spectral and analytical grades produced a response at the same retention time as I around or below 9.0×10^{-8} g. With identical extraction conditions, the amount of I extracted per hour from nondiscolored caps was determined.

RESULTS AND DISCUSSION

At room temperature, the yellow material was slightly soluble in chloroform. A total of 913 closures, weighing 266.7786 g, was placed in this solvent. After the extraction procedure, they weighed 265.0773 g, a difference of 1.7013 g. A 10-μl injection of the concentrated crude extract into the gas chromatograph revealed 29 distinct substances.

Spectrophotometric examination of an aliquot of the extract showed major absorption bands at 418 and 442 nm and two minor absorption bands at 396 and 218–233 nm.

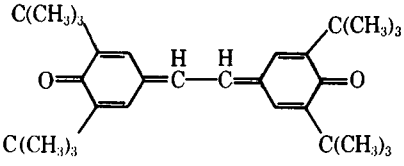
Column chromatography separated the extract into a yellow band and a white polymeric band.

After 10 TLC separations for purification, the yellow substance exhibited an IR spectrum identical to that obtained by Bohn and Campbell (4).

Mass spectra were obtained at various temperatures. Below 110°, poor fragmentation occurred. Above 160°, the compound disintegrated. The ideal conditions for obtaining mass spectra were 110–160° and 70 ev. The mass spectrum obtained was similar to that obtained previously (2).

The NMR spectrum was similar to that reported for II (6). Values of 1.30 and 1.33 ppm resulted from *tert*-butyl groups. Peaks at 6.90 and 7.52 ppm were due to the aromatic CH's. Peaks at 7.08 and 7.18 ppm were due to the olefinic CH's.

Based on the IR, mass, and NMR spectra, the yellow substance was assigned a quinoid structure with empirical formula $C_{30}H_{42}O_2$. Based on these spectral data, the structure of the isolated compound is:



II

For quantification, 334.7895 g of discolored caps was extracted. The amount of I still present after discoloration was 47.7 ppm. After purification, 2.5 mg or 7.46 ppm of II was obtained.

Synthesis of Authentic Yellow Compound—The synthesis of the authentic yellow compound was carried out by a literature method (7). Compound I was put in an oven at 100° for 2 weeks. The yellow material obtained was purified by column chromatography and TLC. The isolation and purification procedures were identical to those used for II extracted from the closures.

IR and mass spectra were recorded. The sample was smeared with mineral oil and sandwiched between two salt blocks to obtain the IR spectrum, which was similar to that obtained for II. The mass spectrum was similar to that obtained for the unknown yellow substance.

The mass spectrum exhibited base peaks at *m/e* 435, 436, and 57. This compound was identical to that isolated from the polyethylene closures.

Synthesis of Yellow Compound by Catalytic Action of Titanium Dioxide—3,3′,5,5′-Tetrabis(*tert*-butyl)stilbenequinone was obtained by adding 1.5 g of rutile titanium dioxide powder to 100 g of I. Yellowing was obtained within 24 hr at 100° in an oven. The yellow compound was purified by the methods used for II and identified by IR and mass spectral analyses. The IR and mass spectra were similar to those reported previously (2, 4, 7). Under identical conditions but without titanium dioxide, discoloration of I to form II only occurred after 2 weeks.

Dihydroquinidine Contamination of Quinidine Raw Materials and Dosage Forms: Rapid Estimation by High-Performance Liquid Chromatography

PREM K. NARANG and WILLIAM G. CROUTHAMEL *x

Received October 3, 1978, from the *Department of Pharmacy, School of Pharmacy, University of Maryland, Baltimore, MD 21201.* Accepted for publication December 28, 1978.

*Present address: Department of Biochemistry and Drug Metabolism, Hoffmann-La Roche Inc., Nutley, NJ 07110.

Abstract □ Dihydroquinidine is a commonly encountered contaminant in quinidine raw materials. The USP allows 0–20% dihydroquinidine in quinidine products, but the assays used to quantitate dihydroquinidine have been lengthy or have required sophisticated equipment. The present method separates dihydroquinidine from quinidine and provides rapid, precise quantitation of both dihydroquinidine and quinidine. The clinical importance of dihydroquinidine contamination of quinidine dosage forms remains unanswered.

Keyphrases □ Hydroquinidine—analysis, high-performance liquid chromatography, as contaminant in quinidine raw materials and dosage forms □ Quinidine—analysis, high-performance liquid chromatography, hydroquinidine contamination in raw materials and dosage forms □ High-performance liquid chromatography—analysis, hydroquinidine contamination of quinidine raw materials and dosage forms

Quinidine raw materials and dosage forms routinely contain dihydroquinidine as a contaminant. The amount of the dihydro derivative varies from 0 to 25% (1), although dosage form dihydroquinidine content is limited to 20% by the USP (2). Many methods reported for quinidine quantitation do not separate the dihydroquinidine contaminant from quinidine. Previous methods for dihydroquinidine quantitation in dosage forms and raw materials include TLC (3), NMR (4), chemical-ionization mass spectrometry (5), and normal phase high-performance liquid chromatography (HPLC) (3). These methods are time consuming or tedious or require expensive equipment. The described HPLC method separates the dihydroquinidine contaminant from quinidine and allows rapid, precise quantitation of both compounds.

EXPERIMENTAL

Apparatus—The high-performance liquid chromatograph was equipped with a multiwavelength UV detector[1] and a microparticulate C-18 column[2]. A filter[3] with a 1.2-μm pore size was used for solution filtration prior to injection.

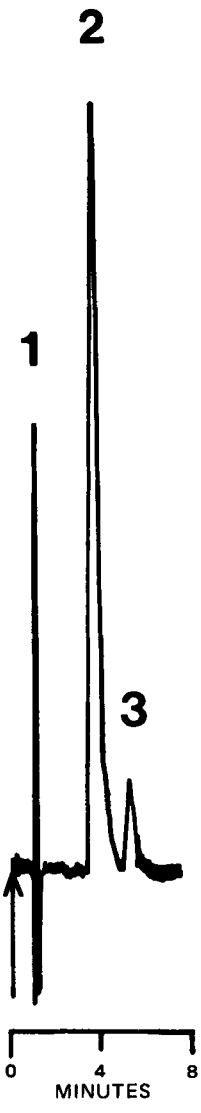

Figure 1—*Typical chromatogram for quinidine and dihydroquinidine in a tablet dosage form. Key: 1, solvent front; 2, quinidine peak; and 3, dihydroquinidine peak. Arrow indicates sample injection time.*

Reagents—All chemicals and reagents were analytical grade unless otherwise indicated. Quinidine sulfate[4,5], quinidine[5,6], and dihydroquinidine[7] were used as obtained. Glass-distilled methanol was used for the mobile phase[8]. Quinidine sulfate tablets from three different suppliers[9] were obtained from a local pharmacy.

Procedure—A quinidine sulfate tablet was weighed accurately, crushed carefully using a mortar and pestle, and added (25 mg) to a 100-ml volumetric flask. Then 5 ml of methanol was added to the powder, and the solution was diluted to 100 ml with acetic acid–water (1:1). This solution was shaken, and an aliquot was diluted 10 times with acetic acid–water (1:1). Then the solution was filtered[3] to remove suspended matter, and a 10-μl aliquot was injected into the chromatograph under the following conditions: flow rate, 2 ml/min; detection, 254 nm; and mobile phase, methanol–acetic acid–water (25:4:71).

The retention times for quinidine and dihydroquinidine under these conditions were 3.83 and 4.86 min, respectively. The assay sensitivity was a function of injection volume; at 10 μl, the dihydroquinidine sensitivity was 0.25 μg/ml, but larger injection volumes or smaller dilutions increased the sensitivity.

Dihydroquinidine standards were prepared in water or acetic acid–water (1:1). Both vehicles gave the same peak height results. Dihydroquinidine concentration was estimated by comparing the peak heights to a standard curve. Theobromine (10 μg/ml) could be added as an internal standard to correct for injection volume errors. Theobromine retention time was 2.25 min under these conditions.

To estimate the dihydroquinidine concentration in various raw materials, quinidine base and quinidine sulfate solutions (20 μg of quinidine/ml) were made as described.

Table I—Dihydroquinidine Content in Three Marketed Quinidine Sulfate Tablet Formulations

Tablet	Dihydroquinidine, %		
	Product PD[a]	Product PP	Product PR
1	9.81[b]	3.19	6.50
2	9.49	3.80	6.57
3	9.09	3.38	6.25
	—	—	—
Mean	9.47 ± 0.52	3.49 ± 0.39	6.44 ± 0.24

[a] For product identification, see *Experimental*. [b] Each value represents the mean of four determinations.

RESULTS

Figure 1 shows a typical chromatogram for quinidine and dihydroquinidine in a tablet. No interfering peaks due to excipients were observed in the quinidine tablets. Slight variations in retention times could be seen from day to day.

The standard quinidine and dihydroquinidine curves for peak height *versus* concentration are linear over a wide concentration range and pass through the origin. Quinidine and dihydroquinidine concentration can be estimated accurately over 0–75 μg/ml, which encompasses the range used in this assay.

All quinidine raw materials contained dihydroquinidine, but no other cinchona alkaloids were detected. Samples from different commercial sources contained 3–29% dihydroquinidine. The mean dihydroquinidine concentration in the two quinidine sulfate raw materials varied from 3 to 16% whereas the content ranged from 25 to 29% in the two quinidine base materials. The percent of dihydroquinidine in the quinidine sulfate samples was (mean ± *SD*): Sample ME, 3.19 ± 0.13%; and Sample KK, 15.7 ± 1%. Similar values for quinidine base samples were (mean ± *SD*): Sample ME, 27.2 ± 1.9%; and Sample MA, 29.3 ± 1.1%. Each reported value is a mean of four determinations from the same sample.

Table I shows the dihydroquinidine content in three commercial quinidine sulfate tablets. Each reported value represents the mean of four determinations from the same solution. The mean dihydroquinidine content varied from 3.19 to 9.81%. Dihydroquinidine content was least in Product PP (3.49%), maximum in Product PD (9.47%), and intermediate in Product PR (6.44%).

DISCUSSION

No significant differences were observed in concentration when estimating dihydroquinidine and quinidine content from filtered or nonfiltered solutions. Thus, there was no significant adsorption to the filter[3]. Filters should be soaked in distilled water for at least 0.5 hr prior to use to remove any surfactant that might interfere with the assay.

The USP monograph for quinidine (2) allows dihydroquinidine concentrations up to 20% of the quinidine concentration, and the content uniformity requirement allows a tablet range of ±15%. Thus, a 200-mg quinidine sulfate tablet could contain as little as 148 mg of quinidine sulfate and 37 mg of dihydroquinidine sulfate (185-mg tablet) or 215 mg of quinidine sulfate with no dihydroquinidine. The three quinidine sulfate tablet formulations tested ranged from 3.4 to 9.5% dihydroquinidine. The sulfate raw materials contained 3.2 and 15.7% dihydroquinidine, and the two base samples contained 27 and 29%.

Quinidine in tablets was quantitated employing the quinidine peak height and the standard curve. All three tablet formulations met the USP content uniformity test; *e.g.*, the quinidine content was 87.5, 94.5, and 95.8% for Products PD, PR, and PP, respectively. The quinidine content of raw materials varied from 84 to 96% for the sulfate and 100–103% for the two base samples.

However, the question of differences between quinidine and dihydroquinidine persists. Previous studies showed that dihydroquinidine has a lower partition coefficient (4) and a slower dissolution rate from formulations (6) than quinidine. In a recent study in rats (7), quinidine and dihydroquinidine had similar efficacy and toxicity when given intravenously, but dihydroquinidine had a 40% higher oral LD_{50}. This

finding is in agreement with a study conducted in humans (8) where quinidine gluconate gave higher blood levels than dihydroquinidine gluconate after single and maintenance doses. These studies suggest that the cardiovascular activities of quinidine and dihydroquinidine are similar but that differences may exist when these two components are incorporated into dosage forms. For these reasons, monitoring of the dihydroquinidine content in quinidine raw materials and dosage forms may have practical importance.

Controlled Drug Release by Polymer Dissolution II: Enzyme-Mediated Delivery Device

J. HELLER ˣ **and P. V. TRESCONY**

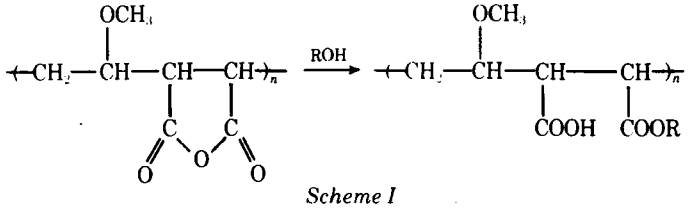
Received November 14, 1978, from the *Polymer Sciences Department, SRI International, Menlo Park, CA 94025.* Accepted for publication January 9, 1979.

Abstract □ A novel, closed-loop drug delivery system was developed where the presence or absence of an external compound controls drug delivery from a bioerodible polymer. In the described delivery system, hydrocortisone was incorporated into a *n*-hexyl half-ester of a methyl vinyl ether–maleic anhydride copolymer, and the polymer–drug mixture was fabricated into disks. These disks were then coated with a hydrogel containing immobilized urease. In a medium of constant pH and in the absence of external urea, the hydrocortisone release was that normally expected for that polymer at the given pH. With external urea, ammonium bicarbonate and ammonium hydroxide were generated within the hydrogel, which accelerated polymer erosion and drug release. The drug delivery rate increase was proportional to the amount of external urea and was reversible; that is, when external urea was removed, the drug release rate gradually returned to its original value.

Keyphrases □ Dosage forms—controlled-release delivery devices, *n*-hexyl half-ester of a methyl vinyl ether–maleic anhydride copolymer, urease, pH-controlled hydrocortisone release □ Hydrocortisone—controlled-release delivery, pH controlled, *n*-hexyl half-ester of a methyl vinyl ether–maleic anhydride copolymer, urease □ Copolymers—controlled-release delivery devices, *n*-hexyl half-ester of a methyl vinyl ether–maleic anhydride, urease, pH-controlled hydrocortisone release □ Urease—controlled-release delivery devices, pH-controlled hydrocortisone release □ Corticosteroids—hydrocortisone, controlled-release delivery device

Drug formulations that deliver an active agent to a specific body site in precisely regulated amounts are superior to those that indiscriminately flood the whole body with a therapeutic agent. Consequently, sustained drug release is receiving great attention (1).

However, even precisely controlled sustained delivery is not always the optimum therapeutic regimen. In many applications, a better delivery system is one that delivers the active agent only when needed. The essential ingredients of such a system are a sensing mechanism that can detect minute amounts of a specific compound in a complex mixture such as blood and some means of transferring this information to a delivery device that can then modify therapeutic agent delivery. While electromechanical devices that use microelectronics and enzyme probes to control miniaturized pumps are possible, this study centers on purely chemical methods.



Scheme I

BACKGROUND

A previous paper (2) described the dissolution and concomitant drug release from partially esterified copolymers of methyl vinyl ether and maleic anhydride prepared as shown in Scheme I. Two notable features of these polymer systems were: (*a*) their ability to undergo surface erosion and, hence, to release an incorporated drug by zero-order kinetics, and (*b*) an extraordinary sensitivity of the erosion rate to the surrounding aqueous environment pH. These systems also exhibited a characteristic pH above which they were completely soluble and below which they were completely insoluble. This pH was very sharp and depended on the size of the alkyl group in the copolymer ester. Consequently, polymer erosion behavior can be tailored to fit any desired pH environment; even very small pH variations will have a major effect on the erosion rate and, thus, on drug release.

Any sensing mechanism that can convert the presence of a specific compound in the external environment to a pH change can be used to control polymer dissolution and therapeutic agent delivery. Enzymes almost ideally fit this requirement because their mode of action is highly specific; in many cases, enzyme–substrate reaction products are acidic or alkaline compounds.

For this study, an enzyme was needed that, after reaction with a substrate, liberated an alkaline product so that the net effect of the enzyme–substrate reaction would be a pH increase at the polymer–water interface. The enzyme urease, which interacts with urea as shown (3), was selected (Scheme II).

$$(NH_2)_2CO + 3H_2O \xrightarrow{\text{urease}} HCO_3^- + 2NH_4^+ + OH^-$$

Scheme II

The purpose of this study was to develop a system in which urea in an external environment would affect the release of hydrocortisone incor-

Controlled Drug Release by Polymer Dissolution II: Enzyme-Mediated Delivery Device

J. HELLER ˣ **and P. V. TRESCONY**

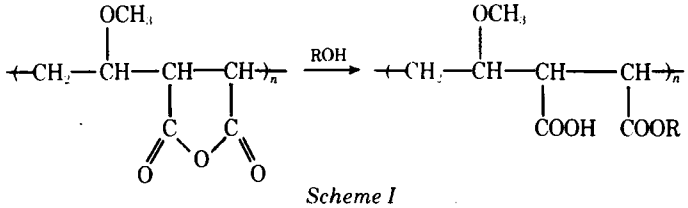
Received November 14, 1978, from the *Polymer Sciences Department, SRI International, Menlo Park, CA 94025.* Accepted for publication January 9, 1979.

Abstract □ A novel, closed-loop drug delivery system was developed where the presence or absence of an external compound controls drug delivery from a bioerodible polymer. In the described delivery system, hydrocortisone was incorporated into a *n*-hexyl half-ester of a methyl vinyl ether–maleic anhydride copolymer, and the polymer–drug mixture was fabricated into disks. These disks were then coated with a hydrogel containing immobilized urease. In a medium of constant pH and in the absence of external urea, the hydrocortisone release was that normally expected for that polymer at the given pH. With external urea, ammonium bicarbonate and ammonium hydroxide were generated within the hydrogel, which accelerated polymer erosion and drug release. The drug delivery rate increase was proportional to the amount of external urea and was reversible; that is, when external urea was removed, the drug release rate gradually returned to its original value.

Keyphrases □ Dosage forms—controlled-release delivery devices, *n*-hexyl half-ester of a methyl vinyl ether–maleic anhydride copolymer, urease, pH-controlled hydrocortisone release □ Hydrocortisone—controlled-release delivery, pH controlled, *n*-hexyl half-ester of a methyl vinyl ether–maleic anhydride copolymer, urease □ Copolymers—controlled-release delivery devices, *n*-hexyl half-ester of a methyl vinyl ether–maleic anhydride, urease, pH-controlled hydrocortisone release □ Urease—controlled-release delivery devices, pH-controlled hydrocortisone release □ Corticosteroids—hydrocortisone, controlled-release delivery device

Drug formulations that deliver an active agent to a specific body site in precisely regulated amounts are superior to those that indiscriminately flood the whole body with a therapeutic agent. Consequently, sustained drug release is receiving great attention (1).

However, even precisely controlled sustained delivery is not always the optimum therapeutic regimen. In many applications, a better delivery system is one that delivers the active agent only when needed. The essential ingredients of such a system are a sensing mechanism that can detect minute amounts of a specific compound in a complex mixture such as blood and some means of transferring this information to a delivery device that can then modify therapeutic agent delivery. While electromechanical devices that use microelectronics and enzyme probes to control miniaturized pumps are possible, this study centers on purely chemical methods.



Scheme I

BACKGROUND

A previous paper (2) described the dissolution and concomitant drug release from partially esterified copolymers of methyl vinyl ether and maleic anhydride prepared as shown in Scheme I. Two notable features of these polymer systems were: (*a*) their ability to undergo surface erosion and, hence, to release an incorporated drug by zero-order kinetics, and (*b*) an extraordinary sensitivity of the erosion rate to the surrounding aqueous environment pH. These systems also exhibited a characteristic pH above which they were completely soluble and below which they were completely insoluble. This pH was very sharp and depended on the size of the alkyl group in the copolymer ester. Consequently, polymer erosion behavior can be tailored to fit any desired pH environment; even very small pH variations will have a major effect on the erosion rate and, thus, on drug release.

Any sensing mechanism that can convert the presence of a specific compound in the external environment to a pH change can be used to control polymer dissolution and therapeutic agent delivery. Enzymes almost ideally fit this requirement because their mode of action is highly specific; in many cases, enzyme–substrate reaction products are acidic or alkaline compounds.

For this study, an enzyme was needed that, after reaction with a substrate, liberated an alkaline product so that the net effect of the enzyme–substrate reaction would be a pH increase at the polymer–water interface. The enzyme urease, which interacts with urea as shown (3), was selected (Scheme II).

$$(NH_2)_2CO + 3H_2O \xrightarrow{\text{urease}} HCO_3^- + 2NH_4^+ + OH^-$$

Scheme II

The purpose of this study was to develop a system in which urea in an external environment would affect the release of hydrocortisone incor-

porated into a polymer matrix. Such a system serves as a model; it has no obvious therapeutic application. More useful systems are being developed.

EXPERIMENTAL

***n*-Hexyl Half-Ester of a Methyl Vinyl Ether–Maleic Anhydride[1] Copolymer (50:50)**—A three-necked 2000-ml, round-bottom flask equipped with a mechanical stirrer, a heating oil bath, a condenser, and a nitrogen inlet and exit was charged with 109.30 g of the copolymer (1.400 equivalent) and 794.82 g of 1-hexanol (7.779 moles). The alcohol, present in an 11:1 molar excess, was sufficient to produce a 20% (w/w) solution of the half-ester product.

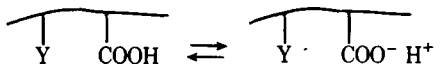
After the flask was purged with nitrogen, the reactants were vigorously stirred and heated over 0.5 hr to 145°. The reaction was followed by IR analysis of the carbonyl peaks associated with residual cyclic anhydride in the copolymer and with the formed ester linkage in the half-ester product. The reaction was judged complete after 2.5 hr at 145°. The solution was cooled to room temperature with an ice bath and precipitated in 8 liters of methanol–water (1:1 v/v). The precipitated polymer was dissolved in 2 liters of acetone and precipitated in 8 liters of methanol–water (1:2 v/v). This step was repeated twice. The product was dried in a forced-air oven for 3 days at 50°. A tough, clear-to-slightly-hazy material (148.10 g) was collected in an 82% yield.

Test Specimens—*Film Casting*—The polymer and micronized hydrocortisone[2] were added to 2-ethoxyethyl acetate–isopropylacetone (7:3 w/w) to produce a 9% polymer solution containing 10 parts of dispersed hydrocortisone/100 parts of resin. A homogeneous solution was obtained by using a jar mill. Films were cast by pouring this solution into level polytef-lined molds. The molds were then partially covered and, to prevent bubble formation in the film, were dried slowly for 8 days. They were further dried in a forced-air oven at 35° for 1 day and then *in vacuo* for 1 day.

Disks, 9.5 mm in diameter, were cut from the film using a drill press and hole cutter. The disks were weighed after being placed in a vacuum oven for 48 hr at room temperature and then being equilibrated to a constant weight in air. The disks selected for release-rate testing weighed 47.5–52.5 mg and were ~0.75 mm thick.

Enzyme Coating—Initial attempts to incorporate the enzyme urease into the polymer matrix involved dissolving the enzyme and polymer in acetone, dispersing micronized hydrocortisone in the solution, casting films, and gently drying at room temperature. However, considerable enzyme denaturation took place.

Subsequent successful urease coupling with the polymer matrix was based on the work of Mascini and Guibault (4). A small locking forceps was affixed to the edge of each polymer disk so that it could be manipulated without touching the surfaces during the immobilized enzyme-coating procedure. A 30% aqueous solution of bovine serum albumin was prepared, and 1 g of urease was added to 10 ml of this solution. After quick stirring until the urease had dissolved, the solution was chilled in an ice



water insoluble water soluble

Scheme III

bath. Each disk was held horizontally by the attached forceps, and 1 drop of the albumin–urease solution was added to the upper disk face. The disk was quickly rotated, and a drop was added to the opposite face. Similarly, 1 drop of 25% aqueous glutaraldehyde was added to each face. One minute after the glutaraldehyde addition, the coating had gelled sufficiently to allow the disks to be hung vertically.

After standing in air for 15 min, the coated disks were immersed in cold, deionized water for 15 min, in 0.1 *M* glycine for 15 min, and in pH 5.75 phosphate buffer for 2 hr. Finally, they were immersed in fresh pH 5.75 phosphate buffer for 4 hr.

Release Rate Measurements—The coated disks were heat sealed in polypropylene mesh bags having 0.5-mm openings. Care was taken to apply heat only to the edges of the bags and to avoid applying heat to the disks. The mesh bags were attached to 10-gauge stainless steel wires and moved vertically up and down at ~140 cm/min in test tubes[3], as described previously (2). Hydrocortisone release was followed spectrophotometrically at 242 nm.

RESULTS AND DISCUSSION

A previous paper (2) described the erosion behavior of a hydrophobic polymer system where dissolution occurred by carboxyl group ionization. This solubilization behavior has been represented generally as shown in Scheme III (COOH is a solubilizing group and Y is a hydrophobic substituent). The dissolution behavior also was rationalized in terms of the model shown in Fig. 1. In this model, the erosion rate is principally determined by the rate at which hydrogen ions are neutralized within the boundary layer, so the induced pH change in that layer will significantly affect polymer erosion and, hence, drug release.

In the system described, a hydrophobic *n*-hexyl half-ester of a methyl vinyl ether–maleic anhydride copolymer containing hydrocortisone was surrounded by a hydrogel consisting of the enzyme urease immobilized in bovine serum albumin by crosslinking with glutaraldehyde. In the absence of external urea, the polymer dissolution and hydrocortisone release occur by the mechanism shown in Fig. 1, *i.e.*, hydrogen-ion neutralization by external buffer and diffusion of hydrogen ions away from the eroding polymer.

When urea is in the external environment, it diffuses into the hydrogel layer and is converted to ammonium bicarbonate and ammonium hydroxide by the immobilized urease. These basic species neutralize hy-

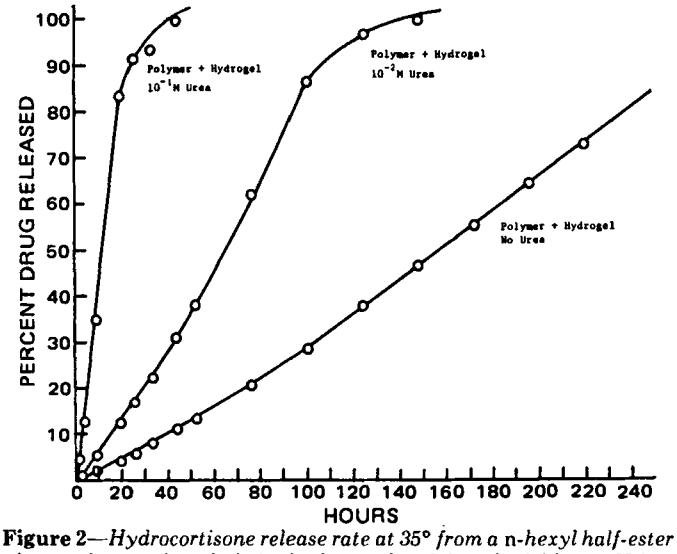


Figure 2—*Hydrocortisone release rate at 35° from a* n*-hexyl half-ester of a copolymer of methyl vinyl ether and maleic anhydride at pH 6.25 in the absence and presence of external urea. The stirring rate was ~140 cm/min*[3].

[3] Approximately 18.4 cycles/min at a total sample travel distance of 7.62 cm/cycle.

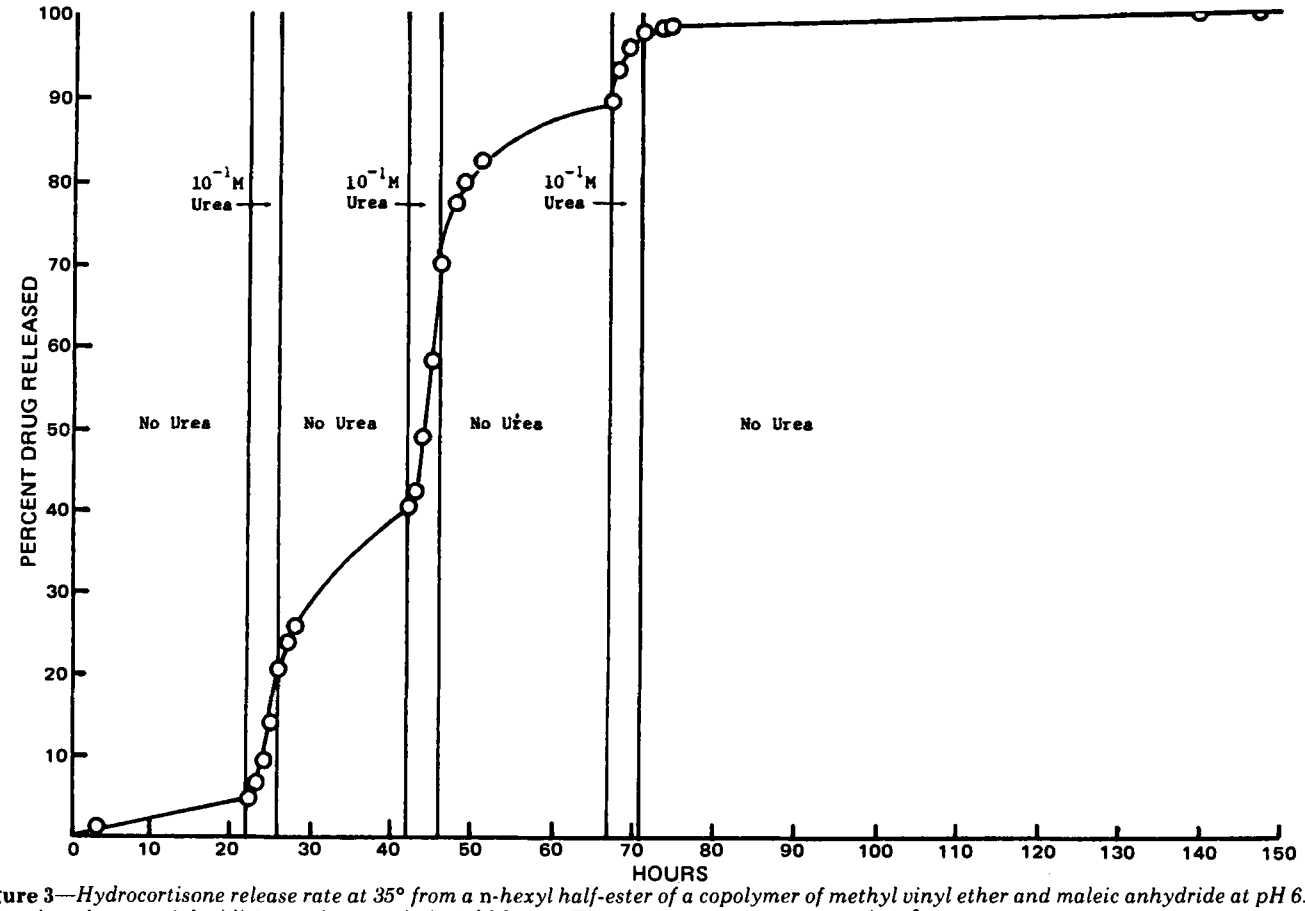

Figure 3—*Hydrocortisone release rate at 35° from a* n*-hexyl half-ester of a copolymer of methyl vinyl ether and maleic anhydride at pH 6.25 as a function of sequential addition and removal of* 10^{-1} M *urea. The stirring rate was ~140 cm/min*[3].

drogen ions generated by the eroding polymer, thus accelerating the process. Consequently, urea in the external environment should lead to accelerated drug release, and this acceleration should be directly proportional to the external urea concentration. Data in Fig. 2 corroborate these expectations.

While care was taken to maintain a constant pH in the external environment, this goal was accomplished only with 10^{-2} *M* urea. In the presence of 10^{-1} *M* urea, basic species generation was so rapid that the external medium buffering capacity was exceeded and a pH increase of ~0.25 occurred. Furthermore, the polymer dissolution rate was such that when the solubilized polymer chains diffused through the hydrogel, presumably through open pores, they precipitated again when exposed to the lower external pH. Because of the considerable difference in polymer dissolution rates between the hydrogel and the bulk solution, the devices gradually acquired a significant thickness of precipitated gelatinous polymer. Nevertheless, even though a rigorous comparison between no urea and urea is possible only in the 10^{-2} *M* case, the device definitely delivers hydrocortisone significantly faster in the presence of 10^{-1} *M* urea than in the presence of 10^{-2} *M* urea.

Data in Fig. 2 illustrate a situation where a device had a fixed and constant drug delivery rate that increased in response to the presence and concentration of external urea. The next question was whether this situation was reversible; that is, whether the drug delivery rate would return to its original value when urea was removed from the external environment.

Results illustrating this situation are shown in Fig. 3. As in the previous experiments, polymer erosion in the presence of 10^{-1} *M* urea was so rapid that the polymer precipitated around the device. Nevertheless, when the device was removed from a buffer solution without urea and placed in a buffer solution with 10^{-1} *M* urea, a significant increase in delivery immediately took place. When the device was next removed from that solution and again placed in a solution without urea, a delivery rate decrease took place.

The decrease in delivery was not abrupt but showed a first-order dependence. This first-order dependence was a consequence of the relatively water-insoluble hydrocortisone being trapped in the hydrogel layer and in the precipitated polymer around the device from which it was slowly released by a diffusional mechanism when the device was in the low rate erosion regimen. In the high rate delivery regimen, a zero-order delivery was noted because the slow diffusional release was masked by the rapid erosional release.

Stability-Indicating Sulfa Drug Analysis Using High-Performance Liquid Chromatography

H. UMAGAT, P. F. McGARRY, and R. J. TSCHERNE ˣ

Received October 16, 1978, from the *Quality Control Department, Hoffmann-La Roche Inc., Nutley, NJ 07110.* Accepted for publication January 8, 1979.

Abstract □ Sensitive and efficient methods for sulfonamide determination as single entities and in combination with other drug substances in pharmaceutical dosage formulations were developed using high-performance liquid chromatography. These stability-indicating procedures involved a nitrile bonded phase column and nonaqueous mobile phases having diverse polarities. Sample potency was determined using peak height measurements. The methods may be used to determine trace sulfonamide quantities because detection limits are in the nanogram range.

Keyphrases □ High-performance liquid chromatography—analysis, sulfonamides in various pharmaceutical formulations, stability indicating □ Sulfonamides, various—analysis, high-performance liquid chromatography, various pharmaceutical formulations, stability indicating □ Dosage forms, various—analysis, sulfonamides, high-performance liquid chromatography, stability indicating

Methods for sulfonamide determination include potentiometric (1) or nonaqueous (2) titrations as well as direct spectrophotometric measurement (3). When sulfonamides are formulated in combination with other drug substances, the analysis of all components often requires more than one procedure, none being stability indicating. An interest in determining the active constituents of multicomponent sulfa drugs utilizing a single analytical method led to the development of a high-performance liquid chromatographic (HPLC) procedure.

BACKGROUND

Several studies were published on sulfonamide separation and determination using HPLC. Sulfonamides varying widely in pKa and hydrophobicity were separated using ion-pair partition chromatography (4). Liquid chromatographic sulfonamide separation also was accomplished using an "ether" bonded phase packing (5). Sulfonamides, including sulfisoxazole, sulfamethoxazole, *N'*-acetylsulfisoxazole, and sulfisoxazole diolamine, were separated on a strong anion-exchange column using a 0.01 *M* sodium borate mobile phase containing varying amounts of sodium nitrate (6).

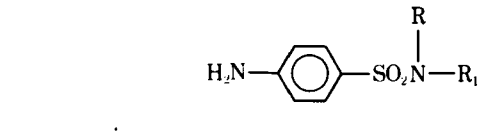
Retention volume data for various sulfonamides on a pellicular-bonded reversed-phase packing, a pellicular packing coated with squalene, or a pellicular packing coated with octanol were reported (7). The partition coefficients, pKa values, and biological activity of each compound were correlated with retention volume.

Trace level quantitation of sulfamethazine residue in bovine tissue was reported (8). With this method, 0.07 ppm of sulfamethazine in tissue could be detected.

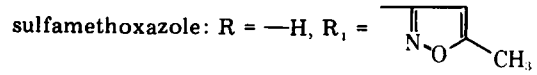
This paper describes a sensitive and efficient HPLC procedure for sulfonamide determination in pharmaceutical formulations. The assays involve a nitrile bonded phase column and nonaqueous mobile phases of varying polarity. The assays are stability indicating because precursors and decomposition products can be determined simultaneously with the drugs. Furthermore, compounds present in combination drug formulations are quantitated.

EXPERIMENTAL

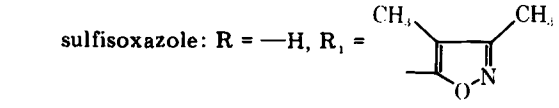
Apparatus—A high-performance liquid chromatograph equipped with a UV detector[1] was used to monitor the eluted compounds at 254 nm. Separation was obtained on an alkylnitrile bonded phase column[2].



sulfanilamide: R = —H, R_1 = —H



sulfamethoxazole: R = —H, R_1 =



sulfisoxazole: R = —H, R_1 =

sulfanilylsulfanilamide: R = —H, R_1 =

Reagents and Chemicals—The methanol, methylene chloride, and ethyl acetate were ACS reagent grade. "Distilled-in-glass" heptane[3] was used. The diethylamine and hydrochloric acid were reagent grade. Released lots of sample material and in-house reference standards were used[4].

Mobile Phases—A mobile phase of methanol–methylene chloride–heptane (10:15:75) was used for sulfamethoxazole, *N'*-acetylsulfisoxazole, sulfisoxazole, and sulfadimethoxine analyses as well as for samples containing phenazopyridine hydrochloride in combination with sulfamethoxazole or sulfisoxazole.

A mobile phase of diethylamine–ethyl acetate–methanol–heptane (1:8:16:75) was used for samples containing trimethoprim or ormetoprim in combination with sulfamethoxazole or sulfadimethoxine, respectively.

Internal Standard Solution—Sulfanilylsulfanilamide was prepared by the Bauer (9) procedure and used as an internal standard. Approximately 600 mg of this material was accurately weighed into a 100-ml volumetric flask and diluted to volume with methanol (internal standard solution).

Sample Solution—Each sulfa drug solution was prepared by dissolving 100 mg in 100 ml of methanol except when in combination with

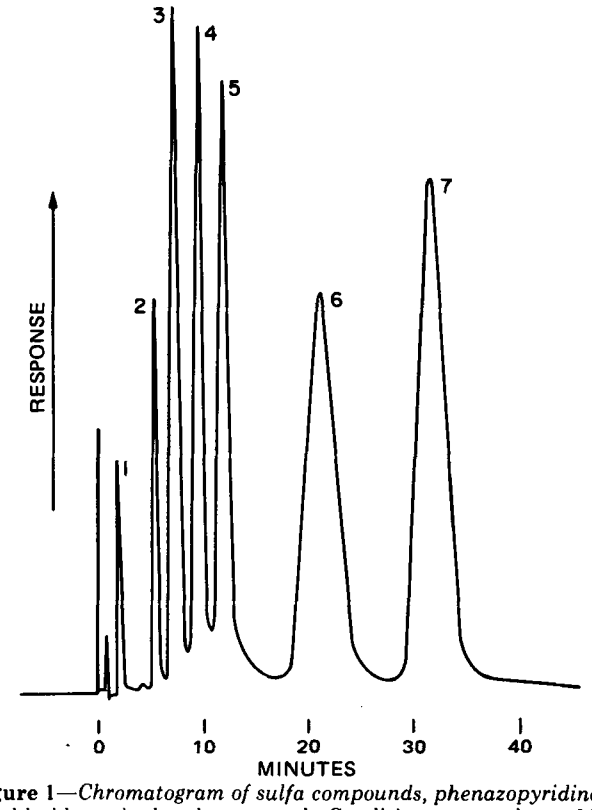

Figure 1—*Chromatogram of sulfa compounds, phenazopyridine hydrochloride, and related compounds. Conditions were: column, Micro-Pak CN-10; mobile phase, methanol–methylene chloride–heptane (10:15:75); and flow rate, 1.0 ml/min. Key: 1, phenazopyridine hydrochloride; 2, N′-acetylsulfamethoxazole; 3, sulfamethoxazole; 4, sulfisoxazole; 5, sulfanilamide; 6, isosulfamethoxazole; and 7, sulfanilylsulfanilamide.*

trimethoprim or ormetoprim, where 0.1 *N* HCl in methanol was used as the solvent. Four milliliters of the clear solution was pipetted into a 10-ml volumetric flask containing 2 ml of the internal standard solution and diluted to volume with methanol (working sample solution).

Reference Standard Solution—Reference standard solutions were prepared by diluting reference standard materials to a concentration similar to that of the samples with the same solvent (working reference standard solution).

Procedure—Five microliters of working sample and working reference standard solutions were alternately injected into the liquid chromatograph to determine the retention volumes for the compounds. Duplicate standards and samples were chromatographed, and the respective responses were determined using peak height measurements.

Calculations—Relative response ratios (*RR*) were calculated for the working reference standard solution using the chromatographic data. Calculation of drug potency for each tablet was made using:

$$\text{mg of drug/tablet} = \frac{(H_{spl})(W_{int})(\text{A.W.T.})(0.5)}{(H_{int})(W_{spl})(RR)} \qquad \text{(Eq. 1)}$$

where:

H_{spl} = sample peak height
H_{int} = internal standard in sample solution peak height
W_{int} = internal standard weight (milligrams)
W_{spl} = sample weight (milligrams)
RR = response ratio
0.5 = dilution factor
A.W.T. = average tablet weight (milligrams)

Formulas for calculating potency for other dosage forms (suspensions, solutions, creams, *etc.*) were adjusted to fit the particular dosage form.

RESULTS AND DISCUSSION

The sulfa drugs sulfamethoxazole, sulfisoxazole, *N′*-acetylsulfisoxazole, and sulfadimethoxine, both as single entities and in combination with ormetoprim, trimethoprim, and phenazopyridine hydrochloride, were analyzed successfully using normal phase partition HPLC. Two different mobile phases and a nitrile-bonded phase column were used to separate and determine all compounds of interest within a reasonable time. Typical chromatograms are shown in Figs. 1 and 2.

While the sulfa drugs could be chromatographed using either mobile phase, trimethoprim and ormetoprim did not elute in a reasonable time in the mobile phase without diethylamine. Sulfanilamide and sulfanilic acid, which are sulfonamide degradation products, were well resolved

Table I—Comparison of HPLC with Wet Chemical Results

Dosage Form	Compound Determined	Results for Various Lots, % claim HPLC	Wet Chemical
Tablet	Sulfisoxazole	100.1	102.1
		100.6	102.3

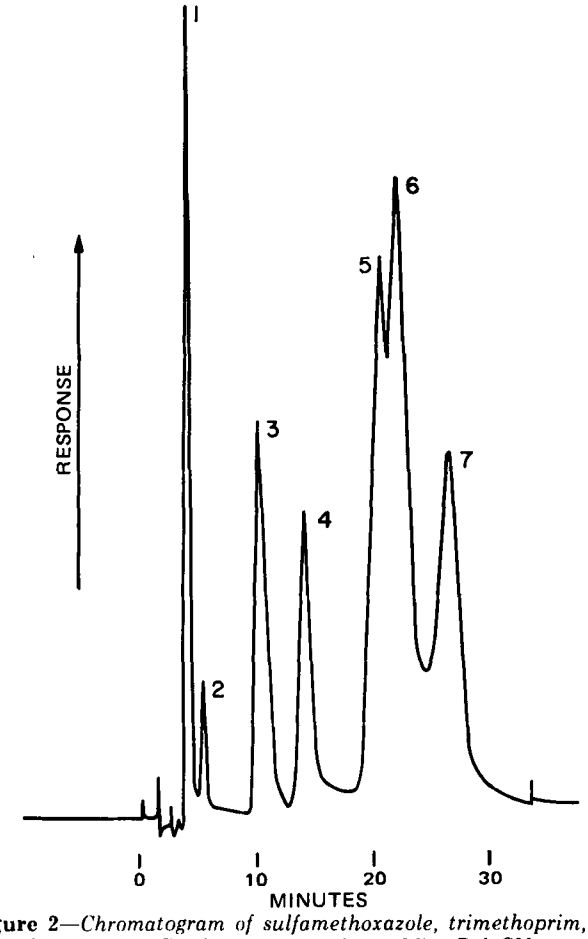

Figure 2—*Chromatogram of sulfamethoxazole, trimethoprim, and related compounds. Conditions were: column, MicroPak CN-10; mobile phase, methanol–ethyl acetate–diethylamine–heptane (16.8:1:75); and flow rate, 1.0 ml/min. Key: 1, trimethoprim precursor A; 2, trimethoprim precursor B; 3, trimethoprim; 4, N'-acetylsulfamethoxazole; 5, sulfanilamide; 6, sulfamethoxazole; and 7, isosulfamethoxazole.*

from the compounds of interest using the system without diethylamine; sulfanilic acid was eluted after all of the other sulfa compounds.

In some instances, 0.1 *N* HCl in methanol was chosen as the extraction solvent to ensure complete extraction of the drug substances from the matrix. Comparison of the HPLC results with results obtained using wet chemical procedures is made in Table I. Peak height responses *versus* amounts injected were linear for the formulation ranges for all components; however, deviations from linearity were found for many constituents when very high amounts were injected. Using the procedures described in this report, detection limits in the nanogram range were obtained. The determination of any compound tested in Table I, alone or in combination with another active drug substance, had a relative standard deviation of ±1.2%. An exception was found for the determination of trimethoprim and sulfamethoxazole formulated together, where the relative standard deviation was ±2.5%.

To ensure column-to-column duplication of the separation, three columns from the same supplier were evaluated. Differences in component retention times were noted with these columns, but only a slight modification in the mobile phase ratio was needed to effect resolution within a reasonable time.

In summary, the HPLC method presented was reliable, reproducible, rapid, and specific and should be useful for sulfa drug determinations in tablets, solutions, creams, and suspensions.

Antibacterial Activity of *Artemisia herba-alba*

JACOB YASHPHE *x, RUTH SEGAL ‡, AVIVA BREUER ‡, and GABI ERDREICH-NAFTALI ‡

Received July 31, 1978, from the **Department of Microbiological Chemistry, The Hebrew University—Hadassah Medical School, Jerusalem, Israel,* and the ‡*Department of Pharmacognosy, School of Pharmacy, The Hebrew University, Jerusalem, Israel.* Accepted for publication January 12, 1979.

Abstract □ The antibacterial activity of *Artemisia herba-alba* was investigated. Only its essential oil was active against some Gram-positive and Gram-negative bacteria. The essential oil was fractionated by column chromatography, and these fractions were tested for antibacterial activity. The principal component of the most active fraction was santolina alcohol.

Keyphrases □ *Artemisia herba-alba*—antibacterial activity, essential oil, column chromatography □ Antibacterial activity—evaluated for *Artemisia herba-alba* essential oil, column chromatography □ Folk medicine—*Artemisia herba-alba*, antibacterial activity of essential oil

Artemisia herba-alba Asso.[1], known as the desert wormwood, is a dwarf shrub growing in North Africa and the Middle East. This plant is used by the local population as an anthelmintic and for other purposes in folk medicine such as relief of coughing, intestinal disturbances, colds, measles, and muscle weakness.

Recently, several compounds were isolated from the aerial parts of this plant and their structures were established. These compounds were the sesquiterpene lactones

[1] Plant material was collected and identified as *Artemisia herba-alba* Asso. (Compositae) by Dr. Avinoam Danin, Department of Botany, The Hebrew University, Jerusalem, Israel. A voucher specimen (AHA-1) representing material collected for this investigation is available for inspection at the Department of Pharmacognosy (Dr. R. Segal), School of Pharmacy, The Hebrew University, Jerusalem, Israel.

Antibacterial Activity of *Artemisia herba-alba*

JACOB YASHPHE *x, RUTH SEGAL ‡, AVIVA BREUER ‡, and GABI ERDREICH-NAFTALI ‡

Received July 31, 1978, from the **Department of Microbiological Chemistry, The Hebrew University—Hadassah Medical School, Jerusalem, Israel,* and the ‡*Department of Pharmacognosy, School of Pharmacy, The Hebrew University, Jerusalem, Israel.* Accepted for publication January 12, 1979.

Abstract □ The antibacterial activity of *Artemisia herba-alba* was investigated. Only its essential oil was active against some Gram-positive and Gram-negative bacteria. The essential oil was fractionated by column chromatography, and these fractions were tested for antibacterial activity. The principal component of the most active fraction was santolina alcohol.

Keyphrases □ *Artemisia herba-alba*—antibacterial activity, essential oil, column chromatography □ Antibacterial activity—evaluated for *Artemisia herba-alba* essential oil, column chromatography □ Folk medicine—*Artemisia herba-alba*, antibacterial activity of essential oil

Artemisia herba-alba Asso.[1], known as the desert wormwood, is a dwarf shrub growing in North Africa and the Middle East. This plant is used by the local population as an anthelmintic and for other purposes in folk medicine such as relief of coughing, intestinal disturbances, colds, measles, and muscle weakness.

Recently, several compounds were isolated from the aerial parts of this plant and their structures were established. These compounds were the sesquiterpene lactones

[1] Plant material was collected and identified as *Artemisia herba-alba* Asso. (Compositae) by Dr. Avinoam Danin, Department of Botany, The Hebrew University, Jerusalem, Israel. A voucher specimen (AHA-1) representing material collected for this investigation is available for inspection at the Department of Pharmacognosy (Dr. R. Segal), School of Pharmacy, The Hebrew University, Jerusalem, Israel.

I

santonin (2), herbolides A, B, and C (3), and a flavone derivative (4). Santonin is well known as a "vermifuge" (5) and is probably responsible for the anthelmintic activity of *A. herba-alba*. No other biological activities of *A. herba-alba* or of compounds isolated from it have been reported.

Because the plant extracts were never contaminated with microorganisms, even after staying at room temperature for very long periods, the antibiotic activity of *A. herba-alba* was investigated.

EXPERIMENTAL

Extraction of Plant Material—*A. herba-alba* was collected near Sde-Boker (Negev desert), Israel. The dried flowers, leaves, and small stems (5 g) were crushed and extracted with methanol in a soxhlet apparatus. The waxy materials, which precipitated after cooling, were filtered and discarded. The methanol was evaporated, and the dark-green residue was dissolved in methanol to a defined concentration.

Steam Distillation of Plant Material—The dried flowers, leaves, and small stems (100 g) of *Artemisia* were crushed and steam distilled. The oil yield was about 1%. The plant material left after steam distillation was filtered, dried at 40°, and extracted with methanol as described.

Column Chromatography of Distillate—The volatile oil (200 mg) was chromatographed on a 10-g silica gel column and eluted with methylene chloride. The column was monitored by TLC, and five crude fractions were collected. These fractions were screened for antibiotic activities without further purification.

Bacterial Strains—The bacterial strains[2] used were: *Staphylococcus aureus*[3], *Escherichia coli*[4], *Salmonella typhosa*[5], *Shigella sonnei*[6], and *Streptococcus hemolyticus*[7].

Antibacterial Activity Detection by Disk Method—The essential oil and its fractions were diluted with methanol to a concentration (per milliliter) that was 100-fold the amount applied on the disks. Paper disks[8] of 6-mm diameter were impregnated with 0.01 ml of these solutions. The tested bacterial strains (0.1 ml of a log phase suspension of 10^9 cells/ml) were spread on petri plates containing nutrient agar[9]. The dried impregnated disks were placed on the inoculated plates. The plates were incubated at 37° for 24 hr, and the inhibition zones were measured.

Antibacterial Activity Assay in Liquid Cultures—The preparations were dispersed in 2% dimethyl sulfoxide (5 mg/ml), and 15 ml of this solution was added to 7.5 ml of sterile nutrient broth[9]. Further dilutions were made by the transfer of 4.5 ml of the solution to 4.5 ml of sterile nutrient broth. Similar dilutions were made from 2% dimethyl sulfoxide as a control. The suspension (0.1 ml) of the tested bacterial strains (10^4 log phase cells/ml) was added to each tube, and the cultures were incubated at 37° for 24 hr. Turbidity was measured by a photometer[10] at 420 nm. The absorption of the uninoculated control was subtracted.

[2] Taken from the strain collection of the Department of Clinical Bacteriology, The Hebrew University-Hadassah Medical School, Jerusalem, Israel.
[3] Identified as Gram-positive cocci, which fermented mannitol and coagulated plasma.
[4] Identified as motile Gram-negative rods, which fermented lactose, produced acid from glucose (methyl red test) and indole from tryptophan, utilized citrate, and did not produce acetoin (Voges-Prosqauer test).
[5] Identified as motile Gram-negative rods, which did not ferment lactose, produced acid but no gas from glucose and mannose, and produced hydrogen sulfide from thiosulfate.
[6] Identified as nonmotile Gram-negative rods, which fermented mannitol and lactose.
[7] Identified as Gram-positive cocci, which produced β-hemolysis on blood agar.

	S. aureus	*E. coli*
Whole plant extract	14[b]	11
Essential oil (2.5 mg)	18	13
Residue extract[c] (2.5 mg)	6[d]	6

[a] Including 6-mm diameter of the disk. [b] By an amount extracted from 1 g of dry plant material as described. [c] Extract of the residual material after steam distillation. [d] Lack of activity.

Table II—Inhibition[a] of Growth of Various Bacterial Strains in Liquid Cultures by the Essential Oil

Essential Oil Concentration, mg/ml	*S. aureus*	*E. coli*	*Sal. typhosa*	*Sh. sonnei*	*St. hemolyticus*
0.8	100	50	100	78	100
0.4	40	26	73	67	100
0.2	0	16	64	55	73
0.1	0	6	45	45	46
0.05	0	0	45	45	36

[a] Inhibition was determined by the dilution method described and is expressed as percentage of decrease in culture turbidity from the turbidity of the control culture.

Table III—Antibacterial Activity of Essential Oil Fractions against *S. aureus* Tested by the Disk Method

Fraction	Diameter of Growth Inhibition[a], mm
1	6[b]
2	14
3	56
4	16
5	16

[a] Including 6-mm diameter of the disk. Each disk contained 1 mg of material. [b] Lack of activity.

RESULTS AND DISCUSSION

The aerial parts of *A. herba-alba* were tested for antibacterial activities. The antibiotic activity observed for the whole plant extract was concentrated in the essential oil (Table I). The oil inhibited the growth of five bacterial strains (Table II), both Gram positive (*S. aureus* and *St. hemolyticus*) and Gram negative (*E. coli, Sal. typhosa,* and *Sh. sonnei*). *St. hemolyticus* was slightly more sensitive to the oil than were the other tested organisms.

For the detection of the active antibacterial principle, the oil was subjected to column chromatography. Five fractions were collected according to their polarity and were tested for antibiotic activity by the disk method. *E. coli* and *S. aureus* were selected as representatives from Gram-negative and Gram-positive bacteria. The results (Table III) indicate that only fraction 3 possessed significant antibiotic activity, so the chemical composition of this fraction was investigated. Repeated column chromatography yielded a pure compound, which was identified as santolina alcohol (I) by its optical rotation value and IR and NMR spectra (6).

Quantitative Dexamethasone and Dexamethasone Sodium Phosphate Determinations in Pharmaceutical Dosage Forms by High-Pressure Liquid Chromatography

V. DAS GUPTA

Received August 28, 1978, from the *College of Pharmacy, University of Houston, Houston, TX 77004.* Accepted for publication January 5, 1979.

Abstract □ A high-pressure liquid chromatographic procedure for quantitative dexamethasone and dexamethasone sodium phosphate determinations in all types of commercially available pharmaceutical dosage forms was developed. The method also separates dexamethasone from its phosphate salt and separates dexamethasone or its salt from a number of inactive ingredients such as benzoic acid, benzyl alcohol, some colors, creatinine, and parabens. Inactive ingredient concentrations may be estimated without additional cost. Part of the parabens present in the commercial injections may be adsorbed by the rubber closures.

Keyphrases □ High-pressure liquid chromatography—analysis, dexamethasone and dexamethasone sodium phosphate, various pharmaceutical dosage forms □ Dexamethasone—analysis, high-pressure liquid chromatography, various pharmaceutical dosage forms □ Dexamethasone sodium phosphate—analysis, high-pressure liquid chromatography, various pharmaceutical dosage forms

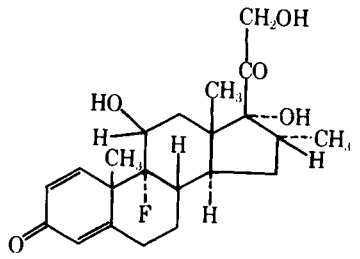
The USP methods (1) for quantitative dexamethasone (I) and dexamethasone sodium phosphate (II) determinations in pharmaceutical dosage forms (elixir, injections, ointment, ophthalmic solution, and tablets) are tedious and time consuming. The USP methods involve many different preliminary extraction procedures and then reactions with blue tetrazolium at room temperature for 45 min or with phenylhydrazine at 60° for 2 hr. For testing the injection, a 2-hr preliminary treatment with alkaline phosphatase is required to free the base before reacting with blue tetrazolium.

Obviously, the analyst has to use different techniques to analyze similar active ingredients. Moreover, determining the presence of dexamethasone base in dexamethasone phosphate salt involves an additional and different method.

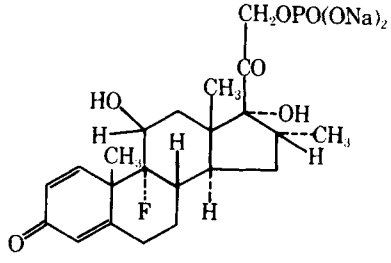
A high-pressure liquid chromatographic (HPLC) procedure for quantitative dexamethasone determination in creams and ointments was reported (2). In this method, the mobile phase was 0.2% acetonitrile in hexane, and the column was β,β'-oxydipropionitrile on Zipax (2). Application of this method to other pharmaceutical dosage forms, such as an elixir containing colors and benzoic acid and creams and injections containing dexamethasone sodium phosphate and parabens, was not reported.

Another HPLC procedure for quantitative dexamethasone determination in milk (3) involved a complicated preliminary extraction. The HPLC method reported (4) for quantitative plasma dexamethasone determination also involved complicated preliminary extraction. Furthermore, these methods (3, 4) were not investigated to determine their applicability to pharmaceutical dosage forms with numerous inactive ingredients.

This paper describes a simple HPLC procedure for the quantitation of dexamethasone and its phosphate salt in all pharmaceutical dosage forms available commercially which also separates dexamethasone base from its salt. The HPLC procedure was preferred because it can often assay some inactive ingredients without additional cost.



I



II

EXPERIMENTAL

Chemicals and Reagents—All chemicals and reagents were USP, NF, and ACS grade and were used without further purification. Dexamethasone[1] (I) and dexamethasone sodium phosphate[1] (II) were used as received.

Apparatus—The high-pressure liquid chromatograph[2] was equipped with a fixed wavelength (254 nm) detector, a recorder[3], and an integrator[4].

Column—The nonpolar prepacked column[5] consisted of a monomolecular layer of octadecyltrichlorosilane permanently bonded to silica (30 cm long and 4 mm i.d.).

Chromatographic Conditions—The chromatographic solvent was 0.01 *M* KH_2PO_4 in water containing 50% (v/v) methanol. The temperature was ambient, the flow rate was 1.6 ml/min, and the chart speed was 30.5 cm/hr. The attenuation units for full-scale deflection were 0.04 for I and 0.1 for dexamethasone phosphate (III), which was made using an equivalent quantity of II.

Assay Solutions—The elixir (label claim of 0.1 mg of I/ml) was diluted from 5.0 to 25.0 ml with water. Injections (label claim of 4 mg of III/ml from an equivalent amount of II) were diluted from 2.0 to 100.0 ml with water. The ophthalmic solution (label claim of 0.1% of III) was diluted from 8.0 to 100 ml with water.

Extraction of III from Ointment (Label Claim of 0.05% of III)—Ointment (0.8 g) was dissolved in 25 ml of methylene chloride in a separator and extracted with 25.0 ml of water. The clear water layer was

Table I—Assay Results

Product	Results, % of label claim
Synthetic injection 1 with parabens	100.5
Synthetic injection 2 with benzyl alcohol	99.8
Commercial injections	
1	99.6[a]
2	100.1[b]
3	99.1[c]
Commercial elixir[d]	99.8
Commercial ointment[e]	106.9[f]
Ophthalmic drops[g]	109.3[h]
Commercial tablets	
1 (0.75 mg/tablet, blue)	98.3[i]
2 (4.0 mg/tablet, white)	99.4[i]

[a] With parabens similar to synthetic solution 1. The results on parabens were estimated to be only ~80% of the claim. To estimate parabens, the attenuated units for full-scale deflection were 0.2 for methylparaben and 0.04 for propylparaben. [b] Same as footnote *a*, except that the results on parabens were about 76% of the label claim. [c] With benzyl alcohol similar to synthetic solution 2. The result on benzyl alcohol was estimated (using peak 1 in Fig. 1C) to be 99.2% of the label claim. [d] Also contained red color and 0.1% benzoic acid as preservative. [e] White petrolatum and mineral oil base. [f] The result using the blue tetrazolium method as provided by the manufacturer was 105.0%. [g] Also contained creatinine, sodium borate, sodium citrate, sodium bisulfite (0.32%), phenylethyl alcohol (0.25%), and benzalkonium chloride (0.02%). [h] The result using the blue tetrazolium method as provided by the manufacturer was 110.0%. [i] The results with the blue tetrazolium method were between 302 and 425%.

assayed using attenuation units for full-scale deflection of 0.04 instead of 0.1. The standard solution contained 16 μg of III/ml.

Extraction of I from Tablets (Label Claim of Sample 1, 0.75 mg of I/Tablet; Label Claim of Sample 2, 4 mg of I/Tablet)—Ten tablets were weighed and ground to a fine powder. Powder representing 2.0 mg of the active ingredient was weighed accurately and transferred to a 150-ml beaker. Ethanol (80 ml) was added, heated just to boiling, cooled, and brought to volume (100.0 ml) with alcohol. The solution was filtered, the first 20 ml of filtrate was rejected, and a sample was collected for analysis.

Standard Solutions—Two milliliters of a stock I solution (1 mg/ml) in alcohol was diluted to 100.0 ml with water for the elixir or with alcohol for the tablets. Ten milliliters of a stock II solution (contained an equivalent amount of 0.8 mg of III/ml of water) was diluted to 100.0 ml

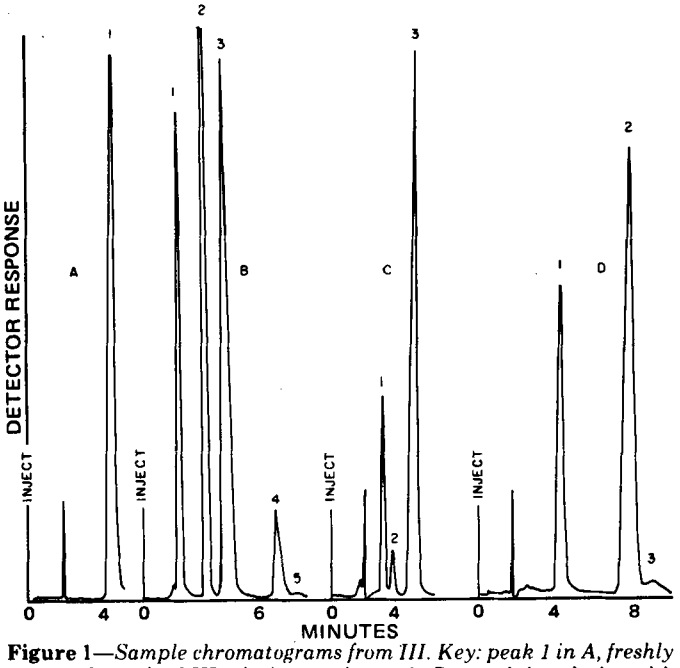

Figure 1—*Sample chromatograms from III. Key: peak 1 in A, freshly prepared standard III solution; peaks 1–5 in B, creatinine eluting with the solvent, methylparaben (out of scale when using 0.1 aufs), III, propylparaben, and a small quantity of a decomposition product, respectively (the chromatogram was obtained from a commercial injection sample); peaks 1 and 2 in C, benzyl alcohol present in a commercial injection from a different manufacturer; peak 3 in C, III; peak 1 in D, III in a 53-day-old aqueous solution of III (160 μg/ml); and peaks 2 and 3 in D, decomposition products. For chromatographic conditions, see text.*

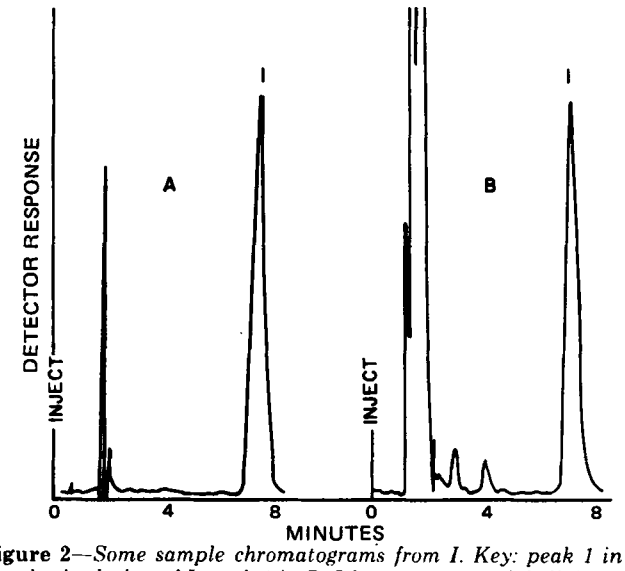

Figure 2—*Some sample chromatograms from I. Key: peak 1 in A, standard solution of I; peak 1 in B, I from a commercial elixir; other peaks, red color and benzoic acid (which comes out with the solvent). For chromatographic conditions, see text.*

with water. For the ointment, it was diluted further, 10.0 ml to 50.0 ml with water. Fresh II solutions were prepared every 4 hr.

Solutions Similar to Two Commercial Injections—One solution contained, per milliliter, 4.0 mg of III, 8 mg of creatinine, 10 mg of sodium citrate, 1.0 mg of sodium bisulfite, 1.5 mg of methylparaben, and 0.2 mg of propylparaben. The second contained, per milliliter, 4.0 mg of III, 1.0 mg of sodium sulfite, and 10 mg of benzyl alcohol. These solutions were diluted from 2.0 to 100.0 ml with water for quantitative analysis.

Assay—An aliquot (20.0 μl) was injected into the chromatograph as described. For comparison, an identical standard solution volume was injected after the sample was eluted.

Since preliminary investigations indicated that peak areas were directly related to concentrations (range of 0.2–0.6 μg for I, 0.5–2.0 μg for III for injections and ophthalmic solutions, and 0.1–0.4 μg of III for ointment), the results were calculated using the following equation:

$$\frac{A_a}{A_s} \times 100 = \text{percent of label claim} \qquad \text{(Eq. 1)}$$

where A_a is the assay solution peak area and A_s is the standard solution peak area. The results are presented in Figs. 1 and 2 and Table I.

For comparison, the commercial tablets also were assayed by the blue tetrazolium method as described in the USP (5) using the assay solution described (Table I).

DISCUSSION

The results indicate (Table I) that a single and simple assay can be used for the quantitative determinations of I and III in elixir, injections, ointment, ophthalmic solution, and tablets. The relative percent standard deviations based on five standard solution injections were 2.3 and 2.1 for I and III, respectively.

The USP assay methods (1) involve different preliminary treatments depending on the dosage form. These treatments are tedious and time consuming. After the preliminary treatment, color development by reaction with either blue tetrazolium or phenylhydrazine is also time consuming.

The standard III solution must be prepared fresh since it decomposes on standing. The single wash procedure with methylene chloride recommended in the USP to remove I from III extracted only ~97% of the total I present. The mixture contained 120 μg of III/ml and 40 μg of I/ml in water. A 10.0-ml quantity of the aqueous solution was extracted with 25 ml of methylene chloride. This estimation was possible since the developed procedure separates I and III very efficiently (see Figs. 1A and 2A for retention times).

There was no interference from: (*a*) red color and benzoic acid present in the elixir (Fig. 2B); (*b*) creatinine, parabens, and benzyl alcohol present in the injections (Figs. 1B and 1C); (*c*) phenylethyl alcohol present in ophthalmic solution; and (*d*) blue color and other inactive ingredients present in the tablets. With the tablets, there was significant interference

with the blue tetrazolium procedure (Table I, footnote *i*), presumably due to the heat used to extract the active ingredient. An extraction procedure using cold alcohol gave inconsistent and sometimes low results.

Another advantage of the developed method is that some inactive ingredients can be estimated without additional cost. For example, in commercial injections, parabens were estimated to be only between 76 and 80% of the label claim (Table I, footnotes *a* and *b*). This finding is presumably due to paraben adsorption onto the rubber closures. This problem was not recorded with benzyl alcohol (Table I, footnote *c*) as the preservative.

Terpenoid Biotransformation in Mammals II: Biotransformation of *dl*-Camphene in Rabbits

T. ISHIDA *[x], Y. ASAKAWA [‡], T. TAKEMOTO [‡], and T. ARATANI [§]

Received September 28, 1978, from the **Hiroshima Institute of Technology, Itsukaichi, Hiroshima 738, Japan*, the [‡]*Institute of Pharmacognosy, Tokushima-Bunri University, Tokushima 770, Japan*, and the [§]*Faculty of Integrated Arts and Sciences, Hiroshima University, Hiroshima 730, Japan.* Accepted for publication January 11, 1979.

Abstract □ The biotransformation of *dl*-camphene in rabbits was investigated. Four neutral metabolites, 6-*exo*-hydroxycamphene, 10-hydroxycamphene, and diastereoisomers of camphene-2,10-glycol, were identified and two alcohols, 7-hydroxycamphene and 3-hydroxytricyclene, were estimated by IR, UV, NMR, and mass spectra and chemical degradations. The formation of these compounds can be explained through a homoallylic oxidation or an epoxide formation.

Keyphrases □ Camphene—biotransformation in rabbits, four urinary metabolites identified by spectrometry and chemical degradations □ Biotransformation—camphene in rabbits, four urinary metabolites identified by spectrometry and chemical degradations □ Choleretic activity—camphene, biotransformation in rabbits, four urinary metabolites identified by spectrometry and chemical degradations

During investigations into terpenoid detoxification in mammals, the biotransformation of 3-carene and α- and β-pinenes having a *gem*-dimethyl group on the three- or four-membered ring, respectively, was reported (1). In this paper, the biotransformation of camphene in rabbits is reported. Camphene has a *gem*-dimethyl group on the five-membered ring.

Camphene is found in the essential oils of most plants, and conifers containing this compound are often damaged worldwide by field animals. The choleretic activity of camphene in rats has been studied (2). The present investigation was carried out to clarify camphene biotransformation in mammals with respect to xenobiotics.

RESULTS

Characterization and Identification of Free Neutral Metabolites—TLC and GLC revealed the products in the urinary extracts as shown in Fig. 1. The metabolites were column chromatographed on silica gel in *n*-hexane with gradually increasing amounts of ethyl acetate. When necessary, metabolites were isolated by preparative GLC.

Metabolites 1-3 (M-I–M-III)—Peak 2 was isolated preparatively by GLC as one component (TLC and GLC) and had a fragrant odor; mass spectrum: *m/e* (%) 152 (M^+, $C_{10}H_{16}O$, 3), 134 (9), 119 (24), 108 (base), 93 (67), 72 (21), and 66 (28); IR: ν ($CHCl_3$) 3625, 3450, and 890 cm^{-1}. Its NMR spectrum showed two kinds of metabolites (M-I and M-II) in a 2:1 ratio. The major signal group assigned was: δ ($CDCl_3$) 4.84 and 4.63 (each 1H, s, *endo*-methylene), 3.80 [1H, q, $J_{5\text{-}exo\text{-}6\text{-}endo} = 7$, $J_{5\text{-}endo\text{-}6\text{-}endo} = 3$ Hz, —C*H*(OH)], 2.62 (1H, b, bridge head), 2.21 (1H, octet, $J_{5\text{-}exo\text{-}5\text{-}endo} = 13$, $J_{5\text{-}exo\text{-}6\text{-}endo} = 7$, $J_{5\text{-}exo\text{-}4} = 2$ Hz, *exo*-5), 1.89 (1H, b, *endo*-5), 1.63 (2H, b), and 0.98 and 1.04 (each 3H, *gem*-dimethyl). All of these M-I signals agreed well with those of the synthetic 6-*exo*-hydroxycamphene (I) (3).

The Jones oxidation of I yielded 6-oxocamphene [ν ($CHCl_3$) 1740 and 890 cm^{-1}] (4) with a minor ketone; mass spectrum (minor ketone): *m/e* (%) 150 (M^+, $C_{10}H_{14}O$, 25), 135 (12), 121 (15), 108 (41), 107 (98), 93 (base), 91 (54), and 79 (41); IR: ν ($CHCl_3$) 1740 and 890 cm^{-1}; NMR: δ ($CDCl_3$) 4.98 and 4.76 (each 1H, s), 3.08 (1H, b), and 1.16 and 1.07 (each 3H, s). These spectra revealed the minor ketone to be 7-oxocamphene. Therefore, 7-hydroxycamphene (II) (M-II) was estimated as the camphene metabolite.

The minor signal group found in the I NMR spectrum can be attributed to II: δ ($CDCl_3$) 4.73 and 4.48 (each 1H, s), 4.24 (1H, bs), 2.68 (1H, bs), and 1.04 (6H, s). The other minor ketone was obtained as the Jones oxidation product from M-III following M-I. Its spectra were considerably different from those of the above-mentioned ketones; mass spectrum: *m/e* (%) 150 (M^+, $C_{10}H_{14}O$, 7), 122 (16), 107 (base), 105 (12), 91 (28), and 79 (14); IR: ν ($CHCl_3$) 1740 cm^{-1}; NMR: δ ($CDCl_3$) 1.21, 1.04, and 1.00 (each 3H, s). Disappearance of the *endo*-methylene group suggests some camphene rearrangement. Accordingly, this ketone was assigned as 3-ketotricyclene

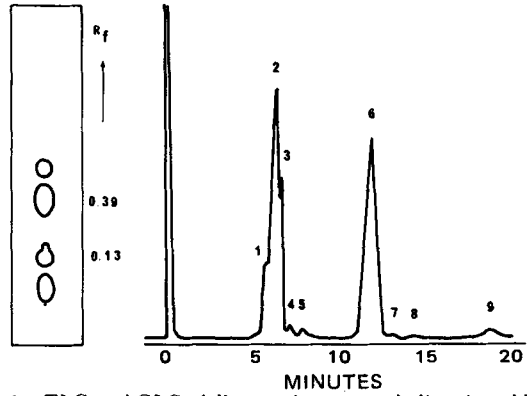

Figure 1—*TLC and GLC of* dl-*camphene metabolites in rabbits. The TLC solvent system was benzene–n-hexane–ethyl acetate (14:5:6); GLC utilized an SE-30 (5%) column.*

Terpenoid Biotransformation in Mammals II: Biotransformation of *dl*-Camphene in Rabbits

T. ISHIDA *[x], Y. ASAKAWA [‡], T. TAKEMOTO [‡], and T. ARATANI [§]

Received September 28, 1978, from the **Hiroshima Institute of Technology, Itsukaichi, Hiroshima 738, Japan*, the [‡]*Institute of Pharmacognosy, Tokushima-Bunri University, Tokushima 770, Japan*, and the [§]*Faculty of Integrated Arts and Sciences, Hiroshima University, Hiroshima 730, Japan.* Accepted for publication January 11, 1979.

Abstract □ The biotransformation of *dl*-camphene in rabbits was investigated. Four neutral metabolites, 6-*exo*-hydroxycamphene, 10-hydroxycamphene, and diastereoisomers of camphene-2,10-glycol, were identified and two alcohols, 7-hydroxycamphene and 3-hydroxytricyclene, were estimated by IR, UV, NMR, and mass spectra and chemical degradations. The formation of these compounds can be explained through a homoallylic oxidation or an epoxide formation.

Keyphrases □ Camphene—biotransformation in rabbits, four urinary metabolites identified by spectrometry and chemical degradations □ Biotransformation—camphene in rabbits, four urinary metabolites identified by spectrometry and chemical degradations □ Choleretic activity—camphene, biotransformation in rabbits, four urinary metabolites identified by spectrometry and chemical degradations

During investigations into terpenoid detoxification in mammals, the biotransformation of 3-carene and α- and β-pinenes having a *gem*-dimethyl group on the three- or four-membered ring, respectively, was reported (1). In this paper, the biotransformation of camphene in rabbits is reported. Camphene has a *gem*-dimethyl group on the five-membered ring.

Camphene is found in the essential oils of most plants, and conifers containing this compound are often damaged worldwide by field animals. The choleretic activity of camphene in rats has been studied (2). The present investigation was carried out to clarify camphene biotransformation in mammals with respect to xenobiotics.

RESULTS

Characterization and Identification of Free Neutral Metabolites—TLC and GLC revealed the products in the urinary extracts as shown in Fig. 1. The metabolites were column chromatographed on silica gel in *n*-hexane with gradually increasing amounts of ethyl acetate. When necessary, metabolites were isolated by preparative GLC.

Metabolites 1-3 (M-I–M-III)—Peak 2 was isolated preparatively by GLC as one component (TLC and GLC) and had a fragrant odor; mass spectrum: *m/e* (%) 152 (M^+, $C_{10}H_{16}O$, 3), 134 (9), 119 (24), 108 (base), 93 (67), 72 (21), and 66 (28); IR: ν ($CHCl_3$) 3625, 3450, and 890 cm^{-1}. Its NMR spectrum showed two kinds of metabolites (M-I and M-II) in a 2:1 ratio. The major signal group assigned was: δ ($CDCl_3$) 4.84 and 4.63 (each 1H, s, *endo*-methylene), 3.80 [1H, q, $J_{5\text{-}exo\text{-}6\text{-}endo} = 7$, $J_{5\text{-}endo\text{-}6\text{-}endo} = 3$ Hz, —C*H*(OH)], 2.62 (1H, b, bridge head), 2.21 (1H, octet, $J_{5\text{-}exo\text{-}5\text{-}endo} = 13$, $J_{5\text{-}exo\text{-}6\text{-}endo} = 7$, $J_{5\text{-}exo\text{-}4} = 2$ Hz, *exo*-5), 1.89 (1H, b, *endo*-5), 1.63 (2H, b), and 0.98 and 1.04 (each 3H, *gem*-dimethyl). All of these M-I signals agreed well with those of the synthetic 6-*exo*-hydroxycamphene (I) (3).

The Jones oxidation of I yielded 6-oxocamphene [ν ($CHCl_3$) 1740 and 890 cm^{-1}] (4) with a minor ketone; mass spectrum (minor ketone): *m/e* (%) 150 (M^+, $C_{10}H_{14}O$, 25), 135 (12), 121 (15), 108 (41), 107 (98), 93 (base), 91 (54), and 79 (41); IR: ν ($CHCl_3$) 1740 and 890 cm^{-1}; NMR: δ ($CDCl_3$) 4.98 and 4.76 (each 1H, s), 3.08 (1H, b), and 1.16 and 1.07 (each 3H, s). These spectra revealed the minor ketone to be 7-oxocamphene. Therefore, 7-hydroxycamphene (II) (M-II) was estimated as the camphene metabolite.

The minor signal group found in the I NMR spectrum can be attributed to II: δ ($CDCl_3$) 4.73 and 4.48 (each 1H, s), 4.24 (1H, bs), 2.68 (1H, bs), and 1.04 (6H, s). The other minor ketone was obtained as the Jones oxidation product from M-III following M-I. Its spectra were considerably different from those of the above-mentioned ketones; mass spectrum: *m/e* (%) 150 (M^+, $C_{10}H_{14}O$, 7), 122 (16), 107 (base), 105 (12), 91 (28), and 79 (14); IR: ν ($CHCl_3$) 1740 cm^{-1}; NMR: δ ($CDCl_3$) 1.21, 1.04, and 1.00 (each 3H, s). Disappearance of the *endo*-methylene group suggests some camphene rearrangement. Accordingly, this ketone was assigned as 3-ketotricyclene

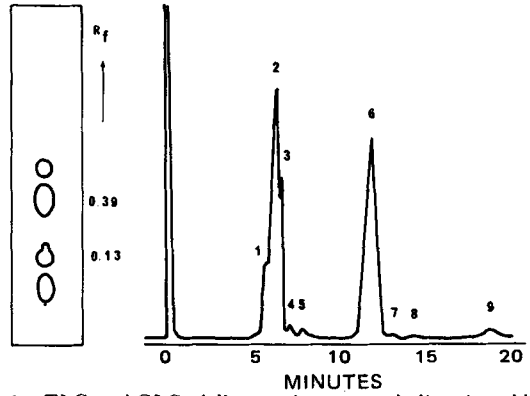

Figure 1—*TLC and GLC of* dl-*camphene metabolites in rabbits. The TLC solvent system was benzene–n-hexane–ethyl acetate (14:5:6); GLC utilized an SE-30 (5%) column.*

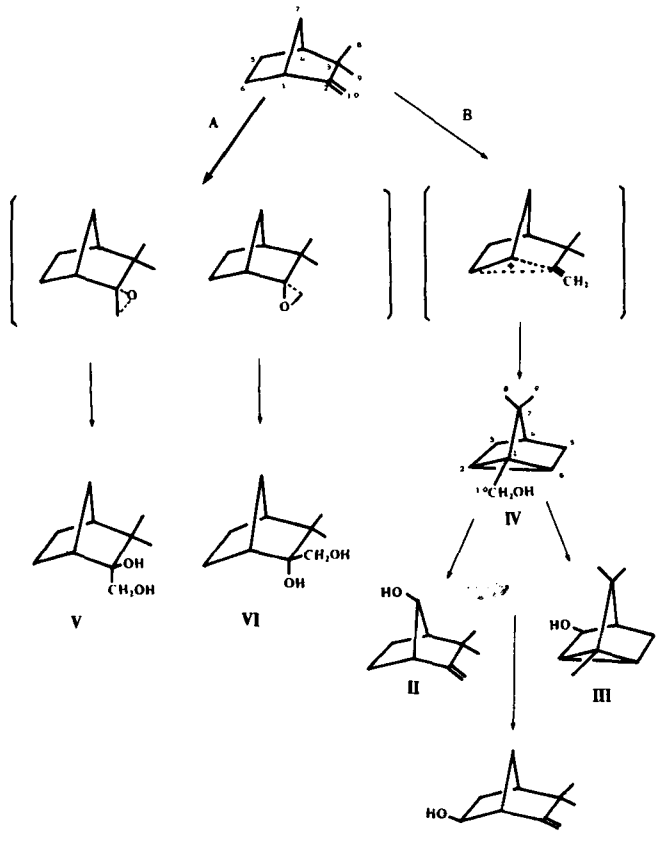

Scheme I—Proposed dl-*camphene metabolic pathway in rabbits. Pathway A is camphene epoxidation followed by cleavage of the oxirane ring by hydration. Pathway B consists of the formation of the nonclassical cation and cation rearrangement followed by hydroxylation.*

from those spectra. The corresponding alcohol, 3-hydroxytricyclene (III) (M-III), might be produced from camphene in rabbits. The peak 2 fragrance was due to I.

Metabolite 4 (M-IV)—Peak 1 also was isolated by preparative GLC. The mass spectrum of M-IV was: *m/e* (%) 152 (M^+, $C_{10}H_{16}O$, 35), 121 (49), 108 (base), 85 (72), and 79 (65); IR: ν ($CHCl_3$) 3640, 3455, 3070, and 850 cm^{-1}; NMR: δ ($CDCl_3$) 3.75 (2H, ss), A_2B_2 at 1.79, 1.68, 1.17, and 1.05 (each 1H, s); NMR: δ (dimethyl sulfoxide-d_6) 4.71 (t, J = 5 Hz, 1H, a primary hydroxyl). From these results, M-IV was identified as 10-hydroxytricyclene (IV).

Metabolite 5 (M-V)—The R_f 0.1 spot was in accord with peak 6, which was isolated by column chromatography. The mass spectrum of M-V was: *m/e* (%) 170 (M^+, $C_{10}H_{18}O_2$, 27), 152 (6), 139 (base), 121 (13), 101 (50), and 87 (60); IR: ν ($CHCl_3$) 3450 cm^{-1}. The NMR spectrum of the M-V acetate showed signals at δ 4.20 (in chloroform-d_1, methylene group adjacent to acetoxyl) and 3.27 (in dimethyl sulfoxide-d_6, s, *tert*-hydroxyl group) and clarified that M-V is a primary-tertiary diol.

This diol was oxidized by sodium periodate with sulfuric acid in ethanol and gave a ketone, camphenylon (VIII); IR: ν ($CHCl_3$) 1740 cm^{-1}. The NMR spectrum of VII showed only two signals of *gem*-dimethyl at δ 1.07 and 1.05. On the other hand, the spectrum of M-V showed four tertiary methyls [δ 1.02 and 0.98 (each 3H) and 0.96 (6H)] and two kinds of hydroxymethylene groups at δ 3.64 and 3.59. From these observations, it was decided that M-V consisted of two C-2 epimers (1:1) as shown in V and VI. The presence of diastereoisomers also was demonstrated by the remarkable melting-point difference; camphene-2,10-glycol obtained from rabbit urine had a melting point of 111–112° whereas that of 2-*exo*-hydroxycamphene glycol was reported as 196–198° (5).

DISCUSSION

The following camphene metabolic pathway (Scheme I) in rabbits can be proposed from the metabolites.

On the basis of the good glycol yields (260 mg), pathway A was assumed to be the main route. Glycol formation through epoxides has been demonstrated in many other metabolic pathways (6). The homoallylic camphene oxidation products (I–IV) apparently were formed through the nonclassical cation as the intermediate, as shown in pathway B. The ketone (VII) showed the negative optical rotation, $[\alpha]_D$ −8°, and the negative circular dichroism curve ($\Delta\epsilon$ −0.12) (Fig. 2*a*). On the other hand, the synthetic (+)-camphenylon was reported to give the positive circular dichroism curve ($\Delta\epsilon$ +0.50) (7).

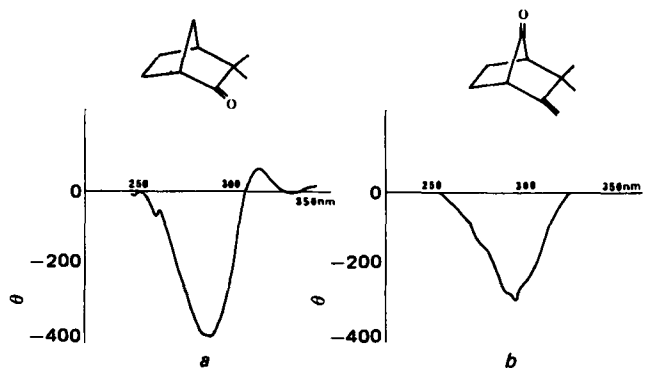

Figure 2—*Circular dichroism curves of camphenylon* (a) *and 7-oxocamphene* (b). *The concentrations were 3.77 × 10^{-2} M in ethanol* (a) *and 6.07 × 10^{-2} M in chloroform* (b).

Based on these results, the ratio was calculated as (−)/(+) = 0.6:0.4. Formation of the (−)-enantiomer from (−)-camphene was assumed to be more likely than formation of the (+)-enantiomer from (+)-camphene. Therefore, it was surmised that the degradation of (+)-camphene is faster than that of (−)-camphene and/or that the conversion of (+)-camphene into (−)-camphene may partly occur in rabbits just as in cicroprofen metabolism in rats (8). The negative circular dichroism curve of 7-oxocamphene (Fig. 2*b*) supports the proposal. The hydroxyl group orientation in II is considered to be *anti*- to the *gem*-dimethyl due to the steric factor.

EXPERIMENTAL[1]

Animals and Dosing—Five male albino rabbits[2], 2–3 kg, were starved for 2 days before the experiments. Camphene (10 g) was dissolved in water (90 ml) containing polysorbate[3] (0.1 g) and homogenized for 20 min. This solution (20 ml), followed by water (20 ml), was administered to each rabbit through a stomach tube. This camphene dose corresponds to 800 mg/kg, and the total amount of camphene fed to all rabbits equaled 8 g.

The animals were housed in individual stainless steel metabolism cages and were allowed rabbit food[4] and water *ad libitum*. The urine was collected daily for 3 days after drug administration and stored at 0–5° until use.

Extraction and Fractionation of Free Neutral Metabolites—The urine was centrifuged at under 3000 rpm at 0° to remove feces and hairs, and the supernate was used for experiments. The urine was adjusted to pH 4.7 with acetate buffer and then incubated with β-glucuronidase–arylsulfatase (3 ml/1000 ml of the fresh urine) at 37° for 48 hr followed by continuous ether extraction for 48 hr. The ether extracts were washed with 5% $NaHCO_3$ and 5% NaOH to remove the acidic and phenolic fractions, respectively, and dried over magnesium sulfate. Ether was evaporated under reduced pressure to give free neutral metabolites (1.471 g).

---

[1] *dl*-Camphene (above 90%) (Tokyo Kasei Kogyo), β-glucuronidase–arylsulfatase (Boehringer Manheim), Wako gel 200, and reagent grade solvents (Wako Chemicals) were used. A Shimadzu GC-6A gas chromatograph was equipped with a hydrogen flame-ionization detector and a thermal conductive detector. For neutral metabolite detection, the following were used: a 2-m × 2.6-mm i.d. glass column, 5% SE-30 or 5% OV-1 on Diasolid L (60–80 mesh); an injector at 250°; an oven programmed at 100–250° at 10°/min; a detector at 250°; and a nitrogen flow rate of 40 ml/min. For preparative use, the same size glass column of 5% DEGS on Diasolid L (60–80 mesh, AW-DMCS) (Japan Chromato) was employed under the same conditions.

TLC plates (20 × 20 cm) were glass, precoated with silica gel 60 F-254, and were 0.25 cm thick (Merck). The solvent system was benzene–ethyl acetate–*n*-hexane (14:5:6 v/v). The chromatograms were visualized with iodine vapor and under UV light (254 nm). NMR spectra were recorded on a Hitachi R-22 or a Varian T-60 spectrometer. IR spectra were run in chloroform using a Hitachi 215 spectrometer. Mass spectra were obtained on a Shimadzu LKB-9000B. UV spectra were obtained on a Shimadzu US 200S. Circular dichroism spectra were recorded on a JASCO ORD/UV-5 spectrometer with a circular dichroism attachment.

6-Oxocamphene from M-I—M-I (9 mg) was dissolved in acetone (1 ml). Anhydrous chromic acid (1.33 g) was added to the dilute sulfuric acid (1.15 g in 2 ml of water) and well stirred. This oxidant (0.1 ml) was added by drops to the acetone solution at 0°, and the reaction mixture was shaken for 20 min. After 13 hr, R_f 0.41 of M-I changed to 0.58. The reaction mixture was neutralized with 5% NaOH, extracted with methylene chloride (1 ml), and dried over magnesium sulfate. Evaporation of this solvent gave 6-oxocamphene (2.4 mg); mass spectrum: *m/e* (%) 150 (M^+, 54), 135 (24), 107 (base), 106 (78), 93 (40), 91 (60), 79 (34), and 77 (21); NMR: δ ($CDCl_3$) 5.07 and 4.82 (each 1H, s), 3.09 (1H), and 1.21 and 1.11 (each 3H, s).

Camphene-2,10-glycol 10-Acetate from M-V—Acetylation of M-V (100 mg) with acetic anhydride and pyridine gave its monoacetate (84.7 mg); mass spectrum: *m/e* (%) 214 (M^+, 4), 194 (13), 171 (82), 152 (78), 137 (53), 109 (base), and 43 (77); IR: ν ($CHCl_3$) 3550 and 1730 cm^{-1}; NMR: δ ($CDCl_3$) 4.20 (2H, s), 2.08 (3H, s), and 1.03 and 0.93 (each 3H, s); NMR: δ (dimethyl sulfoxide-d_6) 4.03 (2H, s), 2.03 (3H, s), 0.93 and 0.88 (each 3H, s), and 3.27 (1H, s, exchanged with deuterium oxide). The anhydrous ethereal solution (10 ml) of lithium aluminum hydride (38.8 mg) was added to the ethereal solution (20 ml) of the monoacetate (80 mg) under a nitrogen atmosphere and stirred at room temperature for 4 hr. Decomposition of the excess lithium aluminum hydride with ethyl acetate, filtration through a short column packed with magnesium sulfate, and evaporation of the solvent recovered camphene-2,10-glycols.

Camphenylon (VII) from M-V—The ethanol solution (5 ml) of M-V (100 mg) was added to the sodium periodate (130 mg)–1 *N* sulfuric acid solution (6 ml) at 40° and stirred for 13 hr until it became transparent (9). The reaction mixture was neutralized with 5% $NaHCO_3$, extracted with ether, and dried over magnesium sulfate. Evaporation of the solvent gave camphenylon (VII) (23.0 mg); mass spectrum: *m/e* (%) 138 (M^+, 28), 95 (10), 81 (5), 72 (14), 69 (base), 67 (67), and 41 (31); UV: λ_{max} (ethanol) 287 (ε 24) and 240 (21) nm; $[\alpha]_D$ −8.3° (c 2.4, $CHCl_3$).

New Compounds: Arylsulfonylhydrazones Derived from Various Heterocycles

RICHARD JUNEAU *x, SCOTT MITCHELL *, and GARY WOLGAMOTT ‡

Received November 20, 1978, from the **Department of Medicinal Chemistry, School of Pharmacy, and the* ‡*Department of Microbiology, Southwestern Oklahoma State University, Weatherford, OK 73096.* Accepted for publication January 24, 1979.

Abstract □ Ten arylsulfonylhydrazones were prepared from various heterocycles. The antimicrobial activity of these compounds was investigated, as was the cytotoxic activity of one of them.

Keyphrases □ Arylsulfonylhydrazones—derived from various heterocycles, antimicrobial and cytotoxic activity □ Hydrazine—derivatives, various heterocycles, antimicrobial and cytotoxic activity □ Antineoplastic agents, potential—arylsulfonylhydrazones, derived from various heterocycles, antimicrobial and cytotoxic activity

Arylsulfonylhydrazones of 2-formylpyridine and its oxide have been investigated as cytotoxic agents (1). Since studies involving the preparation and biological properties of arylsulfonylhydrazones derived from aromatic heterocycles other than pyridine and quinoline are not numerous, the synthesis and antibacterial screening of the compounds listed in Table I were attempted.

DISCUSSION

Chemistry—The compounds listed in Table I were synthesized by standard procedures, consisting of reaction between hydrazine and *p*-toluenesulfonyl chloride or α-toluenesulfonyl chloride followed by condensation with the appropriate heterocyclic 2-carboxaldehyde (Scheme I). For IV and IX, the requisite 5-nitrofurfural was obtained by the acid hydrolysis of 5-nitrofurfurylidene diacetate according to a literature method (2). Compounds IV, VIII, and IX are not new compounds and were reported previously (3–5).

The hydrazone linkage in the synthesized compounds allows geometric isomers to be formed. Attempts to detect *E*- and *Z*-isomers by TLC in several solvent systems were successful only with III and VII. Compounds III and VII demonstrated the presence of a trace amount of a second compound. However, only in the case of III were the two compounds nonoverlapping and amenable to dry column chromatography.

The IR and NMR spectra of III*a* and III*b* were practically superimposable and offered no aid in configurational assignments. Compound III*a* showed a bathochromic shift in the UV spectrum of only 3 nm (285–288) in going from a polar to a nonpolar solvent (ethanol to benzene), whereas III*b* showed a bathochromic shift of 10 nm (272–282). These data suggest the *Z*-configuration for III*b*, the trace component and more mobile compound on TLC (silica gel, chloroform), and the *E*-configu-

[a] All compounds were recrystallized from alcohol, except IIIa and IIIb which were recrystallized from ether.

ration for IIIa in analogy to previously prepared thiosemicarbazones (6).

Biological—Compounds I–X were screened for antibacterial activity against *Staphylococcus aureus* and *Escherichia coli* and were inactive except for the weak inhibitory activity by IV. Because VII is the pyrrole analog of the active arylsulfonylhydrazone derived from 2-formylpyridine (1), it was chosen for antineoplastic screening, but it was devoid of activity.

EXPERIMENTAL[1]

General Synthetic Procedure—The heterocyclic 2-carboxaldehyde, 0.01 mole, was dissolved in 20 ml of methanol and maintained at ice bath temperatures. To this well-stirred solution was added dropwise the sulfonylhydrazide (0.01 mole) in 20 ml of methanol. After addition, the mixture was stirred for an additional 1 hr and placed in the refrigerator overnight. Then the solvent was removed under vacuum to yield semicrystalline solids. The solids were recrystallized from solvents (Table I) and were easily characterized by their NMR and IR spectra.

Biological Screening—The standard filter paper disk method on an agar culture medium was used to screen for antimicrobial activity against *S. aureus* and *E. coli*[2]. The disk was saturated with a methanol solution of the sulfonylhydrazone, and solutions as concentrated as 100 mg/ml were used before inactivity was pronounced.

Compound VII was screened against P-388 leukemia in CDF-1 mice. The compound was administered intraperitoneally as a suspension in polysorbate 80 and 5% ethanol. Doses as high as 120 mg/kg failed to show increased survival time relative to controls.

[1] Melting points were taken with a Thomas-Hoover Uni-Melt apparatus and are uncorrected. IR spectra were determined with a Beckman AccuLab spectrophotometer. NMR spectra were obtained with a Varian model 360-A spectrometer relative to an internal standard of tetramethylsilane with deuterochloroform or deuterated dimethyl sulfoxide as the solvent. UV spectra were determined with a Beckman model 25 spectrophotometer. TLC was performed on silica gel (Eastman chromagram) and visualized with either iodine vapors or UV light. Dry column chromatography was performed on silica gel Woelm (ICN Pharmaceuticals) with chloroform as the solvent. Elemental analyses were performed by Galbraith Laboratories, Knoxville, Tenn.

[2] The bacterial cells employed in the screening test were stock cultues originally derived from Midwest Culture Service (Terre Haute, Ind.) and currently designated as *Staphylococcus aureus* (SW43) and *Escherichia coli* (SW17).

Mathematical Treatment of Linear Mammillary Models Using Inverse Laplace Transforms

Keyphrases □ Mammillary models, linear—mathematics, inverse Laplace transforms □ Laplace transforms—inverse, in mathematical treatment of linear mammillary models □ Mathematics—inverse Laplace transforms in linear mammillary models

To the Editor:

In discussing linear mammillary models, Benet (1) used Laplace transform methods to solve the differential equations describing the compartmental exchanges of drug. Several investigators (2–5) described this method and gave it broader application and understanding relative to this type of pharmacokinetic modeling. However, none of these authors indicated a mathematical correction in the use of the Laplace transform to derive Eqs. 12 and 23 (1). In this article, we attempt to identify previous mathematical oversights and to offer a corrected derivation of the equations describing this model.

Equation 12 (1):

$$a_{s,1} = \frac{k^0(s + E_2)(s + E_3)(1 - e^{-bs})}{s(s + \alpha)(s + \beta)(s + \gamma)} \quad \text{(Eq. 1)}$$

is the Laplace transform for the amount of drug in the central compartment, Compartment 1, in a three-compartment model for an intravenous infusion over the time interval $0 \leq t \leq b$. The given equation is correct but, in determining the inverse Laplace transform of $a_{s,1}$, the numerator $k^0(s + E_2)(s + E_3)(1 - e^{-bs})$ has been misinterpreted as a polynomial in the variable s and, therefore, the General Partial Fraction Theorem has been misapplied. The presence of the factor $(1 - e^{-bs})$ destroys the polynomial character of the numerator, so neither the General Partial Fraction Theorem nor the Heaviside expansion immediately pertains (6).

The following modifications should be made:

$$a_{s,1} = \frac{k^0(s + E_2)(s + E_3)}{s(s + \alpha)(s + \beta)(s + \gamma)} - \frac{k^0(s + E_2)(s + E_3)}{s(s + \alpha)(s + \beta)(s + \gamma)} e^{-bs} \quad \text{(Eq. 2)}$$

The first term in this difference is the quotient of two polynomials, so the Heaviside expansion applies as follows:

$$L^{-1}\left\{\frac{k^0(s + E_2)(s + E_3)}{s(s + \alpha)(s + \beta)(s + \gamma)}\right\} = \frac{k^0(E_2)(E_3)}{\alpha\beta\gamma} + \frac{k^0(E_2 - \alpha)(E_3 - \alpha)}{-\alpha(\beta - \alpha)(\gamma - \alpha)} e^{-\alpha t} + \frac{k^0(E_2 - \beta)(E_3 - \beta)}{-\beta(\alpha - \beta)(\gamma - \beta)} e^{-\beta t} + \frac{k^0(E_2 - \gamma)(E_3 - \gamma)}{-\gamma(\alpha - \gamma)(\beta - \gamma)} e^{-\gamma t} \quad \text{(Eq. 3)}$$

To compute the inverse Laplace transform of the second term, a shift theorem should be used. Let $H(t - b)$ be a function defined by the expression

$$H(t - b) = \begin{cases} 0 & t < b \\ 1 & t > b \end{cases} \quad \text{(Eq. 4)}$$

This function is usually called the unit-step function or the Heaviside function (7). With $H(t - b)$, the needed shift theorem is easily stated. Let $b > 0$ and let the Laplace transforms of $F(t)$, $L\{F(t)\}$, exist. Then:

$$L\{F(t - b)H(t - b)\} = e^{-bs}L\{F(t)\} \quad \text{(Eq. 5)}$$

By applying this theorem under the assumption that:

$$F(t) = L^{-1}\left\{\frac{k^0(s + E_2)(s + E_3)}{s(s + \alpha)(s + \beta)(s + \gamma)}\right\} \quad \text{(Eq. 6)}$$

it is found that:

$$L^{-1}\left\{\frac{k^0(s + E_2)(s + E_3)}{s(s + \alpha)(s + \beta)(s + \gamma)} e^{-bs}\right\} = \left\{\frac{k^0E_2E_3}{\alpha\beta\gamma} + \frac{k^0(E_2 - \alpha)(E_3 - \alpha)}{-\alpha(\beta - \alpha)(\gamma - \alpha)} e^{-\alpha(t-b)} + \frac{k^0(E_2 - \beta)(E_3 - \beta)}{-\beta(\alpha - \beta)(\gamma - \beta)} e^{-\beta(t-b)} + \frac{k^0(E_2 - \gamma)(E_3 - \gamma)}{-\gamma(\alpha - \gamma)(\beta - \gamma)} e^{-\gamma(t-b)}\right\} H(t - b) \quad \text{(Eq. 7)}$$

When Eqs. 3 and 7 are combined, the solution becomes:

$$a_1 = k^0\left[\frac{E_2E_3}{\alpha\beta\gamma} - \frac{(E_2 - \alpha)(E_3 - \alpha)}{\alpha(\beta - \alpha)(\gamma - \alpha)} e^{-\alpha t} - \frac{(E_2 - \beta)(E_3 - \beta)}{\beta(\alpha - \beta)(\gamma - \beta)} e^{-\beta t} - \frac{(E_2 - \gamma)(E_3 - \gamma)}{\gamma(\alpha - \gamma)(\beta - \gamma)} e^{-\gamma t}\right] \quad \text{(Eq. 8)}$$

in the time interval $0 \leq t \leq b$ and:

$$a_1 = k^0\left[\frac{(E_2 - \alpha)(E_3 - \alpha)(e^{\alpha b} - 1)}{\alpha(\beta - \alpha)(\gamma - \alpha)} e^{-\alpha t} + \frac{(E_2 - \beta)(E_3 - \beta)(e^{\beta b} - 1)}{\beta(\alpha - \beta)(\gamma - \beta)} e^{-\beta t} + \frac{(E_2 - \gamma)(E_3 - \gamma)(e^{\gamma b} - 1)}{\gamma(\alpha - \gamma)(\beta - \gamma)} e^{-\gamma t}\right] \quad \text{(Eq. 9)}$$

in the time interval $t > b$. This solution coincides exactly with that of Benet (1) for $t > b$ and gives a more explicit solution for $0 \leq t \leq b$. It is a fact that if the constant b is allowed to vary while infusion continues, *i.e.*, $b = t$ in Ref. 1, one can simplify Benet's solution to the one proposed. However, changing constants to variables in the middle of a derivation confuses the reader and the simplification requires very tedious calculations. The proposed approach is more direct and leaves b as a fixed constant in the model.

With Eq. 23 (1):

$$a_{s,3} = \frac{k_{13}k^0(s + E_2)(1 - e^{-bs})}{s^2(s + \alpha)(s + \beta)} \quad \text{(Eq. 10)}$$

Benet wished to demonstrate how to handle a partial fraction decomposition in which the denominator has a repeated root. However, the numerator is misread as a polynomial in s. The term $a_{s,3}$ may be written as follows:

$$a_{s,3} = k_{13}k^0\left\{\frac{s + E_2}{s^2(s + \alpha)(s + \beta)} - \frac{(s + E_2)e^{-bs}}{s^2(s + \alpha)(s + \beta)}\right\} \quad \text{(Eq. 11)}$$

Then, by using the expansion described by Benet in the Appendix (1) and the shift theorem quoted above, the following expression is obtained from Eq. 11:

$$L^{-1}\{a_{s,3}\} = k_{13}k^0\left[\frac{1 - (\alpha + \beta)E_2}{\alpha\beta} + \frac{tE_2}{\alpha\beta} + \frac{(E_2 - \alpha)e^{-\alpha t}}{\alpha^2(\beta - \alpha)} + \frac{(E_2 - \beta)}{\beta^2(\alpha - \beta)} e^{-\beta t}\right] \quad \text{(Eq. 12)}$$

0022-3549/79/0700-0932$01.00/0
© 1979, American Pharmaceutical Association

for $0 \leq t \leq b$ and:

$$L^{-1}\{a_{s,3}\} = k_{13}k^0\left[\frac{E_2 b}{\alpha\beta} + \frac{(E_2-\alpha)(1-e^{\alpha b})e^{-\alpha t}}{\alpha^2(\beta-\alpha)} + \frac{(E_2-\beta)(1-e^{\beta b})e^{-\beta t}}{\beta^2(\alpha-\beta)}\right] \quad \text{(Eq. 13)}$$

for $t > b$. Equation 13 coincides with Eq. 24 (1), which is valid for the model only after infusion has ceased. Equation 12 gives a very explicit form of the solution during the infusion time.

It is hoped that the corrections made in this article can contribute to the broader application and understanding of the method proposed by Benet.

Mathematical Treatment of Linear Mammillary Models Using Inverse Laplace Transforms: A Reply

Keyphrases □ Mammillary models, linear—mathematics, inverse Laplace transforms □ Laplace transforms—inverse, in mathematical treatment of linear mammillary models □ Mathematics—inverse Laplace transforms in linear mammillary models

To the Editor:

The impetus for preparing my 1972 paper on the general treatment of linear mammillary models as used in pharmacokinetics (1) was a sense of frustration with the pages of mathematical derivation included as part of each pharmacokinetic paper that appeared in print up to that time. As I stated in the introduction (1): "This paper intends to present some very simplified general treatments which will allow workers to derive equations for any linear mammillary compartment model with any first- or zero-order input process." I believed then, as I believe now, that pharmacokinetic compartment models are useful only as a convenient means to describe and predict the time course of measurable body fluid compartments such as plasma, blood, and urine following single and multiple doses. I did not consider the possibility of input into a peripheral compartment or the general derivation for such a treatment, as was described by Vaughan and Trainor (2), since I believe this use of compartment models is inappropriate, *i.e.*, defining one compartment in the model as specifically describing an organ in the body such as the liver. Such a combination of compartment and perfusion models requires exponential terms that are not needed to fit the minimal compartment model adequately and leads to difficulties in interpreting "absorption" rate constants for such a system.

Haborak *et al.* (3) questioned the solution of two equations in my earlier paper, stating: "The presence of the factor $(1 - e^{-bs})$ destroys the polynomial character of the numerator, so neither the General Partial Fraction Theorem nor the Heaviside expansion immediately pertains." They are correct. However, the correct solution is also obtained using the one-step method that I proposed (1, 4). Apparently, the restriction concerning the polynomial character of the numerator may be relaxed when exponential functions appear in the numerator due to the inclusion of a zero-order input function. Since I am no mathematician, I shall leave the proof of this exception to others. However, I have tested the one-step method and found that it gives the correct equations for the usual multicompartment pharmacokinetic models with zero-order input into the central or peripheral compartments.

The authors of the preceding article (3) were most disturbed by the fact that I proposed the use of a single equation to describe the time course of drug in the central compartment during infusion *and* when infusion has ceased. Although I did explain, following Eq. 13 (1), that this approach was equivalent to using two independent variables, t = clock time and b = infusion time, Haborak *et al.* (3) stated that "changing constants to variables in the middle of a derivation confuses the reader . . .." I must admit that this point has led to questions by a number of readers over the years. Perhaps the preceding note and this reply will help readers to understand the appropriate use of Eqs. 13 and 24 in the 1972 paper (1).

Haborak *et al.* (3) also stated that my use of a single equation "requires very tedious calculations." This statement I do not understand; it certainly would be quicker to calculate A_1 values in Eq. 13 on any programmable calculator using a single equation with two inputs during the infusion phase than it would be using two different equations. But "calculation" is not the important functional use for Eq. 13. In 1972, I was concerned that investigators were fitting data from the postinfusion phase separately from the infusion phase. This procedure is inappropriate, as I stated previously (1). In 1972, many of the computer programs used to fit pharmacokinetic data, particularly the BMD series (5), only allowed the investigator to fit one function at a time. However, I stated then (1) that: "All the least-squares nonlinear fitting programs usually utilized in pharmacokinetic treatments have the ability to fit data to Eq. 13. . . ."

In conclusion, the previous article (3) points out the detailed solution for the Laplace derivation when an exponential operator term appears in the numerator of the

for $0 \leq t \leq b$ and:

$$L^{-1}\{a_{s,3}\} = k_{13}k^0\left[\frac{E_2 b}{\alpha\beta} + \frac{(E_2-\alpha)(1-e^{\alpha b})e^{-\alpha t}}{\alpha^2(\beta-\alpha)} + \frac{(E_2-\beta)(1-e^{\beta b})e^{-\beta t}}{\beta^2(\alpha-\beta)}\right] \quad \text{(Eq. 13)}$$

for $t > b$. Equation 13 coincides with Eq. 24 (1), which is valid for the model only after infusion has ceased. Equation 12 gives a very explicit form of the solution during the infusion time.

It is hoped that the corrections made in this article can contribute to the broader application and understanding of the method proposed by Benet.

Time-Dependent Kinetics VI: Direct Relationship between Equations for Drug Levels during Induction and Those Involving Constant Clearance

Keyphrases □ Pharmacokinetics—time dependent, equations for drug levels during induction and during constant clearance □ Models, pharmacokinetic—equations for drug levels during induction and during constant clearance

To the Editor:

In a previous report (1), equations were derived to describe the time course of drug levels during enzyme induction under various drug input conditions: single-dose intravenous (Case I) and oral (Case II) administration, constant rate intravenous infusion (Case III), and multiple-dose intravenous (Case IV) and oral (Case V) administration. These equations were based on the following assumptions:

1. Drug distribution is instantaneous (one compartment of volume V).
2. Drug is excreted unchanged by first-order processes.
3. Metabolism occurs by several first-order pathways, with one being controlled by a single inducible enzyme.
4. Metabolic clearance (pre- and postinduction) approaches intrinsic clearance.
5. Total body drug clearance increases during induction from a preinduction value $Q(t \leq \lambda)$ to a maximum Q' according to (2):

$$Q(t) = Q' - (Q' - Q)\exp[-k'(t - \lambda)] \qquad \text{(Eq. 1)}$$

where k' represents the first-order degradation rate constant of the induced enzyme, $k' < 0.1\ Q'/V$, and λ is the time at which induction begins.

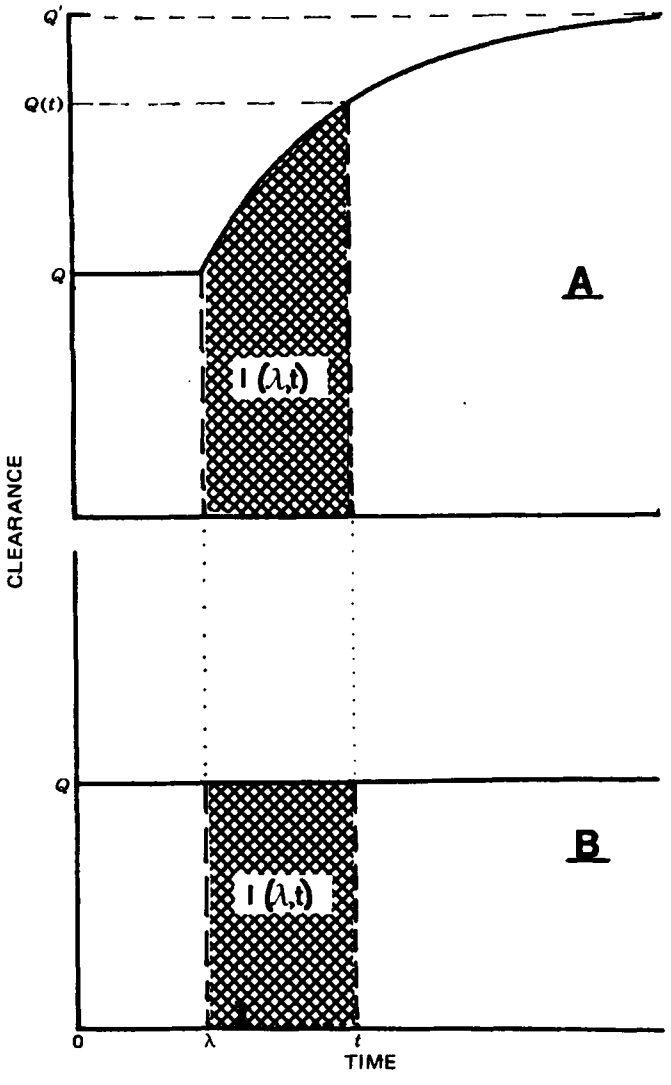

Figure 1—*Exponent* I(λ, t) *in time-dependent kinetics (A) and in linear kinetics (B). Whereas in linear kinetics (constant clearance) the area term* I(λ, t) *increases proportionately with time, in time-dependent kinetics the increase in area is more than proportional.*

To date, equations based on an exponentially increasing clearance have been validated only to the extent that the time course of blood levels that they predict is compatible with some experimental observations (3–7). In this report, a mathematical proof is presented to show that these equations are consistent with the corresponding equations of the classical one-compartment model with constant clearance. In fact, the latter represent a particular case of the former.

Table I presents solutions for Cases I–V with corresponding solutions for the one compartment with constant clearance.

Figure 1 is a plot of $Q(t)$ *versus* time. The term $I(\lambda, t)$ in every equation involving a time-dependent clearance (Table I) is defined as:

$$I(\lambda, t) = \int_{\lambda}^{t} Q(u)\,du \qquad \text{(Eq. 2)}$$

and, therefore, represents the area under the $Q(t)$ *versus*

Time-Dependent Kinetics VI: Direct Relationship between Equations for Drug Levels during Induction and Those Involving Constant Clearance

Keyphrases □ Pharmacokinetics—time dependent, equations for drug levels during induction and during constant clearance □ Models, pharmacokinetic—equations for drug levels during induction and during constant clearance

To the Editor:

In a previous report (1), equations were derived to describe the time course of drug levels during enzyme induction under various drug input conditions: single-dose intravenous (Case I) and oral (Case II) administration, constant rate intravenous infusion (Case III), and multiple-dose intravenous (Case IV) and oral (Case V) administration. These equations were based on the following assumptions:

1. Drug distribution is instantaneous (one compartment of volume V).
2. Drug is excreted unchanged by first-order processes.
3. Metabolism occurs by several first-order pathways, with one being controlled by a single inducible enzyme.
4. Metabolic clearance (pre- and postinduction) approaches intrinsic clearance.
5. Total body drug clearance increases during induction from a preinduction value $Q(t \leq \lambda)$ to a maximum Q' according to (2):

$$Q(t) = Q' - (Q' - Q)\exp[-k'(t - \lambda)] \qquad \text{(Eq. 1)}$$

where k' represents the first-order degradation rate constant of the induced enzyme, $k' < 0.1\ Q'/V$, and λ is the time at which induction begins.

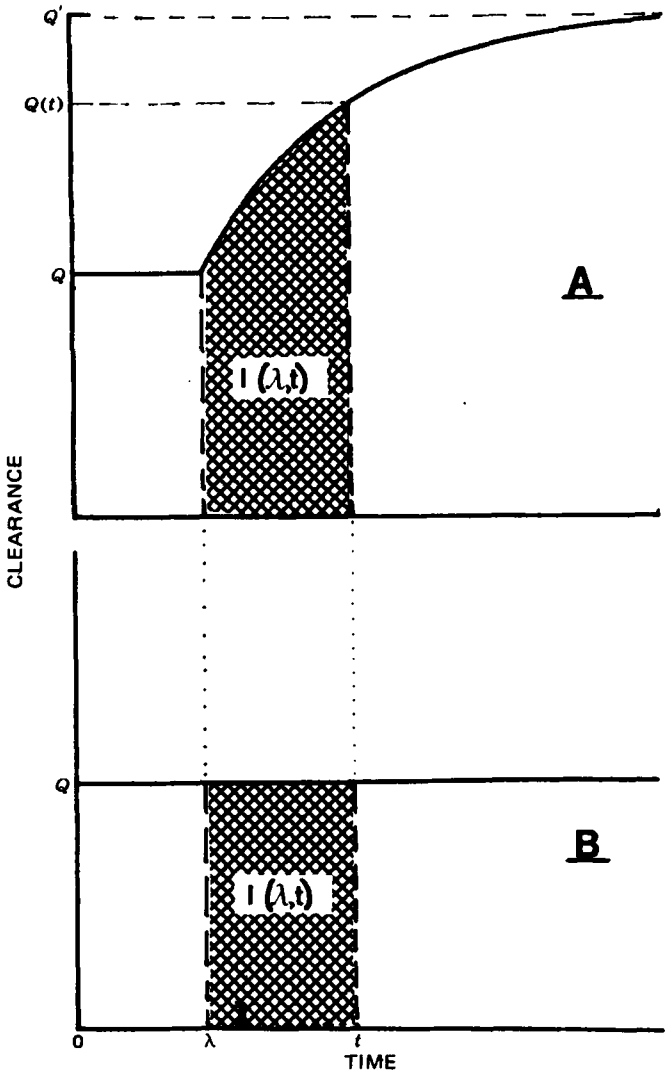

Figure 1—*Exponent* I(λ, t) *in time-dependent kinetics (A) and in linear kinetics (B). Whereas in linear kinetics (constant clearance) the area term* I(λ, t) *increases proportionately with time, in time-dependent kinetics the increase in area is more than proportional.*

To date, equations based on an exponentially increasing clearance have been validated only to the extent that the time course of blood levels that they predict is compatible with some experimental observations (3–7). In this report, a mathematical proof is presented to show that these equations are consistent with the corresponding equations of the classical one-compartment model with constant clearance. In fact, the latter represent a particular case of the former.

Table I presents solutions for Cases I–V with corresponding solutions for the one compartment with constant clearance.

Figure 1 is a plot of $Q(t)$ *versus* time. The term $I(\lambda, t)$ in every equation involving a time-dependent clearance (Table I) is defined as:

$$I(\lambda, t) = \int_{\lambda}^{t} Q(u)\,du \qquad \text{(Eq. 2)}$$

and, therefore, represents the area under the $Q(t)$ *versus*

Table I—Equations [a] for Blood Concentration at Any Time When Clearance Increases Exponentially (A) and When Clearance Is Constant (B)

Case	A. Time-Dependent Clearance	B. Constant Clearance
I: Intravenous single dose	$C = \frac{X_0}{V}\exp\{-[Q\lambda + I(\lambda, t)]/V\}$ (Eq. I-1)	$C = \frac{X_0}{V}\exp(-Qt/V)$ (Eq. I-2)
II: Oral single dose	$C = \frac{FX_0k_a}{k_aV - Q}\exp\{-[Q\lambda + I(\lambda, t)]/V\} - \frac{FX_0k_a}{k_aV - Q(t)}\exp(-k_at)$ (Eq. II-1)	$C = \frac{FX_0k_a}{Vk_a - Q}\left[\exp\left(-\frac{Qt}{V}\right) - \exp(-k_at)\right]$ (Eq. II-2)
III: Constant rate infusion	$C = \frac{R}{Q(t)} - \frac{R}{Q}\exp\{-[Q\lambda + I(\lambda, t)]/V\}$ (Eq. III-1)	$C = \frac{R}{Q} - \frac{R}{Q}\exp(-Qt/V)$ (Eq. III-2)
IV: Intravenous multiple dose	$C = \frac{X_0}{V}\left\{\left[\frac{1 - \exp(-Q\lambda/V)}{1 - \exp(-Q\tau/V)}\right]\exp\{-[Q\tau + I(\lambda, t)]/V\} + \sum_{j=m}^{n-1}\exp[-I(j\tau, t)/V]\right\}$ (Eq. IV-1)	$C = \frac{X_0}{V}\left[\frac{1 - \exp(-n\tau Q/V)}{1 - \exp(-Q\tau/V)}\exp(-Qt'/V)\right]$ (Eq. IV-2)
V: Oral multiple dose	$C = \frac{FX_0k_a}{Vk_a - Q}\frac{1 - \exp(-Q\lambda/V)}{1 - \exp(-\tau Q/V)}\exp\{-[Q\tau + I(\lambda, t)]/V\} + \frac{FX_0k_a}{V}\left[\sum_{j=m}^{n-1}\frac{\exp[-I(j\tau, t)/V]}{k_a - Q(j\tau)/V} - \frac{\exp(-k_at')[1 - \exp(-n\tau k_a)]}{k_a - Q(t)/V[1 - \exp(-k_a\tau)]}\right]$ (Eq. V-1)	$C = \frac{FX_0k_a}{Vk_a - Q}\left[\frac{1 - \exp(-n\tau Q/V)}{1 - \exp(-\tau Q/V)}\exp(-Qt'/V) - \frac{1 - \exp(n\tau k_a)}{1 - \exp(-\tau k_a)}\exp(-k_at')\right]$ (Eq. V-2)

[a] X_0 = dose, V = single-compartment volume of distribution, F = fraction of dose absorbed, k_a = first-order absorption rate constant, τ = fixed dosing interval, n = number of doses, and:

$$I(\lambda, t) = Q'(t - \lambda) - \frac{(Q' - Q)}{k'}\{1 - \exp[-k'(t - \lambda)]\}$$

$$I(j\tau, t) = Q'\{t' + [n - (j + 1)]\tau\} - \frac{(Q' - Q)}{k'}(\exp[-(j - m)\tau k'] - \exp[-k'\{t' + [n - (m + 1)]\tau\}])$$

All other symbols are as defined in the text.

time plot between λ and t (Fig. 1A). The term $Q\lambda + I(\lambda, t)$ is equal to the total area under the $Q(t)$ *versus* time plot from 0 to t.

When $Q(t)$ is defined by Eq. 1, $I(\lambda, t)$ is given by:

$$I(\lambda, t) = Q'(t - \lambda) - \frac{(Q' - Q)}{k'}\{1 - \exp[-k'(t - \lambda)]\} \quad \text{(Eq. 3)}$$

For the one-compartment model with a constant clearance Q, the term $I(\lambda, t)$ as defined in Eq. 2 becomes:

$$I(\lambda, t) = \int_\lambda^t Q\,du = Q(t - \lambda) \quad \text{(Eq. 4)}$$

In this latter case, $I(\lambda, t)$ is equal to the area under the rectangle with height Q and width $t - \lambda$ (Fig. 1B).

For Case I, the term Qt in Eq. I-2 (Table I) can be written as:

$$Qt = Q\lambda + Q(t - \lambda) \quad \text{(Eq. 5)}$$

Using the definition of $I(\lambda, t)$ in Eq. 4, Qt becomes:

$$Qt = Q\lambda + I(\lambda, t) \quad \text{(Eq. 6)}$$

and, therefore:

$$C = \frac{X_0}{V}\exp(-Qt/V) = \frac{X_0}{V}\exp\{-[Q\lambda + I(\lambda, t)]/V\} \quad \text{(Eq. 7)}$$

Similarly in Case II, Eq. II-1 reduces to Eq. II-2 by substitution of Qt for $[Q\lambda + I(\lambda, t)]$ in the first term and Q for $Q(t)$ in the second term. In Case III also, Eq. III-1 reduces to Eq. III-2 by substitution of Q for $Q(t)$ in the first term and Qt for $[Q\lambda + I(\lambda, t)]$ in the second term.

In Cases IV and V, the relationships between Eqs. IV-1 and V-1 and between Eqs. V-1 and V-2 become apparent only after a few substitutions:

1. The term $I(j\tau, t)$, which appears in Eqs. IV-1 and V-1, is also defined by Eq. 2 with $j\tau$ as the lower bound of the integral ($\lambda \leq j\tau \leq t$). When the clearance is constant, it is given by:

$$I(j\tau, t) = Q(t - j\tau) = Q\{t' + [n - (j + 1)]\tau\} \quad \text{(Eq. 8)}$$

where $t' = t - (n - 1)\tau$.

2. The term $Q\tau + I(\lambda, t)$ can also be expressed in terms of t':

$$Q\tau + I(\lambda, t) = Q(t' + n\tau - \lambda) = Q[t' + (n - m)\tau] \quad \text{(Eq. 9)}$$

where $\lambda = m\tau$.

3. By using Eqs. 8 and 9, Eq. IV-1 can be written as:

$$C = \frac{X_0}{V}\exp(-Qt'/V)\frac{\exp[-(n - m)\tau Q/V] - \exp(-n\tau Q/V)}{1 - \exp(-Q\tau/V)} + \frac{X_0}{V}\sum_{j=m}^{n-1}\exp(-Q\{t' + [n - (j + 1)]\tau\}/V) \quad \text{(Eq. 10)}$$

4. The second term in Eq. 10 is a geometric series and, therefore, multiplication by:

$$1 = \frac{1 - \exp(-Q\tau/V)}{1 - \exp(-Q\tau/V)}$$

results in the following expression for Eq. IV-1:

$$C = \frac{X_0}{V}\exp(-Qt'/V)\left[\frac{\exp[-(n - m)\tau Q/V] - \exp(-n\tau Q/V)}{1 - \exp(-Q\tau/V)}\right] + \frac{X_0}{V}\exp(-Qt'/V)\left[\frac{1 - \exp[-(n - m)\tau Q/V]}{1 - \exp(-Q\tau/V)}\right] \quad \text{(Eq. 11)}$$

Equation 11 yields Eq. IV-2 after addition of its two terms.

5. Substitution of Q for $Q(j\tau)$ in Eq. V-1 shows that the sum of its first two terms becomes identical to Eq. IV-1, except for the difference between $FX_0k_a/(Vk_a - Q)$ and X_0/V. Correspondingly, the first term in Eq. V-2 is equal to Eq. IV-2 (except for $X_0/V \neq FX_0k_a/(Vk_a - Q)$. The third term in Eq. V-1 becomes the second term in Eq. V-2 after substitution of Q for $Q(t)$.

Thus, it appears that for all of the input modes considered, the equations commonly used for the one-compartment model with constant clearance represent only particular cases of the corresponding equations involving a time-dependent clearance. This direct correspondence provides further validation of the equations proposed to describe drug levels when metabolic clearance increases exponentially.

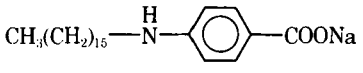
Cetaben Sodium, an Antiatherosclerotic Agent

Keyphrases □ Cetaben sodium—synthesis, antiatherosclerotic activity □ Antiatherosclerotic agents—cetaben sodium, synthesis □ Sodium 4-(hexadecylamino)benzoate—synthesis, antiatherosclerotic activity

To the Editor:

We wish to report the synthesis of cetaben sodium [sodium 4-(hexadecylamino)benzoate], a substance that shows promise as an antiatherosclerotic agent.

Ethyl 4-(hexadecylamino)benzoate (mp 85–86°) was prepared (yield 65–85%) from hexadecyl bromide or mesylate and 2 moles of ethyl 4-aminobenzoate at 135° in hexamethylphosphoric amide. Of the liquid amides, hexamethylphosphoric amide was the best reaction solvent (faster rate and fewer by-products); however, some dialkylation did occur. With dimethylformamide or *N,N*-dimethylacetamide at 135–150° as solvents, *N*-formyl and *N*-acetyl products were obtained as well as some 4-(hexadecylamino)-*N,N*-dimethylbenzamide by-product. Among various alternative synthetic methods, the diborane reduction of ethyl 4-(hexadecanoylamino)benzoate gave ethyl 4-(hexadecylamino)benzoate in good yield and can be used for preparing various isomers and analogs.



cetaben sodium

Cetaben sodium can be obtained directly from the quantitative alkaline hydrolysis of the ester but is generally prepared from 4-(hexadecylamino)benzoic acid (double mp 108–110 and 126–128°) since the latter is more easily purified. This salt, which is moderately soluble (about 2%) in 75% alcohol, is crystallized from a solution of the acid and a slight sodium hydroxide excess in aqueous ethanol in 95% yield.

The 4-(alkylamino)benzoic acids (1) are substantially less toxic and more hypolipidemic than the 4-alkoxybenzoic acids (2, 3) and 4-alkylbenzoic acids (3). Extensive studies have elucidated the structure–activity relationships in the aminobenzoic acid series, which are different from those in the alkoxybenzoic acids. The tabulated data show the hypolipidemic activity of representative aminobenzoic acids as well as of clofibrate under the same test conditions (Table I). The hypocholesterolemic activity falls off as the alkyl chain is increased to 20 or decreased to eight carbon atoms (1). However, the hypotriglyceridemic activity is relatively unaffected by the alkyl chain length. Cetaben is also the most effective member of the series in inhibiting ^{14}C-acetate and ^{3}H-glycerol incorporation into liver triglycerides, phospholipids, and cholesterol in rats. It is not esterogenic, and its hypocholesterolemic mechanism of action does not involve inhibition of a late stage in cholesterol biosynthesis. Hypocholesterolemic activity has been demonstrated also in the rabbit and monkey.

The considerable therapeutic potential of cetaben is suggested by its activity in two experimental atherosclerosis models in laboratory animals. First, cetaben sodium was shown to possess antiatherosclerotic activity in a rabbit model (4). Average reductions of 32–73% in the incidence of atherosclerotic lesions and of 24–28% in abdominal aortic cholesterol accumulation were observed in treated animals at doses below those that were hypolipidemic[1]. The reductions in aortic cholesterol were essentially all due to the decreases in cholesterol ester.

Second, Hollander *et al.* (5) reported on the antiatherosclerotic activity of cetaben sodium in the cynomolgus monkey. Serum cholesterol concentrations were reduced by 37% in the treated animals as compared to controls fed the atherogenic diet alone. This change was reflected in an altered lipoprotein distribution with decreases in very low density lipoproteins (by 30%) and low density lipoproteins (by 38%) but an increase in high density lipoproteins (by 96%). Such a shift in lipoprotein concentrations in humans is considered to be antiatherogenic (6, 7). Antiatherosclerotic activity was manifested by changes in the disease incidence and severity as well as in the chemical composition of the lesions present in the drug-treated monkeys.

Table I—Hypolipidemic Effect of 4-(*n*-Alkylamino)benzoic Acids and Clofibrate in Normal Rats

n-Alkyl Group	Oral Dose in Diet[a], mg/kg/day	Percent Lowering[b] of Serum	
		Sterol	Triglyceride
C_{12}	86	11[c]	68[d]
	47	20[e]	60[d]
	25	14[f]	49[d]
C_{14}	82	9	47[d]
	46	9	49[d]
	23	9	36[d]
C_{16} (cetaben)	89	44[d]	69[d]
	64	30[d]	48[f]
	42	26[d]	40[f]
	22	27[d]	38[f]
	10	27[d]	29[d]
C_{18}	91	18[g]	40[e]
	48	6	28[c]
	23	14[f]	29[c]
Clofibrate	375	26[d]	43[c]
	106	5	30
	33	0	32

[a] The method used was described in detail in Ref. 2. Oral dosing was by normal rat chow containing drug; 0.05% in the diet corresponds to a measured average daily dosage of 46 mg/kg, *etc.* [b] Percent lowering of the mean serum concentrations relative to the mean values in control animals in the same test; control groups averaged 75 ± 3 mg % sterol and 85 ± 6 mg % triglyceride. The significant level (p), determined by the Student t test, is denoted by the appropriate footnote. Numbers without a footnote are not statistically significant lowerings. [c] $p < 0.05$. [d] $p < 0.001$. [e] $p < 0.005$. [f] $p < 0.02$. [g] $p < 0.01$.

Most important was the presence of only half as much luminal narrowing in four major coronary arteries (5). Accompanying this effect on lumen size were increases in myocardial blood flow in the nonstressed and stressed heart. In the stressed heart, regional blood flow toward the endocardium was improved as well. Reductions in luminal narrowing and incidence of atherosclerotic lesions also were seen in several major peripheral arteries. In the aortas of treated monkeys, average 48% reductions in cholesterol accumulation resulted predominantly from decreases in esterified cholesterol. Additionally, there was complete prevention of a 2.5-fold calcium increase in the aortic wall and a 70% inhibition of the increase in aortic fibrous connective tissue. Up to now, such pronounced therapeutic effects on this atherosclerosis model (5, 8, 9) have not been reported with any other drug.

The reduced cholesterol ester content in the rabbit and monkey aortas may result from cetaben inhibition of the cholesterol-esterifying enzyme in the aortic wall. With a cell-free preparation of fatty acyl-CoA: cholesterol acyl transferase (ACAT) from rabbit aortas, cetaben sodium substantially inhibited the enzyme at therapeutically obtainable concentrations[1] (~5 μg/ml). This effect is especially significant in view of the greater proportion of esterified to free cholesterol in atheromatous lesions in humans (10) as well as the lower experimental reversibility of ester deposition in rabbits (11).

In a series of papers, we shall fully report on the biological activity described here and elaborate the structure–activity relationships of alkyl size; branching, cyclization, substitution, and unsaturation of the alkyl group; further substitution of the amino nitrogen and its position isomers; additional substitution on the benzene ring and its replacement with other rings; and carboxyl group derivatization, modification, and extension.

Effective atherosclerosis therapy probably will require drugs that have several modes of action such as those displayed by cetaben sodium. Cetaben sodium is now undergoing clinical trials as an antiatherosclerotic agent in humans.

pKa of 2-Methylamino-5-chlorobenzophenone, a Diazepam Hydrolysis Product

Keyphrases □ Methylaminochlorobenzophenone—pKa, diazepam hydrolysis product, structure–activity relationships □ Diazepam—hydrolysis products, methylaminochlorobenzophenone, pKa, structure–activity relationships □ Structure–activity relationships—diazepam hydrolysis products, pKa

To the Editor:

The compound 2-methylamino-5-chlorobenzophenone (I) is the aromatic product of diazepam (II) hydrolysis in acidic aqueous solution (1). It was of interest to estimate the pKa of I because of its importance in kinetic stability and analytical studies of prazepam (2) and II (1, 3–8).

The pKa of I[1] was determined spectrophotometrically[2] at 25° at 415 nm in a concentration of 4.07×10^{-5} *M* (10 μg/ml). All samples contained 7% (v/v) ethanol. The pH was varied by preparing samples in 0.02–0.40 *N* HCl. The spectrum of the conjugate acid was obtained in 60% (w/w) H_2SO_4 ($H_0 = -4.4$), and that of the nonionized base was obtained in buffers of pH 7.20 and 9.23. The conjugate acid species showed no absorbance at 415 nm, and the base had an absorbance of 0.23. The other spectral characteristics included decreasing absorbance at 410–420 nm and a hypsochromic shift from ~268 to 238 nm with increasing

	106	5	30
	33	0	32

[a] The method used was described in detail in Ref. 2. Oral dosing was by normal rat chow containing drug; 0.05% in the diet corresponds to a measured average daily dosage of 46 mg/kg, *etc.* [b] Percent lowering of the mean serum concentrations relative to the mean values in control animals in the same test; control groups averaged 75 ± 3 mg % sterol and 85 ± 6 mg % triglyceride. The significant level (p), determined by the Student t test, is denoted by the appropriate footnote. Numbers without a footnote are not statistically significant lowerings. [c] $p < 0.05$. [d] $p < 0.001$. [e] $p < 0.005$. [f] $p < 0.02$. [g] $p < 0.01$.

Most important was the presence of only half as much luminal narrowing in four major coronary arteries (5). Accompanying this effect on lumen size were increases in myocardial blood flow in the nonstressed and stressed heart. In the stressed heart, regional blood flow toward the endocardium was improved as well. Reductions in luminal narrowing and incidence of atherosclerotic lesions also were seen in several major peripheral arteries. In the aortas of treated monkeys, average 48% reductions in cholesterol accumulation resulted predominantly from decreases in esterified cholesterol. Additionally, there was complete prevention of a 2.5-fold calcium increase in the aortic wall and a 70% inhibition of the increase in aortic fibrous connective tissue. Up to now, such pronounced therapeutic effects on this atherosclerosis model (5, 8, 9) have not been reported with any other drug.

The reduced cholesterol ester content in the rabbit and monkey aortas may result from cetaben inhibition of the cholesterol-esterifying enzyme in the aortic wall. With a cell-free preparation of fatty acyl-CoA: cholesterol acyl transferase (ACAT) from rabbit aortas, cetaben sodium substantially inhibited the enzyme at therapeutically obtainable concentrations[1] (~5 μg/ml). This effect is especially significant in view of the greater proportion of esterified to free cholesterol in atheromatous lesions in humans (10) as well as the lower experimental reversibility of ester deposition in rabbits (11).

In a series of papers, we shall fully report on the biological activity described here and elaborate the structure–activity relationships of alkyl size; branching, cyclization, substitution, and unsaturation of the alkyl group; further substitution of the amino nitrogen and its position isomers; additional substitution on the benzene ring and its replacement with other rings; and carboxyl group derivatization, modification, and extension.

Effective atherosclerosis therapy probably will require drugs that have several modes of action such as those displayed by cetaben sodium. Cetaben sodium is now undergoing clinical trials as an antiatherosclerotic agent in humans.

Table I—pKa Values of Some Aniline Derivatives

Substance	Substituent	Position	pKa[a]
Aniline	—	—	4.60[b]
Aniline	Benzoyl	4	2.2[c]
Aniline	Chloro	4	3.98[b]
N-Methylaniline	—	—	4.85[b]
N-Methylaniline	Chloro	4	3.9[c]

[a] At 25°. [b] References 10 and 11. [c] Reference 11.

absorbance, both in relation to the increasing sample acidity. The I pKa was calculated from Eq. 1 (9) to be 1.45 ± 0.04[3]:

$$\text{pKa} = \text{pH} + \log (A_b - A/A - A_i) \qquad \text{(Eq. 1)}$$

where A_b, A_i, and A = the absorbances of the nonionized base, the conjugate acid, and the various samples, respectively.

The pKa values of substituted anilines such as I are lowered more by an *ortho*- than by a *meta*- or *para*-electron-withdrawing substituent (10, 11). Thus, the inductive effect of 2-benzoyl and 4-chloro groups on *N*-methylaniline (*i.e.*, I) as regards the pKa of the anilino nitrogen atom would be predicted to exceed that of the sum of these substituents at the 4-position. From Table I, the pKa differences among anilines substituted with *N*-methyl, 4-benzoyl, and 4-chloro groups are 0.25, −2.4, and −0.62 units, respectively. The arithmetic sum of these differences is −2.77 units, thereby predicting a pKa of ~1.8 (*i.e.*, 4.6 − 2.8) for I. However, the pKa lowering caused by a 4-chloro substituent is 0.1 unit greater for *N*-methylaniline than for aniline. Therefore, the observed anilino pKa decrements (Table I), augmented by the expected superior electron-inducing capability of a 2-benzoyl (*ortho*) over that of a 4-benzoyl *N*-methylaniline substituent, appear to be in reasonable agreement with the pKa estimate of 1.4–1.5 for I.

Drug Dissolution within a Cascade Barrier Bed

Keyphrases □ Dissolution—test apparatus, cascade barrier bed □ Pharmacokinetics—drug dissolution tests, apparatus, cascade barrier bed □ Cascade barrier bed—for testing drug dissolution

To the Editor:

When dissolution limits the rate of drug absorption, *in vitro* dissolution tests are useful for quality control or in formulation development only if they correlate well with *in vivo* drug levels. Where satisfactory correlations have not been found, differences in solubility behavior among the polydisperse particles produced during dosage unit disintegration may be a factor. Where the relative intrinsic solubilities of particles are size dependent and sensitive to formulation variables, a single dissolution test method cannot be relied upon. Depending on the desired degree of resolution among formulations, at least two procedures are needed that produce linearly independent functional relationships between particle size and dissolution hydrodynamics. To accomplish this result, they must control the dissolution fluid mechanics as a function of particle size.

This communication discusses a cascade barrier bed test method, which complements existing procedures by providing distinctly different dissolution conditions. It differs from the USP–NF (1, 2), stationary basket–rotating filter (3), and flowthrough cell (4, 5) methods by favoring the dissolution of small particles over large.

The device consists of a vertical cylindrical cell (Fig. 1). It is partially filled with discrete layers, B, of uniformly sized, silanized glass balls. The ball size of each layer is successively increased from the bottom to the top of the bed. The prototype tested contained five layers, each 6.25 cm in height and composed of 0.25-, 0.56-, 1-, 2-, and 4-mm balls. The cell was 50 cm in height × 1.9 cm i.d.

In preparation for a run, solvent was introduced through the efflux chamber, C, to the top of the previously loaded bed so as to preclude air entrapment. The powder was then placed on top of the bed; the solvent receiving chamber, A, was filled with solvent; and flow was initiated. Flow was controlled and maintained by hydrostatic pressure; solvent flowed from an elevated reservoir through Tygon tubing to the receiving chamber, A. Samples of effluent were collected through tubing attached to chamber C and assayed. A sintered-glass frit, D, retained and supported the bed within the cell.

In operation, drug particles are carried into the bed by viscous drag forces and by gravity to a level where they are trapped. Their location is determined by drug particle size and the pore size characteristic of each layer in the bed. Particles from polydispersed systems are thus separated into various size fractions within the bed.

Although fluid flow fields in this type of packed bed are complicated, the hydrodynamics within the various layers are simply related. With column and ball diameters in a practical range for dissolution testing, random packing fractions of uniform spheres are size independent. For a constant column cross-sectional area, the average linear velocity of the solvent also will be constant throughout the bed for incompressible fluids. Voids and pores are geo-

metrically similar among the various bed layers and have dimensions in direct proportion to ball size. Therefore, solvent laminar flow shear rates are inversely proportional to ball size at equivalent locations within the voids and pores of various layers. This result is a direct consequence of the principle of geometric similarity from dimensional analysis of fluid mechanics (6). Under these conditions, shear rate gradients are inversely proportional to the square of ball dimension. No loss of solubility rate dependency on particle size will occur in going from sink to nonsink conditions, provided significant saturation does not occur in a single pass of solvent through the cell.

Table I—Regression Coefficients for Sulfadiazine Dissolution by Cascade Barrier Bed (CBB) and USP Basket Methods

Method	Sulfadiazine, mg	Particle Size, mesh	Linear Coefficient, $b \times 10^3$, min^{-1}	Quadric Coefficient, $c \times 10^5$, min^{-2}
CBB	10	100/200[a]	21.0	31.4
	10	30/50[a]	2.7	1.6
	5, 5	100/200[b], 30/50	14.5	19.7
USP	10	100/200[a]	11.1	9.1
	10	30/50[a]	2.5	2.6
	5, 5	100/200[b], 30/50	7.1	5.4

[a] Average of duplicate runs. [b] Average of triplicate runs.

It is apparent that the size and quantity of balls comprising the layers, B, the desirable number of such layers, and the solvent selected will depend on the size distribution, the amount of multiparticulate material, excipients, and drug solubility. The preliminary experiments reported were designed to test the operation of the fluid mechanical principle, which is the basis of the method.

The prototype cell was tested using deaerated 0.01 N H_2SO_4 at a flow rate of 30 ml/min under sink conditions. For comparison, the USP–NF rotating-basket method was run at 120 rpm using the same solvent, essentially under sink conditions due to low saturation levels. Sulfadiazine USP powder was compressed into tablets, coarsely ground in a mortar, and screened through U.S. standard sieves. Two size fractions were used as test materials: those passing a 30-mesh and retained on a 50-mesh sieve and those passing a 100-mesh and retained on a 200-mesh sieve.

The nondisintegrating powders were placed either on top of the bed or in the basket[1], depending on the apparatus, at the start of each run. All experiments were conducted at 25 ± 0.1°, and samples withdrawn at 3–5-min intervals were assayed by UV absorption at 243 nm. The cumulative fraction dissolved, f, was fitted to the equation $f = bt - ct^2$ by the method of least squares. Results are shown in Table I. Equally satisfactory cleaning of the cell following a run was obtained by simply continuing solvent flow or by disassembly and washing with solvent.

The ratio of the initial dissolution rate of the small particles to that of the large particles can be taken as the

[1] Hanson Research Corp., Northridge, CA 91324.

ratio of the corresponding b values. These ratios are 7.7 and 4.4 for the cascade barrier bed and USP methods, respectively. If a uniform size distribution for each powder fraction is assumed, the finer powder should have approximately four times the specific surface area of the coarse powder. Thus, the initial dissolution rate per unit surface area of the fine powder is nearly twice that of the coarse powder for the cascade barrier bed method and is comparable to the coarse powder for the USP method. These observations conform to expectations based on apparatus design and fluid mechanical theory.

Figure 2 shows the cascade barrier bed dissolution behavior of a mixture of 5 mg each of the fine and coarse sulfadiazine powders. For comparison, results of separate cascade barrier bed runs of 5 mg of the individual powder grades were added and the sum was plotted. The two plots closely correspond and indicate independent dissolution behavior of the two powder fractions within the bed.

These findings do not indicate the superiority of one *in vitro* dissolution apparatus over another. Instead, they suggest that, where particle-size effects prevent useful correlations with *in vivo* drug levels, parallel use of two such contrasting methods is necessary.

REVIEWS

Analytical Profiles of Drug Substances, Volume 7. Edited by KLAUS FLOREY. Academic, 111 Fifth Ave., New York, NY 10003. 1978. ix + 504 pp. 15 × 23 cm.

Volume 7 of this series includes individual drug monographs dealing with supplementary information that is not listed in the official compendia. The entire series of volumes was undertaken as a cooperative venture by the Pharmaceutical Analysis and Control Section, Academy of Pharmaceutical Sciences. The profiles of drug substances in each volume are submitted by contributors and checked by selected reviewers. A typical profile includes such topics as a description of the compound (name, formula, molecular weight, color, odor, and salts), physical properties (IR, NMR, UV, and mass spectra, melting or boiling point, solubility, partition coefficient, and dissociation constant), syntheses, stability, analysis methods, and metabolism and pharmacokinetic data.

The monographs include up-to-date references, and many contributors state that their references are complete through a certain year, a worthwhile piece of information for the reader. Among the drugs covered in Volume 7 are allopurinol, amoxicillin, chlorpheniramine maleate, dihydroergotoxine methanesulfonate, diphenoxylate hydrochloride, droperidol, epinephrine, ethambutol hydrochloride, fluoxymesterone, hexetidine, hydroflumethiazide, hydroxyzine dihydrochloride, 6-mercaptopurine, phenobarbital, sulfamethazine, thiostrepton, trimethoprim, and tubocurarine chloride.

The entire series should be included in school of pharmacy library reading rooms and in university science libraries. They contain important drug data that have not been available previously in one single reference source. The series is not meant to be used as a textbook but can be employed effectively as reference material for any pharmaceutical or medicinal chemistry course.

ratio of the corresponding b values. These ratios are 7.7 and 4.4 for the cascade barrier bed and USP methods, respectively. If a uniform size distribution for each powder fraction is assumed, the finer powder should have approximately four times the specific surface area of the coarse powder. Thus, the initial dissolution rate per unit surface area of the fine powder is nearly twice that of the coarse powder for the cascade barrier bed method and is comparable to the coarse powder for the USP method. These observations conform to expectations based on apparatus design and fluid mechanical theory.

Figure 2 shows the cascade barrier bed dissolution behavior of a mixture of 5 mg each of the fine and coarse sulfadiazine powders. For comparison, results of separate cascade barrier bed runs of 5 mg of the individual powder grades were added and the sum was plotted. The two plots closely correspond and indicate independent dissolution behavior of the two powder fractions within the bed.

These findings do not indicate the superiority of one *in vitro* dissolution apparatus over another. Instead, they suggest that, where particle-size effects prevent useful correlations with *in vivo* drug levels, parallel use of two such contrasting methods is necessary.

The *Journal of Pharmaceutical Sciences* (ISSN 0022-3549) is published monthly by the American Pharmaceutical Association (APhA) at 2215 Constitution Ave., N.W., Washington, DC 20037. Second-class postage paid at Washington, D.C., and at additional mailing office.

All expressions of opinion and statements of supposed fact appearing in articles or editorials carried in this journal are published on the authority of the writer over whose name they appear and are not to be regarded as necessarily expressing the policies or views of APhA.

Offices—Editorial, Advertising, and Subscription: 2215 Constitution Ave., N.W., Washington, DC 20037. Printing: 20th & Northampton Streets, Easton, PA 18042.

Annual Subscriptions—United States and foreign, industrial and government institutions $50, educational institutions $50, individuals *for personal use only* $30; single copies $5. All foreign subscriptions add $5 for postage. Subscription rates are subject to change without notice. Members of APhA may elect to receive the *Journal of Pharmaceutical Sciences* as a part of their annual $70 (foreign $75) APhA membership dues.

Claims—Missing numbers will not be supplied if dues or subscriptions are in arrears for more than 60 days or if claims are received more than 60 days after the date of the issue, or if loss was due to failure to give notice of change of address. APhA cannot accept responsibility for foreign delivery when its records indicate shipment was made.

Change of Address—Members and subscribers should notify at once both the Post Office and APhA of any change of address.

Photocopying—The code at the foot of the first page of an article indicates that APhA has granted permission for copying of the article beyond the limits permitted by Sections 107 and 108 of the U.S. Copyright Law provided that the copier sends the per copy fee stated in the code to the Copyright Clearance Center, Inc., P.O. Box 8891, Boston, MA 02114. Copies may be made for personal or internal use only and not for general distribution.

Microfilm—Available from University Microfilms International, 300 N. Zeeb Road, Ann Arbor, MI 48106.

PHARMACEUTICAL EXCIPIENTS COME OF AGE

For a great variety of reasons, but all with the objective of serving the needs of its membership specifically and the needs of the profession of pharmacy and the health care community in general, APhA has embarked on a broad publication program which now includes a complete spectrum of journals, pamphlets, workbooks, textbooks, audio-visual aids, newsletters, and so on. If it is true that *"Heinz has pickles,"* then it can equally be said that *"APhA has publications!"*

Given the fact that the Association is knee-deep in the products of its publications program, something really special would need to come along for us to devote this column to a discussion of just one of these literary undertakings. Moreover, if the end-product of that undertaking is still a couple of years off, then it needs to be more than special but even extra-special. And, in our opinion, the prospective item we have in mind looks as if it will be just that.

For many years, pharmaceutical scientists have devoted considerable time, attention, and effort to devising definitions, tests, standards, assays, specifications, and the like for drug entities and drug dosage forms. Indeed, they did such a good job that Congress legally recognized two products of this activity—the *United States Pharmacopeia* and the *National Formulary*—as "official compendia," and mandated that bulk drug substances and marketed drug dosage forms comply with the standards or be subject to enforcement actions on legal grounds of misbranding or adulteration.

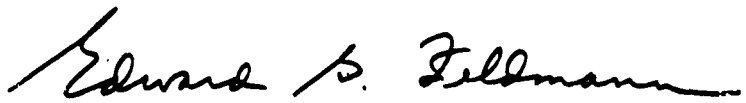
In formulating drug dosage forms, pharmaceutical research and development staff will generally utilize a variety of substances that are intended to transform the simple drug active ingredient into a pharmaceutically elegant dosage form. These substances are broadly referred to as pharmaceutical excipients, aids, or adjuncts, and while contributing to the overall quality of the product, they are not intended to have any physiological effect of their own. They impart improved properties such as appearance, flavor, stability, ease of administration, and convenience.

Although standards, specifications, and the like have also been devised for some of these excipients, neither the breadth nor the depth of these efforts has compared to that devoted to the drug entities and dosage forms. Moreover, no concerted effort has been made to pull all this information together in a single reference source where it would be conveniently available as well as presented in a uniform and consistent format. Finally, the *kinds* of information most useful to a pharmaceutical scientist involved in product formulation are often quite different from those that may be appropriate for an excipient which is recognized in a compendium of tests and standards.

Given this background, a pharmacist and pharmaceutical scientist with a long background in drug product formulation, research, development, analysis, and specifications concluded that the time was over-ripe for someone to respond to this need. The man of vision in this case is Jack Cooper, a person who has been long active in APhA, its old Scientific Section and Industrial Pharmacy Section, and then the initial Past President when the APhA Academy of Pharmaceutical Sciences was created in the mid-1960's.

Approximately three years ago, Mr. Cooper conceived of the idea of developing a *Handbook of Pharmaceutical Excipients*, and then went about the job, virtually single-handedly, of convincing others of the value and need for such a compilation. In this process, he took his proposal to the APhA Academy of Pharmaceutical Sciences, and he won their endorsement, support, and agreement to take on the task as an Academy-sponsored project. He also recruited some 120 pharmaceutical scientists for service as volunteer collaborators on the various committees to identify and select excipients for inclusion, to ascertain and compile information currently known about those excipients, to develop new information in order to fill gaps in what is known, to verify literature values and data, and to prepare the resultant information in an orderly, organized monograph format.

Presently, Mr. Cooper reports that the project is moving steadily along, but it is still too early to predict a completion date. We do, however, wish to take this opportunity to congratulate the APS for taking on the sponsorship of this important project, and to salute Jack Cooper for his vision, determination, and dedication in undertaking immediate responsibility for its development. At the same time, we would encourage any of our readers with an interest in this subject to volunteer their efforts. As Project Chairman, Mr. Cooper can use all the assistance he can get. In his own words, "*. . . it has become increasing clear that a direct relationship exists between the amount of technical data in the monographs and the potential value of the book to pharmaceutical scientists.*"



Hospital Pharmacy and the CGMP

Doctor Feldmann's editorial in the May issue[1] charges FDA with requiring hospital pharmacists to comply with the revised current Good Manufacturing Practice Regulations (CGMP).

Not so.

The quotation in this editorial comes from paragraph 43 of the preamble to the CGMP's[2] in which FDA responded to the general comments received from the public on the proposed amendments. Retrospectively, it is apparent that paragraph 43 is not as clear as it should be. Nevertheless, we can state unequivocally that FDA is not interested in, and has *never* asserted jurisdiction over, a hospital pharmacy that limits its activities to serving the hospital of which it is a part. We would only consider the hospital pharmacy to be a repacker if the unit dose packages that it prepares are marketed outside the hospital. Even then, if it shares its unit dose services with other hospitals, we have special, separate guidelines covering such services.

FDA's position is best expressed by the Commissioner's endorsement of the unit dose repackaging guidelines prepared by The American Society of Hospital Pharmacists and published in the December 1977 issue of the *American Journal of Hospital Pharmacy*. Dr. Kennedy said:

> *"We applaud the American Society of Hospital Pharmacists for preparing this important guide to a better quality control system for drugs repackaged by hospital pharmacists for use in a unit dose drug distribution system. We recognize it as a major step forward in assuring that patients receive safe and efficacious drugs. In our judgment it is an excellent example of what a professional society can do to improve patient care in hospitals."*

It is FDA's view that the ASHP guidelines are suitable equivalents to our CGMP's for normal hospital pharmacy practice.

J. Joseph Belson, Director
Division of Drug Product Quality

Hospital Pharmacy and the CGMP: A Response

We appreciate this response from Mr. Belson and Mr. Loftus and their effort to clarify the FDA intent of the current GMP regulations.

Our May editorial was originally stimulated by a series of discussions between APhA (and ASHP) staff on the one side and FDA staff on the other side during the 1977–1978 period. The background facts, as we were told them, differ from those described in the Belson–Loftus letter.

Specifically, FDA *did* attempt to assert jurisdiction over hospital pharmacy *via* challenges to certain operating procedures pertaining to unit dose repackaging. These challenges took several forms, one of which was directed at an arrangement whereby a "contract repackager" would bring unit dose repackaging equipment to the hospital and operate it to fulfill the current repackaging needs of the hospital. Under these arrangements, the operation (*a*) took place at the pertinent hospital, (*b*) functioned under the direct supervision of the hospital pharmacist, and (*c*) was limited to producing unit dose packages exclusively for use within that hospital. But, nevertheless, FDA did assert jurisdiction in at least several such instances, thereby causing significant problems and generally hassling the various parties involved.

After considerable skirmishing, an unwritten "truce" eventually emerged, and both sides appeared content to leave the matter rest—although basically unresolved, the issue was not actively pursued further.

But the wording of the September 1978 *Federal Register* preamble—plus pharmacist West's correspondence—made it appear to us that FDA was again preparing to flex its muscle.

Upon receipt of the Belson–Loftus letter, we checked once more to ensure that we had correctly stated our recollection of the situation and its past history. One of the APhA staff members familiar with the situation stated that: "FDA is now trying to do a disappearing act." And an ASHP staff member pointed out that in this letter the operable word is "asserted"; that is, even here, FDA is not conceding any lack of jurisdiction over such pharmacy practice in the hospital setting, but only that it is not presently asserting such jurisdiction.

Nevertheless, both of these staff members also added that this Belson–Loftus letter was far less equivocating than past FDA statements on this issue. Furthermore, had FDA actually followed the policy described in this letter in the past, the entire controversy would never have arisen in the first place!

Amphetamine Analogs

The recent article on "Heterocyclic Analogs of Amphetamine . . ." by W. O. Foye and S. Tovivich[1] listed two pyridine compounds without reference to previous work. β-(6-Methyl-2-pyridyl)-isopropylamine was reported by A. Burger and G. E. Ullyot [*J. Org. Chem.*, **12**, 342 (1947)], and β-(3-pyridyl)isopropylamine was reported by A. Burger and C. R. Walter, Jr. [*J. Am. Chem. Soc.*, **72**, 1988 (1950)].

Even then, if it shares its unit dose services with other hospitals, we have special, separate guidelines covering such services.

FDA's position is best expressed by the Commissioner's endorsement of the unit dose repackaging guidelines prepared by The American Society of Hospital Pharmacists and published in the December 1977 issue of the *American Journal of Hospital Pharmacy*. Dr. Kennedy said:

> *"We applaud the American Society of Hospital Pharmacists for preparing this important guide to a better quality control system for drugs repackaged by hospital pharmacists for use in a unit dose drug distribution system. We recognize it as a major step forward in assuring that patients receive safe and efficacious drugs. In our judgment it is an excellent example of what a professional society can do to improve patient care in hospitals."*

It is FDA's view that the ASHP guidelines are suitable equivalents to our CGMP's for normal hospital pharmacy practice.

Hospital Pharmacy and the CGMP: A Response

We appreciate this response from Mr. Belson and Mr. Loftus and their effort to clarify the FDA intent of the current GMP regulations.

Our May editorial was originally stimulated by a series of discussions between APhA (and ASHP) staff on the one side and FDA staff on the other side during the 1977–1978 period. The background facts, as we were told them, differ from those described in the Belson–Loftus letter.

Specifically, FDA *did* attempt to assert jurisdiction over hospital pharmacy *via* challenges to certain operating procedures pertaining to unit dose repackaging. These challenges took several forms, one of which was directed at an arrangement whereby a "contract repackager" would bring unit dose repackaging equipment to the hospital and operate it to fulfill the current repackaging needs of the hospital. Under these arrangements, the operation (*a*) took place at the pertinent hospital, (*b*) functioned under the direct supervision of the hospital pharmacist, and (*c*) was limited to producing unit dose packages exclusively for use within that hospital. But, nevertheless, FDA did assert jurisdiction in at least several such instances, thereby causing significant problems and generally hassling the various parties involved.

After considerable skirmishing, an unwritten "truce" eventually emerged, and both sides appeared content to leave the matter rest—although basically unresolved, the issue was not actively pursued further.

But the wording of the September 1978 *Federal Register* preamble—plus pharmacist West's correspondence—made it appear to us that FDA was again preparing to flex its muscle.

Upon receipt of the Belson–Loftus letter, we checked once more to ensure that we had correctly stated our recollection of the situation and its past history. One of the APhA staff members familiar with the situation stated that: "FDA is now trying to do a disappearing act." And an ASHP staff member pointed out that in this letter the operable word is "asserted"; that is, even here, FDA is not conceding any lack of jurisdiction over such pharmacy practice in the hospital setting, but only that it is not presently asserting such jurisdiction.

Nevertheless, both of these staff members also added that this Belson–Loftus letter was far less equivocating than past FDA statements on this issue. Furthermore, had FDA actually followed the policy described in this letter in the past, the entire controversy would never have arisen in the first place!

Hospital Pharmacy and the CGMP

Doctor Feldmann's editorial in the May issue[1] charges FDA with requiring hospital pharmacists to comply with the revised current Good Manufacturing Practice Regulations (CGMP).

Not so.

The quotation in this editorial comes from paragraph 43 of the preamble to the CGMP's[2] in which FDA responded to the general comments received from the public on the proposed amendments. Retrospectively, it is apparent that paragraph 43 is not as clear as it should be. Nevertheless, we can state unequivocally that FDA is not interested in, and has *never* asserted jurisdiction over, a hospital pharmacy that limits its activities to serving the hospital of which it is a part. We would only consider the hospital pharmacy to be a repacker if the unit dose packages that it prepares are marketed outside the hospital. Even then, if it shares its unit dose services with other hospitals, we have special, separate guidelines covering such services.

FDA's position is best expressed by the Commissioner's endorsement of the unit dose repackaging guidelines prepared by The American Society of Hospital Pharmacists and published in the December 1977 issue of the *American Journal of Hospital Pharmacy*. Dr. Kennedy said:

In Vivo Methotrexate Transport in Murine Lewis Lung Tumor

K. H. YANG *, W. P. FUNG *, R. J. LUTZ ‡, R. L. DEDRICK ‡, and D. S. ZAHARKO *x

Received November 29, 1978, from the **Laboratory of Chemical Pharmacology, National Cancer Institute, and the* ‡*Biomedical Engineering and Instrumentation Branch, Division of Research Services, National Institutes of Health, Bethesda, MD 20014.* Accepted for publication February 5, 1979.

Abstract □ Methotrexate uptake by murine Lewis lung tumor was measured *in vivo* over a wide dose range. The data were analyzed according to a model previously developed for tissues in which methotrexate uptake is rate limited by transport across the cell membrane. Methotrexate transport in this tumor followed Michaelis–Menten kinetics with a rate constant for permeability (k/K) of 0.012 min^{-1}. The methotrexate binding capacity of dihydrofolate reductase in the tumor was not exceeded at any dose studied. A low membrane permeability in conjunction with a high dihydrofolate reductase level explains the resistance of this tumor to methotrexate.

Keyphrases □ Methotrexate—transport in murine Lewis lung tumor, *in vivo*, dihydrofolate reductase binding, tumor resistance □ Antineoplastic agents—methotrexate, transport in murine Lewis lung tumor, *in vivo*, dihydrofolate reductase binding, tumor resistance □ Lung neoplasms—Lewis, methotrexate transport, dihydrofolate reductase binding, *in vivo*

A previous study (1) found that when mice bearing Lewis lung tumor were infused with methotrexate to maintain a 0.01-μg/ml plasma level, the incorporation of ^{3}H-deoxyuridine into DNA was nearly completely blocked in the small intestine but virtually unaffected in the tumor. This difference was thought to occur because tumor cells contain a higher dihydrofolate reductase level and are less permeable to methotrexate than are intestinal cells. Subsequent measurements of this enzyme showed that its level in tumor cells is about six times higher than that in intestinal cells (2).

The question of membrane permeability remained. It is well known that many solid tumors are resistant to standard chemotherapeutic treatments (3). A relatively low permeability was recently demonstrated *in vivo* for methotrexate in spontaneous canine lymphosarcoma (4). The Lewis lung tumor, a solid metastasizing carcinoma insensitive to many chemotherapeutic agents (5), has been used as a valuable experimental tumor model (6, 7). Therefore, the membrane permeability of this tumor to methotrexate *in vivo* was examined to gain insights into the nature of tumor resistance through model simulations.

THEORETICAL

A general model was described (8) for methotrexate uptake in normal tissues, in which the uptake rate is limited by the membrane permeability. This model is now applied to the Lewis lung tumor tissue (Fig. 1). Implicit in this tumor model are the assumptions that: (*a*) the capillary membrane offers no barrier to passage, (*b*) no methotrexate binding occurs in the extracellular compartment, whereas saturable binding to dihydrofolate reductase occurs in the intracellular compartment, and (*c*) instantaneous, complete mixing takes place in the extracellular compartment. For such a model, the following equations apply:

$$\left(\frac{V_e}{V}\right)\frac{dC_e}{dt} = \left(\frac{Q}{V}\right)(C_p - C_e) - \frac{jA}{V} \qquad \text{(Eq. 1)}$$

$$\left(1 - \frac{V_e}{V}\right)\frac{dq_i}{dt} = \frac{jA}{V} \qquad \text{(Eq. 2)}$$

$$dq_i = C_i + \frac{aC_i}{E + C_i} \qquad \text{(Eq. 3)}$$

where C is the free methotrexate concentration, Q is the blood flow rate, jA is the net transport rate of methotrexate over total area A, q is the total intracellular methotrexate concentration, a is the maximum dihydrofolate reductase binding capacity for methotrexate, E is the dissociation constant of the dihydrofolate reductase–methotrexate complex, and V

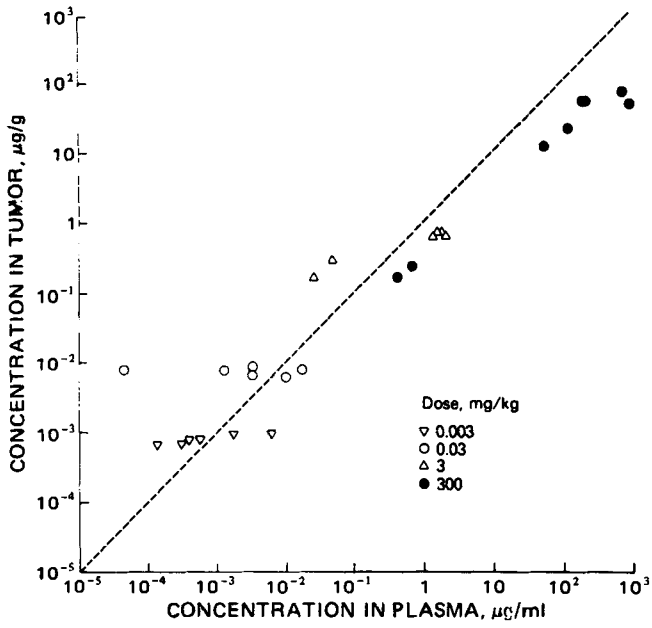

Figure 2—*Methotrexate distribution between plasma and Lewis lung tumor of mice at several doses and various times after dosing.*

is the total tissue volume. The subscripts e, i, and p denote extracellular, intracellular, and plasma, respectively.

Methotrexate transport across most normal and tumor cell membranes is generally assumed to be a carrier-mediated process (9, 10). At high concentrations, passive diffusion may play a role (11). With the assumption that the efflux and influx of the facilitated process are characterized by the same parameters, the net methotrexate transport rate into the cells is given by:

$$\frac{jA}{V} = \frac{kC_e}{K + C_e} - \frac{kC_i}{K + C_i} + b(C_e - C_i) \qquad \text{(Eq. 4)}$$

where k is the maximum transport rate per unit volume, K is the Michaelis constant for the transport, and b is the passive permeability coefficient per unit volume. At doses low enough so that virtually all methotrexate entering the cells becomes tightly bound to dihydrofolate reductase (*i.e.*, $C_i = 0$) and where the passive process is relatively insignificant compared with the facilitated process (*i.e.*, $b = 0$), Eq. 4 reduces to:

$$\frac{jA}{V} = \frac{kC_e}{K + C_e} \qquad \text{(Eq. 5)}$$

For low doses where $C_e \ll K$, Eq. 5 becomes:

$$\frac{jA}{V} = \left(\frac{k}{K}\right) C_e \qquad \text{(Eq. 6)}$$

Since $C_e \simeq C_p$, Eq. 6 predicts a linear increase of jA with C_p. For a time τ sufficiently large such that $C_e V_e \ll q_i V_i$, Eq. 6 leads to:

$$\left(\frac{k}{K}\right) \simeq \frac{C_T(\tau)}{\int_0^\tau C_p(t)\,dt} \qquad \text{(Eq. 7)}$$

where C_T is the average concentration of methotrexate in tumor cells and is given by:

$$C_T = (C_e V_e + q_i V_i)/V \qquad \text{(Eq. 8}a\text{)}$$

$$C_T = q_i + (V_e/V)(C_e - q_i) \qquad \text{(Eq. 8}b\text{)}$$

Equation 7 then gives a first estimate of k/K from $C_T(t)$ and $C_p(t)$, both of which can be determined experimentally. The resolution of the k/K ratio into its components was discussed in detail previously (4, 8). Based on the parameters k, K, Q/V, V_e/V, a, and E, the time course of methotrexate uptake in the tumor cell can be simulated through Eqs. 1–4.

EXPERIMENTAL

Lewis Lung Tumor-Bearing Mice—CDF_1 male mice, 18 ± 2 g, were transplanted subcutaneously with Lewis lung tumor of ~2 mm^3 in size.

Table I—Percentage of Radioactivity Associated with Methotrexate in Plasma and Tumor Samples of CDF_1 Mice Given ^{3}H-Methotrexate Intravenously

Sample	Dose, mg/kg	Percentage[a] of Radioactivity Associated with Methotrexate after 30 min	180 min
Plasma[b]	0.03	82	10
	3	89	29
	300	—	24
Tumor[c]	0.03	—	93
	3	—	76
	300	—	32

[a] Based on the total radioactivity put on the column. [b] In control experiments, where ^{3}H-methotrexate was added to the pooled blood from the tumor-bearing mice and identical preparative procedures were followed, nearly 100% of the radioactivity was associated with methotrexate. [c] In control experiments, where ^{3}H-methotrexate was mixed with the homogenizing medium and added to the pooled tumors, the radioactivity associated with methotrexate was 96%.

Three weeks later, these tumor-bearing mice were used in the study. At this time, the primary tumors weighed 0.5–1.0 g.

Drug Solution Purification and Preparation—3′,5′,9′(*n*)-Methotrexate[1] was purified by diethylaminoethylcellulose chromatography (12) each time before use. The sodium salt of ^{3}H-methotrexate, 250 μCi, was taken up with 0.75 ml of 0.1 *M* ammonium bicarbonate buffer and applied onto a 0.7 × 9-cm column. The column was then eluted at 18 ml/hr with a linear gradient of the buffer at pH 8.3 from 0.1 to 0.4 *M*. The fractions containing methotrexate were pooled and lyophilized.

The lyophilized ^{3}H-methotrexate was reconstructed into a solution of the desired concentration with unlabeled methotrexate dissolved in an aqueous solution of 0.25% $NaHCO_3$ and 0.9% NaCl. The unlabeled methotrexate, of which the purity was checked by the column chromatography, was relatively free of impurities and was used without further purification. The specific activity of the solution, determined from measurements of its optical density at 302 nm and its disintegrations per milliliter, ranged from 1.6 to 17 μCi/μg.

Uptake Study—The tumor-bearing mice were injected with the drug solution *via* the tail vein at doses of 0.003, 0.03, 3, and 300 mg/kg. Then the animals were killed by decapitation at specified times. Blood samples were collected in heparinized tubes and centrifuged to separate the plasma. The tumors were removed surgically.

Aliquots of the plasma and of the nonnecrotic portion of the tumor were digested in a tissue solubilizer[2] and counted[3] for tritium in a counting cocktail consisting of 0.01% 1,4-bis[2-(5-phenyloxazolyl)]benzene[4] and 0.3% 2,5-diphenyloxazole[4] in methanol–toluene (6:14). The counting error was <5%. Appropriate corrections for quenching were made using the automatic external standard ratio method.

Two control mice, which received no drug, were processed for each dose.

Plasma and Tumor Sample Radiopurity—The radiopurity of the plasma and tumor samples was determined at several doses and time points by column chromatography. Six tumor-bearing mice were used for each time point. The drug solution was administered as in the uptake studies. Pooled plasma samples were heated in a boiling water bath for 10 min and centrifuged. An aliquot of the supernate thus obtained was applied onto the same column system described in the purification procedure and eluted similarly, starting, however, with a 0.05 *M* buffer. Each 0.75-ml fraction was collected, mixed with 15 ml of a scintillation cocktail[5], and counted for tritium content with appropriate corrections for quench. Pooled tumors weighing 1.5 g were homogenized with 2 ml of an ice-cold aqueous solution of 0.25% $NaHCO_3$ and 0.9% NaCl. The homogenate was treated similarly to the pooled plasma samples.

All procedures were carried out under minimal incandescent light to prevent the photodecomposition of these pteridine derivatives. The total radioactivity obtained from fractions that coincided with the absorbance of the coeluted methotrexate, which was added to the sample before fractionation as a marker, divided by the total radioactivity put on the column gave the fraction of remaining methotrexate in the samples. The radioactivity from these boiled plasma or tumor tissue extracts accounted

for greater than 90% of the radioactivity as determined by digested and counted aliquots of similar tissues. Control experiments, in which the purified ^{3}H-methotrexate solution was added either to the blood pooled from the tumor-bearing mice receiving no drug or to the homogenizing medium for tumors from control mice, were also performed.

RESULTS AND DISCUSSION

Plasma and Tumor Sample Radioactivity—Methotrexate is significantly metabolized in rodents by the host intestinal bacteria (13–15). Thus, the measured radioactivity is the sum of the radioactivity associated with both methotrexate and its metabolites. The radioactivity fraction associated with methotrexate in the samples, however, will vary with the dose given, the administration route, and the time after injection, as was observed in this study.

As can be seen in Table I, at times shorter than 30 min, methotrexate remained largely intact regardless of the dose. By 3 hr, only 10–20% of the radioactivity measured in the plasma (depending on the dose) was associated with methotrexate; the remainder was associated with metabolites and, in a few cases (plasma sample at 3 hr and 300 mg/kg; tumor sample at 3 hr and 300 mg/kg), with ^3H_2O. However, nearly all tritium measured in the tumor at 0.03 mg/kg at 3 hr was in methotrexate. The same result is to be expected for the 0.003-mg/kg dose. The lower percentage found in the tumor sample at 3 mg/kg can be attributed to the relatively significant amount of metabolite in the extracellular compartment, which is insignificant at lower doses. At 300 mg/kg, most of the radioactivity in both samples came from ^3H_2O, which largely accounted for the low percentages associated with methotrexate. These findings were used to make corrections in the uptake studies.

Membrane Transport as Rate-Limiting Step—After corrections were made in accordance with Table I, the methotrexate concentrations in tumors at different time points for all doses were plotted against the corresponding concentrations in plasma (Fig. 2). The tumor methotrexate concentration was not a unique function of its concentration in the plasma, which would be expected if the uptake were flow limited. The dependence of the tumor methotrexate concentration on the dose given as well as on the plasma concentration strongly suggests that membrane resistance can be a rate-limiting factor for methotrexate uptake in this tumor. Similar observations were made with such tissues as the small intestine, spleen, and bone marrow of the rat (8) and lymphosarcoma of the dog (4).

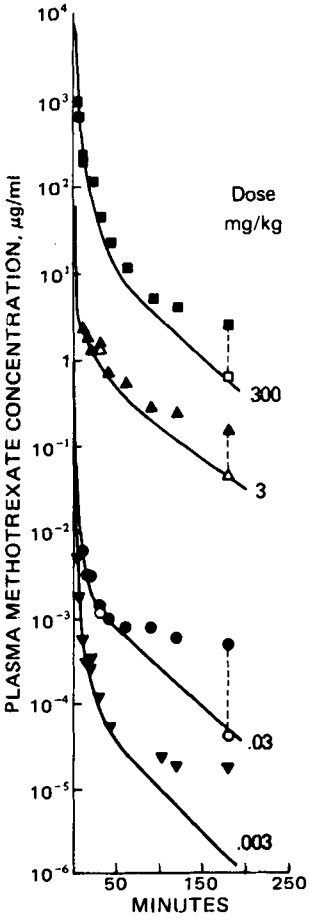

Figure 3—*Plasma methotrexate concentrations* versus *time following several intravenous doses. Dark symbols are experimental data. Open symbols are corrected data. Solid lines represent triexponential curve fitted as described in the text. Each point is from one mouse.*

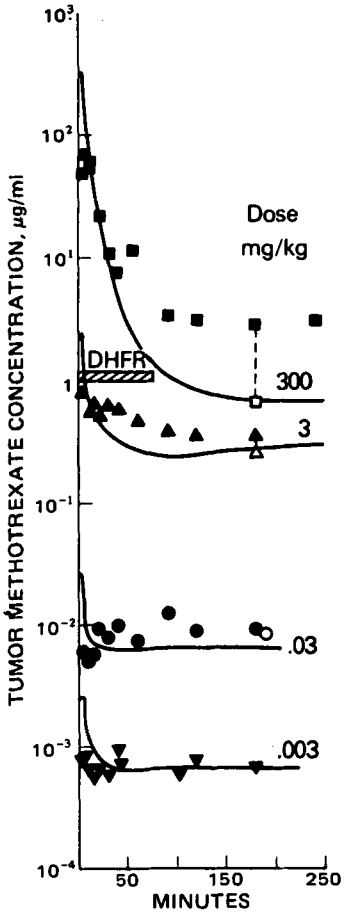

Figure 4—*Average tumor methotrexate concentrations* versus *time following several intravenous doses. Dark symbols are experimental data. Open symbols are corrected data. Solid lines represent model simulations. Shaded bar represents dihydrofolate reductase level. Each point is from one mouse.*

Plasma Data—The plasma methotrexate concentrations obtained for each dose up to 3 hr are shown in Fig. 3. Corrections for tritium not associated with methotrexate were made in accordance with Table I. For the lowest dose, a correction was made at 3 hr in proportion to that made for 0.03 mg/kg. Based on these points and with the assumption of 100% radiopurity at time zero, a linear interpolation provided the points between 30 min and 3 hr. The resulting corrected plasma data sets for each dose were then curve fitted (16) with the following triexponential equation:

$$C_p(t) = a_1 \exp(-b_1 t) + a_2 \exp(-b_2 t) + a_3 \exp(-b_3 t) \quad \text{(Eq. 9)}$$

where $C_p(0)$ for each dose was obtained from the whole animal model developed earlier (17). These equations thus served to evaluate the denominator in Eq. 7 and as input functions for tumor model simulations.

Tumor Data—The measured tumor methotrexate concentrations as a function of time are plotted for each dose in Fig. 4. Also shown are the corrections made in accordance with Table I. The tumor methotrexate concentrations were indeed proportional to the doses at the two lowest doses, indicating the validity of Eq. 6. As the dose increased, the tumor concentration did not increase proportionally, and the transport mechanism apparently became saturated.

The data obtained at either of the two lowest doses were then used, together with the corresponding plasma data, in Eq. 7 to estimate k/K. Equations 1, 2, 6, and 8 can be solved simultaneously on a digital computer for C_T as a function of time for the two lowest doses, using the estimated value of k/K once V_e/V and Q/V are determined. The value of V_e/V was conveniently evaluated from Fig. 2, where $V_e/V \simeq C_T/C_p$ at short times following the highest dose when most of the drug is confined in the extracellular space due to transport saturation. To evaluate Q/V, it is noted that the change in C_T during the first few minutes following the highest dose can be approximated by:

$$\frac{dC_T}{dt} \simeq \left(\frac{Q}{V}\right)(C_p - C_T) \quad \text{(Eq. 10)}$$

Table II—Model Parameters for Murine Lewis Lung Tumor

Parameter	Value
Q/V, flow rate for unit volume, min^{-1}	0.1
V_e/V, fractional extracellular volume	0.2
a, maximum binding capacity, μg/ml	1.0[a]
E, dissociation constant, μg/ml	0.00001[b]
k, maximum transport rate for unit volume, μg/ml/min	0.0036
K, Michaelis constant for transport, μg/ml	0.3

[a] Reference 2. [b] Reference 8.

An approximate value of Q/V was thus found from the best fit of Eq. 10 to the experimental data under such conditions. Since the uptake is not flow limited, a precise knowledge of Q is not required. These parameters, along with other model parameters, are given in Table II. The predicted C_T values were made to best fit the experimental data at the two lowest doses by slightly adjusting the initial k/K estimate. The final k/K value was compared to that of the small intestine in Table III.

The nonresponsiveness of the Lewis lung tumor to methotrexate clearly results from a combination of at least two factors: higher dihydrofolate reductase and lower membrane permeability. With drug doses that are not lethal to the mouse, there is probably always free dihydrofolate reductase present in the tumor to produce sufficient coenzymes for the utilization of nucleotides in DNA and RNA synthesis. The molecular mechanism of decreased tumor permeability as compared to normal tissues certainly cannot be elucidated from this study alone. As an indication, however, it is seen in Table III that since the K's are the same for different tissues, the difference in the permeability thus reflects the difference in k's as shown. Acceptance of the hypothesis of a carrier-mediated transport (18) suggests that the carrier quantity and/or accessibility is less in the tumor cell membrane than in the normal cell membrane.

Model Simulation—The simulations of the average methotrexate concentrations in tumors for all doses are shown in Fig. 4. The model simulates the experimental data over a wide concentration range, spanning six logarithms. The tight binding (19) of methotrexate to dihydrofolate reductase was recently shown to be ionic in nature (20), and the overwhelmingly high dihydrofolate reductase content of this tumor ensures a sink condition within the tumor cell and a one-way

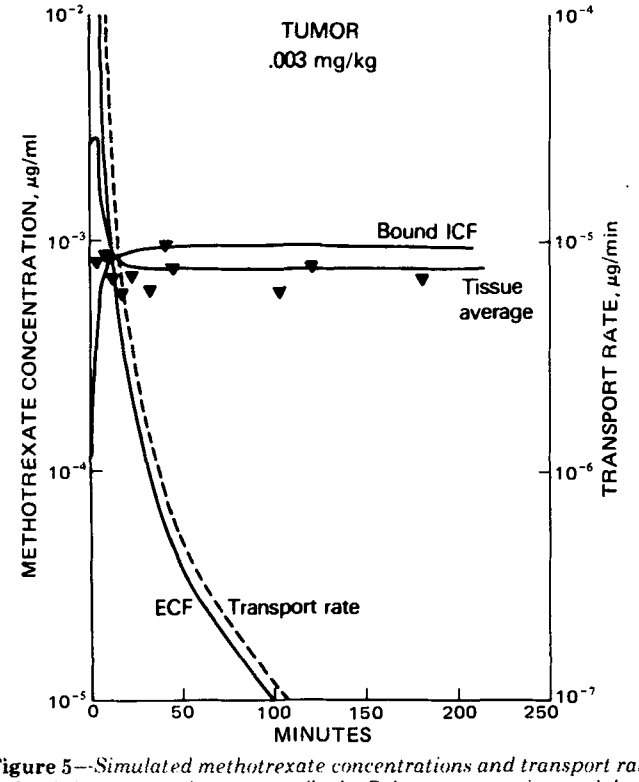

Figure 5—*Simulated methotrexate concentrations and transport rate in Lewis lung tumor for 0.003 mg/kg iv. Points are experimental data. ECF = extracellular fluid. ICF = intracellular fluid. The level of dihydrofolate reductase is at 1 μg of methotrexate equivalents/ml.*

Table III—Transport Parameters and Enzyme (Dihydrofolate Reductase) Activity for Murine Lewis Lung Tumor as Compared to the Small Intestine

Tissue	Permeability (k/K), min^{-1}	k, μg/ml/min	K, μg/ml	Enzyme Activity[a], nmoles of dihydrofolate/hr/mg of protein
Lewis lung tumor	0.012	0.0036	0.3	97
Small intestine	0.024[b]	0.0072[b]	0.3[b]	16

[a] Reference 2. [b] Bile-diverted mice (R. J. Lutz, D. S. Zaharko, K. H. Yang, and R. L. Dedrick, to be published).

transport involving influx only. This condition greatly simplifies the experimental system and may account for the apparent success of the simple model used here. Therefore, the conformity of the model predictions with the data should not be construed as indicating that the influx and efflux parameters of the transport system in the present case are indeed identical. The contrary, in fact, was suggested in some other tumor lines (21–23).

The events that take place are illustrated in Figs. 5 and 6 for 0.003 and 300 mg/kg, respectively. Figure 5 shows that methotrexate enters the cell quickly and binds to dihydrofolate reductase. With the extracellular concentration rapidly decreasing, very little methotrexate enters after 15 min; from then on, the measured tissue averages closely represent the bound intracellular concentrations. The transport rate is directly proportional to the extracellular concentration.

In Fig. 6, for the highest dose, the extracellular concentration dominates the measured concentration for the first 30 min. Only after ~3 hr does the intracellular concentration become significant. More impor-

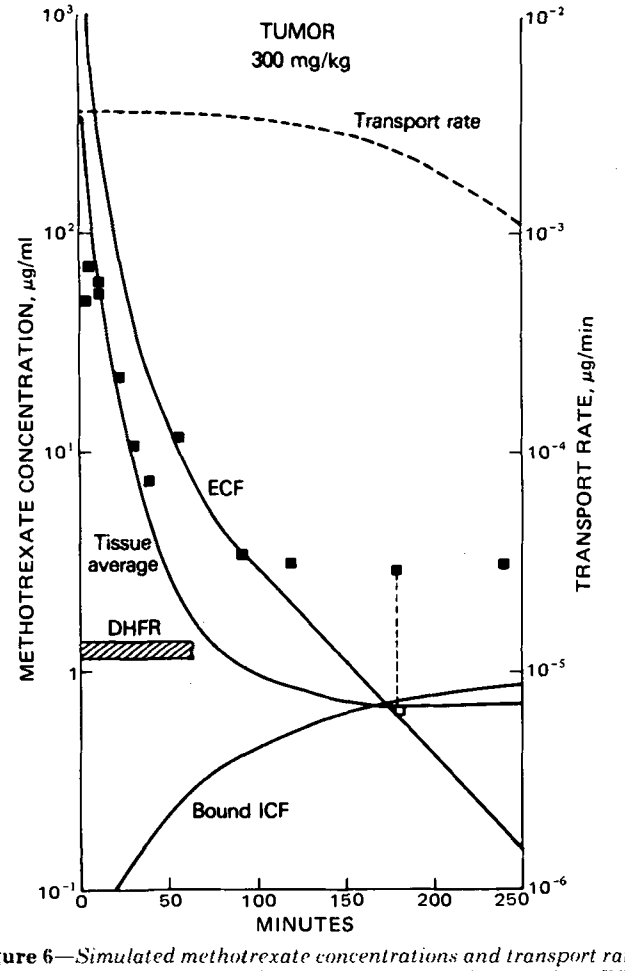

Figure 6—*Simulated methotrexate concentrations and transport rate in Lewis lung tumor for 300 mg/kg iv. Points are experimental data. ECF = extracellular fluid. ICF = intracellular fluid. The level of dihydrofolate reductase (DHFR) is at 1 μg of methotrexate equivalents/ml.*

tantly, there is insufficient methotrexate entering the cell to saturate all the dihydrofolate reductase present and, therefore, little free methotrexate exists inside the cell at any time. It has been demonstrated (24, 25), however, that the persistence of the free intracellular methotrexate accounts for its cytotoxic action. Thus, through model simulations, the measured concentrations in tumors are shown to consist almost entirely of extracellular and bound intracellular concentrations in various proportions, depending on the time and the dose. Since the transport rate has already reached its maximal value at this high dose (Fig. 6), a further increase in the dose would only shift the extracellular curve and, correspondingly, the tissue average curve upwards without a large concomitant increase in the intracellular concentration during the first 2–3 hr. The transport rate would be near the maximum level, only dropping at a later time.

These predictions will be altered, however, if a passive process plays an increasingly significant role as the dose is increased further. This role is still largely unknown at the present time. Nevertheless, what happens at even higher doses is probably of theoretical interest only. In practice, there is a limit to which the dose can be further increased; the LD_{50} of the drug in mice is 350 mg/kg (26).

Effect of Enzyme-Inducing and Enzyme-Inhibiting Agents on Drug Absorption II: Influence of Proadifen on 3-*O*-Methylglucose Transport in Rats

WILLIAM R. RAVIS * and STUART FELDMAN ‡×

Received September 5, 1978, from the **School of Pharmacy, Auburn University, Auburn, AL 36830*, and the ‡*Department of Pharmaceutics, College of Pharmacy, University of Houston, Houston, TX 77004.* Accepted for publication January 22, 1979.

Abstract □ Studies utilizing the *in vitro* everted rat jejunum were performed to investigate the effects of proadifen pretreatment and fasting on active and passive intestinal transfer of 3-*O*-methylglucose. Animals were pretreated 24 hr prior to the experiments with 100 mg of proadifen/kg ip. With mucosal concentrations of 0.1 m*M* 3-*O*-methylglucose and ^{14}C-3-*O*-methylglucose, transfer to the sugar-free serosal buffer after pretreatment with proadifen was 50% greater than controls after a 24-hr fast and 120% greater than controls after a 48-hr fast. Everted intestinal segments obtained from unfasted control animals showed diminished ability to transfer the sugar derivative, with transfer rates approximately 50% less than those of segments obtained from 24-hr fasted control animals. Wet and dry tissue weights for 24- and 48 hr-fasted groups increased following proadifen pretreatment. The results suggest that proadifen enhances 3-*O*-methylglucose transport across the rat jejunum and also increases intestinal tissue weight.

Keyphrases □ Enzyme induction—effect of proadifen on intestinal methylglucose transport, rats, fasting □ Enzyme inhibition—effect of proadifen on intestinal methylglucose transport, rats, fasting □ Methylglucose—effect of proadifen on intestinal transport, rats, fasting □ Proadifen—effect on intestinal methylglucose transport, rats, fasting

Several monosaccharides, amino acids, vitamins, and clinically employed drugs are absorbed from the intestinal lumen by carrier-mediated processes. A 3-*O*-methyl derivative of *d*-glucose has been shown to be absorbed across the mucosal epithelia by an active transport mechanism (1, 2). Since this derivative is not utilized by animal tissue (1), as is *d*-glucose, it is a useful agent for specific examination of active sugar transport by intestinal tissue.

Chemical agents capable of altering cell metabolism influence active absorption processes in the intestine (3–8).

tantly, there is insufficient methotrexate entering the cell to saturate all the dihydrofolate reductase present and, therefore, little free methotrexate exists inside the cell at any time. It has been demonstrated (24, 25), however, that the persistence of the free intracellular methotrexate accounts for its cytotoxic action. Thus, through model simulations, the measured concentrations in tumors are shown to consist almost entirely of extracellular and bound intracellular concentrations in various proportions, depending on the time and the dose. Since the transport rate has already reached its maximal value at this high dose (Fig. 6), a further increase in the dose would only shift the extracellular curve and, correspondingly, the tissue average curve upwards without a large concomitant increase in the intracellular concentration during the first 2–3 hr. The transport rate would be near the maximum level, only dropping at a later time.

These predictions will be altered, however, if a passive process plays an increasingly significant role as the dose is increased further. This role is still largely unknown at the present time. Nevertheless, what happens at even higher doses is probably of theoretical interest only. In practice, there is a limit to which the dose can be further increased; the LD_{50} of the drug in mice is 350 mg/kg (26).

Dicumarol in mucosal solutions inhibited galactose active uptake by the rat small intestine (3). Cardiac glycosides such as strophantidin (4) and ouabain (5) reduced active sugar absorption, possibly due to influence on Na^+-K^+ ATPase, an apparently important component of the translocation mechanism. On the other hand, pretreatment of rats with parathion, a widely used insecticide, elevated intestinal glucose transport, as shown by increases in serosal–mucosal gradients (6). Subcutaneous phenobarbital in rats increased active bile salt ileal absorption (7) and enhanced the ability of duodenal tissue to take up ^{59}Fe-iron sulfate (8).

Previous studies demonstrated that 24-hr pretreatment of rats with 100 mg of proadifen/kg ip increased intestinal transport capabilities for 3-*O*-methylglucose (2). Phenobarbital and 3,4-benzo[*a*]pyrene treatment schedules had no significant influence on 3-*O*-methylglucose transport. In addition, proadifen possessed spasmolytic activity on the small intestine since 24-hr fasting periods prior to the experiments were insufficient to render the lumen free of food and fecal materials.

The present investigation was undertaken to distinguish the nonfasting effects on active 3-*O*-methylglucose absorption from the proadifen pretreatment effects.

EXPERIMENTAL

Animals and Treatment—Male Sprague-Dawley rats[1], 176–255 g, were maintained on regular rat chow and water *ad libitum*. Prior to preparation of *in vitro* everted sacs, the rats were fasted for 24 or 48 hr, depending on the experiment. Water was allowed *ad libitum*.

Proadifen hydrochloride[2]-pretreated animals received 100 mg of drug/kg ip either 24 or 48 hr prior to the experiment. The necessary proadifen hydrochloride dose was administered in <0.5 ml of water, with control animals receiving 0.4 ml of water.

Preparation of Everted Jejunal Sacs—While anesthesia was maintained with ether, a midline incision was made; the small intestine was removed carefully and then rinsed several times with cool saline. The first 15 cm distal to the pylorus was discarded, and the remaining intestine was everted over a glass rod.

Ten-centimeter segments of everted intestine were prepared as everted ligated sacs as described previously (9) or were cannulated (10). Both the serosal and mucosal bathing buffers consisted of pH 7.4 Krebs–Henseleit buffer with the pH determined before and after incubation in the tissue preparation. The serosal buffers were bubbled with 95% oxygen–5% carbon dioxide before installation into the sacs; the mucosal buffers were bubbled prior to and during the experiment. Temperature over the incubation period was maintained at 37 ± 0.2° by a circulating water bath[3].

Uptake and Transfer of ^{14}C-3-*O*-Methylglucose from 0.1 m*M* Mucosal Solutions—Everted ligated sacs from 24- and 48-hr fasted and unfasted animals were filled with 1.0 ml of buffer free of 3-*O*-methylglucose and incubated in 0.1 m*M* methylglucose in 10 ml of mucosal buffer. Sugar transfer and uptake were examined for sacs from both control and proadifen-pretreated animals under various fasting conditions, with one-half of all sacs incubated in 0.08 m*M* phlorizin[4] as well. All mucosal solutions contained initially 0.3 μCi of ^{14}C-3-*O*-methylglucose[5] with appropriate addition of unlabeled 3-*O*-methylglucose[6]. In separate studies, 10^{-3} *M* proadifen hydrochloride was incorporated into mucosal and serosal buffers of segments from control animals.

After 30 min of incubation, the sacs were emptied and the volumes were recorded with sequential dilution of 2 ml with water. One-tenth-milliliter serosal and mucosal samples were saved for liquid scintillation counting. Following rinsing and weighing of the sac tissue, the tissue was homogenized[7] with 2 ml of methanol and centrifuged. A portion of the methanol supernate was counted. Approximately 90% of the total initial label could be accounted for by the buffer and tissue samples.

Table I—Effects of Fasting and Proadifen Pretreatment on ^{14}C-3-*O*-Methylglucose[a] Transfer and Tissue Uptake across the Everted Rat Small Intestine

Condition	*n*	Amount Transferred to Serosal Fluid in 30 min[b], m*M* × 10^{-6}	30-min Tissue Uptake[b], m*M* × 10^{-6}
1-Day fast			
Untreated	19	21.82 ± 4.56	26.60 ± 3.74
Proadifen	8	33.09 ± 7.84[c]	33.64 ± 7.11[c]
2-Day fast			
Untreated	4	17.73 ± 2.64	26.68 ± 4.71
Proadifen	4	39.04 ± 8.40[c]	32.82 ± 3.29[c]
Unfasted			
Untreated	6	9.95 ± 1.25[d]	20.45 ± 0.99[d]

[a] Initial mucosal concentration = 0.1 m*M*. [b] Mean ± *SD*. [c] $p < 0.05$ compared to untreated of same fast period. [d] $p < 0.05$ compared to 1-day untreated.

Serosal to Mucosal Concentration Gradients—Cannulated sacs from 24-hr fasted treated and control animals as well as untreated unfasted animals were incubated with 1.0 m*M* 3-*O*-methylglucose in both mucosal and serosal buffers. The mucosal volume was 60 ml; the serosal volume was 2 ml. After 30 min, the concentration and amount of ^{14}C-3-*O*-methylglucose in the mucosal solution, the serosal solution, and the intestinal tissue were determined. Before the segments were homogenized with methanol, they were rinsed with 1 ml of water and their wet weights were recorded.

Transfer Rates of ^{14}C-3-*O*-Methylglucose as a Function of Incubation Time—Ten-centimeter everted segments from 24-hr fasted control and proadifen-pretreated animals were suspended in 60 ml of 10 m*M* 3-*O*-methylglucose buffer. Of the two segments utilized from each animal, one was randomly chosen for incubation with either 0.08 or 0.8 m*M* phlorizin. Two milliliters of sugar-free buffer was placed into the serosal compartment. Every 10 min over the 2-hr experiment, the 2 ml of buffer was withdrawn followed by a 2-ml serosal rinse and instillation of another 2 ml for the subsequent time interval. The rinse was combined with the initial sample for that 10-min period, and its radioactivity was determined.

Determination of Tissue Weights and Extracellular Space—In separate experiments, wet and dry intestinal tissue weights were recorded for 24- and 48-hr fasted control and pretreated animals. Wet weights were measured after segments were thoroughly rinsed and drained. The wet tissue was placed on tared slides, dried for 2 hr at 120°, and reweighed.

Extracellular space values were obtained for whole sac preparations. Five-centimeter ligated everted segments were incubated with serosal and mucosal buffers containing 0.625 μCi/ml of ^{14}C-carboxyinulin[5] (0.05 mCi/19.6 mg). The mucosal volume was 10 ml; the serosal volume was 0.5 ml. All buffers were gassed with the oxygen carbon dioxide mixture, and the preparations were incubated at 37° for 60 min.

Upon completion of the incubation, the sacs were rinsed, drained, and halved for weighing in tared vials. The tissue contents of the vials were then digested with 1.5 ml of alkaline digestant[8] at 45° until digestion was complete. Before neutralization with acetic acid, the vials were allowed to cool. Five milliliters of liquid scintillation cocktail[9] was added to each vial, and the radioactivity was determined. Values of extracellular space were calculated from the following relationship (11):

$$\text{extracellular space (ml/g)} = \frac{\text{cpm/g of tissue}}{\text{cpm/ml of mucosal inulin solution}} \quad \text{(Eq. 1)}$$

Assay—Samples of serosal buffers, mucosal buffers, and tissue extracts were placed in vials containing 7 ml of scintillant, and their radioactivity was determined with a liquid scintillation spectrometer[10]. Counts per minute were corrected for quenching by standardized quench curves.

RESULTS

These studies were designed to examine the effect of proadifen pretreatment and length of fast on active and passive 3-*O*-methylglucose

[a] Initial mucosal concentration = 0.1 mM. [b] Concentration of phlorizin in mucosal and serosal buffer = 0.08 mM. [c] Mean ± SD. [d] $p < 0.05$ compared to untreated of same fast period. [e] $p < 0.05$ compared to 1-day fasted untreated.

transfer across everted rat intestinal segments. Following 24 hr pretreatment with proadifen, the lumens of the 24-hr fasted group were distended with fecal matter; 48-hr fasting provided lumens free of matter. Variation of fasting periods allowed an assessment of fasting and proadifen effects on the mucosal to serosal sugar transfer. By including phlorizin, a glucose transport inhibitor (12), in the incubation medium, passive 3-*O*-methylglucose transfer could be examined separately. Further studies were conducted to determine alterations in wet and dry intestinal tissue weight and whole tissue extracellular space as a result of fasting and proadifen pretreatment.

Study A: Uptake and Transfer of ^{14}C-3-*O*-Methylglucose from 0.1 m*M* Mucosal Solutions—To examine the effects of fasting and proadifin pretreatment on mucosal to serosal transfer and tissue uptake of the actively transported sugar, animals were divided into five groups: unfasted animals, 24- and 48-hr fasted control animals, and 24- and 48-hr fasted animals that were pretreated with proadifen 24 hr prior to segment preparation. Table I gives values for the amount of 3-*O*-methylglucose transferred to the initially sugar-free serosal buffer in 30 min. Everted segments from 24- and 48-hr fasted proadifen-pretreated animals transferred significantly greater amounts of the labeled sugar than the corresponding fasted controls, with increases approximating 52 and 120%, respectively. Segments obtained from unfasted animals transferred 54% less labeled 3-*O*-methylglucose in 30 min than the 24-hr fasted controls.

Tissue sugar levels were elevated in the proadifen-treated group while the sugar levels in the sacs from unfasted animals were significantly ($p < 0.05$) lower than the fasted controls. Due to measured increases in wet tissue weight for the pretreated group, no differences were noted between treated and control fasted groups when comparisons were made based on counts per gram of tissue. Counts per gram of tissue determined from sacs from unfasted animals were significantly ($p < 0.05$) less than the other experimental groups.

Of the two 10-cm intestinal segments utilized from each animal, one was chosen in an alternating pattern for incubation in a similar 3-*O*-methylglucose buffer containing 0.08 mM phlorizin. In experiments where the phlorizin concentration was varied, this inhibitor level provided maximum 3-*O*-methylglucose transport inhibition. Phlorizin dramatically reduced sugar mucosal to serosal transfer and tissue uptake in all experimental conditions, and this transfer was assumed to represent the

[a] Initial mucosal and serosal concentration = 1.0 mM. [b] Mean ± SD. [c] $p < 0.05$ compared to 1-day fasted control. [d] Obtained by subtracting initial amount from final amount.

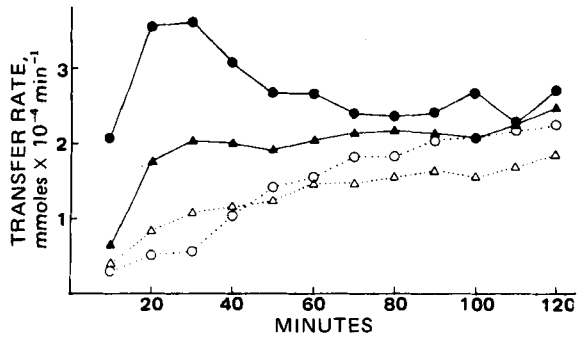

Figure 1—*Mean 10-min transfer rates of ^{14}C-3-O-methylglucose across the everted rat intestine of control and proadifen-pretreated animals* versus *incubation time in a 10 m*M *mucosal buffer. Key:* ●, *proadifen pretreated alone;* ▲, *control alone;* ○, *proadifen pretreated in the presence of phlorizin (0.08 m*M*); and* △, *control in the presence of phlorizin (0.08 m*M*).*

passive component of the sugar transfer. As can be seen in Table II, significantly less 3-*O*-methylglucose was transferred to the serosal compartment for unfasted and 24-hr fasted treated animals.

Study B: Serosal to Mucosal Concentration Gradients across Intestinal Segments from 1-Day Fasted Control, 1-Day Fasted Proadifen-Treated, and Unfasted Control Animals—The ability of everted segments from unfasted control, 24-hr fasted control, and 24-hr fasted proadifen-treated animals to generate concentration gradients for the sugar between mucosal and serosal buffers was examined. 3-*O*-Methylglucose, 1 mM, was incorporated into both the 60-ml mucosal buffers and the 2-ml serosal buffers followed by a 30-min incubation. Final concentration ratios, net serosal gains in 3-*O*-methylglucose, and wet tissue weights are presented in Table III. Segments from pretreated animals exhibited greater final gradients than those of the control and unfasted groups. Intestinal tissue from treated and unfasted animals was greater in wet tissue weight per length than that of 24-hr fasted controls.

Study C: ^{14}C-3-*O*-Methylglucose Transfer as a Function of Incubation Time—Cannulated everted intestinal sacs, prepared from 24-hr fasted control and pretreated animals, were utilized to examine active and passive transfer of 3-*O*-methylglucose across isolated segments over extended incubation periods. The sugar transfer rates at 10-min intervals as a function of incubation time appear in Fig. 1. With phlorizin excluded from the bathing solutions, marked increases in 3-*O*-methylglucose transfer to the serosal buffers were noted at 10, 20, and 30 min for segments obtained from pretreated animals, with percentage increases over controls of 120, 100, and 75% for the three time periods, respectively.

After 30 min, the average rate for the proadifen group progressively fell; rate values from 70 to 120 min were similar to those of the control sacs and phlorizin-incubated sacs of treated and untreated animals for the same time period. The fall in transfer rates and the similarity to passive rates may represent transport system deterioration in isolated segments with long incubation times.

For phlorizin-incubated sacs, the amount of labeled sugar appearing in the serosal buffers up to 30 min was reduced in the proadifen group compared to controls. Passive transfer rates in both control and treated groups progressively increased with incubation, possibly suggesting mucosal membrane barrier deterioration with extended incubation periods (13).

Study D: Uptake and Transfer of ^{14}C-3-*O*-Methylglucose by Intestinal Tissue following 40-hr Proadifen Pretreatment—Preliminary studies examining concentration gradients across ligated sacs from 24-hr fasted animals representing control, 12-hr proadifen pretreatment, and 24-hr proadifen pretreatment groups demonstrated only moderate increases in final concentration gradients following 12-hr pretreatment. To determine whether the effects noted after 24 hr were temporary or became more evident when longer intervals separated the time of injection and transfer measurements, a 40-hr interval between dosing and sacrifice was chosen.

The animals were fasted 24 hr prior to the experiment. Thirty-minute transfer and uptake were determined for ligated sacs in 0.1 mM 3-*O*-methylglucose buffers. No differences were observed between control and 40-hr treated animals, with serosal transfer values of 2.26 ± 0.50 × 10^{-5} and 2.75 ± 0.24 × 10^{-5} mM/10 cm/30 min, respectively. Likewise, tissue levels of the labeled sugar suggested no enhanced sugar uptake by

Table IV—Effects of *In Vitro* Proadifen on 10-min Serosal Transfer and Tissue Uptake of ^{14}C-3-*O*-Methylglucose [a] across the Everted Rat Small Intestine (n = 4)

Treatment	Amount Transferred to Serosal Fluid in 10 min [b], $mM \times 10^{-6}$		10-min Tissue Uptake [b], $mM \times 10^{-6}$	
	Phlorizin [c]	Control	Phlorizin [c]	Control
Untreated	1.454 ± 0.255	4.534 ± 0.220	6.302 ± 0.860	17.910 ± 6.259
Proadifen incubated	1.594 ± 0.333	5.133 ± 0.576	7.082 ± 0.933	17.838 ± 4.449

[a] Initial mucosal concentration = 0.1 m*M*. [b] Mean ± *SD*. [c] Phlorizin concentration in serosal and mucosal buffer = 0.08 m*M*.

the treated group, with a value of $2.68 \pm 0.24 \times 10^{-5}$ m*M*/10 cm/30 min for the 40-hr pretreated group.

Study E: Uptake and Transfer of ^{14}C-3-*O*-Methylglucose for Ligated Segments Incubated in 10^{-3} *M* Proadifen—Possible direct alterations of sugar transport by proadifen were investigated by dissolving 10^{-3} *M* proadifen in the incubation buffers. This concentration was based on reported alterations in the permeability of human erythrocytes (14) and rat hepatocytes (15) in the presence of 10^{-9}–10^{-4} *M* proadifen. *In vitro* drug incubation did not influence mucosal to serosal passive transfer of the sugar in the sac preparations (Table IV). Wet tissue weights were also similar.

Study F: Determination of Wet and Dry Intestinal Tissue Weights—To determine whether the larger values for wet tissue weight were the result of fluid accumulation or tissue proliferation, wet and dry intestinal tissue weights of 24-hr fasted control and treated animals as well as 48-hr fasted groups were recorded. While the lumens of 24-hr fasted proadifen-treated animals were filled with fecal matter, the lumens of the remaining three groups were clear. In both treated groups, the wet and dry tissue weight increased significantly over controls (Table V). Wet tissue weight determinations were greater by 23 and 32% and dry tissue weight determinations were greater by 30 and 27% for 24- and 48-hr fasts, respectively.

Study G: Determination of Whole Tissue Extracellular Space—Measurements of the intestinal tissue extracellular space of 24- and 48-hr fasted, control and treated groups were conducted with ^{14}C-carboxyinulin. No significant differences in whole tissue extracellular space were demonstrated (Table V).

DISCUSSION

As noted in Studies A and C, intestinal segments from unfasted and 24-hr fasted proadifen-treated animals displayed reduced mucosal to serosal passive transfer compared to fasted controls. These two groups coincided with those found to have fecal material in their lumens at the time of sac preparation. Literature reports suggest that differences exist between fasted and unfasted animals with respect to intestinal absorption (16, 17). Alterations in extracellular space as a result of fasting or drug treatment could influence the passive absorption of water-soluble drugs that transverse the mucosal epithelia by aqueous channels. Similar increases in passive transfer rates with incubation time, as seen with 3-*O*-methylglucose in Study C, were reported for water-soluble drugs that are believed to pass the mucosal epithelia by aqueous pathways (13). However, in the present study, no differences were observed in the estracellular space volume per gram of tissue. On the other hand, such measured values are based on whole tissue space and may not be useful in evaluating aqueous channel volume in the absorption-limiting mucosal epithelia (11).

In the present study, segments from unfasted animals displayed diminished serosal transfer when the active transport pathway was not inhibited. If active and passive transfer and uptake are additive, the lower transfer in the absence of phlorizin for unfasted segments cannot be accounted for solely by lower passive transfer rates but must represent the reduced ability of unfasted tissue to transport sugar actively. In contrast, Newey *et al.* (18) found that fasting for 72 hr reduced active D-glucose transport in hamsters. However, other investigators (19) reported elevations in glucose and histidine transport with fasting.

Transfer and tissue weight data indicate that an intestinal segment's transfer abilities are not correlated with segment weight. Proadifen elevated both the amount of 3-*O*-methylglucose transferred and the tissue weight. However, increased intestinal weights noted for the unfasted groups did not coincide with elevations in transfer rates but with reduced rates. Newey *et al.* (18) also showed the inappropriateness of direct comparisons of the amount of sugar transported per gram of tissue in hamsters.

Table V—Effects of 24-hr Proadifen Pretreatment on Rat Intestinal Tissue after 1- and 2-Day Fast [a]

Tissue	Control [b,c]	Treated [b,c]
1-Day fast		
Wet tissue weight, mg/cm	62.14 ± 7.58	76.30 ± 13.70 [d]
Dry tissue weight, mg/cm	7.04 ± 0.82	9.16 ± 1.84 [d]
Extracellular space, ml/g	44.15 ± 5.30	42.27 ± 2.56
2-Day fast		
Wet tissue weight, mg/cm	62.12 ± 1.94	82.10 ± 4.98 [d]
Dry tissue weight, mg/cm	7.30 ± 0.26	9.30 ± 0.48 [d]
Extracellular space, ml/g	41.58 ± 3.43	41.59 ± 3.84

[a] One- and 2-day fast studies performed on separate days. [b] Number of sacs = 8. [c] Mean ± *SD*. [d] $p < 0.05$ compared to control.

Despite the presence or absence of fecal material in the intestinal lumen as noted in Study A, proadifen pretreatment elevated mucosal to serosal transfer of the sugar derivative. Likewise, wet and dry tissue weights were greater in all pretreated groups than in controls of the same fast period. Both effects appeared to be caused by an indirect mechanism and/or *via* a proadifen metabolite since direct drug incubation did not alter sugar transfer (Study E). Of the three pretreatment periods in Study D, 24-hr pretreatment produced optimum enhancement.

Possible indirect mechanisms include the prolongation of the half-life of endogenous steroids (20) or stimulated pituitary hormone release (20) by proadifen or its metabolites. The hepatic microsomal enzyme inducer phenobarbital increased intestinal tissue weight following several days of administration (8). Further studies are necessary to clarify the mechanism of proadifen's effects on intestinal tissue and to evaluate possible alterations in drug absorption following exposure to enzyme-inducing and inhibiting agents.

In summary, enhanced 3-*O*-methylglucose transfer across *in vitro* everted intestinal sacs and increased wet and dry intestinal tissue weights were observed in 24-hr proadifen-pretreated rats. Both effects apparently were unrelated to the unfasted state of the lumen, resulting from proadifen's spasmolytic effects, since 48-hr fasting of treated animals provided material-free lumens with the same effects. Proadifen enhancement of sugar transport appeared to be indirect since drug incubation of segments produced no alterations. In control animals, 24- and 48-hr fasting decreased intestinal weight and increased mucosal to serosal sugar transport as determined by everted intestine techniques.

Prostaglandin Prodrugs III: Synthesis and Biological Properties of C_9- and C_{15}-Monoesters of Dinoprost (Prostaglandin $F_{2\alpha}$)

W. MOROZOWICH ˣ, T. O. OESTERLING, W. L. MILLER, C. F. LAWSON, J. C. CORNETTE, J. R. WEEKS, and S. L. DOUGLAS

Received September 15, 1975, from the *Research Laboratories, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication November 5, 1975.

Abstract □ Methods are described for the synthesis of dinoprost C_9- and C_{15}-monoesters using protective groups. Esters at C_9 were synthesized by acylation of dinoprost 11,15-bis(tetrahydropyran-2-yl)ether followed by acid-catalyzed protective group removal. Esters at C_{15} were synthesized by initial formation of the protected intermediate, dinoprost 9,11-*n*-butylboronate, followed by acylation and hydrolytic protective group removal. Many esters were active *in vivo* in the hamster antifertility screen. Plasma hydrolysis studies showed that the C_{15}-esters were more readily cleaved than the C_9-esters. *In vivo* studies in the rat showed that both the C_9- and C_{15}-esters resulted in urinary excretion of 5α,7α-dihydroxy-11-ketotetranorprosta-1,16-dioic acid in amounts comparable to those obtained after dosing with dinoprost, indicating that ester hydrolysis occurred *in vivo*.

Keyphrases □ Dinoprost—prodrugs, C_9- and C_{15}-monoesters, synthesis, bioactivity □ Prostaglandins—dinoprost, prodrugs, C_9- and C_{15}-monoesters, synthesis, bioactivity □ Prodrugs—dinoprost, C_9- and C_{15}-monoesters, synthesis, bioactivity

Previously, methods were described for the synthesis of aromatic and aliphatic prostaglandins C_1-esters, and the utility of these prodrugs in improving solid-state stability and oral absorption was reported (1, 2). This report describes synthetic routes for dinoprost C_9- and C_{15}-monoesters and an evaluation of ester bioactivity.

EXPERIMENTAL

Materials and Methods—Dinoprost and dinoprost 11,15-bis(tetrahydropyran-2-yl)ether (I)[1] (3) were pure by silica gel TLC. The acid chlorides were obtained commercially[2]. Pyridine (analytical reagent) was dried over molecular sieves[3] for 1 week prior to use. All other solvents were glass-distilled quality[4].

Column chromatography was conducted on 0.063–0.2-mm silica gel[5]. Silica gel TLC was conducted on 250-μm layer plates[6], and visualization was by spraying the developed plates with aqueous 15% ammonium sulfate followed by charring on a hot plate. Prostaglandin ester mass spectra were obtained[7] for (*a*) the trimethylsilyl derivative, (*b*) the C_1-methyl ester of the trimethylsilyl derivative, and (*c*) the nonderivatized compound. The methyl esters were obtained using diazomethane, and the trimethylsilyl derivatives were obtained with a mixture of hexamethyldisilazane – trimethylchlorosilane – bis(trimethylsilyl)acetamide–pyridine (2:2:1:5).

Synthesis—Representative ester syntheses are described. The other esters were synthesized similarly.

Dinoprost 9-n-Butyrate (*III*b)—A solution of 100 mg of I (3) in a mixture of 0.5 ml of butyric anhydride and 1 ml of pyridine was allowed to stand at room temperature for 24 hr. Upon solvent removal at 45° under vacuum, the residue was dissolved in 50 ml of acetone–acetic acid–water (1:1:1). After 24 hr at 40°, the solvent was removed and the residue was subjected to column chromatography on 75 g of silica gel. Elution was achieved with ethyl acetate–acetic acid (97:3), and the product fractions were identified by silica gel TLC with the same solvent system. Evaporation of the pooled product fractions gave 51 mg of a colorless oil, which was pure by TLC.

Dinoprost 15-Acetate (*VIII*a)—A solution of 48.4 mg (0.137 mmole) of IV and 24 mg (0.236 mmole) of *n*-butylboronic acid in 2 ml of dry pyridine was allowed to stand at room temperature for 1 hr. Acetic anhydride, 2 ml, was added; after 24 hr at room temperature, 3 ml of water was added and the solvent was removed at 45° under vacuum. The residual oil was dissolved in 50 ml of ethyl acetate and extracted with 50 ml of 0.2 *M* citrate buffer, pH 3.0.

The organic phase was dried over sodium sulfate; upon solvent removal, the residue was subjected to column chromatography on 50 g of silica gel. Elution was achieved with ethyl acetate–acetic acid (97:3). The product fractions were identified by TLC; upon solvent removal, 25.3 mg of a colorless oil was isolated.

Biological Activity—The ester activity was studied in the gerbil colon assay, the rat pressor blood pressure assay, and the hamster antifertility assay (subcutaneous administration) as described previously (1, 4).

Plasma Hydrolysis—Standard aqueous solutions (0.1 ml) of dinoprost, the 9-acetate (IIIa), the 15-acetate (VIIIa), the 9-*n*-butyrate (IIIb), and the 15-*n*-butyrate (VIIIc) containing quantities in terms of IV ranging from 5 to 20×10^3 ng/ml were incubated separately with 0.05 ml of each of the following: (*a*) saline solution, (*b*) heparinized rat plasma, (*c*) heparinized monkey plasma, and (*d*) heparinized human plasma. After 2 hr at 37°, the affinity of each incubated sample for anti-dinoprost serum was determined using a double antibody radioimmunoassay (5). Relative cross-reactivity was calculated by comparing the amount of the compound required to displace 50% of the label with the amount of IV required. Increased antibody affinity occurred as ester hydrolysis proceeded to yield IV.

***In Vivo* Metabolism**—Mature Sprague–Dawley female rats were injected subcutaneously with one of the following: I, IIIa, VIIIa, IIIb, VIIIc, and the vehicle as the control. The compounds were administered in amounts equivalent to 1 mg of IV dissolved in 0.5 ml of vehicle consisting of polyethoxylated vegetable oil[8]–ethanol–5% aqueous dextrose (1:1:8).

The animals were kept in metabolism cages, and total urine volumes

VIIIg	$C_{36}H_{64}O_6$	B	318 ($M^+ - C_{15}H_{31}COOH - H_2O$), 300 ($M^+ - C_{15}H_{31}COOH - 2H_2O$)

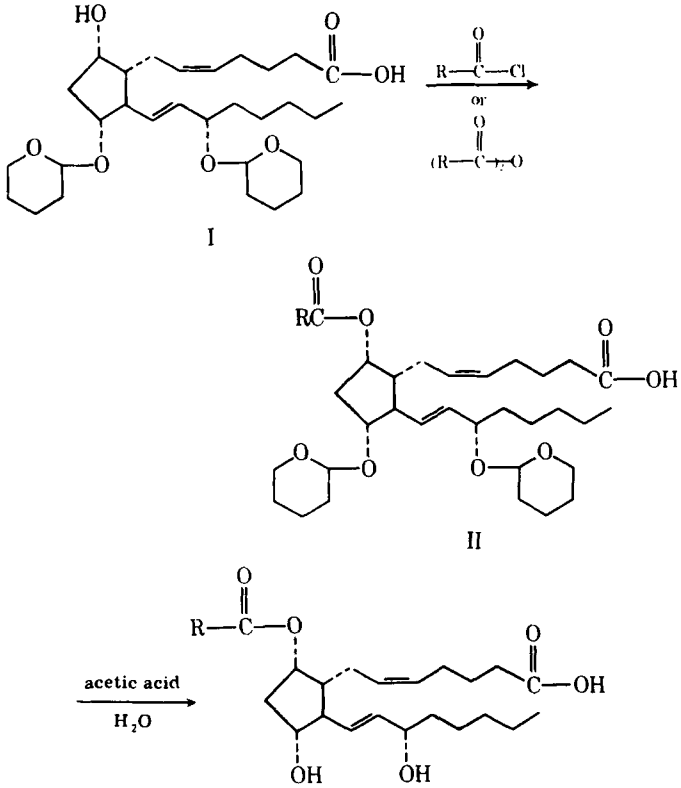
[a] The compounds were liquids, except IIIc (mp 55.9–60.5°). [b] A = trimethylsilyl derivative, B = no derivatization, and C = C_1-methyl ester trimethylsilyl derivative.

were collected over 2 days. Each 24-hr urine sample was assayed for 5α,7α-dihydroxy-11-ketotetranorprosta-1,16-dioic acid (IX), an ultimate major urinary IV metabolite (6), using the radioimmunoassay and the antibody specific for this compound (7).

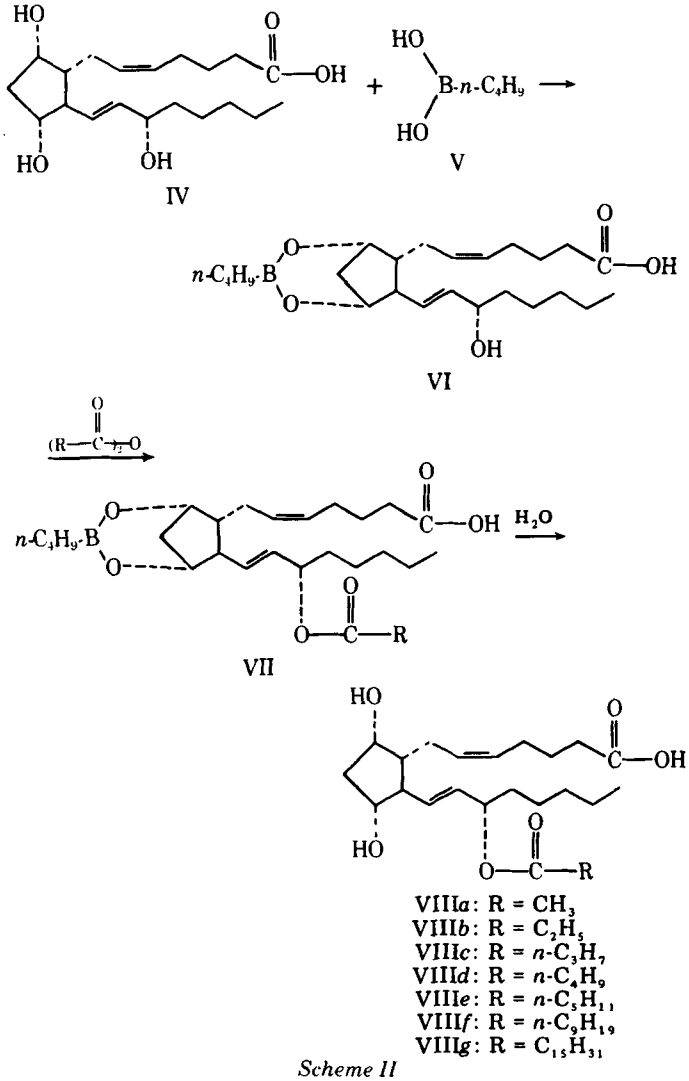
RESULTS AND DISCUSSION

Synthesis—Since selective monoesterification of dinoprost (IV) with acid anhydrides or acid chlorides in pyridine was not possible, protective groups were necessary (8).

The C_9-esters (III) were synthesized by reacting the 11,15-bis(tetrahydropyran-2-yl)ether (I) (3) with an acid anhydride or an acid chloride in pyridine at room temperature (Scheme I). Only the acetate ester could be synthesized *via* the acid anhydride in high yields (>90%) at room temperature in 24 hr, and acid chlorides were required for the synthesis of the higher esters at room temperature.



Scheme I



Scheme II

Tetrahydropyranyl protective group removal from ester II was achieved with aqueous acetic acid, and the resulting C_9-esters (III) were purified by column chromatography.

The C_{15}-esters (VIII) were synthesized by initial protection of the C_9- and C_{15}-hydroxyl groups with *n*-butylboronic acid (V) (9) (Scheme II). The reaction proceeded rapidly at room temperature (15–60 min) in the presence of a 1–2-mole excess of *n*-butylboronic acid to give the cyclic 9,11-boronate ester (VI).

Compound VI formation generally was quantitative, as evidenced by GLC upon trimethylsilylation of a reaction mixture aliquot. Occasionally,

Table II—Biological Activity of Dinoprost Esters

Compound	Hamster Antifertility[a] Percent Non-pregnant	Dose, μg/animal	Gerbil Colon[b]	Rat Blood Pressure (Depressor)[c]
IIIa	50	125	0.03–0.1	0.01–0.03
IIIb	75	125	0.03–0.1	0.01–0.03
IIIc	100	200	<0.001	0.003–0.01
IIId	17	100	0.01–0.03	0.03–0.1

VIIIb	0	100	0.01–0.3	0.3–1
VIIIc	83	125	0.03–0.1	0.3–1
VIIId	17	100	0.1–0.3	0.3–1
VIIIe	33	100	0.01–0.03	0.3–1
VIIIf	0	100	0.03–0.1	0.3–1
VIIIg	0	100	0.001–0.003	0.3–1

[a] Administered subcutaneously. The minimum effective dose for 100% inhibition of pregnancy was 100 μg of IV/animal. [b] The dinoprost (IV) activity score in this assay was 2. Prostaglandin E_1 = 1. [c] Dinoprost = 1.

a larger (3–5 mole) excess of *n*-butylboronic acid had to be employed to provide a quantitative reaction, presumably due to the inhibition by trace moisture contamination. Silica gel TLC was ineffective in monitoring the reaction since severe streaking occurred due to apparent VI hydrolysis during chromatography.

Compound VI esterification with an acid anhydride proceeded smoothly to give the protected C_{15}-esters (VII). After hydrolysis with water, the C_{15}-esters (VIII) were isolated by column chromatography.

All C_9- and C_{15}-esters were isolated as oily liquids, except C_9-*n*-octanoate (IIIc), which was a solid, mp 55.9–60.5°. The ester structures were confirmed by mass spectral analysis of the trimethylsilyl derivatives, and the fragmentation patterns supported the structures (Table I).

Biological Activity—The biological activity of the esters in three test systems (1, 4) is summarized in Table II. In the hamster antifertility assay, the minimum effective dose for 100% pregnancy inhibition was 100 μg/animal for IV; the assay results indicate significant C_9-ester activity at the dosage level tested. In the C_{15}-ester series, VIIIa and VIIIc–VIIIe showed significant activity; VIIIb, VIIIf, and VIIIg were inactive.

In the gerbil colon assay, IV had an activity score of 2. The biological data show that the C_9- and C_{15}-esters displayed activities significantly less than the parent compound.

In the rat blood pressure assay, the pressor activity of VIIIa–VIIIg approached that of IV whereas IIIa–IIId were significantly less active.

***In Vitro* and *In Vivo* Hydrolysis**—The cleavage of the acetate and *n*-butyrate esters IIIa, IIIb, VIIIa, and VIIIc was studied both *in vitro* and *in vivo*. The *in vitro* studies were conducted by equilibrating the esters with rat, monkey, and human plasma for 2 hr at 37°. Hydrolysis was measured by the radioimmunoassay using the antibody specific for IV (5). The percent hydrolysis was determined by comparing the assay response of the esters to that of an equimolar amount of IV treated similarly. The results (Table III) showed that the 9-acetate (IIIa) and 9-butyrate (IIIb) esters were resistant to cleavage by the three plasma samples.

Table III—Plasma Hydrolysis (Percent in 2 hr at 37°) of Dinoprost Esters[a]

Compound	Saline Control	Rat Plamsa	Monkey Plasma	Human Plasma
IIIa	1.0	0.9	1.0	0.6
IIIb	1.3	1.5	0.7	0.5
VIIIa	22.0	50.8	28.6	9.1
VIIIc	5.0	40.0	6.7	2.6

[a] Solutions of the compounds in 0.1 ml of water diluted with 0.05 ml of plasma or saline control. The amount of IV liberated was determined by the radioimmunoassay.

Table IV—Total Daily Urinary Metabolite IX Excretion (Micrograms) in Rats Dosed Subcutaneously[a]

Compound	Day 1	Day 2
(Vehicle control)	(0.8)	(0.8)
IV	138	1.4
IIIa	116	2.5
IIIb	155	5.0
VIIIa	195	5.0
VIIIc	132	1.6

[a] Determined by the radioimmunoassay.

The 15-acetate (VIIIa) and 15-butyrate (VIIIc) esters were appreciably hydrolyzed by rat plasma but less efficiently by monkey plasma. Compound VIIIa hydrolysis by human plasma was unusual since partial hydrolysis occurred in the saline control, presumably due to the esterases present in the antiserum; C_{15}-ester hydrolysis did not occur in water at 37° for 2 hr. The decreased hydrolysis by human plasma may be due to an hydrolysis-inhibiting component present in human plasma or to extensive ester protein binding.

In vivo ester hydrolysis was studied in rats by monitoring the urinary excretion of the major urinary IV metabolite, 5α,7α-dihydroxy-11-ketotetranorprosta-1,16-dioic acid (IX) (6), using the radioimmunoassay (7). The esters were injected subcutaneously in rats, and the daily urinary IX excretion was determined using the antibody specific for this compound. Thus, if ester hydrolysis occurred *in vivo*, the resulting IV would be converted to IX.

Table IV shows that the acetate and butyrate esters at both the 9- and 15-positions yielded approximately the same amount of urinary metabolite IX as was found upon administration of IV, indicating complete ester hydrolysis *in vivo*. The data imply that all four esters should be as active as IV in the antifertility assay, but IIIa was somewhat less active. *In vivo* IIIa hydrolysis probably occurs competitively with metabolism at C_1 or C_{15}, and the low antifertility activity of this ester could be due to preferential metabolism to yield an inactive ester metabolite. Ultimate ester hydrolysis and metabolism to IX would account for the full bioavailability of the metabolite from IIIa.

Bioavailability and Dissolution Parameters of Seven Lithium Carbonate Products

T. E. NEEDHAM *x, **P. JAVID** ‡, **and W. BROWN** §

Received November 7, 1978, from the *Department of Pharmaceutics, School of Pharmacy, University of Georgia, Athens, GA 30602.* Accepted for publication January 26, 1979. *Present address: Baxter Travenol Laboratories, Morton Grove, Ill. ‡Present address: University of Tehran, Tehran, Iran. §University Health Service, Gilbert Health Center, Athens, GA 30602.

Abstract □ Seven commercial products and a standard powder of lithium carbonate were administered to healthy human volunteers in a crossover study. An analysis of variance of saliva levels and urinary excretion as well as an analysis of variance of peak concentration and the area under the curve from 0 to 24 hr for the saliva levels showed no significant difference between the powder and products, but a significant difference between subjects. A significant difference was found between the time of peak saliva levels, which was attributed to faster powder absorption. A dissolution study using the USP basket method at 50 and 100 rpm and the Levy beaker at 50 rpm also showed no significant difference between products after the lag time for the capsule dosage forms. With a regression analysis, a significant correlation was found between the saliva levels of the products at 2 hr and dissolution in the USP basket at 50 rpm at 4 min.

Keyphrases □ Lithium carbonate—bioavailability and dissolution, various commercial products, powder, humans □ Bioavailability—lithium carbonate, various commercial products, powder, humans □ Dissolution rate—lithium carbonate, various commercial products, powder, humans □ Antidepressants—lithium carbonate, bioavailability and dissolution, various commercial products, powder, humans

Lithium salts have been used extensively in the management of the manic episodes in manic–depressive illness (1–3). Lithium carbonate is the salt form of choice and is used in most oral products available in this country.

The therapeutic plasma range (0.5–1.5 mEq/liter) and the toxic plasma levels (>1.6 mEq/liter) are very close (4). This critical proximity in combination with large variability in patient drug response requires careful plasma level monitoring during lithium therapy.

Lithium carbonate pharmacokinetics have been defined, and the bioavailabilities of several different products have been investigated (5–10). Shepherd *et al.* (11) investigated the dissolution of three lithium carbonate capsule dosage forms and one tablet product and found a large difference in *in vitro* drug release. The USP later required a dissolution standard for lithium carbonate products of 60% dissolved in 30 min at 100 rpm using the basket method (12).

The purpose of this study was to investigate the bioavailabilities of the seven oral lithium carbonate products currently available in this country and to compare *in vitro* drug release as a function of dissolution methods and their defined parameters.

EXPERIMENTAL

Dosage Forms—Seven commercial dosage forms containing 300 mg of lithium carbonate/tablet or capsule were used[1]. Lithium carbonate powder was used as received from the manufacturer.

***In Vivo* Studies**—Seven healthy male subjects, 22–48 years old and within 90–110% of their ideal weight (13), volunteered for this study. Informed written consent was obtained from each subject. Each volunteer was given a general physical examination including a chest X-ray, an ECG, and normal blood and urine profiles prior to initiation of the study. All were within normal limits. Volunteers were asked to refrain from taking any medications or alcohol prior to and during the study.

Following an overnight fast, each subject was instructed to void and to drink 250 ml of water. An hour later, the zero-time urine and saliva samples were taken and 600 mg of drug was administered. The powder was administered as a suspension in water. Cumulative urine samples were subsequently taken at 1, 2, 3, 4, 6, 8, 12, and 24 hr. Fifteen to 20 ml of urine and the saliva samples were refrigerated immediately. Each subject was instructed to drink 250 ml of water after each urine collection for the first 2 hr. Subjects were allowed to eat after the 2-hr sample.

Urine samples were diluted and analyzed, with appropriate blanks, at 670.8 nm using an atomic absorption spectrophotometer[2]. Results are expressed in terms of percent drug excreted. Saliva samples were taken simultaneously with urine samples. All subjects produced saliva freely in amounts from 1 to 6 ml. Saliva samples were diluted with water, homogenized by shaking for 30 min, and analyzed.

The seven products and the powder were administered to the seven volunteers according to an 8 (formulations) × 7 (subjects) crossover design.

***In Vitro* Studies**—Two dissolution apparatuses were used, the USP basket (12) and the modified Levy beaker method (14–16). A stirring rate

of 50 rpm was used for the modified Levy beaker, and rates of 50 and 100 rpm were used for the USP basket method. Temperature was controlled at 37.0 ± 0.5°. Six hundred milliliters of potassium biphthalate buffer (pH 3.0) was used as the dissolution medium.

At appropriate times, a 1-ml sample was withdrawn and an equal volume of medium was added to maintain a constant volume. Samples were filtered, diluted, and analyzed at 670.8 nm using the atomic absorption spectrophotometer.

RESULTS AND DISCUSSION

***In Vivo* Studies**—Table I shows the cumulative percent of dose excreted in the urine for the seven lithium carbonate products and powder as a function of time. There was little apparent difference in urinary excretion among all eight doses during the 24 hr of sampling. Comparison of these results with work previously reported (8) shows an excellent agreement in cumulative excretion of lithium at 4, 8, and 24 hr.

An analysis of variance using a repeated measures design was employed at each sampling time. This analysis showed no significant difference in drug excretion between brands ($p = 0.05$) during any sampling time up to 24 hr. However, a significant difference was found among subjects at all time intervals. These results aptly illustrate the wide variability mentioned previously and the need to monitor individual patients during drug administration.

Since it has been reported that the saliva/plasma lithium concentration ratio is constant and reproducible for a given individual (17), the saliva lithium concentration also was determined for the dosage forms and the powder for all seven subjects (Table II). Very little difference was apparent, although the average drug concentration produced by the powder seemed to be higher at 1.0 and 2.0 hr. However, the repeated-measures analysis of variance at each sample time showed no significant difference between the products or the powder ($p = 0.05$). Again, the difference among subjects was significant at all sample times.

The constant plasma/saliva lithium ratio makes feasible a comparison of the saliva peak drug level (C_{pk}), the peak level time (t_{pk}), and the area under the saliva level curve (AUC) as a means of measuring the bio-

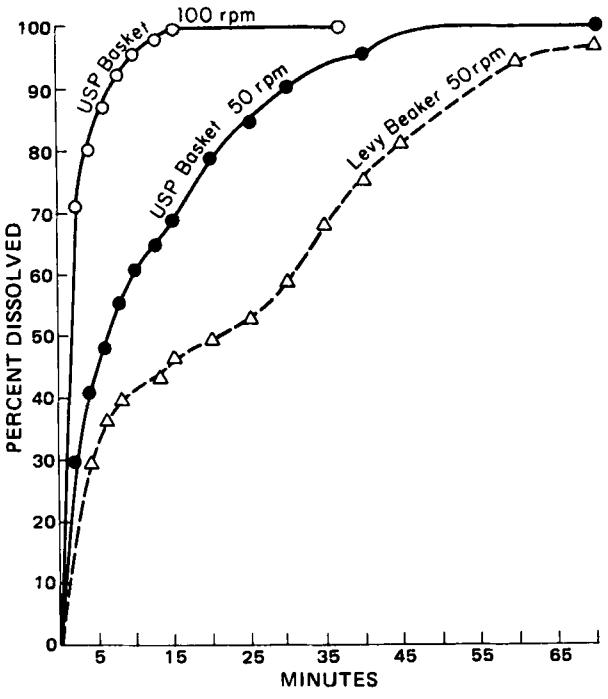

Figure 2—*Dissolution profiles for Product C using the three different dissolution methods/agitation speeds.*

availability of the seven products and powder. Table III shows the C_{pk} and t_{pk} values for each administered dose in each subject. The peak level time is presented as an estimate based on saliva data interpolation.

A two-way analysis of variance for peak concentration to include seven subjects and eight dose administrations produced an F value (7, 42) of 1.16 for the between-brands comparison and an F value (6, 42) of 9.08 among these subjects. These results indicated that no significant differences ($p = 0.05$) existed among the peak saliva concentrations for the seven different lithium carbonate brands and the powder. Significant differences existed among the subjects.

A further analysis of variance of the time required to reach the peak saliva lithium concentration was performed. An F value (7, 42) of 6.80 was calculated for the between-brands comparison. This result indicated a significant difference ($p = 0.05$). A Newman–Keuls (18) analysis was performed to determine which of the t_{pk} means of the administered brands or powder was significantly different. The powder, with an average t_{pk} of 1.57 hr, was different from all of the commercial products. No significant difference was found among any of the remaining seven lithium carbonate products. Interestingly, the calculated F value (6, 42) of 1.84 indicated no significant difference ($p = 0.05$) among subjects for t_{pk}.

The area under the saliva level curve for 0–24 hr was calculated using the trapezoidal rule with average AUC values of 4.406 (Brand E), 4.823 (Brand A), 4.962 (Brand C), 4.972 (Brand D), 4.981 (Brand G), 4.992 (Brand B), 6.789 (powder), and 8.020 (Brand F). A two-way analysis of variance for the AUC *versus* subjects produced an F value (7, 42) of 1.02 for the between-brands comparison, which was not significant ($p = 0.05$). The calculated F value (7, 42) of 6.13 for the between-subjects comparison was significant.

***In Vitro* Dissolution Studies**—The seven lithium carbonate brands were dissolved using three systems: a modified Levy beaker method at 50 rpm and the USP basket method at 50 and 100 rpm.

Figure 1 illustrates the average percent dissolved for all seven products in the USP basket at 50 rpm. This method and agitation speed illustrate the behavior seen in both the USP basket at 100 rpm and the Levy beaker.

These results were compared using an analysis of variance. The percent of drug dissolved was transformed using a log arc sine transformation to ensure homogeneity of variance and additivity of effects (19). Since previous work had determined that an analysis of variance across time produces significant interaction effects (20), a 7 (brands) × 3 (methods/rpm) with five replications repeated-measures analysis of variance at each sample time was performed. This analysis showed a significant difference between brands ($p = 0.05$) in drug dissolution from the dosage forms at 2 and 4 min. Comparison of the average percent dissolved showed that these differences were due to capsule dosage forms Brands B, D, and F, which displayed the expected lag time. However, the analysis of variance showed a significant difference in the dissolution between methods at all sample times. Figure 2 illustrates an example comparison, using Product C, of the average percent dissolved for each method and agitation speed. The order of decreasing rate of dissolution was USP 100 rpm, USP 50 rpm, and Levy 50 rpm for all brands at all sampling times.

All products adhered to the USP regulation that 60% of drug dissolve in 30 min at 100 rpm in the USP basket. In fact, the time to achieve 60% dissolution ranged from <2 min for Brands C and E to <8 min for Brand F.

A correlation of the *in vivo* saliva concentrations of the different lithium carbonate brands with the *in vitro* drug release from the dosage forms at all possible combinations of sample times was attempted using a regression analysis. A significant correlation at the 0.95 level was found for the Levy 50-rpm and USP 50-rpm methods at the 2-min sample time *versus* the *in vivo* time of 1 hr. However, comparison of the presented results showed that this correlation occurred during the only *in vitro* sample time that showed a significant difference between brands and at the *in vivo* sampling time that had no difference between brands. Apparently, the regression analysis produced a mathematical correlation of little practical significance.

A second significant correlation was found at the 0.99 level for the USP basket at 50 rpm at 4 min with the *in vivo* sample time of 2 hr. In this comparison, the significance level was higher. The analysis of variance of both the *in vivo* and *in vitro* data for the USP basket at 50 rpm showed no significant difference between brands, and the dosage forms were in that phase of absorption and dissolution where drug release was significant. This finding seems important since the assumption inherent in *in vivo–in vitro* correlation requires a comparison based on drug release from dosage form, manifested as dissolution or as absorption. To determine the practicality of this means of correlation as a control method, further work employing dosage forms designed to produce diverse drug concentration levels is necessary.

Synthesis of Substituted 2-Aminopyrrole Analogs of Lidocaine II

RONALD W. JOHNSON *, THOMAS H. KEENAN ‡, JOSEPH W. KOSH, and J. WALTER SOWELL, Sr. ˣ

Received December 18, 1978, from the *College of Pharmacy, University of South Carolina, Columbia, SC 29208.* Accepted for publication January 30, 1979. *Present address: Medical University of South Carolina, Charleston, S.C. ‡Present address: Purdue University, West Lafayette, Ind.

Abstract □ The synthesis and local anesthetic and antiarrhythmic properties of eight substituted 2-diethylaminoacetamido-3-carbamyl-4-methylpyrroles are described. Three compounds showed significant local anesthetic activity by the guinea pig wheal test, and four showed antiarrhythmic activity against chloroform-induced ventricular arrhythmias in mice.

Keyphrases □ Lidocaine analogs—synthesis of 2-diethylaminoacetamido-3-carbamyl-4-methylpyrroles, local anesthetic activity, antiarrhythmic activity, structure–activity relationships □ Structure–activity relationships—lidocaine analogs, local anesthetic activity, antiarrhythmic activity □ Local anesthetic agents—lidocaine analogs, synthesis, structure–activity relationships □ Antiarrhythmic agents—lidocaine analogs, synthesis, structure–activity relationships

The synthesis and local anesthetic and antiarrhythmic properties of a series of substituted 2-diethylaminoacetamido-3-cyano-4-methylpyrrole (I) analogs of lidocaine (II) were reported previously (1). The biological activity exhibited by members of I prompted further research on heteroaromatic pyrrole analogs of II.

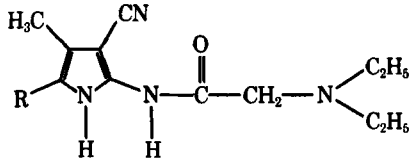
This report describes the synthesis and preliminary pharmacological evaluation for local anesthetic and antiarrhythmic activities of a series of substituted 2-diethylaminoacetamido-3-carbamyl-4-methylpyrroles (III).

DISCUSSION

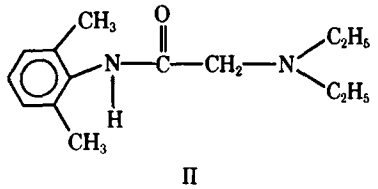
Chemistry—The utilization of substituted 2-amino-3-cyano-4-methylpyrroles (IV*a*–IV*h*) (2–4) as precursors to substituted 2-chloroacetamido-3-cyano-4-methylpyrroles (V*a*–V*h*) was reported previously (1). In the present work, V*a*–V*h* were utilized as intermediates in the synthesis of III (Scheme I).

Nitrile hydrolysis proceeded smoothly, by heating V*a*–V*h* in 85% phosphoric acid, to yield the corresponding substituted 2-chloroacetamido-3-carbamyl-4-methylpyrroles (VI*a*–VI*h*). The lower molecular weight analogs (V*a* and V*b*) and analogs possessing polar R groups (V*d* and V*g*) were hydrolyzed easily in 85% phosphoric acid at 120–125° for 5–10 min. The higher molecular weight analogs with nonpolar R groups (V*e*, V*f*, and V*h*) required more drastic conditions for hydrolysis. These conditions included more phosphoric acid, a temperature of 135–140°, and a total hydrolysis time of 10 min. With V*d*, the more drastic reaction conditions resulted in a decreased yield of VI*d*.

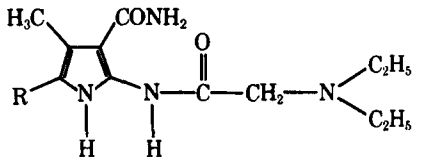
In general, the hydrolyzed compounds VI*a*–VI*h* were less soluble in organic solvents than their immediate precursors V*a*–V*h*. The decreased solubility can be explained, in part, by the increased potential for intramolecular hydrogen bonding. NMR and IR spectra were consistent with the assigned structures. Elemental analysis and TLC were used in determining chloroacetamide purity (Table I).



I



II



III

The substituted 2-diethylaminoacetamido-3-carbamyl-4-methylpyrroles (VII*a*–VII*h*) were obtained by refluxing a suspension of the corresponding chloroacetamide (VI*a*–VI*h*) in methanol or ethanol with

[a] Ethyl acetate.

excess diethylamine. During the reactions, solutions were achieved within 0.5–3 hr. An exception was observed for the synthesis of VII*h*; a solution was not achieved after refluxing for 9 hr. In general, the solutions were refluxed for an additional hour, the solvent and excess diethylamine were removed *in vacuo*, and the residues were dissolved in 10% HCl. Unreacted chloroacetamides were removed by filtration, and the amines were precipitated by the addition of 5% aqueous NaOH. Yields, melting points, and purification data are given in Table II.

All amine hydrochlorides were prepared by treating an acetone solution of the free amine (VII*a*–VII*e*) or an acetone suspension of the free amine (VII*f* and VII*h*) with concentrated hydrochloric acid. Compound VIII*g* separated from acetone as a red oil when this procedure was employed for salt formation. IR spectra of the amine hydrochlorides (VIII*a*–VIII*f* and VIII*h*) exhibited typical N–H stretching absorption bands between 3500 and 3100 cm^{-1} and broad absorption in the 3100–2600-cm^{-1} region for the amine salts. Two intense carbonyl absorption bands at 1690–1680 and 1645–1640 cm^{-1} were observed for each compound.

NMR spectra of the amine hydrochlorides in dimethyl sulfoxide-d_6 exhibited a typical triplet and quartet for the methyl and methylene of the diethylamino group, respectively. Chemical shifts for the triplet ranged from 1.15 to 1.20 ppm, and those for the quartet ranged from 3.10 to 3.15 ppm. The triplet and quartet integrated for three protons and two protons, respectively. A singlet in the 2.00–2.15-ppm region, integrating for three protons, was assigned to the methyl group at the C-4 position. In the 4.05–4.15-ppm region, the spectra exhibited a singlet, integrating for two protons, which was assigned to the methylene located alpha to the carbonyl. A broad singlet at 6.55–6.85 ppm, integrating for two protons, was assigned to the carbamyl function protons.

The salt NH proton was observed as a broad singlet, integrating for one proton, in the 9.8–10.5-ppm region. Two additional broad singlets, one in the 10.7–11.0-ppm region and the other in the 10.95–11.0-ppm region, were assigned to the amide and pyrrole ring NH protons. Miscellaneous absorptions for the various hydrochloride salts were consistent with their structure. The purity of VIII*a*–VIII*f* and VIII*h* was determined by elemental analysis and TLC (Table III).

Pharmacology—*Antiarrhythmic Activity*—Cardiac rates less than the mean rate of 200 beats/min were used as an index of protection from arrhythmia at 70 mg/kg. Compounds VIII*a*, VIII*b*, VIII*d*, and VIII*e* (Table IV) showed activity at this dosage. Compounds VIII*c* and VIII*f* also may be effective if the standard error of the mean is considered.

Local Anesthetic Activity—Compounds VIII*c* and VIII*e*–VIII*g* possessed local anesthetic activity at all three solution concentrations whereas the remaining compounds possessed weak activity only at the highest solution concentration. Compounds VIII*e* and VIII*f* were the most active, having activity comparable to that of lidocaine (Table V).

EXPERIMENTAL[1]

Chemistry—*2-Chloroacetamido-3-carbamyl-4,5-dimethylpyrrole (VI*a*)*—The procedure for the synthesis of VI*a* is given as representative for VI*b*–VI*h*. A suspension of 2-chloroacetamido-3-cyano-4,5-dimethylpyrrole (V*a*) (15.0 g, 0.07 mole) (1) in 100 ml of 85% phosphoric acid was stirred at room temperature for 5 min. The vessel was placed into an oil bath preheated to 120° and stirred vigorously for 10 min. During this time, solution was achieved, and some of the product precipitated on the stirring solution surface. The vessel was removed from the oil bath and cooled to room temperature. The resulting semisolid was diluted with 300 ml of water and stirred for 10 min.

The crude product was collected by filtration, washed with water, and air dried. One gram of the pale-yellow product (15.6 g, 96.9%) was recrystallized twice from absolute methanol to yield yellow needle-shaped crystals (homogeneous on TLC, ethyl acetate, R_f 0.46), mp 210–211° dec.; IR (KBr): 3520, 3350, 3160, 1680, 1645, 1600, 1570, 1460, 1445, 1400, 1385, 1280, 1215, 790, 735, and 625 cm^{-1}; NMR (dimethyl sulfoxide-d_6): δ 1.95 (s, 6H, $-CH_3$ at C_4 and C_5), 4.20 (s, 2H, $-CH_2-$), 6.42 (broad s, 2H, $-CONH_2$ at C_3), 10.72 (broad s, 1H, NH of amide at C_2 or N_1H), and 10.89 (broad s, 1H, N_1H or NH of amide at C_2) ppm. (See Table I for analyses.)

*2-Diethylaminoacetamido-3-carbamyl-4,5-dimethylpyrrole (VII*a*)*—The procedure for the synthesis of VII*a* is given as representative for VII*b*–VII*h*. A suspension of VI*a* (9.2 g, 0.04 mole) in 125 ml of methanol

[1] IR spectral data were determined on a Beckman IR-20A grating spectrophotometer using the potassium bromide techniques. NMR spectra were determined on a Hitachi Perkin-Elmer R24 high-resolution spectrophotometer with tetramethylsilane as the internal reference. Melting points were obtained using a Thomas-Hoover capillary apparatus and are uncorrected. Carbon, hydrogen, chlorine, and nitrogen values were obtained from analysis performed by Atlantic Microlab, Inc., Atlanta, Ga. TLC was performed using Eastman chromatogram sheets, type 6060 (silica gel), and the sheets were developed in an iodine chamber.

acetone to yield light-tan crystals (homogeneous on TLC, ethyl acetate, R_f 0.40), mp 244–245° dec.; IR (KBr): 3420, 3340, broad absorption from 3200 to 2600, 1675, 1635, 1600, 1570, 1545, 1470, 1435, 1380, 1370, 1355, 1270, 1240, 1155, 955, 805, and 630 cm^{-1}; NMR (dimethyl sulfoxide-d_6): δ 1.19 (t, 6H, $-CH_3$ of diethylamino), 2.08 (s, 6H, $-CH_3$ at C_4 and C_5), 3.14 (q, 4H, methylenes of diethylamino), 4.05 (broad s, 2H, $COCH_2$), 6.55 (broad s, 2H, $CONH_2$), 9.90–10.50 (broad s, 1H, N^+H), 10.70 (broad s, NH of amide at C_2 or N_1H), and 10.95 (broad s, 1H, N_1H or NH of amide at C_2) ppm. (See Table III for analyses.)

Pharmacology—*Antiarrhythmic Activity*—With the method of Lawson (5), fibrillations were induced in 20–30-g male mice by exposure to chloroform vapor until respiration ceased. The heart was exposed, and the cardiac rate was determined with a binocular microscope. Mice with cardiac rates >200 beats/min were considered unprotected (Table IV).

Local Anesthetic Activity—The guinea pig wheal method of Bülbring and Wajda (6) was used to determine the activity. The back of the guinea pig was shaved 1 day prior to the test, and 0.25 ml of the aqueous drug solution was administered intradermally at two sites along the midline. The resulting wheals were tested by pricking the area six times with a pin at 5-min intervals for 1 hr. Local anesthesia was present if the pinprick did not elicit a skin twitch. The number of pinpricks that failed to elicit a response was then recorded at each time interval (Table V).

Comparative Pharmacokinetics of Coumarin Anticoagulants XLI: Effect of Phenobarbital on Systemic Availability of Orally Administered Dicumarol in Rats

JAMES W. CROW, MILO GIBALDI, and GERHARD LEVY ×

Received December 8, 1978, from the *Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Amherst, NY 14260.* Accepted for publication January 26, 1979.

Abstract □ The purpose of this investigation was to determine the effect of phenobarbital on the systemic availability of orally administered dicumarol in rats. Adult male Sprague–Dawley rats, matched for dicumarol free fraction in serum, received either phenobarbital sodium, 75 mg/kg, or saline solution, orally or intravenously, daily for 7 days. On Day 6, they also received ^{14}C-dicumarol, 2 mg/kg iv, and unlabeled dicumarol, 50 mg/kg po, in aqueous suspension. Venous blood samples were obtained serially over 32 hr through an indwelling cannula. Systemic dicumarol availability was determined from the dose-normalized ratio of areas under the plasma concentration–time curves. Phenobarbital treatment almost doubled the total clearance of dicumarol and the intrinsic clearance of free dicumarol, with no significant difference between the inductive effects of oral and intravenous doses of phenobarbital. Systemic dicumarol availability in control rats (mean ± *SD*) was 84 ± 8% (n = 10) and 84 ± 10% (n = 6) in the oral and intravenous phenobarbital studies, respectively. The systemic dicumarol availability in phenobarbital-treated rats was appreciably lower: 48 ± 7% (n = 10) and 61 ± 12% (n = 6) for orally and intravenously treated animals, respectively. The effect of oral phenobarbital on systemic dicumarol availability was more pronounced than that of intravenous phenobarbital ($p < 0.025$). The apparent first-order absorption rate constants for the fraction of the dose available systemically were similar for control and treated animals. There was a positive correlation between systemic dicumarol availability and total dicumarol clearance in control animals ($p < 0.001$). Proper matching of control and treated animals is, therefore, important for this type of study. The rat appears to be a good model for investigating the mechanism of the inhibitory effect of phenobarbital on dicumarol absorption observed previously in humans.

Keyphrases □ Phenobarbital—effect on systemic availability of oral dicumarol, comparison of oral and intravenous doses □ Bioavailability—dicumarol in rats, effect of oral and intravenous phenobarbital □ Dicumarol—bioavailability, effect of oral and intravenous phenobarbital □ Anticoagulants—dicumarol, effect of oral and intravenous phenobarbital on systemic availability

The bioavailability of orally administered dicumarol in humans is reduced by pretreatment of the subjects with an orally administered barbiturate (1). Similar effects have been observed with respect to two other poorly water-soluble drugs, griseofulvin and diethylstilbestrol. The bioavailability of orally administered griseofulvin in humans is reduced by pretreatment with orally administered phenobarbital (2). Such a reduction in griseofulvin bioavailability has also been observed in rats (3). Pretreatment with phenobarbital has been reported to decrease diethylstilbestrol absorption from the rat intestine (4).

Little is known about the mechanism of the barbiturate effect on drug absorption. A study was designed to determine the effect of orally and intravenously administered phenobarbital on GI absorption of dicumarol in rats. The results of this investigation have bearing not only on the specific interaction under study but also on the design of studies to determine the bioavailability of drugs that are subject to enzyme induction and that exhibit pronounced interindividual differences in pharmacokinetic characteristics.

EXPERIMENTAL

The studies were carried out on adult male Sprague–Dawley rats weighing 250–375 g. Groups of animals were screened for plasma free fraction values of dicumarol, using serum obtained from ~5 ml of blood withdrawn from the tail artery under light ether anesthesia. The free fraction determinations were performed in duplicate by dialyzing, to

Serum free fraction × 10^4	2.00 ± 0.96[d]	2.02 ± 0.92[d]	0.993 ± 0.107	—[e]

[a] Based on ^{14}C-dicumarol injected intravenously. [b] All data are mean ± SD, n = 6. [c] Paired two-tailed t-test. [d] Determined before phenobarbital and dicumarol administration. [e] Not analyzed statistically because animals were matched with respect to serum free fraction.

equilibrium (20–24 hr), 1-ml samples of serum with 30 μg of added ^{14}C-dicumarol[1] against an equal volume of isotonic Sorensen phosphate buffer, pH 7.4, at 37° (5). The serum and buffer phases were assayed after selective extraction (6).

Each group of 20 rats yielded, on the average, four pairs of animals, with the members of any one pair having similar serum free fraction values. One member of each pair was assigned to the control group, and the other was assigned to the treatment group. Treatment with either normal saline solution or phenobarbital was started 1–2 weeks after screening. Phenobarbital sodium, 75 mg/kg, or saline solution was administered intravenously or orally daily for 7 days. The volumes of the intravenous and oral solutions were 0.75 and 1.8 ml/kg, respectively. Rats that received intravenous treatments had the solutions injected through a right femoral vein catheter exteriorized at the back of the neck, which was implanted 1 day before the treatment period. On the 5th day of the treatment period, the right external jugular vein was cannulated (7) to facilitate blood withdrawal, and the rats were placed in individual metabolism cages in a room maintained at 21°. Food, but not water, was withdrawn for 24 hr, starting that evening at about 9 pm.

On the 6th day at about 9 am, the animals received an intravenous injection of ^{14}C-dicumarol (2 mg/kg in Sorensen buffer solution containing 1.3 mg/ml) and an oral dose of dicumarol[2], 50 mg/kg in aqueous suspension, by gastric tube. On the day of dicumarol administration, the daily phenobarbital dose was given immediately after the anticoagulant.

Dicumarol suspensions were prepared with 0.25% aqueous methylcellulose[3] solution. The solution was made by sprinkling the suspending agent on the water, refrigerating, and gently stirring the cold solution with a glass rod. Dicumarol was incorporated on the day of dosing by making a paste with a small volume of the solution and then adding the remaining solution. This was done with a spatula in a beaker, and care was taken not to grind the dicumarol particles. Pairs of control and phenobarbital-treated animals always received the same lot of dicumarol suspension.

Blood samples (0.5 ml) were obtained from the intravenous cannula at about 0.5, 2, 4, 6, 8, 10, 14, 16, 18, 24, 28, and 36 hr and were transferred to heparinized micro-blood collecting tubes. These tubes were centrifuged, and duplicate 0.1-ml plasma samples were collected and quick frozen pending assay.

Plasma was assayed simultaneously for radiolabeled and nonlabeled dicumarol (6, 8). Duplicate 0.1-ml plasma portions were adjusted to pH 3.1 and extracted into heptane. One portion of the extract was added to scintillation fluid and counted. The other portion was extracted into sodium hydroxide solution, which was assayed spectrophotometrically. The concentration of unlabeled dicumarol was determined by subtracting the concentration of radiolabeled drug, determined by scintillation spectrometry, from the concentration determined by spectrophotometry.

Pharmacokinetic constants were obtained in the usual manner (5, 9, 10) from the ^{14}C-dicumarol (intravenous) concentrations in plasma. Intrinsic clearance of free drug was calculated by dividing total clearance by the serum free fraction of dicumarol. The area under the nonlabeled (orally administered) dicumarol plasma concentration–time curve (AUC) was obtained by the trapezoidal method (11). The area beyond the last concentration point was obtained by two methods: (a) extrapolating the apparently exponential concentration decay phase to zero concentration (Method I), and (b) dividing the last concentration by the β value obtained concomitantly in the same animal from the plasma ^{14}C-dicumarol concentrations (Method II). Systemic availability was calculated by dividing AUC_{oral} by AUC_{iv} after multiplying the latter by the oral/intravenous dose ratio. The cumulative fraction of the oral dose absorbed as a function of time was determined by a literature method (12) modified such that the denominator was $\beta \cdot AUC_{iv}$ (oral dose/intravenous dose).

RESULTS

Initial screening of a large group of rats yielded 17 pairs with similar dicumarol serum free fraction values in any given pair. Eleven pairs were assigned to the experiment with orally administered phenobarbital, and the other six pairs were assigned to the experiment with intravenous phenobarbital. One member of the 11-pair group was lost during the study, so the reported results for the experiment with orally administered phenobarbital are based on 10 pairs of animals.

The serum free fraction values for the group of 10 pairs ranged from 7.24×10^{-5} to 4.40×10^{-4}, and the correlation coefficient between free fraction values for members of each pair was 0.99 ($p < 0.001$). The range of serum free fraction values in the group of six pairs was 8.08×10^{-5}–3.39×10^{-4}, with a correlation coefficient of 0.96 ($p < 0.001$). In view of the excellent match of serum free fraction values in any one pair and the consequent similarity of dicumarol total clearance within each pair [total clearance of dicumarol is proportional to the drug's free fraction in serum (13)], statistical analyses of observed differences in pharmacokinetic parameters due to phenobarbital treatment were performed by paired t-test.

Figures 1 and 2 show typical results obtained when ^{14}C-dicumarol was injected intravenously and unlabeled dicumarol in an aqueous suspension was administered orally to control and phenobarbital-treated rats. Prolonged absorption was often evident in both control and treated animals during the entire experimental period (*i.e.*, for more than 30 hr), as reflected by the difference in the log concentration *versus* time slopes of ^{14}C-dicumarol and unlabeled drug in plasma.

Pharmacokinetic constants for dicumarol disposition were determined from plasma concentrations of ^{14}C-dicumarol following intravenous injection of that drug (Tables I and II). Phenobarbital caused approxi-

mately twofold increases in total clearance, β, and in intrinsic clearance but had no significant effect on the apparent distribution volume. There was no statistically significant difference between the total and intrinsic clearance ratios, control/phenobarbital, of dicumarol in the oral and intravenous phenobarbital studies. Thus, the enzyme inductive effect of intravenous and oral phenobarbital was of similar magnitude.

Figure 3 shows the average time course of dicumarol absorption by control rats and by rats pretreated orally with phenobarbital. The individual dicumarol systemic availability data obtained in that experiment are listed in Table III. Calculation of the *AUC* of unlabeled plasma dicumarol was complicated by prolonged absorption. Two methods were used for the extrapolation of the plasma concentration *versus* time curve from the last assayed concentration (36 hr) to infinity. Method I involved the extrapolation of the apparently exponential terminal concentration decay phase. This implied that absorption was continuing in a predictable manner until the dicumarol concentration approached zero. Method II involved extrapolation of postexperimental plasma concentrations such that these concentrations declined at the same relative rate as the post-

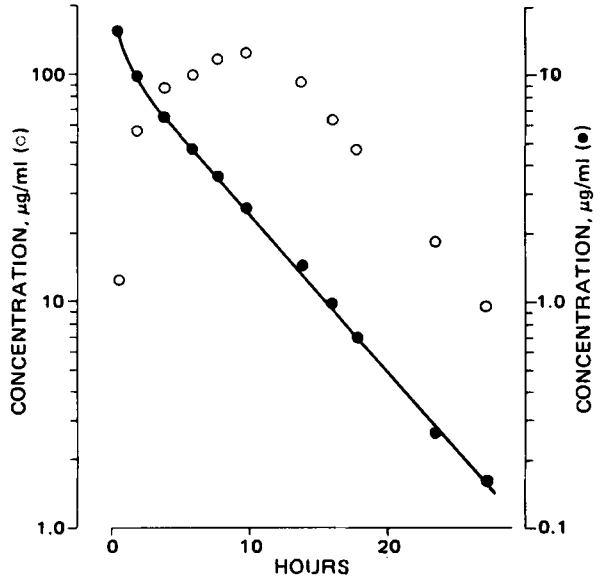

Figure 1—*Plasma dicumarol concentrations as a function of time after simultaneous administration of 50 mg/kg po (○) and 2 mg/kg iv (●) to a control rat. ^{14}C-Labeled drug was used for the intravenous injection.*

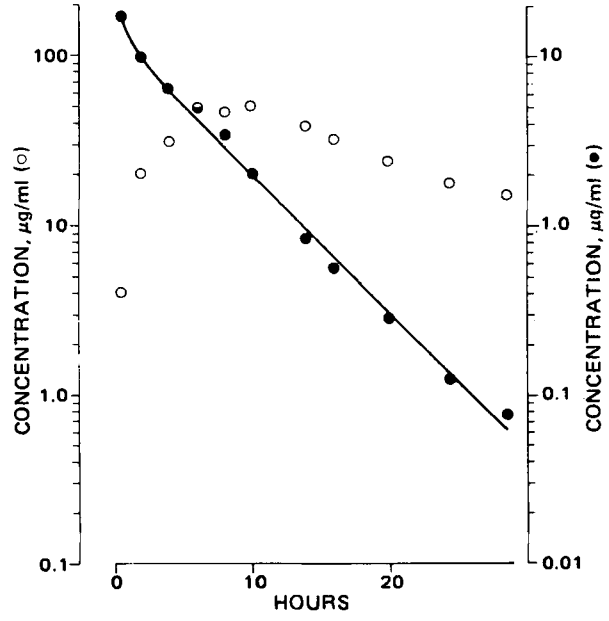

Figure 2—*Plasma dicumarol concentrations as a function of time after simultaneous administration of 50 mg/kg po (○) and 2 mg/kg iv (●) to a rat treated with phenobarbital sodium, 75 mg/kg/day iv, beginning 5 days before dicumarol administration. ^{14}C-Labeled drug was used for the intravenous injection.*

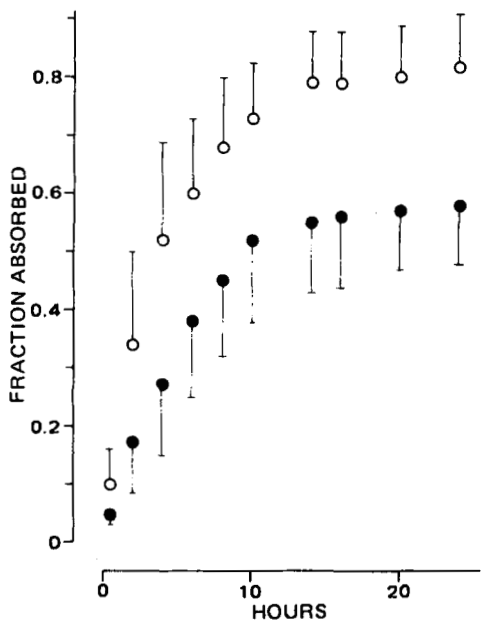

Figure 5—*Time course of dicumarol absorption after administration of 50 mg/kg po to control rats (○) and to rats treated with phenobarbital sodium, 75 mg/kg/day, iv beginning 5 days before dicumarol administration (●). Points are means ± SD (in one direction) of six animals each.*

distribution concentrations of intravenously injected ^{14}C-dicumarol. As evident from Table III, the results from the two methods were virtually identical.

Oral phenobarbital treatment reduced the absorption of orally administered dicumarol from 84% (control animals) to 48% on the average. While phenobarbital treatment reduced the amount of dicumarol absorbed, it had little or no effect on absorption kinetics. The drug was absorbed by apparent first-order kinetics, and the absorption rate constant *for the amount absorbed* apparently was not affected by phenobarbital (Fig. 4).

Figure 5 shows the time course of dicumarol absorption in control rats and in rats treated with intravenous phenobarbital. Individual systemic availability data for this experiment are listed in Table IV. Like the control animals for the oral phenobarbital experiment, the intravenous controls absorbed 84% of the oral dicumarol dose on the average. Intravenous phenobarbital reduced the extent of absorption to 61% of the dose, *i.e.*, to a lesser degree than the 48% average following oral phenobarbital. This difference is statistically significant ($p < 0.005$). Again, phenobarbital treatment had no apparent effect on the dicumarol absorption kinetics (Fig. 6).

Additional examination of the data revealed a statistically significant positive correlation ($r = 0.76$; $p < 0.001$) between the systemic availability and the total dicumarol clearance in control animals but not in phenobarbital-treated animals (Fig. 7).

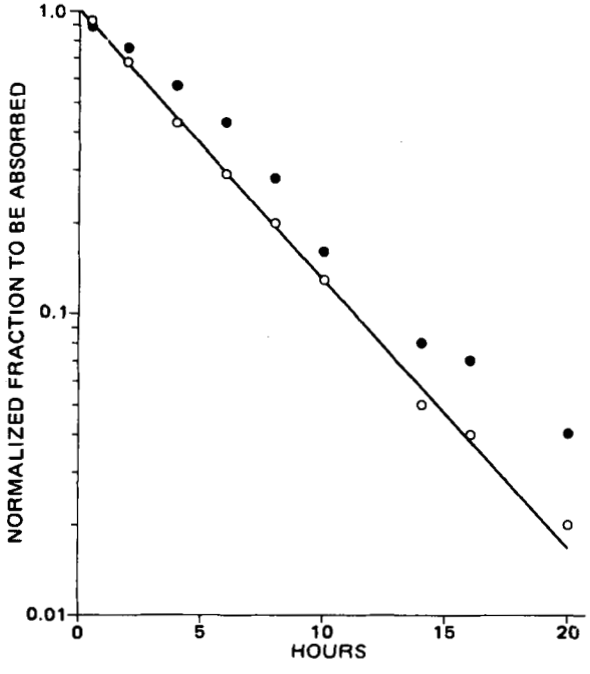

Figure 4—*Apparent first-order dicumarol absorption kinetics in 10 control (○) and 10 oral phenobarbital-treated rats (●). Plotted on the ordinate is the fraction of the total amount of dicumarol eventually absorbed that is remaining to be absorbed at various times after a 50-mg/kg po dose.*

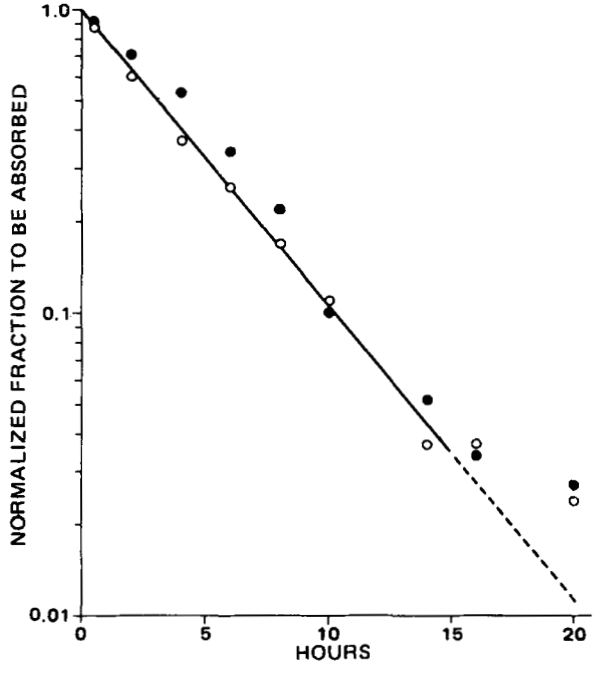

Figure 6—*Apparent first-order dicumarol absorption kinetics in six control (○) and six intravenous phenobarbital-treated rats (●). See Fig. 4 for further explanation.*

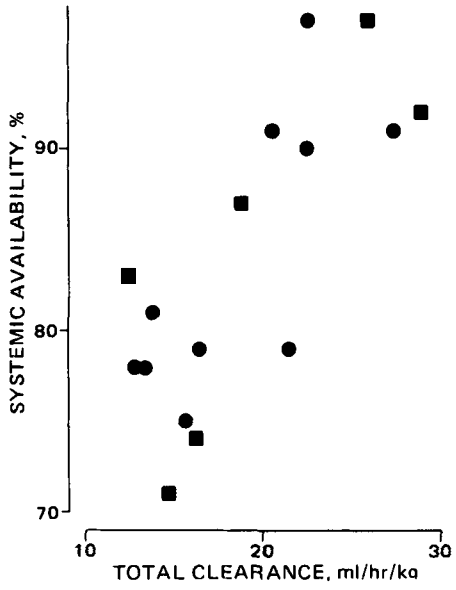

Figure 7—*Relationship between total clearance of intravenous dicumarol and systemic availability of oral dicumarol in 16 rats. Ten rats were control animals in the oral phenobarbital study (●), and six rats were control animals in the intravenous phenobarbital study (■). Correlation coefficient = 0.76, p < 0.001.*

DISCUSSION

Assessment of the effect of phenobarbital on the systemic availability of orally administered dicumarol requires consideration of numerous experimental design variables. There are pronounced interindividual differences in dicumarol pharmacokinetics in rats (5, 14) and humans (15). Phenobarbital is an enzyme inducer known to enhance dicumarol elimination (16). This enzyme induction may be prolonged, making crossover studies in rats difficult if not impossible. In addition, the results of the present investigation reveal that the systemic dicumarol availability in control rats increases with increasing total clearance. The reason for this correlation is not known.

To deal with these complicating factors, the systemic availability of orally administered dicumarol was determined by simultaneous administration of unlabeled dicumarol orally and ^{14}C-dicumarol intravenously as an "internal standard." Since crossover studies could not be performed, the control and phenobarbital-treated groups were matched with respect to their serum free fraction values of dicumarol. It was found previously that serum protein binding is the major determinant of interindividual differences in dicumarol elimination by rats (13).

A problem encountered in the pharmacokinetic assessment of dicumarol systemic availability was the very prolonged drug absorption, which had been observed also in humans (1). This prolonged absorption complicated calculations of the *AUC* values of orally administered drug. Fortunately, plasma concentrations were monitored long enough to encompass most of the *AUC*. Consequently, extrapolations based on the assumption of two different limiting cases yielded essentially identical *AUC* and systemic availability estimates.

The slow and prolonged absorption of dicumarol can cause "flip-flop" kinetics (11) in animals that eliminate the drug rather rapidly. This may have been the case in a recent study (17), which was commented upon subsequently (18, 19).

Plasma dicumarol concentrations decline triexponentially with time after rapid intravenous injection (10). However, the so-called distribution phase is so small that the apparent volume of distribution estimated by the area method and by the intercept ("single-compartment") method are almost identical [159 *versus* 166 ml/kg in a recent study (10) on 10 animals]. The data obtained in the present study were insufficient for a multiexponential characterization of the time course of dicumarol elimination (Figs. 1 and 2) because the number of blood samples during the first hours after drug administration had to be minimized to permit blood withdrawals for 36 hr without serious depletion of the blood volume. Therefore, absorption kinetics were estimated by the Wagner–Nelson method, which is based on the assumption of monoexponential elimination kinetics. The error introduced by that data treatment probably is minor.

Phenobarbital had a pronounced inductive effect on dicumarol elimination kinetics. It was established previously that phenobarbital treatment does not affect the serum protein binding of dicumarol in rats (20). There was no significant difference in the inductive effect of identical intravenous and oral phenobarbital doses.

Consistent with previous observations in humans (1), phenobarbital had a pronounced inhibitory effect on dicumarol absorption from an oral aqueous suspension in rats. The effect of oral phenobarbital was somewhat greater than that of intravenous phenobarbital, perhaps due to greater exposure of gut tissue to the orally administered drug. Little or no phenobarbital is excreted as such in the bile of rats (21); thus, intravenous phenobarbital-treated animals have little or no phenobarbital in their GI tracts. Considering this fact and the absorption inhibition by intravenous phenobarbital, it is our opinion that the inhibition of dicumarol absorption is unlikely to be the result of a direct physicochemical interaction between dicumarol and phenobarbital.

An "hepatic first-pass" effect on dicumarol in the rat can be excluded (16). However, the possibility must be considered that phenobarbital caused induction of dicumarol metabolizing enzyme systems in the gut wall. The results obtained in the present study are consistent with dissolution rate-limited absorption and subsequent partial biotransformation of some absorbed drug as it passes through the intestinal wall. However, studies in humans have shown that the amount of unmetabolized dicumarol found in the stool after oral administration of the anticoagulant increased following treatment with a barbiturate (1). It cannot be excluded, in our view, that some of the drug found in the stool of humans was derived from the hydrolysis of a conjugate formed by, or excreted into, the intestine.

Phenobarbital treatment affects bile flow (22) and, particularly in the large doses used in this study, may affect GI motility. The role of these variables cannot be determined from the present investigation. The possible role of bile in dicumarol absorption will be examined in a subsequent report.

Short-Term Effects on *Artemia salina* of Aponin and *Gomphosphaeria aponina* in Unialgal Cultures and in Mixed Cultures with *Gymnodinium breve*

DAVID L. ENG-WILMOT * **and DEAN F. MARTIN** ˣ

Received August 19, 1977, from the *Department of Chemistry, University of South Florida, Tampa, FL 33620.* Accepted for publication January 26, 1979. *Present address: Department of Chemistry, University of Oklahoma, Norman, OK 73019.

Abstract □ Previous investigations showed that the natural marine substance aponin, produced by the blue-green alga *Gomphosphaeria aponina*, was cytolytic toward Florida's red tide organism, *Gymnodinium breve*. As part of a study of the aponin–alga biological interactions, the effects of unialgal (*G. aponina*) and mixed cultures (*G. aponina* + *G. breve*) on the viability of *Artemia salina* were investigated. Two contrasting effects were observed in mixed cultures: survival of *A. salina* was promoted in low *G. aponina* populations, while enhanced toxicity of *G. breve* to *A. salina* occurred at higher culture populations. Unialgal *G. aponina* cultures exerted no adverse effects on *A. salina*. The apparent protective effect is thought to result from the observed change in *G. breve* morphology (motile to sessile); toxicity was the result of enhanced toxin release by cytolyzed *G. breve* cells. In dose–response studies, aponin exhibited no adverse effect on *A. salina* at concentrations (1 unit) that were deleterious to *G. breve*. However, at higher applied levels (4–6 units), mortality was substantial (>70%) after 48 hr of incubation. Probit analysis yielded an apparent LD_{50} of 2.3 units, where 1 unit was that amount required to cytolyze 50% of the *G. breve* cells (2000 cells/ml) after 20 hr of incubation.

Keyphrases □ Aponin—effect on *Artemia salina*, unialgal and mixed cultures with *Gomphosphaeria aponina* and *Gymnodinium breve*, potential biological control agent □ *Gymnodinium breve*—effect of aponin, *Gomphosphaeria aponina*, unialgal and mixed cultures, potential biological control □ *Artemia salina*—effect of aponin, bioassay method □ Biological control—*Gymnodinium breve*, effect of aponin and *Gomphosphaeria aponina* in unialgal and mixed cultures, *Artemia salina* bioassay

Interest in localized management measures for the ichthyotoxic blooms of Florida's red tide organism, *Gymnodinium breve* (an unarmored dinoflagellate), was rekindled with the isolation and partial purification of a biologically active natural marine product, aponin, from cultures of the blue-green alga, *Gomphosphaeria aponina* (1, 2). Earlier reports (3, 4) described aponin cytolysis of *G. breve* cells; presumably, this action results from either a direct lytic interaction with the cell membrane or a perturbation/inhibition of a vital cellular function, causing cell degeneration. The aponin effect on *G. breve* cells is rapid (<24 hr), irreversible, and dosage dependent. Further aponin purification is underway and should provide a better understanding of its structural, chemical, and biological properties.

BACKGROUND

Additional evidence for aponin cytolysis of *G. breve* was demonstrated in mixed culture studies with *G. aponina* (4). *G. breve* cultures incubated with various amounts of log-phase *G. aponina* cells declined linearly with the number of blue-green alga cells present after 10 days of growth. This effect was not attributed to organism–organism competition for a growth-limiting nutrient; freeze-dried *G. aponina* cells also were cytolytic toward *G. breve* cells (4). The incubation period required prior to the initiation of *G. breve* degeneration (8–10 days) and the growth response of *G. aponina* were in good agreement with the time of maximum aponin elaboration (6–8 days) and inocula size–growth rate relationships observed in unialgal cultures of the blue-green alga (5).

In contrast to the neurologic (6) and hemolytic (7) properties exhibited by components of the ichthyotoxin associated with *G. breve*, aponin has not been shown to possess any short-term (25 hr) ichthyotoxic activity when applied at high levels (about 15 units, or 7.5 times the amount required to cytolyze all *G. breve* cells) to several fish species. A 25-hr test period corresponds to 83 times the standard death time of fish exposed to *G. breve* toxin (8). An increase in the mean survival time of *Poecilia spenops* and *Mollienesia latipinna* was observed when aponin was incubated at low concentration with *G. breve* cells for 25 hr; enhanced ichthyotoxicity of *G. breve* cultures toward these species also was noted at higher aponin dosages, resulting from the anticipated *G. breve* cell degeneration and subsequent toxin release into the test vessels (2, 4).

Aponin possesses nine significant characteristics that are favorable for its use as a biocontrol agent for Florida's red tide organism, including thermal stability and slow activity loss in alkaline solutions (base labile) (3). The problems of aponin specificity and of its effects on biological systems other than *G. breve* cells have been addressed only recently. This paper considers findings on short-term effects of aponin (cytolytic factor) and *G. aponina* on *Artemia salina* (brine shrimp) in unialgal and in mixed cultures with *G. breve*.

A. salina may not be widely used in biological assays, but ample precedent exists, including the assay of ciguatera (9), *G. breve* (10), fungal toxins (11), and insecticides (12). The importance of *A. salina* in tropical food chains and its commercial value as a potential food source in shrimp and fish mari-culture (13) render *A. salina* an important organism for consideration. However, *A. salina* is more tolerant to *G. breve* toxin than are fish (10), which may mitigate against its use in some bioassays. For example, one *A. salina* (6 mg) could tolerate more than 10 times the amount of *G. breve* toxin than a 60-mg *Gambusia affinis* fish could withstand (10). Such tolerance has been attributed to medium detoxification by chemical absorption or metabolic means and would suggest that a population effect should be considered in the interpretation of bioassay results (10).

EXPERIMENTAL

Organism Source and Culture—Unialgal *G. breve*[1] cultures were maintained as axenic stock cultures in artificial sea water medium enriched with modified Wilson's B-5 supplements (14). *G. aponina*, isolated as detailed previously (1), were maintained as bacteria-free unialgal stock cultures, as described elsewhere (15). *A. salina* (mean dimensions: length = 7 ± 0.8 mm and wet weight = 2 mg) were obtained through local sources, and the stock organisms were maintained in artificial sea water.

The crustacea were nourished periodically with a few drops of Baker's yeast solution and aerated continuously (~250 ml/min). Stock cultures of the three organisms were maintained under similar salinity (34‰), pH (7.8), and temperature (24 ± 1°) conditions and under continuous illumination (approximately 2000 lux) provided by 40-w cool-white fluorescent lamps with lead shielded cathodes (16).

Organism Enumeration—Microorganism cultures were routinely sampled, and populations were enumerated with an electronic particle counter[2] using the electronic and threshold settings reported elsewhere (17). Organisms also were examined microscopically with an inverted binocular microscope.

A. salina cultures were observed and counted visually. Individual crustacean mortality was defined as the cessation of all peleopod locomotor activity for no less than 5 min.

Isolation and Bioassay of Aponin—Aponin was isolated from the

10-day-old *G. aponina* cultures using the procedure of McCoy (2). *G. aponina* cells were cultured in a large-scale (20-liter) continuous culture system (18) and were harvested by continuous centrifugation using a Szent-Gyorgi apparatus[3]. The cell-free centrifugate was extracted for 24 hr with redistilled chloroform (50 ml/liter of centrifugate). The chloroform layer was then evaporated to dryness by rotary evaporation, and the residues were redissolved in a known chloroform volume.

Cytolytic activity of the crude aponin extract was determined using a modification of the bioassay described previously (2). In triplicate, serial volumes of the crude preparation were placed in 15-ml test tubes, and the chloroform was removed in an evacuated oven (41°). Ten milliliters of well-mixed *G. breve* culture[4] were pipetted carefully into each assay tube, and the cultures were mixed gently for 1 hr. After 20 hr of incubation, the *G. breve* cells remaining were counted and viability was checked microscopically.

One (relative) unit of aponin activity was defined as that amount of material required to produce 50% mortality of *G. breve* cells, at an initial concentration of 2000 cells/ml, after 20 hr of incubation (2000 lux, 25 ± 2°).

Unialgal and Mixed Culture Studies—Six pairs of sterile culture vessels (500-ml Fleaker flasks fitted with foam stoppers and aeration ports) were prepared; one set was designated as the unialgal (U) cultures, and the other was designated as the mixed (M) cultures. Into each U flask was placed 400 ml of sterile artificial sea water (34‰) enriched with the modified B-5 supplements; 400 ml of *G. breve* culture (cell counts >1400/ml) were introduced into the M flasks. Equal volumes of log-phase *G. aponina* cell concentrate and B-5 medium were pipetted into corresponding pairs of vessels.

The final volume of each culture was adjusted to 450 ml with artificial sea water medium and then both organisms were counted. After 24 hr of incubation (constant illumination of ~2000 lux) and aeration (~6 ml/min), *A. salina* (25–30 organisms in 15 ml of medium) were introduced into each vessel. Survival of *A. salina* individuals was monitored continuously for the initial 24 hr and regularly (3–6 hr) thereafter. *G. breve* and *G. aponina* were sampled and enumerated periodically, and cell viability was observed.

Aponin Toxicity—The protocol to test the toxicity of aponin on *A. salina* was similar to the bioassay procedure described. In triplicate, serial aponin solution volumes (in chloroform) were pipetted into 50-ml test tubes. Solvent and medium controls also were prepared. After the solvent was evaporated, 35 ml of modified B-5 medium (filtered, sterilized artificial sea water, 34‰) were placed into each tube, and the solutions were mixed for 24 hr at 25°.

Following mixing, five healthy *A. salina* (in 5 ml of medium) were added gently to the cultures, which were illuminated (2000 lux) and aerated (6 ml/min) continuously. *A. salina* survival was monitored hourly for the first 12 hr and periodically (3–4 hr) thereafter. To establish dosage levels applied to the organisms, a bioassay of the same aponin preparation with *G. breve* was run concurrently.

RESULTS

Three approaches were used to assess aponin and *G. aponina* effects on *A. salina* survival: direct presentation (surviving *A. salina* as a function of time), kinetic treatment (calculation of the zero-order mortality constant, K_D, where $K_D = m$, the slope of the linear portion of the direct presentation plot), and probit transformation[5]. These approaches were used appropriately with three groups of studies.

First, preliminary unialgal (*G. aponina* + *A. salina*) studies (Fig. 1) revealed two interesting results. *A. salina* survival (adults and larvae) was promoted in the presence of *G. aponina* relative to controls (B-5 medium without *G. aponina* and mixed culture systems). A threefold (1.3–4.3×) reduction in mortality constant values, K_D, for unialgal cultures of *G. aponina* (flasks U_2–U_6) was noted relative to control values (U_1, artificial sea water only). In addition, a twofold reduction in K_D values was observed for mixed culture systems (flasks M_2–M_6) relative to *G. breve* controls (M_1, 1400 cells/ml initially). These results also were confirmed by statistically significant (*t* test, $p < 0.001$) differences in the percent brine shrimp surviving for 90 hr in unialgal (80%) *versus* mixed (30%) cultures.

No apparent increase in the mixed culture toxicity to *A. salina* was noted, as anticipated for cultures containing high initial *G. aponina* populations. However, the *G. breve* cells used were relatively old (early stationary phase). Although *G. breve* cell numbers were sufficient to cause ichthyotoxic mortality, reported as populations greater than 250,000 cells/liter (20), the toxicity of this particular culture may have been reduced by enzymatic or physicochemical toxin degradation or by reduced toxin biosynthesis during the stationary phase of culture growth (21).

In contrast, at low initial *G. aponina* concentrations, a definite protective influence was exerted, as evidenced by the reduced *A. salina* mortality constants at these levels. This result may have been due in part to feeding of the brine shrimp on *G. aponina*, as suggested from inspection of fecal remains. Microscopic examination of the mixed cultures revealed sessile *G. breve* forms in cultures M_2–M_4 after 10 days; motile forms were observed in M_1 (*G. breve* only), and a few motile cells and cell debris were observed in cultures M_5 and M_6.

A second group of unialgal and mixed culture studies confirmed the original observations with a few notable exceptions (Table I). In these studies, log-phase *G. breve* cells (3 weeks old, 1900 cells/ml initially) were used. Enhanced *A. salina* mortality rates were observed in mixed cultures with high initial *G. aponina* populations, resulting from the expected cytolytic action exerted on *G. breve* cells. Furthermore, increased *A. salina* survival was noted at low initial *G. aponina* concentrations (cultures M_2 and M_3).

Aeration had no adverse effect on *G. breve* (viability or morphology), as evidenced by an increase in cell counts and size distributions. However, sessile *G. breve* forms were noted only in the latter mentioned cultures; cell debris and a few motile forms were found in M_4–M_6, and motile cells were observed in M_1. These differences in morphology also were reflected in culture population size distributions. Motile cells had morphologies as described previously (22), with cell volumes ranging from 3608 to 6220 μm^3, while sessile forms similar to those described previously (23) had volumes of 2240–4168 μm^3.

No significant deleterious short-term effect of unialgal *G. aponina* cultures on *A. salina* viability was found; *G. aponina* promoted brine shrimp survival, although the mortality rate increased slightly at intermediate initial cell populations. In addition, *G. aponina* cultures exerted no obvious effect on larval maturation or viability. Hatchlings were observed in the unialgal cultures and survived the duration of the experiment. In the mixed cultures, however, larvae did not persist for more than 3–4 days after hatching. Death of *A. salina* individuals in cultures containing *G. breve* followed a period of confused hyperactivity, disorientation, and contortions (curling) (10). These symptoms were not noted in the unialgal *G. aponia* cultures, where more subtle signs of death were

[3] Centrifugation was carried out at 12,000×*g* in a SS-3 centrifuge (DuPont-Sorvall); the flow rate was 100 ml/min.

[4] A stock culture was swirled for 30 min at 120 rpm on a G-22 Gyrotory shaker bath (New Brunswick Scientific).

[5] The probit transformation converts a sigmoidal relationship (percent killed *versus* dose) to a linear one (probits *versus* $\log_e$ dose); a probit of 5 corresponds to 50% killed (19).

[a] One aponin unit (relative) is defined as that amount required to cause 50% mortality in *G. breve* culture of 2000 cells/ml: units = 2 × fraction cells killed × [cells per milliliter used/(2000 cells/ml)]. [b] Estimation based on volumetric dilution.

noted: a slow, prolonged loss of motor-related activity associated with the peleopods, which ceased at death.

A third group of studies, involving crude aponin and *A. salina* (Table II), revealed two significant results. First, aponin concentrations (up to 0.8 unit of aponin) had little adverse effect on either adults or larvae, at least as indicated by the mortality constant, K_D. Second, higher concentrations exhibited adverse effects. For example, the K_D for 1.6 units was 72% greater than the value for 0.8 unit, and the time for 100% mortality decreased by a similar amount (82%).

Little or no aponin effect on *A. salina* was noted at concentrations less than 1 unit, as compared with control organisms (artificial sea water enriched with the B-5 supplements, and chloroform), which survived without loss of any individuals up to 60 hr. *A. salina* mortality at higher aponin levels (4 and 6 units) was observed within 24 hr. Probit analysis performed on percent *A. salina* killed after 48 hr yielded a linear relation and gave an apparent aponin LD_{50} for *A. salina* of 2.3 units (Fig. 2). Larvae survived the duration of the experiment (96 hr), except at the higher doses (4 and 6 units) where none survived. Aponin produced signs of death similar to those described for *G. aponina*.

DISCUSSION

The present study of the short-term effect on *A. salina* viability of the cytolytic factor aponin and of *G. aponina* in unialgal and mixed cultures with the toxic dinoflagellate *G. breve* suggested the following:

1. Although relatively high aponin concentrations accelerated brine shrimp (*A. salina*) mortality, these concentrations were at or beyond those levels required to cause complete cytolysis of *G. breve* cells. In addition, test conditions were unrealistically stressful in the sense of being static.

2. In unialgal cultures, the crustacea (adults and larvae) were relatively unaffected by the presence of, or variations in, *G. aponina* populations. In fact, *G. aponina* enhanced the *A. salina* viability, presumably due to grazing, as compared to control cultures.

3. In mixed cultures with *G. breve*, *G. aponina* exerted two contrasting effects on *A. salina* viability. At high blue-green alga concentrations, adult and larval *A. salina* mortality was accelerated, at rates comparable to or greater than the mortality rates of *G. breve* cultures. In contrast, at lower *G. aponina* populations, mortality was reduced.

The noted toxicity to *A. salina* of mixed *G. breve* cultures incubated with large numbers of *G. aponina* is attributed to the additional endotoxin released from cytolyzed *G. breve* cells. Similar enhancements of *G. breve* toxicity were reported for two fish species when incubated with large doses (15–30 units) of aponin (2, 4). However, the apparent protective effect (increased survival) exerted by *G. aponina* toward *A. salina* when incubated in low populations with the dinoflagellate is more complex and not well defined. *A. salina* grazing on the blue-green algae was observed and would account for the decline in mortality rates of indi-

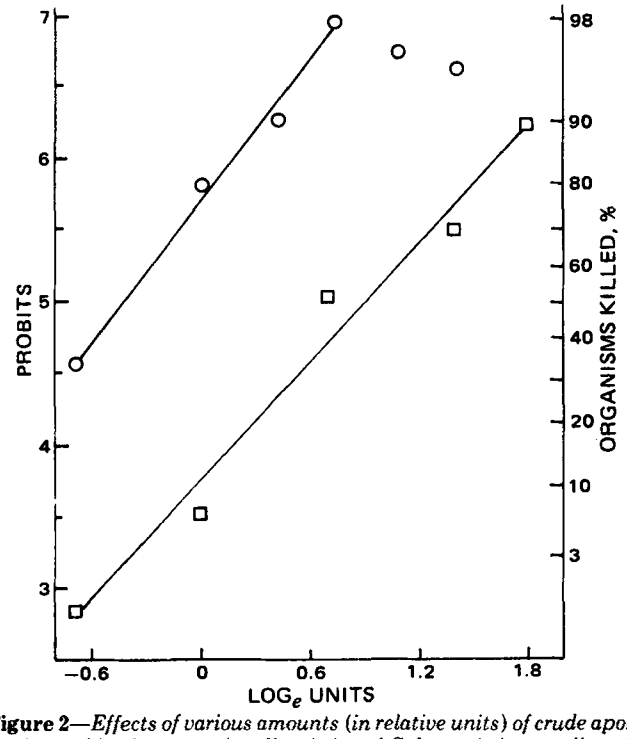

Figure 2—*Effects of various amounts (in relative units) of crude aponin on the probit of percent* A. salina (○) *and* G. breve (□) *mortality after 48 and 20 hr of incubation, respectively. Corresponding percent killed is given.*

viduals observed in unialgal cultures compared to controls. Feeding in mixed cultures also occurred, although ingestions of *G. breve* cells would enhance mortality of *A. salina* individuals, as was observed when compared with unialgal systems. However, feeding might not be directly responsible for the protective effect inasmuch as increases in the survival times of two fish species were noted when *G. breve* cells were incubated with small amounts (<1 unit) of aponin (4).

The appearance of sessile *G. breve* forms in certain mixed cultures would indicate that their presence might be related to the increased *A. salina* survival. Little is known about the nature and toxicity of the sessile or "resting" *G. breve* stage. In laboratory studies, high light intensities and spurious radiation from fluorescent lamps (16), as well as agitation and swirling (23), will initiate their formation. Agitation (aeration and periodic swirling) had no effect on *G. breve* viability or morphology in these experiments. Moreover, the fluorescent lamp cathodes were shielded, and illumination intensities were considerably less (2000 lux) than those thought to initiate sessile formation [10,000 lux (12)].

If such subtle external perturbations as those mentioned induce sessile formation, then other phenomena might also initiate such a change. One factor to consider is competition between organisms for a vital nutrient such as iron, which would result in rapid growth and dominance of one species (15). Equally important is biochemical "conditioning" of the medium by elaborated substances of one organism that are deleterious to the other. At low *G. aponina* populations, sufficient aponin may not be present to cause cytolysis, but perhaps enough is present to initiate a change in *G. breve* morphology. If, indeed, the *G. breve* sessile phase is a protective one or an intermediate of the encysted form, then it is reasonable that toxin release by *G. breve* would be reduced. Recent reports (24) demonstrated that benthic cysts of a New England red tide organism, *Gonyaulax tameranesis*, were highly toxic to shellfish and crustacea. However, preliminary fish assays (5) indicated that in laboratory cultures the sessile *G. breve* form exhibited less toxicity to *Gambusia affinis* than did motile organisms of the same age and concentration.

CONCLUSION

The cytolytic factor, aponin, did not adversely affect or significantly increase the mortality of adult and larval *A. salina* incubated at aponin concentrations (1 unit) that cause *G. breve* cytolysis. However, at application levels (4–6 units) considerably higher than those that might realistically be used for red tide control, >70% mortality was observed after 48 hr.

In addition, two contrasting effects on *A. salina* were observed in mixed cultures of the dinoflagellate and the blue-green alga, *G. aponina:* (*a*) survival was promoted at low *G. aponina* populations, a result of the presence of sessile *G. breve* forms; and (*b*) enhanced mortality was observed at high *G. aponina* populations, caused by toxin released from cytolyzed *G. breve* cells. Unialgal *G. aponina* cultures exerted no adverse effect on adult and larval *A. salina*, as compared to controls.

Despite the obvious need for an environmentally and economically practical control measure for the red tide (25), it is too early to judge the utility of aponin without additional scrutiny of its broad biological implications. Nonetheless, these studies indicated its potential use as a biocontrol agent.

Automated Analysis of Chlorthalidone

MARTHA M. JOHNSTON ˣ, MARC ROSENBERG, and BURDE KAMATH *

Received October 20, 1978, from the *Biochemistry and Drug Disposition Department, USV Pharmaceutical Corporation, Tuckahoe, NY 10707.* Accepted for publication January 31, 1979. *Present address: Arnar-Stone Laboratories, Mount Prospect, Ill.

Abstract □ Chlorthalidone inhibition of the enzymatic hydrolysis rate of *p*-nitrophenyl acetate by bovine erythrocyte carbonic anhydrase was used as a basis for chlorthalidone determination in plasma and urine. For urinary samples, a completely automated, continuous flow system was developed to extract the samples and perform the enzymatic reaction. Over 100 samples per day could be assayed by one person. The assay had a sensitivity of 0.5 μg/ml and thus could determine urinary concentrations after a therapeutic chlorthalidone dose. To determine plasma concentrations after a therapeutic dose, a manual extraction procedure was used in combination with a second continuous flow system for the enzymatic reaction. This system was optimized to detect the lowest chlorthalidone concentration allowed by the enzymatic inhibition constant and could detect 25 ng/ml.

Keyphrases □ Chlorthalidone—analysis, automated, plasma and urine, carbonic anhydrase inhibition, humans □ Diuretic agents—chlorthalidone, automated analysis, plasma and urine, carbonic anhydrase inhibition, humans □ Automated analysis—chlorthalidone, plasma and urine, carbonic anhydrase inhibition, humans

Previously (1), a method was described in which urinary chlorthalidone was determined by measuring the amount of inhibition of carbonic anhydrase caused by the chlorthalidone. This method was partially automated; the chlorthalidone extraction from the urine was done manually, but the inhibition measurement was automated using continuous flow equipment[1]. The present paper describes a completely automated method by which one person can analyze over 100 urinary samples per day.

Additionally, a partially automated method for plasma sample analysis is described. Since plasma chlorthalidone concentrations after a therapeutic dose (2) are lower than urinary concentrations (1), a method for plasma requires a greater sensitivity than a method for urinary samples. Neither the previous method (1) for urinary chlorthalidone nor the fully automated method described here have sufficient sensitivity for plasma analysis; however, a manual extraction procedure combined with an optimized automated system for the enzymatic reaction was sensitive enough for plasma analysis after therapeutic doses.

EXPERIMENTAL

Reagents for Automated Analysis System—The buffer was 0.1 *M* tromethamine[2], pH 8.0. The enzyme solution contained 40 mg of bovine erythrocyte carbonic anhydrase[2]/liter of buffer plus 0.1% surfactant[3]. The substrate solution was 2.0 m*M* *p*-nitrophenyl acetate[2] in polyethylene glycol 200[4]. The butanol[5] was saturated by shaking five volumes of it with two volumes of glass-distilled, deionized water. Solutions of 0.01 *N* NaOH[5] and 0.1 *N* HCl[5] were used.

Chlorthalidone Standards—A 100-μg/ml stock solution was prepared by dissolving 10.0 mg of chlorthalidone[6] in 10.0 ml of dioxane[7] and diluting to 100 ml with buffer. For urinary standards, the stock solution was diluted volumetrically with normal human urine to concentrations of 0.5, 1.0, 2.5, 4.0, 5.0, 6.0, and 7.5 μg/ml. For plasma standards, the stock solution was diluted with control plasma[8] to concentrations of 0.05, 0.10, 0.15, 0.20, and 0.25 μg/ml. The standards were extracted by the same procedures as were used for the unknown samples.

Automated Procedure for Urine Samples—Figure 1 is a diagram of the continuous flow system[9,10] for urinary chlorthalidone for extraction and analysis. Absorbance chart paper was used for the recorder. The spectrophotometer was used in the inverse mode in which decreases in absorbance are recorded as positive differences on the chart paper. In this mode, the baseline was set to zero with all reagents pumped through their respective lines and the buffer pumped through the sample line. Substrate solution was kept in an ice bath. The standard calibration of the spectrophotometer was adjusted so that a 5.0-μg/ml standard chlorthalidone sample gave a reading of 50 absorbance units.

Samples were assayed using a 40/hr cam with a 3:1 sample–wash ratio. After each 15 samples, the baseline was checked using a buffer sample, and the calibration point was checked using a 5.0-μg/ml standard. For unknown samples, the absorbance units were read directly off the chart and divided by 10 to obtain the chlorthalidone concentration. Samples beyond the linear range, >60 absorbance units, were diluted and reassayed.

Automated Procedure for Plasma Samples—The continuous flow system[9,11] in Fig. 2 was used for plasma samples because it diluted samples less and thus was able to measure lower chlorthalidone concentrations. The spectrophotometer was used in the direct mode. The baseline was adjusted to zero with the buffer pumped through the sample and enzyme lines and the other reagents pumped through their respective lines. The enzyme line was switched to the enzyme solution.

After the large increase in absorbance was recorded, indicating that the enzyme solution had traversed the entire system, the standard calibration of the spectrophotometer was adjusted so that the enzymatic baseline was between 50 and 60 relative absorbance units (*RA*) on the chart. After the enzymatic baseline was established, the sampler was started, and the inhibition of carbonic anhydrase by the samples was determined by measuring the decrease in relative absorbance (Δ*RA*). Standards were run before and after every 15 unknown samples. The chlorthalidone concentrations of the unknown samples were calculated from a standard Δ*RA versus* concentration curve.

Plasma and urine samples introduced to the carbonic anhydrase and *p*-nitrophenyl acetate reaction decreased the rate of *p*-nitrophenol formed, which decreased the absorbance at 400 nm. In the system for urine samples, these decreases were translated into positive recorder deflections by using the spectrophotometer in the inverse mode. To minimize plasma sample dilution, the spectrophotometer was used in

Table I—Chlorthalidone Standards in Plasma

Chlorthalidone Concentration, ng/ml	Δ*RA*, Mean ± *SD*[a]
0	0.2 ± 0.6
50	6.3 ± 1.3
100	11.5 ± 0.4
150	15.9 ± 0.8
200	20.7 ± 2.5
250	23.5 ± 2.0
300	28.1 ± 0.8

the direct mode in which the decreases in absorbance (ΔRA) were recorded as shown in Fig. 3.

Extraction Procedure—Plasma was prepared by centrifugation from blood containing either citrate[7] or oxalate as an anticoagulant. Plasma, 1.0 ml, was mixed with 5.0 ml of 0.04 *M* sodium tungstate[7] in 0.09 *M* HCl[5] and extracted twice with 5.0 ml of ether[5]. The ether extracts were combined, and the chlorthalidone was back-extracted with 2.0 ml of 0.1 *M* NaOH[5].

The phases were separated, and the aqueous phase was neutralized with 2.0 ml of 0.1 *M* HCl, buffered with 2.0 ml of 0.1 *M* tromethamine[2] (pH 8.0), and extracted twice with 5.0 ml of ether. The ether extracts were combined and evaporated to dryness, and the residue was dissolved in 2.0 ml of buffer.

Table II—Analysis of Clinical Urinary Samples Containing Chlorthalidone

Sample	Chlorthalidone Concentration, μg/ml: Partially Automated Method (1)	Fully Automated Method
17	6.96	6.36
25	4.97	4.93
36	3.51	3.52
44	4.50	3.95
52	5.15	5.07
63	11.76	11.70
71	6.67	6.13
78	3.22	3.52
90	13.98	13.40
98	3.92	3.57

RESULTS

Standard Curves—The response of the automated system for urine samples to a series of standard chlorthalidone concentrations in urine was linear up to 6.0 μg/ml. Between 6.0 and 10.0 μg/ml, the response was a nonlinear function of the concentration. Linear regression analysis of urine standards from 0 to 6.0 μg/ml, analyzed 16 times over 2 days, yielded a regression coefficient of $r = 0.999$ and a standard error in chlorthalidone concentration of ±0.12 μg/ml.

Figure 3 shows the response of the system for plasma samples to a series of chlorthalidone standards after extraction from plasma. A plot of ΔRA *versus* chlorthalidone concentration yielded a function that was slightly curved, a phenomenon that had been observed earlier (1). In Table I, the mean and standard deviation values are reported for a series of quadruplicate standards extracted from plasma and analyzed. The sensitivity

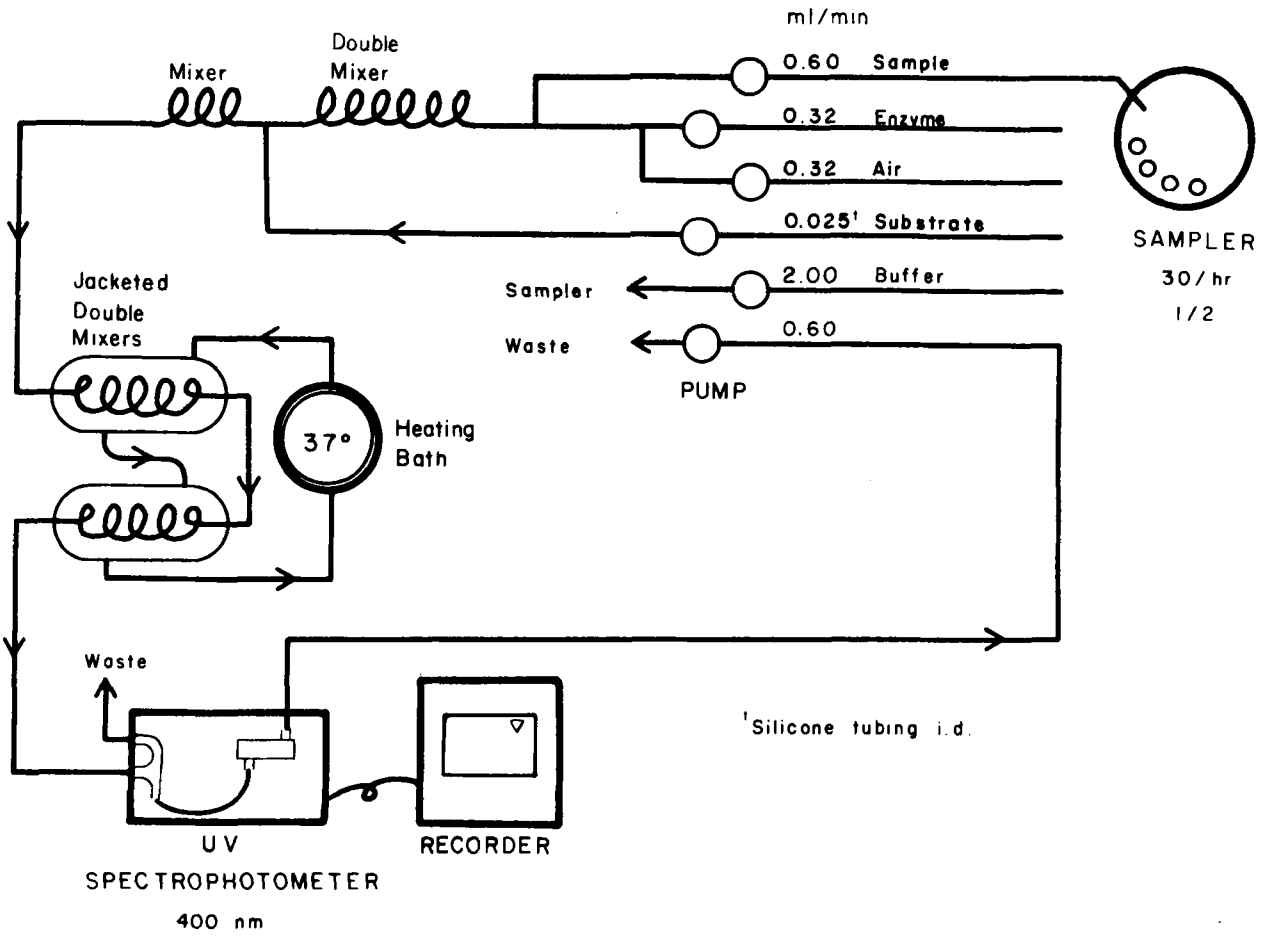

Figure 2—*Continuous flow system for plasma chlorthalidone analysis.*

of the assay was ~25 ng/ml. The extraction procedure efficiency was 50–55% throughout the concentration range.

Clinical Samples—Urinary samples from a subject who had received a therapeutic chlorthalidone dose were analyzed by the previous reported method (1) and by the fully automated procedure described here. Table II shows that both procedures yielded the same results within experimental error. Plasma samples from subjects who had received 100-mg tablets were analyzed, and the concentration–time curves were similar to those obtained by other authors (2, 3) who used GLC methods.

DISCUSSION

Using the fully automated system for urinary samples, one person could analyze 100 or more unknown samples a day. The assay specificity was discussed previously (1). Unknown samples were assayed by both methods, and the results were the same within experimental error. The method is reproducible (±0.12 μg/ml) and is sensitive enough to determine chlorthalidone concentrations after a therapeutic dose (1). Because of these factors, especially speed, this automated method appears to be ideally suited for the analysis of a large number of samples, as would be encountered in a clinical bioavailability or bioequivalency study.

An assay for plasma samples needs to be more sensitive than one for urinary samples because plasma chlorthalidone concentrations after a therapeutic dose are lower than urinary concentrations (2, 3). Since this assay depends on carbonic anhydrase inhibition by chlorthalidone, the ultimate sensitivity of the method is dependent on the inhibition constant, $K_I = 3 \times 10^{-7}\ M$ (4). Thus, a 10% decrease in enzymatic velocity (a detectable decrease) would be observed with a chlorthalidone concentration of $3.3 \times 10^{-8}\ M$ in the reaction mixture.

To obtain this maximum sensitivity, the continuous flow system shown in Fig. 2 was designed to minimize sample dilution between the sampler and the substrate addition that starts the reaction. This optimization was discussed in detail previously (5). From the inhibitor concentration at 10% inhibition ($I_{10} = 3.3 \times 10^{-8}\ M$), the chlorthalidone molecular weight (339 g/mole), the dilution in the continuous flow system (0.60 ml sample/1.15 ml total), and the extraction efficiency (0.55), an approximate sensitivity of 38 ng/ml was calculated:

$$\text{sensitivity} = \frac{339\ \text{g/mole} \times 3.3 \times 10^{-8}\ M}{(0.60/1.15) \times 0.55} = 38\ \text{ng/ml} \quad \text{(Eq. 1)}$$

The experimental limit as estimated from Table I is 25 ng/ml, probably a result of detecting less than a 10% change in enzymatic velocity. Automation of the extraction procedure for plasma samples was considered but is probably not possible since continuous flow system mechanics involve sampling only part of a desired phase, which would result in lower recovery, greater dilution, and loss of the necessary sensitivity.

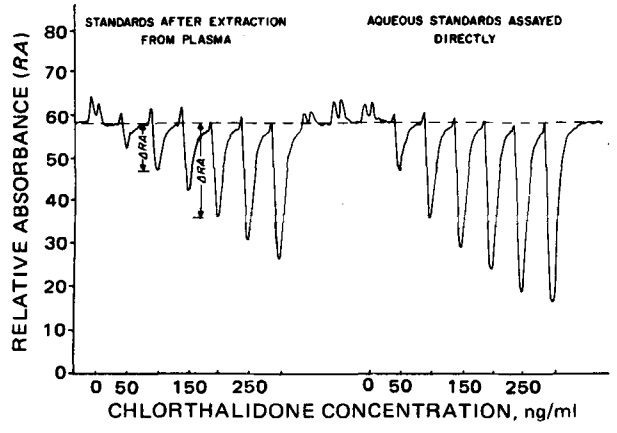

Figure 3—*Typical recording from standard samples analyzed on the continuous flow system (Fig. 2). The samples on the left were extracted from plasma, as described in the text, before introduction into the system. The samples on the right were prepared as known chlorthalidone concentrations in buffer for sampling by the system.*

For clinical studies, especially bioavailability or bioequivalency studies, collection and analysis of urine samples rather than plasma samples may be preferable (6). The distribution of chlorthalidone between plasma and erythrocytes is not instantaneous, so it is difficult to obtain a blood sample and to prepare the plasma quickly enough so that the determined chlorthalidone concentration is the same as the plasma concentration *in vivo* (7). The analysis of urinary samples can be accomplished rapidly with the fully automated system.

Progestin Permeation through Polymer Membranes IV: Mechanism of Steroid Permeation and Functional Group Contributions to Diffusion through Hydrogel Films

G. M. ZENTNER, J. R. CARDINAL ˣ, J. FEIJEN, and SUK-ZU SONG

Received September 7, 1978, from the *Department of Pharmaceutics, College of Pharmacy, University of Utah, Salt Lake City, UT 84112.* Accepted for publication January 26, 1979.

Abstract □ Hydrogel films were prepared from hydroxyethyl methacrylate, both with (Film II) and without (Film I) 5.25 mole % of ethylene glycol dimethacrylate. Permeation, diffusion, and partition coefficients for progesterone, testosterone, nandrolone, norethindrone, 17α-hydroxyprogesterone, estradiol, and hydrocortisone were determined. A solute permeation model was proposed based on the separation of a domain (B) composed of "bulk-like" water and a domain (A) composed of polymer, interfacial water, and bound water present in the films. The separate contributions from the "pore" and "solution–diffusion" mechanisms to the total permeability were calculated from the model. Steroid permeabilities through Films I and II were analyzed in accordance with this model. Permeation of Film II occurred *via* the solution–diffusion mechanism. Permeation of Film I occurred predominately by the pore mechanism with a small contribution (~20%) from the solution–diffusion mechanism. The latter contribution was dependent on the solubility of the solute within the A domains of the hydrogel film. Functional group contributions to permeation of Film II were ascribed to either steric or hydrogen bonding effects.

Keyphrases □ Progesterone—permeation through hydrogel films, models, structure–activity relationships, steroids □ Hydrogel films—progesterone permeation, structure–activity relationships, steroids, models □ Structure–activity relationships—steroid permeation through hydrogel films □ Models—steroid permeation through hydrogel films

In previous reports from this laboratory (1, 2), the permeation mechanisms of a model hydrophobic drug, progesterone, through poly(hydroxyalkyl methacrylate) films were examined. The importance of film hydration was emphasized. Similar conclusions were drawn by others (3–5) for hydrophilic solute permeation through hydrogel films. Several investigators (2, 4, 5) indicated that, depending on the hydrogel composition, either a "pore" or a "solution–diffusion" mechanism may dominate permeation. For polymers prepared from various comonomers or from hydroxyethyl methacrylate without added cross-linking agents, the pore mechanism dominates. At high concentrations of the cross-linking agent, ethylene glycol dimethacrylate and possibly tetraethylene glycol dimethacrylate, the solution–diffusion mechanism appears to dominate permeation. These results were found for both hydrophobic (2) and hydrophilic (4, 5) solutes.

These conclusions are tenuous without further investigation. One problem is the partition coefficient reported for the hydrophobic solute progesterone (2). This value, which is >100, appears to be inconsistent with a pore mechanism in which transport presumably occurs within water-filled pores or microchannels present in the film. For permeation within these channels, partition coefficients close to one are expected. Hydrophilic solutes in hydrogels generally exhibit partition coefficients close to this value (6).

For this reason, the permeation mechanism of hydrophobic solutes through hydrogel films was examined in greater detail. The permeation characteristics for several steroids that have systematic structural differences were determined in films prepared from hydroxyethyl methacrylate, both with and without 5.25 mole % of ethylene glycol dimethacrylate as a cross-linking agent. The results substantiate previous conclusions concerning the two mechanisms for solute permeation in hydrogel films, provide an explanation for the proposed pore-type permeation mechanism for solutes having high hydrogel–water partition coefficients, and demonstrate the effects of steroid structural differences on permeation rates through hydrogel films.

EXPERIMENTAL

Materials—Hydroxyethyl methacrylate[1] was a highly purified sample containing the following levels of impurities[1]: methacrylic acid, 0.06%; ethylene glycol dimethacrylate, 0.024%; and diethylene glycol methacrylate, 0.24%. Ethylene glycol dimethacrylate[2] was purified by base extraction and distillation. Azobis(methylisobutyrate) was prepared by the method of Mortimer (7).

Hydrocortisone[3], 17α-hydroxyprogesterone[3], progesterone[3], testosterone[3], nandrolone[3], estradiol[3], norethindrone[4], 6,7-^{3}H-estradiol[5], and 1,2-^{3}H-progesterone[6] were used as received. TLC analysis, with 20% (v/v) ethyl acetate in toluene and 5% (v/v) methanol in chloroform as developing reagents, indicated that all steroids were pure. In all cases, a single UV-detectable spot was observed. Radiolabeled steroids had the same R_f values as the unlabeled counterparts, with >95% of the detectable activity associated with the primary spot. The remaining radioactivity was distributed evenly throughout the remainder of the plate.

Methods—Hydrogel films were prepared by polymerization between sealed polyethylene plates at 60° for 24 hr. Azobis(methylisobutyrate) (7.84 mmoles/liter of monomer) was the initiator.

Film I was prepared from a mixture of hydroxyethyl methacrylate and 40% (v/v) deionized water. Film II was prepared from a mixture of hydroxyethyl methacrylate with 5.25 mole % ethylene glycol dimethacrylate as the cross-linking agent and 40% (v/v) ethanol as the solvent. These mixtures were homogeneous before and after polymerization. Subsequent to polymerization, the films were soaked in water (changed repeatedly) for 3–4 weeks prior to use.

The diffusion experiments were performed at room temperature (24 ± 1°) in an all-glass cell described previously (1). An aqueous solution of 17α-hydroxyprogesterone, progesterone, testosterone, nandrolone, norethindrone, estradiol (~5 μg/ml), or hydrocortisone (~250 μg/ml) was placed into one chamber. The second chamber was filled with deionized water. The concentration increase was followed in the initially steroid-free chamber by UV spectrophotometry[7] or by liquid scintillation counting of the radiolabeled compounds using scintillation fluid[8] and a scintillation counter[9].

Partition coefficients, defined as the ratio of the concentrations in the film and in the bulk aqueous phase, were determined by a solution depletion technique (1) in which 50 ml of a steroid solution was allowed to equilibrate with a known volume of polymer. Adsorption of the steroids onto glass was checked and was not a problem. The steroid equilibrium concentration in the bulk aqueous solutions was obtained as described previously.

Film thicknesses (~0.03 cm) were measured on the water-swollen films using a lightwave micrometer[10].

RESULTS AND DISCUSSION

Permeability and diffusion coefficients for steroids in hydrogel films were calculated using:

$$\ln\left\{\frac{C_0V - (2V + K_dV_m)C_4}{C_0V - (2V + K_dV_m)C_2}\right\} = -\frac{2AU}{Vl}(t_{ss} - t_{oss}) \qquad \text{(Eq. 1)}$$

where:

C_0 = initial drug concentration in Compartment I
V = compartment volumes (176 ml)
K_d = partition coefficient
V_m = membrane volume
C_2 = concentration in Compartment II at the onset of steady state (t_{oss})
C_4 = concentration in Compartment II at the time t_{ss}
A = membrane area (14.2 cm^2)
l = wet membrane thickness
$U = DK_d$
D = diffusion coefficient
t_{ss} = any time during steady state

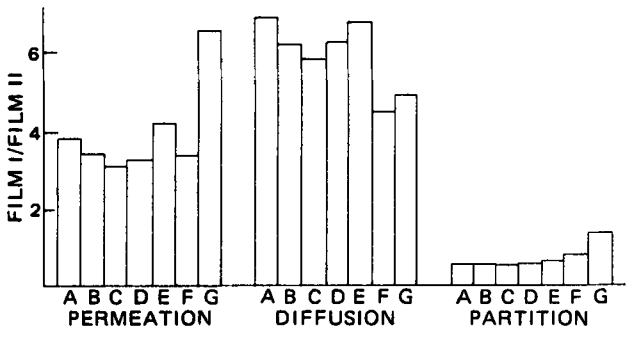

Figure 1—*Relative comparison of steroid permeation, diffusion, and partition coefficients in Films I and II. Key: A, testosterone; B, norethindrone; C, nandrolone; D, progesterone; E, 17α-hydroxyprogesterone; F, estradiol; and G, hydrocortisone.*

The values of U, D, and K_d for the various steroids in Films I and II are given in Table I. The relative values for each steroid in these films are shown in Fig. 1. Except for hydrocortisone and possibly estradiol, the relative permeation factors for all steroids were the same. This finding suggests that similar mechanisms control the permeation of these solutes.

Equation 1 differs somewhat from that used previously (Eq. A15, *Appendix*) (1, 2, 8). An assumption implicit in the previous work is that the amount of drug within the polymer film during steady-state diffusion is small (9). However, the K_d values in Tables I and II suggest that, during steady-state diffusion, a significant portion of the initial drug load added to Compartment I of the diffusion cell will be associated with the polymer film. In effect, this association of drug with the film reduces the concentration gradient between the aqueous compartments and results in permeability coefficients that are too low if the amount of drug in the film is assumed to be small. The magnitude of the effect depends on K_d. For example, with progesterone, which has a K_d of 129, Eq. 1 yields a value of 8.44×10^{-7} cm^2/sec for the permeability in polyhydroxyethyl methacrylate, whereas the equation used in previous work (Eq. A15, *Appendix*) provides a value of 5.62×10^{-7} cm^2/sec for progesterone in the same film. The difference in the calculated permeability coefficients for hydrocortisone, $K_d = 27$, is much less for the same film, *i.e.*, 2.39×10^{-7} cm^2/sec *versus* 2.32×10^{-7} cm^2/sec.

Equation 1 is derived on the assumptions that the drug partitions into the film in accordance with its equilibrium partition coefficient and that the partition coefficient is concentration independent. Experiments with several steroids over a wide concentration range suggest that this assumption is valid for the hydrogels. The derivation of Eq. 1 from Fick's first law is given in the *Appendix*.

These results raise questions with respect to the validity of conclusions reached in previous work (1, 2, 8) on the effects of various factors on the permeability of hydrogel films to progesterone. The conclusions reached depended primarily on relative changes in permeability and/or diffusion coefficients. All previously reported values of U and D were recalculated according to the methods outlined in the present paper. The new values are consistent with the conclusions stated in those papers.

Steroid Permeation through Hydrogel Films—Solute permeation through polymeric films is normally described in terms of either a "pore" or a "solution-diffusion" mechanism. In the pore mechanism, transport occurs *via* diffusion through solvent present within microchannels or pores. The K_d values are usually less than one and reflect solute distribution between the membrane solvent and bulk solvent. Solution-diffusion transport occurs *via* dissolution and diffusion of the solute within the segments making up the polymer matrix. The K_d values for this mechanism vary widely but usually are much greater than one.

For progesterone diffusion through hydrogel films, previous work (2) indicated that the solution-diffusion mechanism dominates in Film II whereas the pore mechanism dominates in Film I. These conclusions are based on an analysis of permeation data according to methods outlined by other investigators (4, 5).

The data in Table I indicate that the K_d values for both Films I and II are much greater than one. These high K_d values for Film I appear to be inconsistent with the pore mechanism for solute transport. The possibility remains, however, that K_d is dominated by the high solute solubility within the hydrophobic regions of the hydrogel (10) whereas permeation is dominated by diffusion within "fluctuating pores" (11) or microchannels within this film.

Separation of pore and solution-diffusion contributions to total per-

meation is necessary to determine the dominant mechanism in Film I. The following discussion concerns the development of a model for diffusion within hydrogels that will provide for the calculation of these separate contributions from the data in Table I. This model is based on the physical–chemical properties of hydrogels and, in particular, on the water distribution within these films.

Macroscopically, hydrogel films are homogeneous single-phase systems having water and polymer as components. Microscopically, the polymer and water can be visualized as separate dispersed phases.

Jhon and Andrade (12) hypothesized that water can exist in at least three different environments within synthetic hydrogel films in a fashion analogous to that proposed (13) for biological membranes. These environments include hydration or bound water, interfacial water, and normal or "bulk-like" water. The bound water is strongly associated with the polymer, probably as water hydrating the hydrophilic polymer groups. Interfacial water is not well defined but may be associated with hydrophobic interactions between the polymer segments. Bulk-like water is similar to bulk water in aqueous solutions.

Sung (14) defined the concentrations of these various water types within poly(hydroxyethyl methacrylate) films, prepared with and without 1 mole % of ethylene glycol dimethacrylate. The amount of bulk-like water is highly dependent on the total hydrogel water content. Films cross-linked with ethylene glycol dimethacrylate have a lower percentage of bulk-like water than hydrogels prepared without cross-linker at equal total water contents. Interpolation of Sung's data is possible with the assumption that the distribution of water into bound, interfacial, and bulk-like fractions is similar in a 1-mole % ethylene glycol dimethacrylate cross-linked gel containing the same weight fraction of total water (nonequilibrium value) as a 5.25-mole % cross-linked gel that is equilibrated with water.

The equilibrium weight fraction of water in Film II is 0.35. A 1-mole % cross-linked gel contains less than 5 volume % of bulk-like water at this weight fraction. From this value, it may be inferred that the volume percent of bulk-like water in Film II approaches zero. A value of 22.8 volume % of bulk-like water is obtained for hydrogel films prepared without cross-linker having a total water weight fraction of 0.43 (Film I).

These results, together with other data (2–6) on solute permeation through hydrogel films, provide the basis for the model of solute permeation through these films.

In this model, the hydrogel films prepared without cross-linker are composed of two domains, A and B. Domain A is composed of polymer segments that associate by hydrophobic interactions and are surrounded by bound and interfacial water. Domain B is bulk-like water and forms the fluctuating pores described previously (11). Increasing the mole percent of cross-linker increases the amount of A and reduces the amount of B. A hydrogel such as Film II, having no bulk-like water, is assumed to be composed entirely of A-type domains. Although the relative amounts of Domains A and B change as the mole percent of cross-linker is changed, the inherent permeabilities of the domains are assumed to remain constant. Therefore, the total permeability of a hydrogel film is a summation of the individual permeabilities of Domains A and B and varies in accordance with the volume percent of bulk-like water present.

Transport in the hydrogel A domains occurs through the bound and interfacial water, through the hydrophobic regions, or through some combination of these. Irrespective of the specific transport region, permeation in the A regions occurs by the solution–diffusion mechanism as previously defined. The K_d values for transport in the A regions vary widely, depending on the solute solubility characteristics.

Transport in the B domains occurs by simple diffusion in bulk-like water. The K_d values must be precisely one since the solute is simply partitioning from bulk water into hydrogel domains of bulk-like water.

Film II, having no bulk-like water, is a diffusion barrier composed exclusively of A-type domains. As postulated in the model, solute transport occurs only by the solution–diffusion mechanism in such a film.

Several lines of evidence support this contention and are consistent for both hydrophobic and hydrophilic solutes:

1. It is supported by the cited data, which indicate that films containing high cross-linker concentrations have little or no bulk-like water.

2. Past work has shown that both hydrophobic (2) and hydrophilic (4, 5) solutes exhibit limiting values for the diffusion coefficient as the cross-linking agent concentration increases. This result is inconsistent with a pore mechanism since, if this mechanism is operative, the diffusion

Table II—Model Analysis of Steroid Permeation Data

Steroid	Partial Molar Volume[a], cm³/mole	Diffusion Coefficient in Water, $D_0 \times 10^6$ cm²/sec	Diffusion Coefficient in Bulk-Like Water of Film I, $D_B \times 10^7$ cm²/sec	ln (D_B/D_0)	D_B/P_T
Testosterone	237.4	6.04	7.20	−2.13	0.80

[a] Calculated from group contributions, Ref. 24.

coefficients must decrease with increasing cross-linker content due to a reduction in the average pore size as a consequence of reduced polymer chain mobility.

3. Film II was nearly impermeable to hydrophilic solutes such as inositol and sucrose (6). Since sucrose is of approximately the same molecular weight as the steroids used in the present study, its diffusion coefficient should be similar to the steroids if the pore mechanism is operative in Film II.

4. The conclusion that transport occurs by the solution-diffusion mechanism in Film II is consistent with the high partition coefficients obtained for the steroids used in the present study.

5. The disproportionately large decrease in the permeability coefficient of hydrocortisone, a relatively water-soluble steroid, in Film II compared with Film I, coupled with a lower partition coefficient in Film II than in Film I, suggests a dependence on bulk water not seen with the more hydrophobic steroids yet consistent with the pattern exhibited by the sugars.

Film I contains 22.8% of bulk-like water making up the B domains; the remainder is designated as A-type domains. Based on the proposed model and using the data in Table I, it is possible to estimate the contribution of each domain to the total permeability. Total Film I permeability can be represented as a summation of the individual domain contributions:

$$P_T = P_A + P_B \qquad \text{(Eq. 2)}$$

where:

P_T = total permeability in Film I
P_A = permeability coefficient in the A domains
P_B = permeability coefficient in the B domains

The P_A value is obtained from the relation $P_A = (\phi_A)P_T^{II}$, where P_T^{II} is the permeability coefficient of the solute in Film II and ϕ_A is the volume fraction of A-type domains in Film I. The ϕ_A value is given by $\phi_A = 1 - \phi_B$, where ϕ_B is the volume fraction of bulk-like water present in Film I (0.228).

Equation 2 may be rewritten as:

$$P_T - (\phi_A)P_T^{II} = P_B \qquad \text{(Eq. 3)}$$

The calculated P_B values represent the total permeability attributable to the pore mechanism in Film I. By definition, the partition coefficient in the B domains equals one. Therefore, P_B quantitatively equals the diffusion coefficient, D_B, using $P_B = K_d D_B$. These values are given in Table II along with the ratio D_B/P_T, which is the percent pore-type permeation in Film I. This ratio is approximately 0.77 for all of the steroids investigated except hydrocortisone, which is 0.88. This finding indicates that the pore contribution to transport in Film I is similar for the more hydrophobic steroids, with the relatively water-soluble steroid hydrocortisone permeating *via* pores to a greater extent. This result is consistent with the proposed model. The relatively high values of D_B/P_T for all steroids suggest that permeation through Film I is dominated by the pore mechanism, a result consistent with previous work (2).

The high K_d values with Film I are consistent with the model. Although permeation is dominated by the pore mechanism, Film I is composed primarily of A-type domains, which dominate the partitioning of hydrophobic solutes but make little contribution to permeability.

An implicit assumption of the model is that the A domains are similar in Films I and II. Were this strictly true, the partition coefficients, which are dominated by A-type domains, in Film I should be related to those in Film II according to the volume fraction of A-type domains present in Film I (0.772). These values are given in Table I as the ratio K_d^I/K_d^{II}. The estradiol value is in close agreement with the predicted value. However, for the other steroids, except hydrocortisone, this ratio is approximately 0.54. Thus, qualitative agreement with the predicted value is found, but the quantitative agreement is not good. This finding implies that differences exist between the A domains of Films I and II. This conclusion is expected based on the high cross-linker content in Film II. The corrections that must be made to overcome this deficiency in the model are not readily apparent.

Sufficient data were available from previous work (2) to test the model in predicting progesterone permeation in gels containing intermediate concentrations of the cross-linking agent ethylene glycol dimethacrylate. From the data of Sung (14), the volume percent of bulk-like water in a film prepared from 0.75 mole % of cross-linker is approximately 0.15. Based on this value, the permeability coefficient for progesterone in this cross-linked gel can be calculated from Eq. 3 by assuming that the total permeation arising from transport in the B regions is given by $P_B = \beta D_B$; β is defined by the ratio ϕ_B^I/ϕ_B, where ϕ_B^I is the volume fraction of bulk-like water in the cross-linked film. By using the values found in Tables I and II for P_T^{II} and D_B, 0.15 for ϕ_B^I, 0.228 for ϕ_B, and 0.85 for ϕ_A, the total permeability for a film containing 0.75 mole % cross-linker is calculated to be 6.45×10^{-7} cm²/sec. This value is in good agreement with the experimental value of 5.64×10^{-7} cm²/sec (2).

A theoretical treatment of solute permeability in hydrated polymer films was developed by Yasuda *et al.* (15). This treatment examines solute diffusion as a function of the free volume of the water–polymer system and predicts a linear correlation for plots of ln (D/D_0) *versus* the square of the cross-sectional solute radius; D is the diffusion coefficient in the polymer film and D_0 is the diffusion coefficient in bulk water. All solutes should correlate with a single straight line for a given polymer film provided the free volumes accessible to the various solutes are equal or can be resolved into equivalent contributions.

Wisniewski and Kim (6) examined the permeabilities of ions and various other hydrophilic solutes in Film I-type hydrogels. A plot of ln (D/D_0) *versus* the square of the cross-sectional radius was linear, with partition coefficients approximately equivalent to the volume fraction of bulk-like water in the film. This information suggested (6) that these solutes are restricted to permeation through the free volume of bulk-like water that is located in the B-type domains proposed in the present study. The D_B values obtained in the present study represent the diffusion coefficients of hydrophobic steroids in the bulk-like water and, therefore, should correlate with the previous data (6). The values of ln (D_B/D_0) are given in Table II. The D_0 values were calculated by a literature method (16).

Lacey and Cowsar (17) showed that the minimal cross-sectional area for steroids of the type investigated in the present study is about 36 Å². When using this value to determine the minimal cross-sectional radius, a value of −2.7 for ln (D_B/D_0) is required for an exact correlation with the data of Wisniewski and Kim (6). The data given in Table II are, in general, somewhat more positive than this value. Thus, as with the comparison with the K_d values in Films I and II discussed previously, the model presented here fits the expected value qualitatively but not quantitatively. The somewhat larger values of ln (D_B/D_0) compared to the predicted value arise from D_B values that are too large. This result indicates that the model predicts a contribution from pore-type permeation that is too large. This discrepancy probably arises from the assumption that A-type domains have similar permeation characteristics in Films I and II. The A domains are probably more permeable in Film I due to a lower cross-link density, leading to increased values for $\phi_A P_T^{II}$. Therefore, the observed deviations are in the right direction.

Table III—Functional Group Contributions to Diffusivity

Pair	Functional Group Changes		Relative Molecular Volume	Relative Diffusivity Factor
1	 Nandrolone	 Testosterone	1.09	0.78
2	 Nandrolone	 Norethindrone	1.16	0.63
3	 Progesterone	 17α-Hydroxyprogesterone	1.01	1.37
4	 Progesterone	 Hydrocortisone	1.01	1.59
5	 17α-Hydroxyprogesterone	 Hydrocortisone	1.01	1.16
6	 Progesterone	 Testosterone	0.88	2.41
7	 Nandrolone	 Estradiol	0.99	0.35

Effect of Steroid Structure on Permeation through Hydrogel Films—Previous work (1, 2, 18–23) demonstrated that hydrogels are excellent candidates for use in controlled-release drug delivery systems. The major advantages of these polymers for this purpose are biocompatibility (24, 25) and the potential for controlling permeation characteristics through modifications in the hydrogel composition. Several studies using hydrophobic (2) and hydrophilic (4, 5, 20, 21) solutes indicated that permeability coefficients can be varied by more than an order of magnitude by changing either the cross-link density or the monomer composition.

Several studies (6, 26) demonstrated effects of molecular structure on solute permeation in films prepared without added cross-linker. The importance of the solute molecular volume on the permeation characteristics has been demonstrated. However, no studies have considered the effects of molecular structure on permeability in films containing high cross-linker concentrations. Studies on the permeation characteristics of these films are of interest since intermolecular interactions between the solute and polymer segments are expected to increase and should dominate the overall permeability of these films.

For poly(dimethyl siloxane), a film in which solutes permeate by the solution-diffusion mechanism, small changes in steroidal structure can lead to variations in the diffusion coefficients of more than two orders of magnitude (17). These dramatic changes in the diffusion coefficients in the solution-diffusion-type poly(dimethyl siloxane) films are not observed with Film II, a solution-diffusion-type hydrogel. Changes in permeability coefficients are even less, indicating the importance of solute partitioning in the overall film permeation characteristics. Specific effects of solute structure on the diffusion coefficients in Film II are demonstrated more clearly by the comparisons made in Table III. In this table, relative diffusivity factors, defined as the ratio of diffusion coefficients for steroids that differ by one structural feature, have been calculated. From the results in this table, the following conclusions were obtained:

1. The addition of a C-19 angular methyl group decreases diffusivity by a small factor (0.78) due to steric hindrance (relative K_d values are independent of cross-linker content).
2. The same effect is seen on the addition of a C-17 ethynyl group, where diffusivity decreases by a factor of 0.63.
3. The addition of hydroxyl groups increases diffusivity by rather substantial factors, as seen from Comparisons 3–6 in Table III. However, the effect of the first hydroxyl group is proportionately greater than the second and third hydroxyl groups (Table III, Comparisons 3 and 5).
4. Changing the A ring of the steroid nucleus from an alicyclic (nandrolone) to an aromatic (estradiol) ring produces a decrease in diffusivity by a factor of 0.35. This decrease occurs in spite of the change from a keto to a hydroxy function at the 3-position of the steroid nucleus, which should increase diffusivity (Table III, Comparison 6).

The outlined group contributions to diffusivity should be valuable in predicting approximate diffusion coefficients for other steroids. For example, the diffusion coefficient of testosterone may be approximated as follows. Beginning with progesterone, the effect of removing the side chain at C-17 may be approximated by a factor of 1/0.63 (*i.e.*, the inverse of the effect noted for the addition of a C-17 ethynyl group to nandrolone) times a factor of 1.37 (the effect of the addition of a C-17 hydroxyl group to progesterone). The result of this calculation gives 2.42×10^{-9} cm^2/sec for the diffusion coefficient of testosterone in Film II, a result that compares favorably with the experimental value of 2.70×10^{-9} cm^2/sec.

CONCLUSIONS

Steroid permeation in poly(hydroxyethyl methacrylate) films is complex. However, to a first approximation, the total observed permeability can be separated into pore and solution-diffusion components by applying a model describing the polymer films in terms of domains. Such an analysis supports the contentions of Film I being a pore-type and Film II being a solution-diffusion-type barrier for both hydrophilic and hydrophobic solutes.

As expected from the inherent nature of solution-diffusion permeation, structural alterations in steroidal solutes affect diffusion. Decreases in molecular volume and increases in hydrogen bonding capacity increase diffusivity. By quantifying these effects for specific functional groups, it is possible to predict diffusion coefficients.

APPENDIX

When a linear concentration gradient exists within a barrier film, the instantaneous concentration gradient within the film may be expressed as:

$$-\frac{dC}{dl} = \frac{C_I' - C_{II}'}{l} \qquad \text{(Eq. A1)}$$

where C_I' and C_{II}' represent the surface concentrations of the diffusant in the membrane at the donor (I) and receptor (II) sides of the film and l represents the thickness of the film. Provided that the partition coefficient, K_d, is independent of the solute concentration, this equation may be rewritten as:

$$-\frac{dC}{dl} = \frac{K_d(C_I - C_{II})}{l} \qquad \text{(Eq. A2)}$$

where C_I and C_{II} are the donor and receptor phase concentrations, respectively. The flux of solute within the film can be described by Fick's first law as:

$$J = -D\frac{dC}{dl} = -D\frac{(C_I' - C_{II}')}{l} \qquad \text{(Eq. A3)}$$

which can be rewritten as:

$$J = \frac{DK_d}{l}(C_I - C_{II}) = \frac{U}{l}(C_I - C_{II}) \qquad \text{(Eq. A4)}$$

where the permeability $U = DK_d$.

During steady state, the flux out of Compartment I equals the flux into Compartment II, which also equals the flux within the film barrier. This may be expressed as:

$$-J = \frac{V}{A}\frac{dC_I}{dt} \qquad \text{(Eq. A5)}$$

and:

$$J = \frac{V}{A}\frac{dC_{II}}{dt} \qquad \text{(Eq. A6)}$$

where V is the compartment volume and A is the film area. Subtracting Eq. A6 from Eq. A5 and equating to Eq. A4 give:

$$\frac{d(C_I - C_{II})}{dt} = -\frac{2UA}{lV}(C_I - C_{II}) \qquad \text{(Eq. A7)}$$

Equation A7 is valid only during steady-state flux. Under these conditions, the concentrations of solute in Compartments I and II are C_1 and C_2 at t_{oss} (onset of steady state) and C_3 and C_4 at t_{ss} (any time during steady state). When using these concentrations and times for the limits of integration, Eq. A7 gives:

$$\ln\left\{\frac{C_3 - C_4}{C_1 - C_2}\right\} = \frac{-2UA}{lV}(t_{ss} - t_{oss}) \qquad \text{(Eq. A8)}$$

Steady-state mass balance gives:

$$C_0V = C_1V + C_2V + C_mV_m \qquad \text{(Eq. A9)}$$

$$C_0V = C_3V + C_4V + C_mV_m \qquad \text{(Eq. A10)}$$

where C_0 is the initial concentration in the donor phase, C_m is the solute concentration within the film, and V_m is the film volume. The film concentration may be defined as:

$$C_m = K_d\frac{(C_1 + C_2)}{2} = K_d\frac{(C_3 + C_4)}{2} \qquad \text{(Eq. A11)}$$

Substitution of Eq. A11 into Eqs. A9 and A10 and rearranging give:

$$C_1 = \frac{2}{2V + K_dV_m}\left(C_0V - C_2V - \frac{K_dC_2V_m}{2}\right) \qquad \text{(Eq. A12)}$$

and:

$$C_3 = \frac{2}{2V + K_dV_m}\left(C_0V - C_4V - \frac{K_dC_4V_m}{2}\right) \qquad \text{(Eq. A13)}$$

Substituting Eqs. A12 and A13 into Eq. A8 and rearranging give:

$$\ln\left\{\frac{C_0V - (2V + K_dV_m)C_4}{C_0V - (2V + K_dV_m)C_2}\right\} = -\frac{2UA}{lV}(t_{ss} - t_{oss}) \qquad \text{(Eq. A14)}$$

In the limit where K_d is small and t_{oss} approaches zero, C_2 also approaches zero and Eq. A14 may be written as:

$$\ln\left\{1 - \frac{2C_4}{C_0}\right\} = -\frac{2UAt}{lV} \qquad \text{(Eq. A15)}$$

Equation A15 was developed (9) for the case of quasi-steady-state diffusion in a film, assuming that the amount of solute in the film is negligible.

Simple Field Test for Marijuana

C. A. LAU-CAM ˣ and V. PIZZITOLA

Received October 30, 1978, from the *Department of Pharmaceutical Sciences, College of Pharmacy and Allied Health Professions, St. John's University, Jamaica, NY 11439.* Accepted for publication February 2, 1979.

Abstract □ A simple, rapid, sensitive, and specific field test for marijuana and its products is described. The test employs an extracting-eluting solvent and an inert adsorbent microcolumn coated with Fast Blue B salt as the reagent. One milligram or less of the suspect material can be tested within 1 min. Of >80 nonmarijuana plant samples tested, only nutmeg and its mace responded similarly to marijuana initially. A differentiation was possible by careful evaluation of the colored microcolumn and of the elution behavior of the colored products. The test also provides for a confirmatory step, based on spectrophotometric analysis of the colored eluates. The reagent microcolumn was very stable to environmental factors such as moisture, light, and air.

Keyphrases □ Marijuana—analysis, microcolumn, field test, compared to other plant substances □ Chromatography, microcolumn—analysis, marijuana, field test, compared to other plant substances

With the recent relaxation of the laws governing marijuana use and possession in several states, the illicit market will increase. Consequently, there is a pressing need for a field test that will enable law enforcement agents, custom officers, and other responsible personnel readily to obtain presumptive evidence on suspected sample identity.

BACKGROUND

Fast Blue B salt (3,3'-dimethoxybiphenyl-4,4'-bis-diazonium chloride) is probably the most widely used reagent for marijuana detection and identification. In addition to high sensitivity and characteristic chromogenic reaction with several cannabinoids, Fast Blue B also is reasonably selective for these substances. Its low cost and ready availability further contribute to its popularity.

Marijuana samples were field tested on pieces of filter paper by means of a solid Fast Blue B reagent (1, 2). Although quite specific, this method requires special precautions in reagent preparation, reaction performance, and interpretation of results (1, 3). A very specific field test for hashish was reported, which utilized a suspension of Fast Blue B in chloroform in conjunction with aqueous sodium hydroxide (4). However, this method requires a large apparatus and two liquid reagents.

A "breathanalyzer" for the breath analysis of marijuana smokers was described (5). The suspect was required to breathe onto pieces of filter paper or tissue freshly dampened with aqueous Fast Blue B. The reagent was unstable, and the color response was slow. Hashish also was detected with filter paper strips pretreated with methanolic Fast Blue B (6). The reagent papers were unstable and decreased in sensitivity upon long storage (3, 6).

This paper describes a marijuana field test that circumvents many problems encountered with existing procedures. In addition to using a stable Fast Blue B color reagent, it requires few steps, one liquid reagent, and little apparatus. The test capability to differentiate false-positive responses also was investigated.

EXPERIMENTAL

Reagents—Fast Blue B salt[1], neutral alumina for chromatography[2], analytical reagent grade solvents[2] (petroleum ether, bp 60–90°; methanol; and chloroform), collodion USP[2], and microcrystalline cellulose[3] were used as obtained from commercial sources.

Apparatus—Spectrophotometric curves were recorded using 1-cm semimicro quartz cells on a double-beam recording spectrophotometer[4] equipped with a digital readout accessory and a strip-chart recorder.

Reagent Preparation—Neutral alumina–microcrystalline cellulose (3:1) was intimately mixed by manual stirring and bottle tumbling. For every 12 g of this mixture, a suspension of 0.2 g of Fast Blue B salt in 25 ml of chloroform was added with stirring. The smooth slurry was transferred to a large glass petri dish and allowed to air dry inside a hood. The dry residue was homogenized to a fine powder and stored in an amber glass container.

Microcolumn Preparation—A small glass wool or absorbent cotton pledget was placed at the bottom of a glass tube (3 × 0.7 cm), approximately 3 mm away from one end. Small portions of the reagent were introduced into the tube with gentle tapping until an ~2-cm high column was obtained. The upper end of this column was closed with another glass wool or cotton pledget. A 1-cm space remained over the packed reagent column. Both ends of the glass tube were sealed by immersion into collodion followed by air drying.

The microcolumns were stored in an amber glass container.

Extracting-Eluting Solvent Preparation—Isopropanol, 10 ml, was added, with stirring, to 80 ml of petroleum ether, bp 60–90°, and 20 ml of anhydrous methanol. The solution was stored in a dropping bottle.

Field Test—The collodion seals were removed from both ends of a microcolumn. A small amount of suspect material, preferably powdered, was layered ~2 mm high on top of the microcolumn. The extracting-eluting solvent was added dropwise until the liquid reached the bottom of the microcolumn. The color that developed along the microcolumn within 1 min was recorded. A red, purple-red, or burgundy-red color, deepening with time and rapidly spreading downward, was interpreted as a positive test.

Differential Test—To a still wet or to a dry colored microcolumn, sufficient extracting-eluting solvent was added until the colored product emerged at the lower end of the tube and could be collected. A rapidly eluting red, purple-red, or burgundy-red liquid signified a positive test.

Spectral Analysis—The colored eluate from the differential step was transferred to a semimicro spectrophotometric cell, and its visible absorption spectrum was recorded against the extracting-eluting solvent serving as the blank. If the eluate separated into two phases, the addition of 1–2 drops of chloroform reestablished the single phase.

RESULTS AND DISCUSSION

Microcolumn—Several common chromatographic support media were tested for suitability in the microcolumn preparation. Among those investigated were microcrystalline cellulose, infusorial earth, neutral alumina, silica gel, nylon, and methylcellulose. Selection criteria were: (*a*) inertness toward Fast Blue B, (*b*) rate at which solvents such as petroleum ether, chloroform, and petroleum ether–methanol eluted when

Table I—Samples Tested

Part Tested	Name
Bark	*Cascara sagrada*, cinchona, cinnamon, quassia, sassafras, wild cherry
Fruit	Anise, black pepper, capsicum, caraway, cardamom, coriander, fennel, juniper, paprika, star anise
Leaf	Basil, belladonna, boldo, buchu, catnip, digitalis, eucalyptus, hamamelis, henna, hyoscyamus, jaborandi, marijuana (Mexican, New York), oregano, parsley, rosemary, rumex, sage, savory, senna, spearmint, stramonium
Root, rhizome	Aconite, aspidium, belladonna, gentian, ginger, golden seal, hellebore (American), ipecac, jalap, licorice, orris, rauwolfia, rhubarb, rumex, sarsaparilla
Seed	Betel, cacao, coffee (decaffeinated, ground, instant), colchicum, cumin, kola, mace, mustard (black), nutmeg, *Nux vomica*, strophanthus
Miscellaneous	Aloe, clove, curry, ergot, gum benzoin, gum kino, gum myrrh, nutgall, squill, tolu, turmeric

passed through a microcolumn, (*c*) ease of handling and packing, and (*d*) provision of contrasting background for the color reaction interpretation.

Neutral alumina best fulfilled the requirements. However, to promote a better interaction between the cannabinoids contained in the mobile phase and the Fast Blue B present on the microcolumn, the elution rate was decreased by admixing the alumina with microcrystalline cellulose (3:1).

Extracting-Eluting Solvent—The solvents investigated were those commonly used for cannabinoid extraction from marijuana samples, *i.e.*, petroleum ether, chloroform, benzene, and toluene. None of these solvents by themselves produced a color reaction following incorporation into a microcolumn loaded with marijuana, probably due to the insolubility of the Fast Blue B in the liquid phase. Addition of a small amount of methanol to the solvents brought about azo dye solubilization and interaction with the cannabinoids. Based on cost, organoleptic properties, and human safety, petroleum ether was the most satisfactory solvent. Furthermore, mixtures of methanol with chloroform, benzene, and toluene were less selective in extracting exclusively cannabinoids than were the corresponding mixtures with petroleum ether.

Petroleum ethers of bp 30–75°, 60–90°, and 90–120° were admixed with methanol in 9:1, 8:2, and 7:3 (v/v) ratios, respectively. A 9:1 ratio was inadequate in producing readily discernible marijuana color reactions. A 7:3 ratio yielded the strongest colors but at the same time produced more false-positive reactions with samples other than marijuana. Of the three petroleum ethers, the lower boiling solvent was the only one completely miscible with methanol in the stated ratios; those with higher boiling points gave a two-phase system. The former, however, occasionally separated from methanol upon storage. The possibility that the field test would be carried out in hot climates also discouraged further testing of this type of petroleum ether.

Perfect and stable solutions of methanol in petroleum ether of bp 60–90 or 90–120° in an 8:2 ratio could be obtained by the addition of a small quantity of isopropanol. Petroleum ether (bp 60–90°)–methanol–isopropanol (8:2:1) was preferred over a similar combination containing petroleum ether of bp 90–120°, because the former was more compatible with methanol. Mixtures of any of these two petroleum ethers with the alcohols in a 7:3:1 ratio invariably separated into two phases upon storage. On the other hand, combinations of all three types of petroleum ether with isopropanol in 9:1, 8:2, and 7:3 ratios did not produce distinguishable color reactions.

Test Selectivity—Table I lists the plant samples tested by the proposed field test. A positive reaction was when red, purple-red, or burgundy-red zones developed almost immediately at the top of the microcolumn and, on further addition of extracting–eluting solvent, rapidly moved downward as a red band. Of the >80 samples investigated, only those listed in Table II were initially confused with marijuana, but they were ultimately differentiated by careful evaluation of the colored microcolumn characteristics. For example, nutmeg and its mace gave red zones in a hue almost identical with those obtained for marijuana samples. Nevertheless, on repeated addition of the extracting–eluting solvent mixture, the colored products barely moved downward and the eluate emerging at the other end was colored light brown to light orange.

Rhubarb and *Cascara sagrada* also yielded red bands, even when Fast Blue B was absent from the microcolumn, due to extraction of certain red to brown-red constituents by the mobile phase. Their eluates were usually yellow to greenish yellow in contrast to the red tones recorded for marijuana. Various ground and instant coffees gave lavender to light-violet zones, which could be eluted rapidly out of the microcolumn as lavender to light-violet solutions.

Spectrophotometric Analysis—When a more conclusive identification of the field-tested material is needed, a confirmatory step may be added. The colored product may be eluted into a spectrophotometric cell, and the visible absorption spectrum may be recorded. Tables II and III summarize the spectral characteristics of those samples submitted to the spectrophotometric analysis. Marijuana samples typically exhibited two absorption maxima, at ~300 and ~475 nm. Entirely different spectral patterns were recorded for coffee, nutmeg, and mace, which initially approximated the marijuana chromogenic response.

The absorption spectra of the three main cannabinoids, *i.e.*, cannabi-

Table IV—Comparison of Various Field Tests for Marijuana Using Fast Blue B Salt

Characteristic	de Faubert Maunder (Refs. 1 and 2)	Watanabe (Ref. 4)	Woodhouse (Ref. 6)	McCarthy and van Zyl (Ref. 5)	Proposed

Stability of Fast Blue B reagent	Stable	Stable	Unstable	Unstable	Stable

diol (I), cannabinol (II), and tetrahydrocannabinol (II), demonstrated that the marijuana absorption curve was primarily contributed by a combination of these three substances (Table III) rather than by any single cannabinoid or cannabinoid pair. The fact that these constituents occur only in marijuana confers high specificity and diagnostic value on the spectrophotometric analysis.

Test Comparison—Table IV compares the proposed field test with those reported in the literature in terms of reagent requirements, steps involved, and reported interferences.

CONCLUSIONS

The proposed field test was rapid, simple, sensitive and selective. It required only one liquid reagent, which served as the extracting-eluting solvent. Color development and sample extraction were accomplished simultaneously. Colors appeared almost immediately and were easy to interpret against the white background of the microcolumn. The use of a dry absorbent such as alumina offered several advantages since it acted as a diluent for the color reagent and as a medium for the color reaction, and, more importantly, provided a means for differentiating marijuana from other plant materials such as nutmeg and its mace, rhubarb, and *C. sagrada*, whose colored products remained tightly adsorbed to the microcolumn and were not eluted by petroleum ether–methanol mixtures.

The dry microcolumn formulation of Fast Blue B resulted in a reagent that remained stable to ambient conditions such as light and air for periods over 6 months. Since both ends of the glass tube enclosing the microcolumn could be sealed with collodion, adverse effects from moisture, air, and contaminated atmospheres were avoided. The inclusion of differential and confirmatory steps improved the test from a simply presumptive one to a tool with diagnostic capability. None of the plant samples tested by this procedure was confused with marijuana.

Metabolic Performance and GI Function in Magnesium-Deficient Rats

WENDELL E. LANDIN, FRANCIS M. KENDALL, and MARTIN F. TANSY ˣ

Received January 5, 1979, from the *Department of Physiology and Biophysics, Temple University, Philadelphia, PA 19140.* Accepted for publication February 6, 1979.

Abstract □ A quantitative evaluation of the mass balance and GI motor effects of dietary magnesium deficiency in the adult male Sprague–Dawley rat is described. Seventy-seven animals were used. Both sham control and experimental groups were maintained on a commercial stock laboratory diet *ad libitum* for 30 days, after which the experimental rats were switched for 30 days to the magnesium-deficient diet *ad libitum*, containing a magnesium concentration of 16.2 ppm. Ten rats were used to determine the acetylcholine responsiveness of duodenal muscle segments *in vitro*. In all cases, the segments from the deficient rats were hyperresponsive to a fixed acetylcholine dose. Forty-six rats were used to determine the average intestinal transit rate, which increased significantly in 30-day magnesium-deficient rats. A final series employed 21 rats who were housed in individual metabolic cages. After 5 days on the deficient diet, the average daily fecal pellet counts and fecal weights were significantly reduced. It is concluded that chronic magnesium deficiency is associated with altered GI motor function in the adult male rat.

Keyphrases □ Magnesium deficiency—GI motility, metabolism, rats □ GI tract—magnesium deficiency, motility, metabolism, rats □ Nutritional disorders—magnesium deficiency, GI motility, metabolism, rats

With few exceptions, most of the existing literature concerning the effects of chronic magnesium deficiency in the rat considers the GI tract only as a defective intake route: magnesium deficiency resulting from malabsorption, failure of magnesium conservation in the gut, and loss of fluid and ions *via* the intestines.

Curiously, the effect of magnesium deficiency on the functioning of the GI tract itself was not considered until the motor effects from exposure of the small intestines of rats (1) and humans (2–4) to ionizing radiation were significantly associated with hypomagnesemia. The data also indicated that prophylactic administration of soluble magnesium salts prior to exposure had a mitigating effect in both cases. These observations led to the proposal that the GI symptomatology defined by the acute intestinal radiation syndrome in the rat was the result of acute hypomagnesemia (5, 6).

Another interesting relationship is that between magnesium deficiency and the GI secretory apparatus. The effect of magnesium on gastric structure and function has received some attention, but reported results have been inconsistent. Recent observations (7) showed that dietary magnesium deficiency in rats alters the ratio of chief to parietal cells. Additional evidence (8) indicated that rats treated with parathyroid hormone for 2 weeks exhibited a reduced basal gastric acid secretory rate associated with nonspecific gastric mucosal damage. Veilleux (9) demonstrated that mast cells increase in the duodenum and kidney of magnesium-deficient rats. Unfortunately, these latter studies were not extended to the gastric mucosa. The foregoing results and the finding that the inhibition of calcium-induced acid secretion by magnesium may be caused by blockade of a calcium effect directly on the parietal cell (10) preclude any simple explanation of the effect of magnesium on gastric secretion.

Practically speaking, sufficient attention has not been directed to the effect of magnesium on the GI system. Therefore, the purpose of this study was to determine whether the GI motor functions of rats maintained on a magnesium-deficient diet were different from similar functions in control animals.

Dextrose	572.94
Choline chloride	4.84

[a] Standard fortification mix. Produced by Bioserv Inc., Frenchtown, N.J.

EXPERIMENTAL

Animals—The Sprague–Dawley rat was chosen as the experimental animal because a large portion of the relevant literature employed this breed (7, 9, 10). To obviate variations due to body size and estrus stage, only adult male rats weighing 125–150 g were used. The rats were acclimatized in the laboratory for 7 or more days before use. They were kept two per cage in an air-conditioned room under constant temperature (22°) and light cycles and were fed pelleted stock laboratory diet and water *ad libitum*. Some rats were housed in colony cages accommodating six animals. When necessary, coprophagy was minimized by employing cages with wire mesh false bottoms.

Magnesium-Deficient Diet—The basal magnesium-deficient diet[1] (Table I) was assayed[2] to contain ~16.2 ppm of magnesium. The magnesium content of the stock diet was reported by the manufacturer to be 2400 ppm.

Gross Metabolic Behavior—The first series of experiments was designed to determine whether magnesium-deficient rats would show any significant differences in gross metabolic behavior. Twenty-one adult rats were divided into two groups: an experimental group of 11 rats fed the magnesium-deficient diet and a control group of 10 rats fed the stock laboratory diet. With a week of preliminary conditioning, both groups became adjusted to a small individual cage, to a water bottle, and to a pelleted ration.

Both groups were then placed in individual plastic metabolism cages[3] where they consumed individual rations of pelleted stock diet and tap water *ad libitum*. An additional 30 days was allowed for the rats to adjust to the metabolism cages. The experimental group was then switched to the magnesium-deficient diet.

All animals, identified by coded ears, were weighed daily. The unconsumed water and food and urine and feces were collected daily. Water was supplied *ad libitum*, and water intake was measured by recording the water bottle contents. Food intake was more difficult to determine because of spillage. Feeders with narrow openings that permitted only the snout to enter reduced spillage. Food spillage could be further minimized by not filling the attached food containers to maximum capacity.

The usual food supply was 40 g of pelletized chow and 100 ml of water. Both quantities were sufficient for >2 days. Daily food and water intake

were determined by differences in the weights and volumes that were supplied the previous day. The collected feces from each animal were counted, weighed, and dried in an oven at 55° over 24 hr. The dry fecal weight was defined as net solid output. The loss in weight of the dry feces represented the fecal moisture weight. Net fluid output was obtained by adding the difference between wet and dry fecal weight in grams to the urine volume excreted in milliliters.

Corrected values for solid and fluid intake were made by subtracting a fixed percentage of the weight in grams of food consumed and directly adding this value to the volume of water consumed in milliliters. For such computations, the manufacturer of the magnesium-deficient diet specified the water content as being 6% by weight. The stock diet water content was 10.5% by weight. Utilization of these percentages and the requirement that weights in grams of water be numerically equal to volumes in milliliters at room temperature contributed to less absolute error than that produced by the inherent variability of the raw data collected.

***In Vitro* and *In Vivo* Intestinal Motor Activities**—The second series of experiments determined whether magnesium deficiency was associated with a change in overall small intestinal peristaltic activity in the rat. Two procedures were used. The classical contractile force measurement of isolated intestinal muscle segments in a tissue bath was used as a screening procedure. This measurement indicates muscular activity at a localized bowel region. The propulsive motility technique, which measures actual transit of intestinal contents over a given period, was used to assess overall small bowel activity.

The *in vitro* experiments were performed on 10 rats after 4 weeks on the diets. Each animal was fasted overnight. The animals were sacrificed by decapitation, followed quickly by the removal of 2–3-cm segments of the duodenum, jejunum, ileum, and descending colon. The responses of small and large intestinal segments to test drugs were recorded isometrically[4]. The particular segments were mounted in parallel in an isolated organ-tissue bath[5] with Tyrodes solution of the following composition (percent): NaCl, 0.8; KCl, 0.02; $CaCl_2$, 0.02; $MgCl_2$, 0.01; $NaHCO_3$, 0.1; NaH_2PO_4, 0.005; and glucose, 0.1. The solution was gassed with 95% oxygen and 5% carbon dioxide and maintained at 38 ± 1°. The pH of the solution varied between 7.4 and 7.6.

Comparison between the reactivity of two uneverted bowel segments was made simultaneously in parallel sets, with the respective segments mounted aborally from top to bottom in the bath chamber. The free proximal portion of the bowel segment was attached to a strain-gauge transducer, with the distal end fixed to the bottom of the bath. The bowel segment was attached by thread so that it was completely submerged in the Tyrodes solution, yet closed at each end so that the lumen was not bathed by the bath solution. No undue tension was applied to the segments during the mounting procedure.

System response amplitude was the measured variable and was always calibrated initially to the same value by means of an initial lever displacement, which was effected by hanging the same calibrating weight on each transducer system in turn. To avoid any differences due to the lever systems–transducers–polygraph channels, the two tested segments were alternated in successive experiments with the corresponding isometric lever force transducer and polygraph channel. The contraction height of the bowel segments after addition of fixed acetylcholine doses

was taken as a measure of the segment's responsiveness. After the segment had contracted in response to acetylcholine, the medium was rinsed once or twice and replaced with fresh Tyrodes. After such procedures, the preparation was allowed to equilibrate for a few minutes before further stimulant was added.

All contraction measurements refer to maximum contraction amplitude observed on the polygram within a few seconds of drug addition to the bath. Acetylcholine was prepared immediately before use by dilution with the same physiological solution used in the bath and was added directly into the bath.

Intestinal transit measurement was made by the procedure of Macht as cited by VanLiere *et al.* (11). Briefly, 1 ml of a standard test meal, consisting of 10% charcoal suspended in an aqueous solution of 10% gum acacia, was fed by intragastric tube to 19, 48-hr fasted magnesium-deficient rats and 27 comparably fasted sham controls. The experimental rats, which had been fed the deficient diet for 30 days, were killed by decapitation in groups of 10 and 9 at 15 and 30 min, respectively, following intubation. The sham control groups for the 15- and 30-min intervals consisted of 13 and 14 rats, respectively.

Following sacrifice, the stomach and intestines were removed. The total small intestine length from pylorus to cecum was measured. The net distance that the charcoal had traversed from the pylorus was measured at the same time. Transit was defined as the distance traversed divided by the total intestine length.

Histopathology—Complete necropsies were done on sacrificed animals. The entire visceral contents were inspected visually to determine the presence of such obvious pathology as focal or generalized lesions and hemorrhage. The following organs and tissues were subjected to microscopic examination: stomach, representative segments of the small and large intestines, liver, heart, kidneys, and skeletal muscle from the thigh. Tissue samples were fixed in formaldehyde solution and embedded in paraffin. Sections were cut at 6 μm and stained with hematoxylin–eosin for routine histopathologic examination. All microscopic examinations were on a blind basis.

Reduction of Data and Interpretation of Results—All recorded values for the metabolic performance studies were normalized to 100 g of body weight to reduce the variations caused by differences in weights. The daily mean of the individual normalized values for each variable studied was plotted for the sham control and experimental groups, and least-squares linear regression lines were fitted through the points. Then, a pooled variances t test of the difference between regression coefficients was performed. This test only allows a determination of the significance of differences between average rates of change of metabolic performance; but if the difference between the rates is significant, it can be assumed that the metabolic performances of the two groups with respect to the variable being studied are not the same.

An F test to check for homogeneity of variance between the two least-squares lines to be compared was performed utilizing the mean square deviation from regression ($S^2_{y \cdot x}$) for each group. The appropriate degrees of freedom associated with each $S^2_{y \cdot x}$ are $n - 2$. If variance homogeneity could be assumed, the following pooled variances t test was used to compare the two regression coefficients:

$$t = \frac{b_1 - b_2}{\sqrt{S^2_{y \cdot x_{pooled}} \left(\frac{1}{S_{y \cdot x_1}} + \frac{1}{S_{y \cdot x_2}} \right)}} \quad \text{(Eq. 1)}$$

with $(n_1 + n_2 - 4)$ degrees of freedom, and where:

$$S^2_{y \cdot x_{pooled}} = \frac{S_{y \cdot x_{pooled}}}{n_1 + n_2 - 4} \quad \text{(Eq. 2)}$$

and:

$$S_{y \cdot x_{pooled}} = S_{y \cdot x_1} + S_{y \cdot x_2} \quad \text{(Eq. 3)}$$

Table IV—Effect of a 30-Day Magnesium-Deficient Diet on Small Intestinal Transit Performance and Related Data in 48-hr Fasted Rats [a]

Parameter	Sham Control Group		Experimental Group	
	15 min	30 min	15 min	30 min
Body weight, g	173.69 ± 18.42 (13)	174.32 ± 13.26 (14)	184.30 ± 26.45 (10)	197.56 ± 22.95[b] (9)
Length of small intestine, cm	119.15 ± 11.55	124.07 ± 5.68	116.80 ± 6.66	119.33 ± 4.00[b]
Normalized small intestinal length, cm/100 g of body weight	68.81 ± 4.97	71.53 ± 5.92	64.44 ± 9.25	61.19 ± 7.96[b]
Length of small intestine traversed, cm	54.92 ± 13.62	81.64 ± 12.18	83.00 ± 15.39[b]	90.00 ± 12.48
Percentage of small intestine traversed	46.02 ± 10.02	65.80 ± 9.35	70.83 ± 11.20[b]	75.33 ± 9.40[b]

[a] The ± indicates 1 *SD*; parentheses contain number of animals. [b] Statistically significant difference when compared with the mean values of sham control rats ($p \leq 0.05$).

Pooling increases the degrees of freedom and sensitivity of the test and is possible if the ratios of the mean square deviation from regression are satisfactorily homogeneous. If the F test showed that the ratios of the mean square deviation from regression were not satisfactorily homogeneous, a modified Welch test to test the significance of difference between slopes was used. The following formula expresses this test:

$$t' = \frac{b_1 - b_2}{\sqrt{\frac{S^2_{y \cdot x_1}}{x_1^2} + \frac{S^2_{y \cdot x_2}}{x_2^2}}} \qquad \text{(Eq. 4)}$$

The approximate degrees of freedom for t' was calculated using the following formula:

$$df = \frac{\left(\frac{S^2_{y \cdot x_1}}{x_1^2} + \frac{S^2_{y \cdot x_2}}{x_2^2}\right)^2}{\left(\frac{1}{df_1}\right)\left(\frac{S^2_{y \cdot x_1}}{x_1^2}\right)^2 + \left(\frac{1}{df_2}\right)\left(\frac{S^2_{y \cdot x_2}}{x_2^2}\right)^2} \qquad \text{(Eq. 5)}$$

For propulsive motility, a simple Student t test was used to compare the significance of the mean differences. In all statistical tests, significance was tested at the 5% level.

RESULTS

The progressive magnesium deficiency syndrome was observed in the deficient animals: hyperemia of the skin, nose, ears, footpads, and tail appeared on the 5th day and progressed to weeping, crusting lesions (Fig. 1).

The magnesium-deficient rats were inactive but irritable when stimulated with a blast of air. At the end of the 2nd week, the appetite of the animals improved considerably, although irritability became increasingly prominent. The weight curves of the sham control and magnesium-deficient groups are given in Fig. 2. The deficient group rats lagged in the rate of weight increase compared to the sham control group until the 3rd week, when they ceased to gain weight.

Results of changes in food intake, net water intake, and fecal and urinary excretions are given as daily average values for the rats fed the magnesium-deficient diet. After 5 days, the average daily wet fecal weight (Fig. 3), dry fecal weight (Fig. 4), and fecal pellet count (Fig. 5) were significantly less for the magnesium-deficient animals. At no time could it be concluded that differences existed in daily average food intake (Fig. 6), net water intake (Fig. 7), or net fluid output (Fig. 8). The regression equations fitted to the data points in Figs. 2–7 are presented in Tables II and III.

In all cases, muscle strips from the small intestine of magnesium-deficient animals showed a greatly increased contraction strength in response to a test acetylcholine dose (Fig. 9). This response was present 4 weeks following initiation of the magnesium-deficient regimen. Although not depicted, muscle segments from the colons of magnesium-deficient

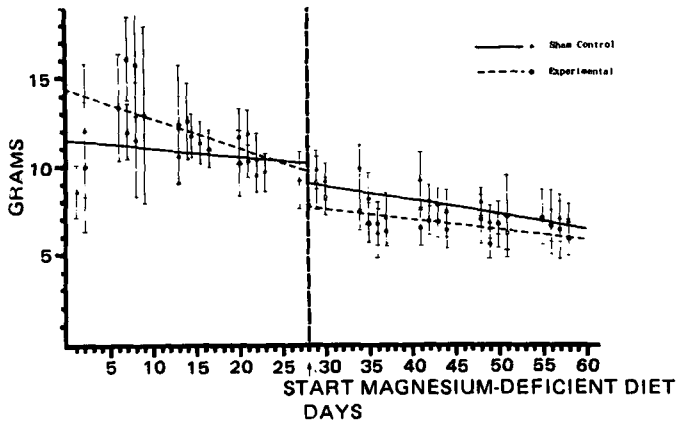

Figure 6—*Time courses of mean daily food intakes from sham control and magnesium-deficient rats.*

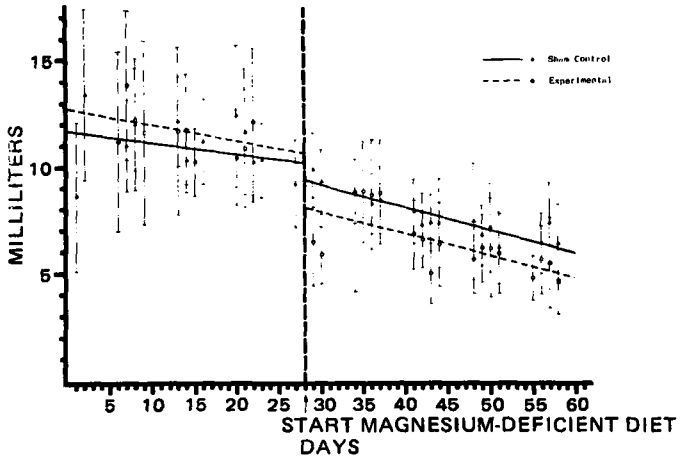

Figure 8—*Time courses of mean net fluid outputs from sham control and magnesium-deficient rats.*

animals either failed to show increased contractile force to acetylcholine or showed a decreased response. As seen in Table IV, statistically significant increases in the small intestinal transit rate were noted in the 4-week magnesium-deficient animals when contrasted to the sham controls. The mass transit data indicate that the effects noted in isolated duodenal muscle segments probably are generalized to other regions of the small intestine as well.

All animals carried for 30 days on the magnesium-deficient diet displayed significant morphological differences from the sham controls in the heart, liver, skeletal muscle, kidney, and gastric mucosa. In all magnesium-deficient rats of this group, there were focal degenerative and inflammatory changes in the myocardium. In the liver, areas of focal degeneration and increased vacuolization were noted. In the magnesium-deficient group, degenerative and inflammatory changes appeared in the voluntary muscles. The lesions consisted chiefly of a degenerative change and associated muscle bundle swelling, with an accompanying loss of sarcolemmal nuclei.

In the stomach, alterations were seen in the mucosa. These changes included occasional dilation and engorgement of small vessels and enlargement of gastric pits. Elsewhere, chief cells appeared reduced in number and compressed by swollen adjacent parietal cells. However, the most consistent abnormalities noted were in the kidneys. The kidneys of all magnesium-deficient rats showed large calcium deposits in the medullary tubule lumina, with a preponderance near the corticomedullary junction. These deposits were laminated, the affected tubules were dilated, and their epithelium was flattened.

DISCUSSION

The pathophysiological findings of magnesium deficiency in the rat were in good agreement with numerous previous studies (12–16). Hyperexcitability, cutaneous hyperemia, general fur loss, shaggy coat, ringed eye dermatitis, encrusted nostrils, and signs of early diarrhea were consistent findings. Histological findings also were in agreement with previously reported data to an extent that they confirmed that hypomagnesemia existed in the experimental rats (15).

However, certain metabolic effects were not found. For example, unlike the findings of Orent *et al.* (17), the average weight of the magnesium-deficient group never fell below the initial average weight of this parameter; and although the average rate of weight increase was less than that of the control group, the difference was not significant. Such inconsistencies may have been due to the use of different strains and ages of rats and to variations in the formulations of the deficient diets, particularly in earlier days when it was more difficult to make an accurately defined diet with simple magnesium deficiency alone.

Fecal wet weight and pellet count performance of the deficient group were reduced while the mean small intestinal transit fraction increased. These results are in agreement with *in vitro* studies which showed that isolated duodenal muscle segments were hyperreactive to a cholinergic stimulus, while no differences in acetylcholine reactivity were apparent in the colons of the deficient group. Upon necropsy, the colons of the magnesium-deficient rats were visually observed to be enlarged.

It is concluded that, in the rat, GI motor activity and, to some degree, excretory performance are affected by chronic magnesium deficiency. Frank liver damage suggests that the function of this organ may become impaired. Thus, the function of the digestive system is affected to such an extent that it cannot be regarded merely as a conduit for magnesium intake, excretion, and conservation.

The increased small intestinal transit rate in the deficient state suggests that a regeneratively destructive response may exist in this organ in response to magnesium deficiency: intake restriction results in impaired ability to absorb and/or conserve magnesium in the small bowel. The visual appearance of distended colons in deficient rats is consistent with the reduction in fecal water content in these animals; a condition of partial constipation would be consistent with efforts to conserve magnesium by increasing colonic residence time. This hypothesis is attractive in the particular case of the rat where, under normal circumstances, approximately 70% of the total magnesium absorption occurs in the cecum and ascending colon (18).

Absorption and Penetration of Dinoprost (Prostaglandin $F_{2\alpha}$) and Dinoprost Methyl Ester into Perfused Mesenteric Circulation in Rats

BRUCE M. TAYLOR ˣ and FRANK F. SUN

Received March 6, 1978, from *Experimental Biology, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication February 6, 1979.

Abstract □ The absorption of dinoprost (prostaglandin $F_{2\alpha}$) and its methyl ester in rat jejunum was studied. A 22-cm segment of rat jejunum was cannulated at both ends and connected to an oscillating perfusion pump system. The mesenteric vasculature supplying this isolated segment also was cannulated and perfused with Kreb's bicarbonate buffer with dextran. Solutions of ^{3}H-dinoprost or its methyl ester were introduced into the lumen and oscillated through the segment. The disappearance of radioactivity from the lumen and the appearance of radioactivity in the vascular perfusate were monitored. The metabolite patterns in the vascular perfusate were analyzed by TLC. A lag between the time the drug disappeared from the lumen and the time it appeared in the mesenteric circulation was detected. This lag was longer for the methyl ester than for the free acid, even though the ester disappears from the lumen faster than does the free acid. Upon removal of dinoprost from the gut lumen, a gradual decrease in the amount of drug appearing in the mesenteric circulation could be detected. However, with the ester, a slight increase could be observed for ~0.5 hr, followed by a decrease. Metabolism by the gut wall appears to be greater for the ester than for the acid. The results suggest that, although the ester disappears from the lumen more quickly than does the acid, it actually penetrates to the blood at a slower rate and undergoes greater metabolism.

Keyphrases □ Dinoprost—absorption and penetration, mesenteric circulation, rats, metabolism □ Dinoprost—methyl ester, absorption and penetration, mesenteric circulation, rats, metabolism □ Pharmacokinetics—dinoprost and dinoprost methyl ester, mesenteric circulation, rats □ Prostaglandins—dinoprost, dinoprost methyl ester, absorption and penetration, mesenteric circulation, rats, metabolism

Prostaglandins have been viewed as potential panaceas almost since the moment of their discovery. Much research has been devoted to their endogenous and exogenous functions in various organs and tissues, and various roles have been assigned to this family of compounds. Because of their ubiquity and functional diversity, prostaglandins are appealing prospects as therapeutic agents for many conditions. However, before this potential can be realized, a practical administration route must be developed. The most desirable route would be oral. When dinoprost (prostaglandin $F_{2\alpha}$) or its methyl ester are administered orally, the major absorption site appears to be the small intestine since there is little absorption from the stomach[1]; although there can be some absorption by the large intestine, most of the compound disappears before reaching this area (1).

The present study was designed to gain insight into intestinal absorption of prostaglandins: their disappearance from the intestinal lumen, their appearance in the mesentric circulation, and the extent of their metabolism in the intestinal wall. Investigations into the rates of prostaglandin disappearance from the intestinal lumen (1, 2) have been based on studies of prostaglandin disappearance from the mucosal side of the intestine. From such studies, Ho and coworkers (3, 4) proposed that dinoprost absorption is diffusion dependent and that its metabolism may affect the absorption rate. In addition, previous work[2] showed that the lymphatic system does not play a role in the transport of orally administered prostaglandins.

This study looked at the serosal side of the intestine *via*

Absorption and Penetration of Dinoprost (Prostaglandin $F_{2\alpha}$) and Dinoprost Methyl Ester into Perfused Mesenteric Circulation in Rats

BRUCE M. TAYLOR ˣ and FRANK F. SUN

Received March 6, 1978, from *Experimental Biology, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication February 6, 1979.

Abstract □ The absorption of dinoprost (prostaglandin $F_{2\alpha}$) and its methyl ester in rat jejunum was studied. A 22-cm segment of rat jejunum was cannulated at both ends and connected to an oscillating perfusion pump system. The mesenteric vasculature supplying this isolated segment also was cannulated and perfused with Kreb's bicarbonate buffer with dextran. Solutions of ^{3}H-dinoprost or its methyl ester were introduced into the lumen and oscillated through the segment. The disappearance of radioactivity from the lumen and the appearance of radioactivity in the vascular perfusate were monitored. The metabolite patterns in the vascular perfusate were analyzed by TLC. A lag between the time the drug disappeared from the lumen and the time it appeared in the mesenteric circulation was detected. This lag was longer for the methyl ester than for the free acid, even though the ester disappears from the lumen faster than does the free acid. Upon removal of dinoprost from the gut lumen, a gradual decrease in the amount of drug appearing in the mesenteric circulation could be detected. However, with the ester, a slight increase could be observed for ~0.5 hr, followed by a decrease. Metabolism by the gut wall appears to be greater for the ester than for the acid. The results suggest that, although the ester disappears from the lumen more quickly than does the acid, it actually penetrates to the blood at a slower rate and undergoes greater metabolism.

Keyphrases □ Dinoprost—absorption and penetration, mesenteric circulation, rats, metabolism □ Dinoprost—methyl ester, absorption and penetration, mesenteric circulation, rats, metabolism □ Pharmacokinetics—dinoprost and dinoprost methyl ester, mesenteric circulation, rats □ Prostaglandins—dinoprost, dinoprost methyl ester, absorption and penetration, mesenteric circulation, rats, metabolism

Prostaglandins have been viewed as potential panaceas almost since the moment of their discovery. Much research has been devoted to their endogenous and exogenous functions in various organs and tissues, and various roles have been assigned to this family of compounds. Because of their ubiquity and functional diversity, prostaglandins are appealing prospects as therapeutic agents for many conditions. However, before this potential can be realized, a practical administration route must be developed. The most desirable route would be oral. When dinoprost (prostaglandin $F_{2\alpha}$) or its methyl ester are administered orally, the major absorption site appears to be the small intestine since there is little absorption from the stomach[1]; although there can be some absorption by the large intestine, most of the compound disappears before reaching this area (1).

The present study was designed to gain insight into intestinal absorption of prostaglandins: their disappearance from the intestinal lumen, their appearance in the mesentric circulation, and the extent of their metabolism in the intestinal wall. Investigations into the rates of prostaglandin disappearance from the intestinal lumen (1, 2) have been based on studies of prostaglandin disappearance from the mucosal side of the intestine. From such studies, Ho and coworkers (3, 4) proposed that dinoprost absorption is diffusion dependent and that its metabolism may affect the absorption rate. In addition, previous work[2] showed that the lymphatic system does not play a role in the transport of orally administered prostaglandins.

This study looked at the serosal side of the intestine *via*

the mesenteric circulation to obtain a more complete intestinal absorption profile. Since it has been proposed that prostaglandin esters are absorbed faster and achieve greater circulating levels than the free acids (2, 5), the differences in absorption between dinoprost and its methyl ester were examined.

EXPERIMENTAL

Materials[3]—[9(*N*)-^{3}H]-Dinoprost was commercially prepared[4]. ^{3}H-Dinoprost methyl ester was produced by reacting ^{3}H-dinoprost with diazomethane.

Methods—Several techniques have been developed for studying intestinal absorption and transfer into the mesenteric circulation (6–10). The experimental technique employed for this study was an expansion of Ho's modified Doluisio absorption method (5) (Fig. 1).

Male Sprague–Dawley rats, 600–800 g (these larger animals were chosen because the mesenteric blood vessels were much easier to cannulate), were anesthetized with cyclopal sodium and placed on a temperature control platform[5] to maintain body temperature at 37°; body temperature was monitored with a rectal probe. The abdomen was opened, and branches of the superior mesenteric artery and vein supplying the superior jejunum were cannulated with polyethylene tubing[6].

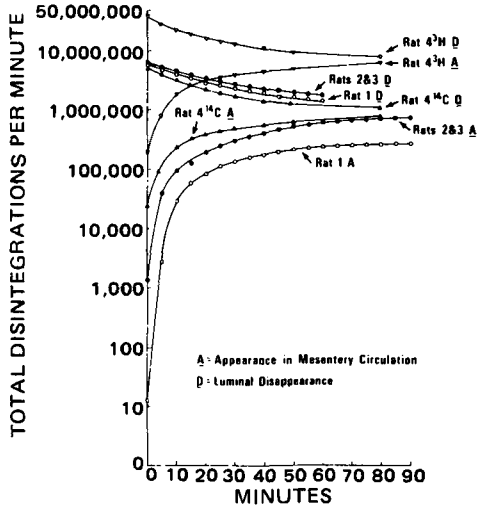

Figure 2—*Dinoprost disappearance and appearance curves.*

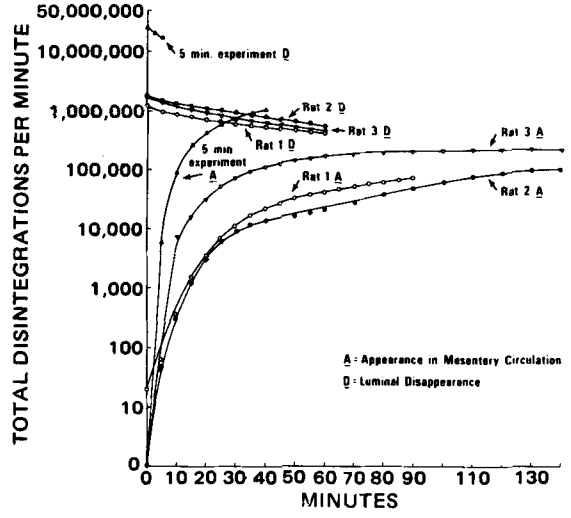

Figure 3—*Dinoprost methyl ester disappearance and appearance curves.*

The vasculature was perfused with an oxygenated solution of Kreb's bicarbonate buffer (pH 7.4) with 10% dextran and 150 IU of heparin/ml *via* a parastaltic pump[7]. Perfusion pressure was monitored by a pressure transducer[8]. Perfusate passed from the arterial cannula[6] through the vasculature and into the venous cannula[6], where it drained into collecting tubes. Next, a 22-cm section of jejunum supplied by the perfused vasculature was laid out in a S pattern and washed free of fecal matter. Cannulas were inserted at each end such that syringe barrels could be inserted into the cannulas and secured.

The exposed gut temperature was monitored (thermometer) and regulated with a lamp. Radiolabeled drug solution[9] (2 ml) containing 10 μg of prostaglandin in pH 6 buffer was placed in the gut, and a reversible pump[10] was connected to the syringe barrels, allowing the solution to be oscillated slowly through the gut (0.75 ml/min). [Moving the solution is reported to reduce the thickness of the aqueous diffusion layer (4).] The drug solution was prepared in isoosmotic pH 6.0 phosphate buffer (prepared by diluting 9.07 g of anhydrous monobasic potassium phosphate and 11.93 g of potassium sulfate to 1 liter with water). The pH was adjusted with 1 *N* NaOH (11). This buffer produces no water flux into or out of the gut in experiments with ^{14}C-polyethylene glycol.

Two minutes was allowed for mixing before the first luminal fluid sample was taken, followed by sampling at 5-min intervals. Effluent from

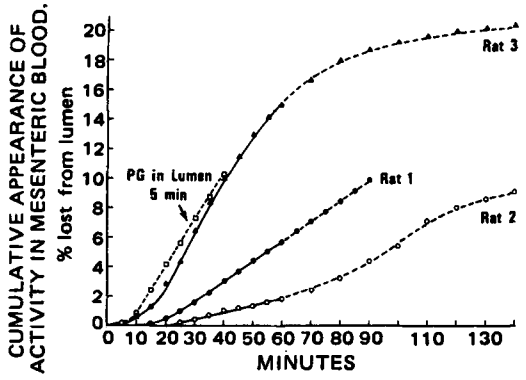

Figure 5—*Dinoprost methyl ester appearance in mesenteric circulation. Dotted lines indicate time after drug removal from lumen.*

the venous cannula was collected in separate tubes for each sampling interval. The drug solution remained in the gut for the designated time—usually 60 min—and was then removed; the gut was then washed free of drug. The vascular perfusion was continued for an additional period to check for drug holdup in the intestinal wall and to follow drug release. Upon completion of the perfusion, the experimental intestine section was removed, and the amount of radioactivity remaining in the wall was determined.

Analysis—The radioactivity in the luminal samples and that in the vascular perfusate were determined by direct counting of small aliquots in a scintillation counter[11]. These and all other counting data were corrected for quench. Intestinal wall tissue was homogenized[12] and oxidized with an oxidizer[11], and the oxidation products were counted to determine the residual radioactivity in the gut wall.

The metabolism data were obtained by pooling the vascular perfusate samples into three portions (0–30 min, 35–60 min, and 65 min–end), extracting with ethyl acetate, and subjecting the extract to TLC. TLC was carried out on silica gel plates[13] in chloroform–methanol–water (40:10:1) and then chloroform–methanol–acetic acid (40:2.5:5). The plates were scraped, and the areas where the various standards ran were noted and counted.

RESULTS AND DISCUSSION

Several intestinal absorption parameters were determined from the data collected: (*a*) the amount of drug lost from the lumen, (*b*) the amount and pattern of drug appearance in the mesenteric circulation, (*c*) the amount of drug held up in the gut wall, and (*d*) the extent and pattern of intestinal metabolism. In addition, the esterase activity in the gut lumen was determined for the experiments with dinoprost methyl ester[14].

Figure 2 shows dinoprost disappearance from the intestinal lumen and the appearance of the label in the mesenteric circulation plotted on a log scale of the total disintegratious per minute *versus* time. By the time that the zero sample was taken (after a 2-min delay), activity had already begun to appear in the circulation and continued to increase until the drug was removed from the gut. After removal of the drug solution from the lumen, the rate of increase of radioactivity appearing in the mesenteric circulation slowly leveled off; after 30 min, the slope approached zero.

Figure 3 shows the disappearance and appearance of dinoprost methyl ester. Ester disappearance studies are complicated by the presence of a luminal esterase, which converts the ester to the free acid at a highly variable rate. TLC of the luminal extract demonstrated that the only radioactive species present were dinoprost and dinoprost methyl ester and, therefore, indicated no back-diffusion of prostaglandin metabolites into the lumen.

Some differences between the free acid and the ester should be noted. First, there is a delay between the time the drug disappears from the lumen and the time it appears in the circulation since most plots start from zero. Second, radioactivity continues to increase in the circulation

after the drug is removed from the lumen; *i.e.*, the slope remains positive. The slope of the appearance curve for Rat 3 more closely resembles the slopes for dinoprost because the esterases, as measured by the ester to acid ratio in the luminal fluid, were not as active in Rats 1 and 2 as in Rat 3.

The percent of the total activity lost from the lumen appearing in the mesenteric circulation for dinoprost *versus* time is shown in Fig. 4. The broken line indicates the time after drug was removed from the lumen. The radioactivity appeared immediately in the mesenteric circulation, and the slope began to level off shortly after drug removal. A similar plot for dinoprost methyl ester is shown in Fig. 5. There was an apparent delay before radioactivity began to appear, and the slope continued to rise even after drug removal, which was especially apparent when the drug solution was removed after only 5 min in the lumen.

Figure 6 shows the activity distribution in the two compartments, tissue and blood (plotted mean ± *SD*). These results, along with those showing

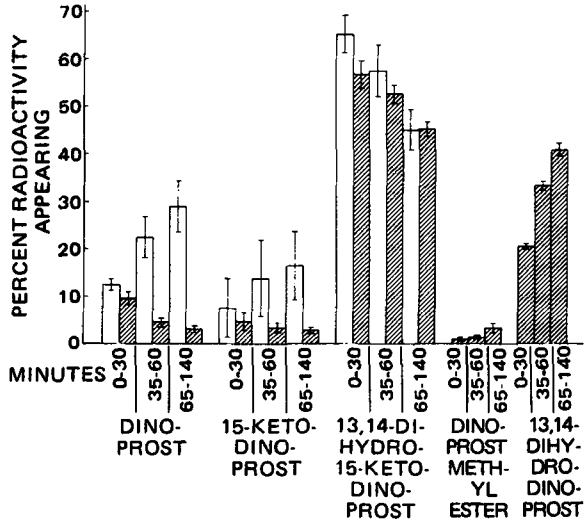

Figure 7—*Metabolites appearing in mesenteric circulation. Key:* □, *dinoprost in intestinal lumen; and* □, *dinoprost methyl ester in intestinal lumen.*

a delay between disappearance from the lumen and appearance in the blood, are in agreement with previous studies (12), which indicate that the greater a compound's lipophilicity, the longer will be its holdup in the intestinal wall and the less will penetrate to the serosal side of the membrane.

Finally, as is expected with longer holdup, the ester is more extensively metabolized than is the acid, as indicated by TLC. With dinoprost, the main metabolites are 15-ketodinoprost and 13,14-dihydro-15-ketodinoprost. As the experiment progressed, the metabolism decreased (Fig. 7). With the ester, four main metabolites are seen: dinoprost, 15-ketodinoprost, 13,14-dihydro-15-ketodinoprost, and 13,14-dihydrodinoprost. Although the amount of intact ester entering the blood increased slightly as the experiment progressed, the total metabolism increased, as indicated by the increase in 13,14-dihydrodinoprost in the circulation.

In summary, intestinal prostaglandin absorbed appears to have at least three phases. First, prostaglandins appear to diffuse rapidly from the gut lumen into the intestinal wall. Second, once in the gut wall, time is required for the compound to reach the other side of the cell. During this transcellular movement, the compound appears to be extensively, although not completely, metabolized. The duration of this second phase appears to be directly related to lipophilicity. Third, the compound and its metabolites are released into the mesenteric circulation. Prostaglandin esters apparently are released slower and over a longer period than the parent acids; however, they also undergo more extensive metabolism.

This study demonstrated differences in dinoprost and dinoprost methyl ester absorption patterns in the rat. However, these differences were not in agreement with the hypothesis that prostaglandin esters are absorbed faster than the parent prostaglandins in this species.

Conjugated Estrogens Bioinequivalence: Comparison of Four Products in Postmenopausal Women

WALLACE P. ADAMS *x, JUN HASEGAWA *, RAYMOND N. JOHNSON ‡, and RONALD C. HARING ‡

Received November 6, 1978, from the **Pharmacy Research and Development Department and the* ‡*Analytical Research and Development Department, Ayerst Laboratories Inc., Rouses Point, NY 12979.* Accepted for publication February 7, 1979.

Abstract □ The bioequivalence of four conjugated estrogens tablets USP was compared by measurement of seven estrogens or estrogen metabolites in the urine during steady-state dosing in postmenopausal women. Two studies compared three generic products with the innovator's product. The urinary excretion of 17α-dihydroequilin, 17α-dihydroequilenin, and 17α-estradiol were significantly greater in all cases with the innovator's product than with the generic products. Statistically significant differences between products were observed occasionally for other components. The generic products thus were bioinequivalent to the innovator's product, although all products essentially met current compendial specifications. A third study observed no significant differences between three batches of the innovator's product for the seven components. Total conjugated estrogens excretion of all products at the steady state was essentially equal and correlated with neither disintegration time nor dissolution half-time. Bioinequivalence between products is discussed in relation to the need for an improved USP conjugated estrogens monograph. Evidence suggesting the metabolism of a fraction of dosed estrone, equilin, and 17α-dihydroequilin to 17β-estradiol, 17β-dihydroequilin, and 17α-dihydroequilenin, respectively, is presented.

Keyphrases □ Estrogens, conjugated—bioinequivalence of generic and proprietary products, postmenopausal women □ Bioequivalence—conjugated estrogens, bioinequivalence of generic and proprietary products, postmenopausal women □ Product substitution—estrogens, conjugated, bioinequivalence of generic and proprietary products, postmenopausal women

Conjugated estrogens of natural origin are composed of at least nine different estrogens or estrogen metabolites, each present in a different amount. The USP monograph for conjugated estrogens (1) contains specifications for total conjugated estrogens and for the two most abundant components, sodium estrone sulfate and sodium equilin sulfate. The sodium estrone sulfate specification is 50–65% and the sodium equilin sulfate specification is 20–35% of the total conjugated estrogens content. The monograph does not contain quantitative specifications for additional components, although an identification test (2) requires the presence of a prominent GLC peak for 17α-dihydroequilin and additional peaks for 17α-estradiol, 17β-dihydroequilin, equilenin, 17β-estradiol, and 9-dehydroestrone.

Broad content ranges are specified for sodium estrone sulfate and sodium equilin sulfate. The content of the third major component, sodium 17α-dihydroequilin sulfate, which by GLC is 15% of the total estrogens in the innovator's product, is unspecified; the specification for this component is an imprecise and nonquantitative identification test. A similar requirement is made for minor components.

Pharmaceutical equivalents are defined (3) as "drug products that contain identical amounts of the identical active drug ingredient. . . ." Drug product compliance with compendial standards is generally assumed to assure pharmaceutical equivalence (4). A consequence of the broad or nonquantitative specifications for both major and minor components is that compendial standards may not

[a] The assay for estrogens content, disintegration times, and dissolution half-times used 20, six, and three tablets, respectively, except the disintegration times for P3, P4, and P5, which used 24 tablets. [b] Tablets were unavailable for dissolution half-time determination.

assure the pharmaceutical equivalence of conjugated estrogens products.

A previous publication (5) presented a sensitive and specific method to quantitate seven estrogens or estrogen metabolites in the urine of postmenopausal subjects after dosing to the steady state. The usefulness of the urinary excretion profile in assessing the bioinequivalence of conjugated estrogens products from multiple sources was discussed. The present investigation examined the bioinequivalence of four conjugated estrogens products based on their urinary excretion profiles. The innovator's product and three generic products, all of which meet or nearly meet current compendial specifications, were studied. The purpose of this study was to investigate the extent to which adherence of these products to compendial specifications assures their bioequivalence.

EXPERIMENTAL

The results of Studies I–III, conducted at intervals of 1 year, are reported.

Subjects—Eleven, 12, and eight postmenopausal women were selected for Studies I, II, and III, respectively. A physical examination and medical history were obtained for each subject. The postmenopausal syndrome was established by documented physiological or surgical menopause of long duration and anestrogenism was established by colpocytogram. Each subject in Studies II and III was requested to take no medication other than the conjugated estrogens. Each subject signed a voluntary informed consent form.

Study I—The two physiologically menopausal subjects' ages were 51 and 54 years, and the nine surgically menopausal subjects' average age was 50 years (range 44–61). The average weight of all subjects was 65 kg (range 54–91). Serum biochemistry tests[1] and urinalyses[2] (pH, glucose, and protein) were conducted to assure normal liver and kidney function. Nine subjects were concomitantly receiving thyroid replacement hormones, digoxin, or an oral hypoglycemic agent.

Study II—The eight physiologically menopausal subjects' average age was 52 years (range 50–57), and the four surgically menopausal subjects' average age was 44 years (range 37–54). The average weight of all subjects was 62 kg (range 54–73). All subjects were in good health, established by physical examination, serum biochemistry tests[1], and urinalyses[2] (pH, glucose, and protein).

Study III—The four physiologically menopausal subjects' average age was 53 years (range 51–56), and the four surgically menopausal subjects' average age was 35 years (range 29–38). The average weight of all subjects was 65 kg (range 51–94). The good health of the subjects was established as in Study II.

[1] SMA 12/60.
[2] Combistix, Ames Co., Elkhart, Ind.

Protocol—*Study I*—The study was divided into four consecutive phases of 28, 21, 14, and 21 days. The first phase was a washout period to permit urinary estrogen levels of those subjects previously taking estrogen medication to return to baseline levels. At the end of this phase, a 24-hr urine sample was collected from each subject.

During the second phase, each subject received a 2.5-mg dose (as two 1.25-mg tablets) of conjugated estrogens daily for 21 days. Each subject received Treatments P1[3] and A (generic product) in a randomized two-way crossover design. Each subject was instructed to select a time for dosing each morning and to take the dose at the same time each morning. On any day between Days 16 and 20 inclusive, a 24-hr urine sample was collected from each subject beginning at the time of dosing. The third phase was a washout period; a 24-hr urine sample was collected on any day between Days 11 and 13 inclusive. The fourth phase was the second half of the crossover design.

Diet was unrestricted throughout the three studies.

Study II—The study was divided into four consecutive 28-day phases. The first phase was a washout period; a 24-hr urine sample was collected from each subject during the latter part of the 4th week. Each subject received two 1.25-mg tablets of conjugated estrogens daily for 21 days during the last three phases. Each subject received Treatments P2[4], B (generic product), and C (generic product) in a randomized three-way crossover design. Each subject was instructed to select a time for dosing each morning and to take the dose at the same time each morning. On Days 17–19, three consecutive 24-hr urine samples were collected from each subject, beginning at the time of dosing. In accord with the recommended cyclic dosing schedule, no medication was administered during the last 7 days of the last three phases.

Study III—The study design was similar to that of Study II. Six subjects were common to Studies II and III. A shorter washout phase of at least 18 days was allowed for these six subjects. Each subject received Treatments P3[5], P4[6], and P5[7] in a randomized three-way crossover design.

***In Vitro* Tests**—The content and disintegration times of each product and batch were determined for conformity to USP specifications. Sodium estrone sulfate, sodium equilin sulfate, and total conjugated estrogens were determined by the spectrophotometric method described in the USP. Disintegration times were determined by the procedure for plain coated tablets described in the USP (6). The content of nine individual sodium estrogen sulfates was determined by a GLC method (7).

Dissolution half-times were determined utilizing USP Dissolution Method II (8). The dissolution medium was simulated gastric fluid TS, 1000 ml, and the stirring speed was 150 rpm. Based upon preliminary studies, at least six 10-ml samples were withdrawn at times above and below the dissolution half-times for each product or batch. The dissolution medium was not replaced after sampling. Results were determined

[a] Approximately 1 μg of 17β-dihydroequilenin was present in Products A–C; accurate quantitation was prevented by an interfering peak in the chromatogram.

by interpolation after correction for the drug and dissolution medium removed by sampling.

Assay—Seven estrogens or estrogen metabolites in the urine were determined using enzyme hydrolysis of urine samples, extraction and purification, and GLC (5). An initial version of the method, in which urine samples were frozen prior to assay and the GLC derivatization reagent contained 1% trimethylchlorosilane catalyst, was used for Study I. Studies II and III used the published method, which specifies refrigerated sample storage and a 10% catalyst level.

Aliquots of each 24-hr urine sample from the three studies were assayed for creatinine (9, 10).

Calculations—Urinary excretion differences between treatments were examined based on the 1-day levels (Study I) or on the 3-day mean levels (Studies II and III) of each estrogen (11–13). Attainment of the steady state in Studies II and III was examined by multivariate analysis of the Day 18 minus Day 17 and Day 19 minus Day 18 differences (14). When significant treatment differences were observed in Study II, differences between individual treatments were evaluated by a Student t test, with the Bonferroni adjustment for multiple comparisons.

RESULTS AND DISCUSSION

Tablet Assays—The total conjugated estrogens content of all products (Table I) was within USP specifications (6) and ranged from 1.18 to 1.31 mg/tablet or from 94.4 to 104.8% of the labeled amount. Sodium estrone sulfate ranged from 52.0 to 62.7% of the total conjugated estrogens content in seven products or batches; Product A exceeded the USP specification range (1) of 50.0–65.0% by 1.1%. Sodium equilin sulfate was within USP specifications (1) in all cases and ranged from 26.7 to 29.7% of the total conjugated estrogens content.

The content in all products of nine individual sodium estrogen sulfates and their total was determined by GLC analysis (Table II).

Disintegration and Dissolution—The disintegration times of all products (Table I) were within the 90 min specified by the USP and ranged from 22.5 to 74.5 min. No correlation was observed between the disintegration times and the amounts of total conjugated estrogens excreted per 24 hr at the steady state.

The USP conjugated estrogens tablets monograph does not contain a dissolution rate requirement. A study was performed to investigate the possible relationship between dissolution rate and estrogens excretion. Mean dissolution half-times ranged from 24.5 to 241 min (Table I); a correlation between these values and mean disintegration times was observed ($r = 0.84$, $p < 0.025$). No correlation between dissolution rate and estrogens excretion was observed.

The correlation was based on data obtained from separate disintegration time and dissolution rate experiments. A previous study[8] of the disintegration times of two batches of the innovator's product and four generic products in simulated gastric fluid TS and assay of conjugated estrogens dissolved in this fluid during tablet disintegration demonstrated no significant difference between disintegration times and times to 90% dissolution. These results, combined with those of the present study, indicate that, for the representative products examined, water-soluble sodium estrogen sulfate dissolution is rate limited by disintegration. Since the total conjugated estrogens excretion of all products was essentially equal, as will be discussed in a subsequent section, and individual tablet disintegration times ranged only up to 81 min, the validity of the 90-min USP disintegration time limit (6) in assuring equal extent of absorption could not be examined.

[8] R. N. Johnson and R. P. Neil, Ayerst Laboratories, Rouses Point, N.Y., unpublished results.

Bioinequivalence Method—Bioequivalent drug products are defined (3) as "pharmaceutical equivalents or pharmaceutical alternatives whose rate and extent of absorption do not show a significant difference . . . ." The present experimental design precluded rate measurements. Equal extent of urinary excretion is a necessary, but not sufficient, condition for bioequivalency. However, unequal urinary excretion is a sufficient condition for bioinequivalence. Therefore, the present method permits assessment of bioinequivalence of conjugated estrogens products if those products differ in the extent of absorption.

Improvements in sample storage and analytical procedure, which resulted in the improved recovery values reported previously, were made after Study I. The subject population was different in all three studies, although six subjects were common to Studies II and III. Therefore, absolute values between studies must be compared cautiously. Mean endogenous urinary estrogen levels (Tables III–V) generally were near, but greater than, the estimated minimum quantifiable levels reported previously.

The frequent occurrence of endogenous estrogens below the minimum quantifiable levels in some subjects increased the uncertainty in their estimation. However, the mean values were considered sufficiently reliable for each study to estimate true increases in excretion by subtraction

[a] See footnote *a* of Table III. [b] The 17α-DHEQ region was masked in six of eight Phase I samples; the 17β-DHEQ region was masked in five of eight samples. Correction for endogenous levels is made using the values obtained in Study II.

of endogenous levels. In this manner, absolute comparisons of excreted estrogens as a function of dose could be made for the combined studies. The absence of information about the specific conjugate estrogen forms excreted does not allow determination of pertinent percentage recovery data. Therefore, the values reported in Tables III–V and subsequent values calculated from these data are not corrected for analytical losses.

The primary advantage of steady-state bioinequivalence studies for the conjugated estrogens is the ability to obtain the highest possible estrogen levels in the biological samples with normal doses while adhering to the recommended cyclic drug dosing schedule. Inadequate knowledge of the elimination pathways and their rates for each estrogen prohibited estimating the time of attainment of the steady state upon daily dosing. Therefore, samples were collected late in the normal 21-day dosing cycle, on a single day between Days 16 and 20 inclusive (Study I) or on Days 17–19 (Studies II and III).

The daily changes in excreted amounts of each estrogen or estrogen metabolite (Day 18 minus Day 17 and Day 19 minus Day 18) were not significantly different from zero. Therefore, the steady state was reached by Day 17, and each study was performed under steady-state conditions.

Metabolic Interconversions—Although metabolism studies were not an objective of the present work, the excretion of three of the seven components in greater than dosed amounts permitted tentative assignment of their conjugated estrogens origin. The high levels of 17β-estradiol in the urine appear to reflect the well-established metabolic reduction of estrone in humans (15). The amount of 17β-dihydroequilin found in the urine was essentially constant among all products tested and independent of the 17β-dihydroequilin content of these products. Also, levels of 17β-dihydroequilin in the urine exceeded the dosed amounts of this component in the generic products and the dosed amounts of 17β-dihydroequilenin in all products. The apparently constant excretion suggests

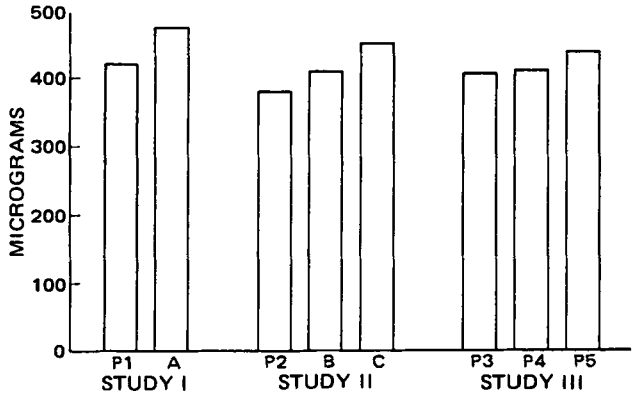

Figure 2—*Summation of estrone and 17β-estradiol, expressed as the sodium estrogen sulfates, excreted in the urine per day at the steady state during daily dosing with two 1.25-mg conjugated estrogens tablets USP. Values are corrected for endogenous levels. Key: see Fig. 1.*

origin from equilin, the tablet content of which was relatively constant for all products. This metabolic conversion is analogous to the reduction of estrone to 17β-estradiol, the only structural difference being the presence of a double bond in the B ring of equilin and 17β-dihydroequilin. The reduction of equilin to 17β-dihydroequilin was observed previously in dogs[9].

The amounts of 17α-dihydroequilenin excreted in the urine are generally greater than the dosed amounts. Possible sources of this compound are 17α-dihydroequilin, equilin, and equilenin. The equilin and equilenin content of all products is relatively constant, whereas the content of 17α-dihydroequilin is much greater in the reference product than in the generic products. A highly significant correlation was observed between the 17α-dihydroequilin dose and the amount of 17α-dihydroequilenin excreted (Fig. 1). Approximately 12% of 17α-dihydroequilin in urine samples is oxidized to 17α-dihydroequilenin during assay (5). This amount would not account for the observed recovery of 17α-dihydroequilenin in the urine and suggests oxidative metabolism of a portion of the dosed 17α-dihydroequilin.

Product Bioinequivalence—The mean endogenous estrogen levels and levels of seven estrogens and estrogen metabolites and their totals excreted during dosing are presented in Tables III–V. Analyses of variance revealed no significant differences in urinary excretion among Treatments P3, P4, and P5 for the seven estrogens (Table V). These three treatments were three batches of the innovator's product manufactured in March, June, and September of 1976 and represented production over a full raw material collection season.

Analyses of variance revealed significant differences in urinary estrogen levels between the innovator's product and the generic products for certain estrogens or estrogen metabolites (Tables III and IV). Levels of

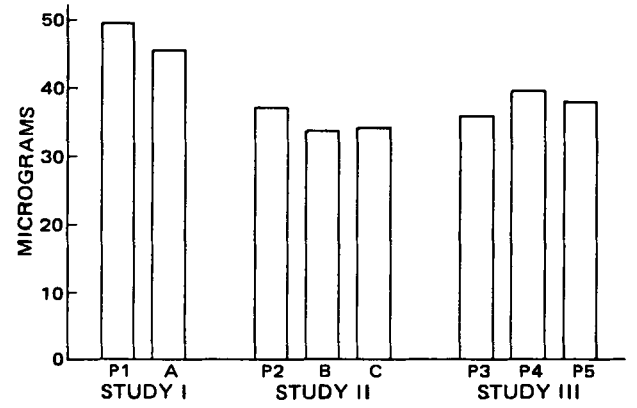

Figure 3—*Summation of equilin and 17β-dihydroequilin, expressed as the sodium estrogen sulfates, excreted in the urine per day at the steady state during daily dosing with two 1.25-mg conjugated estrogens tablets USP. Values are corrected for endogenous levels. Key: see Fig. 1.*

[9] K. Sestanj and D. Dvornik, Ayerst Laboratories, Montreal, Quebec, Canada, unpublished results.

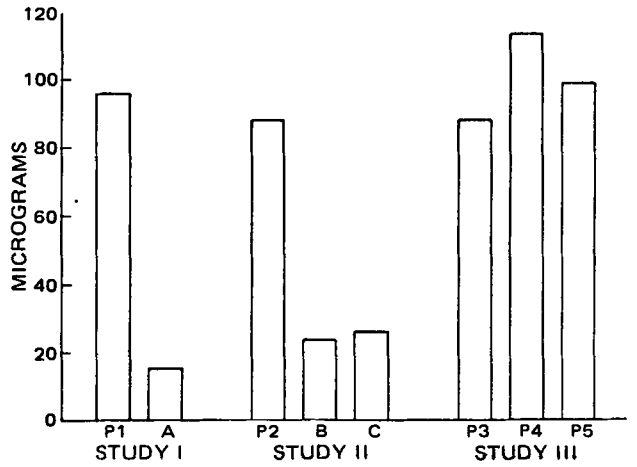

Figure 4—*Summation of 17α-dihydroequilin and 17α-dihydroequilenin, expressed as the sodium estrogen sulfates, excreted in the urine per day at the steady state during daily dosing with two 1.25-mg conjugated estrogens tablets USP. Values are corrected for endogenous levels. Key: see Fig. 1.*

17α-estradiol after dosing with the three generic products were significantly lower than after dosing with the reference product ($p = 0.064$, Treatment A; $p < 0.01$, Treatments B and C). Levels of 17α-dihydroequilin and 17α-dihydroequilenin were also significantly lower with the generic products ($p < 0.01$, Treatments A–C, 17α-dihydroequilin; $p < 0.001$, Treatment A, $p < 0.01$, Treatments B and C, 17α-dihydroequilenin). Levels of estrone were significantly higher after dosing with Treatment A than after dosing with the reference product ($p < 0.05$). Levels of 17β-estradiol were significantly higher after dosing with Treatment C than after dosing with the reference product ($p < 0.05$).

The discussed metabolic relationships provided a basis for separating the urinary excretion of the conjugated estrogens components into groups (Figs. 2–4). Exceedingly small amounts of 17α-estradiol were observed in the urine of a premenopausal woman (16), possibly as a consequence of estrone metabolism. In the present study, the absence of a correlation with dosed estrone, the good correlation with dosed 17α-estradiol, and the mean recovery of only 24.2% of the dose suggest that dosed 17α-estradiol is the source of the excreted compound. Thus, 17α-estradiol was categorized separately (Fig. 5).

Figure 2 indicates relatively small differences between products in the summation of estrone and 17β-estradiol. Of the six instances in which differences between the reference and generic products are possible for these compounds, only two comparisons were statistically significant. Similarly, relatively small differences between products were observed in the equilin plus 17β-dihydroequilin group (Fig. 3). No significant differences between products were observed within this group. In these two groups, variations between the mean urinary estrogen excretion of the reference product and of the generic product(s) within Studies I and II were less than 20%. Similarly, variations between the mean urinary estrogen excretion of the five batches of the reference product and each generic product were less than 20%.

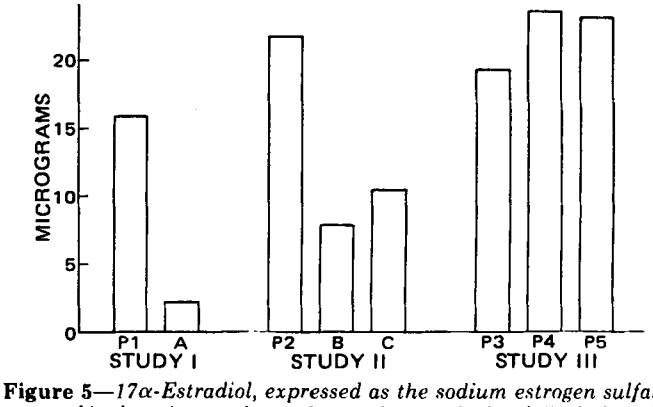

Figure 5—*17α-Estradiol, expressed as the sodium estrogen sulfate, excreted in the urine per day at the steady state during daily dosing with two 1.25-mg conjugated estrogens tablets USP. Values are corrected for endogenous levels. Key: see Fig. 1.*

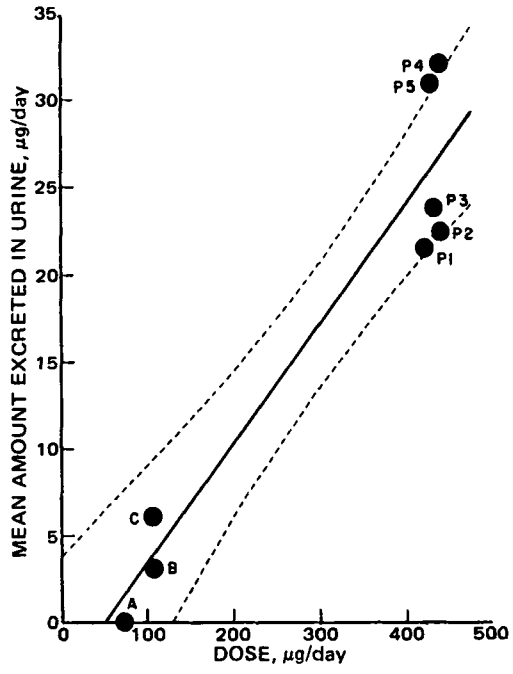

Figure 6—*Correlation between the daily dose of sodium 17α-dihydroequilin sulfate and the amount of 17α-dihydroequilin, expressed as the sodium estrogen sulfate, excreted in the urine per day (r = 0.95, p < 0.001) for each product or batch. Values are corrected for endogenous levels. Key: see Fig. 1.*

Urinary excretion of the 17α-dihydroequilin and 17α-dihydroequilenin group (Fig. 4) and of 17α-estradiol (Fig. 5) was markedly different between the innovator's product and the generic products. In every case, the greater excretion of these components after dosing with the innovator's product was statistically significant compared to dosing with the generic products. The excretion of 17α-dihydroequilin plus 17α-dihydroequilenin of generic Products A, B, and C relative to the reference product was 15.9, 26.5, and 29.4%, respectively. Comparable values for 17α-estradiol excretion from the three generic products relative to the reference product were 13.9, 35.9, and 47.9%, respectively.

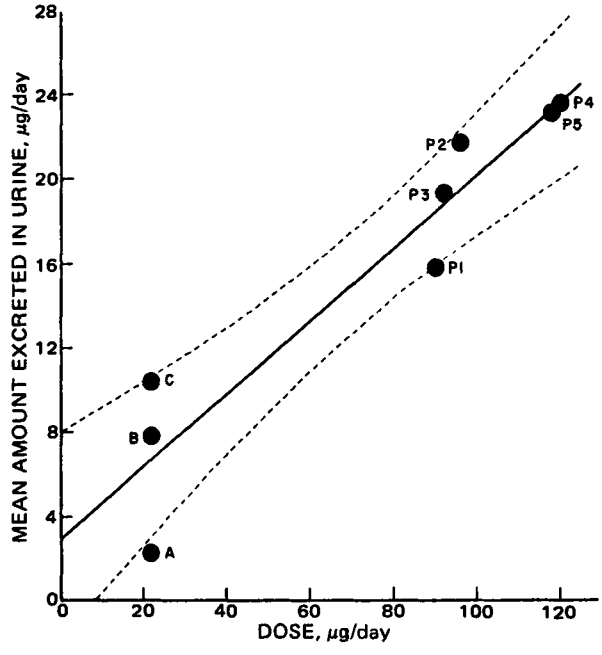

Figure 7—*Correlation between the daily dose of sodium 17α-estradiol sulfate and the amount of 17α-estradiol, expressed as the sodium estrogen sulfate, excreted in the urine per day (r = 0.94, p < 0.001) for each product or batch. Values are corrected for endogenous levels. Key: see Fig. 1.*

If urinary estrogen excretion were a measure of relative extent of absorption, there should be a linear relationship between dose and urinary excretion. This relationship was previously established by demonstrating that at the 1.25- and 2.5-mg dose levels, constant percentages of the individual estrogens were excreted. In the present study, highly significant correlations between the four- to fivefold differences in the dose of 17α-dihydroequilin and 17α-estradiol among the four products and their excretion in the urine were observed (Figs. 6 and 7). These correlations confirm previous findings.

Total estrogen recoveries from all products were similar. Expressed as a percentage of the daily dose and calculated as previously described, the mean total recovery for all treatments was 19.9 ± 1.2 (*SD*) %. The extent of absorption and metabolic fate of the conjugated estrogens are unknown. However, when solutions of 4-^{14}C-estrone sulfate (6-mg dose) and 6,9-^{3}H-equilin sulfate (7-mg dose) were simultaneously ingested by two premenopausal volunteers (21 and 22 years old), a total of 70–88% of the administered radioactivity was recovered in the urine after 5 days[10]. These findings, together with the results of the present study, indicate that these estrogens are both well absorbed and highly metabolized.

The results from Tables III and IV and Figs. 4 and 5 clearly indicate that the three generic conjugated estrogens products studied are bioinequivalent to the innovator's product. This bioinequivalence occurs primarily as a result of large differences in the urinary 17α-hydroxy estrogen levels. As shown in Figs. 6 and 7, the bioinequivalence of the generic conjugated estrogens products relative to the innovator's product is due to differences in estrogens composition among products (Table II). The absence of significant differences between batches of the innovator's product (Table V) is due to the similar composition of each batch. Thus, the bioinequivalence that occurs among conjugated estrogens products is attributable to their pharmaceutical inequivalence. The broad content ranges for sodium estrone sulfate and sodium equilin sulfate and the inadequate specifications for other components suggest the need for more rigorous specifications in the USP conjugated estrogens monograph.

Kinetics and Mechanism of Chlorambucil Hydrolysis

W. R. OWEN and P. J. STEWART ˣ

Received June 20, 1977, from the *Pharmacy Department, University of Queensland, St. Lucia, Australia.* Accepted for publication February 7, 1979.

Abstract □ The kinetics and mechanism of hydrolysis of the cytotoxic drug chlorambucil were investigated. A study of the reaction order and of the pH, dielectric constant, and ionic strength effects on the reaction rate revealed that the hydrolysis was a limiting unimolecular nucleophilic substitution, the rate-determining step being the ionization of the first 2-chloroethylamine chlorine. The hydrolysis rate was markedly dependent on the protonation degree of the chlorambucil basic group, indicating that a cyclic ethyleneimmonium ion may be involved in the rate-determining step.

Keyphrases □ Chlorambucil—hydrolysis, kinetics and mechanism, reaction order, pH, dielectric constant, ionic strength □ Antineoplastic agents—chlorambucil, hydrolysis, kinetics and mechanism, reaction order, pH, dielectric constant, ionic strength □ Hydrolysis—chlorambucil, kinetics and mechanism

The cytotoxic drug chlorambucil has been used clinically in the treatment of malignant conditions associated with white blood cell proliferation (follicular lymphoma, Hodgkin's disease, *etc.*) and ovarian carcinoma (1–3). Dosage forms include intravenous injections and perfusion fluids. In these aqueous media, chlorambucil, an aromatic nitrogen mustard, undergoes hydrolysis by nucleophilic substitution. The hydrolytic pathway involves several consecutive steps. Previous stability studies (4–8) were semiquantitative or revealed little information regarding the kinetics and mechanism of hydrolysis in conditions appropriate to formulation.

The formation of a cyclic ethyleneimmonium ion has been proposed as an intermediate in aliphatic nitrogen mustard hydrolysis (7). A cyclic intermediate has not been suggested for aromatic nitrogen mustards but would seem highly probable by analogy with the aliphatic series. However, in aromatic compounds, such an intermediate would probably be less favored since the availability of the lone electron pair on the nitrogen would be reduced somewhat by resonance with the π-electrons of the aromatic ring. Therefore, this investigation was undertaken to elucidate the reaction mechanism under conditions appropriate to formulation.

EXPERIMENTAL

Materials—Chlorambucil BP (mp 65.8–66.0°) was recrystallized from a light petroleum (bp 40–60°, dried over sodium)–benzene (fractionated and dried over sodium) mixture. Silver chloride was prepared by potentiometrically titrating silver nitrate (25 ml, 0.1 *M*) and nitric acid (1 ml) with sodium chloride (0.1 *M*) to the exact end-point using an automatic titrimeter. The supernatant liquid was decanted, and the silver chloride precipitate was washed six times with oxygen-free distilled water. The following buffers were used: boric acid (0.1 *M*) in potassium nitrate (0.1 *M*)–sodium hydroxide (0.1 *M*) for pH 10.1–7.8, and sodium acetate (0.1 *M*)–nitric acid (0.1 *M*) for pH 5.5–1.63. Other chemicals were reagent grade.

The silver–silver chloride electrodes were prepared electrolytically (9, 10) and possessed asymmetric potentials of $< \pm 0.02$ mv.

Kinetic Methods—*Potentiometric*—An alcoholic solution of chlorambucil (1 ml, 10 mg/ml) was added to the buffer (500 ml) in the reaction half-cell of the silver–silver chloride concentration cell (Fig. 1). The concentration cell was equilibrated previously in a water bath (25.00 ± 0.01°). The pH was measured[1] (±0.002 pH unit) initially and on completion of the kinetic run (pH difference was within ±0.05 pH unit in all experiments). The temperature was monitored throughout the experiment. Throughout the hydrolysis, the electromotive force (emf) and time were monitored on a data logging unit[2]. Selection of the appropriate range and sensitivity multiplier ensured maximum accuracy in the electromotive force measurement.

The silver–silver chloride concentration cell allowed continuous monitoring of the liberated chloride. At low chloride-ion concentrations and constant ionic strength, the electromotive force of the concentration cell was related to the liberated chloride by the following equation (10):

$$E = E' + 2.303RT/nF \log [c_A/2 + \sqrt{K_S + (c_A/2)^2}] \quad \text{(Eq. 1)}$$

where E is the electromotive force of the concentration cell; E' is the standard potential of the concentration cell, dependent on the reference half-cell potential and the activity coefficient correction term; R is the gas constant (8.314 J mole^{-1} deg^{-1}); T is the absolute temperature (°K), F is the Faraday constant (96,487 coulomb equivalents^{-1}); n is the number of electrons transferred per ion; c_A is the liberated chloride; and K_S is the silver chloride solubility product.

Preliminary electrode response calibrations showed that the concentration cell operated in a theoretical and reproducible manner. Use of E', slope ($2.303RT/nF$), and K_S, derived by a nonlinear parameter estimation (11) for each ionic strength, allowed calculation of the liberated chloride concentration. The first-order rate constants were determined by a linear least-squares regression–orthogonal polynomial analysis (12), using the c_∞ derived from all of the data by a nonlinear parameter estimation (10).

Conductimetric—An alcoholic chlorambucil solution was added to

the reaction medium (500 ml) in a stoppered reaction vessel previously equilibrated in a water bath (25.00 ± 0.01°). The conductance was measured[3] at predetermined times with a platinized conductance cell (13). The temperature and pH were monitored throughout the experiment.

The ionized chlorambucil decomposition products (mainly chloride) were monitored conductimetrically. Preliminary experiments showed that the conductance–chloride-ion response calibrations were linear over the chloride concentration range required for the kinetic study. Rate constants were determined as in the potentiometric method, using conductance instead of concentration terms.

RESULTS AND DISCUSSION

Order of Reaction—The general shape of the chloride concentration–time curve (Fig. 2) typified first-order behavior. Fitting the data to the first-order model:

$$\log [(c_\infty - c_0)/(c_\infty - c)] = kt/2.303 \qquad \text{(Eq. 2)}$$

where c is the concentration of chloride at time t, c_0 is the initial concentration of chloride at time $t = 0$, c_∞ is the concentration of chloride at infinity, and k is the first-order rate constant (seconds^{-1}), and testing the linearity of this model (12) confirmed first-order behavior (Fig. 2). Attempts to fit more complex models were unrewarding and did not improve the fit.

The infinite chloride concentration in Fig. 2 was indicative of the hydrolysis of both chloroethyl chains (*i.e.*, 0.114×10^{-3} *M* compared to 0.120×10^{-3} *M*). This situation was typical of all kinetic runs. Therefore, the rate-determining step must be the hydrolysis of the first chlorine, because a consecutive pathway involving the hydrolysis of the chlorohydrin as the rate-determining step would result in a nonlinear first-order plot. This result was consistent with previous reports (5). For a first-order reaction, the hydrolysis mechanism of the first chlorine must be either limiting unimolecular ($k_1 \gg k_2$ and $k_3 \gg k_1$), with the rate-determining step being the ionization of the first chlorine (Scheme I*b*), or limiting bimolecular ($k_1 \ll k_2$), with the rate-determining step being the reaction of chlorambucil with H_2O or OH^- (Scheme I*a*).

pH Effect—Duplicate rate determinations for chlorambucil hydrolysis were made over pH 1.63–10.10 using the potentiometric method (Fig. 3).

Two discrete sections of the profile were obvious. First, at pH 5–10, the chlorambucil reaction rate with the amino group unionized [*i.e.*, pKa = 2.499 (10)] was independent of hydroxide ion, and a bimolecular substitution with the poorly nucleophilic water molecule seemed unlikely (14). Therefore, a unimolecular hydrolytic mechanism is suggested. Second, below pH 5, a decrease in the reaction rate occurred with a decrease in pH, *i.e.*, with increased protonation of the chlorambucil amino group. The decreased availability of the lone pair of nitrogen electrons should have little effect on conventional S_N1 or S_N2 reaction rates owing to the two-carbon separation from the chlorine. If any influence did occur in a bimolecular solvolysis, the decreased inductive effect should promote the reaction rate.

The lone pair, however, is essential for the formation of the cyclic ethyleneimmonium ion as the intermediate in a unimolecular pathway (Scheme I). Amino group protonation will greatly affect the reaction rate by decreasing the "effective" species concentration. The formation of a cyclic ethyleneimmonium ion would adequately explain the rate dependence on the availability of a free lone pair on the nitrogen atom.

Proposed Kinetic Models—While the primary chlorambucil decomposition pathway was the limiting unimolecular hydrolysis of the unprotonated basic species, the possibility of a secondary parallel reaction mechanism, which could become dominant as the ratio of the protonated to unprotonated species increased, must be considered. Two possible secondary mechanisms emerge.

Unimolecular Ionized Base Hydrolysis Involving Noncyclic Carbonium Ion—

$$dc_T/dt = k_A c_A + k_{AH} c_{AH} \quad \text{(Eq. 3)}$$

where c_T is the total chlorambucil concentration equal to the sum of the unionized concentration (c_A) and the ionized concentration (c_{AH}), k_A is the unimolecular rate constant for free base decomposition, and k_{AH} is the unimolecular rate constant for ionized base decomposition.

$$\therefore dc_T/dt = k_A(1 - \alpha)c_T + k_{AH}\alpha c_T$$

$$= kc_T \quad \text{(Eq. 4)}$$

where k is the observed first-order rate constant and equals $k_A(1 - \alpha) + k_{AH}\alpha$ and α is the degree of ionization.

Therefore, the model (Model A) to be tested is:

$$k = k_A + (k_{AH} - k_A)\alpha \quad \text{(Eq. 5)}$$

Bimolecular Hydrolysis for Ionized Base Involving Noncyclic Intermediate—

$$dc_T/dt = k_A c_A + k_{AH} c_{AH} c_{OH} \quad \text{(Eq. 6)}$$

where k_{AH} is the bimolecular rate constant for decomposition of the ionized base and c_{OH} is the concentration of hydroxyl ions.

$$\therefore dc_T/dt = [k_A(1 - \alpha) + k_{AH}\alpha c_{OH}]c_T \quad \text{(Eq. 7)}$$

For pseudo-first-order kinetics at constant pH:

$$k = k_A(1 - \alpha) + k_{AH}\alpha c_{OH} \quad \text{(Eq. 8)}$$

where k = observed first-order rate constant (seconds^{-1}).

$$\therefore k = (k_A K_a + k_{AH} K_w)/(K_a + c_H) \quad \text{(Eq. 9)}$$

where c_H is the hydrogen-ion concentration, K_a is the dissociation constant for the basic group of chlorambucil, and K_w is the water dissociation constant.

Therefore, the model (Model B) becomes:

$$\log k = \log (k_A K_a + k_{AH} K_w) - \log (K_a + c_H) \quad \text{(Eq. 10)}$$

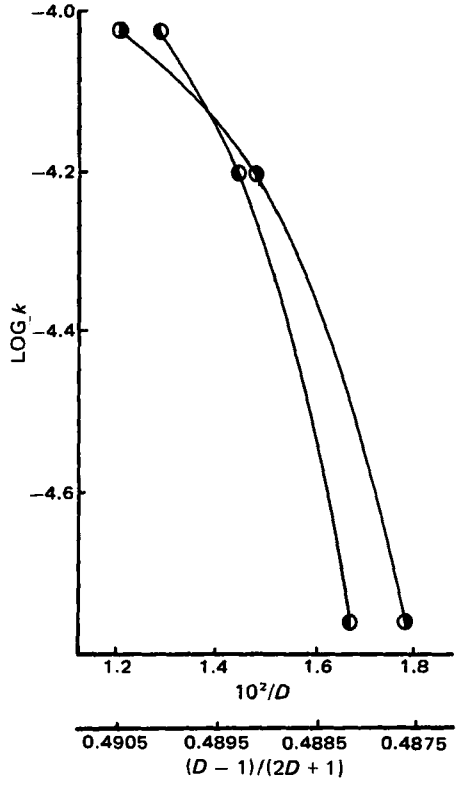

Figure 5—*Solvent effect on the chlorambucil hydrolysis rate in aqueous-alcohol solutions at 25.0°. Key:* ◑, *dielectric constant function* = (D − 1)/(2D + 1); *and* ◐, *dielectric constant function* = 1/D. *Each point is the mean of three replicates.*

Model A was tested by regressing the observed rate constant (k) against the degree of ionization (α) (Fig. 4). An analysis of variance showed no significant deviations from linearity ($p > 0.2$). Thus, the data can be adequately interpreted by this model; *i.e.*, the reaction proceeds by a unimolecular hydrolysis of the free base *via* a cyclic intermediate in parallel with a similar unimolecular hydrolysis of the ionized base.

The magnitude of the two parallel mechanisms can be determined by calculation of the rate constants k_A and k_{AH}. Linear regression analysis provided the following results:

$$k_A = 9.436 \times 10^{-5} \pm 0.988 \times 10^{-6} \quad (p = 0.95) \qquad \text{(Eq. 11)}$$

$$k_{AH} = -0.210 \times 10^{-5} \pm 0.225 \times 10^{-5} \quad (p = 0.95) \qquad \text{(Eq. 12)}$$

The hypothesis that k_{AH} does not differ significantly from zero cannot be rejected [t test: $p(t = 1.93, 22\ df) = 0.1$–$0.05$]. Under these circumstances, the rate constant k_{AH} must be extremely small or zero. Hence, the decomposition occurred substantially by unimolecular hydrolysis of the free base. Hydrolysis of the ionized base was insignificant. Therefore, the data can be adequately represented by the model:

$$k = k_A(1 - \alpha) \qquad \text{(Eq. 13)}$$

In addition, since there was no significant departure from linearity shown by the analysis of variance, nonlinear terms such as $k_{AH}\alpha c_{OH}$ in the bimolecular Model B were unnecessary. Consequently, testing of Model B was irrelevant.

Solvent Effects—Replicate rate determinations were made in 0.0, 20.0, and 40.0% (v/v) ethanol in water at zero ionic strength by the conductimetric method. The effect of the dielectric constant on the hydrolysis rate is shown in Fig. 5, where log k is plotted as a function of the dielectric constant (15), *i.e.*, log k *versus* $1/D$ (Amis theory) or log k *versus* $(D - 1)/(2D + 1)$ (Laidler and Eyring theory). The chlorambucil reaction rate increased markedly with the solvent dielectric constant. For a unimolecular mechanism, this finding reflected the increased solvation (and, therefore, stabilization) of the transition state (*i.e.*, ethyleneimmonium ion) with respect to the uncharged reactant (14). In contrast, for a bimolecular reaction, an increase or decrease could be expected depending on whether the attacking nucleophile is uncharged or charged and, therefore, on the degree of charge dispersion in the transition state (14). The results obtained are thus consistent with the proposed unimolecular model but do not provide absolute proof of the reaction pathway.

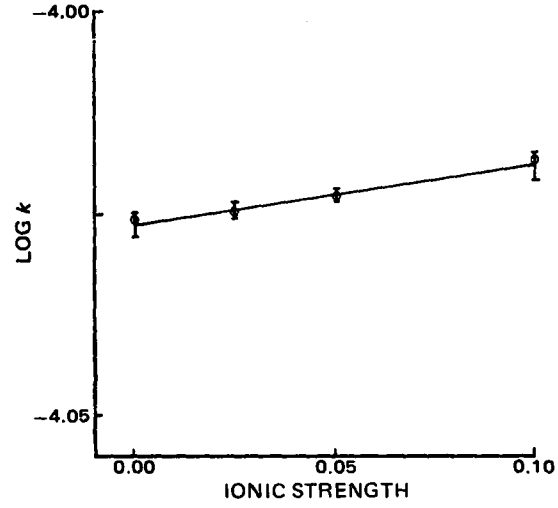

Figure 6—*Ionic strength effect on the chlorambucil hydrolysis rate in borate buffer (pH 9.0) at 25.0°. Key:* ○, *mean of three replicate rate determinations; and* —, *fitted linear least-squares regression with the confidence limits* (p = 0.95).

Neither kinetic model provided a linear representation of the data. However, nonelectrostatic effects in the Laidler–Eyring and Amis models were assumed to be negligible. Therefore, specific effects such as hydrogen bonding and van der Waal's forces of interaction between the solvent and reactant, which may be prevalent in chlorambucil hydrolysis in a hydroalcoholic solution, could modify the efficiency of the solvent in promoting the reaction rate. If so, linearity of the log k–dielectric constant function cannot be expected (16).

Salt Effects—The effect of common ions (chloride) on the reaction rate could not be ascertained since the required added chloride concentrations markedly reduced the sensitivity of the silver–silver chloride electrode. However, the effect of noncommon ions (*e.g.*, acetate, borate, and nitrate used in the study of pH effect) on the reaction rate was negligible, as evidenced by the pH-independent region of the log k–pH profile in Fig. 3. The results are indicative of a unimolecular substitution where the rate-determining step is independent of nucleophilicity. For a bimolecular mechanism, however, the reaction rate would be markedly dependent on the concentration and nucleophilic character of the attacking species (14).

The general ionic strength effect also was studied. Replicate rate determinations using the potentiometric method were performed for chlorambucil hydrolysis in borate buffer (pH 9.0, 0.01 M), adjusted to ionic strengths 0.100, 0.050, and 0.025 with potassium nitrate. Rate constant determinations at zero ionic strength were performed conductimetrically. Log k is regressed against the ionic strength (16) in Fig. 6. An increase in ionic strength caused a small acceleration of chlorambucil hydrolysis, which reflected the greater solvation and stabilization of the transition state at higher solvent polarity. For both the unimolecular and bimolecular pathways, an increase in the reaction rate with an increase in ionic strength would be expected (14). The small degree of acceleration of the observed rate was indicative of a reaction in a high dielectric constant solvent.

Effects of Aspirin on ^{14}C-Pirprofen Disposition in Rats

THOMAS A. THOMPSON ˣ, CORNELIUS H. BORMAN, ROSALIND S. GOODBLATT, and WILLIAM J. ROTH, III

Received December 18, 1978, from the *Research Department, Pharmaceuticals Division, Ciba-Geigy Corporation, Ardsley, NY 10502.* Accepted for publication February 8, 1979.

Abstract □ The effects of aspirin on ^{14}C-pirprofen disposition in the rat were studied. An oral 60-mg/kg dose of aspirin significantly reduced plasma radioactivity during the 1–8-hr interval after an intravenous 5-mg/kg injection of ^{14}C-pirprofen. The aspirin-treated group had only 69% as much area under the radioactivity curve as the control group. The radioactive material in plasma consisted almost entirely of ^{14}C-pirprofen, as shown by GLC. The plasma clearance of ^{14}C-pirprofen was 7.4 ml/hr for the aspirin-treated group and 5.1 ml/hr for the control group, while the volumes of distribution were 0.32 and 0.20 liter/kg, respectively. The apparent elimination half-life was unchanged at 5.9 hr. ^{14}C-Pirprofen was approximately 98.6% bound to plasma proteins, and the binding decreased to an average of 97.2% in the presence of salicylate. Binding to blood cellular constituents was insignificant. Rats given ^{14}C-pirprofen by intravenous injection without aspirin secreted 36.0–42.8% of the dose radioactivity into bile during 4 hr while a comparable group given 60 mg of aspirin/kg secreted 46.4–70.8%. TLC and GLC demonstrated that the radioactivity in rat bile was 80–90% conjugated ^{14}C-pirprofen. The increased radioactive material secretion into bile was compensated in the intact rat by reabsorption, since the total radioactive material excreted in urine was not changed by aspirin administration.

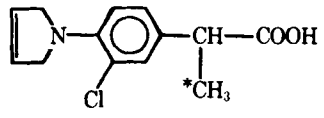
Keyphrases □ Aspirin—effect on pirprofen disposition, rats □ Pirprofen—disposition, effect of aspirin, rats □ Anti-inflammatory agents—pirprofen, disposition, effect of aspirin, rats

Pirprofen, 2-[3-chloro-4(3-pyrrolinyl)-phenyl] propionic acid, is a new anti-inflammatory drug of the arylalkanoic acid type (1).

Salicylate has been reported to reduce the plasma concentration of various arylalkanoic acid compounds including indomethacin (2), fenoprofen (3, 4), naproxen (5, 6), and diclofenac (7) in animals and humans. Pirprofen concentrations in human plasma as well as that bound to plasma proteins were reduced by salicylate[1], and the present study was undertaken to examine salicylate effects on the biological disposition of pirprofen in the rat.

EXPERIMENTAL

Radioactive Pirprofen—^{14}C-Pirprofen (I), with the radioactive atom in position three of the propionic acid moiety, was used[2]. The specific



I

activity was 13 μCi/mg. The labeled compound was examined by TLC using the procedures described later. The major constituent chromatographed like authentic pirprofin, and the only impurity was a substance comprising about 5% of the radioactivity.

Animal Procedures—Young adult male Wistar rats[3], ~200 g, were used.

^{14}C-Pirprofen dosage solutions were prepared in 0.2 *M* $NaHCO_3$ to provide 5 mg/kg and 3 μCi/animal in volumes of 0.3 ml for injection and 1.0 ml for intubation. Aspirin[4] was administered as a 60-mg/kg aqueous dose by intubation.

Blood samples were obtained by anesthetizing the rats with ether, opening the abdominal cavity, and exsanguinating *via* the abdominal aorta into a heparinized 10-ml syringe. Blood plasma was frozen pending analysis.

Bile duct cannulations were done under ether anesthesia for rats that were to receive intravenous ^{14}C-pirprofen, and these rats were confined in restraining cages[5] during bile collection. Rats receiving ^{14}C-pirprofen orally were anesthetized with urethan[4] rather than ether to preclude the necessity for restraint. A 25% solution of urethan in water was administered as a 1.25-g/kg ip dose.

Radioactivity Measurements—A solubilizer–phosphore solution was prepared by mixing one volume of a commercial solubilizer[6] with four volumes of toluene containing 0.5% 2,5-diphenyloxazole[7] and 0.01% *p*-bis(*o*-methylstyryl)benzene[8]. The solubilizer–phosphore solution (15 ml) was mixed with 10 μl of injection solutions, 50 μl of ultrafiltrates, or 0.1 ml of plasma, bile, or urine prior to duplicate sample counting in a liquid scintillation spectrometer[9]. Counting efficiency was measured by external standardization.

Whole blood (0.1 ml) was pipetted onto 2.5-cm circles of filter paper and dried before combustion[10]. The resulting carbon dioxide was absorbed in 4 ml of ethanolamine to which 9 ml of methanol and 6 ml of scintillator solution, containing 15.0 g of 2,5-diphenyloxazole and 1.0 g of *p*-bis(*o*-methylstyryl)benzene/liter of toluene, were added for counting.

TLC—Aliquots (20 μl) of bile or an equivalent amount of hydrolyzate

TLC and GLC demonstrated that the radioactivity in rat bile was 80–90% conjugated ^{14}C-pirprofen. The increased radioactive material secretion into bile was compensated in the intact rat by reabsorption, since the total radioactive material excreted in urine was not changed by aspirin administration.

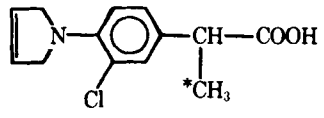
Keyphrases □ Aspirin—effect on pirprofen disposition, rats □ Pirprofen—disposition, effect of aspirin, rats □ Anti-inflammatory agents—pirprofen, disposition, effect of aspirin, rats

Pirprofen, 2-[3-chloro-4(3-pyrrolinyl)-phenyl] propionic acid, is a new anti-inflammatory drug of the arylalkanoic acid type (1).

Salicylate has been reported to reduce the plasma concentration of various arylalkanoic acid compounds including indomethacin (2), fenoprofen (3, 4), naproxen (5, 6), and diclofenac (7) in animals and humans. Pirprofen concentrations in human plasma as well as that bound to plasma proteins were reduced by salicylate[1], and the present study was undertaken to examine salicylate effects on the biological disposition of pirprofen in the rat.

EXPERIMENTAL

Radioactive Pirprofen—^{14}C-Pirprofen (I), with the radioactive atom in position three of the propionic acid moiety, was used[2]. The specific



I

activity was 13 μCi/mg. The labeled compound was examined by TLC using the procedures described later. The major constituent chromatographed like authentic pirprofin, and the only impurity was a substance comprising about 5% of the radioactivity.

Animal Procedures—Young adult male Wistar rats[3], ~200 g, were used.

^{14}C-Pirprofen dosage solutions were prepared in 0.2 *M* $NaHCO_3$ to provide 5 mg/kg and 3 μCi/animal in volumes of 0.3 ml for injection and 1.0 ml for intubation. Aspirin[4] was administered as a 60-mg/kg aqueous dose by intubation.

Blood samples were obtained by anesthetizing the rats with ether, opening the abdominal cavity, and exsanguinating *via* the abdominal aorta into a heparinized 10-ml syringe. Blood plasma was frozen pending analysis.

Bile duct cannulations were done under ether anesthesia for rats that were to receive intravenous ^{14}C-pirprofen, and these rats were confined in restraining cages[5] during bile collection. Rats receiving ^{14}C-pirprofen orally were anesthetized with urethan[4] rather than ether to preclude the necessity for restraint. A 25% solution of urethan in water was administered as a 1.25-g/kg ip dose.

Radioactivity Measurements—A solubilizer–phosphore solution was prepared by mixing one volume of a commercial solubilizer[6] with four volumes of toluene containing 0.5% 2,5-diphenyloxazole[7] and 0.01% *p*-bis(*o*-methylstyryl)benzene[8]. The solubilizer–phosphore solution (15 ml) was mixed with 10 μl of injection solutions, 50 μl of ultrafiltrates, or 0.1 ml of plasma, bile, or urine prior to duplicate sample counting in a liquid scintillation spectrometer[9]. Counting efficiency was measured by external standardization.

Whole blood (0.1 ml) was pipetted onto 2.5-cm circles of filter paper and dried before combustion[10]. The resulting carbon dioxide was absorbed in 4 ml of ethanolamine to which 9 ml of methanol and 6 ml of scintillator solution, containing 15.0 g of 2,5-diphenyloxazole and 1.0 g of *p*-bis(*o*-methylstyryl)benzene/liter of toluene, were added for counting.

TLC—Aliquots (20 μl) of bile or an equivalent amount of hydrolyzate

14.0	4.1 ± 1.2	3.0 ± 0.4	2 ± 0
17.0	2.3 ± 0.8	2.1 ± 0.8	—

[a] Rats were intubated with 60 mg of aspirin/kg in solution or with an equal volume of water and injected intravenously 1 hr later with 5 mg of ^{14}C-pirprofen/kg. [b] Four rats at each time point, except the aspirin-treated group at 4 hr which had three.

were spotted on silica gel plates[11] and developed in chloroform–methanol–formic acid (70:30:1) or benzene–ethanol–formic acid (90:10:1). The dried plates were examined under UV light and scanned for radioactivity[12].

Pirprofen Analysis—Pirprofen was determined quantitatively (8), using 3.0-ml aliquots of rat plasma containing 0–120 μg of pirprofen. The conjugated pirprofen in bile was hydrolyzed before analysis. Bile (0.2 ml) was mixed with 50 μl of 0.5 *N* KOH and stored 15 min at room temperature. The reaction mixture was neutralized with hydrochloric acid, and 1.0 ml of 0.4 *M*, pH 5.4 acetate buffer was added. Pirprofen was extracted by adding 2.0 ml of 20% methylene chloride in ether and rotating[13] for 20 min. The extraction was repeated, and the combined extracts were processed as described previously (8).

Protein Binding Measurement—Cellulose dialyzer tubing[14] was soaked 0.5 hr in water, and excess water was removed by blotting. A 20-cm length of tubing was formed into a U-shape, 2.0 ml of plasma was introduced, and the tubing was placed into a 2.8 × 10-cm polypropylene centrifuge tube containing eight or 10 0.5-cm diameter glass beads. A cork was used to close the tube and wedge the ends of the tubing with the bottom of the loop supported on the beads. Centrifugation at 1100×*g* for 30 min produced ~100 μl of ultrafiltrate, and 50-μl aliquots were taken for radioactivity counting.

Salicylate Analysis—Plasma (0.5 ml) was mixed with 1.0 ml of water, 0.3 ml of 6 *N* HCl, and 20 ml of methylene chloride. The tubes were rotated 30 min and centrifuged. The aqueous phase was aspirated off, and 10.0 ml of organic phase was mixed with 10.0 ml of 1 *N* NaOH. After rotating for 25 min and centrifuging, the aqueous phase fluorescence was measured[15] at an excitation wavelength of 310 nm and an emission wavelength of 400 nm.

RESULTS

The radioactivity concentrations found in the plasma of control and aspirin-treated rats are shown in Table I, expressed as the average and standard deviation for micrograms of apparent ^{14}C-pirprofen per milliliter. Lower apparent pirprofen concentrations were found for the aspirin-treated rats. Table I also contains the mean and standard deviation for the salicylate concentrations. Selected plasma samples from the same experiment also were analyzed for unbound radioactivity (Table II). For the aspirin-treated animals, binding was decreased slightly until the plasma salicylate concentrations declined to low values, at which point the binding had returned to the control value.

The radioactivity concentration in a few whole blood samples also was measured. No association of radioactive material with the cellular blood constituents was found.

A separate experiment was done to obtain sufficient plasma for quantitative pirprofen determination by GLC. As shown in Table III, very good agreement was found by radiometric and chromatographic analyses.

Table II—Effect of Aspirin on Binding of ^{14}C-Pirprofen by Rat Plasma Proteins *In Vivo*[a]

Time after ^{14}C-Pirprofen, 5 mg/kg iv	Plasma ^{14}C-Pirprofen, mean μg/ml ± SD	Plasma Salicylate, mean μg/ml ± SD	Binding, % ± SD
Controls—no aspirin			
5 min	35.9 ± 1.6	—	98.8 ± 0.4

5 min	31.0 ± 1.4	114 ± 8	96.6 ± 1.4
6 hr	6.4 ± 1.0	66 ± 22	96.5 ± 1.2
14 hr	3.0 ± 0.4	2 ± 0	99.6 ± 0.2

[a] Four rats at each time point.

The binding of ^{14}C-pirprofen to rat plasma proteins also was measured in the presence and absence of salicylate in an *in vitro* experiment. ^{14}C-Pirprofen (17 μg/ml) was added to pooled plasma from control rats, and sodium salicylate (100 μg/ml) was added to half of the plasma aliquots prior to a 30-min equilibration and binding measurements. All three control samples showed 98.6% binding. Samples containing salicylate had values of 97.6, 97.7, and 97.6%.

The urinary radioactivity excretion after 5 mg of ^{14}C-pirprofen/kg iv was measured after intubation with 60 mg of aspirin/kg or an equal volume of water. As shown in Table IV, the amount and time course for urinary radioactivity excretion were not altered by aspirin administration under these conditions.

The effect of aspirin on biliary secretion of radioactivity from ^{14}C-pirprofen was examined in bile duct-cannulated rats. Rats were given 60 mg of aspirin in aqueous solution/kg or an equal volume of water by intubation. The bile ducts were cannulated. One hour after the aspirin or water intubation, the animals were given 5 mg of ^{14}C-pirprofen/kg by tail vein injection or by intubation. The bile volume collected each hour was not different for the aspirin and water-treated rats. The radioactivity secretion into bile was much greater for the aspirin-treated rats than for the control rats (Fig. 1). Similar results were seen after oral rather than intravenous ^{14}C-pirprofen administration.

TLC of rat bile collected within 2 hr of oral ^{14}C-pirprofen administration showed one major constituent, which comprised 80–90% of the radioactivity. Four or five minor, unknown metabolites also were present. None of these constituents was identical to pirprofen. Base treatment

[a] Plasma from three rats was pooled and analyzed in duplicate by the two methods.

of bile resulted in a change in the TLC pattern. The major radioactive constituent was converted to a material that behaved like pirprofen on TLC in two different solvent mixtures. Quantitative analysis by GLC confirmed that the hydrolyzed material was pirprofen.

DISCUSSION

Oral administration of aspirin (60 mg/kg) to rats 1 hr before intravenous ^{14}C-pirprofen administration (5 mg/kg) resulted in markedly reduced radioactive material in plasma, and GLC analysis showed the radioactive material to be unchanged ^{14}C-pirprofen. The effect was significant ($p = 0.01$) during the 1–8-hr interval and decreased as salicylate concentrations declined to average values of 11 μg/ml or less (Table I). Comparison of area under the curve (*AUC*) values, calculated from time zero to infinity, showed the aspirin group to have 69% as much area as the control group.

Accordingly, pirprofen is another example of an arylalkanoic acid for which concentrations in plasma are reduced by salicylate. Yesair *et al.* (2) found that salicylate altered indomethacin disposition in the rat, resulting in reduced concentrations in plasma, decreased excretion in urine, and increased elimination *via* the bile and feces. For pirprofen, aspirin had no effect on the amount of radioactivity excreted in urine. Four rats excreted 74.9 ± 4.5% of the radioactivity from a dose of 5 mg of ^{14}C-pirprofen/kg iv in urine during 48 hr when given 60 mg of aspirin/kg po. This finding can be compared to 77.4 ± 2.3% for four rats given ^{14}C-pirprofen without aspirin (Table IV).

A similar situation was described by Rubin *et al.* (3) for fenoprofen in humans. The fenoprofen concentration in plasma and the *AUC* were reduced by concomitant aspirin administration without a change in the total amount of material excreted in urine. This finding could result from increased clearance by the liver if the rate with which metabolites are released into blood by the liver is greatly exceeded by renal metabolite clearance. The metabolites will be present in plasma only in low concentrations and will contribute little to the *AUC* for radioactive material, while the bile serves as a depot due to increased recycling.

Aspirin administration with ^{14}C-pirprofen greatly affected biliary radioactivity in rats. Five rats given intravenous ^{14}C-pirprofen without aspirin secreted 40.5 ± 2.7% of the dose radioactivity into bile during 4 hr, while a comparable aspirin-treated group secreted 58.6 ± 9.6% (Fig. 1). The bile production rate was similar for the aspirin-treated and the control animals, precluding increased choleresis as a factor. Similar results were obtained on administration of ^{14}C-pirprofen by intubation rather than by intravenous injection.

The major radioactive constituent (80–90%) in bile of both the aspirin-treated and the control animals was a material that was converted on alkaline hydrolysis to a product indistinguishable from pirprofen by TLC and GLC. In the intact rat, reabsorption compensated for the increased secretion into bile caused by aspirin, as indicated by unaltered urinary excretion.

Calculation of plasma clearance according to the equation:

$$\text{clearance} = \frac{\text{dose}}{AUC} \qquad \text{(Eq. 1)}$$

Table IV—Effect of Aspirin on Urinary Excretion of Radioactivity by Rats after an Intravenous Dose of ^{14}C-Pirprofen

Postdose[a], hr	Average ± *SD* for Cumulated Percent of Dose[b] Control Rats	Aspirin-Treated Rats
1	6.0 ± 1.7	4.9 ± 4.4
2	11.7 ± 4.7	13.0 ± 1.8
3	19.3 ± 5.8	18.2 ± 3.1
4	21.4 ± 6.2	25.5 ± 4.3
6	34.5 ± 4.8	37.8 ± 7.0
8	42.0 ± 7.2	44.6 ± 9.4
10	51.7 ± 8.4	51.3 ± 7.0
24	74.3 ± 3.9	70.2 ± 7.1
48	77.4 ± 2.3	74.9 ± 4.5

[a] Rats were intubated with 60 mg of aspirin/kg in 10 ml of aqueous solution or with an equal volume of water and injected intravenously 1 hr later with 5 mg of ^{14}C-pirprofen/kg. [b] Each group contained four rats.

gave values of 5.1 ml/hr for control rats and 7.4 ml/hr for aspirin-treated rats. The apparent volumes of distribution were 0.20 liter/kg for the control group and 0.32 liter/kg for the aspirin group. As a result of the compensatory changes in plasma clearance and apparent volume of distribution, no change in half-life resulted from aspirin administration; half-life values of 5.9 hr were found for both the aspirin and control groups.

Rubin *et al.* (4) reported that the fenoprofen half-life in humans was decreased by aspirin, but the change only became apparent after repeated fenoprofen and aspirin administration. A short study reported in the same publication showed no change in either the half-life or the *AUC* for indomethacin in humans, although the indomethacin concentrations were reduced by aspirin in the early part of the plasma curve.

Binding of ^{14}C-pirprofen to plasma proteins in the rat was extensive and reduced slightly by salicylate. Binding of 98.6% was reduced by salicylate to an average value of 97.2% in the *in vivo* and *in vitro* experiments. This modest decrease in binding represents a marked increase in the unbound drug availability. Binding to the blood cellular constituents did not occur in either the presence or absence of salicylate.

Pirprofen, indomethacin (9), naproxen (5, 6), and fenoprofen (3) are all highly bound to plasma proteins, and all except fenoprofen are displaced by salicylate. Chaplin (5) suggested that the mechanism by which aspirin reduced plasma naproxen concentrations was by increasing the unbound naproxen availability for transformation or excretion. Evidently, this factor is not the sole causative mechanism for decreasing the plasma concentrations of all arylalkanoic acids, because Rubin *et al.* (3) found that fenoprofen was not displaced. An additional factor such as altered hepatic extraction or increased splanchnic blood flow may be involved.

In conclusion, concomitant administration of aspirin and ^{14}C-pirprofen to rats reduced plasma concentrations and reduced *AUC* values of radioactive material. No change in half-life was found, due to increases in both the plasma clearance and the volume of distribution. Binding to plasma proteins decreased slightly. Urinary radioactivity excretion was unchanged by aspirin administration. Secretion of pirprofen metabolite(s) into bile was increased but was compensated by reabsorption.

Doxycycline Determination in Human Serum and Urine by High-Performance Liquid Chromatography

ANDRÉ P. De LEENHEER ˣ **and HANS J. C. F. NELIS**

Received October 6, 1978, from the *Laboratoria voor Medische Biochemie en voor Klinische Analyse, Faculteit van de Farmaceutische Wetenschappen, Rijksuniversiteit Gent, 135 De Pintelaan, B-9000 Gent, Belgium.* Accepted for publication February 8, 1979.

Abstract □ A reversed-phase high-performance liquid chromatographic method for quantitative doxycycline determination in human serum and urine is described. The drug was extracted from buffered (pH 6.1) serum or urine into ethyl acetate. A structural analog, demeclocycline, was added as the internal standard. A 10-cm × 2-mm i.d., 5-μm Lichrosorb RP8 column with acetonitrile–0.1 *M* citric acid as the eluent was used. The effluent was monitored at 350 nm. The extraction recovery from spiked serum was 87.8 ± 4.3% (mean ± *SD*, $n = 11$); for urine, a value of 92.2 ± 2.0% (mean ± *SD*, $n = 10$) was found. Within-run and within-day relative standard deviations averaged 1.80% ($\bar{x} = 2.5$ μg/ml, $n = 10$) and 4.75% ($\bar{x} = 2.6$ μg/ml, $n = 9$), respectively. The detection limit was estimated at 50 ng/ml of serum. No significant extra peaks were observed in chromatograms obtained on serum or urine extracts, suggesting the probable absence of metabolic processes *in vivo*.

Keyphrases □ Doxycycline—analysis, human serum and urine, high-performance liquid chromatography □ High-performance liquid chromatography—analysis, doxycycline in human serum and urine □ Antibiotics—doxycycline, high-performance liquid chromatographic analysis, human serum and urine

	R_1	R_2	R_3	R_4
oxytetracycline	CH_3	OH	OH	H
tetracycline	CH_3	OH	H	H
demeclocycline	H	OH	H	Cl
chlortetracycline	CH_3	OH	H	Cl
methacycline	$=CH_2$		OH	H
doxycycline	CH_3	H	OH	H

The disposition of the antibiotic doxycycline in the human body has been the subject of numerous investigations. Owing to its stronger lipophilicity, this drug has a higher absorption rate and a longer half-life than the other tetracyclines (I). Although the absence of metabolites *in vivo* has been postulated (1), this has not been proven due to the lack of specific assay methods.

The existing fluorometric (2–4) and microbiological (5, 6) procedures provide good sensitivity but are unable to differentiate doxycycline from its analogs, including possible metabolites. In addition, the latter technique only allows estimation of total biological activity without correlation to the chemical structure of the substance. It also overlooks possible metabolites without antimicrobial activity.

Therefore, the incorporation of a suitable chromatographic step in the analysis is highly desirable. Several TLC methods allow the separation and densitometric quantitation of tetracyclines in pure solutions (7–10). However, no attempt has been made to investigate their potential for analysis in biological materials.

High-performance liquid chromatography (HPLC) combines a fast and reliable chromatographic technique with the relatively high sensitivity of on-line UV detection. A few papers (11–13) report its use for tetracycline, oxytetracycline, and chlortetracycline determination in serum and urine. However, none of these systems was applied to doxycycline. Disadvantages include the poor efficiency of some chromatographic separations (11, 13), the lack of an internal standard (11, 12), and bad detection limits (12, 13).

During some preliminary work, an HPLC system capable of separating doxycycline from several analogs in pure solutions was developed (14). A new system is now reported for quantitative doxycycline determination in human serum and urine. The procedure described involves a simple one-step solvent extraction followed by reversed-phase HPLC, using a structural analog as an internal standard.

EXPERIMENTAL

Reagents—All chemicals were analytical grade[1]. Acetonitrile and distilled water were used without further purification for the preparation of the chromatographic eluent. A pH 6.1 phosphate sulfite buffer was prepared by dissolving 27.6 g of monobasic sodium phosphate and 25.2 g of sodium sulfite in 100 ml of water to give a final concentration of 2 *M* for each salt. Stock solutions of doxycycline hydrochloride[2] and demeclocycline (demethylchlortetracycline) hydrochloride[3] were prepared by dissolving the compounds in methanol–0.1 *M* HCl. All glassware was silanized using a 10% (v/v) solution of hexamethyldisilazane in toluene.

Apparatus and Operating Conditions—The basic liquid chromatographic unit consisted of a single pumping system[4] and a sampling valve[5] with a 20-μl loop. A variable-wavelength detector[6] was used to monitor the column effluent at 350 nm. Chromatography was performed on a homemade 10-cm × 2-mm i.d., 5-μm Lichrosorb RP8[1] column with acetonitrile–0.1 *M* citric acid (24:76 v/v) as the mobile phase. The flow rate was 0.5 ml/min (9.65 MPa or 1400 psi). A filtration device was assembled by pressing a filter disk[7] in a pasteur pipet.

Column Preparation—The column was slurry packed using a modified version of the viscosity method (15). A 9% (w/v) slurry was prepared in glycerol–methanol (20:80 v/v) and introduced into a 4.1-ml reservoir directly assembled on top of the column. A pressure of 34.47 MPa (5000 psi) was applied by pumping acetonitrile through the column, using the maximum flow rate setting of the pump[4]. This procedure allowed reproducible packing of some 30 columns, which were all of the required standard, *i.e.*, 2000 theoretical plates or more under the working conditions described.

Extraction Procedure—A 0.5-ml sample of human serum, 50 μl of a 6% (w/v) aqueous ascorbic acid solution, 50 μl of the internal standard stock solution, and 1 ml of the pH 6.1 phosphate sulfite buffer were combined in a screw-capped polytef-lined tube. After mixing[8] for 30 sec, 6 ml of ethyl acetate was added. The tube was placed for 10 min on a rotating mixer[9] and centrifuged for 6 min at 3000 rpm.

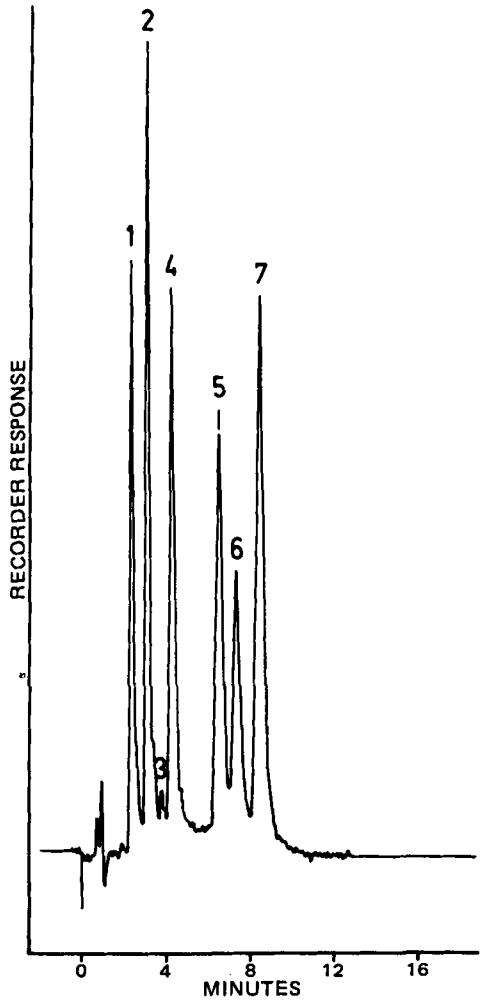

Figure 1—*Separation of seven tetracyclines. Key: 1, oxytetracycline; 2, tetracycline; 3, unidentified by-product of doxycycline; 4, demeclocycline; 5, chlortetracycline; 6, methacycline; and 7, doxycycline. The column was 10-cm × 2-mm Lichrosorb RP8 (5 μm), the mobile phase was acetonitrile–0.1 M citric acid (24:76 v/v), the flow rate was 0.5 ml/min, and the temperature was ambient.*

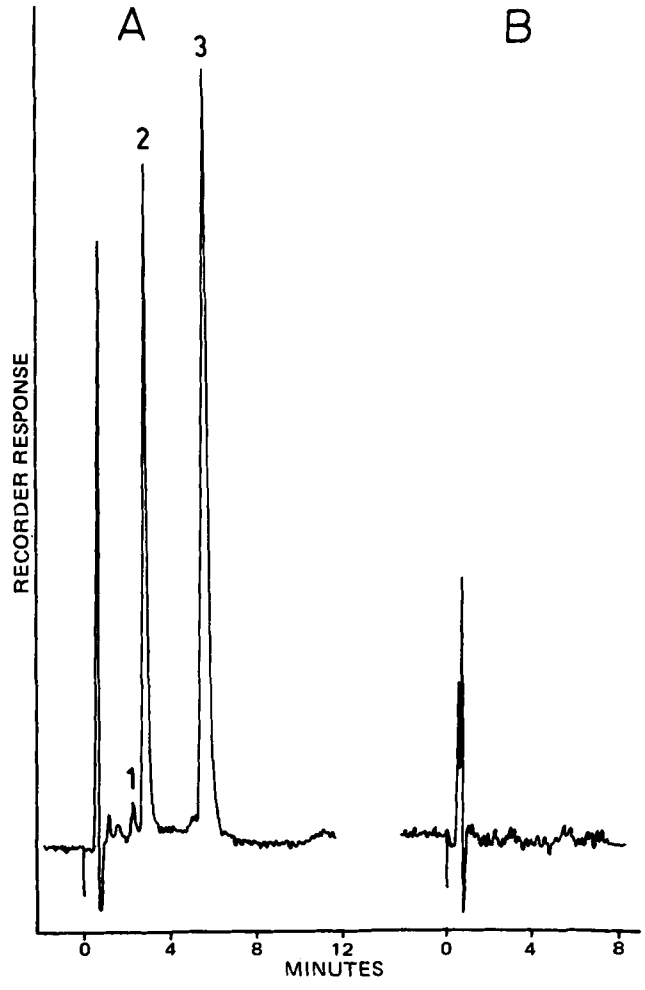

Figure 2—*Chromatograms of serum containing 3 μg of doxycycline/ml (dose of 200 mg iv) (A) and of blank serum (B). Key: 1, unidentified by-product of doxycycline; 2, demeclocycline (internal standard); and 3, doxycycline. Conditions were as in Fig. 1 except for the temperature (30°); detector sensitivity was 0.02 aufs.*

The organic layer was transferred to a conical evaporation tube containing 100 μl of a 0.2% (w/v) methanolic ascorbic acid solution. The mixture was evaporated[10] to dryness at room temperature by applying vacuum under continuous vortexing of the tubes. The residue was finally dissolved in 200 μl of the chromatographic eluent. After mixing[8], the solution was filtered and kept in ice until a 20-μl aliquot was injected into the chromatograph.

A procedure identical to the plasma assay was followed for urine extraction, except that a 100-μl sample, 0.4 ml of buffer, and 3 ml of ethyl acetate were used.

Calculations—Standard curves were constructed by analyzing serum samples containing known drug amounts and plotting peak height ratios (doxycycline/internal standard) *versus* the corresponding doxycycline concentration.

RESULTS AND DISCUSSION

Chromatography—The excellent selectivity of the chromatographic system for the separation of seven tetracyclines is illustrated in Fig. 1. A previously used 25-cm × 4.6-mm i.d. RP8 column (14) was replaced by a short narrow-bore column to improve the detection limit. The extremely small void volume reduces dilution in the column (16) but requires severe precautions to minimize extracolumn band broadening, which especially occurs in the connecting tubes and the detector cell. In addition, injection of components in a solvent that is stronger than the eluent, *e.g.*, methanol, must be strictly avoided since such solvents cause a severe loss of column efficiency due to a secondary solvent effect.

On the basis of this elution pattern, as well as its structural analogy, demeclocycline was chosen as the internal standard. Both other closely eluting derivatives, *i.e.*, chlortetracycline and methacycline, were unsuitable. The former showed a pronounced chemical instability, and low extraction yields (5–10%) were obtained for the latter.

Extraction—The development of a suitable extraction step for this very polar, amphoteric, and labile compound involved various problems. A few techniques, used as a part of some fluorometric assay methods for tetracyclines in general, have been reported (2, 3, 17, 18). Only medium polar organic solvents, *i.e.*, ethyl acetate, amyl acetate, *n*-butanol, and 1-pentanol, can be considered for the isolation of these compounds from a weakly acidic medium (2, 17). Several authors also used chelate extraction performed with divalent cations in a strong alkaline medium (3, 4, 12, 13, 18). However, subsequent concentration of the organic extract proved inconvenient; a dense salt residue prevented redissolution of the compounds in a limited aqueous solvent volume.

The isolation procedure is a modification of a previously described method (2). Amyl acetate was replaced by ethyl acetate to accelerate the final evaporation step. Partition into the organic solvent was particularly favored by salting out the compounds in the nearly saturated phosphate sulfite buffer. Three different buffers consisting of 3, 2, and 1 *M* sodium dihydrogen phosphate and 1, 2, and 2 *M* sodium sulfite gave corresponding pH values of ~5.4, 6.1, and 6.5, respectively. The second buffer system was chosen because it provided the least aggressive medium and gave slightly superior extraction yields. In fact, all tetracyclines are subject to a reversible epimerization process of the C_4-dimethylamino group, occurring preferentially in various buffers over a pH 2–6 range (19, 20).

Despite these precautions, the internal standard, unlike doxycycline, initially deteriorated when serum extracts in ethyl acetate were evaporated at 60°. The additional peak appearing in the chromatogram was identified as 4-epidemethylchlortetracycline on the basis of its retention time and UV characteristics (absorption rate method). No degradation occurred when a standard solution of demeclocycline in ethyl acetate was taken to dryness at 60°. However, considerable epimerization took place even when the compound was added to the organic layer after the extraction of a blank serum sample. Apparently, one or more coextracted

serum component(s) act as a catalyst to this effect. Doxycycline itself was more stable under the same conditions. As previously suggested (20), a hydroxyl group at position 5 of the molecule should prevent epimerization by forming an intramolecular hydrogen bond with the dimethylamino group at carbon 4.

Mild evaporation conditions (room temperature, vacuum) and addition of a little ascorbic acid to the ethyl acetate eliminated the epimerization reaction. Although other tetracycline-stabilizing properties of ascorbic acid are reported (21), its action in suppressing the epimerization was somewhat surprising.

Dissolution of the residue in the chromatographic eluent was adopted for column efficiency. It also served as an ultimate purification step. Most of the coextracted lipids and yellow serum pigments finally remained undissolved in this medium and were filtered off. Colorless and cleaner extracts were thus injected. This practice contributed markedly in prolonging the column life. If loss of column efficiency is occasionally noticed, a simple replacement of the PTFE inlet filter will restore most of the original efficiency.

Extraction Recovery—Recovery studies were carried out by extracting samples containing known drug amounts and adding the internal standard after the extraction was completed. An external calibration curve for this experiment was constructed from the direct analysis (without extraction) of mixtures of doxycycline and the internal standard. Results for serum and urine are summarized in Tables I and II.

Linearity, Sensitivity, and Reproducibility—Linear relationships were observed up to concentrations of 6 μg/ml for serum and 100 μg/ml for urine. The amounts covered the entire anticipated therapeutic range. A pooled standard curve for serum, based on 30 values (0–6 μg/ml) obtained on 12 different days, had a slope of 0.305, an intercept of +0.008, and a correlation coefficient of 0.9995. A similar curve constructed for urine (0–100 μg/ml) yielded 0.073, + 0.002, and 0.9999, respectively. The detection limit in serum is estimated at 50 ng/ml, a value much lower than the concentrations occurring at usual dosage regimens. A within-run relative standard deviation for serum at the 2.5-μg/ml level of 1.8% (n = 10) was obtained. Long-term reproducibility was evaluated over a 20-day period (n = 9) at a concentration of 2.6 μg/ml and yielded a value of 4.75%.

Applications—The assay method presented has been used routinely in this laboratory to monitor serum drug levels in patients receiving doxycycline therapy (130 samples, 38 subjects). Levels after 2–3 hr ranged from 2 to 9 μg/ml after a single intravenous dose of 200 mg.

Figure 2A shows a typical HPLC record of a human serum extract containing doxycycline and the internal standard. Capacity ratios (k') of both compounds were 4.5 and 9.6, respectively. No interfering peaks were observed in a blank serum extract (Fig. 2B).

Chromatograms of a blank urine extract (B) and of a urine extract (A) from a patient who received 100 mg of doxycycline are shown in Fig. 3.

No large extra peaks were present in serum or in urine extracts. The small unidentified peak (Figs. 2 and 3) was probably due to a doxycycline degradation product since it was found in freshly prepared standard solutions and in serum and urine samples from patients receiving doxycycline therapy. Because metabolites are generally more polar than the parent compound, they should elute earlier than doxycycline from a reversed-phase column. Therefore, it is noteworthy that no such metabolites could be detected.

Furthermore, the method can be valuable for determining the pharmacokinetic parameters of the drug to optimize its dosage scheme. Its application to other biological materials requires a few modifications and is presently under study.

Examination of Blood Clobazam Levels and Several Pupillary Measures in Humans

JEFFREY A. KOTZAN ˣ, THOMAS E. NEEDHAM, IRVING L. HONIGBERG, JOSEPH J. VALLNER, JAMES T. STEWART, WALTER J. BROWN, and HUNG W. JUN

Received January 23, 1978, from *Biological Group Studies, School of Pharmacy, University of Georgia, Athens, GA 30602.* Accepted for publication February 7, 1979.

Abstract □ The State–Trait Anxiety Inventory was administered to 15 subjects before initiation of the experiment. Three subgroups of five subjects were defined by computing the unweighted sum of the state and trait anxiety scores. A 40-mg dose of clobazam, a 1,5-benzodiazepine, was administered to each subject and repeated with two additional dosage forms following a 2-week washout period. Blood samples were withdrawn, and blood levels were determined by fluorometric analysis. Additionally, pupillary measures of critical flicker fusion, constriction, and dilation in response to a cognitive task were obtained at 0, 2, 4, and 6 hr. A repeated measures analysis of variance revealed that blood levels were, as expected, statistically different over time and dosage form. The pupillary constriction mirrored the blood levels in statistical patterns. The pupillary measure of cognition related to the anxiety state after the performance effects of the cognitive task were statistically removed. The results suggest that clobazam has less immediate human effect than does diazepam.

Keyphrases □ Clobazam—analysis, fluorometry, blood levels, effect on pupillary constriction, and anxiety level □ Pupillary constriction—clobazam effect, blood level, and anxiety level □ Tranquilizers, minor—clobazam, fluorometric analysis, blood levels, effect on pupillary constriction, and anxiety level

Clobazam, a 1,5-benzodiazepine, is effective in the treatment of anxiety neurosis (1, 2). The immediate and long-term effects of the benzodiazepines on human performance ability likewise have been demonstrated. Generally, the benzodiazepines decrease human ability to perform complex tasks (3–5). Additionally, the benzodiazepine drug class affects physiological measures such as auditory reaction times and complex visual reaction times (6–8).

Pupillometrics is defined as the aspect of psychology that deals with the assessment of pupillary alterations elicited by any stimulus other than light (9). Pupil dilation in response to complex cognitive tasks can be observed with proper instrumentation and experimental controls (10). A sensitive means of generating pupillary cognition curves by verbally presenting randomized digits to subjects was described (11, 12). Furthermore, diazepam consumption was shown to alter the pupil cognition curves and recall ability (12).

The objective of this research was to determine if clobazam consumption related to pupillometry involving human cognition and two noncognitive pupillary measures. Critical flicker fusion and miotic effect of the drug were selected as noncognitive measures.

EXPERIMENTAL

Fifteen male volunteers were recruited and subjected to the State–Trait Anxiety Inventory (13). A high anxiety subgroup, consisting of five members, was defined operationally by a combined state–trait anxiety score of >72.0. A five-membered, low anxiety group was defined by a combined score of <64.0. The remaining five subjects were assigned to the middle anxiety group.

A randomized Latin-square design was employed to assign the subjects to a three-level dosage form treatment group. Each subject received separate 40-mg doses by tablet, solution, and capsule dosage forms in randomized and matched sequences. Blood samples were obtained for up to 144 hr following ingestion (14). The blood levels were determined by a fluorometric assay, which did not distinguish between the drug and its active major metabolite, the *N*-desmethyl compound (15).

[a] Not significant.

Pupillary measures were obtained for all subjects and all doses immediately preceding ingestion of the 40-mg dose. Additional pupillary observations were obtained immediately preceding the 2-, 4-, and 6-hr blood samplings.

The total pupillary recordings required approximately 7 min for each subject–dosage form–time set. The subjects entered an experiment room illuminated at 5 foot-candles, and critical flicker fusion measures were obtained. Ascending and descending measures were recorded individually for each eye. The flicker fusion apparatus was calibrated to balanced maximum brightness, a neutral density wedge setting of 3, and 15% light[1].

The cognitive task methodology outlined previously (11, 12) was employed after determination of the critical flicker fusion rates. Thus, the subject's pupils were accommodated to the experimental room illumination level before the cognition recordings commenced. The subjects were required to remember the exact order of seven randomized digits between zero and nine. The digits were presented in monotone fashion at 1-sec intervals. The pupillary dilation pattern was simultaneously recorded[2] and continued for several seconds following the presentation of the seventh digit, which permitted the subjects to resort the numbers and finalize their thought processes. Each trial covered 14 sec, and two trials were executed at each subject–dosage form–time interval and averaged to reduce variability. Finally, a measure of satisfactory completion of the cognitive task was obtained by recording the number of digits correctly recalled at each trial.

All pupillary and blood level data were reduced to machine-readable form. To isolate the pupillary cognition curve from the constriction effect of the drug, the initially recorded diameter at the 1st sec of the cognitive task was subtracted from that at each remaining second of the cognitive curve. In this manner, a constriction factor was created. A program was written that computed the areas under the "cleansed" cognition curves, employing the trapezoidal rule (16).

Thus, the final data base contained 15 subjects categorized into one of three anxiety levels. Each subject's file contained fluorometric blood level recordings, pupillary constriction measures, pupillary cognitive area under the curve measures, a recording of the correct number of responses, and critical flicker fusion measures. All measures were repeated at 0, 2, 4, and 6 hr and further repeated using three dosage forms of tablet, solution, and capsule. The data were analyzed by means of an analysis of variance and covariance (17). The anxiety level was input as the grouping factor.

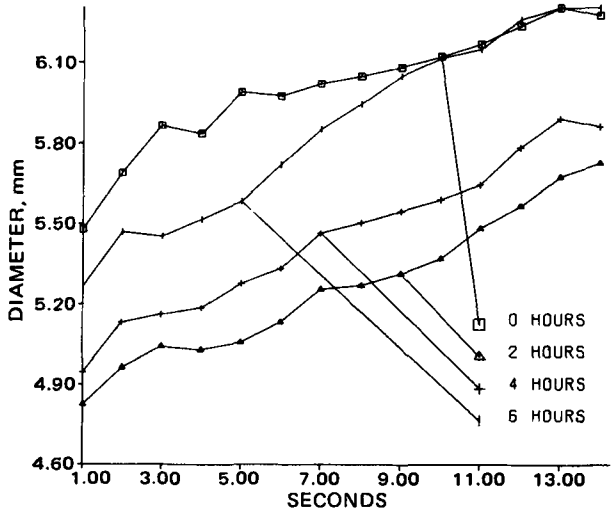

Figure 1—*Average pupil cognition curves for 15 male subjects following consumption of 4 × 10-mg clobazam tablets.*

[2] Polymetric model V11651R, U. S. Testing Co., Hoboken, N.J.

RESULTS

The ability of the random digit task to stimulate pupil dilation was substantiated. Figures 1–3 display the average pupil dilation pattern for the three dosage forms and four time levels. It was immediately apparent that the pupil-constricting effect of clobazam was substantial.

The blood levels were highly significant for the time and dosage form factors, as expected (Table I). The anxiety level did not relate to the blood level, but the dosage form–anxiety interaction proved significant. In a similar pattern, the pupil-constricting effect of the drug proved highly significant for the time and dosage form factors. Table II displays the analysis of variance of the constriction measures, and Table III compares the mean blood levels and pupillary constriction at each time level, summing over the three dosage forms. The pupil was constricted to the greatest degree at the 2-hr point, at which time the greatest average blood level was recorded. The pupil diameter returned to the baseline at the 6-hr point, but the blood level of the parent compound and the metabolites exceeded 350 ng/ml. The factors of critical flicker fusion and number of correct responses proved insignificant for the time factor, which was not anticipated.

An initial analysis of variance of the cognition curves over time and dosage forms proved significant for the anxiety and dosage form factors. However, the variance terms were not homogeneous, and previous research indicated that the ability of subjects to recall randomized digits correctly affects the cognition curves (11, 12). Therefore, the number of digits correctly recalled was input in the analysis as covariates, and the analysis of variance was repeated. In such a manner, the effect of recalling all, or less than all, of the randomized digits was removed from the pupillary cognition curves.

The results of the combined analysis of variance and covariance are presented in Table IV. Only the anxiety factor remained statistically significant in terms of the area under the cognition curve. The covariates removed the statistical significance from the dosage form factor. The

Table III—Comparison between Blood Levels and Pupil Diameter at Four Time Levels for All Dosage and Anxiety Levels

Hours	Pupil Diameter, mm	Blood Level, ng/ml
0	5.3567	3.2444
2	4.8289	436.4221
4	5.0711	363.9110
6	5.3622	352.3110

mean areas under the cognition curves, corrected for accuracy of recall, were 5.9631, 4.1535, and 7.1379 mm-sec for the low, medium, and high anxiety groups (n = 5), respectively.

CONCLUSIONS

The major conclusion of this study was that the drug and its metabolite reduced the diameter of the pupil when blood levels peaked. However, pupil diameters did not remain constricted at the 6-hr point when blood levels exceeded 350 ng/ml. These results are similar to reports that many psychomotor functions such as coordination tests, tracing tests, sorting tests, and letter cancellation tests returned to baseline values 5 hr after subjects consumed 20 mg of diazepam (18). However, the average blood diazepam level exceeded 300 ng/ml at the 5-hr point. Furthermore, at 105 min, blood diazepam levels exceeded 800 ng/ml and most psychomotor functions were impaired (18). Thus, the benzodiazepines clobazam and diazepam appear to produce a detectable human response at higher blood levels.

Anxiety state proved to be significantly related to the area under the cognition curve after correction was made for recall ability. The low and high anxiety subgroups generated greater areas under the curve than did the middle anxiety group at all times and with all dosage forms. Apparently, anxiety is partly related to the nonresponsive phenomenon, and the nonsensitive subjects were assigned to one of the three groups. The anxiety results manifest the high degree of intersubject pupillary variation in response to the cognitive task.

Some evidence suggests considerable variance among the benzodiazepines in their ability to alter human performance. In fact, clobazam demonstrated little effect on adaptive tracking and reaction times when compared to diazepam and chlordiazepoxide (3). However, the results of this experiment demonstrated a measurable alteration in human pupillary response at higher blood levels of clobazam and its metabolites.

Physical Characterization of Solid Iopanoic Acid Forms

WILLIAM C. STAGNER and J. KEITH GUILLORY ˣ

Received December 1, 1978, from the *Division of Pharmaceutics, College of Pharmacy, University of Iowa, Iowa City, IA 52242.* Accepted for publication February 9, 1979.

Abstract □ Three solid forms of iopanoic acid were characterized by X-ray diffraction, differential scanning calorimetry, scanning electron microscopy, thermal microscopy, IR spectroscopy, and dissolution studies. X-ray analysis demonstrated that two solid forms were crystalline and that the third was amorphous. The amorphous form had been reported previously as crystalline. Enthalpies and entropies of transition were calculated using differential scanning calorimetry. A fourth form, a benzene solvate, also was isolated but proved to be too unstable at room temperature to permit conclusive characterization. The amorphous form demonstrated a 10-fold greater intrinsic dissolution rate than the commercially available form (Form I). Form II's intrinsic dissolution rate was 1.5 times greater than that of Form I. In powder dissolution studies, the peak solubilities of the different forms followed the same rank order as their intrinsic dissolution rates. Form II was relatively stable in aqueous saturated solutions, but the amorphous form was rapidly converted to Form I under similar conditions.

Keyphrases □ Iopanoic acid—solid forms, physical characterization, polymorphism, thermal behavior □ Polymorphism—iopanoic acid, physical characterization, thermal behavior □ Radiopaque media—iopanoic acid, solid forms, physical characterization, polymorphism, thermal behavior

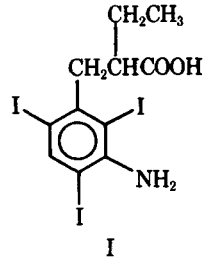
Gallbladder disease, a commonly occurring medical problem, is most frequently diagnosed through the use of oral radiographic agents. Over 2,000,000 patients in the United States alone undergo oral cholecystography each year (1). The agent most commonly prescribed to produce gallbladder opacification is iopanoic acid[1] (I), an iodinated organic acid poorly soluble in water; it is administered orally in tablet form.

However, in approximately 25–50% of patients with apparently normal gallbladders, iopanoic acid reaches the gallbladder in insufficient concentration to permit radiographic opacification (1, 2). Consequently, a second examination with another dose of contrast material is often required. Nevertheless, iopanoic acid continues to be widely used because of its ability to permit accurate visualization of gallstones and because of its relatively low toxicity.

BACKGROUND

Inadequate normal gallbladder visualization on initial examination is a complex problem. Ingestion of an insufficient amount of contrast medium, faulty dosing instructions, changes in gastric pH, and decreases in bile flow associated with dietary control are often mentioned as causes for initial nonvisualization. In 1971, Evens *et al.* (3) postulated that poor visualization of normal gallbladders on initial examination was due to incomplete absorption of the radiocontrast medium. They observed large amounts of coarse radiopaque residue on abdominal radiographs of normal patients for whom poor gallbladder opacification had been obtained. Subsequent investigators (4) reported that iopanoic acid exhibited dissolution rate-limited absorption.

Numerous studies (5–8) showed that the sodium salt of iopanoic acid is more rapidly and completely absorbed than the free acid. Sodium iopanoate may react with hydrochloric acid in the stomach to precipitate the free acid as an amorphous material. In a recent investigation, Goldberger *et al.* (9) isolated the precipitated iopanoic acid immediately following acid addition to an aqueous solution of the sodium salt. The dissolution rate of the "freshly precipitated" acid was compared to that of the "dried precipitate," which was assumed to be analogous to the commercially supplied compound. Marked differences in the dissolution rates of the two forms were observed. On examination of the commercial acid, the recent precipitate, and the dried precipitate by oil immersion light microscopy and electron microscopy, the authors concluded that all three forms are crystalline. Consequently, they noted that use of the term "amorphous" to describe the recently precipitated material is not justified.



I

The purposes of the present study were: (*a*) to characterize further the previously reported crystalline iopanoic acid forms, and (*b*) to crystallize the material from various solvent systems in an attempt to isolate a polymorph with a rapid dissolution rate that might be stable in the solid state for a reasonable period.

EXPERIMENTAL

Solid Forms—Attempts were made to prepare polymorphs of iopanoic acid by crystallization from various solvent systems using the customary (10) techniques of shock cooling, crystallization at room temperature, and slow crystallization at elevated temperatures. Some 30 samples of crystalline material were examined by thermal microscopy, differential scanning calorimetry, IR spectroscopy, and other techniques, but only in the instances described here were unique crystalline forms obtained.

Commercial iopanoic acid[2] (Form I) was used in the preparation of three other solid forms. A free acid precipitate was obtained by a procedure similar to that described by Goldberger *et al.* (9). Iopanoic acid (3–5 g) was dissolved in 0.1 *N* NaOH, and the final solution pH was adjusted to ~12.5. Nitrogen was bubbled into the solution, and mixing was by a magnetic stirrer. Hydrochloric acid, 0.1 *N*, was added at a rate of 15 ml min^{-1} until the pH reached 2.15. The precipitate was vacuum filtered and stored *in vacuo* (380 mm Hg) for 12 hr at 35°.

In the preparation of Form II, a warm solution of commercial iopanoic acid in analytical reagent grade benzene was frozen rapidly in a dry ice–acetone mixture and then slowly allowed to melt at room temperature. Crystals obtained by filtration of this mixture were identified as a benzene solvate of iopanoic acid. Form II, free of benzene, was obtained when these crystals were stored *in vacuo* (380 mm Hg) for 12 hr at 70°.

X-Ray Analysis—All X-ray data were collected on an automated diffractometer[3] with monochromatized CuKα (λ = 1.5413 Å) radiation. The diffractometer was equipped with a 2θ compensating slit and a graphite monochromator. The instrument was calibrated to within ±0.02° 2θ using the quartz peak at 26.66°. The patterns were recorded both from 2 to 60° 2θ at a scanning speed of 2.4° 2θ min^{-1} and from 6 to 46° 2θ at a scanning speed of 6° 2θ min^{-1}.

Differential Scanning Calorimetry—A thermal analyzer[4], equipped with a differential scanning calorimeter cell, was used to record transition temperatures and heats. Thermograms were recorded simultaneously on an *x–y* recorder[4] and on an external time-base recorder equipped with a mechanical integrator[5]. A 10° min^{-1} heating rate was employed, and a nitrogen purge was maintained throughout each run.

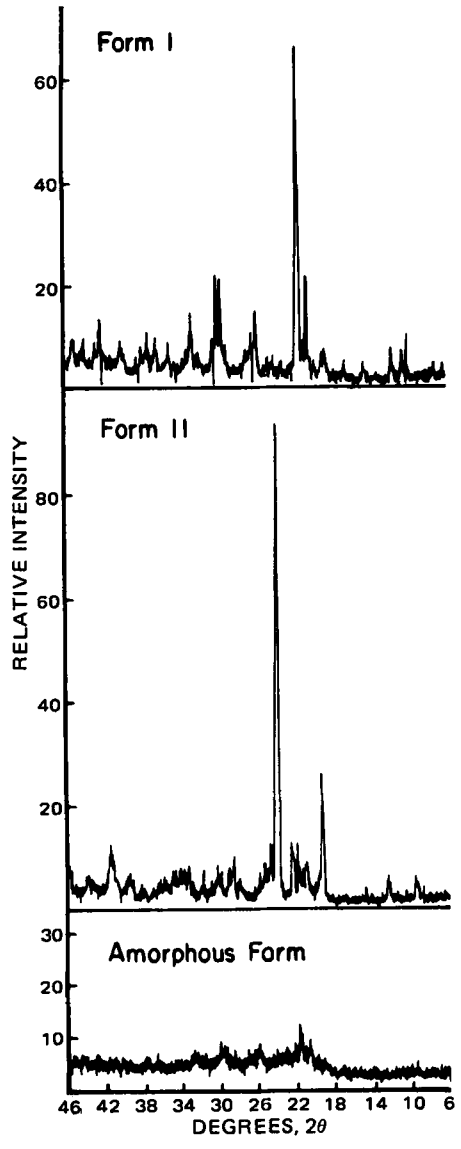

Figure 1—*X-ray powder diffraction patterns of solid iopanoic acid forms.*

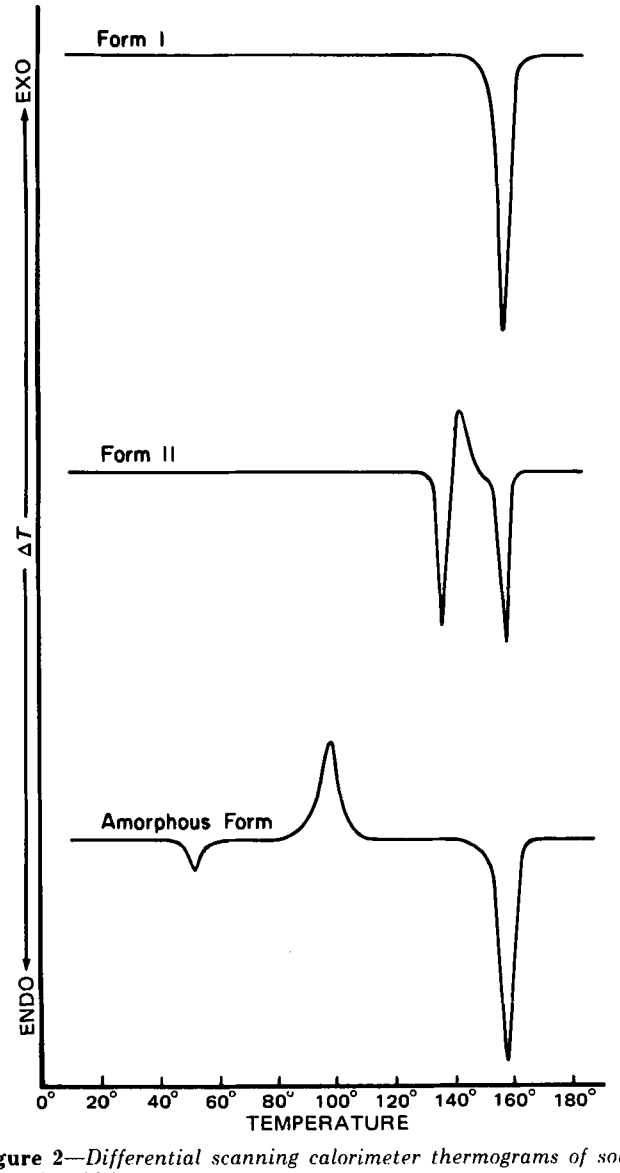

Figure 2—*Differential scanning calorimeter thermograms of solid iopanoic acid forms.*

Area measurements were obtained either by planimetry[6] or from the mechanical integrator trace. When areas were measured by planimetry, a line was drawn from the point at which the thermogram first departed from the baseline to the point, following the transition peak, at which the baseline was resumed.

Benzophenone[7] [ΔH_{fus} 23.5 cal g^{-1}; mp 48.2° (11)], stearic acid[8] (99+%) [ΔH_{fus} 47.5 cal g^{-1}; mp 69.0° (11)], and indium[9] (99.99%) [ΔH_{fus} 6.97 cal g^{-1} (12); mp 156.4° (11)] were used to prepare the calibration curve and to calibrate the temperature axis. The benzophenone was recrystallized twice from absolute alcohol. The stearic acid and indium were used without further purification. All samples were weighed on an electrobalance[10] to the nearest 0.001 mg. Peak area measurements, when performed by planimetry, were repeated with a precision approaching 0.1%. The relative standard deviation for the area measurements ranged from 3.16% for indium fusion to 1.70% for stearic acid fusion.

Thermal Microscopy—Thermal microscopic examinations of the samples were performed on a Kofler micro hot stage[11]. A few sample particles were placed on a microscope slide and examined between crossed Nicols. A heating rate of 1° min^{-1} was used to determine transition temperatures. Known melting-point standards were utilized to check the thermometer calibration and the technique used. The magnification employed was 100×, and the numerical aperture was 0.25.

Scanning Electron Microscopy—Scanning electron micrographs[12] were obtained for each iopanoic acid form. Solid samples were coated with a thin gold film and maintained under a vacuum of 1×10^{-5} mm Hg. A 100-μm aperture was used to obtain magnifications of 1000–6000×.

IR Spectroscopy—Spectra of solid samples, prepared as potassium bromide[13] pellets in a miniature press[14], were recorded on a double-beam IR spectrophotometer[15]. A polystyrene film was used to check the spectrophotometer wavelength calibration. After the spectra were obtained, thermograms of the triturated and compressed samples were recorded to detect possible alterations in crystalline form due to the grinding operations and the pressures used.

Dissolution Studies—Powder dissolution profiles were obtained for each solid iopanoic acid form. A quantity of solute approximately equivalent to twice the saturation solubility was employed. No attempt was made to control particle size. The powder was added to 500 ml of preheated 0.02 *M* phosphate buffer solution, pH 6.50. The dissolution medium was stirred at 228 rpm with a stainless steel propeller, which was positioned 3 cm from the bottom of a USP dissolution flask. All experiments were performed at 37.0 ± 0.1°.

Fifteen-milliliter samples were withdrawn periodically through a me-

dium fritted glass disk, 3 cm in diameter. The volume withdrawn was immediately replaced with a equal volume of thermally equilibrated buffer. After appropriate dilution, samples were analyzed spectrophotometrically[16] at 230 nm, and a correction (13) was applied for the amount of solute removed during sampling.

Intrinsic dissolution rates also were determined. Approximately 500 mg of powder was placed in a 1.27-cm diameter flat-faced punch and die set and compressed under vacuum for 1 min with an applied load of 4545 kg[17]. The disk was removed from the die and mounted, with epoxy glue, in a glass tube, 2 cm in height and 1.27 cm in diameter, so as to expose only the upper surface of the pellet to the dissolution medium. Four extenders were attached to the bottom of the glass tube to stabilize the holder when it was placed in the dissolution medium. The intrinsic dissolution studies were carried out under sink conditions. All other experimental conditions and procedures were identical with those used in the powder dissolution studies.

RESULTS AND DISCUSSION

Three crystalline iopanoic acid forms and an amorphous form were obtained. With only one exception, all solvent systems used and all crystallization techniques attempted produced crystals identical with those of commercially available iopanoic acid (Form I). Crystals obtained by shock cooling a warm, saturated solution of iopanoic acid in benzene were identified as benzene solvate crystals. These crystals rapidly lost solvent when stored in air at room temperature.

Because the benzene solvate loses solvent to the atmosphere so quickly under ordinary temperature and pressure conditions, it is virtually impossible to obtain reproducible physical data on this form. Thermograms of the solvate are affected markedly by sample size and history, by heating rate, and by the tightness of the seal used on the sample pans. The typical thermogram of this form, however, is very similar to that of Form II, except for a broad, dual peak centered around 80°, the approximate benzene boiling point. When solvate crystals, after having been stored under a benzene atmosphere since preparation, are subjected to X-ray diffraction analysis, their X-ray pattern is essentially superimposable on that of Form II.

X-ray diffraction patterns of Forms I and II and of the amorphous form are shown in Fig. 1. The patterns indicate that the commercially available iopanoic acid (Form I) and Form II are both crystalline and that they are distinctly different. Peak positions and relative intensities for these forms are listed in Table I. Differences in peak positions and intensities can be attributed to alterations in the crystal lattice molecular arrangement. The X-ray pattern of the precipitated form, on the other hand, is characteristic of an amorphous solid. Identical patterns were obtained from "recently precipitated" iopanoic acid and from precipitated iopanoic acid that had been stored in a desiccator for more than 1 year. This observation is in contrast to that of Goldberger *et al.* (9), who reported that the dried precipitate is crystalline.

When longer radiation times and higher sensitivities were employed, peaks of low intensity were observed in some precipitated samples. Further analysis indicated that the peaks can be attributed to contamination of the largely amorphous material by Form I crystals. The degree of crystallinity in the precipitated samples is apparently a function of the iopanoic acid precipitation rate.

Thermograms of three solid forms are reproduced in Fig. 2. Sample weights of Form I and of the amorphous form varied from 12 to 17 mg, but smaller samples (7–9 mg) of Form II were used. Form I exhibits a single endothermic peak at 153.8°. The reported melting range for iopanoic acid is 152–158° (14). The Form II thermogram has a sharp endothermic peak at 132.6°, an exothermic peak at 141.2°, and a melting peak at 153.4°. The amorphous solid demonstrates a relatively small endothermic glass transition peak at 54.9°, a broad exothermic peak at 99.9°, and a melting peak at 153.2°. Over a two-year storage period, samples of both the amorphous form and of Form II underwent gradual transformations, which were reflected in minor changes in their thermograms.

Interpretation of the differential scanning calorimetry thermograms is facilitated by observations from thermal microscopy. Form I crystals are needle shaped; when examined between crossed Nicols, they exhibit a wide color spectrum. They begin to liquefy at 147°, and melting is complete at 155°. Kuhnert-Brandstatter (15), who employed a similar technique, reported a melting range of 148–155° for iopanoic acid.

Form II is plate-like and demonstrates birefringence when viewed between crossed polars. At 131°, its crystals begin to soften; in some samples, total liquefaction occurs at 135°. As the temperature is increased further, birefringent, needle-like crystals are formed, which eventually melt at 155°.

The amorphous powder is extremely electrostatic, and it is difficult to separate individual particles so that they can be examined microscopically. However, no distinct crystalline habit can be detected. As the temperature is increased to 50°, the centers of the particles become somewhat translucent, so that they acquire a donut-like appearance. At ~80°, the outer edges of the particles also become translucent. At >80°, there is virtually no change in appearance until melting occurs. No polarization of colors can be observed during the heating process.

Scanning electron micrographs of three solid forms are illustrated in

Table I—X-Ray Diffraction Patterns of Iopanoic Acid Forms I and II

Form I		Form II	
d, Å	I/I_1	d, Å	I/I_1
8.429	11.63	4.577	23.65
7.608	15.54	4.235	13.99
4.344	23.46	4.160	12.69
4.258	13.63	4.069	19.52
4.145	100.00	3.940	16.62
3.472	14.02	3.688	100.00
3.046	21.55	3.590	15.38
3.004	20.89	3.112	13.05
2.421	15.80	2.932	13.83
2.139	17.78	2.175	15.54

Fig. 3. The crystalline habits of Forms I and II can clearly be distinguished in these photomicrographs. The precipitated iopanoic acid, on the other hand, appears to be amorphous. Even at 6000-fold magnification, there is no evidence of crystallinity.

Differences in peak positions and in absorption intensities can be observed in the IR spectra of the various forms. Spectra of Form II and of the amorphous form are quite similar, with the largest difference being in the 910–940-cm^{-1} region, which is representative of carboxylic acid -OH out-of-plane bending (16). The two peaks at 1211 and 1295 cm^{-1} are both more intense in spectra of Forms I and II than in the spectrum of the amorphous form. These peaks have been attributed (16) to coupled -OH bending and C–O stretching of the carboxylic acid dimer and to C–N stretching, respectively. In addition, the NH symmetric stretching frequency at 3345 cm^{-1} can be used to distinguish Form I from the two other solid forms.

Results of the calorimetric studies are collected in Table II. The heats of transition were calculated from the equation:

$$\Delta H = \frac{K(A)}{m} \qquad \text{(Eq. 1)}$$

where ΔH is the enthalpy of transition, K is a calibration coefficient that is a function of temperature, A is the area of the transition peak, and m is the sample mass. The calibration coefficient is obtained by plotting $\Delta Hm/A$ *versus* the transition temperature for substances with known transition enthalpies (11). The precision reported here is comparable to that achieved by other authors employing similar techniques (17–19). Entropy changes associated with the transitions were obtained by dividing the transition enthalpy by the temperature in degrees Kelvin.

From the temperatures at which Form II and the amorphous form melt,

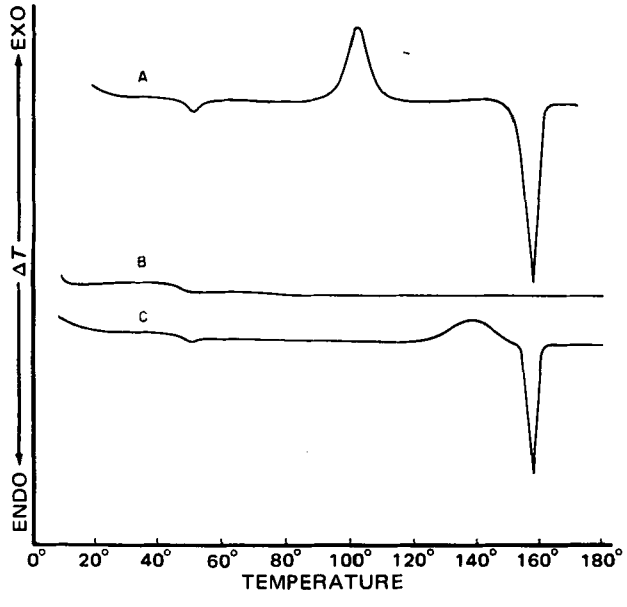

Figure 4—*Effect of thermal history and presence of seed crystals on differential scanning calorimeter thermograms for iopanoic acid. Key: A, typical thermogram of amorphous iopanoic acid; B, thermogram of the resolidified melt of the amorphous form; C, thermogram of the resolidified melt of the amorphous form following cooling in a dry ice–acetone mixture.*

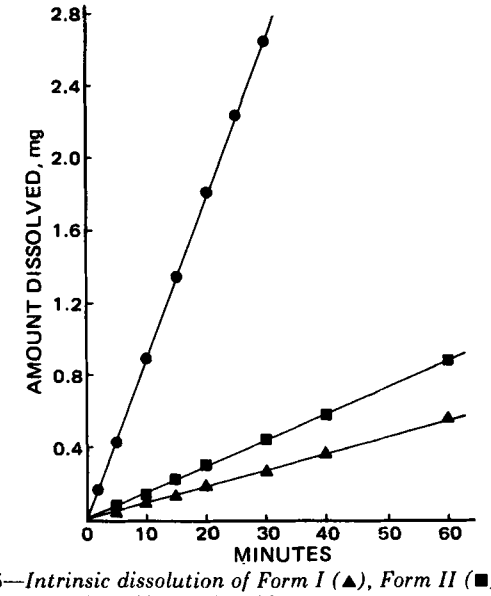

Figure 5—*Intrinsic dissolution of Form I (▲), Form II (■), and the amorphous form (●) of iopanoic acid.*

one can conclude that each is converted to Form I prior to final melting. However, a statistical test of the three ΔH_{fus} values at the 95% confidence level demonstrates a significant difference between the fusion enthalpy of Form II and of the two other forms. This discrepancy can be explained on the basis of incomplete Form I crystallization. The temperature at which the transition from Form II to Form I occurs is so close to the Form I melting point that, at the heating rates employed in this study, the transformation is incomplete when melting begins. This interpretation is corroborated by thermal microscopic observations.

Figure 4 illustrates the influence that seed crystals and thermal history can have on the transition temperature and on the exothermic peak observed in amorphous iopanoic acid thermograms. The top curve is a typical thermogram for the amorphous form heated from room temperature to beyond its melting point. Obviously, no seed crystals remain in this sample; when it is cooled, a glass forms. Curve B demonstrates the thermal behavior of the glass. A change in heat capacity is observed at approximately 48°; however, the typical exotherm and melt transition

	±0.1°	±0.079	±0.02	±0.5°	±0.09	±0.23	±0.3°	±0.23	±0.5

[a] Values reported represent the mean and standard error of the mean of five to eight samples.

are not observed. When the glass is cooled in dry ice, it again exhibits an endothermic and exothermic transition, as well as the usual melting peak (curve C). In this case, however, the exotherm due to crystallization of Form I is broader and occurs at a higher temperature than in the original sample.

The results of the intrinsic dissolution rate studies are shown in Fig. 5. Assuming the dissolution rate is diffusion controlled, one can describe the process by:

$$\frac{1}{A}\frac{dW}{dt} = \frac{D}{h}(C_s - C) \qquad \text{(Eq. 2)}$$

where A is the surface area of the dissolving solid, W is the solute mass at time t, D is the diffusion coefficient, h is the diffusion layer thickness, C_s is the solubility of the substance, and C is its concentration in the bulk solution at time t. In the initial stages of the dissolution process, *i.e.*, when sink conditions prevail, $C_s \gg C$, and the equation reduces to:

$$\frac{1}{A}\frac{dW}{dt} = \frac{DC_s}{h} \qquad \text{(Eq. 3)}$$

All three solid iopanoic acid forms can be characterized by the same D and h values. In addition, the surface area of the dissolving disk is essentially constant, so Eq. 3 may be rewritten in a simpler form:

$$\frac{dW}{dt} = kC_s \qquad \text{(Eq. 4)}$$

where the constant k now includes the terms A, D, and h. Integration from time 0 to t yields:

$$W = kC_s t \qquad \text{(Eq. 5)}$$

Thus, a plot of amount dissolved as a function of time should be linear for the initial dissolution stages. Intrinsic dissolution rates (kC_s/A) can be calculated from the slopes of the three straight lines in Fig. 5. They are 0.00739 mg cm^{-2} min^{-1} for Form I, 0.0117 mg cm^{-2} min^{-1} for Form II, and 0.0703 mg cm^{-2} min^{-1} for the amorphous form. So the intrinsic dissolution rate for Form II is 1.5 times greater, whereas the dissolution rate for the amorphous form is an order of magnitude greater than that of the commercially available form.

Typical dissolution profiles for the three forms are shown in Fig. 6. The peak solubilities of the different forms follow the same rank order as their intrinsic dissolution rates, as predicted by Eq. 5. Form II is relatively stable in saturated aqueous solutions. The excess solid iopanoic acid remaining in the sample containers at the end of a dissolution run was predominantly Form II. With the amorphous form, on the other hand, there was appreciable conversion to Form I after only 2 hr, and conversion was essentially complete at the end of 12 hr of exposure to the dissolution medium.

Aguiar and Zelmer (20) employed the saturation concentrations obtained from powder dissolution profiles to predict whether a given metastable polymorph will demonstrate enhanced bioavailability. According to their hypothesis, differences in human absorption observed following administration of chloramphenicol polymorphs A and B can be explained on the basis of the relatively large (−774 cal mole^{-1}) free energy difference between the two forms. On the basis of the much smaller free energy difference (−231 cal mole^{-1}) between polymorphs I and II of mefenamic acid, the authors predicted that there would be no significant differences in the absorption of these two forms. Their prediction was borne out in subsequent *in vivo* tests.

By applying the Aguiar–Zelmer hypothesis to iopanoic acid, the free energy difference, ΔG, between two solid forms (*e.g.*, A and B) of the same compound can be obtained from:

$$\Delta G = RT \ln \frac{C_s \text{ Form B}}{C_s \text{ Form A}} \qquad \text{(Eq. 6)}$$

Since the saturation solubility, C_s, of each solid form, measured at the same temperature, is directly proportional to its intrinsic dissolution rate, the dissolution rate ratio can be substituted for the ratio of solubilities in Eq. 6. In the case of iopanoic acid, $\Delta G_{\text{II}\rightarrow\text{I},\,37°}$ is −284 cal mole^{-1}, and $\Delta G_{\text{amorphous}\rightarrow\text{I},\,37°}$ is −1390 cal mole^{-1}. Based on these calculations, it seems likely that the bioavailability of Form II should not be appreciably greater than that of Form I. In contrast, the bioavailability of the amorphous form should be considerably greater than that of the stable polymorph. While many other factors affect the optimal opacification of the bladder, it would be of interest to determine whether these thermodynamic data can be quantitatively correlated with bioavailabilities of the three forms.

Guanabenz Degradation Products and Stability Assay

CHARLES M. SHEARER ˣ **and NICHOLAS J. DeANGELIS**

Received October 20, 1977, from the *Pharmacy Research and Development Division, Wyeth Laboratories, Inc., Radnor, PA 19087.* Accepted for publication February 9, 1979.

Abstract □ Guanabenz, [(2,6-dichlorobenzylidene)amino]guanidine, acetate was shown to be the *E*-isomer. It decomposed to form the *Z*-isomer, 2,6-dichlorobenzaldehyde, aminoguanidine, and 2,6-dichlorobenzaldehyde semicarbazone. A stability-indicating assay for the intact drug in the presence of all of its decomposition products by the use of UV spectroscopy is presented.

Keyphrases □ Guanabenz—degradation products, stability, UV spectroscopic analysis □ Antihypertensive agents—guanabenz, degradation products, stability, UV spectroscopic analysis □ Spectroscopy, UV—analysis, guanabenz degradation products □ Stability—guanabenz, degradation products

Guanabenz, [(2,6-dichlorobenzylidene)amino]guanidine, acetate is being evaluated as an antihypertensive agent. To develop a stability-indicating assay, the drug was decomposed by all meaningful modes, *i.e.*, hydrolytic, thermal (dry heat), and photolytic, and all degradation products were isolated and identified. This paper describes the isolation and identification of these degradation products and the development of a rapid spectrophotometric assay specific for guanabenz in their presence.

EXPERIMENTAL

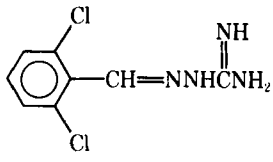
Guanabenz Degradation—Sufficient degradation products for characterization were obtained by using accelerated conditions. The hydrolysates were prepared by refluxing a guanabenz acetate solution in equal volumes of 2 *N* NaOH and ethanol for 8 hr or in 1 *N* HCl for 5 days. These products were separated from the intact drug by a biphase extraction into chloroform from aqueous acid.

Thermal degradation was studied by storing the drug substance at 100 and 75° for several weeks.

The photolytic degradation product was formed by exposing a 1% guanabenz solution in ethanol to UV light in a closed quartz vessel[1] for 1 week. The photolytic product was separated from guanabenz by column chromatography using silica gel[2] as the adsorbent and increasing methanol concentrations in chloroform containing 1% ammonium hydroxide as the eluent.

TLC—TLC was used to determine the purity of the isolated degradation products and to help establish their identity. Silica gel TLC plates with a fluorescent indicator[3] and an eluting solvent of chloroform–methanol–ammonium hydroxide (48.5:50:1.5) were used. Visualization was by shortwave UV light.

For quantitative TLC, 100-μg quantities were applied to the plate; after elution, the silica gel containing the intact guanabenz was scraped off and extracted from the silica gel with 10 ml of 10% 0.1 *N* NaOH in ethanol. The guanabenz concentration was determined by comparing the absorbance of the resulting solution at 305 nm to the absorbance of a standard carried through the same procedure.



I

Spectrophotometric Analysis—UV spectra[4] were obtained using 1-cm path length silica cells and the described solvents. To obtain IR spectra[5], samples were presented in the form of potassium bromide pellets. NMR spectra[6] were obtained by preparing solutions of the samples in deuterated dimethyl sulfoxide containing tetramethylsilane as the internal marker. Mass spectra[7] were obtained using an energy beam of 70 ev with the sample probe at 150°.

Stability-Indicating Assay—*Solvents*—For the pH 4.5 buffer, a 0.2 *M* aqueous monobasic sodium phosphate solution was diluted with an equal volume of methanol.

For the pH 10.8 buffer, a 0.1 *M* aqueous dibasic sodium phosphate solution was adjusted to pH 10.8 with 5 *N* NaOH. Two volumes of this buffer were diluted with one volume of methanol.

Procedure—The sample was quantitatively weighed or diluted into each solvent to obtain a concentration of ~0.01 mg of guanabenz/ml. The method was applicable in the range of 0.004–0.015 mg of guanabenz/ml. If the addition of the sample to the buffer solvent changed the pH by >0.1 unit, the sample was neutralized with acid or base as necessary.

The absorbance of each solution was determined at 265 and 305 nm in a 1-cm silica cell *versus* a solvent blank. The guanabenz concentration (c) in the final solutions was calculated using the following equation:

$$c = \frac{(A_2^{S1} - A_2^{S2}) - 1.32(A_1^{S1} - A_1^{S2})}{78.9} \qquad \text{(Eq. 1)}$$

where A_2^{S1} is the absorbance in pH 4.5 buffer at 265 nm, A_2^{S2} is the absorbance in pH 10.8 buffer at 265 nm, A_1^{S1} is the absorbance in pH 4.5 buffer at 305 nm, and A_1^{S2} is the absorbance in pH 10.8 buffer at 305 nm.

RESULTS AND DISCUSSION

Degradation Product Identification—Guanabenz was synthesized (1) as the acetate by the condensation reaction of 2,6-dichlorobenzaldehyde with aminoguanidine in the presence of acetic acid. Possible degradation hydrolysis routes were: (*a*) the reverse reaction of the synthesis, and (*b*) the replacement of the amino group on the guanidine by oxygen to give 2,6-dichlorobenzaldehyde semicarbazone. Both reactions occurred under reflux conditions in strong acid or base, based on a comparison of TLC R_f values of the degradation products to those of the known compounds.

For further proof of the reactions, the semicarbazone was isolated from the refluxed basic solution and identified by comparison of its IR spectrum with that of an authentic sample prepared from 2,6-dichlorobenzaldehyde and semicarbazide hydrochloride using the classical method (2). The 2,6-dichlorobenzaldehyde was similarly obtained in appreciable quantities from the refluxed acidic solution. No attempt was made to isolate and characterize the aminoguanidine found along with the 2,6-dichlorobenzaldehyde. TLC of the guanabenz-containing layers of the biphase extractions in both refluxed solutions showed a small amount of an additional degradation product, characterized as *Z*-2,6-dichlorophenylmethyleneaminoguanidine and later shown by TLC to be the same as the photoproduct.

In the thermal study, no degradation product was observed by TLC for samples of guanabenz acetate stored at 75 or 100° for 4 weeks. The sample stored at 100° did lose a portion of the acetic acid associated with it, as verified by titrimetric analysis (3) in 50% methanol–water.

The photolytic degradation product was not as readily identified as were the hydrolytic products. Guanabenz in mildly acidic, neutral, or mildly basic solutions undergoes a reversible reaction in the presence of light. The reaction reversibility was established by starting with the photoproduct and allowing it to convert to guanabenz. The same reversible reaction occurred in the dark but only in acidic solution.

Table I—Absorptivities of Guanabenz *E*- and *Z*-Isomers

Wavelength, nm	*E*-Isomer		*Z*-Isomer	
	pH 10.8	pH 4.5	pH 10.8	pH 4.5
305	55.2	14.8	18.2	0.2
265	28.3	53.9	40.1	16.2

The reaction reversibility immediately suggested that the two compounds were isomers. The photoproduct structure proved to be like that of the intact guanabenz by many classical structure elucidation methods. The mass spectra of the two compounds were the same (*m/e* 230), as were the elemental analyses (guanabenz: C, 41.29; H, 3.61; Cl, 30.84; N, 23.99; photoproduct: C, 41.57; H, 3.60; Cl, 30.39; N, 24.35). The equivalent weights, as determined by nonaqueous titrations, were the same and were in agreement with the mass spectrometric molecular weight. The ionization constants were 8.3. These were determined spectrophotometrically, thus assuring that changes in the spectra were due to ionization and not to interconversion of guanabenz and the photoproduct. These data and the reversibility of the reaction support the contention that the two compounds are isomers.

IR spectra of guanabenz and the photoproduct were distinctly different, but no useful information could be derived from these differences. NMR spectra showed four nonexchangeable protons. Three of these protons were aromatic and, although the spectra of the two compounds in the aromatic region were slightly different, these differences are not readily interpreted. The singlet peak for the other proton associated with the imino carbon was at 8.22 ppm for guanabenz and at 7.21 ppm for the photoproduct.

Previous investigators (4–9) extensively studied the NMR spectra of *Z*- and *E*-isomers about imino and similar bonds. In all cases, the signal from the *E*-isomer was downfield from that of the *Z*-isomer. A comparison of these data with those for guanabenz and the photoproduct indicated that the photoproduct is the *Z*-isomer and that guanabenz is the *E*-isomer. However, only aliphatic compounds were studied previously (4–9).

UV spectrophotometry was most important in proving the structure of the two compounds. Other investigators (10) found that phenyl ketone semicarbazones were categorized into two types by their UV spectra. One group had a maximum absorbance around 280 nm, and the second group showed a maximum absorbance only at lower wavelengths, if at all. Stenberg *et al.* (11) reported that *Z*-phenyl acetophenone semicarbazone had no peak in its UV spectrum above 230 nm while the *E*-isomer had a maximum at about 270 nm. When the UV spectra for guanabenz and the photoproduct (Fig. 1) were compared with these observations, it became evident that guanabenz was the *E*-isomer and that the photoproduct was the *Z*-isomer.

Differences in the UV spectra of the two isomers can be explained on the basis of steric hindrance. In an examination of a molecular model, a restricted rotation of the dichlorophenyl group in the *Z*-isomer is apparent. The π orbital of the imino bond is nearly perpendicular to the π orbital of the phenyl ring. The π orbital system for the *E*-isomer is nearly parallel throughout the molecule. Thus, the *E*-isomer, with a longer conjugated π electron system, will have a maximum absorbance at a longer wavelength than the *Z*-isomer.

Well-documented *cis–trans* isomerizations of semicarbazones and similar molecules occur under photolytic conditions as well as acidic conditions. Previous investigators (11) reported the photoisomerization of semicarbazones and gave evidence that the photoproduct of acetophenone semicarbazone, when dissolved in an ether solution, isomerized to the starting semicarbazone on exposure to anhydrous hydrogen chloride. Earlier work (12, 13) showed that *Z*- and *E*-isomers of semicarbazones could be interconverted by UV light.

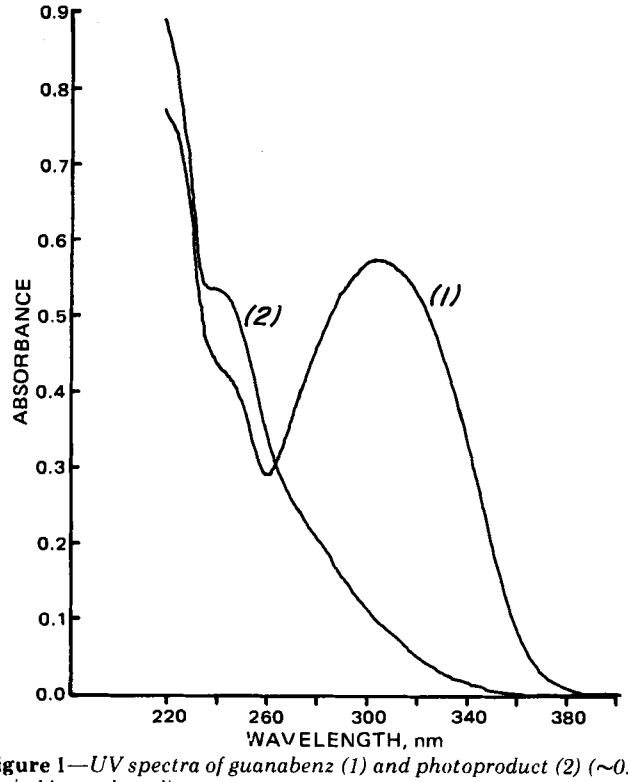

Figure 1—*UV spectra of guanabenz (1) and photoproduct (2) (~0.01 mg/ml in methanol).*

The *cis–trans* photoisomerization of aromatic Schiff bases has been studied (14). Aldehyde 2,4-dinitrophenylhydrazones underwent isomer equilibration in acid solution (15). Methylene bromide solutions of acetaldehyde 2,4-dinitrophenylhydrazone did not reach equilibrium after standing at room temperature for 10 days, while the addition of traces of sulfuric acid effected equilibration in less than a day. Another report (7) gave evidence for acid-catalyzed isomerization of several phenylhydrazones, semicarbazones, and thiosemicarbazones. 2,4-Dinitrophenylhydrazones of α-bromoacetophenone and α-bromobutyrophenone underwent *cis–trans* isomerization when refluxed in an organic solvent in the presence of a trace of hydrochloric acid (16).

Assay Development—The difference in the UV spectra of guanabenz and the *Z*-isomer, as well as the change in spectra with pH as related to the determination of the ionization constant, has been discussed. Figures 2 and 3 present the spectra of the neutral and the protonated species of

5 weeks in direct shortwave UV light (solid)	99	98
3 days at 170° (solid)	72	69

guanabenz and the *Z*-isomer, respectively. Aminoguanidine has no appreciable UV spectrum. The spectra of the two UV-absorbing hydrolysates, 2,6-dichlorobenzaldehyde and 2,6-dichlorobenzaldehyde semicarbazone, do not change between pH 4.5 and 10.8. Thus, only guanabenz and the *Z*-isomer have spectral differences at these two pH values.

By utilizing these differences, a simple stability-indicating assay was developed. The procedure can be considered to be a two-component spectral method; but rather than using the predetermined absorptivities of the two species, this method uses the differences in the absorptivities (Table I) at two wavelengths and the two pH values. Thus, this method combines the concepts of $\Delta\epsilon$ values described by Aulin-Erdtman (17) and Vieroidt's method (18) for two-component mixtures.

Method Validation—To determine the accuracy and specificity of this method, solutions were prepared containing varying amounts of guanabenz and the degradation products (Table II). Solutions containing only small percentages (≤20%) of the decomposition products were prepared since this is the range of interest.

To evaluate this assay procedure further, guanabenz acetate was decomposed in solution and as a dry drug substance under various conditions. These samples were analyzed by the stability-indicating assay, and the results of these analyses were compared with the results of quantitative TLC. The conditions for the degradation and the results are given in Table III.

Structural Biochemistry XIII: Synthesis of Luteinizing Hormone-Releasing Hormone Modification [Trp^8]-LH-RH

GEORGE R. PETTIT ˣ **and THOMAS H. SMITH**

Received February 28, 1978, from the *Cancer Research Institute and Department of Chemistry, Arizona State University, Tempe, AZ 85281.* Accepted for publication August 3, 1978.

Abstract □ A fragment condensation method was utilized for synthesis of the Trp^8-substituted luteinizing hormone-releasing hormone (LH-RH). *tert*-Butoxycarbonyl protection was employed for the α-amino positions, and benzyl protection was used for the phenol group of Tyr and the imidazole nitrogen of His. Peptide bond-forming reactions were performed using *N*-hydroxysuccinimide (for Trp), dicyclohexylcarbodiimide-1-hydroxybenzotriazole, 1-ethyl-3-(3′-dimethylaminopropyl)-carbodiimide hydrochloride, or mixed carbonic anhydride methods. Biological evaluation of [Trp^8]-LH-RH indicated no luteinizing hormone-releasing activity or inhibition of luteinizing hormone release over the dose ranges studied.

Keyphrases □ Luteinizing hormone-releasing hormone—derivatives, synthesis, structure-activity relationships □ Chemical synthesis—luteinizing hormone-releasing hormone derivatives, structure-activity relationships □ Hormones—luteinizing hormone-releasing hormone, derivatives, synthesis, structure-activity relationships □ Structure-activity relationships—luteinizing hormone-releasing hormone derivatives

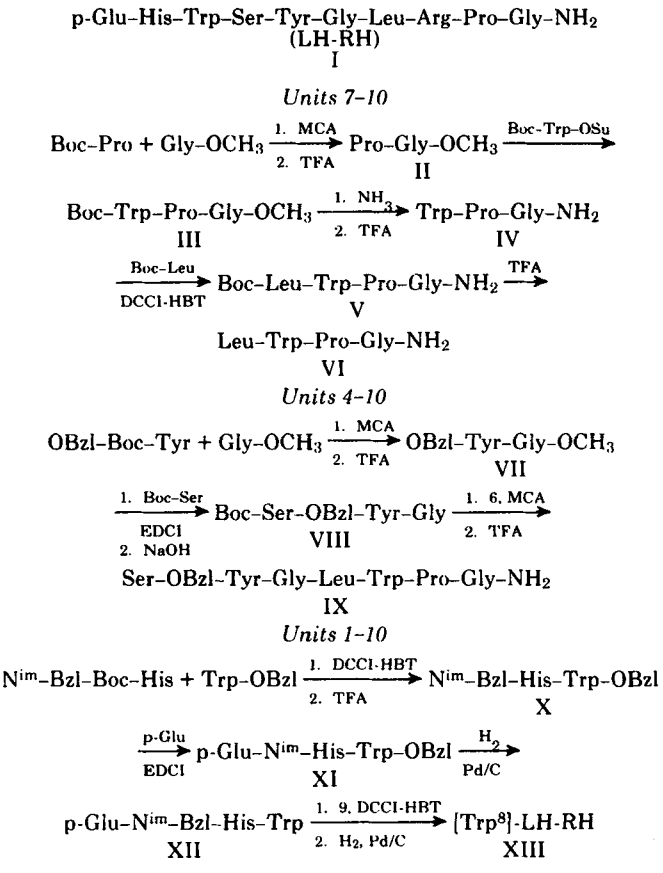
In humans, 1 μg of the hypothalamus decapeptide luteinizing hormone-releasing hormone (LH-RH, I) stimulates the pituitary to synthesize and release the luteinizing hormone (LH). Isolation of this decapeptide hormone from porcine hypothalami was first reported in 1971 (1, 2). This discovery has impressive potential for solving certain medical problems, from overcoming a cause of female sterility to opening new approaches to contraception. Therefore, synthetic efforts directed at the decapeptide hormone and related substances have been undertaken and presently underlie the major effort in decapeptide chemistry (3–15).

BACKGROUND

One facet of the LH-RH potential that seemed particularly attractive was that a suitable modification of this hormone might inhibit certain cancer types, *e.g.*, of the ovary. In 1968, certain tryptophan dipeptides were observed[1] to have antineoplastic activity. This discovery led to attempts to modify LH-RH by replacement of Arg at position 8 with Trp. This amino acid replacement modification also was selected because the hypothalamus growth hormone release-inhibiting tetradecapeptide hormone, somatostatin (16–18), contains Trp at position 8. In addition, LH-RH activity was known to be profoundly affected by modification at the Arg position (19–21).

Decapeptide synthesis was performed by a fragment condensation, as outlined in Scheme I. The *tert*-butoxycarbonyl (Boc) group was used for α-amino protection, and its removal was performed employing 50% trifluoroacetic acid in methylene chloride. With peptides containing a Trp unit, 2-mercaptoethanol was added to prevent oxidative degradation (22). The phenolic group of Tyr was protected as the *O*-benzyl ether, and the imidazole nitrogen of His was protected as the benzylamine derivative. In both cases, deprotection was achieved by hydrogenolysis using palladium-on-carbon.

Methyl ester saponification was effected employing aqueous sodium hydroxide in methanol. Peptide bond-forming reactions were efficiently realized employing the *N*-hydroxysuccinimide (NHS) active ester for coupling Trp (II → III), and either dicyclohexylcarbodiimide 1-hydroxybenzotriazole (DCCI-HBT), 1-ethyl-3-(3′-dimethylaminopropyl)carbodiimide hydrochloride (EDCI), or mixed carbonic anhydride (MCA) techniques at the other positions (13). By this combination of methods, the protected decapeptide was obtained in reasonable yield. After hydrogenolysis, [Trp^8]-LH-RH was isolated and evaluated[2].



Scheme I

The luteinizing hormone-releasing biological assay was performed with 200-g female rats, which were ovariectomized and allowed to rest 6 weeks. Three days following treatment with progesterone and estradiol benzoate, the animals were treated intravenously with 10–1000-ng doses of [Trp^8]-LH-RH with standard LH-RH as a control. Samples were collected 15 min later and analyzed for luteinizing hormone content. While the standard LH-RH produced significant dose-related luteinizing hormone release as expected, the [Trp^8]-LH-RH showed no significant luteinizing hormone release over the same dose range. Also, at doses of 50–200 μg, [Trp^8]-LH-RH showed no inhibition of luteinizing hormone release when given to 25-day-old male rats (23).

Based on these results, preparation of a modified LH-RH decapeptide bearing D-Trp at positions 8 and/or 2 is of interest with respect (24) to influencing luteinizing hormone release (5, 8, 9). Unfortunately, the limited amount of [Trp^8]-LH-RH available did not allow a definitive assessment of antineoplastic activity.

EXPERIMENTAL

All of the precursor L-amino acids and derivatives were employed as

[1] G. R. Pettit and S. K. Gupta, unpublished results.

received[3]. Solvent extracts containing completely protected peptides were washed consecutively with water, 0.5 *M* citric acid, water, 5% aqueous sodium bicarbonate, and saturated aqueous sodium chloride. Each extract was dried over anhydrous sodium sulfate, and the solvent was removed under reduced pressure at 35–40° using a rotating evaporator. Dimethylformamide was distilled (under reduced pressure) from calcium oxide, while tetrahydrofuran was distilled from lithium aluminum hydride just prior to use.

All melting points were recorded using a hot-stage apparatus[4] and are uncorrected. Each analytical specimen gave one spot on TLC and gave IR, PMR, and mass spectral data in accord with the assigned structure[5].

Boc-Pro-Gly-OCH_3—A solution of Boc-Pro (10.75 g, 50 mmoles) in tetrahydrofuran (250 ml) was cooled to −15°, and *N*-methylmorpholine (5.5 ml, 50 mmoles) followed by isobutyl chlorocarbonate (6.95 ml, 50 mmoles) was added. Before Gly-OCH_3 hydrochloride (6.6 g, 50 mmoles) and *N*-methylmorpholine (5.5 ml, 50 mmoles) were added, the mixture was stirred for 15 min at −15°. Stirring was continued for 2 hr at 0° and for 48 hr at 23°. The solvent was removed, and the residue was dissolved in ethyl acetate, washed, and dried. Solvent evaporation yielded a pink solid, which was recrystallized from ether to afford 11.8 g (78%), mp 70–72°; $[\alpha]_D^{25}$ −138° (methanol).

Anal.—Calc. for $C_{13}H_{22}N_2O_5$: C, 54.53; H, 7.74; N, 9.78. Found: C, 54.40; H, 7.86; N, 9.85.

Pro-Gly-OCH_3 (II) Hydrochloride—After 1 hr at room temperature, the solvent was removed from a solution of Boc-Pro-Gly-OCH_3 (102.8 mg, 0.358 mmole) in 50% trifluoroacetic acid (TFA)–methylene chloride (4 ml). The oily residue was treated with cold ethereal hydrogen chloride to form an oily precipitate. The solvent was removed, and the residue was dissolved in water (5 ml) and chromatographed on a column of XAD-2 resin (75 ml). Elution with water (300 ml), concentration to 15 ml, and lyophilization yielded 79.5 mg (100%) of the dipeptide II as a viscous oil.

Boc-Trp-Pro-Gly-OCH_3 (III)—A solution of Pro-Gly-OCH_3 hydrochloride (0.82 g, 3.71 mmoles), Boc-Trp-OSu (1.49 g, 3.71 mmoles), *N*-methylmorpholine (0.41 ml, 3.71 mmoles), and dimethylformamide (6 ml) was stirred at 23° for 8 hr. Ethyl acetate was added, and the mixture was washed and dried. The solvent was removed, and the residue was purified by column chromatography on silica gel (100 g, elution with ethyl acetate) and crystallized from ether–ligroin to afford 0.98 g (56%) of the tripeptide III, mp 86–88°; $[\alpha]_D^{25}$ −112° (methanol).

Anal.—Calc. for $C_{24}H_{32}N_4O_6$: C, 61.00; H, 6.83; N, 11.86. Found: C, 60.86; H, 7.00; N, 11.67.

Boc-Trp-Pro-Gly-NH_2—Boc-Trp-Pro-Gly-OCH_3 (0.82 g, 1.73 mmoles) was dissolved in methanol (40 ml) and cooled to 0°. Ammonia was passed into the solution for 1.5 hr. The reaction flask was tightly stoppered and allowed to stand at room temperature for 24 hr. Following solvent removal, the residue was crystallized from ethyl acetate–ligroin to afford 0.788 g (100%) of amide, mp 120–121°; $[\alpha]_D^{25}$ −49° (methanol).

Anal.—Calc. for $C_{23}H_{31}N_5O_5 \cdot H_2O$: C, 57.98; H, 6.93; N, 14.71. Found: C, 58.38; H, 6.66; N, 14.86.

Trp-Pro-Gly-NH_2 (IV) Trifluoroacetate—A solution of Boc-Trp-Pro-Gly-NH_2 (0.65 g, 1.42 mmoles) in 50% trifluoroacetic acid–methylene chloride (20 ml) containing 1% 2-mercaptoethanol was maintained at room temperature for 1 hr. The solvent was removed, and the residue was triturated with ether. The colorless precipitate was collected, and this hygroscopic solid was dissolved in water (20 ml) and lyophilized to yield 0.65 g (97%) of the amide IV as the trifluoroacetate.

Boc-Leu-Trp-Pro-Gly-NH_2 (V)—Dicyclohexylcarbodiimide (1.33 g, 6.48 mmoles) was added to a solution prepared from Trp-Pro-Gly-NH_2 trifluoroacetate (2.77 g, 5.89 mmoles), Boc-Leu (1.37 g, 5.89 mmoles)[1], 1-hydroxybenzotriazole (1.59 g, 11.8 mmoles), and *N*-methylmorpholine (0.66 ml, 5.89 mmoles) in tetrahydrofuran (80 ml) cooled to 0°. The mixture was stirred at 0° for 1 hr and at 23° for 3 hr. The solution was filtered, the solvent was removed, and the residue was dissolved in ethyl acetate, washed, and dried. After the solvent was evaporated, the residue was recrystallized from ethyl acetate ligroin to afford 2.37 g (70%) of the tetrapeptide amide V, mp 119–120°; $[\alpha]_D^{25}$ −37° (methanol).

Anal.—Calc. for $C_{29}H_{42}N_6O_6 \cdot H_2O$: C, 59.18; H, 7.48; N, 14.29. Found: C, 59.04; H, 7.52; N, 14.48.

Leu-Trp-Pro-Gly-NH_2 (VI) Trifluoroacetate—Cleavage of the protecting group from Boc-Leu-Trp-Pro-Gly-NH_2 (26.8 mg, 0.047 mmole) was conducted with 50% trifluoroacetic acid–methylene chloride (4 ml) containing 1% 2-mercaptoethanol as described for preparation of IV to yield 32.8 mg (84%) of the amide VI as the trifluoroacetate.

OBzl-Boc-Tyr-Gly-OCH_3—To a solution of OBzl-Boc-Tyr (5.0 g, 16.2 mmoles) in tetrahydrofuran (90 ml), cooled to −15°, was added *N*-methylmorpholine (1.81 ml, 16.2 mmoles) and isobutyl chlorocarbonate (2.11 ml, 16.2 mmoles). Before Gly-OCH_3 hydrochloride (2.02 g, 16.2 mmoles) and *N*-methylmorpholine (1.81 ml, 16.2 mmoles) were added, the mixture was stirred for 15 min at −15°. Then the mixture was stirred for 2 hr at 0° and for 26 hr at 23°. The solvent was removed, and a solution of the residue in ethyl acetate was washed, dried, and concentrated to a solid. The solid was recrystallized from ether to provide 5.70 g (92%) of the dipeptide, mp 118–120°; $[\alpha]_D^{25}$ −11° (methanol). The dipeptide VII was previously prepared in a 90% yield (mp 118–120°) by a *p*-nitrophenyl ester peptide bond-forming method (25).

Anal.—Calc. for $C_{24}H_{30}N_2O_6$: C, 65.11; H, 6.78; N, 6.35. Found: C, 64.90; H, 6.96; N, 6.32.

OBzl-Tyr-Gly-OCH_3 (VII) Hydrochloride—Removal of the Boc group from OBzl-Boc-Tyr-Gly-OCH_3 (3.65 g, 8.26 mmoles) was achieved using 50% trifluoroacetic acid–methylene chloride (30 ml, for 1 hr at 23°). The solvent was removed, and the residue was treated with cold ethereal hydrogen chloride. The colorless precipitate was collected and washed with ether. The hygroscopic solid was dissolved in water (20 ml) and lyophilized to yield 3.02 g (97%) of dipeptide ester VII as the hydrochloride.

Boc-Ser-OBzl-Tyr-Gly-OCH_3—A solution prepared from Boc-Ser (0.27 g, 1.31 mmoles), OBzl-Tyr-Gly-OCH_3 hydrochloride (VII, 0.497 g, 1.31 mmoles), and *N*-methylmorpholine (0.15 ml, 1.31 mmoles) in ethyl acetate–dimethylformamide (2:1, 15 ml) was cooled to 0°. Following addition of 1-ethyl-3-(3′-dimethylaminopropyl)carbodiimide hydrochloride (0.27 g, 1.43 mmoles), the mixture was stirred at 0° for 1 hr and at 23° for 20 hr. The reaction mixture was diluted with ethyl acetate, washed, and dried; the solvent was removed to yield a yellow oil. The crude product was purified by column chromatography on silica gel (100 g, elution with 1:1 ethyl acetate–chloroform) and recrystallized from ethyl acetate–ligroin to afford 0.49 g (72%) of the tripeptide, mp 104–105°; $[\alpha]_D^{25}$ −26° (methanol).

Anal.—Calc. for $C_{27}H_{35}N_3O_8$: C, 61.25; H, 6.62; N, 7.94. Found: C, 61.15; H, 6.75; N, 8.07.

Boc-Ser-OBzl-Tyr-Gly (VIII)—Boc-Ser-OBzl-Tyr-Gly-OCH_3 (0.71 g, 1.34 mmoles) was dissolved in a solution of 0.86 *N* NaOH in 90% aqueous methanol (15 ml). After 45 min at room temperature, the methanol was removed and the residue was diluted with water (25 ml) and extracted with ether (10 ml). The aqueous layer was acidified with 1 *N* HCl, saturated with sodium chloride, and extracted with ethyl acetate (3 × 20 ml). The combined extract was concentrated to dryness, and the residue was recrystallized from ethyl acetate–ligroin to give 0.61 g (87%) of tripeptide VIII, mp 88–90°; $[\alpha]_D^{25}$ −24° (methanol).

Anal.—Calc. for $C_{26}H_{33}N_3O_8$: C, 60.57; H, 6.45; N, 8.15. Found: C, 60.44; H, 6.35; N, 8.29.

Boc-Ser-OBzl-Tyr-Gly-Leu-Trp-Pro-Gly-NH_2—By means of the mixed carbonic anhydride procedure described for the preparation of the dipeptide IV, Boc-Ser-OBzl-Tyr-Gly (VIII, 0.27 g, 0.521 mmole) was allowed to react in tetrahydrofuran (15 ml) with *N*-methylmorpholine (58 μl, 0.521 mmole) and isobutyl chlorocarbonate (75 μl, 0.573 mmole) followed by Leu-Trp-Pro-Gly-NH_2 trifluoroacetate (0.30 g, 0.521 mmole) and *N*-methylmorpholine (58 μl, 0.521 mmole) in tetrahydrofuran (2 ml). The product was recrystallized from chloroform–ligroin to afford 0.47 g (94%) of the heptapeptide amide, mp 136–138°; $[\alpha]_D^{25}$ −35° (methanol).

Anal.—Calc. for $C_{50}H_{65}N_9O_{11} \cdot H_2O$: C, 60.91; H, 6.80; N, 12.80. Found: C, 60.56; H, 6.61; N, 12.70.

Ser-OBzl-Tyr-Gly-Leu-Trp-Pro-Gly-NH_2 (IX) Hydrochloride—A solution of Boc-Ser-OBzl-Tyr-Gly-Leu-Trp-Pro-Gly-NH_2 (0.71 g, 0.735 mmole) in 50% trifluoroacetic acid–methylene chloride (40 ml) containing 1% 2-mercaptoethanol was allowed to remain for 1 hr at 23°. Solvent was removed, and the residue was treated with cold ethereal hydrochloric acid to form a colorless precipitate. The precipitate was collected, washed with ether, and dried to yield 0.55 g (85%) of the heptapeptide amide IX, mp 149–150°.

N^{im}-Bzl-Boc-His-Trp-OBzl—A solution prepared from N^{im}-Bzl-Boc-His (5.10 g, 14.8 mmoles) (26), Trp-OBzl hydrochloride (4.87 g, 14.8 mmoles) (27), 1-hydroxybenzotriazole (3.95 g, 29.6 mmoles), *N*-methylmorpholine (1.66 ml, 14.8 mmoles), and dimethylformamide (100 ml) was cooled to 0°, and dicyclohexylcarbodiimide (3.34 g, 16.3 mmoles)

[3] Nutritional Biochemicals Corp. or Koch-Light.

[5] The amino acid analyses provided by Dr. R. H. Ode and Dr. J. Cronin were determined with a Beckman-Spinco 121 amino acid analyzer. Elemental microanalytical data were determined by Dr. A. Bernhardt, Mikroanalytisches Laboratorium, 5251 Elbach über Engelskirchen, West Germany.

was added. The mixture was stirred at 0° for 1 hr and at 23° for 16 hr. The solution was filtered, the solvent was removed, and the residue was triturated with chloroform. The chloroform solution was filtered, and the filtrate was washed, dried, and concentrated to dryness. Recrystallization of the residue from chloroform–ligroin afforded 6.27 g (68%) of the dipeptide, mp 67–68°; $[\alpha]_D^{25}$ +3° (methanol).

Anal.—Calc. for $C_{36}H_{39}N_5O_5$: C, 69.73; H, 6.28; N, 11.27. Found: C, 69.49; H, 6.18; N, 11.12.

N^{im}-Bzl-His-Trp-OBzl (X) Hydrochloride—Elimination of the Boc protecting group was realized as described for preparation of VII hydrochloride employing N^{im}-Bzl-Boc-His-Trp-OBzl (55.8 mg, 0.090 mmole) in 50% trifluoroacetic acid–methylene chloride (8 ml) containing 1% 2-mercaptoethanol. The hygroscopic product was dissolved in water (15 ml) and lyophilized to yield 45.9 mg (91%) of the dipeptide ester (X) hydrochloride.

p-Glu-N^{im}-Bzl-His-Trp-OBzl (XI)—To a dimethylformamide (40 ml) solution of p-Glu (0.45 g, 3.51 mmoles), N^{im}-Bzl-His-Trp-OBzl hydrochloride (1.95 g, 3.51 mmoles), and *N*-methylmorpholine (0.39 ml, 3.51 mmoles), cooled to 0°, was added 1-ethyl-3-(3′-dimethylaminopropyl)carbodiimide hydrochloride (0.74 g, 3.86 mmoles). The mixture was stirred at 0° for 1 hr and at 23° for 12 hr. After concentration to 15 ml, the solution was poured into ice–5% sodium bicarbonate (100 ml). The solid was collected, washed with water, and recrystallized from dimethylformamide–water to afford 1.66 g (75%) of the tripeptide XI, mp 235–237°; $[\alpha]_D^{25}$ +13° (dimethylformamide).

Anal.—Calc. for $C_{36}H_{36}N_6O_5 \cdot H_2O$: C, 66.46; H, 5.85; N, 12.91. Found: C, 65.70; H, 5.64; N, 12.64.

p-Glu-N^{im}-Bzl-His-Trp (XII)—A mixture of p-Glu-N^{im}-Bzl-His-Trp-OBzl (XI, 1.55 g, 2.42 mmoles), 5% palladium-on-charcoal (1.0 g), and methanol–acetic acid (80 ml) (3:2) was stirred under 1 atmosphere of hydrogen at 23° for 8 hr. The solution was filtered through diatomaceous earth, and solvent was removed from the filtrate. The residue was recrystallized from methanol–ether to provide 0.64 g (48%) of the tripeptide XII, mp 165–167°; $[\alpha]_D^{25}$ +19° (methanol).

p-Glu-His-Trp-Ser-OBzl-Tyr-Gly-Leu-Trp-Pro-Gly-NH_2 ([Trp^8]-LH-RH) (XIII)—A dimethylformamide (30 ml) solution of XII (0.335 g, 0.617 mmole), Ser-OBzl-Tyr-Gly-Leu-Trp-Pro-Gly-NH_2 hydrochloride (0.55 g, 0.617 mmole), 1-hydroxybenzotriazole (0.17 g, 1.23 mmoles), and *N*-methylmorpholine (69 μl, 0.617 mmole) was cooled to 0°, and dicyclocarbodiimide (0.14 g, 0.679 mmole) was added. The mixture was stirred at 0° for 1 hr and at 23° for 7 hr. Then the solution was filtered and poured into ice–5% sodium bicarbonate (100 ml). Following collection of the solid and trituration with hot methanol, the resulting solution was filtered. The solvent was removed, and the residue was dissolved in acetic acid (20 ml) and lyophilized to yield 0.60 g (71%) of the protected decapeptide as a powder. Recrystallization from methylethyl ether gave a specimen of p-Glu-N^{im}-Bzl-His-Trp-Ser-OBzl-Tyr-Gly-Leu-Trp-Pro-Gly-NH_2, mp 245–248° dec.; $[\alpha]^{25}$ −19° (acetic acid).

A mixture composed of the decapeptide (89.7 mg, 0.0645 mmole), 5% palladium-on-charcoal (0.10 g), and methanol–acetic acid (40 ml) (4:1) was stirred under 1 atmosphere of hydrogen at 23° for 40 hr. The solution was filtered through diatomaceous earth, and the solvent was evaporated to a solid. The solid was purified by preparative TLC on silica gel with methanol–ethyl acetate (7:3) as the mobile phase. The product was eluted with methanol–acetic acid, dissolved in acetic acid, and lyophilized to yield 55.4 mg (71%) of [Trp^8]-LH-RH (XIII).

The decapeptide XIII (5 mg) was dissolved in 6 *N* HCl and hydrolyzed at 110° for 20 hr in a sealed tube. The solution was freeze dried, and the residue was dissolved in citrate buffer (1 ml). A 500-μl aliquot was diluted to 10.0 ml with the same buffer, and a 1-ml sample of this solution was used for amino acid analysis, which showed: His (0.6), Ser (1.0), Glu (1.0), Pro (1.0), Gly (2.0), Leu (1.0), and Tyr (1.0). Repeated amino acid analyses gave essentially the same results for His. Similar low values for this amino acid were noted with several other modified LH-RH decapeptides (6).

Pharmacokinetic Model for Procaine in Humans during and following Intravenous Infusion

RANDOLPH H. SMITH *x, DANIEL H. HUNT ‡, ASTRIDE B. SEIFEN *, ALFREDO FERRARI *, and DOLA S. THOMPSON *

Received September 1, 1978, from the **Department of Anesthesiology and the* ‡*Department of Pharmacology, University of Arkansas for Medical Sciences, Little Rock, AR 72201.* Accepted for publication February 9, 1979.

Abstract □ A multicompartment pharmacokinetic model is presented to describe procaine distribution in humans during and following intravenous infusion. The model, based on a general perfusion model, relates individual characteristics such as sex, age, weight, height, infusion rate and duration, and hematocrit to general parameters such as drug metabolism, protein binding, ion-trapping effects, and tissue–plasma distribution coefficients to provide an individualized distribution prediction. Experimentally observed kinetics of blood procaine levels collected during intravenous procaine infusion as an adjunct to surgical anesthesia and blood lidocaine levels obtained from the literature compared very well with the model simulation.

Keyphrases □ Pharmacokinetics—procaine in humans, intravenous infusion, drug interactions □ Procaine—pharmacokinetics, intravenous infusion, humans, drug interactions □ Local anesthetics—procaine, pharmacokinetics, intravenous infusion, humans, drug interactions □ Models, pharmacokinetic—procaine, intravenous infusion, humans, drug interactions

Local anesthetics are given intravenously for various clinical purposes. Intravenous procaine is now being studied as a supplement or adjunct to general anesthesia, whereas in the past it has been used for local anesthesia, for intravenous regional anesthesia, and in cardiac arrhythmia treatment.

In these clinical applications, there are potential dangers to the patient such as cardiovascular depression and central nervous system toxicity. The ability to predict drug concentrations in various body organs as the result of intravenous infusion rates could aid the clinician's choice of an infusion rate and thereby offer additional safety in drug administration. Additionally, the clinical application of intravenous local anesthetics is usually simultaneous with the application of other drugs. Therefore, a potential for interaction between the various drugs exists. These interactions can change significantly the degree of pharmacological action expressed by the drugs individually.

This project was undertaken in order to describe and simulate the pharmacokinetics of intravenous procaine used as an adjuvant drug for surgical anesthesia.

BACKGROUND

In traditional pharmacokinetic studies, the drug concentration in the blood is used as an index because the clinical sampling procedure for blood is easier and more convenient than the sampling of other tissues and fluids. The traditional pharmacokinetic approach (1–3) is to correlate the drug concentration in blood data by using one or several exponential terms, with each exponential term representing a compartment, to describe the data. The distribution volumes, rate constant, *etc.*, in the pharmacokinetic model are determined from the parameters of the exponential equation describing the drug concentration in blood (4).

The traditional approach utilizing the pharmacokinetic distribution based on these data alone may not provide sufficient information for adequate therapy when such drugs as ultrashort-acting barbiturates, some cardiovascular drugs, especially cancer chemotherapeutic agents, and local anesthetics are employed. An additional knowledge of the drug distribution in various organs and tissues as well as in the blood may be necessary to provide optimal drug concentrations in areas targeted for treatment without undue risk.

Previous investigators (5–7) developed an entirely different approach to pharmacokinetic modeling to make *a priori* prediction of drug distributions in the body. Included were parameters such as blood flow rates, lipid solubility, protein binding, and metabolism based on *in vitro* studies of well-documented physiological parameters. The model described here is an extension of this perfusion model approach with additional parameters that improve the scaling to different body sizes based on fat-free proportions as well as account for erythrocyte ion trapping.

EXPERIMENTAL

Arterial blood samples were collected from human volunteers undergoing intravenous procaine infusion as an adjuvant to surgical anesthesia along with thiamylal and nitrous oxide. These samples were collected before, during, and after the infusion. An inhibitor of plasma butyrylcholinesterase (pseudocholinesterase) was added to preserve the procaine for analysis. A flame-ionization GLC technique (8) was used to determine the blood concentrations. Additional parameters such as age, weight, height, sex, hematocrit, and other drugs administered were collected for use in the simulation. The exact infusion rates and duration were determined also.

THEORETICAL

The model can be thought of as an interactive blood–drug–tissue system. To describe such a system, previous investigators (5–7) used a four-compartment model with the body divided into the blood pool, the viscera, the lean tissue, and the adipose tissue. They utilized this scheme to describe the pharmacokinetics of several drugs such as thiopental and methotrexate.

This study of clinical intravenous procaine use focuses on the drug concentration in the brain because of anesthetic and potential convulsive effects. The blood pool was divided into separate arterial and venous pools with a lung compartment added to provide a mixing and time delay between the arterial and venous pools since procaine is hydrolyzed very rapidly by the plasma cholinesterases. Additional compartments were added to describe procaine metabolism in the liver and the ion-trapping effect due to the lower pH within the GI tract. The model (Fig. 1) contains nine compartments and adequately describes intravenous procaine pharmacokinetics, although consideration could be given to separating the blood from tissue for the highly perfused organs due to borderline adherence to the basic assumption of instantaneous mixing or flow-limitation of the system.

Each compartment equation describes a material (drug mass) balance between the incoming and outgoing drug rates. For example, blood flowing into a compartment transports an amount of drug at an incoming rate equal to the volume flow times the total concentration. Summation of all incoming and outgoing rates yields a net accumulation rate within the compartment. The free (unbound) concentration of drug leaving a compartment is assumed to equal (is in equilibrium with) the free concentration within that compartment.

This assumption may not be valid for a compartment that is a combination of blood and tissue and is highly perfused (such as viscera). If the drug does not diffuse into and out of the tissue at a rate faster than the transport by blood flow, the assumption also is not correct. Hence, the viscera might be described more accurately as a viscera tissue compartment and a viscera blood compartment. Furthermore, an equation (statement of material balance) written for one compartment contains concentration values from other compartments and, therefore, all compartment equations are interdependent (as are the body functions they describe) and must be solved together.

The venous blood pool compartment is given first, and the terms are

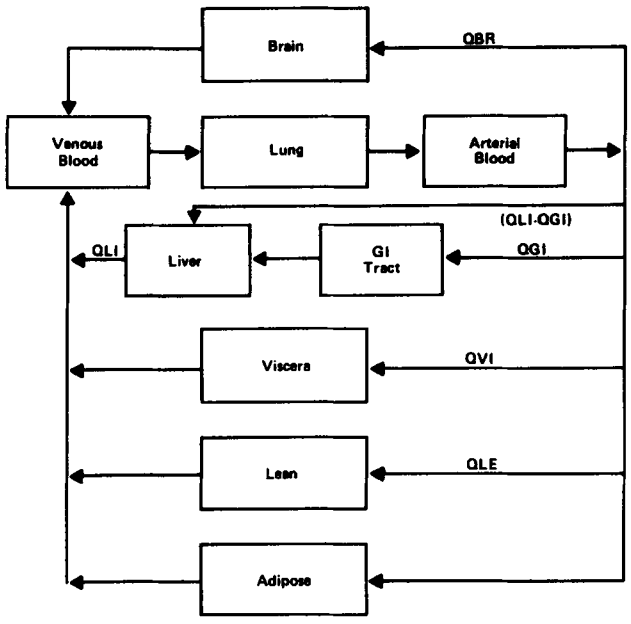

Figure 1—*Body compartments important in procaine distribution.*

elucidated for better understanding of the entire model before stating the other compartment equations.

Venous Blood: Compartment 1—

$$TRAPC(HMT)V_{Vb}F_{W,e}\frac{dC_{Vb}}{dt} + (1 - HMT)V_{Vb}F_{W,Pl}\frac{dC_{Vb}}{dt} + (1 - HMT)V_{Vb}C_{M,Pl}\frac{dX_{Vb}}{dt} = Q_{BR}[TRAPC(HMT)F_{W,e}C_{BR} + (1 - HMT)(F_{W,Pl}C_{BR} + C_{M,Pl}X_{BRb})] + Q_{LI}[TRAPC(HMT)F_{W,e}C_{LI} + (1 - HMT)(F_{W,Pl}C_{LI} + C_{M,Pl}X_{LIb})] + Q_{VI}[TRAPC(HMT)F_{W,e}C_{VI} + (1 - HMT)(F_{W,Pl}C_{VI} + C_{M,Pl}X_{VIb})] + Q_{LE}[TRAPC(HMT)F_{W,e}C_{LE} + (1 - HMT)(F_{W,Pl}C_{LE} + C_{M,Pl}X_{LEb})] + Q_{AD}[TRAPC(HMT)F_{W,e}C_{AD} + (1 - HMT)(F_{W,Pl}C_{AD} + C_{M,Pl}X_{ADb})] - Q[TRAPC(HMT)F_{W,e}C_{Vb} + (1 - HMT)(F_{W,Pl}C_{Vb} + C_{M,Pl}X_{Vb})] - (1 - HMT)V_{Vb}R_{MET,b} + Q_{INF}(BWT) \quad \text{(Eq. 1)}$$

where:

C_i = free (unbound concentration in compartment i) water (micromoles per liter)
Vb = venous blood
LE = lean
AD = adipose
VI = viscera
BR = brain
Ab = arterial blood
LI = liver
LG = lung
e = erythrocyte
Pl = plasma
Q = blood flow rate (liters per minute)
V = volume of the compartment (liters)
HMT = hematocrit of erythrocyte (fraction)
$C_{M,Pl}$ = effective plasma binding protein concentration (kilograms per liter)
$F_{W,Z}$ = fraction water in compartment Z
X = bound concentration (micromoles per kilogram of protein)
$R_{MET,b}$ = metabolism [hydrolysis rate, micromoles per liter (plasma)-minutes]
Q_{INF} = infusion rate [micromoles per kilogram (body)-minutes]
BWT = body mass (kilograms)
$TRAPC$ = ion-trapping constant

Since a compartment contains "free" and "bound" concentrations of drug, summation of these concentrations gives the total concentration. In general, the free drug is assumed to be in the water phase of the compartment, and the bound drug exists in physical attachment to protein or large macromolecules. However, not all protein is effective or available for binding. Therefore, an effective protein concentration as described previously (9) is used to determine the bound drug concentration. The total concentration for a compartment is described as:

$$C_{tot} = F_{W,Z}C + C_{M,Z}X \quad \text{(Eq. 2)}$$

where:

C_{tot} = total concentration (micromoles per liter)
C = free concentration (micromoles per liter)
X = bound concentration (micromoles per liter)
$F_{W,Z}$ = fraction water (W) in region Z
$C_{M,Z}$ = effective protein macromolecule (M) concentrations (kilograms of protein per liter)

For the venous plasma pool, the total plasma drug concentration is of the form:

$$C_{Pl} = F_{W,Pl}C_{Vb} + C_{M,Pl}X_{Vb} \quad \text{(Eq. 3)}$$

However, for total blood, the amount sequestered within the erythrocytes must be included (10). Due to the erythrocyte ion-trapping effect at a slightly lower intracellular pH (erythrocyte water, pH 7.26) as opposed to extracellular medium pH (plasma water, pH 7.40), the concentration ratio can be calculated as:

$$TRAPC = \frac{C_{eW}}{C_{PW}} = \frac{1 + 10^{pKa\text{-}pH_{eW}}}{1 + 10^{pKa\text{-}pH_{PW}}} \quad \text{(Eq. 4)}$$

where:

C = free concentration (micromoles per liter)
pKa = negative logarithm of acid dissociation constant = 8.92 (procaine base)
eW = erythrocyte water
PW = plasma water

The calculation yields a concentration ratio, $C_{eW}/C_{PW} = 1.37$. However, a study (11) of procaine uptake in human platelets, although they are smaller than erythrocytes, showed that the highest concentration ratio occurred at pH 7.4 with $C_{medium} = 100$ mg/liter and was 2.85 ± 0.78. High uptake also was found (12) for several anilide-type local anesthetics. Therefore, it could be concluded that binding was present, but no definitive binding relationship was noted other than a dependence on pH. Hence, in this work, the concentration ratio is only calculated from the ion-trapping effects as per Eq. 4. Additionally, since no difference in uptake was reported (12) from 5 min to 24 hr, a rapid establishment of equilibrium may be assumed.

The drug concentration in erythrocytes as a fraction of blood is determined from the hematocrit (HMT), the erythrocyte water fraction ($F_{W,e}$), the trapping ratio ($TRAPC$), and the plasma water concentration. Combination of the erythrocyte concentration with the total plasma concentration gives the total blood concentration:

$$C_{t,VB} = TRAPC(HMT)F_{W,e}C_{Vb} + (1 - HMT)(F_{W,Pl}C_{Vb} + C_{M,Pl}X_{Vb}) \quad \text{(Eq. 5)}$$

The protein or macromolecular drug binding has a major influence on the concentration relationship (12, 13). The general form for the relationship is:

$$r = \sum_{i=1}^{n}\frac{N_iK_iC}{1 + K_iC} \quad \text{(Eq. 6)}$$

where:

r = moles of bound drug per mole of protein macromolecule (moles per mole of protein)
N_i = average number of type i binding sites per protein macromolecule (moles per mole of protein)
K_i = intrinsic association constant of type i binding site (liters per mole)

A bound concentration of micromoles bound per kilogram of macromolecule is used instead of a mole per mole basis, and the general form of the relationship can be simplified to only one binding site. Therefore:

$$X = \frac{BKC}{1 + KC} \quad \text{(Eq. 7)}$$

where:

X = bound concentration (micromoles per kilogram)
C = free concentration (micromoles per liter)

B = binding site constant (micromoles per kilogram)
K = intrinsic association constant (liters per micromole)

This relationship is sufficient in the presence of a single drug. The presence of two or more drugs may cause competition for a binding site, and the equation describing the binding relationship must take this competitive binding into account (14). The following describes the competition between two drugs for a single site on the protein complex:

$$P + C \underset{K_2}{\overset{K_1}{\rightleftarrows}} PC$$

Scheme I

$$K_c = \frac{K_1}{K_2} = \frac{(PC)}{(P)(C)} \qquad \text{(Eq. 8a)}$$

$$P + D \underset{K_4}{\overset{K_3}{\rightleftarrows}} PD$$

Scheme II

$$K_D = \frac{K_3}{K_4} = \frac{(PD)}{(P)(D)} \qquad \text{(Eq. 8b)}$$

$$r = \frac{(PC)}{(P)} = \frac{N_t K_t C}{1 + K_D D + K_C C} \qquad \text{(Eq. 9)}$$

and:

$$X = \frac{B_C K_C C}{1 + K_D D + K_C C} \qquad \text{(Eq. 10)}$$

where:

B_C = binding site constant for drug C (micromoles per kilogram)
K_C = intrinsic association constant for drug C (liters per micromole)
C = free drug C concentration (micromoles per liter)
D = free inhibitor drug D concentration (micromoles per liter)

The use of the binding equation requires an estimation of the inhibitor drug concentration. A one-compartment model approximation *via* exponential decay of the initial concentration may be sufficient if the inhibitor drug has a half-life much longer than the drug of interest. In this case, the inhibitor drug concentration changes relatively slowly and can be assumed to act in one compartment uniformly throughout the body. Hence, thiamylal, an ultrashort-acting barbiturate having a half-life of at least 2 hr, which is much longer (~20 times) than that of procaine, was handled as a one-compartment drug in this study. In the clinical situation being simulated, thiamylal is given several minutes before procaine so the equation describing the thiamylal concentration would be:

$$C_{th} = C_{tho} \exp \frac{-(T + TD)0.693}{T^1/_2} \qquad \text{(Eq. 11)}$$

where:

C_{th} = thiamylal concentration (micromoles per liter)
$C_{tho} = D_{th}/V_{th}$ = initial concentration
D_{th} = dose (micromoles per kilogram)
V_{th} = volume of distribution (liters per kilogram)
TD = time delay between thiamylal and procaine administration

Another important function of the blood pool with regard to procaine is the metabolism *via* circulating enzymes, procainesterases (assumed to be plasma cholinesterases). The reaction rate has been well investigated (15–17) and is suited to description by the Michaelis–Menten-type equation of the form:

$$R_{MET} = \frac{V_{max} C}{C_{half} + C} \qquad \text{(Eq. 12)}$$

where:

R_{MET} = reaction rate [micromoles per liter (plasma)-minutes]
V_{max} = maximum reaction rate (micromoles per liter-minutes)
C_{half} = free drug concentration (micromoles per liter)

As with protein binding competition, it is necessary to account for the inhibition or competitive effect of other drugs, particularly in the clinical setting where many drugs are administered concurrently. In this work, one such drug of special significance is succinylcholine, a muscle relaxant, which is metabolized by the plasma cholinesterases (18). The derivation and design of the competitive inhibition phenomena for a chemical reaction are almost identical to those for protein binding, differing only in the final form of the equation. The Michaelis–Menten equation becomes:

$$R_{MET} = \frac{V_{max} C}{C_{half}\left(1 + \frac{I}{K_I}\right) + C} \qquad \text{(Eq. 13)}$$

where:

I = free inhibitor concentration (micromoles per liter)
$K_I = K_m$ value or half maximal I concentration (micromoles per liter)

Obviously, the inhibitor increases the value of C_{half}.

Calculation of the final reaction rate requires estimation of the drug I concentration, which in this case is succinylcholine (suxamethonium) (17). Since succinylcholine is very water soluble and sparingly soluble in organic media, it will be assumed that the distribution volume is approximately equal to the extracellular fluid volume. If the intravenously administered dose is eliminated solely by its reaction with plasma cholinesterase, the succinylcholine concentration can be estimated as follows:

$$CSD = \frac{\text{dose} - \frac{VSD(CSD)T}{CKSD(1 - C/C_{half}) + CSD}(1 - HMT)V_b}{V_{EX}} \qquad \text{(Eq. 14)}$$

where:

CSD = free concentration of succinylcholine (micromoles per liter)
VSD = maximum reaction rate [micromoles per liter (plasma)-minutes]
$CKSD$ = K_m value for succinylcholine (micromoles per liter)
V_{EX} = extracellular fluid volume (liters)
V_b = blood volume (liters)
HMT = hematocrit
C = free procaine concentration (micromoles per liter)
C_{half} = K_m value for procaine (micromoles per liter)
dose = intravenous succinylcholine dose (micromoles)
T = time (minutes)

Essentially, the complexity of this model is exhibited in the blood equation. However, the various tissue compartments must be described with particular emphasis on the tissue macromolecular drug binding. Since no literature description of a relationship as a function of free concentration is available for tissue, the plasma binding relationship parameter was assumed to be valid. It remained to determine the effective tissue macromolecule concentration. Values for the partitioning of drug into tissue from plasma are available (10, 19–21). A tissue–plasma partition ratio can be calculated for brain, as an example, as follows:

$$P_{BR} = \frac{F_{W,BRt} C_{BR} + C_{M,BRt} X_{BRt}}{F_{W,Pl} C_{BR} + C_{M,Pl} X_{BRb}} = \frac{\text{plasma}}{\text{tissue}} \qquad \text{(Eq. 15)}$$

The unknown value of $C_{M,BRt}$ (effective macromolecule concentration in brain tissue) can be determined since $F_{W,BRt}$ is available from the literature and the other terms have been previously determined. A slightly different approach to the formulation is needed to handle adipose tissue where the fatty tissue concentration may be approximated by using a Henry's law relationship (21):

$$X_{ADt} = B_{ADt} C_{AD} \qquad \text{(Eq. 16)}$$

where B_{ADt} is Henry's law constant for procaine. Hence, the partition equation becomes:

$$P_{AD} = \frac{F_{W,ADt} C_{AD} + C_{M,ADt} B_{ADt} C_{AD}}{F_{W,Pl} C_{AD} + C_{M,Pl} X_{ADb}} \qquad \text{(Eq. 17)}$$

Even if B_{ADt} is not known, the combination $C_{M,Adt} B_{ADt}$ is sufficient for the descriptive equation since X_{ADb} in the plasma is calculated from Eq. 10. Now the other compartments can be expressed quantitatively.

Lean: Compartment 2—

$$TRAPC(HMT)V_{LEb}F_{W,e}\frac{dC_{LE}}{dt} + (1 - HMT)V_{LEb}F_{W,Pl}\frac{dC_{LE}}{dt}$$
$$+ (1 - HMT)V_{LEb}C_{M,Pl}\frac{dX_{LEb}}{dt} + V_{LEt}F_{W,LEt}\frac{dC_{LE}}{dt}$$

Table I—Model Parameters for Standard 70-kg Man [a]

Parameter	Compartment								
	Arterial Blood	Venous Blood	Brain	Viscera	Liver	Lean	GI Tract	Adipose	Lung
Tissue volume, liters	—	—	1.50	0.64	1.50	3.92	1.50	12.2	0.60

Fraction water	0.714	0.94	0.76	0.78	0.73	0.77	0.74	0.19	0.90
Blood volume, liters	0.58	1.16	0.47	1.05	0.37	0.52	1.05	0.16	0.46

[a] Values modified from Refs. 22 and 25.

$$+ V_{LEt}C_{M,LEt}\frac{dX_{LEt}}{dt} = Q_{LE}[TRAPC(HMT)F_{W,e}C_{Vb} + (1 - HMT)(F_{W,Pl}C_{Vb} + C_{M,Pl}X_{Vb}) - TRAPC(HMT)F_{W,e}C_{LE} + (1 - HMT)(F_{W,Pl}C_{LE} + C_{M,Pl}X_{LEb})] - (1 - HMT)V_{LEb}R_{MET,LEb} \quad \text{(Eq. 18)}$$

Adipose: Compartment 3—

$$TRAPC(HMT)V_{ADb}F_{W,e}\frac{dC_{AD}}{dt} + (1 - HMT)V_{ADb}F_{W,Pl} \times \frac{dC_{AD}}{dt} + (1 - HMT)V_{ADb}C_{M,Pl}\frac{dX_{ADb}}{dt} + V_{ADt}F_{W,ADt}\frac{dC_{AD}}{dt} + V_{ADt}C_{M,ADt}\frac{dX_{ADt}}{dt} = Q_{AD}[TRAPC(HMT)F_{W,e}C_{Vb} + (1 - HMT)(F_{W,Pl}C_{Vb} + C_{M,Pl}X_{Vb}) - TRAPC(HMT)F_{W,e}C_{AD} + (1 - HMT)(F_{W,Pl}C_{AD} + C_{M,Pl}X_{ADb})] - (1 - HMT)V_{ADb}R_{MET,ADb} \quad \text{(Eq. 19)}$$

Because of the highly perfused nature of the brain, heart, and kidneys as well as some other organs, the assumption that mass transfer with each compartment is flow limited, *i.e.*, at the normal blood flow rate, incoming drug is instantly mixed with surrounding tissue and the outgoing free drug concentration is equal to the total compartment free concentration, should be considered. For high lipid-soluble drugs, this assumption is valid; but for less soluble ones, it is not. This subject is treated thoroughly in the literature (5–7).

Instead of a transfer coefficient equal to infinity, a transfer value for procaine equal to the flow rate of the compartment could be used for lack of a more exact determination. It is significant to account for this phenomenon since the rate of procaine appearance into cerebrospinal fluid is less than the ratio of blood flow to tissue volume (19). Conversely, in the lean and adipose compartments, the flow to volume ratio is much less than the transfer rate into tissue, and the uniformity is still assumed to be valid.

The viscera, brain, liver, GI tract, and lung compartments could be described with plasma and tissue separated, where the transfer between plasma and tissue is dependent on the free concentration difference. However, the following description ignores the finite plasma-tissue transfer and combines plasma and tissue into one compartment for simplicity.

Viscera: Compartment 4—

$$TRAPC(HMT)V_{VIb}F_{W,e}\frac{dC_{VI}}{dt} + (1 - HMT)V_{VIb}F_{W,Pl} \times \frac{dC_{VI}}{dt} + (1 - HMT)V_{VIb}C_{M,Pl}\frac{dX_{VI}}{dt} + V_{VIt}F_{W,VIt}\frac{dC_{VIb}}{dt} + V_{VIt}C_{M,VIt}\frac{dX_{VIb}}{dt} = Q_{VI}[TRAPC(HMT)F_{W,e}C_{Ab} + (1 - HMT)(F_{W,Pl}C_{Ab} + C_{M,Pl}X_{Ab}) - TRAPC(HMT)F_{W,e}C_{VIb} + (1 - HMT)(F_{W,Pl}C_{VIb} + C_{M,Pl}X_{VIb})] - (1 - HMT)V_{VIb}R_{MET,VIb} - RC(C_{VIb}) \quad \text{(Eq. 20)}$$

where RC is the renal clearance rate (liters per minute).

Brain: Compartment 5—

$$TRAPC(HMT)V_{BRb}F_{W,e}\frac{dC_{BR}}{dt} + (1 - HMT)V_{BRb}F_{W,Pl} \times \frac{dC_{BR}}{dt} + (1 - HMT)V_{BRb}C_{M,Pl}\frac{dX_{BRb}}{dt} + V_{BRt}F_{W,BRt}\frac{dC_{BR}}{dt} + V_{BRt}C_{M,BRt}\frac{dX_{BRt}}{dt} = Q_{BR}[TRAPC(HMT)F_{W,e}C_{Ab} + (1 - HMT)(F_{W,Pl}C_{Ab} + C_{M,Pl}X_{Ab}) - TRAPC(HMT)F_{W,e}C_{BR} + (1 - HMT)(F_{W,Pl}C_{BR} + C_{M,Pl}X_{BR})] - (1 - HMT)V_{BRb}R_{MET,BRb} \quad \text{(Eq. 21)}$$

Liver: Compartment 6—

$$TRAPC(HMT)V_{LIb}F_{W,e}\frac{dC_{LI}}{dt} + (1 - HMT)V_{LIb}F_{W,Pl}\frac{dC_{LI}}{dt} + (1 - HMT)V_{LIb}C_{M,Pl}\frac{dX_{LIb}}{dt} + V_{LIt}F_{W,LIt}\frac{dC_{LI}}{dt} + V_{LIt}C_{M,LIt}\frac{dX_{LIt}}{dt} = (Q_{LI} - Q_{GI})[TRAPC(HMT)F_{W,e}C_{Ab} + (1 - HMT)(F_{W,Pl}C_{Ab} + C_{M,Pl}X_{Ab})] + Q_{GI}[TRAPC(HMT)F_{W,e}C_{GI} + (1 - HMT)(F_{W,Pl}C_{GI} + C_{M,Pl}X_{GIb})] - Q_{LI}[TRAPC(HMT)F_{W,e}C_{LI} + (1 - HMT)(F_{W,Pl}C_{LI} + C_{M,Pl}X_{LIb})] - (1 - HMT)V_{LIb}R_{MET,LIb} - (V_{LIt}R_{LIt}C_{LIb})/(C_{half} + C_{LIb}) \quad \text{(Eq. 22)}$$

where R_{LIt} is the reaction rate constant for liver metabolism of procaine (minutes^{-1}).

GI Tract: Compartment 7—

$$TRAPC(HMT)V_{GIb}F_{W,e}\frac{dC_{GI}}{dt} + (1 - HMT)_{GIb}F_{W,Pl}\frac{dC_{GI}}{dt} + (1 - HMT)V_{GIb}C_{M,Pl}\frac{dX_{GIb}}{dt} + V_{GIt}F_{W,GIt}\frac{dC_{GI}}{dt} + V_{GIt}C_{M,GIt}\frac{dX_{GIt}}{dt} = Q_{GI}[TRAPC(HMT)F_{W,e}C_{Ab} + (1 - HMT)(F_{W,Pl}C_{Ab} + C_{M,Pl}X_{Ab}) - TRAPC(HMT)F_{W,e}C_{GIb} + (1 - HMT)(F_{W,Pl}C_{GIb} + C_{M,Pl}X_{GIb})] - (1 - HMT)V_{GIb}R_{MET,GIb} \quad \text{(Eq. 23)}$$

Lungs: Compartment 8—

$$TRAPC(HMT)V_{LGb}F_{W,e}\frac{dC_{LG}}{dt} + (1 - HMT)V_{LGb}\frac{dC_{LG}}{dt} + (1 - HMT)V_{LGb}C_{M,Pl}\frac{dX_{LGb}}{dt} + V_{LGt}F_{W,LGt}\frac{dC_{LG}}{dt} + V_{LGt}C_{M,LGt}\frac{dX_{LGt}}{dt} = Q_b[TRAPC(HMT)F_{W,e}C_{Vb} + (1 - HMT)(F_{W,Pl}C_{Vb} + C_{M,Pl}X_{Vb} - TRAPC(HMT)F_{W,e}C_{LG} + (1 - HMT)(F_{W,Pl}C_{LG} + C_{M,Pl}X_{LGb})] - V_{LGb}(1 - HMT)R_{MET,LGb} \quad \text{(Eq. 24)}$$

Arterial Blood: Compartment 9—

$$TRAPC(HMT)V_{Ab}F_{W,e}\frac{dC_{Ab}}{dt} + (1 - HMT)V_{Ab}F_{W,Pl}\frac{dC_{Ab}}{dt} + (1 - HMT)V_{Ab}C_{M,Pl}\frac{dX_{Ab}}{dt} = Q_B[TRAPC(HMT)F_{W,e}C_{LG} + (1 - HMT)(F_{W,Pl}C_{LG} + C_{M,Pl}X_{LGb}) - TRAPC(HMT)F_{W,e}C_{Ab} + (1 - HMT)(F_{W,Pl}C_{Ab} + C_{M,Pl}X_{Ab})] - (1 - HMT)V_{Ab}R_{MET,Ab} \quad \text{(Eq. 25)}$$

The physiological and anatomical parameters were based on those of a standard 70-kg man but were scaled, to simulate each individual studied, on the basis of basal energy metabolism (BEM) which is a

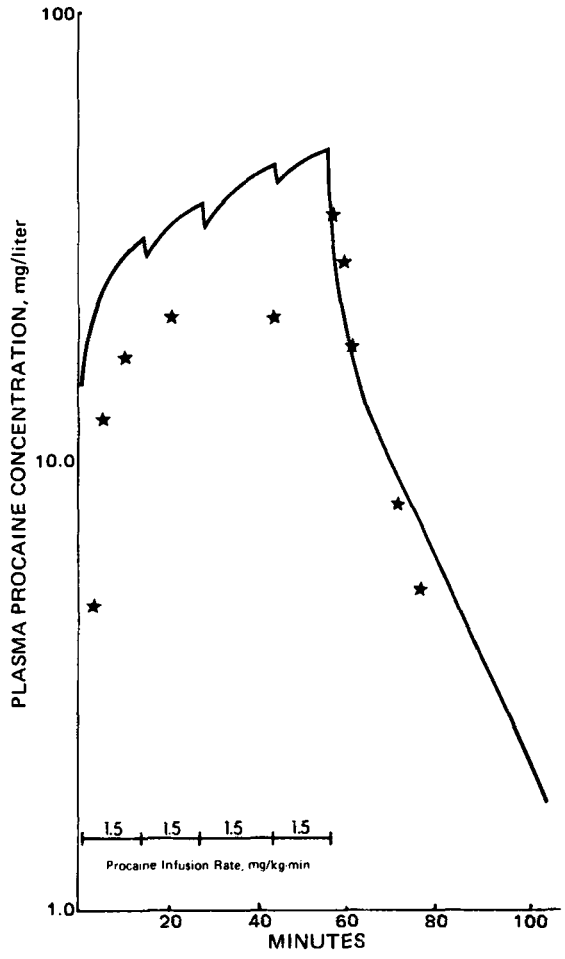

Figure 2—*Model predictions of plasma procaine concentrations* versus *experimental results for a female (age 34, weight 58.7 kg, height 177.8 cm, and hematocrit 35.0) with infusion rates and duration as shown.*

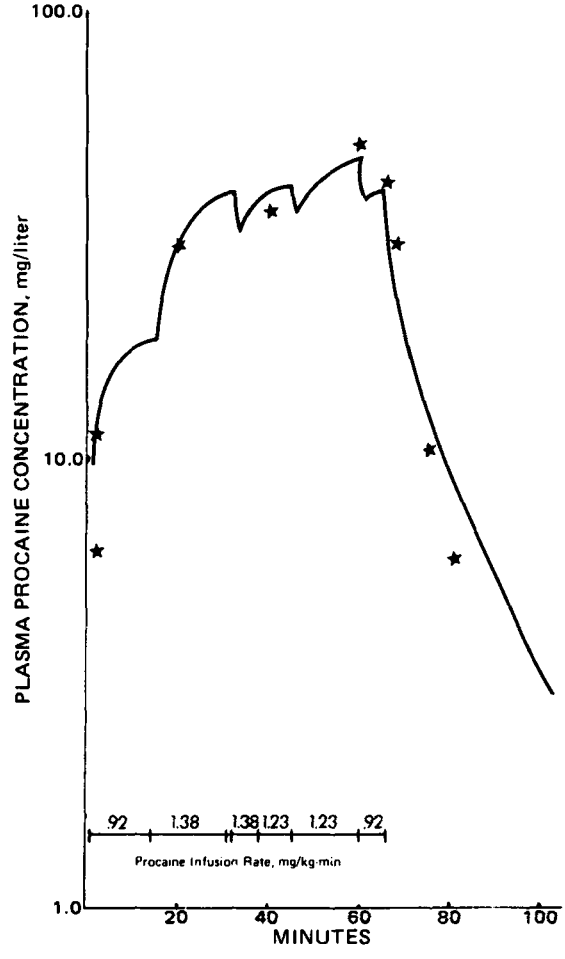

Figure 3—*Model predictions of plasma procaine concentrations* versus *experimental results for a female (age 24, weight 65 kg, height 165 cm, and hematocrit 36.8) with infusion rates and duration as shown.*

function of age, sex, height, and weight. This value was estimated by calculating the body surface area as:

$$S = 0.007184\ (Wt^{0.425})(Ht^{0.725}) \qquad \text{(Eq. 26)}$$

where Wt is weight (kilograms) and Ht is height (centimeters). Then, based on the tables relating age, surface area, and basal energy metabolism (22), for males 18–25 years:

$$BEM = [40.5 - (age - 18) \times 0.3](S)/60 \qquad \text{(Eq. 27}a\text{)}$$

for males over 25 years:

$$BEM = [38.4 - (age - 25) \times 0.11](S)/60 \qquad \text{(Eq. 27}b\text{)}$$

for females 20–40 years:

$$BEM = [35.3 - (age - 20) \times 0.05](S)/60 \qquad \text{(Eq. 27}c\text{)}$$

and for females over 40 years:

$$BEM = [34.3 - (age - 40) \times 0.10](S)/60 \qquad \text{(Eq. 27}d\text{)}$$

The fraction fat can be estimated from the tables (22) by:

$$FRFAT = 1.04 + 0.4\ (Wt - 50)/30 - BEM \qquad \text{(Eq. 28)}$$

Since the standard 70-kg man is considered to contain approximately 17.4% fat, the anatomical scaling was based on the body weight minus the fat contents by:

$$ANA = Wt(1 - FRFAT)/57.8 \qquad \text{(Eq. 29)}$$

where ANA is the scale factor.

RESULTS AND DISCUSSION

Analytical solution of the simultaneous differential equations was not feasible because of the nonlinearities caused by the binding terms. Therefore, the equations were solved by the fourth-order Runge–Kutta numerical method. The model stability was tested by comparing the numerical results from the standard values in Tables I and II with those from variations of the standard value for each of the following parameters:

1. ±10% variation of the volume of any body region
2. ±10% variation of the volume and the blood flow rate of any body region
3. ±10% variation of the water volume fraction of any body region
4. ±10% variation of the lipid solubility constant, BAT
5. ±10% of the binding constant, B
6. ±10% of the metabolism constants, VSD and C_{half}
7. ±10% variation of the effective binding macromolecule concentration of any body region

Figures 2 and 3 compare the model simulation with experimental values for two cases with a wide variation of physiological parameters as well as different infusion rates. The model was designed to account for both variations in the infusion rate and interruptions in the infusion continuity. This flexibility permitted a close simulation of the actual clinical application of the procaine infusion. As shown in the figures, due to rapid procaine hydrolysis in the blood, the rapid decline in concentration resulting from very short interruptions in the infusion can be very pronounced and will result in a substantial error in the simulated prediction of the concentration if it is not accounted for in the model design.

Figure 2 shows the experimental kinetic data of plasma procaine levels (symbol) and the model-predicted kinetics (solid line) for a 1.5-mg/kg/min intravenous infusion in a female. The results are in agreement within the range of measurement accuracy of the experimental data. Similar results are shown in Fig. 3 for a varied infusion rate in a female.

Figure 4 demonstrates the predicted procaine concentrations in the

various body regions for an infusion rate of 1.05 mg/kg/min. Since it was not possible to analyze samples from body regions other than the blood compartments, the basic model was further tested using literature data for lidocaine infusions (1, 20). With the appropriate lidocaine parameters (Table II), several simulations were made (one is shown in Fig. 5). The results of the simulation kinetics and the experimental kinetics are very similar and thus indicate the accuracy of the basic model.

CONCLUSIONS

Knowledge of the kinetic behavior of a drug in blood or plasma may not provide sufficient information for appropriate therapy; additional kinetic information of drug levels in specific organs, tissues, or body regions may be required for the development of improved dosage regimens. The pharmacokinetic model presented can predict detailed distribution in humans of intravenous infusion of local anesthetics, procaine and lidocaine, not only in blood or plasma but also in brain, liver, and other tissues or body regions.

Based on a general perfusion model, this model relates individual characteristics such as sex, age, weight, height, infusion rate, and hematocrit to general parameters such as metabolism, protein binding, ion-trapping effects, and tissue–plasma distribution coefficients to provide an individualized distribution prediction. Since each equation (compartment) in the system contains terms (concentrations) from other compartments and, therefore, all equations are interdependent, changes in any compartment influence the other compartments. This feature of the model has an important application in clinical pharmacokinetics.

Experimentally observed kinetics of blood procaine levels collected during procaine intravenous infusion as an adjunct to surgical anesthesia and blood levels of lidocaine obtained from the literature compared very well with the model simulation. While it was not possible in this study to collect experimental data in any organs or tissues other than the blood to support the predicted drug level, information from the literature derived from animal studies of tissue levels tends to verify the accuracy of the model. Until appropriate data for procaine concentrations are available for comparison with the predicted values, the predictions must be considered only to offer an approximation of what the physiological and pharmacological parameters indicate should occur. However, one application of this model is the comparison of drug levels obtained within a body region as a result of different infusion conditions such as rate changes, addition of thiamylal or succinylcholine, and variations in metabolism without the potential drastic effects an individual might experience under the same conditions. As more conditions are tested, the successful predictions should clarify the pharmacokinetics being described.

Myoinositol Uptake by Rat Hepatocytes *In Vitro*

CHI-PO CHEN ˣ and VAN T. VU

Received November 27, 1978, from the *Section of Pharmacology and Toxicology, School of Pharmacy, University of Connecticut, Storrs, CT 06268.* Accepted for publication February 12, 1979.

Abstract □ Myoinositol uptake by rat hepatocytes *in vitro* was studied. Adult rat hepatocytes were prepared by digestion of the perfused liver with collagenase. Cell suspensions were incubated with tritium-labeled myoinositol in pH 7.4 Krebs bicarbonate solution containing 1% gelatin at 37°. ^{14}C-Carbon-labeled polyethylene glycol was used as a marker of adherent extracellular fluid volume. Myoinositol uptake was demonstrable after 5 min of incubation, but no intracellular concentration in excess of that in the incubation medium was observed after 60 min of incubation. Uptake saturation over a wide myoinositol concentration range could not be demonstrated. Neither the omission of sodium ions nor the inclusion of ouabain suppressed the distribution ratio significantly. Metabolic inhibitors and lower temperatures also showed no effect. Hexoses, phlorizin or mannitol, exerted no observable effect on myoinositol uptake. The results indicated that myoinositol uptake by rat hepatocytes is probably a passive process.

Keyphrases □ Myoinositol—uptake by hepatocytes, *in vitro*, rats, pharmacokinetics □ Hepatocytes—myoinositol uptake, pharmacokinetics, *in vitro*, rats □ Liver—myoinositol uptake, *in vitro*, pharmacokinetics, rats

The liver plays a predominant role in lipid metabolism. Under normal conditions, the influx of nonesterified fatty acids into the liver from the serum is counterbalanced by the formation of lipoprotein, which is transported back to the blood. The whole process requires myoinositol. In myoinositol-deficient animals, fatty livers often can be observed since the rate of fatty acid transport to the liver from the adipose tissue exceeds the capacity of the liver to mobilize the lipid and to transport it back to the plasma (1, 2). The administration of myoinositol to myoinositol-deficient animals often can alleviate the fatty liver condition.

BACKGROUND

Myoinositol has long been considered to be a lipotropic agent because of its ability to prevent and remove fat deposits in the liver (3, 4). This lipotropic action is thought to be due to stimulation of hepatic transferable phosphatidylinositol synthesis. Once formed, the phosphorylated myoinositol can be utilized in β-lipoprotein production in the endoplasmic reticulum. The newly synthesized β-lipoprotein is transported from the liver to the blood (4). In addition, exogenous myoinositol inhibits any further deposition of either liver triglycerols or cholesterol and causes the removal of the lipids deposited during the myoinositol-deficiency period (5–7).

Although there is much evidence that myoinositol is transported into the small intestine (8), kidney (9–12), central nervous system (13–16), and crystalline lens (17–19) *via* a specific carrier-mediated system, hepatic uptake of myoinositol has not been studied in spite of its well-known lipotropic activity. Hauser (11) reported that the radioactive myoinositol distribution ratio in liver slices is less than one-half of the radioactivity in the incubation medium, while the hepatic myoinositol concentration *in vivo* is similar to that of plasma; higher hepatic than blood myoinositol concentrations also were observed (20, 21).

In recent years, the use of isolated hepatocytes for various biochemical and pharmacological studies has gained wide acceptance (22). Studies with isolated liver cells can clarify certain molecular aspects of the transport system, such as binding and metabolism, while cellular integrity is maintained.

The purpose of this study was to investigate hepatic myoinositol uptake using liver cells freshly isolated from normal adult rats.

EXPERIMENTAL

Male rats[1], 200–300 g, were housed in groups in wire-bottomed cages in an air-conditioned room (23°). They received regular laboratory chow and water without restriction.

The methods of liver perfusion and cell isolation were described previously (23, 24). Cell viability was determined by the exclusion of 0.2% trypan blue from the cells and was frequently checked by incubating the cells with α-aminoisobutyric acid, which is actively accumulated by the hepatocytes (23). Cell pellets, following the final wash of the isolation procedure, were resuspended in 10 volumes of pH 7.4 Krebs–Ringer bicarbonate buffer containing 1% gelatin.

Uptake studies were performed by placing 5 ml of the final cell suspension (50–80 mg wet weight/ml of suspension) into 25-ml plastic erlenmeyer flasks. Under control conditions, the cell suspensions contained a trace amount of [2-^{3}H(N)]-myoinositol[2] (3 μCi/nmole/100 ml of suspension) with or without 0.1 μmole of nonlabeled myoinositol/ml. In

Table I—Time Course of Myoinositol Uptake as the Distribution Ratio between Intracellular Fluid and Medium [a]

Minutes	Nonlabeled Myoinositol (*M*)	
	0	1×10^{-4}
5	0.66 ± 0.04	0.92 ± 0.08
15	0.83 ± 0.09	0.89 ± 0.11
30	0.90 ± 0.09	0.96 ± 0.18
45	1.24 ± 0.20	—
60	1.10 ± 0.16	1.06 ± 0.04
90	1.14 ± 0.20	0.91 ± 0.14

[a] Hepatocytes were incubated at 37°. Incubations were terminated at different times. Values are means ± *SD* ($n = 4$).

experiments with a sodium-free medium, tromethamine buffer[3] was used and sodium chloride was replaced by tromethamine chloride (23, 24). The flasks were shaken in a metabolic shaker at 37° under an atmosphere of 95% O_2–5% CO_2 for various times.

At the end of the incubation period, 1 ml of the cell suspension was removed, placed into a preweighed microcentrifuge tube[4], and centrifuged for 30 sec in a microcentrifuge[5]. The supernate was removed, and the tube was weighed. The cell pellets were resuspended in 150 μl of distilled water, transferred into an 8-ml counting vial, and digested at room temperature with 0.5 ml of tissue solubilizer[6] for 16–24 hr or until a clear solution was obtained. Absolute methanol, 250 μl, was added with mixing, and then 5 ml of scintillation cocktail[7] was added.

An aliquot of the supernate was placed into an 8-ml scintillation vial containing 6 ml of scintillation fluid[8]. The extracellular aqueous volume was determined by incubating hepatocytes in the presence of ^{14}C-polyethylene glycol[2] for varying times. The ^{14}C- and ^{3}H-radioactivity was measured in a liquid scintillation counter[9] using methods for double-isotope counting that correct for quenching and ^{14}C-activity appearing in the ^{3}H-channel. Results were corrected on this basis to account for extracellular myoinositol trapping. The distribution ratio (I/M) is referred to as the ratio of intracellular to medium (or extracellular) concentrations.

The extent of macromolecular myoinositol binding was estimated by the following procedures. At the end of 5 and 60 min of incubation, 10 ml of cell suspension was centrifuged at 1000 rpm[10] for 1 min; the supernate was removed by pipet. The cell pellets were washed with 10 volumes of ice-cold Krebs bicarbonate buffer, resuspended in an equal volume of 0.05 *M* phosphate buffer (pH 7.2), and sonicated. Then 0.5 ml of the cell extract was placed on a 0.9 × 8-cm column[11], equilibrated with 0.05 *M* phosphate buffer (pH 7.2), and eluted with the same buffer. One-half-milliliter fractions were collected and counted in 6 ml of scintillation fluid.

Formation of myoinositol metabolites during the transport process was tested by TLC using an acetone–water (9:1) solvent system (25). The sonicated solution was deproteinized with five volumes of absolute

Table II—Effect of Inhibitors Added *In Vitro* on Myoinositol Uptake [a]

Inhibitor	Concentration, *M*	Percent of Control
None	—	100.0 ± 6.1 [b]
Sodium free	—	98.0 ± 12.2
Ouabain	1×10^{-4}	103.3 ± 2.1
2,4-Dinitrophenol	1×10^{-4}	107.7 ± 25.5
Potassium cyanide	1×10^{-3}	95.1 ± 6.1
	5×10^{-3}	100.0 ± 6.1
N-Ethylmaleimide	1×10^{-4}	93.9 ± 2.4

[a] Hepatocytes were incubated at 37° for 30 min in the presence of various inhibitors or the omission of sodium. [b] Each value is expressed as the mean ± *SD* from three to four determinations. All values were not significantly different from the control ($p > 0.05$).

methanol. The methanol solution was concentrated under an air stream and placed on the instant thin-layer plate[12] (5 × 20 cm). After development, the nonsprayed chromatogram was cut into strips (1 cm wide), and the radioactivity of each strip was measured by counting it with 6 ml of scintillation fluid. Authentic myoinositol was cochromatographed with all samples tested.

RESULTS

When isolated liver cells were incubated under normal conditions with radioactive myoinositol, the initial uptake rate was rapid. Uptake was demonstrable after 5 min of incubation; however, the entry rate decreased over time (Table I). Equilibrium was reached after 30 min of incubation, and further incubation did not increase the intracellular myoinositol concentration. When 0.1 m*M* of nonlabeled myoinositol was added to the incubation medium, the initial entry rate increased significantly while the distribution ratio remained unchanged after prolonged incubation.

The concentration dependence of myoinositol uptake also was investigated. There was no evidence of uptake saturation over a wide myoinositol concentration range (0.1–4.8 m*M*) (Fig. 1).

To test whether hepatic myoinositol uptake is energy dependent, isolated hypatocytes were incubated in the presence of various metabolic inhibitors. Myoinositol uptake was not altered significantly by such inhibitors (Table II).

The specificity of myoinositol uptake by isolated liver cells also was examined. The addition of glucose or galactose (5 m*M*) did not appreciably affect the distribution ratio (Table III). Similarly, phlorizin (0.1 m*M*) or mannitol (5 m*M*) produced no measurable effect on myoinositol uptake.

The extent of myoinositol and tissue binding is depicted in Fig. 2.

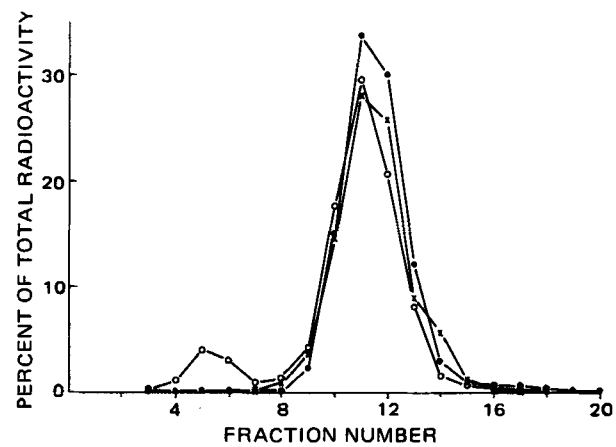

Figure 2—*Chromatographic identification of free and bound myoinositol. Radioactivity found in the aqueous hepatocyte extract after 5 and 60 min of incubation with labeled myoinositol was chromatographed on 0.9 × 8-cm Bio-Gel P-2 columns equilibrated with 0.05* M *phosphate buffer (pH 7.2) and eluted with the same solvent. Table III—Effects of Sugars and Analogs on the Myoinositol Uptake [a]

Addition	Concentration, M	I/M [b]	Percent of Control
None	—	0.91 ± 0.04	100.0 ± 4.4
Glucose	5×10^{-3}	0.95 ± 0.22	104.4 ± 24.2
Galactose	5×10^{-3}	0.79 ± 0.19	86.8 ± 20.9
Mannitol	5×10^{-3}	0.91 ± 0.07	100.0 ± 7.7
Phlorizin	1×10^{-4}	0.81 ± 0.17	89.0 ± 18.7

[a] Hepatocytes were incubated with 1×10^{-4} M myoinositol at 37° for 30 min in the presence of various agents. [b] Distribution ratio between intracellular and medium concentration. Each value is the mean of four determinations with the standard deviation. All values were not significantly different from the control ($p > 0.05$).

Cellular extracts were chromatographed on small columns. Only a small portion of the transported molecules was associated with the cellular macromolecules while most myoinositol existed in a free state. Some metabolic myoinositol alterations apparently took place during the experimental period (Fig. 3).

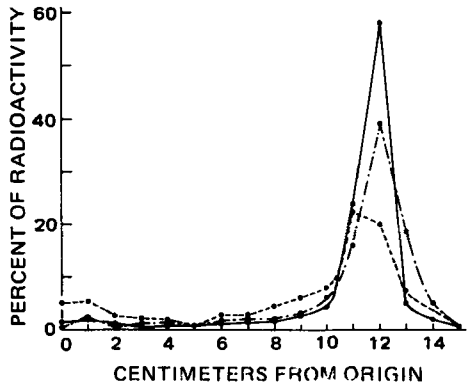

Figure 3—*Chromatographic identification of myoinositol and its metabolites. The aqueous hepatocyte extracts after 20 (●---●) and 30 (●---●) min of incubation with labeled myoinositol were chromatographed on thin-layer plates with an acetone–water (9:1) solvent system. Authentic myoinositol was cochromatographed as a control (●—●).*

DISCUSSION

Although numerous studies demonstrated that isolated rat liver cells can transport various substances into the cellular compartment by a specific carrier-mediated process (22–24), the present study indicated that myoinositol probably enters the hepatocytes by a nonenergy-requiring, noncarrier-mediated process. The nature of hepatic myoinositol uptake appeared to be different from the transport systems for myoinositol in various biological systems (8–19, 26–31).

The failure of hepatocytes to establish a concentration gradient after prolonged incubation demonstrated that hepatic myoinositol uptake is not cumulative. Although demonstrable amounts of intracellular myoinositol were observed after 5 min of incubation, the distribution ratio (I/M) rose slowly with time and reached unity after 30 min of incubation. The I/M ratio remained around one throughout the experimental period. Addition of nonlabeled myoinositol (0.1 mM) did not change the distribution ratio significantly. The absence of saturation kinetics (Fig. 2) in the present study suggested a passive diffusion process.

Myoinositol uptake also was not dependent on metabolic energy. As shown in Table II, inclusion of an uncoupling agent (2,4-dinitrophenol), a cellular respiration poison (potassium cyanide), or sulfhydryl blocking agents (iodoacetic acid and N-ethylmaleimide) in the incubation medium did not cause any significant inhibition. Likewise, ouabain, a "sodium-pump" inhibitor, also showed no effect. Replacement of sodium ions also did not inhibit cellular myoinositol uptake.

The competitive inhibition of hexoses and phlorizin on the transport of myoinositol has been reported in various biological systems (8, 10, 13, 16, 18). The present experiment (Table III), which demonstrated that hepatic myoinositol uptake was not inhibited by monosaccharides or a sugar-carrier inhibitor (phlorizin), also strongly suggests that hepatic myoinositol uptake is not a carrier-mediated process.

Although myoinositol plays an important role in lipoprotein formation in experimental animals (5–7), the present study could not demonstrate significant myoinositol binding to hepatocyte macromolecules, nor was myoinositol metabolized significantly during the experimental periods. There are similar findings in the choroid plexus (13, 16) and the crystalline lens (17).

The results obtained with ouabain, sodium-free medium, metabolic inhibitors, and a lack of saturation all lead to the suggestion that myoinositol uptake into the hepatic parenchymal cells is probably by a passive mechanism.

Binding of Mono- and Bis-*N*-substituted Benzoquinolinium Halides to Butyrylcholinesterase: Fluorescence Measurements

WEN-SHERNG CHEN, GEORGE H. COCOLAS ˣ, and CHESTER J. CAVALLITO

Received October 23, 1978, from the *Division of Medicinal Chemistry, School of Pharmacy, University of North Carolina at Chapel Hill, Chapel Hill, NC 27514.* Accepted for publication February 13, 1979.

Abstract □ The dissociation constants (K_{diss}) of mono- and bis-*N*-substituted benzoquinolinium salts from butyrylcholinesterase were determined by the disappearance of the fluorescence of the free ligand. The K_{diss} value determined by this method agreed closely with the dissociation constants ($K_{I,s}$) of the free enzyme obtained by steady-state kinetic studies. The results indicate that the *N*-substituted benzoquinolinium salts with a strong binding ability to butyrylcholinesterase also are potent inhibitors of the esterolytic properties of the enzyme. Enzyme binding is favored by the coplanar structure and does not require a high concentration of charge on the onium function. The shape of the hydrophobic structures markedly influences binding.

Keyphrases □ Benzoquinolinium halides—binding to butyrylcholinesterase, spectrophotofluorometric analysis □ Spectrophotofluorometry—analysis, benzoquinolinium halides, binding to butyrylcholinesterase □ Butyrylcholinesterase—binding to benzoquinolinium halides, spectrophotofluorometric analysis

A series of mono- and bisquaternary ammonium compounds was reported (1) to be reversible inhibitors of butyrylcholinesterase. The most potent inhibitors were characterized by a large nitrogen-containing conjugated heterocycle such as phenanthridine or acridine. Lineweaver–Burk plots of the enzymatic hydrolysis data showed mixed competitive–noncompetitive inhibition kinetics. Since many potential binding sites are present on the enzyme (2), these mono- and bisquaternary onium compounds were studied to determine if their anticholinesterase activity was produced by binding to sites that affect the esterolytic properties of the enzyme.

EXPERIMENTAL

Horse serum butyrylcholinesterase[1] was purified by gel filtration, using a Sephadex G-200 column (2 × 90 cm) developed with pH 7.5 25 m*M* sodium phosphate, and by ion-exchange chromatography, using a diethylaminoethyl cellulose column (2 × 85 cm) developed with a 1-liter linear gradient of 1.0 *M* NaCl in pH 7.5 25 m*M* sodium phosphate. Protein concentrations (milligrams per milliliter) were determined by the method of Lowry *et al.* (3). Enzyme activities were measured by the continuous automatic titration method, using a pH stat (1). The butyrylcholinesterase solution normality was determined by a titration method using echothiophate iodide (4).

Inhibitors were prepared as described previously (1). The inhibitors, butyrylcholinesterase, and bovine serum albumin were dissolved in 10 m*M* sodium phosphate buffer containing 100 m*M* NaCl and 20 m*M* $MgCl_2$. The enzyme solution was diluted to give concentrations of 50 μN–5.5 n*N*. For the fluorescence measurements, each solution was mixed with an equal volume of inhibitor solution whose concentration was near its $K_{I,s}$ value. UV absorption spectra of the inhibitor solutions (5 μM) in the presence of varying amounts of butyrylcholinesterase or bovine serum albumin were measured on a double-beam spectrophotometer[2].

Disappearance of the fluorescence of the inhibitors in the presence of butyrylcholinesterase or bovine serum albumin was measured on a spectrophotofluorometer[3] equipped with a 150-w xenon lamp and a 1P 21 photomultiplier tube. Excitation at 360 nm caused fluorescence maxima of *N*-substituted acridinium halides at 490 nm, of phenanthridinium halides at 420 nm, of 5,6-benzoquinolinium halides at 440 nm, and of 7,8-benzoquinolinium halides at 460 nm. Fluorescence intensity measurements were made at 25° and were reproducible within 0.5%.

The disappearance of the fluorescence spectra of benzoquinolinium salts in the presence of butyrylcholinesterase was used to determine the dissociation constants (K_{diss}) of the enzyme–benzoquinolinium salt complex. The binding to butyrylcholinesterase or bovine serum albumin can be expressed according to Scatchard *et al.* (5) by:

$$\frac{R}{[I]} = \frac{n}{K_{diss}} - \frac{R}{K_{diss}} \qquad \text{(Eq. 1)}$$

where R is the number of inhibitor molecules bound per subunit (equivalent to 1 mole of echothiophate iodide) of butyrylcholinesterase or per molecule of bovine serum albumin at a free inhibitor concentration, $[I]$, and n is the number of binding sites on a butyrylcholinesterase subunit or a bovine serum albumin molecule. Both R and $[I]$ were determined by utilizing the disappearance of inhibitor fluorescence intensities while being bound by butyrylcholinesterase (6, 7).

The relative intensities, F, of the fluorescence inhibitor were determined for a series of enzyme and inhibitor mixtures of different compositions containing a constant total inhibitor concentration. The expressions for the relative fluorescence intensities in the absence and in an excess of butyrylcholinesterase are $F_0 = r[I]_t$ and $F_e = r'[I]_t$, respectively; $[I]_t$ is the total inhibitor concentration, r is the intensity coefficient of the free inhibitor, and r' is the intensity coefficient of the bound inhibitor (EI) whose concentration is equal to the total free inhibitor concentration when an excess of enzyme is added. It is assumed that all inhibitor molecules are bound in the presence of excess enzyme.

The relative fluorescence intensity of butyrylcholinesterase is much less than that of the inhibitor itself and can be neglected while making enzyme blank measurements. Thus, relative fluorescence at varying butyrylcholinesterase concentrations is expressed by $F = r[I] + r'[EI]$. The fraction of total inhibitor bound, α, is expressed by:

$$\alpha = \frac{F_0 - F}{F_0 - F_e} = \frac{r[I]_t - r[I] - r'[EI]}{r[I]_t - r'[I]_t} = \frac{[EI]}{[I]_t} \qquad \text{(Eq. 2)}$$

The free inhibitor concentration is expressed by:

$$[I] = [I]_t(1 - \alpha) \qquad \text{(Eq. 3)}$$

and if $[E]_t$ is the amount of butyrylcholinesterase used, then:

$$R = \frac{[EI]}{[E]_t} = \frac{\alpha[I]_t}{[E]_t} \qquad \text{(Eq. 4)}$$

Data for the disappearance of the fluorescence of hexamethylene-1,6-bisacridinium diiodide (I) in the presence of butyrylcholinesterase are shown in Table I. The K_{diss} value is the reciprocal value of the Scatchard

Table II—Binding of Some Quaternary Ammonium Salts to Butyrylcholinesterase

	Compound	Butyrylcholinesterase K_{diss}, μM	Butyrylcholinesterase $K_{I,s}$, μM[a]
I[b]		0.0083 ± 0.0002[c]	0.0073 ± 0.0002
II		2.01 ± 0.06[d]	1.5 ± 0.2
III		210 ± 40[d]	120 ± 10
IV[b]		0.14 ± 0.04[c]	0.24 ± 0.03
V		21 ± 3[c]	32 ± 1
VI		6.7 ± 0.5[c]	5.4 ± 0.2
VII		1.2 ± 0.5[c]	1.10 ± 0.02

[a] Determined by steady-state enzyme kinetic studies (1). [b] The K_{diss} values of I and IV *versus* bovine serum albumin, determined by the disappearance of the free ligand fluorescence, were 15 ± 4 and 87 ± 5 μM, respectively. [c] Determined by the disappearance of the free ligand fluorescence. [d] Determined by a fluorescence probe technique (8).

plot slope of $R/[I]$ *versus* R (Fig. 1) and was calculated by fitting the values of $R/[I]$ and R to the least-squares computer program.

The same procedure was used for measuring the binding of the nonfluorescent inhibitor, hexamethylene-1,6-bis-*p*-phenylbenzyl ammonium dibromide (II), with butyrylcholinesterase by the addition of a fluorescent probe (A) such as I (1). The dissociation constant (K_B) of the nonfluorescent inhibitor (B) which competes with A for sites on the enzyme can be determined according to a literature method (8) and expressed by:

$$K_B = (K_A)\left(\frac{\alpha}{1-\alpha}\right)\left(\frac{[B]_t - S}{S}\right) \qquad \text{(Eq. 5)}$$

where K_A is the dissociation constant of the fluorescent probe, $[B]_t$ is the total concentration of the nonfluorescent inhibitor, and S is the bound nonfluorescent inhibitor in moles per liter. The value of S can be calculated by:

$$S = n[E]_t - \alpha[A]_t - \frac{\alpha K_A}{1-\alpha} \qquad \text{(Eq. 6)}$$

where $[A]_t$ is the total fluorescent probe concentration. A Scatchard plot for the probe–enzyme complex in the presence of a nonfluorescent inhibitor is shown in Fig. 2.

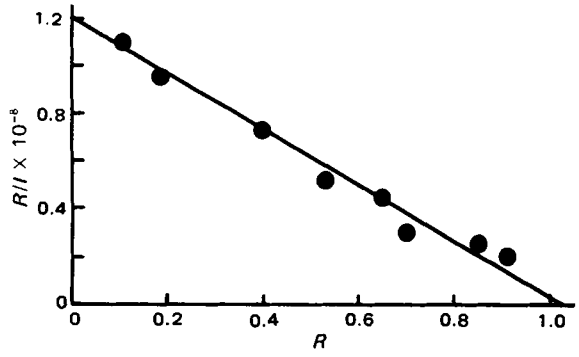

Figure 1—*Scatchard plot for I (50 nM) binding to various concentrations (5.5 nN–1.1 μN) of butyrylcholinesterase by spectrofluorometry.*

RESULTS AND DISCUSSION

The addition of butyrylcholinesterase to aqueous solutions of mono- and bisquaternary ammonium salts that are potent reversible enzyme inhibitors caused a hypochromic shift in their UV spectrum. The UV absorbance of a 5 μM solution of I was altered from maxima at 251 and 258 nm to a single maximum at 253 nm with a decrease of the extinction coefficient as the butyrylcholinesterase concentration was increased from 2.2 to 18 μN (Fig. 3). Similar mixtures of I solutions and bovine serum albumin in concentrations from 0.29 to 72 μM did not cause any significant change in the UV absorption spectrum of I. The acridinium compound spectral changes, which occurred following enzyme addition but not following addition of the same or even higher bovine serum albumin concentrations, suggest a specific and extensive binding by the inhibitor to butyrylcholinesterase.

Dissociation constants (K_{diss}) of mono- and bisonium salts complexed with butyrylcholinesterase were measured by disappearance of the heterocyclic moiety fluorescence spectra in the presence of butyrylcholinesterase (Table II). The K_{diss} of I from butyrylcholinesterase was 8.3 ± 0.2 nM and compared favorably with the inhibition constant ($K_{I,s}$ = 7.3 ± 0.2 nM) determined by the kinetics of the hydrolysis rate inhibition under Michaelis–Menten conditions (1). The dissociation constant of I from bovine serum albumin determined by free ligand fluorescence disappearance showed less affinity by at least 10^3.

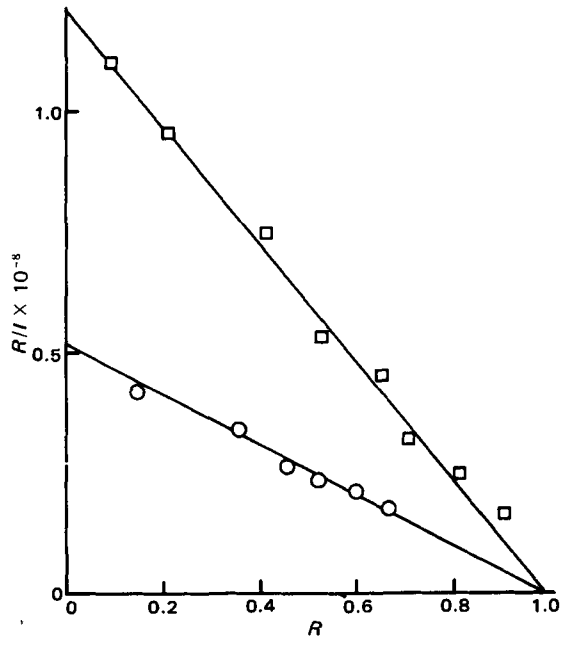

Figure 2—*Scatchard plots for the probe-enzyme complex of I (50 nM) and varying concentrations (5.5 nN–1.1 μN) of butyrylcholinesterase in the absence (□) and presence (○) of hexamethylene-1,6-bisbiphenyl ammonium dibromide (1.0 μM).*

N-Methylacridinium (IV) had a smaller binding affinity than I for butyrylcholinesterase when calculated from fluorescence measurements ($K_{diss} = 0.14 \pm 0.04\ \mu M$) or enzyme kinetic data ($K_{I,s} = 0.24 \pm 0.03\ \mu M$). Binding of IV to bovine serum albumin was also weaker than that of I. The additional acridinium moiety in I undoubtedly contributes to the stronger binding properties on both butyrylcholinesterase and bovine serum albumin. Since butyrylcholinesterase has a single anionic site at the active center (9–12), the enhancement of the binding force of the bis compound to both butyrylcholinesterase and bovine serum albumin could result from the hydrophobic binding of the additional onium moiety to the hydrophobic area adjacent to the anionic site of the enzyme.

The other *N*-methyl benzoquinolinium salts, 7,8-benzoquinolinium (V), 5,6-benzoquinolinium (VI), and 3,4-benzoquinolinium (VII), gave K_{diss} values that were comparable to the $K_{I,s}$ values obtained from enzyme kinetic data. A parallel can be seen between the data from the dissociation constants as determined by fluorescence measurements and by enzyme kinetics. All compounds appeared to bind in a similar manner to the enzyme with binding energies depending on their lipophilic and steric properties. The Scatchard plots showed that both mono- and bis-*N*-substituted benzoquinolinium compounds bound stoichiometrically to the enzyme (*i.e.*, one molecule of inhibitor bound per subunit of enzyme). The esterolytic function was affected proportionately to the intensity of inhibitor binding.

Among these compounds, the onium group probably serves primarily as a carrier to deliver the hydrophobic structure to the active site. The positive charge in these heterocyclic structures may be delocalized by either internal resonance or pseudobase formation (1). Together with the hydrophobic nature of the hydrocarbon mass and the lack of hydrogen bonding substituents, these compounds would be unfavorable to solvation but would probably influence the structure of neighboring water, either in bulk solution or as the inhibitor–enzyme complex.

The effects of hydrocarbon-substituted ammonium salts on water structure were reported to vary with the hydrophobic mass of the substituents, the concentration, and the temperature (13–16). It would be

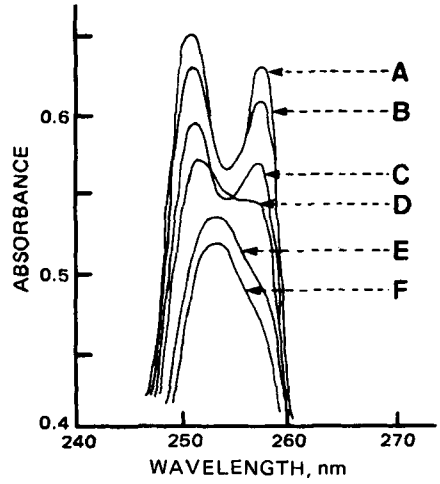

Figure 3—*Hypochromic effect of the UV spectra of I (5.0 μM) in the presence of different butyrylcholinesterase concentrations: A, 0; B, 2.3 μN; C, 4.6 μN; D, 9.2 μN; E, 14 μN; and F, 18 μN.*

of interest to determine the effect of structure of these isomeric monoquaternaries on the structure of the surrounding water. The hydrophobic mass structure may contribute to potency by influencing the difficulty with which other molecules and ions in solution can displace the inhibitor from the inhibitor–enzyme complex.

Osmolality of Parenteral Solutions

H. E. HUBER ˣ, WILLIAM H. STRENG, and HETTY G. H. TAN

Received June 19, 1978, from *Merrell-National Laboratories, Division of Richardson-Merrell Inc., Cincinnati, OH 45215.* Accepted for publication February 14, 1979.

Abstract □ Osmolality–concentration profiles for individual and mixed solute systems are presented. Linear relationships between osmolality and concentration held true in all systems examined at concentrations below 0.2 molal levels. At higher concentrations, linearity existed only in select systems. Deviations from linearity can be greater or less than extrapolated values. In view of the need to determine an osmolarity conversion factor for each parenteral formulation and the many errors possible in the use of these values, adoption of osmolality values for labeling parenteral products rather than osmolarity, as stipulated in USP XIX–NF XIV third supplement, is strongly recommended.

Keyphrases □ Osmolality—parenteral solutions, compared to osmolarity, calculations □ Osmolarity—parenteral solutions, compared to osmolality, calculations □ Parenteral solutions—osmolality and osmolarity compared, calculations

Use of the terms osmolality and osmolarity was once confined largely to clinical laboratories and hospital pharmacies; however, the terms are now being applied to parenteral solutions. The third supplement of USP XIX–NF XIV (1) requires that pharmacopeial solutions providing intravenous replenishment of fluid, nutrients, or electrolytes, as well as the osmotic diuretic mannitol injection, state the osmolar concentration.

These terms are not familiar to many; and with the compendial requirements for labeling, it seems appropriate to discuss them at length. The purposes of this manuscript are to review the important theoretical considerations of osmolality and osmolarity and to present a few experimentally obtained osmolality–concentration profiles to illustrate the interrelation of some representative solutes utilized in parenteral formulas. This information serves as a basis for a recommendation on parenteral labeling.

BACKGROUND

Labeling—In 1975, USP XIX required sodium chloride injection labeling to state the total osmolarity of the solution, expressed in milliosmoles per liter. Since label components of a quantitative nature usually require some analytical method to demonstrate the label claim within limits, it was considered reasonable to determine what production experience would show in lot-to-lot variation.

As some investigators discovered, instrumentation measures the osmolality of a solution, milliosmoles per kilogram of solvent, not the osmolarity, milliosmoles per liter of solution. To be precise for labeling purposes, a search was undertaken for a mathematical expression to relate these two entities. Little was found in the literature or textbooks to equate these two terms. The problems in this area were recognized previously and reviewed at length (2). Previous investigators also attempted to equate the two expressions to resolve the problem and pointed out that solution measurements can be carried out only in terms of osmolality. In the physical chemistry discipline, osmolality is used and is well defined in terms of basic concepts. In pharmaceutical practice, a definition of osmolarity has been developed, but a derivation of the basic relationship between osmolality and osmolarity was not found.

Streng *et al.* (3) carried out this mathematical exercise and determined that osmolarity was not measurable as a defined parameter. The conversion of osmolality measurements to osmolarity requires determination of the partial molal volume of the solute(s) at infinite dilution and the density of the pure solvent. In simple one-solute aqueous systems, this determination is not difficult, and a single conversion factor can be determined for all concentrations. For more complex systems such as hyperalimentation fluids, conversion factor determination becomes more complex and questionable.

The alternative to such a dilemma would be to label the products in osmolality terms, directly measurable by instrumentation, provided the concentrations are within the 100–2000-milliosmoles/kg range usually measurable with commercially available osmometers.

Osmolarity Calculations—Pharmacists over the years have used gravimetric measurements for solids and volumetric measurements for liquids. The preparation of solutions by weighing the liquid occurs primarily in industry. This practice of bringing solutions to volume rather than using a specific solvent weight has led to the term osmolarity.

Although one cannot measure osmolarity (osmoles or milliosmoles per liter of solution), it is commonly assumed the numerical values do not differ significantly from those of osmolality (milliosmoles per kilogram of solvent) and that the two can be used interchangeably. This assumption may be reasonable in some cases. However, these terms must be fully understood so that they can be used correctly and, perhaps, interchangeably where the error is negligible or insignificant.

Calculations in the pharmaceutical literature that utilize osmolality or osmolarity values assume that the values change in direct proportion to the change in solute(s) concentration. The literature also teaches that the osmolality/osmolarity values for individual solute systems can be used

[a] Calculated from $m = 1000 \times M/C_w$. The C_w values were obtained from Ref. 6.

additively to calculate the value for a solution containing two or more solutes.

In reality, few solutions exhibit a linear relationship between osmolality and concentration except in dilute solutions, and the linear concentration range varies from one substance to another. The assumption of an additive property was tested and found to hold for all solutions tested at less than 0.2 molal concentrations. The results constitute the following experimental section.

Basic Principles—Before proceeding further, a review of basic principles should be extended to clarify the terminology. A solution can be characterized by what is referred to in physical chemistry as its colligative properties: (*a*) freezing point, (*b*) boiling point, (*c*) vapor pressure, and (*d*) osmotic pressure. All of these measurable parameters are related to the same physical property: the ratio of solute "particles" to molecules of water or mole fraction of water.

Osmolality is defined as that mass of solute which, when dissolved in 1 kg of water, will exert an osmotic pressure equal to that exerted by a gram-molecular weight of an ideal unionized substance dissolved in 1 kg of water. Osmolarity is defined as that mass of solute which, when dissolved in 1 liter of solution, will exert an osmotic pressure equal to that exerted by a gram-molecular weight of an ideal unionized substance dissolved in 1 liter of solution.

From the derivations of Streng *et al.* (3), osmolality can be described by:

$$\xi_m = \nu m \varphi \frac{\bar{v}_1^0}{\bar{v}_1} \qquad \text{(Eq. 1)}$$

where:

ξ_m = osmolality
ν = number of ions into which the solute theoretically dissociates
m = molality of the solution
φ = osmotic coefficient
$\frac{\bar{v}_1^0}{\bar{v}_1}$ = ratio of the partial molal volumes for the solvent at infinite dilution and in the solution

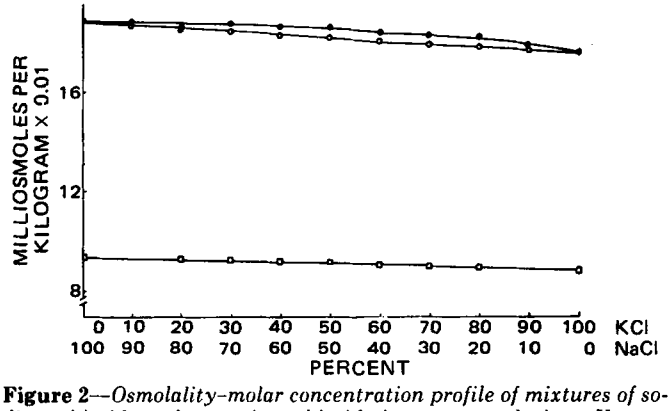

Figure 2—*Osmolality-molar concentration profile of mixtures of sodium chloride and potassium chloride in aqueous solutions. Key:* ●, *measured osmolality values for aqueous solutions containing a mixture of sodium chloride and potassium chloride totaling 1.0* M *concentrations;* O, *calculated osmolality values determined by summing values for each component at its respective concentration; and* □, *measured osmolality and calculated osmolality values for solutions containing mixtures of sodium chloride and potassium chloride at 0.5* M *total concentration.*

For the concentration ranges normally considered, the ratio $(\bar{v}_1^0/\bar{v}_1)$ has a value close to one[1].

Osmolarity is described by:

$$\xi_c = \nu m \varphi [d_1^0(1 - 0.001\bar{v}_2^0)] \qquad \text{(Eq. 2)}$$

where:

ξ_c = osmolarity
d_1^0 = density of the pure solvent
$\bar{v}_2^0$ = partial molal volume of the solute

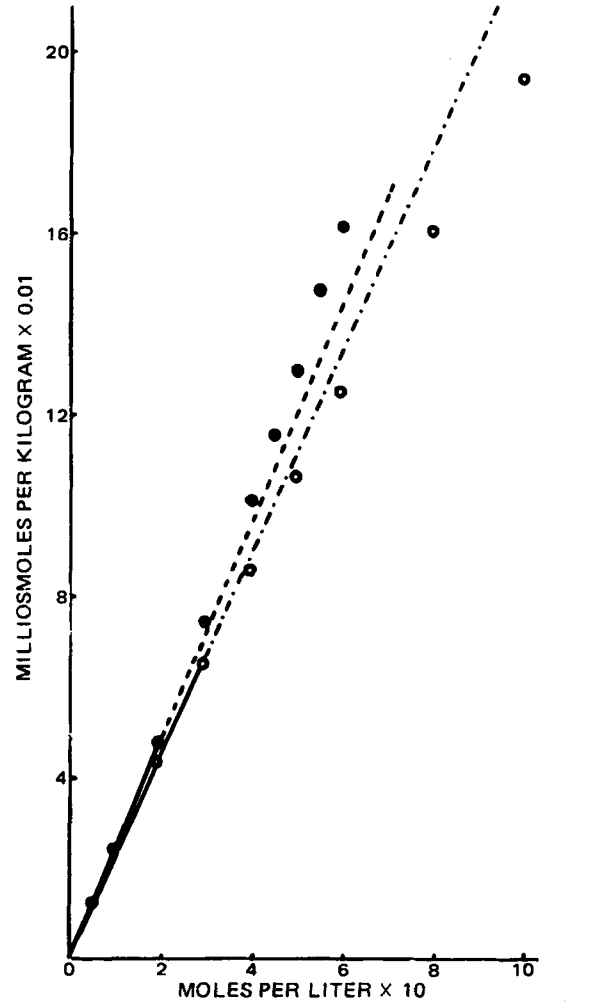

Figure 3—*Osmolality-molar concentration profile for aqueous solutions of calcium chloride* (●) *and sodium sulfate* (O).

[1] The ratio $(\bar{v}_1^0/\bar{v}_1)$ is dependent upon the solute system. There is, however, little difference in this ratio between simple salt solutions. Sodium chloride solution has a value of 1.001 for a 1 molal concentration.

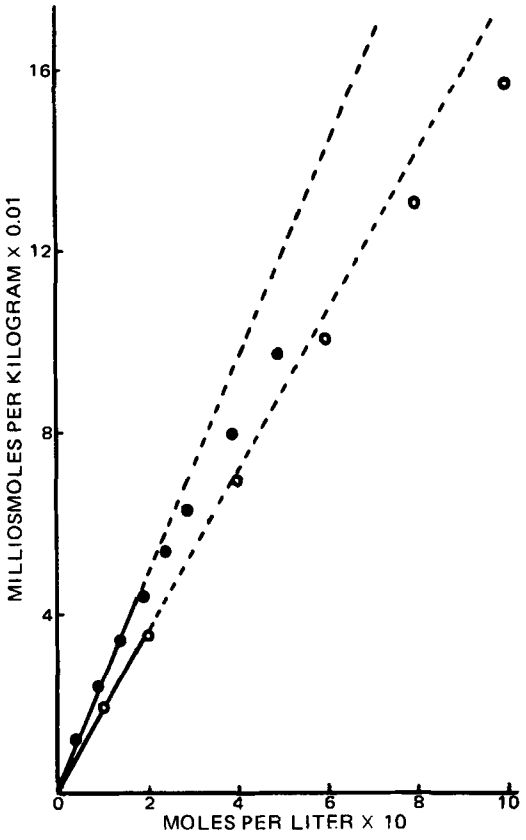

Figure 4—*Osmolality–molar concentration profile for aqueous solutions of dibasic sodium phosphate (●) and monobasic sodium phosphate (○).*

Thus, osmolarity can be calculated from osmolality measurements by:

$$\xi_c = \xi_m[d_1^0(1 - 0.001\bar{v}_2^0)] \qquad \text{(Eq. 3)}$$

The conversion factor $[d_1^0(1 - 0.001\bar{v}_2^0)]$ for sodium chloride solutions is 0.98049; for potassium chloride solutions, it is 0.97041(3).

Partial molal volumes are available in the literature for some solutes; however, for most pharmaceutical compounds, it is necessary to determine these values experimentally.

Table I shows the osmotic coefficients and osmolality values for sodium chloride and calcium chloride solutions taken from the literature (4).

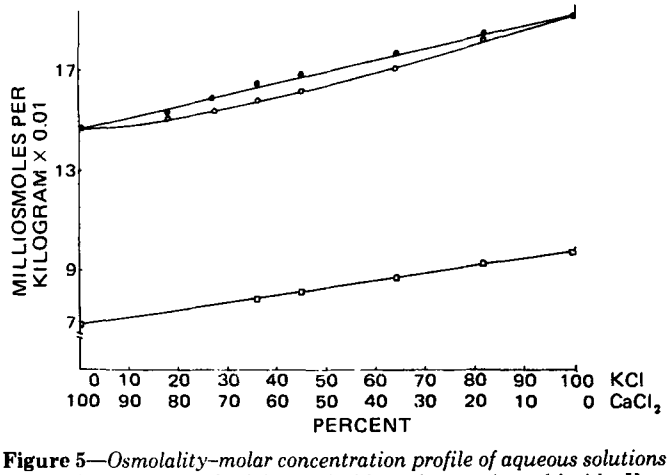

Figure 5—*Osmolality–molar concentration profile of aqueous solutions containing mixtures of calcium chloride and potassium chloride. Key: ○, measured osmolality values for mixtures of calcium chloride and potassium chloride totaling 1.1 M chloride concentration; ●, calculated osmolality values determined by summing values for each component at its respective concentration; and □, measured osmolality and calculated osmolality values for mixtures of calcium chloride and potassium chloride at 0.55 total chloride concentration.*

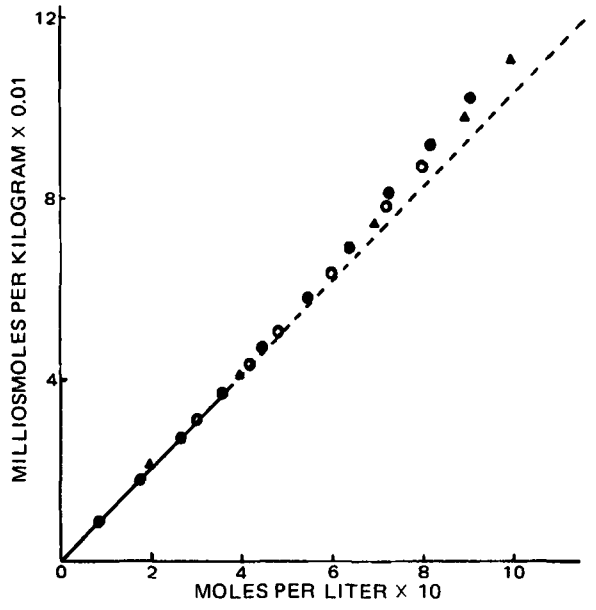

Figure 6—*Osmolality–molar concentration profiles for aqueous solutions of dextrose (●), mannitol (○), and sorbitol (△).*

Osmotic coefficients can be found in these tables for many electrolytes and for a few nonelectrolytes. However, coefficients for most pharmaceutical compounds need to be determined. Examination of Table I shows that deviation from linearity is small for sodium chloride in terms of milliosmoles per kilogram up to a 1.0 molal concentration. For calcium chloride solutions, the deviation becomes much greater. In the case of a twofold dilution of a 0.8 molal solution, the value is about 100 mOs/kg less than expected. For the same dilution with sodium chloride solution, the value is only 7 mOs/kg less than expected. A 0.9% sodium chloride solution is ~0.15 molal.

EXPERIMENTAL

Experiments were carried out to determine the extent of change in the osmolality as a function of concentration for various solutes and for mixtures of these solutes in aqueous solutions.

Solutions were prepared, in the usual manner, on a molar rather than molal basis; a concentration–osmolality profile was obtained for each solute as well as for solute combinations in aqueous solution. Any concentration representation could have been used, such as milligrams per milliliter or molality. All molar concentrations were calculated on an anhydrous basis.

A vapor pressure osmometer[2] was used to measure the osmolality (milliosmoles per kilogram) of each solution. Prior to use, the instrument was calibrated with the appropriate sodium chloride reference standard[3]. A minimum of three readings was taken for each solution, and the standard deviations fell well within the areas of the open or solid geometric forms used in the graphs.

Profiles of the experimental solutions for sodium chloride, potassium chloride, sodium acetate, calcium chloride, sodium sulfate, dibasic sodium phosphate, and monobasic sodium phosphate were checked against calculated profiles obtained by using the osmotic coefficients reported in the literature (4) for the solutes in solutions at 25° ($\xi_m = \nu m\varphi^{25}$). In all cases except calcium chloride, the experimental osmolality values did not differ significantly from the calculated values. For calcium chloride, the values were slightly less than expected, indicating that the material contained water and was not completely anhydrous. Due to the hygroscopic nature of anhydrous calcium chloride, this finding was not surprising.

Profiles for dextrose, mannitol, and sorbitol sugars were also determined. These compounds are used in parenterals and are representative of nonionizing substances. Similar profiles for some of these components were reported previously (2).

[2] Wescor, 5100.

[3] Reference standards were obtained from Wescor, Inc., and prepared by New England Reagent Laboratories (Rhode Island) on a molal basis according to Fiske (5).

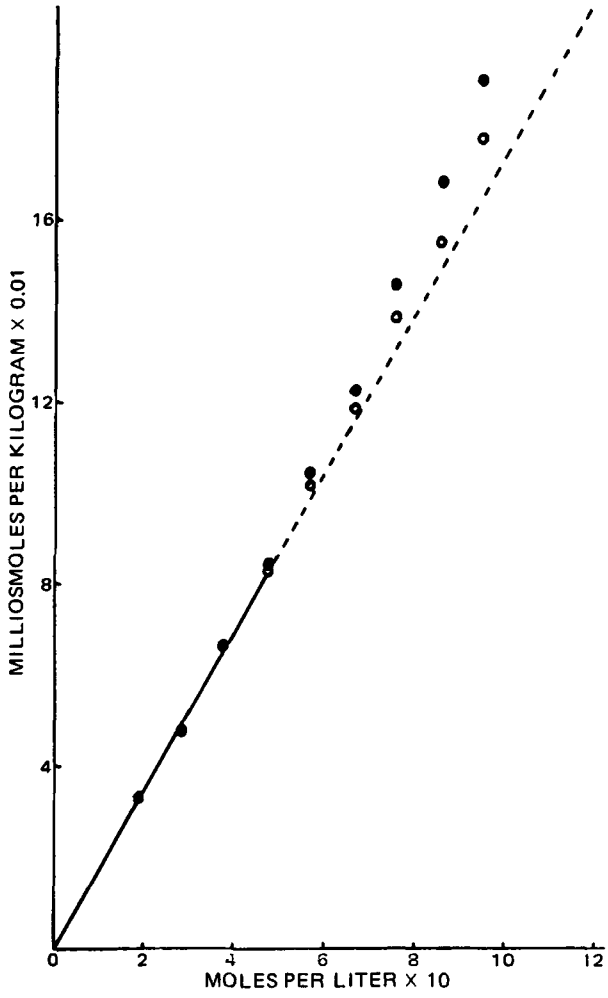

Figure 7—*Osmolality–molar concentration profile for aqueous solutions containing equal molar amounts of calcium chloride and dextrose. Key: ●, measured osmolality values for mixtures of calcium chloride and dextrose; and ○, calculated osmolality values determined by summing values for each component at its respective concentration.*

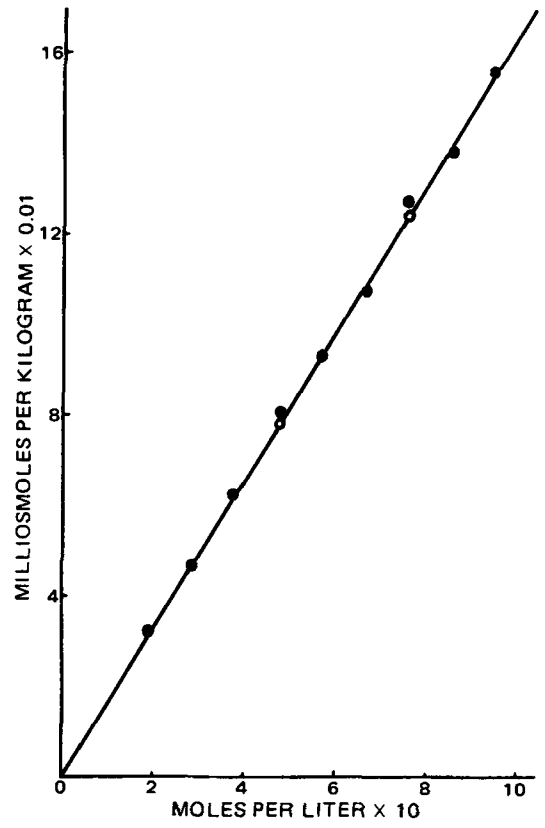

Figure 8—*Osmolality–molar concentration profile for aqueous solutions containing equal molar amounts of sodium sulfate and dextrose. Key: ●, measured osmolality values for mixtures of sodium sulfate and dextrose; and ○, calculated osmolality values determined by summing values for each component at its respective concentration.*

To determine the resulting osmolality values for combinations of these components, solutions with various compositions and concentrations were measured as a function of concentration. The values obtained were then compared to calculated values, assuming additive relationships for each component, as is common practice.

RESULTS

Monovalent Solutes—Figure 1 shows the approximately linear response between osmolality and concentration, up to 1.0 *M*, for sodium chloride, potassium chloride, sodium acetate, and sodium tartrate. Figure 2 shows the measured osmolality values for sodium chloride–potassium chloride mixtures made in different ratios at 1 *M* and diluted to 0.5 *M* total concentrations. The measured osmolality value for each mixture differed or agreed with the sum of the experimentally obtained values for each compound as shown. For the mixed salts at 1 *M* concentration, the values differed by as much as 50 mOs/kg in the region where ratios between 40:60 and 60:40 were used. Upon dilution to 0.5 *M*, these same solutions gave measured results identical to calculated values.

Polyvalent Solutes—Figure 3 shows the values obtained for calcium chloride and sodium sulfate. With calcium chloride, the osmotic coefficient values increased as the concentration increased from 0.1 to 1.0 molal; with sodium sulfate, the coefficient decreased over this same range. The result is a positive deviation (higher values) with increased concentration for calcium chloride solutions but negative deviation (lower values) with increased concentration for sodium sulfate solutions.

Figure 4 illustrates a negative deviation for the phosphate salt (dibasic sodium phosphate and monobasic sodium phosphate) solutions. Although not as obvious as in a plot using molal concentrations *versus* osmolality, the greater negative deviation from linearity of dibasic sodium phosphate solutions over monobasic sodium phosphate solutions is apparent since the number of ions, ν, for dibasic sodium phosphate is three and that for monobasic sodium phosphate is two.

Solutions containing mixtures of potassium chloride and calcium chloride in varying ratios to give 1.1 *M* chloride concentrations were studied in the same manner as potassium chloride and sodium chloride. The difference between the calculated and measured values for 1.1 *M* solutions can be seen in Fig. 5. Again, dilution to 0.55 *M* concentration gave the same calculated values as observed values.

Nonionic Sugar Solutes—Figure 6 shows the relationships obtained for the nonionizing sugars dextrose, mannitol, and sorbitol. All three showed a positive deviation from linearity above 0.4 *M* concentrations, and the osmolality values agreed very closely with each other for the same molar concentrations. For a point of comparison, a 5% dextrose solution is ~0.3 *M* and a 20% solution is ~1 *M*.

Solutions of Ionic and Nonionic Solutes—Finally, solutions prepared with an ionic salt and nonionic dextrose gave the results shown in Figs. 7–9. In the first experiment, calcium chloride and dextrose, both positive deviating solutes, were combined in solution to give the results shown in Fig. 7. A positive deviation greater than that calculated for the contribution of each solute was found for total concentrations above ~0.4 *M*.

Combination of the negatively deviating solute sodium sulfate with dextrose, a positively deviating solute, gave the results shown in Fig. 8. The calculated sum of the values from each single solute system was in close agreement with the measured values. In addition, combination of these two solutes in equal amounts resulted in a linear profile up to 1.0 *M* total concentration.

A combination of equal molar concentrations of sodium chloride and dextrose gave a linear response in total concentrations up to 0.9 *M* and a positive deviation at concentrations above 1 *M* (Fig. 9). For this combination, summation of the osmolality values obtained for each component was on the low side, and the error appeared to increase as the total concentration progressed above 1 *M*.

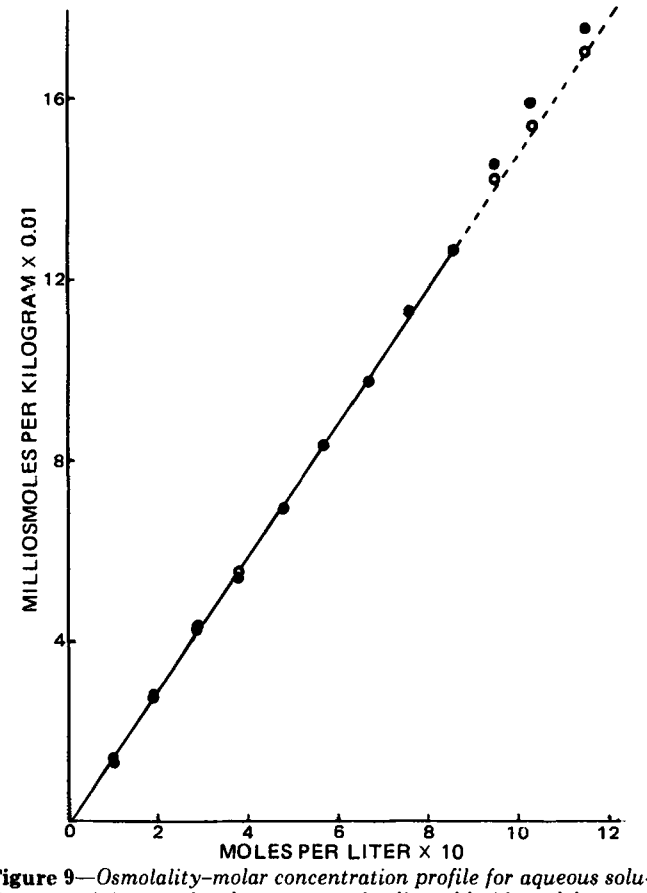

Figure 9—*Osmolality–molar concentration profile for aqueous solutions containing equal molar amounts of sodium chloride and dextrose. Key: ●, measured osmolality values for mixtures of sodium chloride and dextrose; and ○, calculated osmolality values determined by summing values for each component at its respective concentration.*

DISCUSSION

These studies demonstrated that the measured osmolality values for solute mixtures above 0.2–0.4 *M* concentrations differed from calculated values by amounts that were dependent on the total solute concentration and the specific combination of solutes. In general terms, if the osmolality of the solution exceeded 500–800 mOs/kg, a difference between measured and calculated values could be expected. The deviations also could be greater or less than calculated values, depending on the solutes.

Although these experiments were carried out with volumetrically formulated solutions, it would have been well to have used molal concentrations and weighed the solvent as well as the solutes. Recalculation of the molar solutions to molal equivalents in order to compare experimental results with literature values was tedious and not possible in some cases.

Measurement of solution colligative properties is based on the molal relationship; use of molar concentrations makes calculations more difficult or, possibly, incorrect if the molar concentration is assumed to be the same as a molal concentration. Although it may be more convenient to formulate by volumetric measurement, for accuracy and meaningful data interpretation, this practice should be abandoned when carrying out research in this area. There is also the added advantage of avoiding the errors introduced when incorrectly calibrated volumetric equipment is used or when the solution temperature is not controlled.

Based on these considerations, it is recommended that osmolality values be used in labeling parenteral products and that the term osmolarity be avoided. This practice would eliminate the need to determine a conversion factor for each parenteral system. In some cases, it may be impossible to calculate a conversion factor and only osmolality values can be obtained.

Nuclear-Substituted Styryl Ketone Analogs: Effects on Neoplasms, Microorganisms, and Mitochondrial Respiration of Tumorous and Normal Cells

J. R. DIMMOCK ˣ, N. W. HAMON, L. M. NOBLE, and D. E. WRIGHT

Received October 31, 1978, from the *College of Pharmacy, University of Saskatchewan, Saskatoon, Saskatchewan, Canada, S7N 0W0.* Accepted for publication February 15, 1979.

Abstract □ Analogs of some antineoplastic and cytotoxic Mannich bases derived from conjugated styryl ketones were prepared and evaluated for activity in the P-388 lymphocytic leukemia screen. Most of the new compounds had lower antineoplastic and murine toxicity than the parent compounds. Antimicrobial evaluation of some oximes and alcohols related to the Mannich bases revealed activity against certain Gram-positive bacteria and fungi. Primary pharmacological evaluation showed that some compounds containing a dimethylaminomethyl group displayed analgesic and antihistaminic properties. Five of the Mannich bases were evaluated as respiratory inhibitors in mitochondria derived from hepatic tumors, liver tissue from tumor-bearing animals, and normal rat liver. No statistical difference between the sensitivity of the three tissues to the compounds was obtained.

Keyphrases □ Styryl ketones, nuclear substituted—effects on neoplasms, microorganisms, mitochondrial respiration in normal and tumor cells, structure–activity relationships □ Antineoplastic agents, potential—nuclear-substituted styryl ketones, effects on neoplasms, microorganisms, mitochondrial respiration in normal and tumor cells, structure–activity relationships □ Mitochondria—effect of nuclear-substituted styryl ketones on respiration, normal and tumor cells □ Mannich bases—derivatives, effects on neoplasms, microorganisms, mitochondrial respiration in normal and tumor cells, structure–activity relationships

Numerous Mannich bases derived from conjugated styryl ketones (I) have shown promising levels of antineoplastic activity accompanied by murine toxicity (1). The activity of these compounds is due, in part at least, to interference with mitochondrial function (2); examination of the effect of representative compounds on the electron transport chain of rat liver cells showed that competition with coenzyme Q_{10} is an important site of action (3). In addition, various studies revealed that Mannich bases have antimicrobial activity (4–7) as well as other bioactivities (8, 9), including analgesia in both Mannich bases (10) and their derivatives (11).

BACKGROUND

The aim of the present investigation was twofold. First, a study was contemplated involving a systematic modification of the lead compounds (I) to see if antineoplastic activity could be retained while toxicity was diminished. The assessment of the new derivatives for other bioactivities was also of interest. Second, this study compared the effects of representative Mannich bases on the mitochondrial electron transport chain derived from normal rat liver cells and from hepatomas. A structure–activity relationship to antineoplastic activity would permit the rational design of novel anticancer agents.

The modification of the Mannich bases (Ia–If) was through systematic alterations of the basic center, then of the lipophilic pentamethylene chain, and finally of the carbonyl group. Reaction of Ic and If with methyl iodide produced IIa and IIb, which are quaternary ammonium salts, representatives of which are known to cause lysis of cytoplasmic membranes (12). Furthermore, the addition of one bulky group onto the quadrivalent nitrogen atom (IIa and IIb) may reduce absorption onto serum proteins (13).

The activity of certain Mannich bases may be due to deamination to the corresponding conjugated carbonylene (14, 15), and thus IIc and IId may be breakdown products of the precursor derivatives Ic, If, IIa, and IIb *in vivo*. A comparison of the antitumor efficacies of these six compounds may allow certain conclusions about the active species. Compounds IIc and IId, while retaining the conjugated styryl ketone function permitting biological alkylation to occur (16–18), were expected to have considerably lower aqueous solubility than the precursor compounds. By contrast, Mannich bases IIIa and IIIb, in which the lipophilic pentamethylene chain of Ia had been removed, were predicted to have greater aqueous solubility than Ia. Recently, the biological activity of α,β-unsaturated ketones has been attributed partially to a judicious balance between their hydrophilic and hydrophobic portions (19).

The final series of alkylating agents related to I involved ketone modification. Oximes may be ketone prodrugs (20), and the formation of IVa and IVb might allow selective release of the precursor ketones in tumorous tissue due to the acid lability of oximes (21); the claim has been made that the extracellular fluid of certain tumors is more acidic than

normal extracellular fluid (22, 23). In addition, an oxime derived from an α,β-unsaturated ketone had a ninefold increase in aqueous solubility over the precursor ketone (24). Reduction of the Mannich base ketone function would produce the substituted allyl alcohols IV*c*–IV*f*, expected to have alkylating properties due to the stability of the carbonium ion. In the case of these aryl-substituted alcohols, the carbonium ion would be expected to be further destabilized by delocalization of the positive charge on the ring. The murine toxicity of I may be associated with the dimethylaminomethyl function. Hence, nitrogenous analogs of conjugated styryl ketones that were not Mannich bases, were synthesized, namely the oximes VII as well as the aziridines VIII, representatives of which have displayed anticancer activities (25).

The second phase of the investigation involved comparing the effects of certain compounds on mitochondria derived from normal and from tumorous cells. Since the Mannich bases I*a* and I*d*–I*f* interfere with certain processes in the hepatocyte mitochondrial electron transport chain (3), an experimental rat hepatoma model was sought in which to examine the effects of these compounds on mitochondria from nontumorous tissue from normal and tumor-bearing rats.

Since 1960, various Morris hepatomas have become available (26). The 5123 TCH hepatoma chosen has a high mitochondria titer and is a highly differentiated stable growing tumor with an intermediate growth rate. This hepatoma grows in the pelvic region of the Buffalo rat strain, and the tumors develop within 4–5 weeks. Thus, by isolating the mitochondria from these three sources, the effects of I*a*, I*d*–I*f*, and III*a* in the presence of various substrates may permit conclusions about a mitochondrial sensitivity to the cytotoxic and antineoplastic Mannich bases.

RESULTS AND DISCUSSION

The first phase involved the synthesis and screening of derivatives I–VIII. In these compounds, the olefinic double bond of the styryl group was shown by ^{1}H-NMR and IR spectroscopy to have the (*E*)-configuration; ^{1}H and ^{13}C-NMR spectroscopy revealed that allyl alcohols IV*c* and IV*e* had the *threo*-configuration, while IV*f* was a 60:40 mixture of *erythro*- and *threo*-isomers. Purification of IV*d* led to the isolation of the *threo*-isomer (IV*d'*). After considerable difficulty, a small quantity of the *erythro*-isomer (IV*d"*) was isolated as the maleate salt. In the reaction between I*a* and hydroxylamine, the only product isolated was the hydroxylamino derivative, V. An attempt was made to form the IV*d* phosphate ester since the claim has been made that certain cancers contain high phosphatase (27). However, the product showed that IV*d* dehydration had occurred, producing the diolefin VI. NMR spectroscopy (100 MHz) showed that the aziridines VIII had the *cis*-configuration.

The activity of I–VIII against P-388 lymphocytic leukemia and their murine toxicity is summarized in Table I. The Mannich bases (I) increased the survival time in mice by an average 18%, and the related

[a] Figures are the ratios of the survival times of treated animals to those of control animals, expressed as a percentage. A compound is considered to be active if it increases the mean survival time by 25%. The data for I*d*–I*f* and III*b* are from Ref. 1 and are reproduced with permission of the copyright owner. [b] The murine toxicity of the compound is measured by the number of survivors out of six on the 5th day after the dosage schedule commenced. The data for Compounds I*a*, I*b* (200- and 100-mg/kg doses), I*d*–I*f*, II*a* (200- and 100-mg/kg doses), II*c*, III*b*, and IV*c* are from Ref. 1, and the data for II*d* (50-mg/kg dose) are from Ref. 2. These results are reproduced with permission of the copyright owner. [c] The figures, in micrograms per milliliter, in the KB cell culture screen indicate the dose inhibiting 50% of the growth of human epidermoid carcinoma of the nasopharynx in Eagle's medium. A compound is considered to be active if it inhibits 50% of the growth of this tumor at a concentration of 4 μg/ml. The data for I*c*–I*f*, II*a*, II*c*, III*b*, and IV*c* are from Ref. 1, and the result for III*a* is from Ref. 2. This information is reproduced with permission of the copyright owner. [d] The maximum dose administered with this compound was 50 mg/kg. [e] At 400 mg/kg, there were no deaths when the compound was administered twice on Days 2 and 6 to three animals.

Average antimicrobial activity[b]	231	292	262	292	100	167	40	192	0	15

[a] Figures are the minimum inhibitory concentrations of the compounds in micrograms per milliliter. [b] Figures were calculated from (combined antimicrobial activity × 100)/number of microorganisms in the screen. The combined antimicrobial activity was determined by giving the following scores at the highest potency of the compound against the microorganisms: <500:1, 100:2.5, and <100:5.

synthons (II–VIII) caused an average 13% increase. Thus, antineoplastic activity was retained, albeit diminished. In general, murine toxicity also was retained but reduced except for the VII oximes, which did not contain the dimethylaminomethyl function. The oximes VII had an average 11% increase in mean survival time but were virtually bereft of murine toxicity.

All compounds examined in the *in vitro* KB screen displayed cytotoxicity. Quaternization of Ic gave IIa with similar effect in the P-388 screen and murine toxicity; the possible metabolite of both compounds, the $\alpha,\beta,\alpha',\beta'$-diolefinic ketone IIc, retained activity and decreased host toxicity. Quaternization of the highly active Mannich base If gave IIb with lower antineoplastic activity and lower murine toxicity, while the deaminated IId was virtually devoid of antileukemic potency, even though host toxicity was lower than in If. A comparison of the data for the unsubstituted Mannich bases Ia, IIIa, and IIIb revealed that while a similar low activity level in the P-388 screen was observed, murine toxicity increased as the chain length was shortened. While the average increase in mean survival time for Ib and If was 23%, the related oximes IVa and IVb increased survival time by 14% and host toxicity was reduced. The *threo*-isomeric allyl alcohol IV*d'* increased the mean survival time by twice that of either the *erythro*-isomer IV*d''* or the precursor Mannich base Ic.

The dichlorinated alcohols IVe and IVf had markedly inferior antineoplastic activity compared to the related Mannich bases Id and If. While three oximes, VIIa, VIId, and VIIe, showed an average 20% increase in the lifespan of the mice unaccompanied by host toxicity at the maximum doses administered, the aziridines VIIIa–VIIId proved lethal at 100 mg/kg. A representative aziridine, VIIIa, was examined further, but an increase of only 15% in mean survival time was found at the optimum dose level.

Some Mannich base derivatives were screened for antimicrobial activity (4, 5) and other pharmacological activities (11). Since α,β-unsaturated ketones have shown significant mammalian toxicity, it was felt that evaluating some related alcohols and oximes, in which the carbonylene group is masked, might lead to a greater chance of clinical acceptability if antimicrobial or pharmacological activity is found.

The antimicrobial results of 10 of the alcohols and oximes are listed in Table II. The results indicated that compounds containing a dimethylaminomethyl group, namely the oximes IVa and IVb and the alcohols IV*d'* and IVe, had the greatest activity and were virtually equipotent. In the VII series of oximes, the *o*-chloro and 2,6-dichloro oximes VIIb and VII*d* showed the greatest activity. The most sensitive bacteria to these compounds were the Gram-positive organisms *Staphylococcus aureus*, *Streptococcus faecalis*, and *Bacillus subtilis*. Compounds IVb, IV*d'*, and IVe all showed the same activity against the five fungi in contrast to IVa, which was inactive. The VII oximes were virtually devoid of antifungal activity.

Some Mannich bases have demonstrated analgesia (10), and the data generated from the primary pharmacological screening (Table III) indicate that the oximes and alcohols derived from these compounds have this property. Numerous narcotic analgesics have a common structural unit linked together, namely a tertiary nitrogen atom, a two-carbon chain, and a quaternary carbon atom to which an aryl ring is attached (28). The compounds bear some similarity to the general formula of narcotic analgesics, although a styryl group and not an aryl ring is attached to the quaternary carbon atom. The overlap of π-orbitals in this group of

Table III—Evaluation of Some Oximes and Alcohols Derived from Conjugated Styryl Ketones for Analgesic, Anti-Inflammatory, and Antihistaminic Activities

	Analgesic Activity[a]				Anti-Inflammatory Activity[b]			
	Percentage Protection[c]					Percentage Protection

VIIf	49	58	96	42	128	0	0	31

[a] Analgesic activity was measured by the percentage protection in the phenylquinone writhing test. Under these conditions, aspirin gave 50% protection at 52 mg/kg. A compound displaying an effect >50% is considered to be active. [b] Anti-inflammatory activity was measured by the percentage protection afforded by the compound to carrageenin-induced edema. The reference compound, indomethacin, gave 50% protection at 12 mg/kg under these conditions. Compounds showing >50% protection are considered active. [c] Dose levels in milligrams per kilogram. [d] Figures indicate the percentage protection of the compound at 0.1 mg/ml against a standard histamine dose. A compound is considered active if 20% protection is obtained. The reference compound, diphenylhydramine, gave 100% protection at 0.01 mg/ml. [e] Percentage protections at 16 mg/kg for IVa and IVe were 42 and 10, respectively. [f] At a dose level of 0.01 mg/ml, IVa, IV*d'*, and IVe inhibited the histamine action by 52, 70, and 100%, respectively. At 0.001 mg/ml, IVa, IV*d'*, and IVe inhibited the action of histamine by 29, 18, and 52%, respectively. [g] Percentage increases in the number of writhes for VIIa, VIIb, and VIIc were 18, 31, and 6, respectively.

Table IV—Inhibition of Respiration of Mitochondria Obtained from the Hepatic Tumor 5123 TCH, from the Liver of the Tumor-Bearing Animal, and from Normal Rat Liver by the Mannich Bases Ia, Id–If, and IIIa Using Succinate as the Substrate

[a] The percentage increase in respiration indicates the change in respiration after ubiquinone addition.

compounds may not preclude alignment at a nonpolar portion of the receptor, which is normally occupied by the aryl ring. The IV*a* and IV*d'* monochloro derivatives had, on the average, approximately 2.4 times the potency of IV*b* and IV*e*, which have two chlorine atoms in the aromatic ring and may exert some steric impedance to binding at a receptor. Codeine analgesia, expressed as an ED_{50} value, is 14.2 mg/kg in the hot plate test (29); and although the compounds listed in Table III were evaluated by the phenylquinone writhing test, it may be considered that IV*a* and IV*d'* are similar in potency to codeine, while IV*e* and IV*b* are approximately one-half and one-fifth as active as this widely used drug.

The VII oximes displayed a wide spectrum of response in the analgesia screen, ranging from algesia (VII*a*–VII*c*) to weak analgesic activity (VII*d* and VII*e*) to VII*f*, which had approximately one-third of the activity of codeine. The demonstration of analgesia by certain of these compounds would be enhanced if anti-inflammatory properties were also found in the active compounds. Table III indicates that none of the derivatives met the criterion for activity at 3 and 5 hr.

Table III indicates that all of the compounds examined in the antihistaminic screen displayed activity, with maximum potency shown by the dimethylaminomethyl compounds IV*a*, IV*b*, IV*d'*, and IV*e*. These derivatives are related structurally to the propylamine group of antihistaminics, in which halogenation of the aromatic ring enhances activity (30). Both of the alcohols IV*d'* and IV*e* as well as the oxime IV*a* showed histamine-inhibiting properties at a concentration as low as 0.001 mg/ml. None of the compounds listed in Table III demonstrated activity in the cardiovascular, hypoglycemic, and antianaphylactic screens, except IV*e* which inhibited passive cutaneous anaphylaxis in rats by 75% at a dose of 75 mg/kg.

The second phase of the work involved the examination of the effect of the Mannich bases Ia, Id–If, and IIIa on respiration of mitochondria obtained from the 5123 TCH hepatic tumor and from the tumor-bearing animal as well as from normal rat liver using different substrates (Tables IV–VII). Statistical evaluation showed no difference (at $p = 0.05$, analysis of variance) in sensitivity of the three types of tissue to the Mannich bases.

In summary, this work has shown that molecular modification of the Mannich bases (I) produced compounds of lower murine toxicity, generally accompanied by reduced anticancer activity. The results of mitochondrial respiration inhibition studies likewise showed that five of the compounds were not selective for mitochondria from tumor cells.

[a] The percentage increase in respiration indicates the change in respiration after ubiquinone addition.

EXPERIMENTAL

Compound Preparation—The preparation of Ia–If, IIa, and IIc was described previously (31). Compounds IIb, IId, and IIIa were prepared by the literature methodology (2) as was IIIb (1). The synthesis of IVa, IVb, IVe, IVf, and V–VIII was accomplished using a reported procedure (32), and the alcohols IVc and IVd were prepared by the method described previously (33). Compounds IVc and IVe possessed the *threo*-configuration; IVd was obtained as the pure *threo*-isomer, IVd′ (33), and a small quantity of the *erythro*-isomer (IVd″) was isolated as the maleate salt (33). The alcohol IVf was shown by spectroscopic means to consist of a 60:40 mixture of the *erythro*- and *threo*-isomers (32).

Compound Screening—The data summarized in Table I were generated by the Drug Research and Development Division of the National Cancer Institute, using their protocols (34). The compounds were administered in saline (Ia, Ib, Id, If, IIb, IIIa, IIIb, IVa–IVd′, IVe, and IVf), saline with polysorbate 80[1] (Ic, VIId, VIIf, and VIIIa–VIIId), hydroxypropylcellulose (Ie, IIa, IIc, IVd″, V, VI, VIIa–VIIc, and VIIe), and an unspecified solvent (IId) by the intraperitoneal route. The CD_2F_1 strain of mice was used for all compounds except Ie, If, IIa, IIc, IIIb, IVc, IVd′, and IVd″, in which cases the $B_6D_2F_1$ strain of mice was employed.

Injections were made daily for 9 consecutive days, except in the following cases. The maximum increase in mean survival times recorded in Table I for Ie was obtained by making three injections every 4 days; for IIa and IIc, only one injection was made. In addition, the murine toxicity data found in Table I for Id were obtained when three injections were made every 4 days, and the toxicity of IIa at the 50-mg/kg dose level was found when one injection was made. The toxicity data for IIb and IId at the 200- and 100-mg/kg dose levels, respectively, were derived from two injections separated by a 4-day period. The toxicity data for IVc at the 200-mg/kg dose level were obtained by making three injections every 4 days.

For the antimicrobial screen[2], the compounds were dissolved in water or dimethyl sulfoxide and diluted serially to various concentrations. The concentrations of stock solutions were prepared such that when 0.5 ml

[1] Tween 80, Atlas Chemical Industries, Wilmington, DE 19899.

[2] The antimicrobial and pharmacological screens were carried out by Bio-Research Laboratories Ltd., Montreal, Quebec, Canada.

was added to 15 ml of agar medium, the desired final concentrations were obtained. The growth medium for the bacteria was trypticase soy agar with 5% defibrinated rabbit blood added for the growth of *Haemophilus influenzae*, *Streptococcus pyogenes*, and *Streptococcus pneumoniae*. Modified Sabouraud agar was employed for the growth of the fungi. The test organisms were grown previously for 2 days at 35° for bacteria and yeast and for 1 week at 24° for fungi on slants of the same media. The agar plates were streaked with a loopful of cell suspension, which had been washed off the slants and diluted to approximately 10^5 organisms/ml. The plates were incubated for 2–14 days at 24° for fungi and at 35° for bacteria. The results in Table II indicate the minimal inhibitory concentration of the compound that prevents visible growth in the media.

Unless otherwise stated, the same number of animals was used for controls as for pharmacological evaluation of the compound. The screen employed for examining the compounds for analgesic activity was the phenylquinone writhing test (35). Five male Swiss albino mice, 18–22 g, were used for each dose for each compound. The ED_{50} values for five of the compounds listed in Table III were obtained by using five mice at doses of 16, 32, and 64 mg/kg for IV*a* and IV*e* and at 32, 64, and 128 mg/kg for IV*b*, IV*d'*, and VII*f*.

The anti-inflammatory screen measured the antagonism of the test compound to carrageenin-induced rat paw edema (36). Six female Sprague–Dawley rats, 120–160 g, were used for the compounds listed in Table III, except for VII*a*–VII*c* and VII*e* where four animals were used. The edema volume was recorded at the end of 3 and 5 hr. The compounds were examined for antihistaminic activity using four guinea pig ileum preparations (37). The antianaphylactic screen measured the potential of a compound to inhibit passive cutaneous anaphylaxis in rats (38). Four female Sprague–Dawley rats were used for each compound. Compounds were administered intravenously at 125 mg/kg for IV*a*, 100 mg/kg for IV*b* and VII*d*, 25 mg/kg for IV*d'* and IV*e*, 128 mg/kg for VII*a*–VII*c* and VII*e*, and 50 mg/kg for VII*f*. A compound was considered active if it reduced wheal formation by 50%. The reference compound, chromolyn sodium, reduced the wheal area by 90% at a dose of 100 mg/kg.

The antidepressant screen measured the antagonism of a compound to tetrabenazine-induced ptosis in mice (39, 40). Six male Swiss albino mice were used for each compound; the compounds were administered subcutaneously, except VII*a*–VII*c* and VII*e*, which were given intraperitoneally. A dose of 128 mg/kg was used for all compounds except IV*a* and IV*e*, where the dose was 64 mg/kg. A compound should antagonize the tetrabenazine effect by 30% after 30 min and by 10% after 60 min to be considered active. The reference compound, amitriptyline, caused an antagonism of 90 and 50% after 30 and 60 min, respectively, at a dose of 8 mg/kg.

In the cardiovascular screen, a Sprague–Dawley rat of either sex, 250–400 g, was anesthetized by intraperitoneal urethan injection (1.9 g/kg). After cannulation of the femoral vein, the blood pressure was monitored *via* a pressure transducer[3] connected to a cannula in the left carotid artery. The arterial blood pressure and heart rate were recorded on a polygraph[4]. After the preparation had stabilized, the test compound was dissolved in saline and/or polysorbate 80[1] (1%) and administered in a volume of 0.01–0.05 ml. The changes in blood pressure and heart rate were expressed as percentage differences between the pre- and postdrug values. One or two determinations using one rat for each compound were made at the following dose levels: IV*a*, IV*b*, and VII*d* at 20 mg/kg; IV*d'*, IV*e*, and VII*f* at 10 mg/kg; and VII*a*–VII*c* and VII*e* at both 1 and 5 mg/kg. A compound should increase the blood pressure and heart rate by 30% for a time period considerably in excess of 5 min to be considered active.

The screen for hypoglycemic activity involved the measurement of blood sugar concentration in rats (41). Four male Sprague–Dawley rats were used for each compound. Compounds IV*b*, IV*d'*, IV*e*, VII*d*, and VII*f* were administered at a dose of 128 mg/kg po. A dose of 64 mg/kg po was employed for IV*a*. Compounds VII*a*–VII*c* and VII*e* were administered at 100 mg/kg iv. A 20% decrease in blood sugar concentration is required for a compound to be considered active in this screen.

Inhibition of Respiration in Mitochondria Obtained from Hepatic Tumor 5123 TCH and from Rat Liver—The inoculation of the hepatic tumor 5123 TCH into rats proceeded as follows. Adult, male Buffalo strain rats[5] containing a 4–5-week-old tumor[6] were sacrificed and the tumors were removed. The healthy tumor tissue was dissected from the remainder of the neoplasm. A 10% suspension of the tumor tissue in normal saline was prepared and placed in a glass hand homogenizer[7], after which two or three thrusts with a glass pestle were undertaken. The suspension (1 ml) was injected subcutaneously into each side of the inguinal regions of a male Buffalo rat, 100 g.

The mitochondrial pellet containing tumorous tissue was prepared as follows. Adult, male Buffalo rats containing a 4–5-week-old 5123 TCH tumor were sacrificed by decapitation and the tumors were removed. The healthy tumor tissue (5 g) was dissected from the remaining tumor mass and made into a 25% suspension using ice-cold 3.4 m*M* tromethamine hydrochloride[8] buffer (pH 7.40 at room temperature). The 3.4 m*M* tromethamine hydrochloride buffer contained 0.25 *M* sucrose and 1.0 m*M* ethylene glycol-bis(aminoethyl)tetraacetate. All of the following procedures were carried out at 0°.

The tumor tissue was homogenized with 15–20 thrusts with a pestle in a glass homogenizer[7] and then diluted to a 10% homogenate with buffer. The mitochondrial pellet, prepared from the homogenate using the reported methodology (3), was suspended in cold buffer (10 ml) to give a protein concentration of approximately 6 mg/ml; 0.5 ml of this suspension was used in each determination. Homogenates from 10 g of liver from tumor-bearing animals and normal Buffalo rats were prepared in a similar manner and suspended in 10 ml of buffer. One milliliter of this suspension was diluted with 4 ml of buffer, giving a suspension with a protein concentration of ~5 mg/ml; 0.5 ml of this suspension was used in each determination.

The media and methodology for measuring the effect of the Mannich bases on mitochondrial respiration were reported previously (3). The percentage increase in respiration was measured by adding 5 μl of a solution of ubiquinone (9 nmoles) in ethanol to the cell approximately 2 min after the addition of the Mannich base and noting the effect on respiration. The results in Tables IV–VII represent the mean values of five to eight separate determinations. In every case that mitochondria were used, the protein content was determined by a modification (42) of the previously described procedure (43). Results were evaluated statistically by the analysis of variance using the SPSS-Anova program (44) and a computer[9].

Preparation of Diastereomeric Urethane Derivatives of Atropine and *l*-Hyoscyamine Using (−)-1-Phenylethylisocyanate

W. O. LANDEN, Jr. *[x], and DRURY S. CAINE [‡]

Received December 27, 1978, from the **Food and Drug Administration, Atlanta, GA 30309,* and the [‡]*School of Chemistry, Georgia Institute of Technology, Atlanta, GA 30332.* Accepted for publication February 20, 1979.

Abstract □ Diastereomeric urethane derivatives of atropine (*d,l*-hyoscyamine) and *l*-hyoscyamine were prepared by reacting the alkaloids with (−)-1-phenylethylisocyanate. The derivatives, as the picrate ion-pairs, were characterized by their melting points, optical rotations, elemental analyses, and IR, NMR, and UV–visible spectra.

Keyphrases □ Diastereomers—atropine and *l*-hyoscyamine urethane derivatives, chemical synthesis □ Atropine—derivatives, urethane diastereomers, chemical synthesis □ Hyoscyamine—derivatives, urethane diastereomers, chemical synthesis

In an investigation designed to develop a procedure for the quantitation of *d*-hyoscyamine and *l*-hyoscyamine at therapeutic levels in finished drug dosage forms, a method for the preparation and isolation of stable diastereomeric urethane picrate derivatives was found. The derivatives were prepared by reacting the chiral isocyanate reagent (−)-1-phenylethylisocyanate with *l*-hyoscyamine and atropine (*d,l*-hyoscyamine).

The preparation of suitable alcohol derivatives generally is based on ester formation by reactions with acid chlorides or acid anhydrides (1–3) or on urethane formation by reaction with isocyanates (4–6). Little use of optically active isocyanates for the racemic mixture resolution has been reported in the literature. The reaction of (−)-menthylisocyanate with alcohols (7), the use of (−)-menthylisocyanate to prepare derivatives with *tert*-butyl alcohol, lactic acid, and amino acids (8), and the reaction of α-phenylethylisocyanates with amines, alcohols, and Grignard reagents (9) have been studied. Optical activity was retained during these reactions, and the respective derivatives possessed a larger optical rotation than the reagent itself.

Other investigators (10) reported that (−)-1-phenylethylisocyanate does not polymerize and can be stored for long periods, neat or in solution, without a change in the optical rotation value. GLC has been used (11) for the

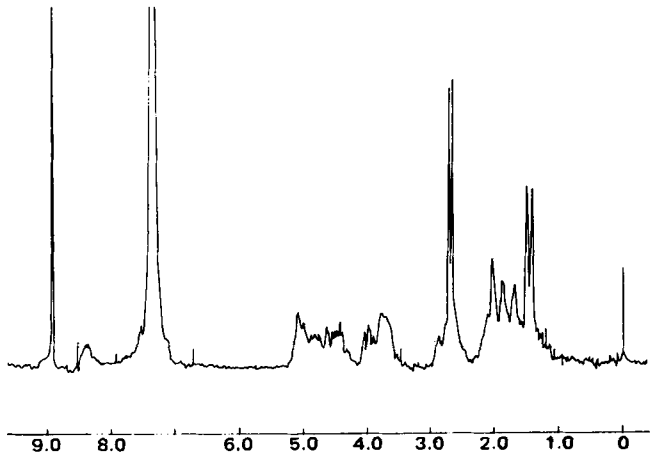

Figure 1—*NMR spectrum of I in deuterochloroform with 0.1% tetramethylsilane as reference (frequency, 99.539 MHz; single pulse width, 4 μsec; repetition, 5 sec; data points, 8k; number of scans, 1001).*

separation of diastereomers of (*R*)-(+)-1-phenylethylurethanes of secondary alcohols.

EXPERIMENTAL

Apparatus—The reaction apparatus was assembled from stock items with 24/40 joints: round-bottom flask, 150 ml, three neck; dropping funnel, 25 ml; reflux condenser, water jacketed; glass inlet tubing with stopcock for nitrogen introduction; heating mantle with rheostat; and rotary vacuum evaporator with dry ice–acetone cold trap and high vacuum pump. NMR spectrometers for operation at 60 MHz[1] and 100 MHz[2] were used. Tetramethylsilane in deuterochloroform was the internal reference for chemical shift measurements.

Reagents—Benzene was analytical reagent grade, thiophene free, dried by refluxing over sodium, and distilled just prior to use. The ether[3] was anhydrous grade, and all other reagents were analytical reagent grade. The nitrogen gas was highly purified, anhydrous grade. *l*-Hyoscyamine and atropine[4] were dried in a vacuum desiccator over silica gel. (−)-1-Phenylethylisocyanate[5], 97% purity, was received in a sealed ampul and maintained under a nitrogen atmosphere after opening.

Procedure—The glass reaction apparatus was assembled with the water condenser in place. The reaction flask was flame dried while the system was purged with nitrogen, and the system was allowed to cool to room temperature while a nitrogen atmosphere was maintained.

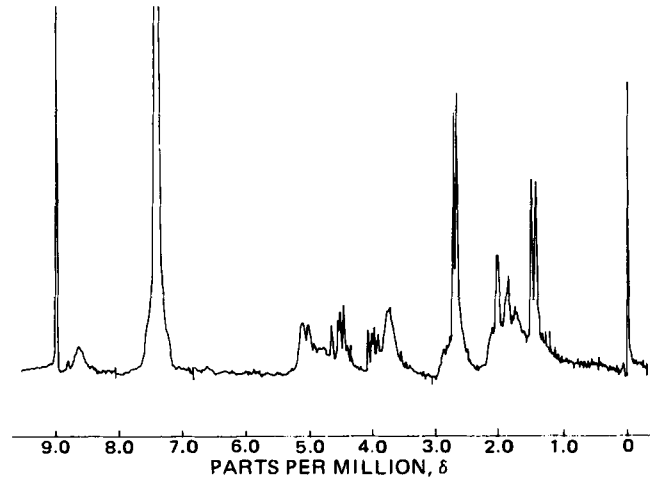

Figure 2—*NMR spectrum of II in deuterochloroform with 0.1% tetramethylsilane as reference. For instrument parameters, see Fig. 1.*

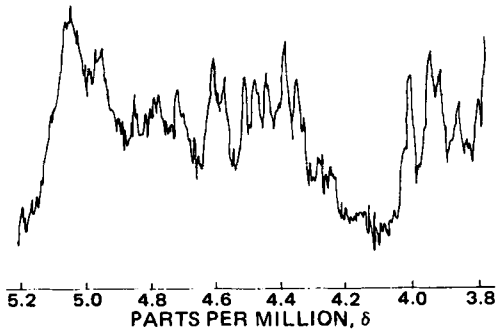

Figure 3—*Expansion of Fig. 1, 3.8–5.2-ppm region.*

To assure anhydrous conditions, the alkaloids (300 mg) were dissolved in 10 ml of benzene in a 50-ml glass stoppered flask, followed by the addition of 2 g of anhydrous magnesium sulfate. This preparation was allowed to stand 2 hr with intermittent stirring and was transferred to the dried reaction flask after filtering.

While a nitrogen atmosphere was maintained, 300 μl of (−)-1-phenylethylisocyanate reagent was added to give a 2:1 molar ratio of reagent to alkaloid. The heating mantle temperature was slowly adjusted to bring the solution to a gentle boil with stirring by a small magnetic stirring bar. After refluxing 2 hr under nitrogen, the reaction flask (intact system) was lowered into a water bath maintained at 5°. The water condenser was removed, and the dropping funnel containing picric acid solution was attached to the system. (The picric acid solution was prepared by dissolving 500 mg of picric acid in 10 ml of benzene; 5 g of anhydrous magnesium sulfate was added and, after standing for 48 hr, the solution was filtered into the dropping funnel.)

The picric acid solution was added dropwise, with stirring, over a 25-min period to the reaction flask maintained at 5°. Ten milliliters of dry benzene was used to wash the dropping funnel and to assure the quantitative addition of the picric acid solution.

All connections were removed from the reaction flask, and the flask was attached to a vacuum rotary evaporator. Glass stoppers (24/40 joint) were used to close the other openings.

The flask was rotated in a water bath at 25°, and the solvent was removed by reduced pressure. The unreacted reagent was removed by maintaining a vacuum (<1 mm Hg) for 4 hr at 25° after the solvent was removed.

The residue was dissolved in 5 ml of methylene chloride and transferred dropwise to a flask containing 300 ml of ether. Crystals formed on cooling the solution to −19°. The solution was allowed to stand for 24 hr before filtering. Crystallization from ether was repeated prior to the characterization studies.

RESULTS AND DISCUSSION

The initial investigation for the preparation of diastereomeric derivatives involved the formation of esters by the reaction of the alkaloids individually with both camphor-*d*-sulfonyl chloride and α-methoxy-α-trifluoromethylphenyl acid chloride (Mosher's acid chloride) in pyri-

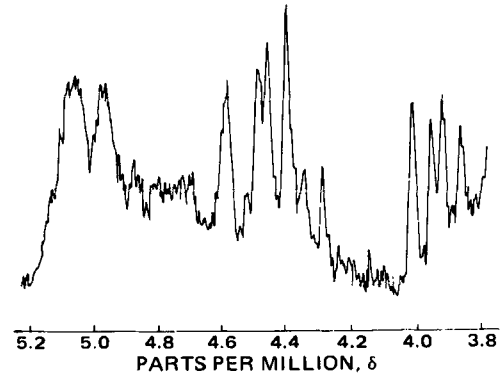

Figure 4—*Expansion of Fig. 2, 3.8–5.2-ppm region.*

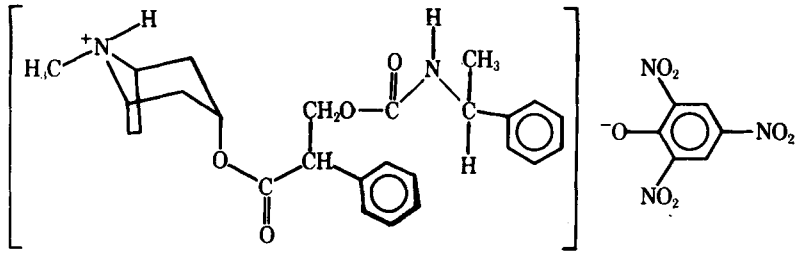

I
II

dine at 10°. The acid produced during the reaction formed salts with the derivatives. However, since these salts could not be induced to crystallize, isolation of the free amine derivatives was attempted. Unfortunately, this attempt was unsuccessful because partial elimination occurred to give apoatropine, which was identified by comparison of the NMR spectrum with a published spectrum (12).

Since the alkaloid reaction with an isocyanate would give the free amine derivatives directly, derivatization with a chiral isocyanate reagent was investigated next. The (−)-1-phenylethylurethane derivatives of l-hyoscyamine and atropine were prepared by reacting the alkaloids with (−)-1-phenylethylisocyanate in benzene. Both the free amine (−)-1-phenylethylurethane derivative and the corresponding hydrochlorides were oils at room temperature. To aid in characterization of these derivatives, a stable crystalline solid was needed. Picrate derivatives of tropane alkaloids are stable solids. Thus, the picrate salts of the diastereomeric derivatives were prepared using picric acid in benzene.

A high-performance liquid chromatographic (HPLC) procedure (13), using the derivatives as the picrate ion-pairs, indicated that less than 2% of the underivatized alkaloids remained in the crude reaction mixtures prepared according to the reaction conditions given under *Experimental*.

The NMR spectra at 60 MHz of atropine (−)-1-phenylethylurethane picrate (I) and *l*-hyoscyamine (−)-1-phenylethylurethane picrate (II) revealed minor differences in chemical shifts for the proton absorbances in the 3.84–4.64-ppm region.

However, more dramatic differences were observed when these NMR spectra were determined at 100 MHz using Fourier transformation.

Table I—Elemental Analyses and Melting Points of I and II

Compound	Trial	Melting[a] Point	Analysis[b], %	Calc.	Found

Table II—UV and Visible Absorptivity Values for I and II

Compound	Wavelength, nm	Absorptivity
I	405	11.3
	345	21.7
	242	18.5
II	405	11.1
	345	21.5
	242	18.9

Figures 1 and 2 compare the complete 100-MHz spectra (0–10 ppm) determined on individual solutions having 10 mg of I and II in 0.5 ml of deuterochloroform containing 0.1% tetramethylsilane. Figures 3 and 4 show expansions (fivefold) of the 3.8–5.2-ppm regions of I and II, respectively. These spectra better demonstrate the differences in the chemical shifts of the absorptions of the methine proton (3.84–4.04-ppm region) and the methylene protons (4.22–4.64-ppm region) of the tropic acid moiety. The absorptions for the tropane ring C-3 proton and for the urethane moiety methine and nitrogen atom protons overlap and occur in the 4.54–5.20-ppm region. These absorptions overlap the lower field peaks for the methylene protons. By preparing various mixtures of I and II, rough diastereomeric composition estimates could be made from the NMR spectra in the 4.22–4.64-ppm region.

The derivatives, as the picrate ion pairs, were characterized by determination of melting points, optical rotations, elemental analyses, and IR, NMR, and UV–visible spectra. Table I contains elemental analysis data and melting points as determined on duplicate preparations of I and II.

In line with the original goal of this project, several HPLC systems were investigated for resolution of the diastereomeric mixture. However, satisfactory resolution was not achieved using various ion-exchange, reversed-phase partitioning, and ion-pairing techniques.

The optical rotations were determined on I and II in chloroform using a recording polarimeter[6]. The specific rotations were calculated for each derivative: I, $[\alpha]_D^{25} = -25.4°$, 0.965; and II, $[\alpha]_D^{25} = -51.2°$, 0.702.

The IR[7] spectra of I and II were identical and gave absorbance bands in agreement with their structure.

The UV and visible[8] absorptivity values for I and II in chloroform are recorded in Table II.

Ionization Kinetics of the Carbon Acid Phenindione

V. J. STELLA ˣ **and R. GISH**

Received December 14, 1978, from the *Department of Pharmaceutical Chemistry, University of Kansas, Lawrence, KS 66045.* Accepted for publication February 20, 1979.

Abstract □ The ionization kinetics of carbon acids are slow relative to those of classical acids and bases. Phenindione (2-phenyl-1,3-indandione) is a 1,3-diketone carbon acid of macroscopic experimental pKa 4.09 at 25° and ionic strength 0.1. The ionization kinetics of phenindione were determined at an ionic strength of 0.1 and 25° using stopped-flow spectrophotometry and a pH jump technique. A log k'_{obs}–pH profile for the approach to the ionization equilibrium was determined, and a mechanism consistent with the profile was postulated. The percent enol *versus* diketo form of phenindione and the pKa_{enol} and pKa_{diketo} were calculated from the kinetic data. Phenindione acid deprotonation kinetics by various oxygen and nitrogen bases suggested that, with bases of pKa 4.7–8.5 and in the pH 5–8.5 range, the acidic phenindione proton was ~45% transferred in the rate-determining transition state.

Keyphrases □ Phenindione—ionization kinetics, stopped-flow spectrophotometric and pH analysis, model □ Anticoagulants—phenindione, ionization kinetics, pH □ Kinetics, ionization—phenindione

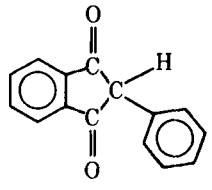
Phenindione (I) (2-phenyl-1,3-indandione) is an anticoagulant used in patients where the more popular anticoagulants are contraindicated. It is a 1,3-diketone carbon acid [lit. pKa 4.13 (1), 4.10 (2), 5.4 (3)]. Recent work (4, 5) suggested that some of the nonclassical phase transport behavior of another carbon acid, phenylbutazone, might be accounted for by its relatively slow ionization rate. Noninstantaneous ionization is a characteristic of some carbon acids (6–10).

The ionization kinetics of phenindione have not been studied previously, although the ionization kinetics of other carbon acids of much higher pKa's than those of phenindione and phenylbutazone have been well documented in the chemical literature (6–24). The immediate objective of this study was to determine the kinetics and mechanism of ionization of phenindione and to compare its behavior to that of phenylbutazone. Studying the kinetics and mechanism of ionization of a number of carbon acids of varying acidity might permit accurate prediction of the ionization kinetics of other pharmaceutically significant carbon acids. The ultimate objective is to use this information, combined with current ongoing mass transport studies, to predict the effect of noninstantaneous ionization kinetics on the mass transport behavior of carbon acids.

EXPERIMENTAL

Materials—Phenindione[1] was used as received. All reactions and pKa determinations were carried out in double-deionized, carbon dioxide-free water, freshly deoxygenated with oxygen-free nitrogen. The sodium chloride used to adjust the ionic strength was analytical reagent quality and was used without further purification. Hydrochloric acid, acetic acid–acetate, phosphate, and imidazole buffers were prepared with analytical grade components without further purification.

Pyridine, 3-methylpyridine (3-picoline), and morpholine were freshly purified by fractional distillation from potassium hydroxide pellets and stored over molecular sieves. A buffer component, 4-methoxypyridine, was prepared by the catalytic reduction of 4-methoxypyridine-*N*-oxide[2] using a literature method (25) for the reduction of 4-ethoxypyridine-*N*-oxide to 4-ethoxypyridine.



I

pKa Determination—The pKa of phenindione was determined spectrophotometrically[3] (26) at 326 nm and the same temperature and ionic strength conditions as in the kinetic studies, *i.e.*, 25 ± 0.2° and μ = 0.1 (sodium chloride). The pKa's of the various buffers used in the kinetic studies were determined potentiometrically using a pH meter[4] standardized with a standard buffer to a pH near the expected buffer component pKa (26).

Kinetic Studies—The procedures used to follow phenindione ionization kinetics were similar to those previously described for phenylbutazone (4). The reactions were followed at 326 nm, and the initial phenindione concentration was 1×10^{-4} *M*. At a pH where the primary reaction was the protonation of the mesomeric phenindione anion to phenindione acid, phenindione at pH ~7 was jumped to acidic pH (hydrochloric acid buffer or acetate buffer). At a pH where the primary reaction was the phenindione acid deprotonation to the mesomeric anion, phenindione in an aqueous solution of μ = 0.1 and with pH adjusted to ~4 with hydrochloric acid was jumped to the final pH by mixing with a buffer of desired final pH but double the desired final concentration.

The pH values after solution mixing were determined independently by mixing equal volumes of the phenindione solution and the buffer component. In most cases, the final pH was identical to that of the buffer solution. The exceptions were the most dilute morpholine buffer concentrations (see *Results and Discussion*), the hydrochloride acid buffer (final hydrochloric acid concentration was half the initial concentration), and one study where an unbuffered phenindione solution (pH ~4) was mixed with a very dilute sodium hydroxide solution (2×10^{-4} *M*). In this last case, the final pH was 8.91, even though the pH was expected to be closer to 10. The pH's used to construct the pH profile (Fig. 1) for the hydrochloric acid solutions and the sodium hydroxide solution were those measured experimentally.

RESULTS AND DISCUSSION

Figure 2 shows the phenindione UV spectrum under basic as well as acidic conditions, 0.1 *M* NaOH and 0.1 *M* HCl, respectively. The strong bathochromic shift from acidic to basic pH conditions is due to the extended conjugation on ionization, *i.e.*, coupling of the two phenindione phenyl rings through the enolate double bond (1). The macroscopic dissociation constant of phenindione was determined by observing the change in absorbance of a 1×10^{-4} *M* phenindione solution (25° and μ = 0.1) at pH 1 (0.1 *M* HCl), in the pH 2–6 range (acetate buffer), and at pH 13 (0.1 *M* NaOH).

The K_a was determined from a plot of $(A - A_0)[H^+]$ *versus* A as described previously (4), where A is the phenindione absorbance at a given hydrogen-ion concentration, $[H^+]$, and A_0 is the phenindione absorbance under acid conditions, *i.e.*, with the ionization completely suppressed (0.1 *M* HCl). The K_a under the experimental conditions was 8.13×10^{-5}, giving a pKa of 4.09. This value compares favorably with the literature pKa values (1–3) when differences in ionic strength and solvent composition are considered.

Table I gives the observed rate constants, k_{obs} (sec^{-1}), for phenindione ionization kinetics under various pH and buffer concentrations. All observed rate constants are the mean of three or more determinations. Also

[a] Experimentally measured final pH. [b] NA = not applicable.

included in this table are the observed rate constants extrapolated to zero buffer concentrations, k'_{obs} (sec^{-1}), obtained from plots of k_{obs} *versus* total buffer concentration. Figure 1 is a plot of log k_{obs} *versus* pH from the phenindione ionization.

A possible model for phenindione ionization kinetics is given in Scheme I, where K is the diketo form of phenindione and the predominant neutral form of phenindione in aqueous solution (1), E is the enol form of phenindione, and E^- is the so-called mesomeric anion (7). The macroscopic dissociation constant for phenindione is defined by:

$$K_a = \frac{[E^-][H^+]}{[K] + [E]} \qquad \text{(Eq. 1)}$$

which can be rearranged to:

$$\frac{1}{K_a} = \frac{1}{K_{a,diketo}} + \frac{1}{K_{a,enol}} \qquad \text{(Eq. 2)}$$

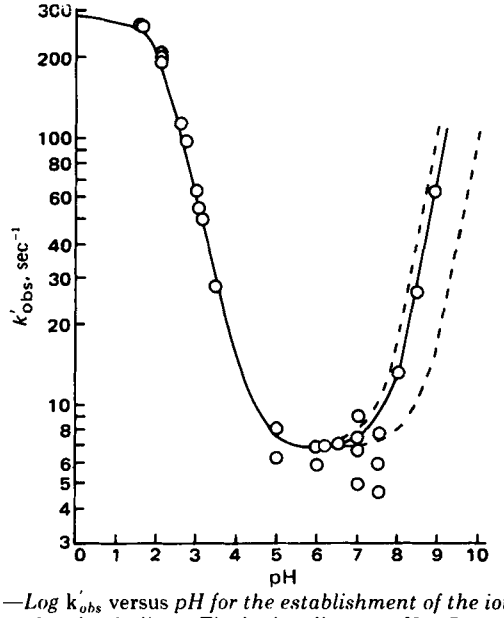

Figure 1—*Log* k'_{obs} versus *pH for the establishment of the ionization equilibrium for phenindione. The broken lines at pH > 7 represent* k_3 *having the limits of* 10^6–10^7 M^{-1} sec^{-1}. *The lack of reproducibility of the data at pH > 8 precludes placing an accurate value on* k_3.

Equation 2 shows the relationship between the macroscopic dissociation constant, K_a, and the microscopic constants, $K_{a,diketo}$ and $K_{a,enol}$. The percent enol present in aqueous solution will be defined by the relative values of $K_{a,diketo}$ and $K_{a,enol}$. The percent enol is defined by:

$$\% \text{ enol} = \frac{[E]}{[K] + [E]} (100) \qquad \text{(Eq. 3)}$$

which can be rearranged to:

$$\% \text{ enol} = \frac{K_{a,diketo}}{K_{a,diketo} + K_{a,enol}} \left(\frac{100}{1}\right) \qquad \text{(Eq. 4)}$$

The assumption can be made that the equilibrium defined by $K_{a,enol}$ is rapid and instantaneous[5] (7). The rate constant k_1 represents the water-catalyzed phenindione deprotonation, k_3 is the hydroxide-ion-catalyzed deprotonation rate constant, and k_{GB} is the general base-catalyzed deprotonation rate constant. The constant k_2 represents the hydronium-catalyzed protonation constant, *i.e.*, the addition of a proton at C-2 of the mesomeric anion; k_4 is the water or spontaneous protonation rate constant, and k_{GA} is the general acid-catalyzed protonation rate constant.

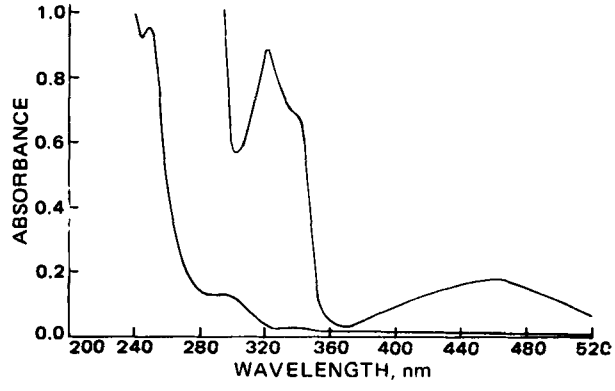

Figure 2—*Phenindione (1 × 10⁻⁴ M) UV spectrum in 0.1 M NaOH (upper curve) and in 0.1 M HCl (lower curve).*

[5] The word instantaneous is used to describe phenomena taking place at rates near the diffusion-controlled limit.

Table II—Final pH after Mixing Equal Volumes of the Initial Morpholine Buffer Solution (Double the Final Concentration) with the Phenindione Solution [a]

Initial Buffer pH	Buffer Concentration (after Mixing), M	Measured Final pH
8.00	2×10^{-3}	7.80[b]
8.00	4×10^{-3}	7.94
8.00	6×10^{-3}	7.98
8.00	8×10^{-3}	8.00
8.00	10×10^{-3}	8.00
8.50	2×10^{-3}	8.44[b]
8.50	4×10^{-3}	8.49
8.50	6×10^{-3}	8.50
8.50	8×10^{-3}	8.50
8.50	10×10^{-3}	8.50

[a] Aqueous phenindione solution of $\mu = 0.1$ with sodium chloride and added hydrochloric acid sufficient to give a pH of ~4. [b] As expected, both of these buffers gave negative deviations in plots of k_{obs} *versus* $[buffer]_T$ so neither was used in the k_{CAT} calculations.

With the assumption of Scheme I, an equation for the approach to the ionization equilibrium can be derived for any perturbation of that equilibrium (4):

$$k'_{obs} = k_1 + k_3[OH^-] + \frac{k_2[H^+]K_{a,enol}}{K_{a,enol} + [H^+]} + \frac{k_4 K_{a,enol}}{K_{a,enol} + [H^+]} \quad \text{(Eq. 5)}$$

For example, if a pH ~ 7 phenindione solution is perturbed rapidly (in the stopped-flow apparatus) to pH ~ 2, the first reaction is the instantaneous protonation of the mesomeric anion to the enol, E, and eventually (at equilibrium) to a mixture of the enol and diketo phenindione forms. Similarly, an acidic phenindione solution perturbed to alkaline pH involves primarily the deprotonation of the diketo phenindione and the small fraction of enol to the mesomeric anion. The observed buffer independent rate constant for the attainment of equilibrium, k'_{obs}, is the sum of both the forward and reverse rate constants because the system under study is a reversible reaction.

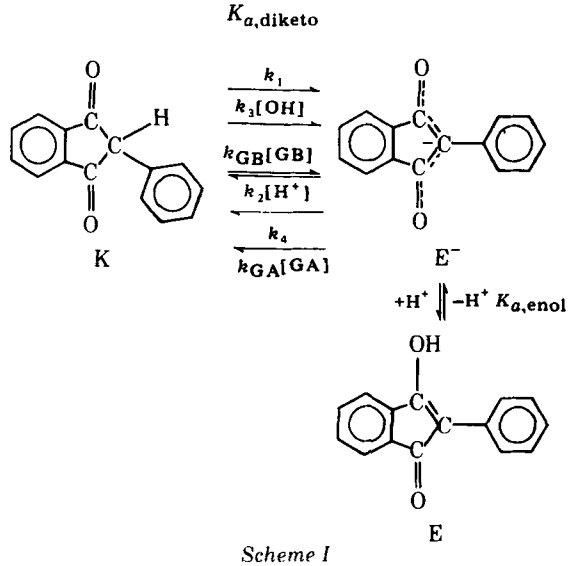
UV spectroscopic studies (1) showed that phenindione exists predominantly in its diketo form in aqueous solution. This means (Eq. 4) that $pKa_{diketo} \gg pKa_{enol}$ so that $pKa_{diketo} \sim pKa$ and $pKa_{enol} \ll 4.09$. From Fig. 1, phenindione deprotonation to form the anion, *i.e.*, pH > pKa_{diketo}, the k'_{obs} can be given by:

$$k'_{obs} = k_1 + \frac{k_4 K_{a,enol}}{K_{a,enol} + [H^+]} + k_3[OH^-] \quad \text{(Eq. 6)}$$

and since $K_{a,enol} \gg [H^+]$ at the pH's in question, Eq. 6 simplifies to:

$$k'_{obs} = (k_1 + k_4) + k_3[OH^-] \quad \text{(Eq. 7)}$$

As discussed previously (4), k_4 is negligible relative to k_1, so the plateau seen in Fig. 1 in the pH 5–7.5 range is essentially due to k_1. The constant k_1 calculated as the mean values of k'_{obs} in the pH 6.0–7.0 range was 6.9 sec^{-1}.



Scheme I

Table III—Kinetic and Equilibrium Constants for Phenindione Ionization at 25° and $\mu = 0.1$ with Sodium Chloride

Parameter	Value
k_1	$6.9\ sec^{-1}$
k_2	$6.5 \times 10^4\ M^{-1}\ sec^{-1}$
k_3	$\sim 6 \times 10^6\ M^{-1}\ sec^{-1}$
k_4	$\sim 5.5 \times 10^{-4}\ sec^{-1}$
$K_{a,enol}$	4.24×10^{-3} ($pKa_{enol} = 2.37$)
$K_{a,diketo}$	1.06×10^{-4} (pKa = 3.97)
K_a	1.03×10^{-4} (pKa = 3.99[a])
	8.13×10^{-5} (pKa = 4.09[b])
% enol	2.4

[a] Determined kinetically. [b] Determined spectrophotometrically.

The limited number of points and the questionable accuracy of the unbuffered hydroxide-ion solution reaction given on the last line of Table I allow only a crude k_3 estimate of between 10^6 and $10^7\ M^{-1}\ sec^{-1}$. For the sake of fitting the observed data to Eq. 5, $6 \times 10^6\ M^{-1}\ sec^{-1}$ was used for k_3. In an earlier study with phenylbutazone (4), borate buffers, which are poor proton-abstracting agents, were used at pH 8.5–9.5. Recent papers and some earlier work suggested that the ionization kinetics of borate buffers themselves are slow (27–33). This then raises the question as to what was the microscopic pH upon perturbing an acid solution of the carbon acid to an alkaline pH maintained with a borate buffer.

In the present study, when a borate buffer study was undertaken in the pH 8.5–9.5 range, an estimate of k_3 of closer to $1 \times 10^6\ M^{-1}\ sec^{-1}$ was made. This would suggest that the earlier k_3 estimate for phenylbutazone deprotonation by hydroxide ion may be low. Unfortunately, other techniques for following fast reactions cannot be applied to the deprotonation reactions in question. Even though k_{obs} is in the measurable range (by stopped-flow spectrophotometry) at pH 8–9, the pH after mixing must be maintained with a buffer of sufficient buffer capacity. Normally, the buffer concentration is varied and plots of k_{obs} *versus* buffer concentrations are extrapolated to zero buffer concentration to obtain k'_{obs}. This approach was attempted with morpholine buffer at pH 8.00 and 8.50 (Table I) and concentrations after mixing of below $1 \times 10^{-2}\ M$.

Table II gives the final pH values after the morpholine buffers were mixed with the phenindione solution (pH ~ 4 with hydrochloric acid). At the low buffer concentrations, significant pH alterations, affecting both the hydroxide-ion concentration and the fraction of total morpholine present in the the unionized state, occurred. Higher buffer concentrations or stronger bases could not be used because the deprotonation reaction became too rapid to be followed by stopped-flow spectrophotometry. The phenindione solution had to be somewhat acidic so that sufficient spectral alteration would occur as a result of the pH perturbation to allow the reaction to be followed spectrophotometrically.

At pH < 8, the $k_3[OH^-]$ term is negligible and, since k_4 is small relative to all other terms:

$$k'_{obs} = k_1 + \frac{k_2[H^+]K_{a,enol}}{K_{a,enol} + [H^+]} \quad \text{(Eq. 8)}$$

which can be rearranged to:

$$\frac{1}{k'_{obs} - k_1} = \frac{1}{k_2[H^+]} + \frac{1}{k_2 K_{a,enol}} \quad \text{(Eq. 9)}$$

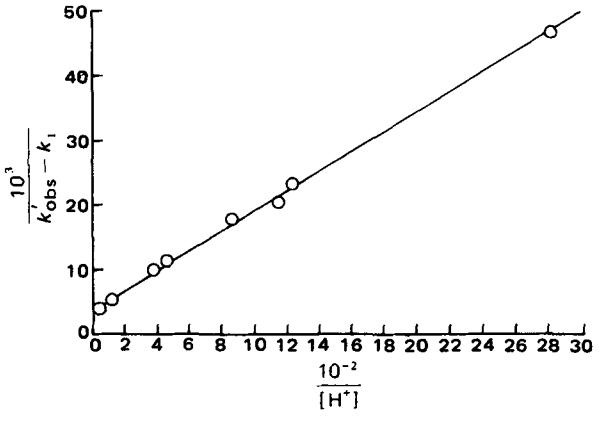


Figure 3—*Plot used to determine* k_2 *and* $K_{a,enol}$ *for phenindione ionization (Eq. 9 and Scheme I).*

predicting that a plot of the left side of Eq. 9 against $1/[H^+]$ should give a straight line of slope $1/k_2$ and intercept $1/k_2K_{a,enol}$, thus allowing both k_2 and $K_{a,enol}$ to be calculated. Such a plot for phenindione is shown in Fig. 3. The calculated values of k_2 and $K_{a,enol}$ are $6.5 \times 10^4\ M^{-1}\ sec^{-1}$ and $4.24 \times 10^{-3}\ M$, respectively ($pK_{a_{enol}} = 2.37$).

According to Scheme I, the equilibrium ionization constant for diketo phenindione is:

$$K_{a,diketo} = \frac{k_1}{k_2} = \frac{6.9}{6.5 \times 10^4} = 1.06 \times 10^{-4}\ M \qquad \text{(Eq. 10)}$$

Having determined $K_{a,enol}$ and $K_{a,diketo}$ and using Eq. 4, the enol was calculated at 2.4%.

Table III summarizes the kinetic and equilibrium constants calculated. The values for rate constants from Table III were placed into Eq. 5 to generate a theoretical curve for phenindione ionization kinetics at various pH's, assuming the mechanism shown in Scheme I. The solid line drawn in Fig. 1 is the line generated by Eq. 5 and the appropriate values in Table III. Apparently, Eq. 5 and Scheme I adequately describe the observed values, although other mechanisms may be possible (4).

A comparison of the values of k_1 and k_2, the two most accurately determined rate constants for both phenylbutazone and phenindione, highlights some interesting points. The lower pKa of phenindione relative to phenylbutazone, 3.99 *versus* 4.33, is due to changes in both k_1 and k_2. *A priori*, based on the strength of the acids, k_1 for phenindione (the stronger acid) would be expected to be greater than that for phenylbutazone. Such is not the case. The constant k_1 has a value of 6.9 sec^{-1} for phenindione compared to 10.1 sec^{-1} for phenylbutazone. The small differences in k_1, ~30%, are more than compensated by the differences in k_2. The constant k_2 has a value of $6.5 \times 10^4\ M^{-1}\ sec^{-1}$ for phenindione relative to $2.1 \times 10^5\ M^{-1}\ sec^{-1}$ for phenylbutazone. The greater acidity of phenindione relative to phenylbutazone is controlled not by how readily the acid gives up its proton but by the ability of its base form to accept a proton.

Equation 5 appears to describe adequately phenindione protonation and deprotonation kinetics in the absence of buffer species capable of acting as general acids and bases. In the presence of acids and bases other than the water species, the observed rate constant for the approach to the ionization equilibrium after a pH perturbation would be given by:

$$k_{obs} = k'_{obs} + k_{GB}[GB] + \frac{k_{GA}[GA]K_{a,enol}}{[H^+] + K_{a,enol}} \qquad \text{(Eq. 11)}$$

and since at pH > 4, $K_{a,enol} \gg [H^+]$, Eq. 11 reduces to:

$$k_{obs} = k'_{obs} + k_{GB}[GB] + k_{GA}[GA] \qquad \text{(Eq. 12)}$$

$$k_{obs} = k'_{obs} + k_{CAT}\,[buffer]_T \qquad \text{(Eq. 13)}$$

where k_{CAT} is the observed catalytic rate constant for any buffer at any given pH value. This is equal to:

$$k_{CAT} = k_{GB}f + k_{GA}(1 - f) \qquad \text{(Eq. 14)}$$

$$k_{CAT} = f(k_{GB} - k_{GA}) + k_{GA} \qquad \text{(Eq. 15)}$$

where f is equal to the fraction of total buffer species in the base form and $(1 - f)$ is the fraction of total buffer species in its acid form at any given pH. For any given singly dissociating buffer species with a known dissociation constant, f can be calculated from:

$$f = \frac{[H^+]}{K'_a + [H^+]} \qquad \text{(Eq. 16)}$$

where K'_a is the dissociation constant of the conjugate acid form of the buffer. Equation 13 predicts that a plot of k_{obs} *versus* total buffer concentrations, $[buffer]_T$, would be linear with slope k_{CAT} and intercept k'_{obs}. A plot of k_{CAT} *versus* f is predicted from Eq. 15 to be linear with an intercept at $f = 0$ of k_{GA} and an intercept at $f = 1$ of k_{GB}. With the buffers studied, acetate, phosphate, pyridine, 3-methylpyridine, 4-methoxypyridine, imidazole, and morpholine, all plots of k_{obs} *versus* total buffer concentration were linear. From plots of k_{CAT} *versus* f, for all cases except acetic acid, k_{GA} was negligible relative to k_{GB}. When a small or even slightly negative intercept at $f = 0$ was seen from plots of k_{CAT} *versus* f, k_{GB} was calculated from k_{CAT}/f and the mean values of k_{GB} for the various bases calculated at different pH's are recorded in Table IV. Table IV is a compilation of the calculated k_{GA} and k_{GB} values for all of the buffers and water species.

A Brønsted plot (19, 23, 34) of log k_{GB} *versus* the pKa''s of the various buffers is given in Fig. 4. When studying a limited number of bases (acetate through morpholine in the present study) for a reaction catalyzed by general bases, apparent linear Brønsted plots usually result (19, 23).

Table IV—Calculated k_{GA} and k_{GB}

Buffer (pKa)	k_2, k_4, or k_{GA}, $M^{-1}\ sec^{-1}$	k_1, k_3, or k_{GB}, $M^{-1}\ sec^{-1}$
H_3O^+ (−1.74)	6.5×10^4	—
H_2O (−1.74 and 15.74)[a]	1×10^{-5} (5.5 $\times 10^{-4}$/55.5)[b]	1.24×10^{-1} (6.9/55.5)[b]
Acetic acid (4.70)	1161	828
Pyridine (5.28)	263	3635
3-Methylpyridine (5.75)	—[c]	5210[c]
4-Methoxypyridine (6.64)	—[c]	6458[c]
Imidazole (7.10)	—[c]	5728[c]
Morpholine (8.53)	—[c]	48123[c]
Phosphoric acid (2.12)	1223[d]	1223[d]
Phosphoric acid (6.75)	—	2861[d]
OH^- (15.74)	—	6×10^6

[a] When H_2O is acting as a base, its conjugate acid is H_3O^+. When H_2O is acting as an acid, its conjugate base is OH^-. [b] From the kinetic study, it was possible to calculate the rate constants for H_2O acting both as an acid and a base. [c] Plots of k_{CAT} *versus* gave either negligible k_{GA} values or slightly negative values. Therefore, k_{GB} was calculated as the mean value for k_{CAT}/f for each pH studied. [d] This refers to $H_2PO_4^-$ acting as either a general acid or a general base. Because of this ambiguity, the point for $H_2PO_4^-$ was not included in Fig. 4. It is not possible to determine in what capacity $H_2PO_4^-$ is acting. Although HPO_4^{2-} is capable of acting either as an acid or a base, it is more likely acting as a base.

It is becoming increasingly obvious that over a more extensive range of bases, nonlinear Brønsted plots, especially for the ionization kinetics of carbon acids, are more the rule than the exception (6, 7, 19, 23). The reason behind the nonlinearity was first discussed by Eigen (7) and quantitated recently by the Marcus theory (23, 35).

The Marcus theory of general base catalysis suggests that a quadratic fit to the Brønsted plot is more accurate and reflects more closely the mechanism of such catalysis. The solid curved line drawn through the points in Fig. 4 is the quadratic fit[6] to the data. The number of bases studied in the present work was limited by the speed of the reaction. Of course, the catalytic effect of water acting as a base could be determined because of its high intrinsic concentration (55.5 *M*), and hydroxide-ion catalysis could be approximately determined because its effective concentration could be determined from pH measurements.

The solid curved line in Fig. 4 is described by:

$$\log k_{GB} = -1.36 \times 10^{-2}\,pKa'^2 + 6.25 \times 10^{-1}\,pKa' + 2.76 \times 10^{-1} \qquad \text{(Eq. 17)}$$

Differentiation of Eq. 17 would give the slope of the line at any point and is described by Eq. 18. For a Brønsted plot, the slope for general base-catalyzed reactions is given the designation β:

$$\beta = \frac{d(\log k_{GB})}{d(pKa')} = -2.72 \times 10^{-2}\,pKa' + 0.625 \qquad \text{(Eq. 18)}$$

The Brønsted plot resulting from the present study could just as easily be described by a linear plot, with the H_2O term and the OH^- term giving

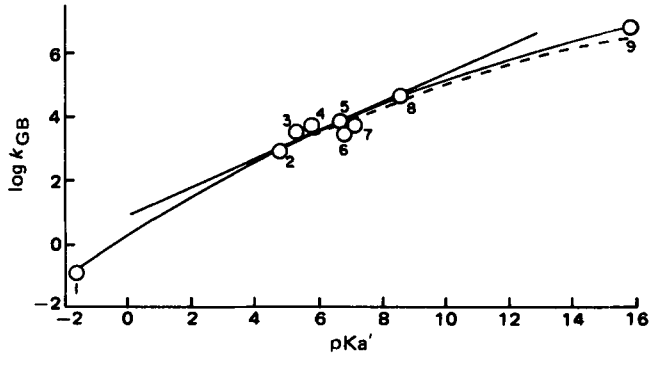

Figure 4—*Log* k_{GB} versus *pKa' for phenindione deprotonation by various general bases of varying pKa. Key: 1, water; 2, acetate; 3, pyridine; 4, 3-methylpyridine; 5, 4-methoxypyridine; 6, monohydrogen phosphate; 7, imidazole; 8, morpholine; and 9, hydroxide ion.*

[6] Least-squares analysis; TI59 programmable calculator utilizing the solid-state statistic module.

negative deviations from the linear plot. Such a plot would be given by the solid straight line in Fig. 4. The slope of the line is 0.45.

The Marcus theory states that when the pKa′ of the general base is equal to the carbon acid pKa, β, the slope of the Brønsted plot, should be equal to 0.5. Substitution of 3.99 for the phenindione pKa into Eq. 18 gives a β value of 0.52. Kresge (23) and Hupe and Wu (19) recently attempted to interpret the nonlinear Brønsted plots often seen for the ionization of various carbon acids. The Marcus theory (35) for such curvature relates the free energy of activation, $\Delta G^{\neq}$, for the proton transfer process to the energy required to bring the reactants together, Wr, and the intrinsic energy involved in the proton transfer, $(1 + \Delta G_0/4\Delta G_0^{\neq})^2\Delta G_0^{\neq}$, as defined by Eq. 19. The term ΔG_0 is the free energy for proton transfer at equilibrium, and $\Delta G_0^{\neq}$ is the free energy of activation for the proton transfer when $\Delta G_0 = 0$. That is, ΔG_0 is equal to zero when the pKa′ of the general base is equal to the pKa of the carbon acid:

$$\Delta G^{\neq} = (1 + \Delta G_0/4\Delta G_0^{\neq})^2\Delta G_0^{\neq} + Wr \qquad \text{(Eq. 19)}$$

The term ΔG_0 can be calculated from:

$$\Delta G_0 = -RT \ln(K_a'/K_a) \qquad \text{(Eq. 20)}$$

From the quadratic fit to the general base data (Eq. 17), k_{GB} at pKa′ 3.99 was calculated to be 357 M^{-1} sec^{-1}; $\Delta G^{\neq}$, calculated by solving for $\Delta G^{\neq}$ from:

$$k_{GB} = 10^{12.74} e^{-\Delta G^{\neq}/RT} \qquad \text{(Eq. 21)}$$

is equal to 13,899 cal/mole (~13,900 cal/mole). It is possible to relate the first coefficient (pKa′^{2} term) of Eq. 17, a, directly to the term $\Delta G_0^{\neq}$ through (23):

$$a = \frac{2.303RT}{16\Delta G_0^{\neq}} \qquad \text{(Eq. 22)}$$

thus allowing $\Delta G_0^{\neq}$ to be calculated. A value of ~6300 cal/mole was thus determined for $\Delta G_0^{\neq}$. Having calculated $\Delta G_0^{\neq}$ as ~6300 cal/mole and $\Delta G^{\neq}$ as ~13,900 cal/mole, at pKa′ = pKa, Wr can be estimated as ~7600 cal/mole. By using the values for $\Delta G_0^{\neq}$ of 6300 cal/mole and Wr of 7600 cal/mole, $\Delta G^{\neq}$ from the full range of bases (H_2O–OH^-) can be calculated and compared to the quadratic fit to Eq. 17. The broken line in Fig. 4 is the line generated from Eqs. 19 and 21. Note that the broken line was generated from Eqs. 19 and 21 using the information that, at pKa′ 3.99, the two lines should have intersected. That is, the solid curved line and the curved broken line intersect at pKa′ 3.99.

The interpretation of these observations is that carbon acid deprotonation involves two processes: (*a*) a work term, which includes desolvation of the incoming base and alteration in the solvation around the reaction center as well as getting the molecule in the correct configuration for proton abstraction, and (*b*) the energy required for breaking the carbon–hydrogen bond. The Wr term in Eq. 19, which is considered to be the work required to bring the two reacting molecules together, has an energy requirement of 7600 cal/mole, which is a little more than the energy required to break a hydrogen bond (36). Similarly, the standard free energy of activation, $\Delta G_0^{\neq}$, which is related to the intrinsic barrier to the breaking of the carbon–hydrogen bond, also has an energy requirement that is a little more than that required to break a weak carbon hydrogen bond (36).

In the past, the apparent negative deviation of hydroxide ion in linear Brønsted plots was always interpreted as the "anomolous" behavior of hydroxide ion. A study involving proton abstraction from a weak carbon acid (19) recently showed that hydroxide-ion behavior is not "anomalous" when other weak oxygen acids are included; *i.e.*, hydroxide ion acted as predicted for a base of pKa 15.74. The Brønsted plot curvature was interpreted as a change in the rate-determining step in going from weak bases to strong bases such as hydroxide ions. That is, with weak bases, the major rate-determining factor is the carbon–hydrogen bond breaking (first term in Eq. 19 is dominant) while with stronger bases the work term, Wr, begins to dominate. The reverse of this step (protonation of the mesomeric anion by a water molecule) has shown similarly anomalous kinetic behavior, suggesting that solvent reorganization around the reaction center may contribute to the rate-determining step (4, 37). As discussed previously (19), the alternative mechanism of a gradual change only in the degree of proton transfer in going from weak to stronger bases does *not* appear to be reasonable for the nonlinear Brønsted plot, although this mechanism cannot be totally ruled out.

If the Brønsted slope, β, *does* approximate the degree of a proton transfer over a limited pKa′ range for weak bases (23), it can be seen from Fig. 4 that a Brønsted slope of 0.45 is calculated for bases with a pKa′ of 4.7–8.53. An interpretation of this result is that the phenindione proton is 45% transferred in the rate-determining transition state for proton abstraction by these bases. A way of testing the hypothesis that a change is occurring at the reaction center in going from proton abstraction by a very weak base (water) to stronger bases (buffers used in present study) to very strong bases (hydroxide ion) would be to study the effects of electron-withdrawing and electron-donating groups on both the pKa and ionization kinetics of 4′-substituted 2-phenyl-1,3-indandiones. Such a study will be reported separately (38).

In summary, the ionization kinetics of phenindione in aqueous solution appear to be qualitatively similar to those of phenylbutazone, but quantitative differences do occur. A study of the effect of various bases in promoting proton abstraction from phenindione has led to some insights into possible rate-determining transition states for the deprotonation reaction. The various rate constants calculated for proton donation and abstraction during phenindione ionization are substantially slower than the diffusion-limited constants for the ionization of normal or classical acids such as carboxylic, phenolic, and nitrogen acids. The ionization kinetics generated from this work will be used along with ongoing mass transport studies to predict the effect of noninstantaneous ionization kinetics on the mass transport behavior of carbon acids.

Kinetics and Mechanism of Ionization of the Carbon Acids 4′-Substituted 2-Phenyl-1,3-indandiones

V. J. STELLA ˣ and R. GISH

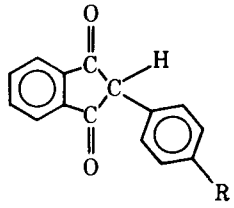
Received December 14, 1978, from the *Department of Pharmaceutical Chemistry, University of Kansas, Lawrence, KS 66045.* Accepted for publication February 20, 1979.

Abstract □ The ionization kinetics of 1,3-diketone carbon acids are slow relative to those of classical acids and bases. The ionization kinetics of three 4′-substituted 2-phenyl-1,3-indandiones, 4′-chloro-, 4′-methoxy-, and 2-phenyl-1,3-indandione itself, were studied at 25° and ionic strength 0.1 using stopped-flow spectrometry and a pH jump technique. A log k'_{obs}–pH profile for the approach to the ionization equilibrium was consistent with a reaction scheme postulated earlier for the ionization of another carbon acid, phenylbutazone. The percent enol *versus* diketo form of the acids and the pKa_{enol} and pKa_{diketo} were calculated from the kinetic data. Hammett plots of the various kinetic and equilibrium constants supported a mechanism for acid deprotonation consistent with proton abstraction being the predominant process when very weak bases such as water were the proton acceptors. Desolvation effects and the work required to get the two reacting molecules together in the correct configurations predominated when the proton abstraction was by stronger proton acceptors.

Keyphrases □ Carbon acids—ionization kinetics, stopped-flow spectrophotometric and pH jump analysis □ Ionization kinetics—carbon acids, anisindione, phenindione, clorindione □ Anticoagulants—anisindione, phenindione, clorindione, ionization kinetics

The objective of this study was to compare the kinetics and ionization of the 1,3-diketone carbon acids anisindione (I), phenindione (II), and clorindione (III). All three compounds are used clinically as anticoagulants. The ionization kinetics of phenindione and phenylbutazone, two carbon acids of pharmaceutical interest, were reported previously (1, 2). Kinetic data for the deprotonation of various carbon acids have appeared in the chemical literature, but few studies of the effects of electron-withdrawing and electron-donating groups on the ionization kinetics and mechanism have been reported. The reported chemical studies have concerned acids of fairly high pKa (3, 4) or substituted nitromethane carbon acids (3, 5–12).

The objectives of this work were to study the effects of electron-withdrawing and electron-donating substituents



I: R = OCH_3
II: R = H
III: R = Cl

on ionization kinetics of I–III and to determine whether the results supported a model proposed previously for phenindione ionization (1).

EXPERIMENTAL

Phenindione[1] and anisindione[2] were used as received. Clorindione was prepared by the reaction of phthalide and *p*-chlorobenzaldehyde in a sodium ethoxide–ethanol solution using a literature procedure (13) for the synthesis of various 2-phenyl-1,3-indandiones. All other materials, kinetic procedures, conditions, and methods of pKa determination were identical to those described previously (1).

RESULTS AND DISCUSSION

The macroscopic dissociation constants for I–III, determined spectrophotometrically in aqueous solution at 25° and $\mu = 0.1$, are given in Table I. These values compare favorably with the literature values for the pKa's when solvent differences are considered.

Figure 1 is a plot of log k'_{obs} *versus* pH for the approach to ionization equilibrium for I–III. The rate constant k'_{obs} is the pseudo-first-order observed rate constant for the approach to ionization equilibrium extrapolated to zero buffer concentration. A possible model for the ionization kinetics of I–III is given in Scheme I. This model is identical to the scheme postulated previously for phenylbutazone ionization (2).

The predominant neutral form of I–III in aqueous solution is the diketo species, K, rather than the enol species, E (14). The dissociated form of I–III is the so-called mesomeric anion, E^- (17). The macroscopic dissociation constant K_a, the percent enol, and k'_{obs} for the approach to ionization equilibrium in the absence of buffers are best described by Eqs. 1–3 (2):

$$\frac{1}{K_a} = \frac{1}{K_{a,enol}} + \frac{1}{K_{a,diketo}} \quad \text{(Eq. 1)}$$

$$\% \text{ enol} = \frac{K_{a,diketo}}{K_{a,enol} + K_{a,diketo}}\left(\frac{100}{1}\right) \quad \text{(Eq. 2)}$$

$$k'_{obs} = k_1 + k_3[OH^-] + \frac{k_2[H^+]K_{a,enol}}{K_{a,enol} + [H^+]} + \frac{k_4 K_{a,enol}}{K_{a,enol} + [H^+]} \quad \text{(Eq. 3)}$$

Table I—Macroscopic Ionization Constants for Anisindione, Phenindione, and Clorindione Determined Spectrophotometrically at 25 ± 0.1° and $\mu = 0.1$ with Sodium Chloride

Compound, Wavelength Used, nm	pKa	Literature pKa Values
Anisindione, 330	4.13	4.09 (14), 4.25 (15), 5.6 (16)
Phenindione, 326	4.09	4.10 (14), 4.13 (15), 5.4 (16)
Clorindione, 284	3.59	3.54 (14), 3.72 (15), 4.8 (16)

III: R = Cl

on ionization kinetics of I–III and to determine whether the results supported a model proposed previously for phenindione ionization (1).

EXPERIMENTAL

Phenindione[1] and anisindione[2] were used as received. Clorindione was prepared by the reaction of phthalide and *p*-chlorobenzaldehyde in a sodium ethoxide–ethanol solution using a literature procedure (13) for the synthesis of various 2-phenyl-1,3-indandiones. All other materials, kinetic procedures, conditions, and methods of pKa determination were identical to those described previously (1).

RESULTS AND DISCUSSION

The macroscopic dissociation constants for I–III, determined spectrophotometrically in aqueous solution at 25° and $\mu = 0.1$, are given in Table I. These values compare favorably with the literature values for the pKa's when solvent differences are considered.

Figure 1 is a plot of log k'_{obs} *versus* pH for the approach to ionization equilibrium for I–III. The rate constant k'_{obs} is the pseudo-first-order observed rate constant for the approach to ionization equilibrium extrapolated to zero buffer concentration. A possible model for the ionization kinetics of I–III is given in Scheme I. This model is identical to the scheme postulated previously for phenylbutazone ionization (2).

The predominant neutral form of I–III in aqueous solution is the diketo species, K, rather than the enol species, E (14). The dissociated form of I–III is the so-called mesomeric anion, E^- (17). The macroscopic dissociation constant K_a, the percent enol, and k'_{obs} for the approach to ionization equilibrium in the absence of buffers are best described by Eqs. 1–3 (2):

$$\frac{1}{K_a} = \frac{1}{K_{a,enol}} + \frac{1}{K_{a,diketo}} \quad \text{(Eq. 1)}$$

$$\% \text{ enol} = \frac{K_{a,diketo}}{K_{a,enol} + K_{a,diketo}}\left(\frac{100}{1}\right) \quad \text{(Eq. 2)}$$

$$k'_{obs} = k_1 + k_3[OH^-] + \frac{k_2[H^+]K_{a,enol}}{K_{a,enol} + [H^+]} + \frac{k_4 K_{a,enol}}{K_{a,enol} + [H^+]} \quad \text{(Eq. 3)}$$

Table I—Macroscopic Ionization Constants for Anisindione, Phenindione, and Clorindione Determined Spectrophotometrically at 25 ± 0.1° and $\mu = 0.1$ with Sodium Chloride

Compound, Wavelength Used, nm	pKa	Literature pKa Values

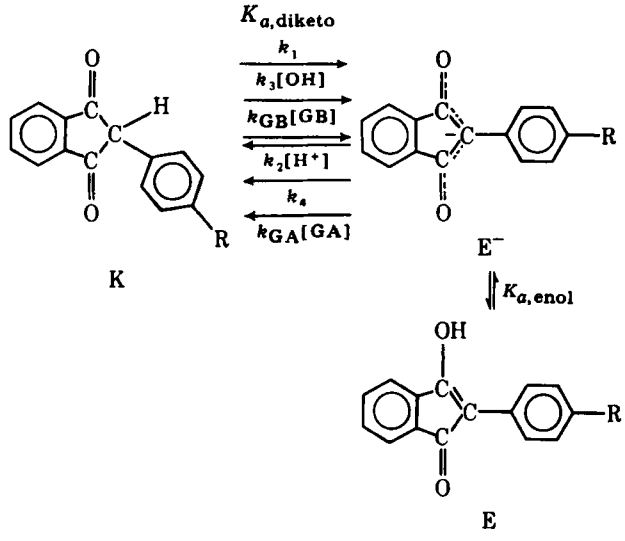
% enol	2.4	2.6	3.0	—

[a] The ρ value refers to the slope of log k *versus* σ for I–III and is a measure of the relative sensitivity of the parameter k to electron-donating and electron-withdrawing groups. [b] The σ value refers to the Hammett σ value for the various substituents, R. The σ values used were those for the ionization of phenols. G. B. Barlin and D. D. Perrin, *Q. Rev.*, **20**, 75 (1966). [c] Because of the inaccuracy in the values of these two rate constants, Hammett σ plots were not attempted.



Scheme I

Treatment of the k_{obs} data as previously described (1) allows estimates of the constants k_1, k_2, k_3, k_4, $K_{a,diketo}$, and $K_{a,enol}$ as well as k_{GB} and k_{GA} for those buffers used in the study. Table II summarizes the calculated buffer-independent kinetic and equilibrium constants. The values for the constants placed into Eq. 3 were used to generate the solid lines in Fig. 1. Apparently, Eq. 3 and Scheme I adequately describe the observed values, although, as discussed previously (1, 2), alternative mechanisms and schemes may be possible. The pKa values determined from the kinetic data compare favorably to those determined experimentally.

Unfortunately, little confidence can be placed on the k_3 values given in Table II since the pH range where the hydroxide-ion-catalyzed proton abstraction begins to be significant is also the region where stronger bases, buffers of high pKa′, must be used to control the pH. Normally the buffer concentration is varied while the pH is maintained constant and plots of k_{obs} *versus* buffer concentration are extrapolated to zero buffer concentration to obtain k'_{obs}. The constant k_{GB} can be calculated from the slopes (1). With stronger bases like morpholine, the plots have such a large slope that intercept values become very inaccurate. The use of lower buffer concentrations is not possible because the desired final pH cannot be maintained. All k_3 values appear to be between 10^6 and 10^7 M^{-1} sec^{-1} for I–III. Similarly, the accuracy of the k_4 values, which are calculated from k_3 and $k_{a,diketo}$, is limited by the accuracy of the k_3 values.

Although Eq. 3 appears to describe adequately the protonation and deprotonation kinetics of I–III in the absence of acids and bases other than water, analysis of kinetic data in the presence of general acids (GA) and bases (GB) (buffer components) requires a more complex equation. The observed pseudo-first-order rate constant for the approach to ionization equilibrium at constant pH could be described by Eq. 4 (1):

$$k_{obs} = k'_{obs} + k_{GB}[GB] + k_{GA}[GA] \qquad \text{(Eq. 4)}$$

The constants k_{GA} and k_{GB} can be determined for various buffer species if the ionization kinetics of I–III are determined at various buffer concentrations and pH values (1). Table III is a compilation of some calculated k_{GB} values for all buffer and water species studied for I–III. The conjugate acids of these bases did not show any significant general acid catalysis.

Table III—Values of k_{GB} for Various General Bases as well as Water and Hydroxide Ion for the Deprotonation at 25° and μ = 0.1 for I–III

General Base (pKa′)	k'_1, k_3, or k_{GB}, M^{-1} sec^{-1} I	II	III	ρ^a
H_2O (−1.74)	9.0×10^{-2} [b]	1.24×10^{-1} [b]	2.34×10^{-1} [b]	1.22
Pyridine (5.28)	2.7×10^3	3.6×10^3	3.8×10^3	0.39
3-Methylpyridine (5.75)	4.6×10^3	5.2×10^3	7.1×10^3	0.56
4-Methoxypyridine (6.64)	5.7×10^3	6.5×10^3	1×10^4	0.73
Imidazole (7.10)	5.2×10^3	5.7×10^3	8.0×10^3	0.56
Morpholine (8.53)	5.0×10^4	4.8×10^4	7.6×10^4	0.59
OH^- (15.74)	10^6–10^7	10^6–10^7	10^6–10^7	—[c]

[a] The ρ values have the same meaning as that described in Table II. The σ values used for substituents R also were the same. [b] These numbers are equal to $k_1/55.5 = k'_1$; *i.e.*, k_1 is a pseudo-first-order rate constant that has to be corrected for the water concentration, 55.5 M, to convert it to the second-order rate constant k'_1. [c] Because of the k_3 inaccuracy, Hammett plots were not attempted.

The effects of various electron-donating or electron-withdrawing substituents on any kinetic or equilibrium constant are best quantitated by linear free energy relations such as the Hammett equation:

$$\log k/k_0 = \rho\sigma \qquad \text{(Eq. 5)}$$

Equation 5 assumes that a free energy difference in any rate or equilib-

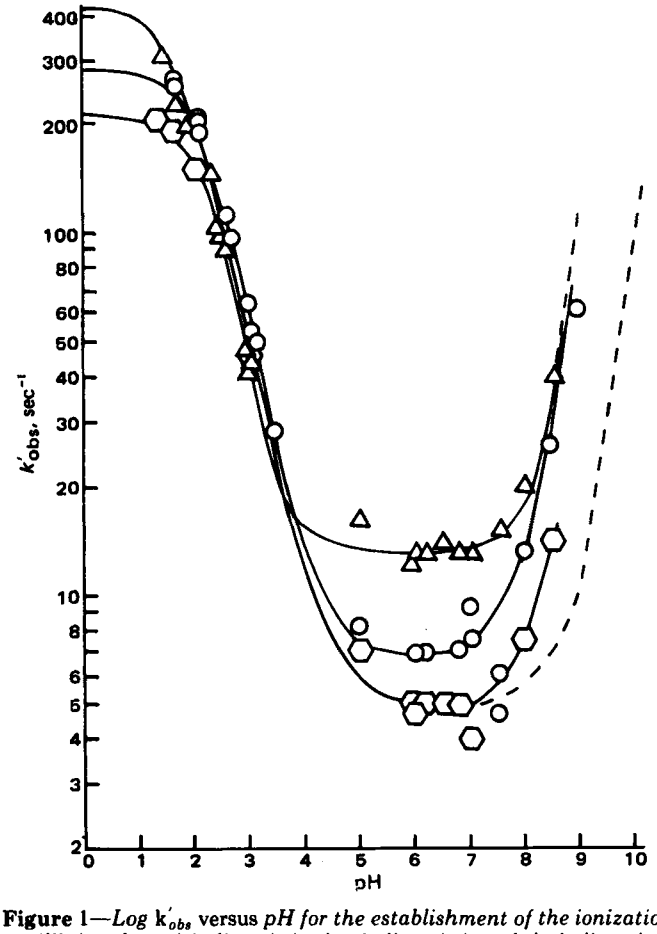


Figure 1—*Log* k'_{obs} versus *pH for the establishment of the ionization equilibrium for anisindione* (○), *phenindione* (○), *and clorindione* (△). *The broken lines at pH > 7 represent* k_3 *having the limits of* 10^6–10^7 M^{-1} *sec*$^{-1}$. *The lack of reproducibility of the data at pH > 8 precludes placing an accurate value on* k_3. *The solid lines drawn at pH > 7–8 are simply the best eyeball fit.*

rium process (given by $\log k/k_0$) between two compounds that differ only by a substituent is a linear function of some property of that substituent group. In Eq. 5, σ, the substituent constant, refers to the relative electron-donating (negative) or electron-withdrawing (positive) power of the substituent and ρ, the reaction constant, is a measure of the sensitivity of the constants, k, to changes in σ values of the substituents (18). The constant k_0 refers to the constant (rate or equilibrium constant) where the substituent is a hydrogen atom, *e.g.*, II.

In the present case, any proton abstraction reaction leading to a buildup of negative charge on the 2-position of the phenylindandiones will be stabilized by electron-withdrawing groups in the 4'-position (R), while electron-donating groups in the 4'-position will destabilize the transition state by increasing electron density at the 2-position. For example, k_1 of Scheme I refers to the pseudo-first-order rate constant for proton abstraction by the base, water. A plot of $\log k_1$ *versus* σ was linear with a slope, ρ, equal to 1.22. The reverse reaction, proton donation to the 2-position by hydronium ion, H_3O^+, represented by k_2 gave a ρ value of −0.88. This finding suggests that the R groups on the 4'-position of the phenylindandiones were having a greater effect on k_1 than on k_2.

The effects of the substituents on $K_{a,\text{enol}}$ and $K_{a,\text{diketo}}$ are also interesting. The $K_{a,\text{diketo}}$ term describes the equilibrium acidity constant associated with proton abstraction from the 2-position of the phenylindandiones. It would be expected to be more sensitive to substituent effects than $K_{a,\text{enol}}$, which represents proton abstraction from the enol form of the phenylindandiones, because the enol proton is further removed from the substituent. The measured ρ values of 2.08 for $K_{a,\text{diketo}}$ *versus* 1.77 for $K_{a,\text{enol}}$ are consistent with this hypothesis.

In an earlier paper (1), it was hypothesized from Brønsted data that the deprotonation rate of phenindione (II) was determined largely by the free energy of the proton abstraction step when weak bases were the proton acceptors, while with the stronger bases the deprotonation was significantly affected by the work necessary to get the molecules into the correct configuration and solvation state for reaction. If this were the case, these effects should be seen in the ρ value of a Hammett plot. Table III lists the ρ values for proton abstraction by various bases. The rate constant for proton abstraction by a weak base like water (pKa' = −1.74), ρ = 1.22, was more sensitive to substituent effects than the rate constants for proton abstraction by various other stronger bases, pyridine through morpholine (pKa' = 5.28–8.53), ρ = 0.39–0.74. The rather small ρ values for this latter group suggest that a smaller negative charge was formed on the 2-carbon of the phenylindandiones in the rate-determining proton abstraction transition state, which supports the hypothesis that the work required to desolvate and bring the two reacting species together probably contributes significantly to the free energy of reaction.

Eigen (17) and others (19) have suggested that proton abstraction from strong carbon acids should be relatively insensitive to pKa differences between the carbon acids. The present study supports this hypothesis when the proton abstracting base is a relatively strong base, *i.e.*, ρ is small. However, if the proton abstracting base is very weak, *e.g.*, water, the proton abstraction step can be sensitive to the pKa differences between the carbon acids; *i.e.*, substituent effects are significant, as measured by larger ρ values.

TLC Differentiation of Butyrophenone and Diphenylbutylpiperidine Compounds from Phenothiazine Derivatives

ACHILLE PLUYM

Received August 7, 1978, from the *Analytical Department, Janssen Pharmaceutica, B-2340 Beerse, Belgium.* Accepted for publication January 26, 1979.

Abstract □ A procedure is described for TLC detection and differentiation of the butyrophenone–diphenylbutylpiperidine group and phenothiazine derivatives at the microgram level. A two-dimensional TLC method to separate butyrophenone and diphenylbutylpiperidine compounds is reported. A variety of possible detection reagents were examined. The solvent systems and spray reagents described should be useful for the identification of these drugs in various dosage forms.

Keyphrases □ Butyrophenones—analysis, TLC, differentiation from phenothiazine derivatives □ Diphenylbutylpiperidines—analysis, TLC, differentiation from phenothiazine derivatives □ TLC—analysis, butyrophenones, diphenylbutylpiperidines, phenothiazine derivatives

Butyrophenones, diphenylbutylpiperidines, and the pharmacologically analogous phenothiazines are currently used for the treatment of various psychotic disorders. A rapid detection and identification method is needed for screening pharmaceutical formulations for these drugs.

Numerous investigators (1–13) described various solvent systems for chromatography of psychotropic drugs, mainly phenothiazine derivatives. However, none of these systems completely separates the two groups of neuroleptic compounds. In the proposed analytical system, group differentiation depends on R_f values and on color reactions to spray reagents. Identification of the butyrophenone or diphenylbutylpiperidine compounds can be accomplished with the described two-dimensional TLC method.

Table I—Guide R_f Values for Phenothiazine Derivatives (Eluent A)

Compound	R_f[a]	RR_f[b]
Acepromazine	0.23	0.72
Acetophenazine	0.20	0.62
Alimemazine (trimeprazine)	0.35	1.09
Chlorpromazine	0.32	1
Dixyrazine	0.31	0.97

EXPERIMENTAL

Adsorbent—Precoated TLC silica gel 60 F 254[1] plates were used.

Eluent Systems—Solvents were analytical grade and were used as received from commercial sources[1]. Eluent A consisted of ethyl acetate–chloroform–methanol–0.1 *M* sodium acetate buffer (pH 4.7) (54:23:18:5). Eluent B consisted of chloroform–ethanol (90:10).

Detection—The following spray reagents were used:

Reagent A—To 250 mg of vanadium pentoxide, 40 ml of concentrated sulfuric acid was added. The mixture was diluted with distilled water to 500 ml (12).

Reagent B—To 5 ml of 5% aqueous iron(III) chloride, 45 ml of 20% perchloric acid and 50 ml of 50% nitric acid were added (12, 13).

Reagent C—Five grams of *p*-dimethylaminobenzaldehyde was dissolved in 100 ml of 18 *N* H_2SO_4 (13).

Reagent D—A 40% (v/v) aqueous sulfuric acid solution was used. After spraying, the TLC plate was heated at 110° for 5–10 min (14).

Reagent E—To 0.1% ethanolic bromcresol purple solution were added a few drops of a 10% ammonia solution until the color changed (15, 16).

Reagent F—Forty milligrams of bromcresol green was dissolved in 100 ml of ethanol, and 0.1 *N* NaOH was added until a blue color appeared (15, 16).

Reagent G—Aconitic acid, 250 mg, was dissolved in 40 ml of acetic anhydride by heating; the mixture was diluted with toluene to 100 ml. After spraying, the TLC plate was heated at 100° for 30 min (17, 18).

Drug Solutions—Ten milligrams of the pure drug reference standards[2] were dissolved in 10 ml of chloroform–methanol (7:3). The compounds investigated are summarized in Tables I and II.

Procedure—*Rapid Group Detection*—Volumes of 10 μl, corresponding to 10 μg of a compound, were applied to a precoated silica gel plate with a syringe[3]. The chromatoplate was developed over 15 cm using Eluent A in a tank[4] without filter paper lining. Use of a saturated paper-lined development tank resulted in a poor separation because of the lower R_f values of all compounds and because many of the phenothiazine derivatives did not migrate from the application point.

The plate was air dried at room temperature and viewed under shortwave UV light[5]. The spots were outlined with a pencil. Finally, the plate was sprayed with one detection reagent for group identification.

Identification of Butyrophenones and Diphenylbutylpiperidines—When the rapid detection method showed the presence of a neuroleptic compound of the butyrophenone–diphenylbutylpiperidine group, identification of this compound could be confirmed using two-dimensional TLC. With a 10-μl syringe, the butyrophenone–diphenylbutylpiperidine mixture was applied to the three corners of a TLC plate prepared as shown in Fig. 1.

After development over 15 cm using Eluent A in a tank without paper lining, the TLC plate was removed and air dried at room temperature. The plate was then developed for 15 cm at right angles to the first run in a second tank containing Eluent B and saturated by lining the walls with filter paper moistened with the mobile phase. The chromatogram

was air dried at room temperature and evaluated by quenching the 254-nm-induced fluorescence.

RESULTS

Guide R_f values for the examined compounds are summarized in Tables I and II.

The described one-dimensional TLC method with Eluent A allows almost a complete differentiation of the phenothiazine group and the butyrophenone–diphenylbutylpiperidine group. With this solvent system, nearly all compounds of the latter group were located between R_f 0.44 and 0.76. Pipamperone (R_f 0.22) was the only compound that did not migrate into this region. Fluanisone, penfluridol, and pimozide were not separated with this eluent. The phenothiazine thiopropazate (R_f 0.71) interfered with these three compounds. All other phenothiazines migrated into the R_f 0.18–0.37 region where pipamperone interference was possible.

Combination of R_f values and the color reactions can facilitate the identification of the compounds. All compounds investigated quenched the 254-nm-induced fluorescence. Group differentiation was possible with different reagents (Table III).

The phenothiazine group reacted positively with Reagents A–D, whereas no color reaction was seen for the butyrophenones and diphenylbutylpiperidines. Reagents C and D gave more intense colors than did Reagents A and B. All compounds examined reacted with Reagents E and F to give lightly bluish-colored spots. Reagent G reacted with butyrophenones and diphenylbutylpiperidines, but spot intensities were so light that identification was very difficult.

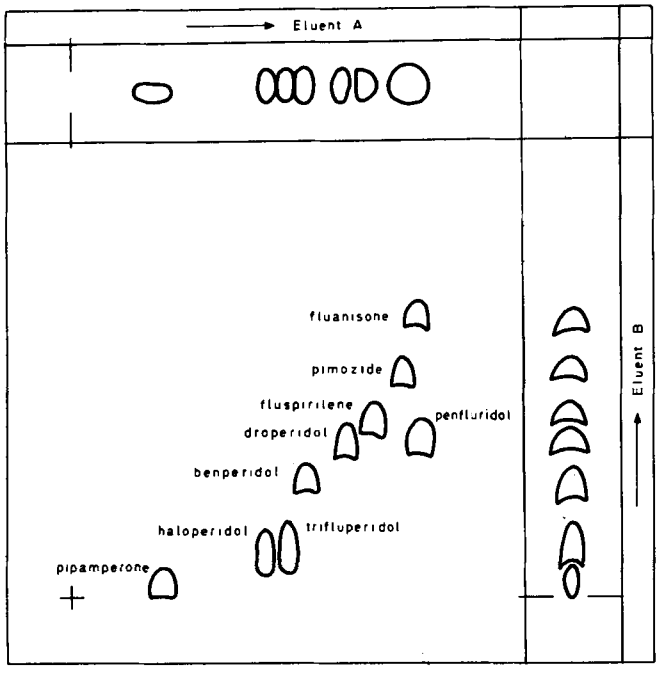

Figure 1—*Type chromatogram of the two-dimensional identification test for butyrophenones and diphenylbutylpiperidines.*

[a] B = brown, BL = blue, O = orange, P = purple, R = red, Y = yellow, W = weak, + = detectable, and – = not detectable.

The color of a compound after TLC and spraying is generally dependent on the concentration of the substance in the sample, on the mode of reagent application, and on the amount of reagent used for detection. In this TLC procedure, identification depends on R_f values (or relative R_f values with, for example, chlorpromazine as a standard) and on color. Neither is an absolute.

Identity of the butyrophenone or diphenylbutylpiperidine compound can be accomplished by the described two-dimensional TLC method. Guide R_f values of the compounds for the two solvent systems are summarized in Table II. A two-dimensional chromatogram is shown in Fig. 1. Because of the great similarity in chemical structure of the butyrophenones and diphenylbutylpiperidines, it is very difficult to find a specific reagent for each compound of this group. Therefore, unspecific detection such as shortwave UV light was used.

Iodine vapors or the Munier–Macheboeuf modification of Dragendorff's reagent can be used also. The use of unspecific detecting agents, however, makes identification dependent on R_f values, which are influenced by numerous parameters. Comparison with reference samples would be absolutely necessary.

High-Pressure Liquid Chromatographic Analysis of Antipyrine in Small Plasma Samples

LEON SHARGEL ˣ, WAI-MAN CHEUNG, and ANDREW B. C. YU

Received August 28, 1978, from the *College of Pharmacy and Allied Health Professions, Northeastern University, Boston, MA 02115.* Accepted for publication January 31, 1979.

Abstract □ A high-pressure liquid chromatographic (HPLC) method was developed for the assay of antipyrine in small (0.1-ml) plasma samples using aminopyrine as the internal standard and a reversed-phase microparticulate column. The assay sensitivity (1 μg/ml) permits development of a plasma level–time curve using a single rat. The mean (± *SE*) plasma elimination half-life in rats was 1.28 ± 0.14 hr. A comparison of the spectrophotometric method with the HPLC method yielded a correlation coefficient of 0.98. The HPLC assay for antipyrine is rapid and precise and can be used for hepatic drug metabolism study in a single animal.

Keyphrases □ Antipyrine—analysis, high-pressure liquid chromatography, plasma, rats □ High-pressure liquid chromatography—analysis, antipyrine, plasma, rats □ Analgesics—antipyrine, high-pressure liquid chromatographic assay, plasma, rats

The plasma antipyrine elimination rate is commonly used to study hepatic drug metabolism *in vivo* (1–5). Antipyrine is metabolized almost completely by the liver enzymes (6), and protein binding of the drug is minimal (7).

BACKGROUND

The spectrophotometric assay of Brodie *et al.* (8) generally is used for measuring plasma antipyrine levels. The spectrophotometric method is tedious and may yield high blank values. Furthermore, the method requires 1–2 ml of plasma, which precludes obtaining multiple samples from a small animal such as the rat.

GLC analyses of antipyrine also have been reported (3, 9). Although these methods appear to be more precise than the spectrophotometric method, they still require a 1.0-ml plasma sample and drug extraction. Another assay for plasma antipyrine using ^{14}C-label drug (4) is very sensitive but requires expensive equipment and involves the hazards of radioactivity.

High-pressure liquid chromatography (HPLC) has been applied to the separation and quantitation of many drugs. A sensitive HPLC procedure for antipyrine using a silica gel column was reported (10). This procedure requires 0.5 ml of plasma for drug extraction. A rapid, sensitive method was needed that utilizes smaller blood samples, 0.1–0.2 ml, so that an antipyrine pharmacokinetic profile can be obtained in a single laboratory animal such as the rat. Recently, HPLC procedures utilizing reversed-phase chromatography were developed for drug analysis in biological tissues (11). The advantage of reversed-phase HPLC is that minimal sample cleanup is required prior to chromatography; therefore, smaller tissue samples may be used.

This report describes a rapid HPLC procedure which is more precise than the spectrophotometric method and utilizes small plasma sample volumes.

EXPERIMENTAL

Materials—Antipyrine NF and aminopyrine NF were used as standards[1]. All other reagents, analytical grade or better, were purchased from commercial sources.

Animals—Adult, male, Sprague–Dawley strain rats[2], 200–350 g, were used.

Plasma Assay and Animal Dosing—For standard curves, heparinized blood samples were removed from the abdominal aorta of nonmedicated ether-anesthetized rats, placed into centrifuge tubes, and centrifuged to obtain the plasma fraction. Plasma aliquots (0.1 ml) were pipetted into 1.5-ml microtest tubes[3] and spiked with 10 μl of concentrated antipyrine solutions to yield final drug concentrations corresponding to 0, 1.5, 3, 4.5, 6, 12, 25, and 50 μg/ml of plasma.

To each microtest tube was added 0.05 ml of 20% (w/v) $ZnSO_4 \cdot 7H_2O$ in 50% (v/v) methanol–water containing aminopyrine, 100 μg/ml, as the internal standard. The mixture was mixed on a vortex mixer. Then 0.05 ml of saturated barium hydroxide solution was added to the mixture. The final mixture was vortexed and centrifuged for 10 min. A 10-μl sample of the supernate was removed and subjected to HPLC.

Rats were given 100 mg of antipyrine/kg ip (injection volume of 0.5 ml/200 g). Blood samples of approximately 250–300 μl were removed from the tail vein at 0, 2, 3, 4, 5, and 6 hr. The samples were placed into heparinized microcentrifuge tubes and centrifuged to obtain the plasma fraction. Plasma aliquots, 0.1 ml, were processed along with the spiked plasma standards described.

HPLC—Samples were chromatographed on a high-pressure liquid chromatograph[4] equipped with a universal liquid chromatographic injector, a UV (254-nm) absorbance detector, and a strip-chart recorder[5]. The deproteinated plasma samples (10 μl) were chromatographed at room temperature on a microparticulate[6] reversed-phase HPLC column, 4 mm × 30 cm, with an eluting mobile phase of methanol–water (50% v/v). The mobile phase flow rate was adjusted to 1 ml/min with an inlet pressure of ~1750 psig. The chart speed was 0.25 cm/min.

A standard curve was obtained by comparing the peak height ratio of antipyrine to aminopyrine and the spiked plasma antipyrine concentration. Unknown plasma sample concentrations were calculated by comparing the peak height ratios of the samples to the processed standards.

Correlation with Spectrophotometric Assay—Ten plasma samples obtained from nonmedicated rats were spiked with antipyrine at con-

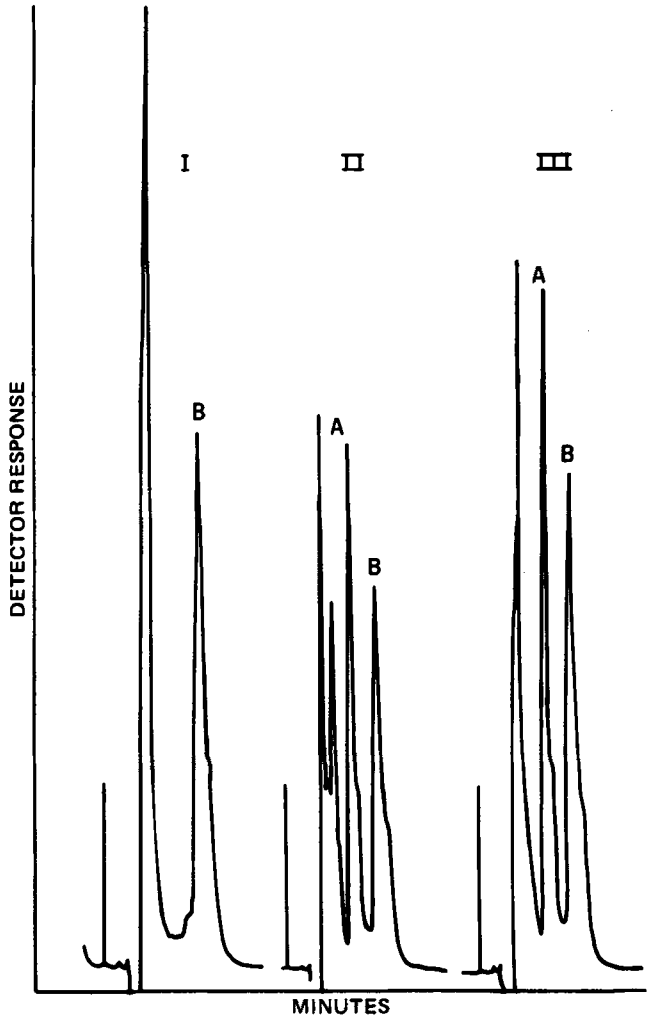

Figure 1—*High-pressure liquid chromatograms of blank plasma with 50 μg of aminopyrine/ml (B) as the internal standard (I), rat plasma collected 2 hr after the intraperitoneal injection of 100 mg of antipyrine/kg (A) containing 50 μg of aminopyrine/ml (B) (II), and processed standards in control rat plasma containing 37.5 μg of antipyrine/ml (A) and 50 μg of aminopyrine/ml (B) (III).*

centrations of 0, 5, 10, 20, and 40 μg/ml of plasma. The samples were split; one portion was assayed by the precipitation procedure of Brodie *et al.* (8), and the second portion was assayed by HPLC. The two assays were compared to obtain a correlation coefficient.

RESULTS

Chromatograms of plasma samples containing antipyrine demonstrated no interfering peaks with normal plasma constituents (Fig. 1). Retention times for antipyrine and aminopyrine were 5.6 and 8.7 min, respectively. Processed standard curves of antipyrine plasma samples were linear to 50 μg/ml, and the assay sensitivity was ~1.0 μg/ml. Standards were processed in triplicate, and the regression line slope was calculated as 27.1 with a correlation coefficient of 0.99, demonstrating excellent linearity. The assay sensitivity was ~1.0 μg of antipyrine/ml of plasma.

A comparison of the HPLC and spectrophotometric assays demonstrated excellent correlation. A correlation coefficient of 0.98 and a slope of 0.97 were obtained.

To demonstrate the application of the HPLC method *in vivo*, three rats were given 100 mg of antipyrine/kg ip. The plasma elimination of antipyrine for each rat was first order (Fig. 2). The mean (± *SE*) plasma elimination half-life for antipyrine was 1.28 ± 0.14 hr, which agrees with the reported value of 85 min (2).

DISCUSSION

The main advantage of the HPLC assay of antipyrine over previous

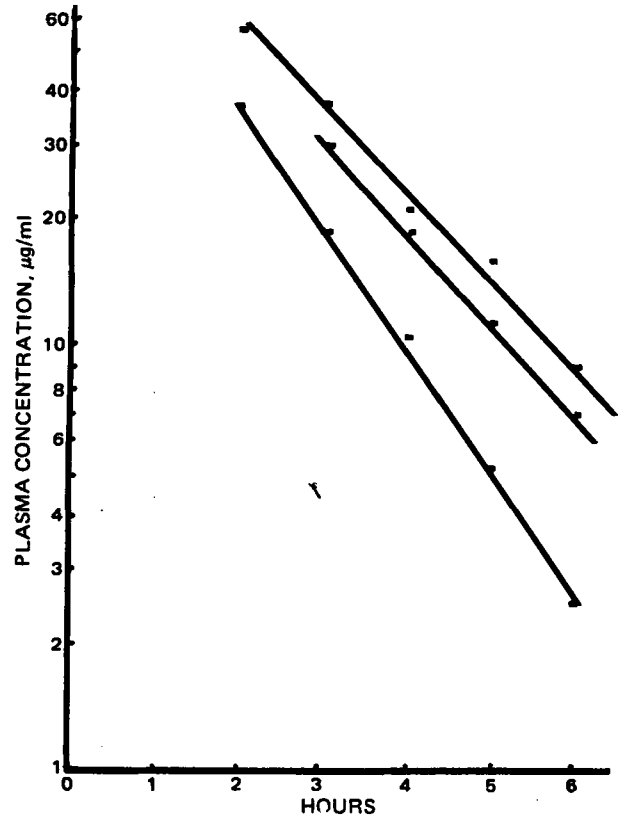

Figure 2—*Plasma antipyrine levels in individual rats. Each rat was given 100 mg of antipyrine/kg ip. Plasma samples were assayed for antipyrine according to the described HPLC procedure.*

methods is that a complete plasma concentration *versus* time curve may be obtained from a single rat. Previously, investigators performing pharmacokinetic and drug metabolism studies *in vivo* with the rat as the animal model needed many rodents to obtain sufficient data points to describe accurately the plasma elimination of antipyrine (2). This micromethod for antipyrine measurement allows the use of the rat as its own control since very small (0.1 ml) plasma samples are used. Although the assay sensitivity is only 1.0 μg/ml, enough data points describing antipyrine elimination kinetics may be obtained quickly and accurately. The assay sensitivity probably could be improved by further sample cleanup and injection of larger sample volumes on the chromatograph.

The *in vivo* data demonstrated that reasonable elimination half-lives for antipyrine may be obtained by this HPLC method. Therefore, this method should be useful for studying the effects of environmental factors of various xenobiotics on hepatic drug metabolism activity in the rat *in vivo* using antipyrine pharmacokinetics as one parameter.

In comparison to the popular spectrophotometric method for antipyrine (8), the HPLC assay is simple, rapid, and precise. Moreover, there is no need for involved separation and purification techniques. Since results of the HPLC method agree well with those of the spectrophotometric method, as shown by a correlation coefficient of 0.98, the HPLC assay offers a reasonable alternative for antipyrine measurement.

Metabolic Fate of N^6-Benzyladenosine and N^6-Benzyladenosine-5′-phosphate in Rats

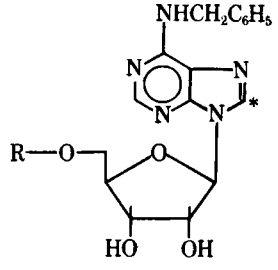
G. B. CHHEDA ˣ, C. I. HONG *, S. K. GURWARA ‡, and A. MITTELMAN

Received February 10, 1978, from the *Department of General Surgery and the Department of Biophysics, Roswell Park Memorial Institute, Buffalo, NY 14263.* Accepted for publication December 8, 1978. *Present address: Department of Neurosurgery, Roswell Park Memorial Institute, Buffalo, NY 14263. ‡Present address: Invenex Pharmaceuticals, Grand Island, NY 14072.

Abstract □ The radiolabeled antitumor nucleoside (^{14}C-8)-N^6-benzyladenosine and its (^{14}C-8)-5′-phosphate were administered to rats intravenously, and their metabolic fate was studied. Twenty-nine percent of the radioactivity was recovered in the 48-hr urine collection after (^{14}C-8)-N^6-benzyladenosine administration. The following metabolites were isolated: unchanged N^6-benzyladenosine (20%), adenine (12%), uric acid (5%), and N^6-benzyladenine (0.3%). In the case of (^{14}C-8)-N^6-benzyladenosine-5′-phosphate, a total of 28% of the radioactivity was recovered in the 48-hr urine collection and the following metabolites were isolated: N^6-benzyladenosine (40%), uric acid (12%), adenine (trace), and unidentified urea derivatives (30%). Metabolism of N^6-benzyladenosine appears to involve N-debenzylation to some extent, followed by conversion to adenine and uric acid. N^6-Benzyladenosine and its 5′-phosphate differ from other adenosine analogs in being retained in significant amounts by the animals.

Keyphrases □ Benzyladenosine—metabolism, rats □ Benzyladenosine phosphate—metabolism, rats □ Antineoplastic agents—benzyladenosine, metabolism, rats

Since N^6-(Δ^2-isopentenyl)adenosine (1) exhibited growth inhibitory activity in mammalian cell lines as well as *in vivo*, several 6-substituted adenosines were synthesized and their antitumor activities were determined (2, 3). Among them, N^6-benzyladenosine (I) was of particular interest since it exhibited a significant growth inhibitory activity against mouse L-1210 leukemia (2). In rats, N^6-benzyladenosine, like N^6-(Δ^2-isopentenyl)adenosine, inhibited the incorporation of precursors into DNA, RNA, and protein (4). More recently, this nucleoside underwent a clinical trial as an antitumor agent (5). Subsequently, because of the poor solubility of N^6-benzyladenosine, a more water-soluble derivative, N^6-benzyladenosine-5′-phosphate (II) (6), was prepared and used instead. Since initial metabolism studies indicated that N^6-benzyladenosine did not behave like other N^6-substituted adenosines (7, 8), investigations were undertaken to determine the metabolic fate of N^6-benzyladenosine and its 5′-phosphate in rats.



I: R = H

II: R = $-P(=O)-(OH)_2$

* = ^{14}C

EXPERIMENTAL

Materials and Methods—(^{14}C-8)-N^6-Benzyladenosine[1] (I) was synthesized by reacting (^{14}C-8)-adenosine[2] (100 μCi, 2 μmoles), adenosine (10 μmoles), benzyl bromide (20 μl), and dimethylformamide at 40° for 24 hr, followed by heating with 14 N ammonium hydroxide (1 ml) and water (2 ml) at 95° for 3 hr (2). The yield was 9.8 μmoles (81.7%), the total radioactivity was 62.3 μCi, and the specific radioactivity was 6.3 μCi/μmole. (^{14}C-8)-N^6-Benzyladenosine-5′-phosphate (II) was synthesized by phosphorylation of (^{14}C-8)-N^6-benzyladenosine, prepared from (^{14}C-8)-adenosine (130 μCi, 10 μmoles), phosphorus oxychloride (50 μl), and triethyl phosphate (1 ml) (6). The yield was 5.1 μmoles (51%), the total radioactivity was 44.93 μCi, and the specific radioactivity 8.81 μCi/μmole.

Chromatography—Paper chromatograms were developed in a descending manner on 3 MM filter paper during initial preparative stages and on acid-washed (No. 1) filter paper when purifications and comparative identification were required[3]. The following solvent systems were utilized for paper chromatography: A, isopropanol–concentrated ammonium hydroxide–water (7:1:2), B, ethyl acetate–2-ethoxyethanol–16% formic acid (4:1:2), upper phase; C, n-butanol–water–concentrated ammonium hydroxide (86:14:5), upper phase; D, n-propanol–concentrated ammonium hydroxide–water (11:2:7); and E, ethyl acetate–n-propanol–water (4:1:2), upper phase. Chromatograms were viewed under a shortwave UV lamp at 254 nm. All UV-absorbing areas were eluted and analyzed in a UV spectrophotometer[4].

Radioactivity Determination—The liquid samples (100–250 μl) were counted for radioactivity in scintillation vials containing 10 ml of the scintillation fluid[5]. The solid samples (feces and organs) were homogenized, aliquots corresponding to 0.5 g were placed in a gelatin capsule and burned in a sample oxidizer[6], and the radioactive carbon dioxide was counted.

Labeled Compound Administration—Two Sprague–Dawley rats (male, 200 g) were given aqueous (^{14}C-8)-N^6-benzyladenosine (0.18 mg,

[1] Aqueous solutions of (^{14}C-8)-N^6-benzyladenosine should be stored frozen at −70° or below. When being kept at −20° for 2 months, 5% of the labeled compound underwent degradation to (^{14}C-8)-N^6-benzyladenine.

Among them, N^6-benzyladenosine (I) was of particular interest since it exhibited a significant growth inhibitory activity against mouse L-1210 leukemia (2). In rats, N^6-benzyladenosine, like N^6-(Δ^2-isopentenyl)adenosine, inhibited the incorporation of precursors into DNA, RNA, and protein (4). More recently, this nucleoside underwent a clinical trial as an antitumor agent (5). Subsequently, because of the poor solubility of N^6-benzyladenosine, a more water-soluble derivative, N^6-benzyladenosine-5′-phosphate (II) (6), was prepared and used instead. Since initial metabolism studies indicated that N^6-benzyladenosine did not behave like other N^6-substituted adenosines (7, 8), investigations were undertaken to determine the metabolic fate of N^6-benzyladenosine and its 5′-phosphate in rats.

EXPERIMENTAL

Materials and Methods—(^{14}C-8)-N^6-Benzyladenosine[1] (I) was synthesized by reacting (^{14}C-8)-adenosine[2] (100 μCi, 2 μmoles), adenosine (10 μmoles), benzyl bromide (20 μl), and dimethylformamide at 40° for 24 hr, followed by heating with 14 N ammonium hydroxide (1 ml) and water (2 ml) at 95° for 3 hr (2). The yield was 9.8 μmoles (81.7%), the total radioactivity was 62.3 μCi, and the specific radioactivity was 6.3 μCi/μmole. (^{14}C-8)-N^6-Benzyladenosine-5′-phosphate (II) was synthesized by phosphorylation of (^{14}C-8)-N^6-benzyladenosine, prepared from (^{14}C-8)-adenosine (130 μCi, 10 μmoles), phosphorus oxychloride (50 μl), and triethyl phosphate (1 ml) (6). The yield was 5.1 μmoles (51%), the total radioactivity was 44.93 μCi, and the specific radioactivity 8.81 μCi/μmole.

Chromatography—Paper chromatograms were developed in a descending manner on 3 MM filter paper during initial preparative stages and on acid-washed (No. 1) filter paper when purifications and comparative identification were required[3]. The following solvent systems were utilized for paper chromatography: A, isopropanol–concentrated ammonium hydroxide–water (7:1:2), B, ethyl acetate–2-ethoxyethanol–16% formic acid (4:1:2), upper phase; C, n-butanol–water–concentrated ammonium hydroxide (86:14:5), upper phase; D, n-propanol–concentrated ammonium hydroxide–water (11:2:7); and E, ethyl acetate–n-propanol–water (4:1:2), upper phase. Chromatograms were viewed under a shortwave UV lamp at 254 nm. All UV-absorbing areas were eluted and analyzed in a UV spectrophotometer[4].

Radioactivity Determination—The liquid samples (100–250 μl) were counted for radioactivity in scintillation vials containing 10 ml of the scintillation fluid[5]. The solid samples (feces and organs) were homogenized, aliquots corresponding to 0.5 g were placed in a gelatin capsule and burned in a sample oxidizer[6], and the radioactive carbon dioxide was counted.

Labeled Compound Administration—Two Sprague–Dawley rats (male, 200 g) were given aqueous (^{14}C-8)-N^6-benzyladenosine (0.18 mg,

[1] Aqueous solutions of (^{14}C-8)-N^6-benzyladenosine should be stored frozen at −70° or below. When being kept at −20° for 2 months, 5% of the labeled compound underwent degradation to (^{14}C-8)-N^6-benzyladenine.

Table I—Radiactivity Excretion in Rat 48-hr Urine and Feces Collection after Intravenous (^{14}C-8)-N^6-Benzyladenosine (I) and (^{14}C-8)-N^6-Benzyladenosine-5′-phosphate (II) [a]

Labeled Compound	Amount Administered, mg (dpm × 10^6)	Radioactivity Excreted, dpm × 10^6	Recovery, %
I	0.18 (7.167)	Urine: 2.08	29.0
		Feces: 0.51	7.1
		Total: 2.59	36.1
II	0.17 (7.583)	Urine: 2.128	28.1
		Feces: 0.857	11.3
		Total: 2.985	39.4

[a] A separate experiment was conducted for determining the excretion of radioactivity beyond 48 hr. About 2% of additional radioactivity was excreted in 6 more days.

7.167 × 10^6 dpm) or (^{14}C-8)-N^6-benzyladenosine-5′-phosphate (0.17 mg, 7.585 × 10^6 dpm) through the tail vein.

Each pair of rats was then placed in a metabolic cage, and urine and feces were collected up to 48 hr postadministration. Precautions were taken to avoid contamination of feces by urine. All materials obtained were subjected to radioactivity measurement to determine excretion levels.

Isolation, Purification, and Identification of Urinary Metabolites—Prior to paper chromatography, the rat urine sample was filtered under 35 psi nitrogen pressure through a membrane filter with a molecular weight retention of ≥1000 with respect to spherical product[7]. After filtration, two generous water washings were employed, and the combined filtrates were evaporated to dryness. The residue was dissolved in minimal water and streaked on four 3 MM filter papers[3] (23 × 57 cm) along with the following markers: N^6-benzyladenine, N^6-benzyladenosine, N^6-benzyladenosine-5′-phosphate, adenine, adenosine, hypoxanthine, inosine, and uric acid.

The paper chromatographic purification was performed first with Solvent A, and major materials were subjected to further purification for the isolation and identification of the radioactive metabolites. Metabolites were identified by comparison of their paper chromatographic mobilities and UV spectra with those of the authentic samples.

RESULTS AND DISCUSSION

The metabolism studies showed that N^6-benzyladenosine behaved differently from some other N^6-substituted adenosines such as N^6-(Δ^2-isopentenyl)adenosine (7) as well as N-(purine-6-ylcarbamoyl)-L-threonine ribonucleoside (8). Fifty percent of N^6-(Δ^2-isopentenyl)-adenosine was metabolized to non-UV-absorbing compounds, and most of the administered radioactivity was excreted in the first 5 hr. N-(Purine-6-ylcarbamoyl)-L-threonine ribonucleoside also was excreted relatively rapidly from the body; however, it usually did not undergo purine ring or side-chain catabolism.

In the case of N^6-benzyladenosine, 36% of the administered radioactivity of I was excreted over 48 hr; 29% was in the urine and 7% was in the feces (Table I). Significant radioactivity was retained in the animal beyond 48 hr. The additional activity excreted was <2.5% during the 6 days after the initial 2 days.

Table II—Radioactivity Distribution in Rat Organs 48 hr after Intravenous (^{14}C-8)-N^6-Benzyladenosine

Organ	Disintegrations per Minute × 10^3	Percent of Administered
Liver	701.6	9.8
Kidney	44.2	0.61
Pancreas	25.9	0.36
Spleen	10.0	0.13
Adrenal	2.0	0.02
Brain	0.7	0.01
Muscle[a]	2313	32.3
Bone[a]	123	1.7
Plasma[a]	2.5	0.03
Red cells[a]	28.4	0.4

[a] These calculations are based on the total of 90 g of muscle, 13 g of bone, 6 ml of plasma, and 6 ml of red cells in an average rat. Actually, the disintegrations per minute values were determined on a weighed sample of muscle and bone and a per milliliter sample of plasma and red cells. Thus, 81.5% of the radioactivity can be accounted for when urine and fecal activities are added.

Table III—Urinary Metabolites Isolated from Urine 48 hr after Intravenous (^{14}C-8)-N^6-Benzyladenosine (I) and (^{14}C-8)-N^6-Benzyladenosine-5′-phosphate (II)

Metabolite	Percent of Total I Radioactivity	Percent of Total II Radioactivity
N^6-Benzyladenosine-5′-phosphate	Not detected	Not detected
N^6-Benzyladenosine	20	40
Benzyladenine	0.3	—
Adenine	12	0.1
Uric acid	5	12
Unidentified compounds (urea test positive)	43	30
Other unidentified compounds	5	6
Losses	15	12

The rats were sacrificed 48 hr after administration, and various organs and tissues were removed and checked for radioactivity (Table II). Among the organs, the liver contained the highest radioactivity (10%). The kidney and pancreas showed less than 1% of the administered radioactivity, and muscle accounted for 32% of the activity. Red cells also retained some radioactivity after 48 hr. The activity in the urine, feces, and organs added up to 81% of the administered radioactivity.

Chromatographic and UV spectral analysis of the radioactivity found in urine revealed that 20% of the excreted radioactivity was in the unchanged parent nucleoside while ~0.3% was in benzyladenine, the free base (Table III). Adenine constituted 12%, and uric acid contained 5% of the activity. Since N^6-benzyladenosine is not a substrate for the enzyme adenosine deaminase (3), formation of adenine and uric acid (Table III) probably takes place after N-debenzylation of the nucleoside. No metabolites with the hydroxylated phenyl nucleus were observed.

Significant radioactivity was found in the unidentified compounds, for which the urea color test was positive[8]. Since N^6-benzyladenosine is a substrate for adenosine kinase and also gets phosphorylated in cultured cells (9), some of it may possibly be converted to the 5′-mono-, di-, and triphosphates *in vivo* in rats. In the studies reported here, however, the tissues were not analyzed for these phosphorylated derivatives. Urine sample analysis did not reveal any 5′-phosphates.

In the case of N^6-benzyladenosine-5′-phosphate, a total of 39% of the administered activity of II was excreted over 48 hr, 20% in the urine and 11% in the feces (Table I). In terms of radioactivity disposition and metabolism studies of the 5′-phosphate, the overall picture was not much different from that of the parent nucleoside. N^6-Benzyladenosine-5′-phosphate was converted to N^6-benzyladenosine *in vivo* and was excreted as the major metabolite (40%); no 5′-phosphate could be detected in the urine. Twelve percent of the radioactivity was excreted as uric acid, and ~35% was excreted as unidentified compounds.

Preliminary studies in humans indicated that this nucleoside (I) and its 5′-phosphate (II) are retained in the body for a long period. Only ~20% of the radioactivity was excreted in urine in 48 hr. The nucleotide is converted into the nucleoside, and the former may serve as a soluble and sustained-release form for the latter (10). Unchanged N^6-benzyladenosine and uric acid are the major urinary metabolites in humans.

Differential Potentiometric Method for Determining Dissociation Constants of Very Slightly Water-Soluble Drugs Applied to the Sulfonamide Diuretic Chlorthalidone

H. L. J. FLEUREN ˣ, C. A. M. van GINNEKEN, and J. M. van ROSSUM

Received December 26, 1978, from the *Department of Pharmacology, University of Nijmegen, 6500 HB Nijmegen, The Netherlands.* Accepted for publication February 6, 1979.

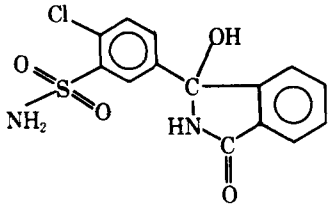
Abstract □ A renewed application of potentiometric acid–base titrations is described, by which dissociation constants of practically water-insoluble drugs can be measured accurately. The method uses the difference in the amount of titrant between a suitable aqueous solvent and a solution of the drug in that solvent. Such potentiometric difference titrations were conducted on a 3.7×10^{-4} *M* solution of chlorthalidone in 0.1 *M* aqueous KCl in the pH 3.5–10.6 range at 25°. Nonlinear least-squares regression analysis was applied to the data. From four determinations, a value of 9.24 ± 0.02 (mean ± *SEM*) resulted for the apparent dissociation constant of the first chlorthalidone acid group. The thermodynamic dissociation constant was calculated at pKa_1 = 9.35 (25°) by using a correction for activity.

Keyphrases □ Chlorthalidone—analysis, differential potentiometry, dissociation constants □ Potentiometry, differential—analysis, chlorthalidone dissociation constants, ibuprofen dissociation constant □ Ibuprofen—analysis, differential potentiometry, dissociation constant

A drug's dissociation constant is an important parameter in pharmacokinetic and pharmacodynamic investigations. Once the pKa is known, the degree of compound dissociation at physiological pH is derived easily; and since only unionized molecules generally pass readily across biological membranes (1), predictions concerning the access to tissue sites of interest can be made. The pKa also has value in the estimation of the lipiphilicity of a compound from its partitioning between an organic solvent and water; if the pKa is known, true partition coefficients can be calculated from the apparent values at any arbitrary pH.

BACKGROUND

Chlorthalidone[1] (I) contains two weakly acidic groups: one sulfonamide and one oxoisoindolin (acid amide) moiety. Although the latter was not expected to contribute to drug dissociation at acid or neutral pH, the former could influence back-resorption of the drug in the renal tubules when pH 8 urine is produced. In this situation, a pH-dependent urinary excretion should become evident. This aspect gains quantitative importance because normally ~70% of an available chlorthalidone dose is excreted unchanged in the urine (2). The present study was undertaken because no chlorthalidone pKa value was available from the literature.



I

Various methods to determine acid and base dissociation constants are used. They were comprehensively evaluated by Albert and Serjeant (3). These authors stated that both potentiometry and UV spectrophotometry produce accurate results, although the latter method is more laborious (3).

One premise for a conventional potentiometric titration is that the weak acid or base concentration must be so high that the amount of titrant needed to titrate the solvent is negligible in comparison with the amount necessary to protonate or deprotonate the dissolved compound. This condition could not be fulfilled at present, because maximum chlorthalidone solubility in neutral aqueous solutions was reported as ~0.12 mg/ml (4), equivalent to 3.45×10^{-4} *M*. In such a case, a difference titration can be conducted, provided that the amounts of strong acid and base, with which the solution of the compound with an unknown pKa and its blank (solvent alone) are titrated, are measured accurately.

Moreover, the pH measurement must be of high precision and very reproducible. To meet this requirement, use was made of automatic potentiometric titration equipment containing a precisely operating, motor-driven microburet and a high-resolution digital voltmeter connected to a low-drift pH meter. The apparatus was used previously to determine pKa values and numbers of titratable groups of purified proteins (5, 6).

EXPERIMENTAL

An aqueous solution of 0.1 *M* KCl served as the blank. A saturated chlorthalidone solution in this solvent was prepared by vigorously stirring ~8 mg of the crystalline drug in 50 ml of solvent at room temperature overnight. After filtration, the concentration, determined in triplicate by GLC (7), was 125.2 ± 0.7 μg/ml (mean ± *SD*), equivalent to 3.695×10^{-4} *M*. Aqueous hydrochloric acid and sodium hydroxide solutions, 0.0604 *M*, were diluted by weighing with four volumes of distilled water and bubbled with nitrogen gas to remove carbon dioxide.

The titrant was added stepwise, using a microburet[2], at 0.01 ml/min with an accuracy of ±0.1%. The titrations were conducted on the chlor-

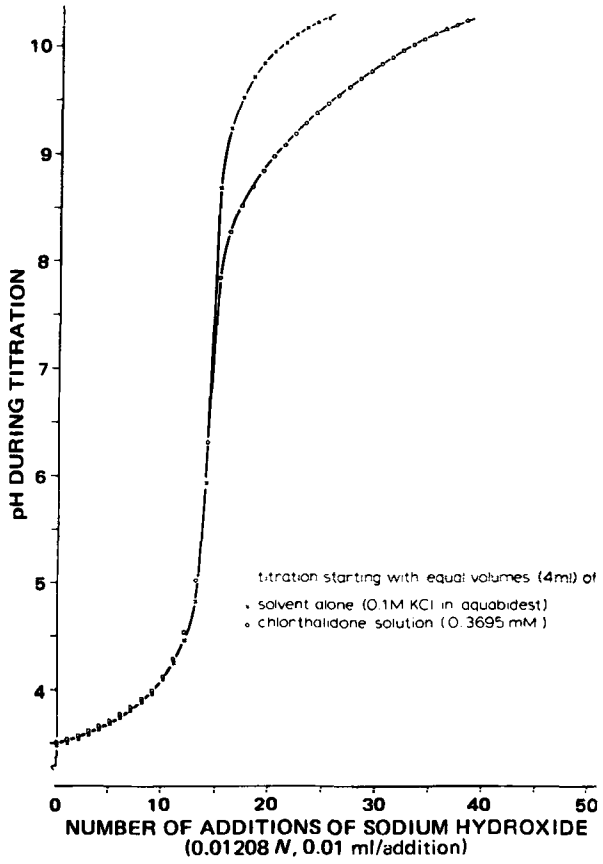

Figure 1—*Acid-base titration of the very slightly water-soluble drug chlorthalidone by measurement of the difference in titrant between samples with and without the substance.*

thalidone solution (4.00 ml) and on the solvent alone (4.00 ml), at 25° and under nitrogen, in both directions of the pH 3.5–10.6 range. Two runs with hydrochloric acid (Experiments B and D) and two with sodium hydroxide (Experiments A and C) were carried out. The actual pH ranges were 3.47–10.28 in A, 8.55–10.58 in B, 8.10–10.50 in C, and 6.61–10.45 in D. A pH meter[3] in combination with a glass[4] and a calomel[5] electrode was used.

A high-resolution digital voltmeter[6] was connected with the pH meter. The pH was measured 10 times after each addition of hydrochloric acid or sodium hydroxide, and the mean of these readings was taken. In this way, very reproducible values, including the third decimal figure, were obtained (8). Detailed descriptions of this automatic potentiometric equipment were published (6, 8). To calibrate the pH meter, phthalate buffer (pH 4.008) and phosphate buffer (pH 6.865) were used.

RESULTS AND DISCUSSION

Typical titration curves are shown in Fig. 1. Equal volumes of 0.1 *M* KCl, with and without chlorthalidone, were titrated with dilute sodium hydroxide from pH 3.5 to 10.3. A larger number of additions of alkali was needed to increase the pH of the drug solution in the region where the drug becomes deprotonated. The difference at each pH value between the number of additions of the two titration runs clearly represents the quantity necessary for titration of the drug itself. When these differences are plotted *versus* the pH, a difference titration curve is obtained. For a weak acid, the titration curve obeys the familiar Henderson–Hasselbalch equation:

$$\mathrm{pH} = \mathrm{pKa}' + \log\frac{\alpha}{1-\alpha} \qquad \text{(Eq. 1)}$$

where α represents the degree of acid group dissociation and pKa′ is its apparent dissociation constant, which becomes equal to the thermodynamic dissociation constant, pKa, at infinite dilution. At higher ionic strength, the following relationship is valid:

$$\mathrm{pKa} = \mathrm{pKa}' - \log\frac{\gamma A^-}{\gamma HA} \qquad \text{(Eq. 2)}$$

in which γA^- and γHA are the activity coefficients of the ionized and unionized forms of the acid, respectively. The activity coefficients can be calculated according to the Debye-Hückel equation (3); for log $\gamma A^-/\gamma HA$, a value of −0.11 was obtained. By using this correction, the pKa_1 is readily obtained if the experimental pKa_1' value is known.

When a strong base is added, an equivalent amount of protons is lost by the weak acid. Then α can be written as $\alpha = Z/A$, where Z represents the amount of strong base added at any moment of the titration and A is the amount added at the titration end-point. Polyacid titration produces the relation:

$$Z = \sum_{i=1}^{n} A_i\alpha_i \qquad \text{(Eq. 3)}$$

where i denotes the identity of a specific weak acid group and n is the total number of classes of weak acid groups.

Chlorthalidone contains two acidic moieties, one sulfonamide and one oxoisoindolin group, potentially dissociating in the pH range under study. Therefore, $A_1 = A_2$ and:

$$Z = A_1(\alpha_1 + \alpha_2) \qquad \text{(Eq. 4)}$$

By applying Eq. 1, one can write:

$$Z = A_1\left(\frac{10^{\mathrm{pH}-\mathrm{pKa}_1'}}{1+10^{\mathrm{pH}-\mathrm{pKa}_1'}} + \frac{10^{\mathrm{pH}-\mathrm{pKa}_2'}}{1+10^{\mathrm{pH}-\mathrm{pKa}_2'}}\right) \qquad \text{(Eq. 5)}$$

The titration data were analyzed by means of a nonlinear least-squares regression analysis program[7]. In every curve-fitting procedure, the correct assignment of independent and dependent variables is essential to obtaining unbiased estimates of the unknown parameters (9). The pH was chosen as the independent variable, because its measurement was highly reproducible (see *Experimental*), such that there existed, apart from a potential calibration error that could influence only the absolute pH scale, a very small error within each experiment. For the dependent variable Z, a constant error of 0.1, expressed as additions of strong base, was taken since this value was the read-off uncertainty of the differences between titration curves of the chlorthalidone solution and the blank (Fig. 1).

At first, the data points were fitted according to the first term of Eq. 5 only, with the assumption that the dissociation of the second acid group was negligible (if pH ≪ pKa_2', the second term approximates zero). Much better fits were obtained when the second term also was considered. For this purpose, the value for pKa_2' was not left free in the least-squares regression analysis, because too few data points were available in the high pH region, only up to pH 10.6, which would introduce large errors in the estimates of the other parameters, A_1 and pKa_1'. Preset values of pKa_2' were systemically changed until the minimum of the sum of weighed

Table I—Superiority of Computer Fits of Difference Titration Curves of Chlorthalidone when the Dissociation of Two Weak Acid Groups Instead of One Is Included[a]

Experiment	Two Titratable Groups Involved in Curve Fitting				One Titratable Group Involved in Curve Fitting

D	9.235	12.67	11.95	6.1	9.26	12.96	11.1
Mean ± *SEM* (n = 4)	9.24 ± 0.02						

[a] pKa_1' = apparent first dissociation constant, A_1 = total amount of base at first titration end-point, k_2 = optimally fixed value for the dissociation of the second acid group, and χ^2 = sum of weighed squared deviations of the experimental data from the fitted curve. The χ^2 (5%) value, the tabulated level of significance at p = 0.05, was 39, 44, 40, and 37 in Experiments A, B, C, and D, respectively. The thermodynamic dissociation constant, pKa_1, is larger than the pKa_1' by a factor of 0.11 due to the contribution of activity coefficients. Therefore, pKa_1 = 9.35 ± 0.02 (mean ± *SEM*).

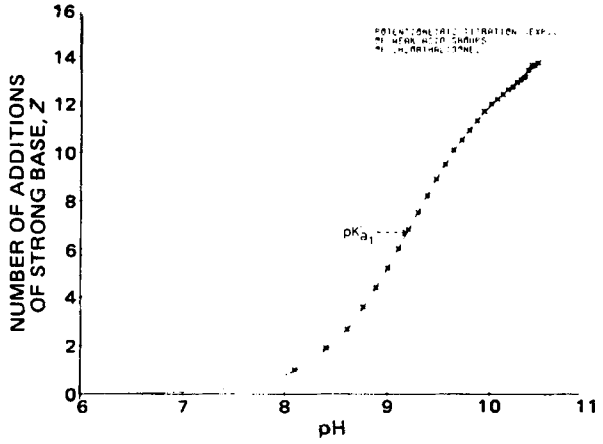

Figure 2—*Computer-fitted difference titration curve of chlorthalidone. From four experiments, the following estimates resulted for* pKa_1': *9.228 (A), 9.287 (B), 9.210 (C), and 9.235 (D), yielding a mean apparent dissociation constant of 9.24 ± 0.02 (±SEM) at 0.1 ionic strength and 25°.*

squared deviations was found. The results of these calculations are included in Table I (pKa_2' has been denoted k_2).

For A_1, the best estimate was sought by the fitting procedure. When this parameter was fixed at its theoretically calculated value (12.24 additions of strong base), it influenced the pKa_1' estimate, with possible errors in the concentration and pipetted volume of the chlorthalidone solution and in the normality and volume of the titrant.

Figure 2 shows a typical difference titration curve, fitted according to Eq. 5 (at fixed optimal pKa_2' values). The decision in favor of such a fit over that based on ionization of only one acid group was made using several criteria: (*a*) visual plot inspection, (*b*) symmetry of the residuals around the fitted curves, and (*c*) calculation of the sum of weighed squared residuals (as χ^2). Table I compares the χ^2 values for both procedures and indicates the superiority of curve fitting according to two titratable groups in all four experiments. In addition, the scatter of the pKa_1' estimates in the left part is much smaller than that in the right part. Also, the A_1 estimates at the left correspond better with the value calculated on the basis of total chlorthalidone in the titration vessel (equivalent to 12.24 additions of strong base), indicating that actually one proton-donor group was dissociated completely at this stage.

The variance of the four pKa_1' estimates exceeds the within-experiment error (the computer-estimated relative errors ranged from 0.0 to 0.1%). This finding points to minor systematic differences between the four experiments caused, for example, by the pH meter calibration. However, the differences are small enough that the pKa_1' (25°) = 9.24 ± 0.02 (mean ± *SEM*) can be treated as a reliable operational ionization constant, suitable for use as a physicochemical parameter in pharmacological studies. When the correction for ionic strength is carried out with Eq. 2, the thermodynamic dissociation constant is calculated at pKa = 9.35 (25°).

Determination of very slightly water-soluble drug dissociation constants appears to be convenient and reproducible by the method described, and no corrections for titrant consumption by the solvent are needed. The technique was applied also to the analgesic ibuprofen[8] in the laboratory (10), indicating that potentiometric difference titrations can be conducted in a wide area of pharmaceutical substances.

Improvements of Dissolution Characteristics and Chemical Stability of 16,16-Dimethyl-*trans*-Δ^2-prostaglandin E_1 Methyl Ester by Cyclodextrin Complexation

KANETO UEKAMA *x, **FUMITOSHI HIRAYAMA** *, **YOSHITSUGU YAMADA** *, **KOJI INABA** ‡, and **KEN IKEDA** §

Received July 31, 1978, from the *Faculty of Pharmaceutical Sciences, Kumamoto University, Kumamoto, 862, Japan, ‡Ono Pharmaceutical Co. Ltd., Osaka, 537, Japan, and the §Faculty of Pharmaceutical Sciences, Nagoya City University, Nagoya, 467, Japan. Accepted for publication February 6, 1979.

Abstract □ Inclusion complexation of 16,16-dimethyl-*trans*-Δ^2-prostaglandin E_1 methyl ester (I), which is effective in early pregnancy termination, with cyclodextrins in water was ascertained by a solubility study. A solid complex of I-β-cyclodextrin in a 1:2 molar ratio was obtained, and its dissolution behavior and chemical stability were examined. The results indicated that the complex may have great utility as a rapidly dissolving form of I with prolonged storage time.

Keyphrases □ Prostaglandin E_1 derivatives—cyclodextrin complexation, dissolution, stability □ Cyclodextrin—complexation with prostaglandin E_1, dissolution, stability □ Complexation—prostaglandin E_1 with cyclodextrin, dissolution, stability

Some naturally occurring prostaglandins such as prostaglandins E_1, E_2, and $F_{2\alpha}$ (dinoprost) have clinical applications (1). 16,16-Dimethyl-*trans*-Δ^2-prostaglandin E_1 methyl ester[1] (I), a prostaglandin E_1 derivative, induced uterine contraction in rats with an efficacy 10 times that of prostaglandin $F_{2\alpha}$ (2, 3). This compound is more acceptable for early pregnancy termination than prostaglandin $F_{2\alpha}$ because it produces fewer side effects. However, the solubility and chemical instability of the prostaglandins, including I, in aqueous solution have limited dosage form development and resulted in a substantial challenge to the pharmaceutical scientist.

Cyclodextrins form inclusion complexes with various drug molecules (4–8). Since I is essentially a methyl ester of long chain unsaturated fatty acids, the relatively hydrophobic cyclodextrin cavity is expected to attract I as an adequate guest molecule (9–11). Thus, the present study dealt with inclusion complexation of I with α- and β-cyclodextrins in anticipation of improved solubilization and stabilization of I.

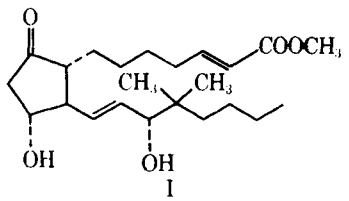
EXPERIMENTAL

Materials—Compound I[1], α-cyclodextrin[2], and β-cyclodextrin[2] were used as supplied. All other materials and solvents were analytical reagent grade. Deionized, double-distilled water was used.

Solubility and Dissolution Studies—Solubility measurement and analytical methods for I were essentially those reported previously (9).

Table I—Thermal Stabilities of I and Its β-Cyclodextrin Complex at 60°

Compound	Decomposition of I, % 1 Day	3 Days	8 Days	14 Days
I	2.2	8.8	30.2	54.0
Complex	0.1	0.5	2.5	4.0



I

The dissolution behaviors of I and its β-cyclodextrin complex in water were compared at the same I concentration according to the dispersed amount method (12). A 120-mg sample of a I-β-cyclodextrin complex as a 100–200-mesh powder was weighed and put in a dissolution cell. Because I is a viscous oil, an ether solution containing 18 mg of I was placed in the dissolution cell and evaporated to dryness. The dissolution medium (25 ml) was maintained at 25° and stirred at 93 rpm. At an appropriate interval, 0.5 ml of solution was sampled by a pipet with a cotton filter. The assay procedure for I was the same as that used in the solubility study (9).

Stability Studies—Stability tests for I and its β-cyclodextrin complex were conducted at 60° in a moisture-free environment. Intact I was quantitatively determined by high-performance liquid chromatography (HPLC). The liquid chromatograph[3] (20-cm column[4]) was operated at a flow rate of 0.5 ml/min, and the mobile phase consisted of acetonitrile–methanol–water (2:8:3). Under these conditions, the disappearance of the I peak was followed by a UV detector[5] at 215 nm.

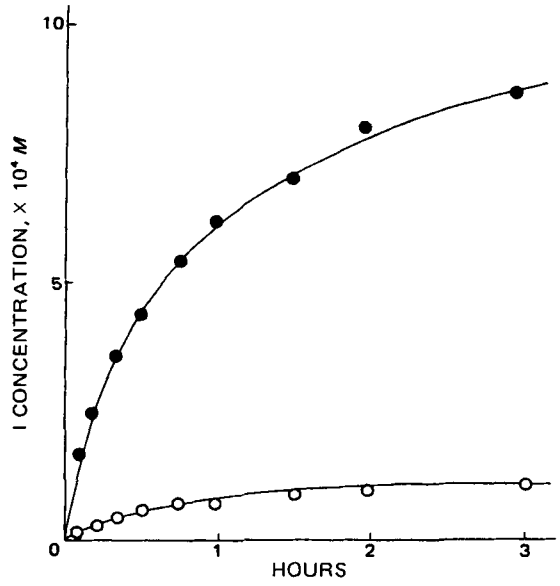

Figure 2—*Dissolution behavior of I* (○) *and its β-cyclodextrin complex* (●) *at the same I concentration in water at 25°.*

RESULTS AND DISCUSSION

The equilibrium phase solubility diagrams obtained for I with α- and β-cyclodextrins in water are shown in Fig. 1. In both of these systems, the solubility of I increased following cyclodextrin addition, and the solubility curves of α- and β-cyclodextrins can be generally classified as types A_p and B_s (13), respectively. According to Higuchi and Kristiansen (14), the stability constants for 1:1 (SL) and 1:2 (SL_2) complexes (S = I, and L = cyclodextrin) were calculated from ascending positive curvatures in Fig. 1. The stability constants for α- ($K_{1:1}$ = 820 M^{-1}, and $K_{1:2}$ = 260 M^{-1}) and β- ($K_{1:1}$ = 1600 M^{-1}, and $K_{1:2}$ = 370 M^{-1}) cyclodextrin complexes were obtained.

The β-cyclodextrin system deposited a crystalline complex of I–β-cyclodextrin (1:2) at high β-cyclodextrin concentrations. Stoichiometry based on the data in the plateau region (13) in Fig. 1 was in good agreement with that obtained by isolation and analysis of the crystalline complex. In sharp contrast, the α-cyclodextrin system did not give any solid complex, a smaller cavity size apparently allowing little penetration of the bulky guest molecule.

The dissolution behavior and chemical stability of the isolated β-cyclodextrin complex were examined. The dissolution rate of the complex in powder was extremely large compared with that of I in water (Fig. 2), indicating an improved bioavailability. As shown in Table I, the decomposition of I was significantly retarded by inclusion complex formation. Thus, the increased dissolution rate, together with improved chemical stability, suggested that the β-cyclodextrin–I complex may have great utility in the development of fast dissolving dosage forms with prolonged storage time.

Furthermore, thermal gravimetric analysis[6] showed that the volatility of I was extremely depressed by binding to β-cyclodextrin. The crystallinity of the complex should facilitate drug formulation, which is difficult with uncomplexed I because it occurs as a viscous oil.

Differential Pulse Polarography of Tetracycline: Determination of Complexing Tendencies of Tetracycline Analogs in the Presence of Cations

T. JOCHSBERGER ˣ, A. CUTIE, and J. MILLS

Received October 18, 1978, from the *Arnold & Marie Schwartz College of Pharmacy and Health Sciences of Long Island University, Brooklyn, NY 11201.* Accepted for publication February 8, 1979.

Abstract □ The complexation tendencies, stoichiometries, and stability constants for tetracycline, minocycline, and demeclocycline with the metallic ions calcium(II), magnesium(II), zinc(II), aluminum(III), iron(II), and iron(III) were evaluated using a polarographic technique. Changes in pulse peak heights for each tetracycline derivative were measured as a function of cation concentration. The method provides an *in vitro* method of evaluating the selectivity of particular metal ions for different tetracycline analogs.

Keyphrases □ Tetracycline analogs—complexation, effect of cations, differential pulse polarography □ Tetracycline—complexation, effect of cations, differential pulse polarography □ Minocycline—complexation, effect of cations, differential pulse polarography □ Demeclocycline—complexation, effect of cations, differential pulse polarography □ Differential pulse polarography—tetracycline analogs, complexation, effect of cations

The phenomenon of complex formation between tetracycline analogs and various cations is well documented (1–3). This study reports the application of differential pulse polarography in determining the apparent complexation parameters for tetracycline, minocycline, and demeclocycline with Fe(II), Fe(III), and Al(III). The effect of other cations on the polarograms of the various tetracyclines was also examined.

EXPERIMENTAL

Apparatus—All polarograms were recorded on a polarograph[1] equipped with a three-electrode system and an *x–y* recorder[2]. The working electrode consisted of a dropping mercury electrode with a 1-sec drop time, which was controlled by a mechanical drop knocker. A commercial calomel electrode was used as the reference electrode, and a platinum wire was used as the auxiliary electrode. The electrolysis cell[3] had a 25-ml total volume, and the tetracycline derivative concentrations were 10^{-4}–10^{-5} *M*. Potential sweeps of 1 or 2 mv/sec and pulse modulations of 10 or 25 mv were employed.

Deaeration was performed by passing a stream of highly purified nitrogen through the solutions for ≥10 min. All experiments were carried out at room temperature, and potentials are reported with respect to the saturated calomel electrode.

Reagents—All salts (ferrous sulfate heptahydrate, ferric nitrate monohydrate, aluminum chloride hexahydrate, magnesium sulfate heptahydrate, calcium nitrate tetrahydrate, and potassium chloride) were reagent grade and used without purification. Compendial grade samples[4] of demeclocycline hydrochloride, minocycline hydrochloride, and tetracycline hydrochloride were utilized without further purification. Acetate buffers were freshly prepared from reagent grade materials.

Procedure—Complexation parameters were determined by measuring the polarograms of the cations in 0.1 *N* KCl in the absence and in the presence of added tetracycline derivative. The shifts in peak potential were determined as a function of concentration (Table I), and the complexation parameters (Table II) were calculated as described later.

In another set of experiments, the effect of successive additions of a given cation on the polarograms of the various tetracycline analogs was determined. In both sets of experiments, the standard addition technique was employed.

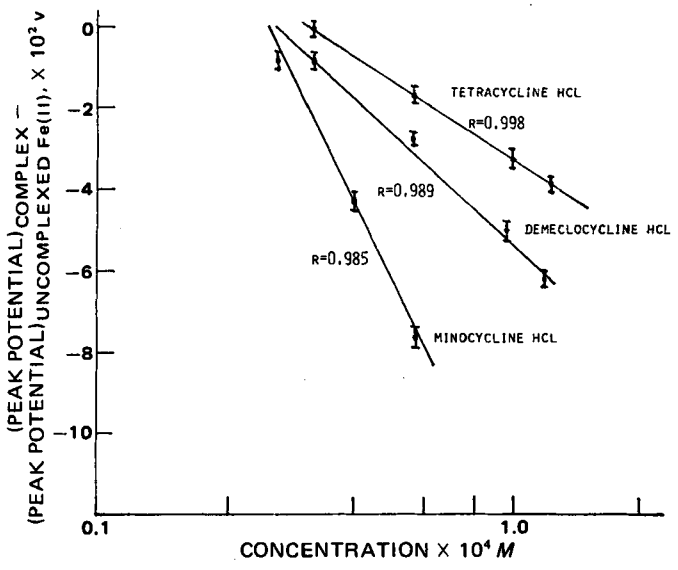

Figure 1—*Effect of tetracycline derivative concentration on Fe(II) peak potential (in 0.1 N KCl).*

RESULTS AND DISCUSSION

The polarography of complexed ions is well documented (4). The basic relationship between potential shifts and concentrations may be expressed by Lingane's equation (5):

$$E^{c}_{1/2} - E_{1/2} = \frac{-0.0591}{n} \log K_f - \frac{0.0591p}{n} \log M_L \qquad \text{(Eq. 1)}$$

where $E^{c}_{1/2}$ is the half-wave potential of a metal ion in the presence of M_L moles per liter of ligand, $E_{1/2}$ is the half-wave potential in the absence of ligand, n is the number of electrons gained in the reduction, K_f is the

Table II—Complexation Parameters for Cation-Tetracycline Derivative Complexes

Cation	Derivative	Log K_f	Apparent Coordination Number of Cation
Al(III)	Tetracycline	14.5	3
Al(III)	Minocycline	34.5	6
Al(III)	Demeclocycline	10.8	2
Fe(II)	Tetracycline	6.9	2
Fe(II)	Minocycline	17.8	4
Fe(II)	Demeclocycline	10.2	3
Fe(III)	Tetracycline	14.0	4
Fe(III)	Minocycline	20.2	4
Fe(III)	Demeclocycline	20.6	6

apparent formation constant, and p is the complex coordination number. There have been few attempts to apply differential pulse polarography to the study of complexation. Since the peak potential observed with the technique is identical to the half-wave potential (6), Eq. 1 can be modified to:

$$E_p^c - E_p = \frac{-0.0591}{n} \log K_f - \frac{0.0591p}{n} \log M_L \qquad \text{(Eq. 2)}$$

where E_p^c is the peak potential of the ion in the presence of M_L moles per liter of ligand and E_p is the peak potential in the absence of ligand. The other symbols have the same meaning as in Eq. 1.

Equation 2 indicates that plots of peak potential shift *versus* the logarithm of the ligand concentration should be linear. The slopes of these plots can be used to determine the complex coordination number, and the intercepts yield values for the formation constants. Figure 1 shows representative plots for ferrous ion and the various tetracyclines analogs. Slopes and intercepts were computed by linear regression, and correlation coefficients ranged from ±0.982 to ±0.999. Apparent complexation parameters determined utilizing this technique are presented in Table II.

The data indicate that minocycline forms more stable complexes with Al(III), Fe(III), and Fe(II) than do the other analogs. Since the exact point of attachment between the cations and the tetracyclines has not been elucidated, it is difficult to assess the precise basis of this greater stability. However, previous investigators (1) suggested the dimethylamino group as one coordinating group of tetracycline; the existence of two such groups on minocycline could account for the increased stability of its complexes. The data indicate that in the presence of Fe(II) and Al(III) ions, the apparent coordination number toward minocycline is twice that of tetracycline; this finding further supports the idea that complexing is *via* the dimethylamino groups.

Apparently, Ca(II) and Mg(II) do not complex as strongly with minocycline as they do with tetracycline and demeclocycline. Due to the close proximity of their reduction potential to that of potassium ion, it was not possible to obtain quantitative data in the form of complexation parameters for Ca(II) and Mg(II). However, these two ions had no effect on the polarogram of minocycline (Table III). The lack of an apparent interaction between Ca(II) and minocycline is consistent with the low effect of dairy products on the *in vivo* availability of this analog compared to tetracycline and other derivatives (7). This effect may also be indicative of an interaction between Ca(II) and Mg(II) and the various tetracyclines that is different from that of other cations (1).

The general effect of cation addition on tetracycline, minocycline, and demeclocycline solutions was to decrease the peak current in the polarograms (Table III and Fig. 2). This effect was not uniform. Al(III), Fe(III), and Fe(II) had significant effects on all three derivatives studied. With Fe(III) and tetracycline, the effect was observable at a peak potential of −1.04 v but not at −1.35 v. Ca(II) had a significant effect on the tetracycline and demeclocycline polarograms but not, as noted, on those of minocycline. Again the Ca(II)-tetracycline interaction appeared at a peak potential of −1.04 v but not at −1.35 v.

The dependence of the observed effect on peak potential is possibly related to the point of attachment between the cation and the tetracycline molecule. The present data, however, do not permit any definitive conclusion about that relationship. Zn(II) had no effect on the −1.35-v peak of the tetracycline polarogram. It was not possible to determine if an interaction occurred in the −1.0-v region due to the reduction of the cation itself. The interaction between Al(III) and the three tetracycline derivatives appears to be somewhat different from that of Fe(II) and Fe(III). The tetracycline and demeclocycline complexes of both iron salts and the minocycline-Fe(II) complex exhibited more negative peak potentials than the uncomplexed species, which is the usual observation with complexed species (8). However, Al(III) complexes exhibited a positive shift in peak potential with increasing ligand concentration.

The relative magnitude of the formation constants (Table II) for the three cations studied is consistent with previous observations made under different experimental conditions (2). The values for the coordination numbers determined by this technique (Table II) are generally consistent with those reported for tetracycline derivative complexes (1, 2). However, both significant clinical effects (9) and spectrophotometric changes occur

Table III—Relative Effect [a] of Cations on Peak Currents in Tetracycline Derivative Polarograms

Derivative	Al(III)	Fe(III)	Fe(II)	Ca(II)	Mg(II)	Zn(II)
Tetracycline	++	++[b]	++	++[b]	++	0[b]
Minocycline	++	++	++	0	0	—[c]
Demeclocycline	++	++	++	++	+	—[c]

[a] 0 = no effect, + = moderate effect, and ++ = significant effect. [b] Effect depends on peak potential. [c] No data.

at equimolar ratios of tetracycline to cation[5] (3). Therefore, even partial complexing can have important effects on both *in vivo* and *in vitro* tetracycline interactions.

Abstract □ Photolytic decomposition of indapamide (I) in nitrogen-flushed methanol yields 3-sulfamoyl-4-chlorobenzamide (II), 2-methylindoline (III), semicarbazide (IV), and 1-(*N*-formamido)-2-methylindoline (V); in oxygen-flushed methanol, II–V, 1-aminocarboxymethyl-2-methylindoline (VI), 3-sulfamoyl-4-chlorobenzoic acid (VII), methyl-3-sulfamoyl-4-chlorobenzoate (VIII), and 2-(*N*-acetamido)-benzoic acid (IX) are formed. A comparison is made with thermal decomposition of I.

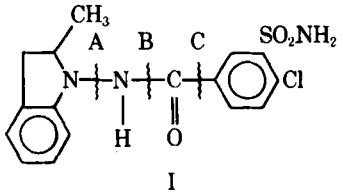
Keyphrases □ Indapamide—photolytic decomposition, thermal decomposition, decomposition products identified □ Photolysis—indapamide, products identified □ Thermolysis—indapamide, products identified □ Diuretics—indapamide, photolytic and thermal decomposition, products identified

There has recently been a growth in drug photosensitization studies. Numerous drugs have photosensitizing properties (1), and these properties appear to show a correlation with *in vivo* photosensitivity. In particular, the saluretic furosemide exhibits a high affinity for oxygen under UV irradiation, and this affinity may be related to the reported skin rash reaction among patients taking the drug (2).

As part of detailed studies of indapamide [*N*-(3-sulfamoyl-4-chlorobenzamido)-2-methylindole] (I), a compound with prolonged saluretic action (3), a study of the photolytic decomposition of this compound was conducted. In contrast to earlier studies (1), the products of *in vitro* photolytic decomposition were identified prior to *in vivo* experiments.

EXPERIMENTAL[1]

Indapamide (I) was supplied as a pure compound[2]. 2-Methylindoline (III), semicarbazide (IV), and 2-(*N*-acetamido)benzoic acid (IX) were supplied as pure reference compounds[3].



I

Photolytic decompositions were performed on 2.7×10^{-3} *M* I solutions in nitrogen- or oxygen-flushed methanol. The reactant solutions were contained in the inner well of a cylindrical quartz reaction vessel, which was mounted vertically before a 1000-w Hanovia medium-pressure mercury lamp. A filter solution of saturated aqueous copper sulfate was pumped through the annular space (4-mm i.d.) surrounding the inner well of the reaction vessel and also was pumped through a heat-exchanger to maintain the reactant solution at 293°K. The filter solution had a short wavelength cutoff at 300 nm. After photolysis for 12 hr, the solution was evaporated to dryness under reduced pressure. The residue was dissolved in a small volume of redistilled methanol prior to spotting on TLC plates.

Thermal decompositions were performed by heating samples in an automatic thermo-recording balance[4]. A 1-g sample of I was heated either at a constant rate of 5°K/min from ambient temperature to 453°K until the weight loss rate stabilized or at 453°K for 12 hr while the sample underwent a regular and continuous weight loss. The solids were dissolved in redistilled methanol prior to spotting on TLC plates.

Preparative TLC was performed using 20 × 20-cm plates coated with a 1-mm layer of silica gel[5]. Two solvent systems were used for plate development: 1, 100% dimethyl carbonate; and 2, the top layer obtained after vigorously shaking pentan-1-ol (85 cm^3) and ammonia (specific gravity 0.880, 15 cm^3) together and then allowing them to stand. All solvent systems were prepared fresh daily, and not more than two developments were carried out in any one preparation.

After development, reactant and product spots were visualized under UV light, scraped off the plates, and extracted into a small volume of redistilled methanol, which was evaporated to dryness under reduced pressure. The residual material was identified spectroscopically.

RESULTS AND DISCUSSION

The results relating to the identification of the products formed by I photolysis are summarized in Table I. These products arise principally as a result of bond cleavages in the N–NH–CO–C linkage.

[1] Mass spectra were recorded on an A.E.I. MS9 spectrometer, IR spectra were recorded on a Perkin-Elmer 257 spectrophotometer, NMR spectra were recorded on a Perkin-Elmer R.10 spectrometer, and UV spectra were recorded on a Unicam SP 8000 spectrophotometer.

Table I—Products from Photolytic and Thermal Decomposition of Indapamide

Photochemical Decomposition in N_2-Flushed Methanol	Photochemical Decomposition in O_2-Flushed Methanol	Thermal Decomposition	Product R_f Value[a]	Method of Structure Assignment[b]
II	II	II	0.19[c]	NMR, IR, UV, and mass spectra
III	III	III[d]	0.68	Comparison of IR, UV, and mass spectra with those of a reference sample
		IV	0.75	Comparison of IR, UV, and mass spectra with those of a reference sample
		V[d]	0.26	UV and mass spectra
VI	VI	VI	0.19[c]	NMR, IR, UV, and mass spectra
VII[e]	VII[e]		0.35	Mass spectrum[f]
	VIII[e]		0.45, 0.44*	Mass spectrum[f]
	IX		0.12*	Comparison of IR, UV, and mass spectra with those of a reference sample
	X		0.65	NMR, IR, UV, and mass spectra
	XI[e]		0.27*	Mass spectrum[f]

[a] The R_f values refer to qualitative TLC plates developed in Solvent System 1, except for those marked with an asterisk, which refer to Solvent System 2. [b] Unless otherwise stated, spectra were obtained for products isolated from each of the three decomposition systems. [c] The product at R_f 0.19 was a mixture of II and VI. Compound VI was sublimed out of the mixture and obtained as a white crystalline compound. [d] Product only observed in those thermal decomposition samples maintained at 453°K for 12 hr. [e] Minor product as judged by quantity of material isolated from TLC plates as compared to other products. [f] Only sufficient material could be isolated for a mass spectrum to be recorded.

Type A cleavage leads to 3-sulfamoyl-4-chlorobenzamide (II and III), type B cleavage leads to 3-sulfamoyl-4-chlorobenzoic acid, and type C cleavage yields 1-(*N*-formamido)-2-methylindoline (V) and 1-aminocarboxymethyl-2-methylindoline (VI). Methyl-3-sulfamoyl-4-chlorobenzoate (VIII) presumably arises as a consequence of esterification of VII by the solvent, while IX arises as a consequence of indoline ring oxidative cleavage in species such as III or I. At present, the origin of IV is not clear.

Thermal decomposition of I yields only II–IV besides 2-methylindole (X) and *N*-(3-sulfamoyl-4-chlorobenzamido)-2-methylindole (XI). Thus, type A cleavage can occur from vibrationally excited levels of the ground (S_0) state, and II and III can arise by this mechanism in photolytic reactions. Such species could be generated by internal conversion from the photolytically generated S_1 state. Presumably, the appropriate S_0 levels for dehydrogenation are not accessible *via* internal conversion. Type B and C cleavages only occur under photolysis and must, therefore, arise from the first excited states. Since such reactions are not inhibited by oxygen, which is known to quench triplet-state molecules (4), the S_1 state is implicated.

Thus, the study has demonstrated the complexity of photolysis of a simple pharmaceutical and has shown the wide range of compounds to be screened in photosensitization tests of such molecules.

Improved Spectrophotometric Determination of Glycerol and Its Comparison with an Enzymatic Method

ROY J. STURGEON ˣ, ROBERT L. DEAMER, and HARRY A. HARBISON

Received November 9, 1978, from *McGaw Laboratories, Irvine, CA 92714.* Accepted for publication February 5, 1979.

Abstract □ A chemical method for the determination of glycerol was developed and compared to an enzymatic assay for sensitivity and reproducibility. The chemical assay is based on glycerol oxidation to formaldehyde and subsequent reaction with chromotropic acid to yield a colored product. With this method, as little as 5 μg of glycerol/ml can be detected. The enzymatic assay is based on enzymatic glycerol phosphorylation followed by glycerol phosphate dehydrogenation by nadide (nicotinamide adenine dinucleotide). The reduced nadide is used to reduce iodonitrotetrazolium violet to its colored formazan product. The enzymatic method can be used to determine 50 μg of glycerol/ml in aqueous samples.

Keyphrases □ Glycerol—analysis, spectrophotometry, comparison with enzymatic method □ Spectrophotometry—analysis, glycerol, comparison with enzymatic method

Glycerol is widely used in pharmaceuticals as a vehicle, sweetening agent, emollient, and humectant. Various analysis methods for glycerol have been reported (1–5), but they are usually nonspecific and are limited to a narrow concentration range that gives linear results. Enzymatic methods (2, 4, 5) for glycerol and glycerol-releasing compounds (*i.e.*, triglycerides) have been used widely but are usually expensive and require rigid temperature control and timing of reagent addition to obtain reproducible results.

Chemical methods (1, 3) usually utilize glycerol oxidation to formaldehyde and subsequent reaction with a chromogenic reagent. These methods generally have been shown to produce linear results over a very limited concentration range. The present investigations were undertaken to develop a chemical analysis for glycerol with improved reaction conditions and to compare this method with a standard enzymatic assay.

double-beam spectrophotometer[1] using 1-cm quartz cells.

Reagents—All inorganic reagents were analytical reagent grade, were used without further purification, and were prepared in distilled deionized water. These reagents included sodium metaperiodate, sulfuric acid, sodium sulfite, and hydrochloric acid[2]. Glycerol[2] was obtained as the analytical reagent and was used without further purification.

Sodium 1,8-dihydroxynaphthalene-3,6-disulfonate[3] (chromotropic acid) was recrystallized several times from water–isopropyl alcohol by dissolution in hot water and then slow addition of an equivalent volume of alcohol until precipitation. The crystals were collected and dried overnight in a vacuum oven.

ATP[4] (8.9×10^{-3} *M*) and nadide (nicotinamide adenine dinucleotide)[4] (1.56×10^{-2} *M*) were obtained as a mixture and reconstituted with distilled water just prior to use. Iodonitrotetrazolium violet[4] and *N*-methylphenazonium methosulfate[4] were supplied in solution as analytical reagents. Glycerol kinase[4] (1780 units) and glycerol phosphate dehydrogenase[4] (150,000 units) were supplied in solution and mixed with the ATP–nadide solution immediately prior to use.

Procedures—*Chemical Assay*—The standard, 2.0 ml, or appropriately prepared sample containing 0–1000 μg of glycerol/ml was pipetted into a 16 × 100-mm test tube. One milliliter of 1% $NaIO_4$ was added and mixed thoroughly, and the mixture was allowed to stand at room temperature for ~15 min. Then 1 ml of 5% Na_2SO_3 was added and mixed, and the mixture was allowed to stand for 5 min.

One milliliter of this solution was pipetted into a 100-ml volumetric flask, and 0.50 ml of a 10% chromotropic acid solution was added. Then 5.0 ml of concentrated H_2SO_4 was added slowly, and the solution was heated at 100° in a water bath for 30 min. After heating for 30 min, air was bubbled through the solution for ~20 min. Distilled water was added to raise the volume to 90%. The solution was allowed to cool to room temperature and raised to volume with distilled water. The solution absorbance was measured at 570 nm.

Enzymatic Assay—Fifty microliters of the standard or appropriately prepared sample was pipetted into a 16 × 100-mm test tube. Glycerol kinase–glycerol phosphate dehydrogenase, 0.5 ml, was added, and the solution was placed in a 37° water bath. Exactly 10 min after the addition of the enzyme mixture, the test tube was removed from the water bath, 0.5 ml of 0.03% iodonitrotetrazolium violet and 0.005% *N*-methylphenazonium methosulfate was added, the test tube was returned immediately to the water bath.

Exactly 10 min after the last addition, the test tube was removed from the water bath, and 2.0 ml of 0.1 *N* HCl was added and mixed. Then the test tube was allowed to stand for 5 min. Within 30 min, the solution absorbance was measured at 505 nm.

Special care must be taken to ensure exact time intervals and proper temperature controls.

RESULTS AND DISCUSSION

After glycerol oxidation to formaldehyde by sodium periodate, the formaldehyde reacts with chromotropic acid in the presence of excess acid to yield a colored product (6). This reaction produces a product that follows Beer's law in the range of 5–1000 μg of glycerol/ml. Several investigators (7–9) have dealt with the optimization of the formaldehyde reaction with chromotropic acid. The critical factors found in the chemical assay procedure reported in this paper are: (*a*) the sulfuric acid concentration in the reaction mixture, (*b*) the chromotropic acid to glycerol concentration ratio, and (*c*) the time of heating at 100°.

Table I contains the results of varying the sulfuric acid concentration during the reaction with a sample originally containing 300 μg of glycerol/ml and after addition of the 0.50 ml of 10% chromotropic acid. The results indicate that 5.0 ml of sulfuric acid is an appropriate volume. Table II indicates that a chromotropic acid–glycerol ratio by weight of at least 50:1 should be used. These data were generated for 500-μg of glycerol/ml samples and 5.0 ml of sulfuric acid. From Table III, it can be seen that the reaction mixture using 300-μg of glycerol/ml samples, 0.5 ml of chromotropic acid, and 5.0 ml of sulfuric acid should be heated approximately 30 min. The color developed in this manner is stable for at least 48 hr. Other references for the reaction of formaldehyde with chromotropic acid (7, 10) have reported very limited concentration ranges over which the reaction will yield linear results. The sodium chromotropate recrystallization is essential to obtain reproducible results and greatly extends the linearity range.

Thus, glycerol in concentrations as low as 5 μg and as high as 1000 μg/ml was determined. The chemical method yields a linear relationship between the glycerol concentration and absorbance, with a correlation coefficient of 0.997. The results from two determinations per day for 5 days of 300-μg of glycerol/ml samples are listed in Table IV and give a standard deviation of 1.4 μg/ml and a coefficient of variance of 0.48%.

In the enzyme assay, following glycerol phosphorylation and glycerol phosphate dehydrogenation by nadide, the reduced nadide reduces iodonitrotetrazolium violet to a colored product (11). This procedure yields a product that follows Beer's law from 50 to 600 μg of glycerol/ml. Of critical importance in enzyme assays is the maintenance of temperature at 37° during the reaction and the time intervals at which reagents are added. The time intervals and temperature were already optimized for triglyceride testing (12) and were not investigated further.

In this method, as low as 50 μg and as high as 600 μg of glycerol/ml were determined. The enzymatic methods yields a linear relationship between the concentration of glycerol and absorbance, with a correlation coefficient of 0.975. As can be seen in Table IV, 10 determinations (two per day for 5 days) of 300-μg of glycerol/ml samples yielded a standard deviation of 22.4 μg/ml and a coefficient of variance of 7.5%.

Both the chemical and enzymatic assays are linear over the regions analyzed, with the working curve slopes being statistically different. The average response factor over the region analyzed in the chemical assay was $1.73 \pm 0.095 \times 10^{-3}$ absorbance unit/μg of glycerol/ml, with a coefficient of variance of 5.5%. The average response factor for the enzymatic assay was $8.3 \pm 1.5 \times 10^{-4}$ absorbance unit/μg of glycerol/ml, with a coefficient of variance of 18.2%. The chemical assay method is more sensitive due to a greater response per unit change in concentration and shows a wider linear concentration range than the enzymatic assay.

[4] Hycel Inc., Houston, Tex.

The reproducibility of the chemical assay (on a day to day basis) is superior to the enzyme assay, as seen by comparing the standard deviations and coefficients of variance from the data obtained from five consecutive test periods. The need for rigid controls of temperature and timing and the low reproducibility of the enzyme assay dictate that a standard working curve be generated each time numerous samples are run. The chemical assay offers a significant improvement in reproducibility and requires only an initial standard curve. The chemical assay described in this paper offers an easy, inexpensive, and reproducible method of determining glycerol in aqueous samples.

Clearance Constants in Physiologically Based Pharmacokinetic Models

HSIAO-SHENG GEORGE CHEN and JOSEPH F. GROSS ˣ

Received December 18, 1978, from the *Departments of Chemical Engineering and Internal Medicine, University of Arizona, Tucson, AZ 85721.* Accepted for publication February 14, 1979.

Abstract □ The intrinsic clearance of an organ is usually approximated by the apparent clearance from that organ in the development of a physiologically based pharmacokinetic model. In this study, the exact relationship between the two clearances was derived and analyzed. When the extraction ratio of the drug was small (<0.05), the approximation was reasonable. However, when the extraction ratio was high (>0.2), serious errors could be made by using the approximation. These errors could be as much as 50% reduction in the estimated extraction ratio and as much as an order-of-magnitude difference in the intrinsic clearance.

Keyphrases □ Pharmacokinetics—drug clearance through an organ, estimation □ Drug clearance—estimation of clearance through an organ, pharmacokinetics □ Antineoplastic agents—estimation of clearance through an organ, pharmacokinetics

In a typical linear physiologically based pharmacokinetic model (1), the drug concentration in an organ such as the kidney is governed by the differential equation:

$$V\frac{dC}{dt} = Q\left(C_p - \frac{C}{R}\right) - K\frac{C}{R} \qquad \text{(Eq. 1)}$$

where C and C_p are the drug concentrations in the organ and plasma (or blood), respectively; V is the physiological volume of the organ; Q is the plasma (or blood) flow rate through the organ; R is the equilibrium partition coefficient for drug distribution between the organ tissue and its venous plasma, and the constant K is a clearance term for drug elimination from the organ.

The development of a physiological model for predicting drug concentration–time histories requires the estimation of V, Q, R, and K. The parameters V and Q are the physiological volumes and blood flow rates through the organs for the subject to be simulated; R can be estimated from animal experiments and calculated according to a recently developed method (2). The clearance K is usually assumed to be equal to K_{app}, the apparent drug clearance from the organ. For example, if the organ is the kidney, K is usually calculated from:

$$K = K_{app} \equiv \text{total urinary excretion} \Big/ \int_0^\infty C_p\,dt \qquad \text{(Eq. 2)}$$

Several questions can be posed regarding K and its significance. What is its physical meaning? Is it equal to the apparent drug clearance from the organ? Can it be greater than Q, the plasma flow rate through the organ? How can K be estimated from experimental data? These questions will be discussed in the present paper.

THEORETICAL

Without loss of generality, the typical organ to be studied will be the kidney. The total cumulative urinary excretion, U, is then given as:

$$\frac{dU}{dt} = K\frac{C}{R} \qquad \text{(Eq. 3)}$$

or:

$$U = \frac{K}{R}\int_0^T C\,dt \qquad \text{(Eq. 4)}$$

where T is the urine collection time interval. Chen and Gross (2) showed recently that the drug concentration in the organ is related to the plasma drug level by:

$$C = \frac{QRC_p}{Q + K - \beta VR} \qquad \text{(Eq. 5)}$$

during the terminal elimination phase after intravenous bolus injection and that:

$$C = \frac{QRC_p}{Q + K} \qquad \text{(Eq. 6)}$$

at steady state after a constant-rate infusion. The parameter β is the apparent elimination rate constant for the terminal phase after intravenous injection. Therefore, Eq. 4 may be approximated as:

$$U = \frac{QK}{Q + K}\int_0^T C_p\,dt \qquad \text{(Eq. 7)}$$

for all modes of drug administration if $K + Q \gg \beta VR$ and if the tissue

Clearance Constants in Physiologically Based Pharmacokinetic Models

HSIAO-SHENG GEORGE CHEN and JOSEPH F. GROSS ˣ

Received December 18, 1978, from the *Departments of Chemical Engineering and Internal Medicine, University of Arizona, Tucson, AZ 85721.* Accepted for publication February 14, 1979.

Abstract □ The intrinsic clearance of an organ is usually approximated by the apparent clearance from that organ in the development of a physiologically based pharmacokinetic model. In this study, the exact relationship between the two clearances was derived and analyzed. When the extraction ratio of the drug was small (<0.05), the approximation was reasonable. However, when the extraction ratio was high (>0.2), serious errors could be made by using the approximation. These errors could be as much as 50% reduction in the estimated extraction ratio and as much as an order-of-magnitude difference in the intrinsic clearance.

Keyphrases □ Pharmacokinetics—drug clearance through an organ, estimation □ Drug clearance—estimation of clearance through an organ, pharmacokinetics □ Antineoplastic agents—estimation of clearance through an organ, pharmacokinetics

In a typical linear physiologically based pharmacokinetic model (1), the drug concentration in an organ such as the kidney is governed by the differential equation:

$$V\frac{dC}{dt} = Q\left(C_p - \frac{C}{R}\right) - K\frac{C}{R} \qquad \text{(Eq. 1)}$$

where C and C_p are the drug concentrations in the organ and plasma (or blood), respectively; V is the physiological volume of the organ; Q is the plasma (or blood) flow rate through the organ; R is the equilibrium partition coefficient for drug distribution between the organ tissue and its venous plasma, and the constant K is a clearance term for drug elimination from the organ.

The development of a physiological model for predicting drug concentration–time histories requires the estimation of V, Q, R, and K. The parameters V and Q are the physiological volumes and blood flow rates through the organs for the subject to be simulated; R can be estimated from animal experiments and calculated according to a recently developed method (2). The clearance K is usually assumed to be equal to K_{app}, the apparent drug clearance from the organ. For example, if the organ is the kidney, K is usually calculated from:

$$K = K_{app} \equiv \text{total urinary excretion} \Big/ \int_0^\infty C_p\,dt \qquad \text{(Eq. 2)}$$

Several questions can be posed regarding K and its significance. What is its physical meaning? Is it equal to the apparent drug clearance from the organ? Can it be greater than Q, the plasma flow rate through the organ? How can K be estimated from experimental data? These questions will be discussed in the present paper.

THEORETICAL

Without loss of generality, the typical organ to be studied will be the kidney. The total cumulative urinary excretion, U, is then given as:

$$\frac{dU}{dt} = K\frac{C}{R} \qquad \text{(Eq. 3)}$$

or:

$$U = \frac{K}{R}\int_0^T C\,dt \qquad \text{(Eq. 4)}$$

where T is the urine collection time interval. Chen and Gross (2) showed recently that the drug concentration in the organ is related to the plasma drug level by:

$$C = \frac{QRC_p}{Q + K - \beta VR} \qquad \text{(Eq. 5)}$$

during the terminal elimination phase after intravenous bolus injection and that:

$$C = \frac{QRC_p}{Q + K} \qquad \text{(Eq. 6)}$$

at steady state after a constant-rate infusion. The parameter β is the apparent elimination rate constant for the terminal phase after intravenous injection. Therefore, Eq. 4 may be approximated as:

$$U = \frac{QK}{Q + K}\int_0^T C_p\,dt \qquad \text{(Eq. 7)}$$

for all modes of drug administration if $K + Q \gg \beta VR$ and if the tissue

0022-3549/79/0800-1066$01.00/0

© 1979, American Pharmaceutical Association

to plasma concentration ratio can be approximated by Eq. 6 during the entire study period.

Comparison of Eq. 7 with the definition of apparent clearance, K_{app}, given by Eq. 2 yields:

$$K_{app} = \frac{QK}{Q+K} \quad \text{(Eq. 8)}$$

and:

$$K = \frac{QK_{app}}{Q-K_{app}} \quad \text{(Eq. 9)}$$

These equations apply to all organs except the lung where all the venous blood from all organs converges. A similar derivation for the lung gives:

$$(K_{app})_{lung} = K_{lung}(Q_{plasma} + K_{plasma})/Q_{plasma} \quad \text{(Eq. 10)}$$

and:

$$K_{lung} = \frac{(Q_{plasma})(K_{app})_{lung}}{Q_{plasma} + K_{plasma}} \quad \text{(Eq. 11)}$$

The reason for the difference is based on the definition of K_{app}; K_{app} is defined as the blood (or plasma) volume from which drug is completely removed in a unit time. For the other organs, the blood flows from the pooled plasma compartment into each individual organ. For the lung, the blood exits from the lung compartment into the plasma pool.

RESULTS AND DISCUSSION

Equation 8 shows that, as Q increases and approaches infinity, K_{app} approaches K. It is clear, then, that K is the true capacity of the organ to eliminate the drug. In other words, K is the intrinsic clearance, a concept developed for hepatic drug clearance (3). In fact, Eq. 8 reduces to the equation for hepatic clearance but is more general and applicable to all drug-eliminating organs except the lung.

In view of Eq. 8, which can be rewritten as:

$$K_{app} = K\left(1 - \frac{K}{Q+K}\right) = Q\left(1 - \frac{Q}{Q+K}\right) \quad \text{(Eq. 12)}$$

the apparent clearance K_{app} is always smaller than K or Q. However, there will be no upper limit for the intrinsic clearance K. Once the value of K_{app} is obtained from experiment using Eq. 2, K can be calculated from Eq. 9 by using the blood flow rate Q through that particular organ.

The alternative to this approach is to rearrange Eq. 12 to yield:

$$K = \frac{K_{app}}{1-E} \quad \text{(Eq. 13)}$$

where:

$$E = \frac{K}{Q+K} = \frac{K_{app}}{Q} \quad \text{(Eq. 14)}$$

is the steady-state extraction ratio, defined as the amount of drug eliminated divided by the amount of drug entering the organ at steady state. The approximation of K by K_{app} is valid only when the extraction ratio E is very small ($E < 0.05$). Most anticancer drugs have small E values, and this approximation is reasonable. However, when E is high and closer to unity, serious error of as much as an order-of-magnitude difference in K and as much as 50% in the estimated E may result from the approximation of K by K_{app}. Therefore, for drugs that have high hepatic extraction ratios such as doxorubicin ($E = 0.6$) (1), fluorodeoxyuridine ($E = 0.95 \sim 0.98$) (4), and fluorouracil [$E = 0.9$ in one study (5) and $E = 0.2$–0.5 in another (4)], Eq. 9 or 13 always should be used to calculate the intrinsic clearance.

New Calculation Method for Mean Apparent Drug Volume of Distribution and Application to Rational Dosage Regimens

Keyphrases □ Drug distribution volume—calculations, arithmetic mean method, harmonic mean method □ Dosage regimens—design, calculation of drug distribution volume, arithmetic mean method, harmonic mean method

To the Editor:

One important purpose of clinical pharmacokinetic studies is to obtain mean pharmacokinetic data to be used as an initial guide for drug therapy. The apparent volume of distribution (V_d) of a drug is a useful pharmacokinetic parameter in the one-compartment open-model system, which is often adequate clinically for the characterization of drug disposition kinetics (1–5). For example, the product of the mean V_d ($\overline{V}_d$) obtained from several subjects and the desired plasma level ($\overline{C}_p$) of the drug could be equal theoretically to the *mean* priming dose recommended for the same type of patient.

The mean V_d of test subjects has been calculated almost exclusively to date by the arithmetic mean method. In this method, the individual V_d values (V_{d1}, V_{d2}, ..., V_{dn}) estimated by various standard or approximate (3) methods are added and the sum is divided by the total number of test subjects (n). The purposes of this communication are to propose a new method for calculating the mean V_d and to point out the potential shortcoming of the conventional arithmetic mean method in predicting rational dosage regimens.

If the test subjects are representative of the mean patient population, one should expect that the recommended mean dose ($\overline{V}_d\overline{C}_p$) when applied to the original test subjects should *ideally* result in an arithmetic mean plasma level of all the test subjects *exactly* equal to the originally targeted $\overline{C}_p$ value. In other words:

0022-3549/79/0800-1067$01.00/0

© 1979, American Pharmaceutical Association

to plasma concentration ratio can be approximated by Eq. 6 during the entire study period.

Comparison of Eq. 7 with the definition of apparent clearance, K_{app}, given by Eq. 2 yields:

$$K_{app} = \frac{QK}{Q+K} \quad \text{(Eq. 8)}$$

and:

$$K = \frac{QK_{app}}{Q-K_{app}} \quad \text{(Eq. 9)}$$

These equations apply to all organs except the lung where all the venous blood from all organs converges. A similar derivation for the lung gives:

$$(K_{app})_{lung} = K_{lung}(Q_{plasma} + K_{plasma})/Q_{plasma} \quad \text{(Eq. 10)}$$

and:

$$K_{lung} = \frac{(Q_{plasma})(K_{app})_{lung}}{Q_{plasma} + K_{plasma}} \quad \text{(Eq. 11)}$$

The reason for the difference is based on the definition of K_{app}; K_{app} is defined as the blood (or plasma) volume from which drug is completely removed in a unit time. For the other organs, the blood flows from the pooled plasma compartment into each individual organ. For the lung, the blood exits from the lung compartment into the plasma pool.

RESULTS AND DISCUSSION

Equation 8 shows that, as Q increases and approaches infinity, K_{app} approaches K. It is clear, then, that K is the true capacity of the organ to eliminate the drug. In other words, K is the intrinsic clearance, a concept developed for hepatic drug clearance (3). In fact, Eq. 8 reduces to the equation for hepatic clearance but is more general and applicable to all drug-eliminating organs except the lung.

In view of Eq. 8, which can be rewritten as:

$$K_{app} = K\left(1 - \frac{K}{Q+K}\right) = Q\left(1 - \frac{Q}{Q+K}\right) \quad \text{(Eq. 12)}$$

the apparent clearance K_{app} is always smaller than K or Q. However, there will be no upper limit for the intrinsic clearance K. Once the value of K_{app} is obtained from experiment using Eq. 2, K can be calculated from Eq. 9 by using the blood flow rate Q through that particular organ.

The alternative to this approach is to rearrange Eq. 12 to yield:

$$K = \frac{K_{app}}{1-E} \quad \text{(Eq. 13)}$$

where:

$$E = \frac{K}{Q+K} = \frac{K_{app}}{Q} \quad \text{(Eq. 14)}$$

is the steady-state extraction ratio, defined as the amount of drug eliminated divided by the amount of drug entering the organ at steady state. The approximation of K by K_{app} is valid only when the extraction ratio E is very small ($E < 0.05$). Most anticancer drugs have small E values, and this approximation is reasonable. Table I—Reported Apparent Volumes of Distribution of Gentamicin in 11 Patients and Simulated Initial Serum Gentamicin Levels after Intravenous Bolus Doses Calculated Based on the Arithmetic and Harmonic Mean Methods for the Calculation of Mean Volume of Distribution and Initial Mean Targeted Level of 10 mg/liter

Patient	V_d, liter/kg	$C_{p(ari)}$, mg/liter	$C_{p(har)}$, mg/liter
1	0.19	12.94	12.11
2	0.19	12.94	12.11
3	0.22	11.18	10.45
4	0.25	9.84	9.20
5	0.20	12.30	11.50
6	0.29	8.48	7.93
7	0.20	12.30	11.50
8	0.49	5.02	4.69
9	0.22	11.18	10.45
10	0.25	9.84	9.20
11	0.21	11.71	10.95
Arithmetic mean	0.246	10.70	10.00

$$\overline{C}_p = (C_{p1} + C_{p2} + \ldots + C_{pn})/n \qquad \text{(Eq. 1)}$$

where $C_{p1}, C_{p2}, \ldots, C_{pn}$ are the resultant individual plasma levels for the n subjects, respectively. Since:

$$C_{pi} = \frac{\text{dose}}{V_{di}} = \frac{\overline{V}_d \overline{C}_p}{V_{di}} \qquad \text{(Eq. 2)}$$

combination of Eqs. 1 and 2 would result in:

$$\frac{1}{\overline{V}_d} = \frac{1}{n}\left(\frac{1}{V_{d1}} + \frac{1}{V_{d2}} + \ldots + \frac{1}{V_{dn}}\right) \qquad \text{(Eq. 3)}$$

This equation clearly shows that for the purpose of predicting a *correct* mean dosage, the mean V_d must be calculated by Eq. 3, which is commonly referred to as the harmonic mean method.

When different doses are used on the test subjects, Eq. 3 becomes:

$$\frac{1}{\overline{V}_d} = \frac{1}{n}\left(\frac{C'_{p1}}{\text{dose}_1} + \frac{C'_{p2}}{\text{dose}_2} + \ldots + \frac{C'_{pn}}{\text{dose}_n}\right) \qquad \text{(Eq. 4)}$$

where $C'_{p1}, C'_{p2}, \ldots, C'_{pn}$ are the resulting plasma levels for the n subjects, respectively. The plasma level from each subject can be corrected further based on the same total dose or some dose per unit of body weight or body surface area:

$$\frac{1}{\overline{V}_d} = \frac{1}{(n)(\text{dose})}(C^*_{p1} + C^*_{p2} + \ldots + C^*_{pn}) \qquad \text{(Eq. 5)}$$

Therefore:

$$\overline{V}_d = \frac{\text{dose}}{(C^*_{p1} + C^*_{p2} + \ldots + C^*_{pn})/n} \qquad \text{(Eq. 6)}$$

$$\overline{V}_d = \frac{\text{dose}}{\text{arithmetic mean plasma level}} \qquad \text{(Eq. 7)}$$

In other words, the mean V_d can be calculated also by dividing the dose (corrected to the same amount for all of the test subjects) by the arithmetic mean plasma level of the test subjects. This method will be referred to as the arithmetic mean–plasma level method. Obviously, these analyses can be applied equally well to the calculation of the mean apparent volume of the central compartment or the mean initial apparent volume of drug distribution in the multicompartment open model or the polyexponential plasma level decay system.

Table II—Reported Apparent Volumes of the Central Compartment of Theophylline in Nine Cirrhotic Patients and Simulated Initial Plasma Theophylline Levels after Intravenous Bolus Doses Calculated Based on Arithmetic and Harmonic Mean Methods for the Calculation of the Mean Central Compartment Volume and Initial Mean Targeted Level of 10 mg/liter

Patient	V_p, liter/kg	$C_{p(ari)}$, mg/liter	$C_{p(har)}$, mg/liter
1	0.448	7.37	4.44
2	0.144	22.92	13.82
3	0.781	4.23	2.55
4	0.095	34.74	20.95
5	0.157	21.02	12.68
6	0.163	20.25	12.21
7	0.146	22.60	13.63
8	0.282	11.70	7.06
9	0.753	4.38	2.64
Arithmetic mean	0.330	16.58	10.00

Literature examples on gentamicin, theophylline, and propranolol will be used to illustrate the differences in the mean volume of distribution and the initial plasma level that might result from the use of the two different methods for the volume of distribution calculation.

The data on the apparent volume of distribution of gentamicin in 11 burn patients (Table I) were reported by Sawchuk and Zaske (6). Their mean V_d based on the arithmetic mean method was 0.246 liter/kg. The mean V_d will be reduced to 0.230 liter/kg if the harmonic mean method is used. The data on the apparent volume of the central compartment (V_p) of theophylline in nine cirrhotic patients (Table II) were taken from a study of Piafsky *et al.* (7). The mean V_p reported, based on the arithmetic mean method, was 0.330 liter/kg. Based on the harmonic mean method, the mean V_p is 0.199 liter/kg. The arithmetic mean V_p of propranolol in three normal subjects was reported by Gomeni *et al.* (8) as 0.867 liter/kg. The mean V_p is, however, only 0.591 liter/kg based on the harmonic mean method. Different methods for calculating the mean V_d or V_p for these three drugs produce discrepancies ranging from 6.96 to 65.8% (Table III).

If the mean doses based on the two methods to achieve a mean serum or plasma level of 10 mg/liter for gentamicin or theophylline were used in these same patients, variations in the same manner in both individual or mean arithmetic mean serum or plasma levels would result (Tables I and II).

Although the arithmetic mean method for the mean volume of distribution calculation appears to be mathematically correct and the information obtained is useful, the harmonic mean or arithmetic mean–plasma level method reported here is the superior or perhaps the only correct method when the mean volume of distribution data

Table III—Summary of the Mean Apparent Volume of Distribution of Gentamicin and Mean Volumes of the Central Compartment of Theophylline and Propranolol in Human Subjects Estimated by Arithmetic and Harmonic Mean Methods

Method	Gentamicin, liter/kg	Theophylline, liter/kg	Propranolol, liter/kg
Arithmetic mean	0.246	0.330	0.867
Harmonic mean	0.230	0.199	0.591
Percent difference based on harmonic mean method as a reference	6.96	65.8	46.7

from the clinical trial are intended for designing a rational dosage regimen. The mean volume of distribution calculated from the test subjects should accurately predict their own plasma levels, even if the information is not intended for designing a rational dosage regimen.

In some studies, all individual plasma or serum data from the test subjects were grouped together and the pharmacokinetic analysis was performed based on these arithmetical *averaged* plasma or serum data (9). In intravenous bolus studies, the calculated mean initial volume of distribution obviously will be identical to the value calculated by the harmonic mean method and different from that calculated by the arithmetic mean method. This fact, which has probably not been pointed out before, might contribute to the difference in values reported from different studies.

In an earlier study (10) on clinical theophylline pharmacokinetics, the investigators reported that, depending on the methods used to calculate the mean total body clearance, as much as a 25–30% difference in the recommended infusion rate could occur. This phenomenon was considered as "unfortunate" (10). This author has made a similar analysis as presented in this communication and concluded that the best method for calculating the mean total body clearance in designing a rational dosage regimen is the harmonic mean method. Details of analyses will be reported later.

The preceding discussion is based on the assumption that the arithmetic mean method be used for the calculation of the mean plasma level. This approach was justified because the arithmetic mean method has been used almost exclusively for averaging peak, trough, steady-state, or mean steady-state plasma levels of drugs or metabolites in pharmacokinetic studies. This is probably also the case with mean levels of endogenous substances such as creatinine and urea reported in the literature. Statistically speaking, if the geometric, harmonic, or other mean method can be shown to be the best method for averaging plasma level data, then a different conclusion regarding the proper method for averaging the apparent volume of distribution can be obtained. The method proposed here can be applied to the calculation of other mean volumes of distribution such as the distribution volume at steady state.

In estimating the apparent volume of distribution of drugs after oral administration, the potential hepatic and pulmonary first-pass effects are often ignored. Appropriate equations are available for correcting for such effects (11–13). The harmonic mean method has been recommended for the calculation of the mean biological half-life of drugs (14).

Prostaglandin Prodrugs IV: Empirical Relationship between Functional Group Contributions and Melting Points of C_1-Esters

Keyphrases □ Prostaglandins—influence of functional group on melting points, dinoprostone and dinoprost C_1-esters □ Prodrugs—prostaglandins, influence of functional group on melting points, dinoprostone and dinoprost C_1-esters □ Dinoprost and dinoprostone C_1-esters—influence of functional group on melting points

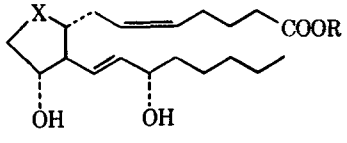
To the Editor:

Many prostaglandins occur as viscous liquids at room temperature, which presents problems in various pharmaceutical processes such as weighing and formulation. We recently showed that certain crystalline esters of the E-series prostaglandins are remarkably more stable than the parent prostaglandins (1). Now, based on melting-point data of numerous dinoprostone (I) and dinoprost (II) C_1-esters accumulated in our laboratories, we present a functional group contribution analysis of the influence of structure on melting points.

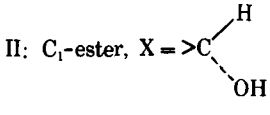
In principle, the melting point (T_m) of a substance can be calculated from:

$$T_m = \frac{\Delta H_f}{\Delta S_f} \qquad \text{(Eq. 1)}$$

where ΔH_f and ΔS_f are the heat and the entropy of fusion,



I: C_1-ester, X = >C=O



II: C_1-ester, X = >C

Prostaglandin Prodrugs IV: Empirical Relationship between Functional Group Contributions and Melting Points of C_1-Esters

Keyphrases □ Prostaglandins—influence of functional group on melting points, dinoprostone and dinoprost C_1-esters □ Prodrugs—prostaglandins, influence of functional group on melting points, dinoprostone and dinoprost C_1-esters □ Dinoprost and dinoprostone C_1-esters—influence of functional group on melting points

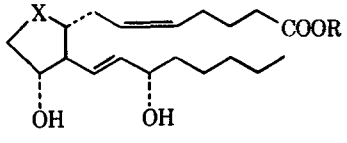
To the Editor:

Many prostaglandins occur as viscous liquids at room temperature, which presents problems in various pharmaceutical processes such as weighing and formulation. We recently showed that certain crystalline esters of the E-series prostaglandins are remarkably more stable than the parent prostaglandins (1). Now, based on melting-point data of numerous dinoprostone (I) and dinoprost (II) C_1-esters accumulated in our laboratories, we present a functional group contribution analysis of the influence of structure on melting points.

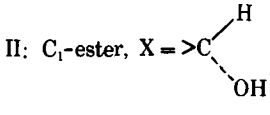
In principle, the melting point (T_m) of a substance can be calculated from:

$$T_m = \frac{\Delta H_f}{\Delta S_f} \qquad \text{(Eq. 1)}$$

where ΔH_f and ΔS_f are the heat and the entropy of fusion,



I: C_1-ester, X = >C=O



II: C_1-ester, X = >C

respectively. When a given substance undergoes an isothermal process, thermodynamic parameters associated with the process such as ΔH_f and ΔS_f can be approximated as the sum of the contributions of each functional group present in the molecule. For an ester, we would like to consider the values of ΔH_f and ΔS_f as the sum of the contributions by the prostaglandin (PG) and the ester alkyl or aryl (R) moieties. Thus, Eq. 1 becomes:

$$T_m = \frac{\Delta H_f^{PG} + \Delta H_f^{R}}{\Delta S_f^{PG} + \Delta S_f^{R}} \qquad \text{(Eq. 2)}$$

The prostaglandin group contribution should be constant for a series of prostaglandin C_1-esters, whereas the R group contribution varies depending on the structure. This group contribution approach appears to be quite valid for a series of dinoprostone C_1-phenyl esters in which the melting points are well correlated with those of the parent phenols (1).

In the present analysis, instead of handling both the heat and the entropy contributions, we are making a key assumption that the overall entropy of fusion is constant for the following two reasons. First, the group entropy contribution of the prostaglandin group is expected to predominate, mainly because the molecular size of these esters is largely determined by the prostaglandin group rather than the R group. The molecular weights of the esters are rather constant (570 ± 100). In this context, the entropy of fusion is considered to consist of two components: that due to the volume change and that due to the true entropy change upon fusion at constant volume (2). Thus:

$$\Delta S_f^{PG} + \Delta S_s^{R} \cong \Delta S_f^{PG} = \text{constant} \qquad \text{(Eq. 3)}$$

Second, we can approximate ΔS_f^{PG} to be constant if ΔS_f^{R} cannot be neglected with respect to ΔS_f^{PG}:

$$\Delta S_f^{R} = \Delta S_s^{R} - \Delta S_v^{R} \qquad \text{(Eq. 4)}$$

where ΔS_s^{R} and ΔS_v^{R} are the entropies of sublimation and vaporization, respectively. The entropy of sublimation is relatively constant for organic compounds of moderately constant size. For example, of 136 compounds for which ΔS_s values were compiled (3), over 100 compounds showed ΔS_s values within 50 ± 15 eu. As expected, extreme deviations are reported when the compounds become very

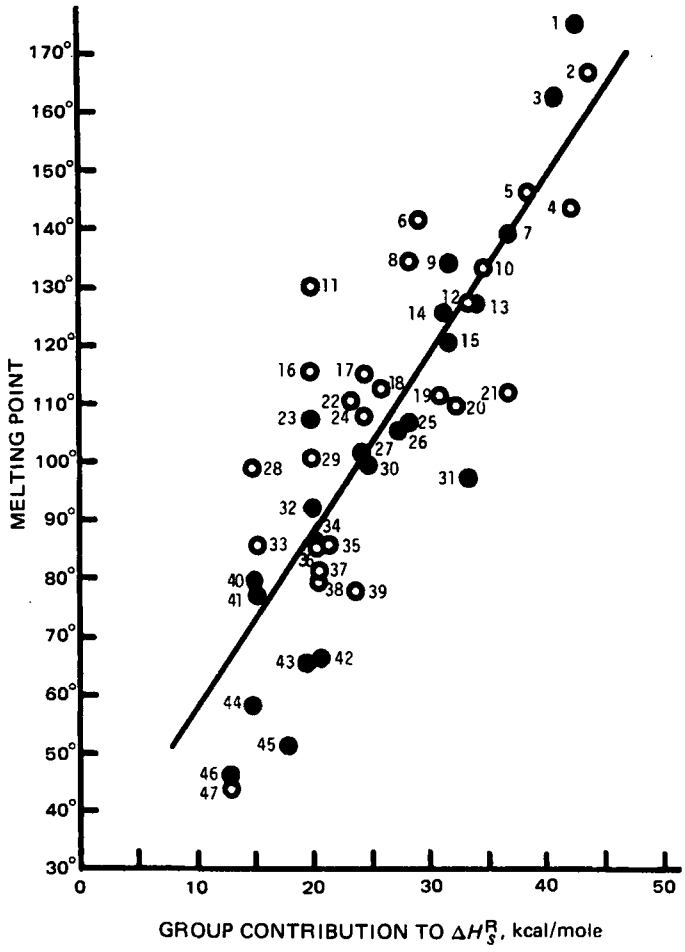

Figure 1—*Plot of melting points of dinoprostone (●) and dinoprost (○) C_1-esters* versus *the group contribution of the alcoholic portion of the ester (R) to the heat of sublimation (ΔH_s^R). The following dinoprostone C_1-esters were derived from the stated parent phenols (1): 1, p,p'-benzamidophenol; 3, N-benzoyl-L-tryosine amide; 7, N-acetyl-L-tyrosine amide; 9, p-benzamidophenol; 14, p-hydroxybenzaldehyde semicarbazone; 23, p-hydroxybenzamide; 25, p-hydroxyphenylurea; 27, acetaminophen; 31, p-tritylphenol; 32, p-phenylphenol; 40, 2-naphthol; and 41, phenyl acetate. The other compounds will be identified in future articles.*

large or very small; *e.g.*, the ΔS_s values for nonadecanoic acid and acetic acid are 151.2 and 25.7 eu, respectively (3). On the other hand, following Trouton's rule, we approximate $\Delta S_v \sim 21$ eu for pure liquids. Thus:

$$\Delta S_f^{R} = \text{constant} \qquad \text{(Eq. 5a)}$$

or:

$$\Delta S_f^{PG} + \Delta S_f^{R} = \text{constant} \qquad \text{(Eq. 5b)}$$

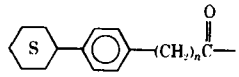
In reality, the combination of these two independent considerations supports the assumption that ΔS_f in Eq. 1 is constant for these esters. Now Eq. 2 becomes:

$$T_m = \alpha + \beta \sum_{i=1}^{n} \Delta H_i \qquad \text{(Eq. 6)}$$

where the summation operates over each functional group present in the R group.

Since no extensive group contribution data on ΔH_f are available in the literature and since ΔH_f is approximately proportional to the heat of sublimation (ΔH_s) in a series of compounds (2), we explored a relationship between the melting points of prostaglandin C_1-esters consisting of

Table II—Prednisolone C_{21}-Esters of



n	Melting Point
0	242°
1	202–203°
2	190–191°
3	160–162°

para-substituted phenyl and substituted alkyl moieties and the sum of ΔH_s contributions of each functional group present in the R moiety in the ester. Some important ΔH_s values used in our study are shown in Table I (2). A straightforward additivity rule was applied in calculating ΔH_s contributions from the R group. For instance, for the *p*-benzamidophenyl ester of dinoprostone, the ΔH_s contribution of the phenolic moiety is the sum of 2 × 10.0 for phenyl, 6.5 for >C=O, and 5.6 for —NH—, giving 32.1 kcal/mole.

The relationship between the melting points of 22 dinoprostone C_1-esters and 25 dinoprost C_1-esters and the ΔH_s contribution of the R groups is shown in Fig. 1. A least-squares analysis resulted in a slope of 3.04°/kcal/mole of ΔH_s and an intercept, the physically meaningless melting point of the prostaglandins without a proton at C_1, of 26.7°. Although the melting points of dinoprostone (63.4°) and dinoprost (~35°) are rather removed, visual inspection of the plot gives no indication of two separate relationships. The correlation coefficient was 0.851, which is surprisingly good considering all of the assumptions and approximations involved.

The reasonably good correlation observed appears to reflect the validity of our basic assumption that the prostaglandin group contribution to the melting point is constant. Both the E and F series of prostaglandins have substantial intramolecular interactions between two alkyl chains in the solid state (4) and the C_1-substituents probably do not disturb this basic molecular conformation, resulting in a rather constant crystal packing arrangement of the esters.

Of the C_1-esters prepared, about 20% of the liquid esters are predicted to be solids. Since it was difficult to crystallize many of the esters (up to 2 weeks of manipulation was sometimes required), many of these liquid esters possibly could be crystallized under proper conditions. Although we attribute the deviations observed largely to assumptions in the analysis, they could originate from polymorph formation. All of the esters were carefully purified by silica gel column chromatography, and it is unlikely that the deviations were due to impurities.

The present analysis applies mainly to terminally substituted prodrugs such as the prostaglandin C_1-esters. Application of the additivity principle may not hold for other prodrugs where the modification is at an internal position. Under these conditions, the assumption that ΔS_f is constant is not warranted due to a significantly higher entropy contribution (mainly rotational) brought about by modification at an internal position. This situation is illustrated by the *decrease* in melting points observed in some prodrug series using internal homologation (Table II). This decrease probably is due to an additional increase in entropy, which would lower T_m (Eq. 1). Therefore, our group contribution approach is not applicable in this case.

Cautious application of the treatment to terminally substituted prodrugs of relatively constant size should be of great use in analyzing the influence of structure on melting points. In these special prodrug series, the melting points may now allow *a priori* estimates of the influence of structure on other related physical properties.

Noncompartmental Determination of the Steady-State Volume of Distribution

Keyphrases □ Volume of distribution—steady state, noncompartmental determination, calculations □ Pharmacokinetics—steady-state volume of distribution, noncompartmental determination, calculations

To the Editor:

Up to the present time, the use in pharmacokinetics of the steady-state volume of distribution (Vd_{ss}) has been limited to specific compartmental mammillary models. However, mathematical methods usually associated in medicine with the use of indicator dilution curves to determine cardiac output and with the determination of mean residence time of endogenous substances following radiolabeled tracer injection permit Vd_{ss} determination without the assumption of a specific compartment model (or its analog, the assumption of a specific number of exponential functions).

Riggs (1) introduced the use of an overall volume of distribution term, Vd_{ss}, defined specifically with respect to the two-compartment open model, with elimination taking place from the central compartment:

$$Vd_{ss} = \left(1 + \frac{k_{12}}{k_{21}}\right) V_1 \qquad \text{(Eq. 1)}$$

The steady-state volume of distribution, as defined by Riggs (1), equals the total quantity of drug in the body divided by the concentration in the reference region of the central compartment when these measurements are taken when the tissue compartment contains the maximum amount of drug. Riegelman *et al.* (2) presented an exten-

Noncompartmental Determination of the Steady-State Volume of Distribution

Keyphrases □ Volume of distribution—steady state, noncompartmental determination, calculations □ Pharmacokinetics—steady-state volume of distribution, noncompartmental determination, calculations

To the Editor:

Up to the present time, the use in pharmacokinetics of the steady-state volume of distribution (Vd_{ss}) has been limited to specific compartmental mammillary models. However, mathematical methods usually associated in medicine with the use of indicator dilution curves to determine cardiac output and with the determination of mean residence time of endogenous substances following radiolabeled tracer injection permit Vd_{ss} determination without the assumption of a specific compartment model (or its analog, the assumption of a specific number of exponential functions).

Riggs (1) introduced the use of an overall volume of distribution term, Vd_{ss}, defined specifically with respect to the two-compartment open model, with elimination taking place from the central compartment:

$$Vd_{ss} = \left(1 + \frac{k_{12}}{k_{21}}\right) V_1 \qquad \text{(Eq. 1)}$$

The steady-state volume of distribution, as defined by Riggs (1), equals the total quantity of drug in the body divided by the concentration in the reference region of the central compartment when these measurements are taken when the tissue compartment contains the maximum amount of drug. Riegelman *et al.* (2) presented an exten-

sive discussion of the steady-state volume of distribution and the advantages of using this term when describing multicompartment distribution of drug in the body. They preferred the use of steady-state volume of distribution because this term (Eq. 1) is independent of the elimination rate constant. However, Benet and Ronfeld (3) pointed out that Vd_{ss} is independent of the elimination rate constant only when elimination occurs exclusively from the central compartment.

Gibaldi (4) showed that under steady-state conditions, as in a zero-order infusion, Vd_{ss} may be calculated without establishing the appropriate model or determining the distribution and elimination rate constants if plasma concentrations are measured from time zero until steady state is reached and then following termination of the infusion until no drug remains in the body. Once again, this determination is only valid when elimination occurs exclusively from the central compartment of a multicompartmental model (3). In practice, Vd_{ss} determinations in the literature (at least up to 1977) have been based on calculations involving microconstants and the volume of the central compartment such as is given in Eq. 1 for a two-compartment model.

Wagner (5) and van Ginneken (6) showed that Vd_{ss} may be determined directly from the coefficients and exponents of a polyexponential equation fit to the plasma concentration time data:

$$Vd_{ss} = \frac{\text{dose} \sum \left(\frac{A_i}{\lambda_i^2}\right)}{\left(\sum \frac{A_i}{\lambda_i}\right)^2} \qquad \text{(Eq. 2)}$$

where A_i defines the coefficients and λ_i defines the exponents in a polyexponential equation such as Eq. 3, an example for data requiring three exponential terms to describe the plasma concentration–time curve:

$$C_p = A_1 e^{-\lambda_1 t} + A_2 e^{-\lambda_2 t} + A_3 e^{-\lambda_3 t} \qquad \text{(Eq. 3)}$$

Wagner (5) stated that the Vd_{ss} value calculated using Eq. 2 applies only to the general model where elimination occurs exclusively from the central compartment. He suggested: "However, because of the dilemma of not knowing from which compartment there are exit rate constants to outside the body, use of Equation 2 will at least make all authors homogeneous in their approach." However, when the distribution constants for the model are determined as was done previously for calculations of Vd_{ss} (2) or when the coefficients and exponentials of a polyexponential equation are utilized (5, 6), the investigator is still required to propose some model and to determine a number of constants and coefficients either by graphical means or through the use of a nonlinear least-squares computer program. We describe a noncompartmental method of determining Vd_{ss} utilizing area under the curve determinations exclusively.

In indicator dilution studies, basic mathematical methodology is based on the Stewart–Hamilton theorems for flow and volume (7, 8). Perl and Samuel (9) generalized these theorems to the case of multiple input channels with partially labeled input in a study of the input rate and traced mass of body cholesterol. More recently, Oppenheimer *et al.* (10, 11) adapted these principles to facilitate calculation of conventionally used parameters in the study of iodothyronine metabolism and distribution. In these endocrinology studies (9, 10), the basic parameter determined using noncompartmental analysis is the mean residence time, $\bar{t}$, following an intravenous bolus dose:

$$\bar{t} = \frac{\int_0^\infty t C_p \, dt}{\int_0^\infty C_p \, dt} = \frac{AUMC_{0\to\infty}}{AUC_{0\to\infty}} \qquad \text{(Eq. 4)}$$

The denominator of Eq. 4 is the familiar (in pharmacokinetic terms) area under the plasma concentration–time curve (AUC) from time zero to infinity. The numerator is the area under the first moment of the plasma curve ($AUMC$), *i.e.*, the area under the curve of the product of time, t, and plasma concentration, C_p, from time zero to infinity.

Oppenheimer *et al.* (10) defined the mean residence time in terms of a rate constant, k, designated as the fraction of the total pool of iodothyronine irreversibly removed per unit of time:

$$k_{ss} = 1/\bar{t} \qquad \text{(Eq. 5)}$$

We have added a subscript to this rate constant to indicate that it is a constant *defined at steady state*. This k_{ss} should not be confused with either the rate constant describing elimination from the plasma compartment of a pharmacokinetic model or the rate constant describing the terminal plasma disappearance curve in a multicompartment model.

At steady state, the product of the rate constant k_{ss} and the volume Vd_{ss} may be defined as the total body clearance:

$$\text{total body clearance} = k_{ss} Vd_{ss} \qquad \text{(Eq. 6)}$$

since clearance may be defined as a product of the rate constant describing the total drug fraction irreversibly removed from the body as a function of time, multiplied by the volume of distribution on which that rate constant is operating. That is, Eq. 6 is identical to other definitions of total body clearance such as $k_{10}V_1$ and βVd_β (5). The total body clearance is a model-independent term and may be calculated for an intravenous injection as dose divided by the area under the plasma concentration–time curve from time zero to infinity. Substituting this quotient into Eq. 6, substituting the area relations for k_{ss} defined in Eq. 4 and 5, and rearranging yield the noncompartmental method for determining the steady-state volume of distribution:

$$Vd_{ss} = \frac{\text{dose}\left[\int_0^\infty t C_p \, dt\right]}{\left[\int_0^\infty C_p \, dt\right]^2} = \frac{\text{dose}[AUMC_{0\to\infty}]}{[AUC_{0\to\infty}]^2} \qquad \text{(Eq. 7)}$$

This calculation will be valid only when the underlying assumptions discussed by Perl and Samuel (9) are valid. In terms of pharmacokinetic analysis, the two most important of these assumptions are: (*a*) the system must respond linearly, *i.e.*, follow first-order kinetics, and (*b*) the exit of tracer or drug from the body must be directly from the measured site, *i.e.*, the plasma or central compartment

Table I—Sample Noncompartmental Vd_{ss} Calculation

Hours	C_p, μg/ml	tC_p, μg hr/ml	$\int_0^t C_p\,dt$ $[AUC_{0\to t}]$, μg hr/ml	$\int_0^t tC_p\,dt$ $[AUMC_{0\to t}]$, μg hr²/ml

[a] All integrals approximated by using the linear trapezoidal rule. Vd_{ss} = (dose $[AUMC_{0\to\infty}]/[AUC_{0\to\infty}]^2$) = 12,332 ml.

in a pharmacokinetic analysis. However, these are the same assumptions necessary to calculate Vd_{ss} by the methods described previously (Eqs. 1 and 2).

Wagner (5) compared Vd_{ss} calculation by Eq. 2 with Eq. 1 by simulating a bolus intravenous injection of a drug following two-compartment kinetics with elimination exclusively from the central compartment. Equation 8 contains the coefficients and exponentials utilized by Wagner to describe plasma concentrations following an intravenous 500-mg bolus dose (5):

$$C_p = 60.9545e^{-5.0605t} + 39.0459e^{-0.03952t} \qquad \text{(Eq. 8)}$$

Using Eq. 8, we calculated plasma concentration values over a 120-hr period (Table I). Column 1 indicates time in hours; column 2 is plasma concentration in micrograms per milliliter; column 3 is the product of columns 1 and 2. The linear trapezoid rule was utilized to calculate areas under the curve. Column 4 tabulates area under the plasma concentration *versus* time curve, and column 5 tabulates the values under the moment curve. The area under the plasma concentration–time curve from $C_{p_{last}}$ until time infinity was estimated using:

$$\int_{t_{last}}^{\infty} C_p\,dt = \frac{C_{p_{last}}}{\lambda_2} \qquad \text{(Eq. 9)}$$

where λ_2 is the terminal rate constant, *i.e.*, $-0.03952\ hr^{-1}$ in Eq. 8. Likewise, the area under the concentration–moment curve from $C_{p_{last}}$ to time infinity is given by Eq. 10 (11):

$$\int_{t_{last}}^{\infty} tC_p\,dt = \frac{t_{last}C_{p_{last}}}{\lambda_2} + \frac{C_{p_{last}}}{(\lambda_2)^2} \qquad \text{(Eq. 10)}$$

By using the coefficients and exponents of Eq. 8 to calculate AUC (*i.e.*, $A_1/\lambda_1 + A_2/\lambda_2$) and $AUMC$ (*i.e.*, $A_1/\lambda_1^2 + A_2/\lambda_2^2$), values of 1000.0 and 25,002.5 are obtained (5). The difference between these values and the summations in columns 4 and 5 of Table I results from the errors inherent in estimating areas using the linear trapezoid rule. If the logarithmic trapezoid rule (12, 13), Eq. 11[1], is used to estimate AUC, then a value of 1000.5 is obtained:

$$AUC_{t_1\to t_2} = \frac{(y_1 - y_2)\,\Delta t}{\ln (y_1/y_2)} \qquad \text{(Eq. 11)}$$

When the time infinity values for AUC and $AUMC$ from Table I are substituted into Eq. 7 with a dose of 500,000 μg, Vd_{ss} is calculated to be 12,332 ml, which is ~1.3% less than the actual 12,500-ml value. (Use of the logarithmic AUC calculation results in a value of 12,537 for Vd_{ss}.) These Vd_{ss} calculations were carried out using simple area under the curve determinations, independent of the assignment of a particular compartment model or a multiexponential computer data fit. Unfortunately, if plasma level measurements are not carried out to characterize accurately the area determinations or the terminal rate constant (as necessary in Eqs. 9 and 10), this simple method to determine Vd_{ss} is just as inaccurate as the classical methods under those conditions. A future publication will discuss the theoretical basis for the method as well as an error analysis. We have been utilizing this method in our recent pharmacokinetic work (14–16).

[1] This equation is only appropriate for decreasing plasma concentrations with time. When calculating AUC for curves that increase to a maximum, the linear trapezoid rule should be used for concentrations up to the peak. Again, Eq. 11 is just an approximation since theoretically the logarithmic trapezoid rule should only give a correct area estimation during the terminal log-linear portion of the plasma–time curve.

BOOKS

REVIEWS

Methods in Pharmacology, Vol. 4B, Renal Pharmacology. Edited by MANUEL MARTINEZ-MALDONADO. Plenum, 227 W. 17th St., New York, NY 10011. 1978. 403 pp. 15 × 25 cm. Price $39.50.

This volume aptly fills a gap in the literature. Although the book was apparently intended for researchers in this area, each topic is treated such that even pharmacologists and physiologists not active in renal research can gain a better understanding of and appreciation for the technology discussed. In addition to the clear treatment of each topic, all chapters are well referenced. This book should be made available to all students of pharmacology, physiology, and medicine.

The first chapter deals with morphological methods for studying the kidney, including fixation methods, light microscopy, and EM procedures. The second and third chapters deal with renal dynamics, including clearance methods and intrarenal blood flow measurements. Chapter 4 deals with micropuncture techniques, while the fifth chapter is concerned with microanalytical methods for analyzing samples obtained by the methods discussed in the previous chapter.

In Chapter 6, methods measuring glomerular dynamics are described, and mathematical models of glomerular ultrafiltration are discussed.

Chapters 7 and 8 provide detailed descriptions of the apparatus used in microelectrode studies; Chapter 7 has to do with electrical potential measurement, and Chapter 8 concerns pH measurement. Chapter 9 is especially interesting, providing methods for dissection and perfusion of isolated tubules.

Chapters 10–12 deal with renal biochemistry: Na–K-ATPase, adenylate cyclase, and intermediary metabolism. The last three chapters describe the methodology used in studying isolated perfused kidney in the dog (*in vitro* and *in vivo*) and the rat (*in vitro*).

The effectiveness of the book would have been greatly enhanced by including with each chapter a brief description of several experiments using the methods described. Including examplary experimental drug application protocols and some typical data obtained by the methods would have provided the pharmacologist reader with a much clearer understanding of how the method might be applied.

In addition, it would probably be helpful for many readers if the names and addresses of manufacturers of critical equipment and supplies had been provided with each chapter.

I have personally experienced a need for such information in my previous experience with other volumes of *Methods in Pharmacology*.

These two shortcomings are the only major problems I see in this volume, and I view it generally as a very informative and useful contribution to the scientific literature.

Cocaine: 1977 National Institute on Drug Abuse (Research Monograph Series 13). Edited by R. C. PETERSON and R. C. STILLMAN. Superintendent of Documents, U.S. Government Printing Office, Washington, DC 20402. Price $3 (paper cover).

The National Institute on Drug Abuse (NIDA) has been publishing monographs on specific substances of abuse. The monograph on cocaine follows a pattern similar to earlier monographs. There are 10 chapters by 13 authors with 350 references dating from 1884 to 1977. There is an adequate author and subject index.

The information in the book could be classified according to history, pharmacology and toxicology, abuse, use, behavioral aspects, and legal aspects.

This book and the others in the series are useful to anyone involved in the area of substance abuse. Their rather low price makes the entire series inviting.

This volume aptly fills a gap in the literature. Although the book was apparently intended for researchers in this area, each topic is treated such that even pharmacologists and physiologists not active in renal research can gain a better understanding of and appreciation for the technology discussed. In addition to the clear treatment of each topic, all chapters are well referenced. This book should be made available to all students of pharmacology, physiology, and medicine.

The first chapter deals with morphological methods for studying the kidney, including fixation methods, light microscopy, and EM procedures. The second and third chapters deal with renal dynamics, including clearance methods and intrarenal blood flow measurements. Chapter 4 deals with micropuncture techniques, while the fifth chapter is concerned with microanalytical methods for analyzing samples obtained by the methods discussed in the previous chapter.

In Chapter 6, methods measuring glomerular dynamics are described, and mathematical models of glomerular ultrafiltration are discussed.

Chapters 7 and 8 provide detailed descriptions of the apparatus used in microelectrode studies; Chapter 7 has to do with electrical potential measurement, and Chapter 8 concerns pH measurement. Chapter 9 is especially interesting, providing methods for dissection and perfusion of isolated tubules.

Chapters 10–12 deal with renal biochemistry: Na–K-ATPase, adenylate cyclase, and intermediary metabolism. The last three chapters describe the methodology used in studying isolated perfused kidney in the dog (*in vitro* and *in vivo*) and the rat (*in vitro*).

The effectiveness of the book would have been greatly enhanced by including with each chapter a brief description of several experiments using the methods described. Including examplary experimental drug application protocols and some typical data obtained by the methods would have provided the pharmacologist reader with a much clearer understanding of how the method might be applied.

In addition, it would probably be helpful for many readers if the names and addresses of manufacturers of critical equipment and supplies had been provided with each chapter.

I have personally experienced a need for such information in my previous experience with other volumes of *Methods in Pharmacology*.

These two shortcomings are the only major problems I see in this volume, and I view it generally as a very informative and useful contribution to the scientific literature.

Cocaine: 1977 National Institute on Drug Abuse (Research Monograph Series 13). Edited by R. C. PETERSON and R. C. STILLMAN. Superintendent of Documents, U.S. Government Printing Office, Washington, DC 20402. Price $3 (paper cover).

The National Institute on Drug Abuse (NIDA) has been publishing monographs on specific substances of abuse. The monograph on cocaine follows a pattern similar to earlier monographs. There are 10 chapters by 13 authors with 350 references dating from 1884 to 1977. There is an adequate author and subject index.

The information in the book could be classified according to history, pharmacology and toxicology, abuse, use, behavioral aspects, and legal aspects.

This book and the others in the series are useful to anyone involved in the area of substance abuse. Their rather low price makes the entire series inviting.

CAUTION URGED IN RATIONING RESEARCH

Remember those long gasoline lines earlier this summer?

Perhaps some of our readers reside in places where the gas crunch didn't hit so badly, but those of us in the Washington, D.C. area were not so lucky. As a result, we won't quickly forget the long lines of frustrated, agonizing motorists. Undoubtedly, our keen recollection is at least in part due to the fact that we ourselves sat in those lines, and we personally underwent the experience involved.

This constituted a vivid, living example of the theory of supply and demand; supply went down and demand went up, with the delicately balanced system thrown completely awry. If the supply falls or can't be increased, and if the demand either continues or expands, then a shortage will result. And the best that anyone can suggest as a remedy is some sort of rationing plan.

All of this is an introduction to another area of "rationing." We had first heard this suggested only within the past year, but have seen it mentioned with increasing frequency in recent months. And that is the idea of "rationing" health care.

In late June of this year, United Press International reported on the release of a Brookings Institute study which stated that health care costs are rising rapidly at a time when the traditional governing control—namely, ability to pay—is being abandoned in favor of the growing belief that no one should have to forgo medical care because of inability to pay.

The author of the study was quoted as saying, *"We must accept the true nature of the cost problem. Once we decide that costs are rising too fast and that, in order to slow them, we are willing to modify the philosophy that costs should not be a consideration in medical care, the next question is, 'How do we want to accomplish the rationing that must take place?' "*

Recognizing that even the idea of rationing health care is an "explosive one" for the medical community as well as the general public, the study points out that only modest economies remain to be achieved by current attacks on waste and fraud. Meanwhile, the demand for care and the cost of care are both soaring.

We might have simply dismissed this Brookings study as some academic speculation and idle theorizing if it were not for several similar reports, projections, and conclusions appearing from other sources. The most startling of these was a full three-page discussion entitled "Is health care 'rationing' inevitable?" which appeared in the weekly newspaper of that bastion of conservatism, the American Medical Association.

This publication labeled the thought as "a somewhat alarming idea," but the message that came through was that ultimately some kind of rationing system will be applied to health care. To quote one of the discussants, *"At some point, society, quite independently of what you and I believe about medicine, will decide that 10% or 12% of the GNP is enough to spend on health care and decide that they aren't going to pay any more. Given that societal decision, then we'll have to decide what the appropriate balance should be between the present marketplace rationing system and the implicit and explicit rationing."*

What does all this have to do with pharmacy and the pharmaceutical sciences? Plenty! Drug products and pharmaceutical service are integral components of health care. Although they account for only a fraction of the health care dollar, they do represent significant costs. Moreover, when government agencies and legislators have looked for places to cut costs in the past, drugs and pharmaceutical services are among the first areas targeted. And when the budget for drug purchase goes down, the drug research budget ultimately is affected as well.

Although "rationing" *per se* would be a new development in the case of pharmaceuticals, we have had some related experiences in which restrictions have been applied or considered in drug development or distribution, due either to the cost or availability of drug products.

For example, each year the question of mass flu immunization programs centers around the cost of such programs *viś-à-viś* their anticipated or projected benefit in terms of health savings to the public. Regarding limited supplies, during World War II shortages of quinine to treat malaria and of the newly developed antibiotic, penicillin, to treat infections caused by battle wounds required a system of priority establishment that certainly approximated rationing. Subsequently, when polio vaccine first became available, the limited supplies required that choices be made as to whom it would be administered.

But in the quest for economy, we hope that the decision-makers recognize that carefully chosen and wisely selected research can often be the most effective route to major economies. For example, countless drugs are now available to use *via* chemical synthesis at a small fraction of their previous cost from biological or botanical sources. In other instances, research has led to the development of greatly improved and more effective agents.

Hence, we must remain vigilant to the need to ensure the continued viability of our drug research effort, so long as it is channeled toward truly productive goals and objectives.

—EGF

Isoproterenol-Induced Cardiac Arrhythmias

The October 1978 issue of the *Journal of Pharmaceutical Sciences* (p. 1390) contained a publication from the Department of Pharmaceutical Sciences, College of Pharmacy and Allied Health Professions, St. John's University, Jamaica, N.Y., entitled "Hemodynamic Alterations in Isoproterenol-Induced Cardiac Arrhythmias in Corticoid-Treated Rats," under the authorship of Michael A. Barletta, David Lehr, and Giancarlo Guideri.

This article was published by Dr. Barletta without approval or knowledge of the coauthors and did not contain any reference to the Department of Pharmacology, New York Medical College, Valhalla, N.Y., where the described studies had been performed and where both coauthors hold full-time positions. Neither coauthor has any association with St. John's University.

The data described in Dr. Barletta's publication were derived from his thesis research carried out from 1971 to 1974, in partial fulfillment of the requirements for a Ph.D. degree in Pharmacology at New York Medical College, under the sponsorship and guidance of Dr. Lehr and with the supervisory collaboration of Dr. Guideri.

Since Dr. Barletta's thesis had been completed early in 1974, the publication cited above does not encompass the current concepts of the coauthors, which are based on comprehensive additional studies carried out in the 5 intervening years. This is true, in particular, for work on the mechanism of sensitization of the corticoid-pretreated rat to ventricular arrhythmias and ventricular fibrillation by β-adrenergic agonists, as well as the role of α- and β-adrenergic stimulation in the elicitation of arrhythmias in the corticoid-pretreated rat and in the production of experimental myocardial necrosis. These aspects have been investigated by the coauthors in association with Ph.D. candidates Mark Green, Cynthia Healy, and Alison Brown[1-9].

An article representative of the present status of these investigations and focusing on data obtained by Mark Green in direct continuation of studies in the area of Dr. Barletta's thesis research has been submitted for publication.

Quality Control in the Pharmaceutical Industry
Edited by MURRAY S. COOPER

This multi-volume treatise represents a convenient, practical and comprehensive guide to nearly every aspect of the quality control of pharmaceutical products. It encompasses the spectrum of relevant scientific disciplines—including biochemistry, analytical chemistry, physiology, and microbiology—as well as administrative matters such as the function of government agencies. The authors discuss each topic in sufficient detail to be of immediate practical value to pharmaceutical quality control managers and their technical staffs. In addition, the treatise will enable the scientist or administrator in the industry to broaden his knowledge of technical areas outside of his own speciality. This treatise will be a necessary addition to the libraries of technical and administrative personnel in the pharmaceutical industry.

Effect of ^{60}Co-Irradiation on Penicillin G Procaine in Veterinary Mastitis Products

KIYOSHI TSUJI ˣ, JOHN F. GOETZ, and WILLIAM VANMETER

Received January 8, 1979, from *Control Analytical Research and Development, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication March 2, 1979.

Abstract □ The effect of ^{60}Co-irradiation on penicillin G procaine in a peanut oil-based veterinary mastitis product was examined by reversed-phase high-performance liquid chromatography (HPLC). The HPLC method is capable of separating and quantifying procaine, penicillin G, and various degradation compounds. Penicillin G recovery from a placebo formulation was 100.4% with a relative standard deviation of <1%. When irradiated at 4.0 Mrads, the penicillin G in two product lots decreased slightly (~1–2%) with a corresponding increase in two compounds inherently present in bulk penicillin G powder. These compounds may be formed in abundance by treating penicillin G in an acidic solution. From the mass spectrometric analysis and the relative retention data with authentic compounds, these compounds were identified as benzylpenilloaldehyde and benzylpenaldic acid. Values obtained by the HPLC method on the product irradiated and stored at various temperatures correlated well with those of the microbiological assay. No significant decrease in the procaine was detected even after 4.0-Mrad irradiation. The HPLC method is applicable for analysis of other β-lactam antibiotics.

Keyphrases □ Penicillin G procaine—effect of cobalt irradiation, veterinary mastitis products, sterilization □ Cobalt irradiation—effect on penicillin G procaine, veterinary mastitis products, sterilization □ Sterilization—penicillin G procaine, veterinary mastitis products, cobalt irradiation

The Ministry of Agriculture, Food, and Fisheries in the United Kingdom has served notice that all new veterinary mastitis products to be marketed in the United Kingdom must be sterile. Moreover, sterility is required for existing veterinary mastitis products at their reregistration time. Since the efficacy and toxicity of ethylene oxide as a sterilization agent are being questioned by both the Food and Drug Administration (1) and the Environmental Protection Agency in the United States (2), ^{60}Co-irradiation was examined as a reliable and economical means to sterilize terminally a veterinary mastitis product. The ^{60}Co-irradiation has been recognized as the method of choice for sterilization of medical devices and has been accepted for terminal sterilization of ophthalmic ointments (3). In many countries, products irradiated at 2.5 Mrads by cobalt 60 may be released as sterile without the final sterility testing.

Although the official microbiological cylinder cup–agar diffusion assay may be used as a stability-indicating method for penicillin G (4), a more precise and accurate method is desirable for monitoring the effect of ^{60}Co-irradiation treatment. Since a reversed-phase high-performance liquid chromatographic (HPLC) assay of β-lactam antibiotics (5) was improved by use of a column packed with 5–10-μm particle size C_{18} (6) and used in this laboratory for many years, this method was selected to assess the effect of ^{60}Co-irradiation on procaine and penicillin G in a veterinary mastitis product. Similar HPLC assays for β-lactam antibiotics have appeared (7–16).

EXPERIMENTAL

Apparatus—A modular liquid chromatograph equipped with a 254-nm UV monitor[1], a high-pressure pump[2], and a 20-μl fixed-loop injector[3] were used. A low C_{18}-loaded reversed-phase column[4] with a stainless steel precolumn[5], 51 × 2.1 mm i.d., was used to separate procaine and penicillin G.

Reagents—For the mobile phase, acetonitrile–water–0.2 *M* ammonium acetate buffer (20:70:10) was used. The pH was adjusted to 6.0 with acetic acid. The 0.2 *M* ammonium acetate buffer was prepared by weighing 15.5 g of ammonium acetate into a 1-liter graduated cylinder and adding water to volume. The mobile phase was filtered through a membrane filter[5].

The mobile phase was pumped through the column at a flow rate of ~1.0 ml/min.

Reference Standard Solutions—*Penicillin G*—The USP penicillin G potassium reference standard was used "as is" at 1590 units/mg. Ap-

proximately 6.7 mg of the reference standard was weighed accurately[6] and placed in a 10-ml volumetric flask. The standard was dissolved and diluted to volume with the mobile phase. The reference standard solution thus prepared was transferred to a 35-ml disposable vial, and 10 ml of isooctane (2,2,4-trimethylpentane) was added. The vial was capped and shaken gently for 5 min on an automatic reciprocal shaker[7]. The top isooctane layer was aspirated off, and 5 ml of isooctane was again added. The vial was shaken again for 5 min and then centrifuged at 1000×*g* for 1 min. The top half of the sample was aspirated off, and the sample was sonicated just prior to chromatographic analysis.

Procaine—Approximately 4.5 mg of procaine hydrochloride USP was weighed accurately[6] and placed in a 50-ml volumetric flask. The standard was dissolved and diluted to volume with the mobile phase. The standard solution was transferred to a 125-ml separator containing 50 ml of isooctane. The flask was shaken gently for 5 min on an automatic reciprocal shaker[7].

The top isooctane layer was aspirated off, and 25 ml of isooctane was added. The flask was shaken again for 5 min. Approximately 10 ml of the lower phase was transferred into a 35-ml disposable vial and centrifuged at 1000×*g* for 1 min. The top half of the sample was aspirated off, and the sample was sonicated just prior to chromatographic analysis.

Sample Preparation—A plastet containing the peanut oil-based mastitis product was weighed. After the plastet was shaken vigorously, the contents were expelled into a 250-ml separator containing 100 ml of the mobile phase. The empty plastet was weighed to calculate by difference the weight of the content being assayed. Approximately 100 ml of isooctane was added, and the flask was shaken gently for 5 min on a reciprocal shaker[7].

Approximately 75% of the top layer was aspirated off, and 50 ml of isooctane was added. The flask was shaken again for 5 min. Approximately 10 ml of the lower phase was transferred into a 35-ml disposable vial and centrifuged for 1 min at 1000×*g*. The top half of the sample was aspirated off.

Table I—Precision of the HPLC Assay for Penicillin G in Peanut Oil-Based Mastitis Product

Net Weight of Product, g	Height of Penicillin G Peak, cm	Peak Height of Penicillin G/ Weight of Product[a]
8.16	27.0	3.31
8.21	27.0	3.29
8.19	27.2	3.32
8.25	27.6	3.35
8.36	28.2	3.37
8.33	28.0	3.36

[a] *RSD* = 0.94%.

[6] Model G electrobalance, Cahn Instrument Corp., Paramount, Calif.
[7] Eberbach, Ann Arbor, Mich.

Penicillin G—For the penicillin G assay, the sample solution was chromatographed.

Procaine—The sample solution was diluted 1:5 with the mobile phase and chromatographed.

Calculations—*Penicillin G*—The penicillin G content in a plastet was calculated from:

$$\text{penicillin G content} = \frac{P_{sm}}{W_{sm}} \times \frac{W_{std}}{P_{std}} \times \text{Sp.G.} \times 100 \times 1590 \quad \text{(Eq. 1)}$$

where P_{sm} is the peak height or peak area of the sample, W_{sm} is the weight of the sample in grams, W_{std} is the weight of the standard in milligrams per milliliter, P_{std} is the peak height or peak area of the reference standard, Sp.G. is the specific gravity of the mastitis product, and 1590 is the potency of the penicillin G USP reference standard (issue F).

Procaine—The procaine content per plastet may be calculated from:

$$\text{procaine content} = \frac{PK_{sm}}{W_{sm}} \times \frac{W_{std}}{PK_{std}} \times \frac{F_1}{F_2} \times F_3 \times F_4 \times F_5 \times \text{Sp.G.} \times P \quad \text{(Eq. 2)}$$

where PK_{sm} is the peak height or peak or peak area of the sample; W_{sm} is the weight of the sample; PK_{std} is the peak height or peak area of the reference standard; W_{std} is the weight of the standard; F_1, F_2, and F_3 are volumes of the sample solution, the reference standard solution, and the plastet, respectively; F_4 is the final volume of the sample; F_5 is the conversion factor from procaine hydrochloride to procaine base (0.866); Sp.G. is the specific gravity of the mastitis product; and P is the purity of the procaine USP reference standard.

RESULTS AND DISCUSSION

Factors Affecting Resolution of Penicillin G and Procaine Peaks—During the evaluation of several silica with bonded octadecylsilane[8] columns, the resolution of penicillin G from the procaine peak

was difficult to reproduce. Factors such as the acetonitrile and methanol concentrations in the mobile phase were examined to obtain the optimum resolution of the two compounds.

As shown in Fig. 1A, an increase in the methanol concentration decreased the elution volume of both the penicillin G and the procaine peaks. The effect on the penicillin G peak was more pronounced than on procaine. The peak elution order, however, remained the same.

Acetonitrile, on the other hand, drastically affected the penicillin G peak elution volume (Fig. 1B). The effect of the acetonitrile concentration on the procaine elution volume was less. In fact, the elution order of

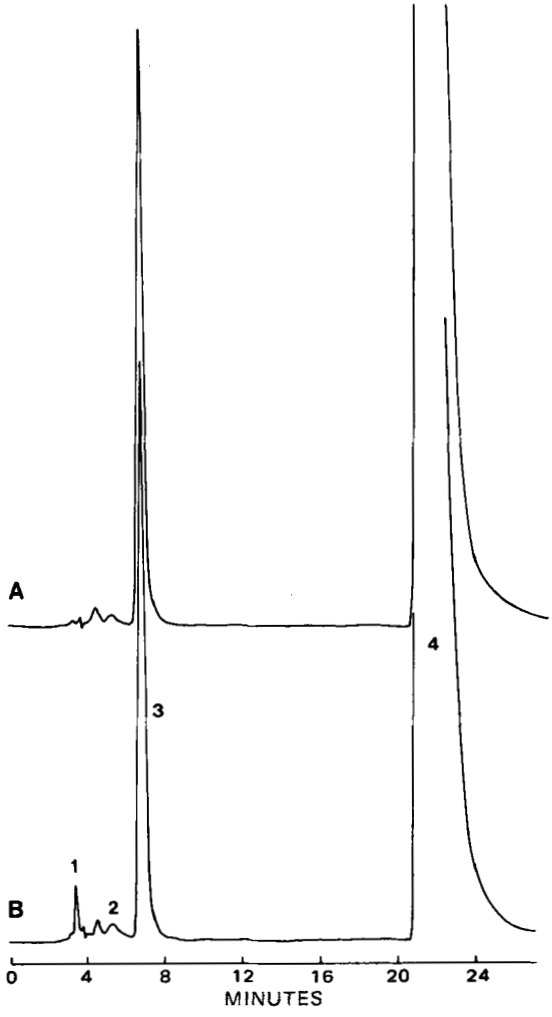

Figure 2—*HPLC analysis of penicillin G procaine irradiated at 0 Mrads (A) and 4.0 Mrads (B) in a mastitis product using a ODS-I column. penicillin G and procaine crossed over at the acetonitrile concentration of ~27–28%. This intersecting point varied from one column to the next. Since the majority of the penicillin G degradation compounds elute earlier than the penicillin G peak, the chromatographic conditions should be adjusted such that penicillin G elutes faster than the procaine peak.

This adjustment cannot always be reliably reproduced, however, especially between columns, and such attempts often caused the penicillin G peak to elute too close to the solvent front. Therefore, various commercially available C_{18} reversed-phase columns[9] were evaluated. In general, use of a highly C_{18} loaded column (more than 10%) resulted in near complete merger of the two peaks. Only a low C_{18} loaded column[4] (about 5%) consistently achieved a complete separation of the two peaks;

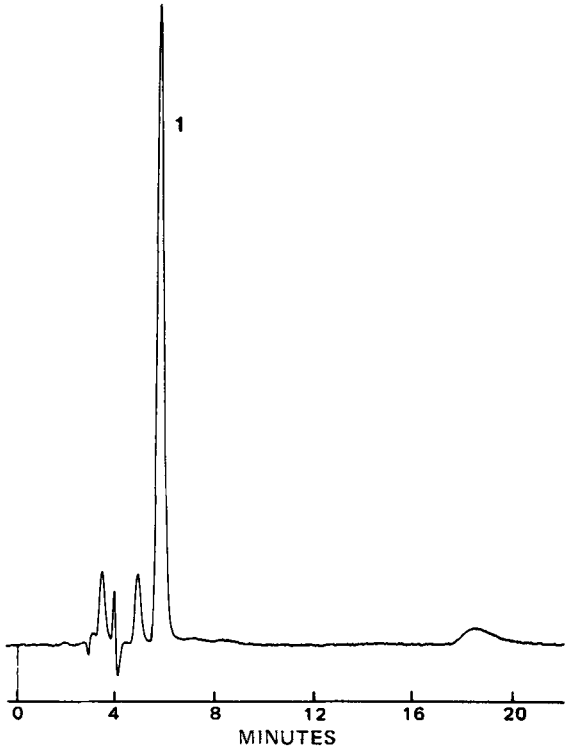

Figure 4—*HPLC analysis of ampicillin (1) in an oral formulation using a μBondapak C_{18} column. The mobile phase was acetonitrile–0.2 M ammonium acetate buffer–water (15:10:85), pH 6.0.*

more than 12 min of elution time separated the procaine and penicillin G peaks (Fig. 2A). It may be theorized that the underivatized hydroxyl groups on the silica column support exhibit strong affinity toward the procaine molecule, resulting in longer procaine retention and the separation of the two compounds.

Precision and Recovery of Penicillin G from Peanut Oil-Based Mastitis Product—Precision of the HPLC assay was evaluated by individually weighing and extracting six replicate mastitis product samples. The relative standard deviation of the HPLC method was <1% (Table I).

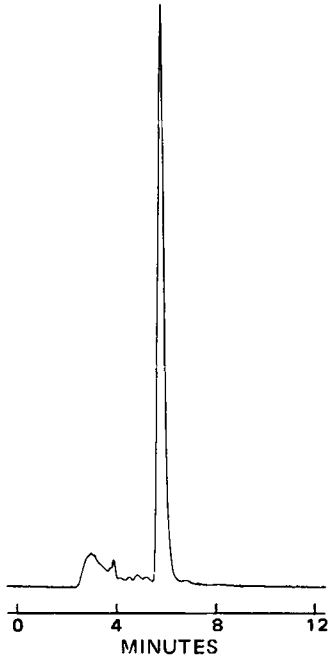

Figure 5—*HPLC analysis of penicillin O using a μBondapak C_{18} column. The mobile phase was acetonitrile–0.2 M ammonium acetate–water (25:10:65), pH 6.0.*

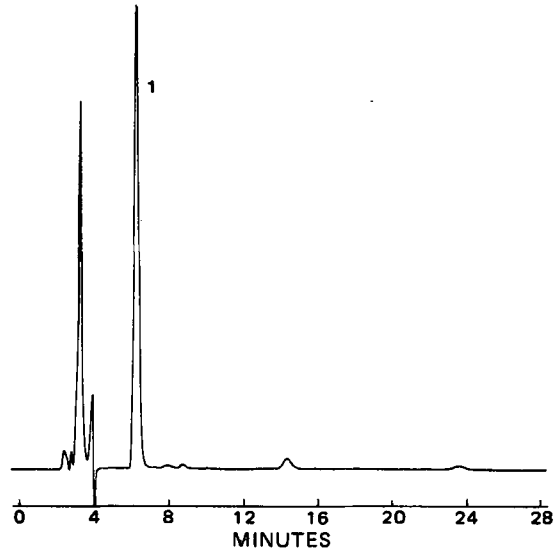

Figure 6—*HPLC analysis of penicillin V (1) in an oral formulation using a μBondapak C_{18} column. The mobile phase was acetonitrile–0.2 M ammonium acetate–water (30:10:60), pH 6.0.*

The extraction technique efficiency for penicillin G recovery from the product was evaluated by adding three independently weighed penicillin G USP reference standard samples to the product base. The penicillin G recovery from the product base was 100.4% (Table II).

Penicillin G Stability to ^{60}Co-Irradiation—Penicillin G in a peanut oil-based veterinary mastitis product was relatively stable to ^{60}Co-irradiation. Even after 4.0 Mrads irradiation, the maximum irradiation level targeted for product sterilization, penicillin G in two product lots showed decreases in potency of only 2.0 and 1.1% (Table III).

Although several impurity peaks were present in unirradiated penicillin G procaine (Fig. 2A), only two peaks were increased by ^{60}Co-irradiation (Fig. 2B). Since these degradation compounds are inherently present in the untreated penicillin G procaine powder, these compounds are not formed uniquely by ^{60}Co-irradiation. These degradation compounds can be formed in abundance when penicillin G powder is treated in a low pH solution (pH 3.0) at 37° for 1 hr.

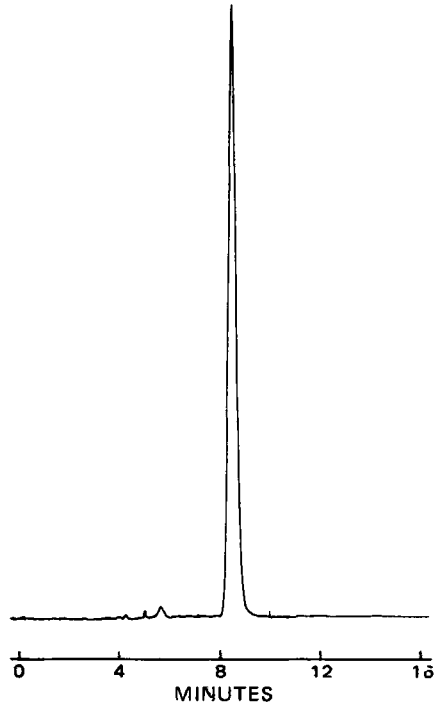

Figure 7—*HPLC chromatogram of cephalothin using a μBondapak C_{18} column. The mobile phase was acetonitrile–0.2 M ammonium acetate–water (25:10:65), pH 6.0.*

Table V—Correlation between HPLC and Microbiological Assay Methods for Penicillin G in Mastitis Product

Lot	Irradiation, Mrads	Storage	Penicillin G, units/plastet HPLC	Microbiological
A	0	Initial	100,500	108,000
		25°, 3 months	100,100	101,000

		40°, 3 months	61,500	62,000
	4.0	Initial	104,600	109,000
		25°, 3 months	100,900	101,000
		40°, 3 months	59,500	34,000
B	0	Initial	105,100	111,000
		25°, 3 months	101,300	101,000
		40°, 3 months	64,200	65,000
	2.5	Initial	105,800	108,000
		25°, 3 months	99,700	104,000
		40°, 3 months	64,800	58,000
	4.0	Initial	106,400	97,000
		25°, 3 months	101,700	102,000
		40°, 3 months	61,600	53,000

Approximately an eightfold increase in degradation compound I (peak 1) was noted, with less than a twofold increase in peak 2, by 4 Mrads irradiation. Increase in the area under peaks 1 and 2 was too great to be accounted for by the decrease in the penicillin G peak. This discrepancy may be attributed to the difference in the molar absorptivity of these compounds at 254 nm.

Degradation Compound Identification—As stated previously, the impurity compounds (peaks 1 and 2) that were increased by ^{60}Co-irradiation also may be formed in abundance by treating a penicillin G powder in a pH 3.0, 0.02 *M* phosphate buffer at 37° for 1 hr. The fact that the retention of peak 2 is greatly influenced by change in the mobile phase

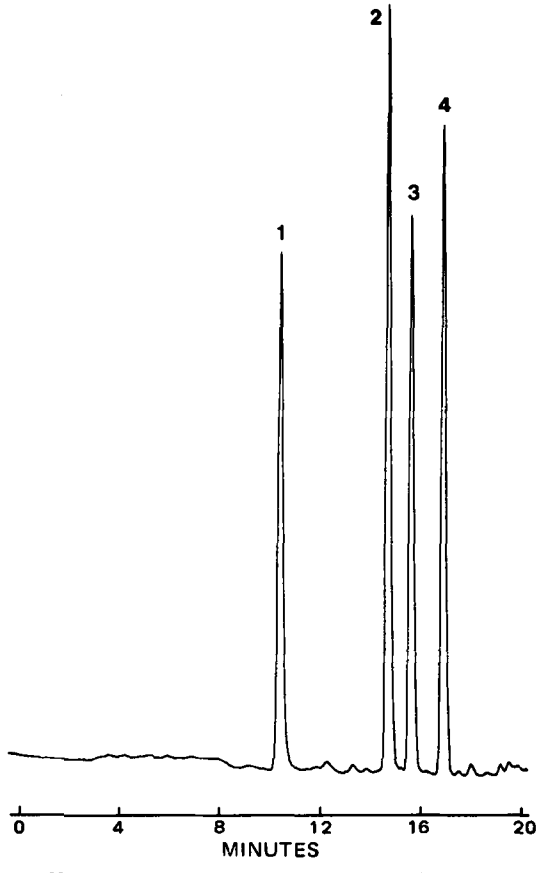

Figure 8—*HPLC gradient elution chromatogram for tentative identification of β-lactam antibiotics using a μBondapak C_{18} column. The linear gradient was from 10:10:80 (acetonitrile–0.2 M ammonium acetate–water), pH 6.0, to 50:10:40, pH 6.0, in 15 min. Key: 1, ampicillin; 2, penicillin O; 3, penicillin G; and 4, penicillin V.*

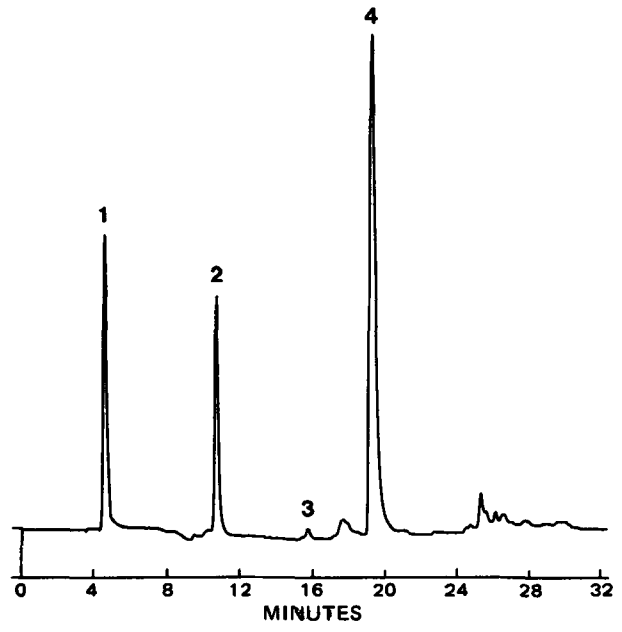

Figure 9—*HPLC gradient elution chromatogram indicating separation of an ampicillin prodrug, bacampicillin, from process intermediates. The convex gradient elution was from mobile phase A, 5:10:85 (acetonitrile–0.2 M ammonium acetate–water), pH 4.0, to mobile phase B, 80:10:10, pH 4.0, in 30 min. Key: 1, phenylglycine; 2, ampicillin; 3, penicillin G; and 4, bacampicillin.*

pH indicates the presence of acidic radical(s) in the molecule. The retention of peak 1 was not affected by the pH change.

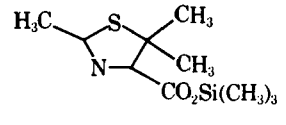
Formation of benzylpenicilloic acid, benzylpenilloic acid, and hydroxybenzylpenicillin in an aqueous penicillin G solution irradiated by cobalt 60 has been reported (17). These radiolytic compounds also may be formed by an alkaline treatment (18). However, the relative retention of these alkaline (pH 10.0) hydrolyzed compounds failed to match the two peaks of interest.

To identify the two degradation compounds, a small preparative liquid chromatograph was constructed with a 122-cm × 7-mm i.d. stainless steel column packed with C_{18}[10].

About 30 mg of penicillin G sodium USP, irradiated at 6.0 Mrads, was dissolved in 10 ml of the mobile phase and introduced onto the column *via* a 100-μl loop injector. The column effluents corresponding to the two peaks were collected in 250-ml round-bottom flasks immersed in a methanol–dry ice bath. The procedure was repeated 10 times. The effluents were freeze dried overnight.

The submilligram quantities of samples thus collected were dissolved in acetonitrile, transferred into microreaction vials[11], and dried under a nitrogen stream. About 100 μl of bis(trimethylsilyl)trifluoroacetamide containing 1% trimethylchlorosilane[12] was added to the two dried samples and penicillin G powder and allowed to react 3 hr at room temperature. The silylated samples were placed in capillary glass tubings and dried under vacuum. The samples were analyzed by mass spectrometry using the electron-impact ionization mode.

The mass spectra of penicillin G and two degradation compounds are shown in Fig. 3. The penicillin G mass spectrum (Fig. 3A) showed that both *m/e* 478 [M^+, bis(trimethylsilyl)penicillin G] and 406 [mono(trimethylsilyl)penicillin G] were weak, indicating instability of the silylated compounds. Another weak peak was observed at *m/e* 306 [M − $C(CH_3)_2CHCO_2Si(CH_3)_3$]. Much stronger peaks were seen at *m/e* 463 (M − 15), 387 (M − $CH_3C_6H_5$), and 247. An intense peak was shown at *m/e* 232 (*m/e* 247 − CH_3).



(*m/e* 247)

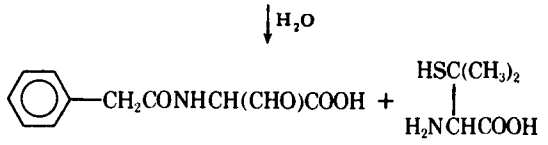
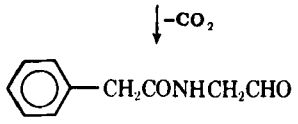
penicillin G (benzylpenicillin)



benzylpenaldic acid penicillamine



benzylpenilloaldehyde

Scheme I

The mass spectrum of the column effluent corresponding to peak 1 (Fig. 3B) is essentially identical to that of benzylpenilloaldehyde and showed the weak molecular ion at *m/e* 250 (M^+) and a strong peak at *m/e* 232 (M − 18). Weak peaks were found at *m/e* 158 (M − $CH_2C_6H_5$), 130 (M − $CH_2C_6H_5CO$), and 43 (M − $CH_2C_6H_5CONH$). A much stronger peak was observed at *m/e* 149 [M − $COSi(CH_3)_3$].

The mass spectrum of Compound II (Fig. 3C) is that of benzylpenaldic acid. The molecular ions at *m/e* 437 [tris(trimethylsilyl) derivative] and 291 [mono(trimethylsilyl) derivative] were relatively weak, indicating incomplete silylation. Much stronger peaks were shown at *m/e* 232 [M − $CH_2C_6H_5CONSi(CH_3)_3$] and 207 [M − CH(COO-trimethylsilyl)-$COSi(CH_3)_3$]. The presence of an acidic radical in this compound was indicated previously.

From the identification, it may be speculated that penicillin G may undergo a slight degradation by ^{60}Co-irradiation as shown in Scheme I. Penicillamine cannot be detected by monitoring at 254 nm.

Procaine Stability to ^{60}Co-Irradiation—The effect of ^{60}Co-irradiation on the stability of procaine is shown in Table IV. Although 0.5 and 1.5%, decreases were noted in two lots of the product irradiated at 4.0 Mrads, these decreases were not statistically significant. Careful examination of the chromatogram of procaine irradiated at 4.5 Mrads failed to detect any peak other than procaine.

Correlation between HPLC and Microbiological Methods—A correlation between the HPLC and the microbiological methods for the penicillin G assay was examined by use of two simulated product lots ^{60}Co-irradiated at 2.5 and 4.0 Mrads and stored at 25 and 40° for 3 months. The microbiological cylinder cup-agar diffusion assay used was as described in the Code of Federal Regulations (4) (Table V). A cross-classified analysis of variance was used to test for lot, radiation dosage, and time–temperature main effects and for all two-way interactions between the main effects. The analysis of variance showed that only the time–temperature effect was statistically significant ($p<0.05$) due to the instability of penicillin G at 40°.

Thus, the HPLC method correlated well with the microbiological assay and was stability indicating.

Other β-Lactam Antibiotics—With a slight modification of the mobile phase, the isocratic reversed-phase HPLC method is applicable to many β-lactam antibiotics (Figs. 4–7) with a relative standard deviation of ~1.0%.

The reversed-phase HPLC method using a gradient elution technique also is applicable for tentatively identifying β-lactam antibiotics (Fig. 8) and for assessing the stability of the prodrug, bacampicillin (Fig. 9).

Quantitative Structure–Selectivity Relationships: Selective Drug Design

ALDO GARZIA *, ALBERTO VILLANTI ˣ, and GIANFRANCO TUCCINI

Received July 21, 1978, from *Tecnofarmaci S.p.A., Via Ardeatina Km. 21,000, 00040 Pomezia, Italy.* Accepted for publication February 23, 1979. *Present address: Istituto Chemioterapico Italiano, S. Grato, 20075 Lodi, Italy.

Abstract □ The concept of complex selectivity (S_c^n) permits the investigation of quantitative structure–selectivity relationships in the presence of n side effects; S_c^n permits differentiation of the most selective molecules rather than the most active ones in a congener series. Selectivity quantification in the presence of n side effects facilitates molecular comparisons. The information provided by S_c^n and its changes with increasing n is discussed. The proposed mathematical model is applied to the study of the selectivity of some antibiotics and antibacterial agents.

Keyphrases □ Structure–selectivity relationships—penicillins, alkylchlorophenols, drug design, bioavailability, structure–activity relationships □ Penicillins—structure–selectivity relationships, bioavailability □ Alkylchlorophenols—structure–selectivity relationships, bioavailability □ Drug design—structure–selectivity relationships, penicillins, alkylchlorophenols □ Antibacterials—structure–selectivity relationships, penicillins

Researchers working on quantitative structure–activity relationships have been mainly examining the most active compound, the one that produces the highest activity characteristic of a series of congeners. Insufficient care has been given to rational drug design.

Identification of the most active molecule is insufficient for therapeutically useful drug design. The ideal compound must be as specific and selective as possible, with minimal side effects. This aim can be achieved by generalizing some results obtained by previous investigators (1–3). These studies extended the multiparameter Hansch analysis (4) to the study of selectivity, taking only one side effect into account.

The purpose of this work was to extend this approach to the study of n side effects considered simultaneously with the main effect. With the proposed method, isolation of the most selective compounds rather than the most active ones in a series of molecules is possible.

This work is a contribution to the development of a general mathematical model for forecasting overall drug action and for quantifying biopharmacological activities in order to direct, *a priori*, the synthetic work toward molecules with optimal therapeutic characteristics.

THEORETICAL

In a series of pharmacologically active congener molecules, all producing the same range of effects but having different intensities from molecule to molecule, the overall effect, E_o, of each molecule can be expressed as a function of the combined single effects:

$$E_o = f(E_m, E_1, \ldots E_i, \ldots E_n) \qquad \text{(Eq. 1)}$$

where E_m is the main effect and E_i represents the n undesirable side effects.

The application of the Hansch approach to each single effect for the whole series gives:

$$E_m: \quad \log \frac{1}{C_m} = a_{0m} + \sum_{j=1}^{r_m} a_{jm}x_{jm} \qquad \text{(Eq. 2)}$$

$$E_1: \quad \log \frac{1}{C_1} = a_{01} + \sum_{j=1}^{r_1} a_{j1}x_{j1} \qquad \text{(Eq. 3)}$$

$$E_i: \quad \log \frac{1}{C_i} = a_{0i} + \sum_{j=1}^{r_i} a_{ji}x_{ji} \qquad \text{(Eq. 4)}$$

$$E_n: \quad \log \frac{1}{C_n} = a_{0n} + \sum_{j=1}^{r_n} a_{jn}x_{jn} \qquad \text{(Eq. 5)}$$

where $1 < i < n$ and r_i is the number of parameters in the ith equation.

The therapeutic index or selectivity, S_i, of each molecule relative to the ith side effect usually is described (5) as the quotient between a standard concentration, C_i, that produces a side effect, E_i, with a given intensity and an effective standard concentration, C_m, relative to the main effect, E_m:

$$S_i = \frac{C_i}{C_m} \qquad \text{(Eq. 6)}$$

A high selectivity, *i.e.*, a high S_i value, depends on a relatively large numerator and a small denominator of Eq. 6. By taking the logarithms, Eq. 6 becomes:

$$\log S_i = \log \frac{C_i}{C_m} \qquad \text{(Eq. 7)}$$

Enlarging a summation to the n selectivities gives:

$$\sum \log S_i = \sum_{i=1}^{n} \log \frac{C_i}{C_m} \qquad \text{(Eq. 8}a\text{)}$$

or:

$$\sum \log S_i = \log \frac{\prod_{i=1}^{n} C_i}{(C_m)^n} \qquad \text{(Eq. 8}b\text{)}$$

where the logarithmic fraction on the right side is the "complex selectivity" and is indicated by the symbol S_c^n where n is the number of side effects studied contemporaneously with the main effect. In this way, one can speak of first-, second-, . . . , nth-order complex selectivity according to the number of side effects simultaneously considered. Therefore, Eq. 8*b* can be rewritten:

$$\log S_c^n = \log \frac{\prod_{i=1}^{n} C_i}{(C_m)^n} \qquad \text{(Eq. 9}a\text{)}$$

or:

$$\log S_c^n = n \log \frac{1}{C_m} - \sum_{i=1}^{n} \log \frac{1}{C_i} \qquad \text{(Eq. 9}b\text{)}$$

If the various C_i's and C_m's in Eq. 9*b* are substituted by their functional expressions as represented by Eqs. 2–5, the following is obtained:

$$\log S_c^n = n\left(a_{0m} + \sum_{j=1}^{r_m} a_{jm}x_{jm}\right) - \sum_{i=1}^{n}\sum_{j=1}^{r_i} a_{ji}x_{ji} - \sum_{i=1}^{n} a_{0i} \qquad \text{(Eq. 10)}$$

The series of values of physicochemical parameters that maximizes $\log S_c^n$ should identify the molecule whose action is the best compromise between therapeutic activity and side effects. This calculus method of complex selectivity is based on the linear combination of the single linear combinations that correlate the main effect and the side effects with their relative physicochemical parameters. In synthesis, this calculus method of quantitative structure–selectivity relationships presumes knowledge of the structure–activity relationships.

A different approach may consist in direct analysis of the eventual correlation between all of the experimental data properly combined according to Eq. 9*a* or 9*b* in a series of $\log S_c^n$ values and the physicochemical parameters:

$$\log S_c^n = a_0 + \sum_{1}^{r} a_r x_r \qquad \text{(Eq. 11)}$$

Equation 11 is a generalization of Eq. 10.

[a] Octanol-water partition coefficients. See Ref. 7, p. 432. [b] The biological activity is expressed as log PC', where PC' is the phenol coefficient converted to a molar basis. See Ref. 7, pp. 431, 432. The biological activity is the minimum concentration effective in 10 min. See Ref. 8, p. 2577. [c] Equation 15: log S_c^2 = −2.07 (±0.81) log P + 0.32 (±0.10) (log P)^2 + 3.30 (±1.51). [d] Equation 17: log S_c^1 = 1.89 (±0.82) log P + 0.30 (±0.11) (log P)^2 + 2.90 (±1.52). [e] Equation 19: log S_c^1 = −0.18 (±0.20) log P + 0.02 (±0.03) (log P)^2 + 0.39 (±0.37). [f] Equation 9*b*.

Table III—Penicillins: Regression Equations Generated from Table I Data According to Eq. 11

	Equation[a]	r	s	EV	F	p
Main effect: against *S. aureus*	12. log S_c^2 = 2.00 (±0.67)R_m + 0.17 (±0.65)	0.91	0.66	0.81	43.82	<0.01
Side effect: against *E. coli*	13. log S_c^1 = 1.55 (±0.47)R_m + 1.43 (±0.45)	0.93	0.46	0.84	53.60	<0.01
Side effect: against *T. pallidum*	14. log S_c^1 = 0.45 (±0.25)R_m − 1.25 (±0.24)	0.80	0.25	0.60	15.68	<0.01

[a] n = 11.

When one considers only one side effect, *i.e.*, when n = 1, the meaning of log S_c^n is obvious; it expresses the relationship between the main effect and the side effect in a qualitative and quantitative way. If log S_c^n is positive, it means that the main effect prevails over the side effect and the value of log S_c^n indicates on a logarithmic scale to what extent the former is superior to the latter. If, on the contrary, log S_c^n is negative, the side effect is stronger than the main effect. When the value of log S_c^n is near zero, the effects are of similar intensities and, therefore, the molecules are hardly selective. The larger the absolute value of S_c^n, the greater is the prevalence of one effect over the other.

If $n > 1$, *i.e.*, if more than one side effect is considered at a time, the question becomes more complicated. If $n = 2$ and log $S_c^2 > 0$ starting from Eq. 9*b*, the following is obtained:

$$2 \log \frac{1}{C_m} > \left(\log \frac{1}{C_1} + \log \frac{1}{C_2} \right)$$

This relationship holds for three different situations. In Case A:

$$\log \frac{1}{C_m} > \log \frac{1}{C_1}$$

$$\log \frac{1}{C_m} > \log \frac{1}{C_2}$$

In Case B:

$$\log \frac{1}{C_m} > \log \frac{1}{C_1}$$

$$\log \frac{1}{C_m} < \log \frac{1}{C_2}$$

with:

$$\log \frac{1}{C_m} < \log \frac{1}{C_2} < \left(2 \log \frac{1}{C_m} - \log \frac{1}{C_1} \right)$$

Table IV—Alkylchlorophenols: Regression Equations Generated from Table II Data According to Eq. 11

	Equation[a]	r	s	EV	F	P
Main effect: against *S. aureus*	15. $\log S_c^2 = -2.07\ (\pm 0.81) \log P + 0.32\ (\pm 0.10)(\log P)^2 + 3.30\ (\pm 1.51)$	0.91	0.21	0.81	55.63	<0.01
	16. $\log S_c^2 = 0.39\ (\pm 0.15) \log P - 1.16\ (\pm 0.63)$	0.73	0.35	0.51	27.28	<0.01
Side effect: against *S. typhosa*	17. $\log S_c^1 = 1.89\ (\pm 0.82) \log P + 0.30\ (\pm 0.11)(\log P)^2 + 2.90\ (\pm 1.52)$	0.91	0.22	0.81	54.68	<0.01
	18. $\log S_c^1 = 0.40\ (\pm 0.15) \log P - 1.25\ (\pm 0.61)$	0.75	0.33	0.55	31.91	<0.01
Side effect: against *S. hemolyticus*	19. $\log S_c^1 = -0.18\ (\pm 0.20) \log P + 0.02\ (\pm 0.03)(\log P)^2 + 0.39\ (\pm 0.37)$	0.42	0.05	0.11	2.49	>0.1
	20. $\log S_c^1 = -0.02\ (\pm 0.02) \log P + 0.09\ (\pm 0.10)$	0.26	0.06	0.03	1.77	>0.1

[a] $n = 26$.

In Case C:

$$\log \frac{1}{C_m} < \log \frac{1}{C_1}$$

$$\log \frac{1}{C_m} > \log \frac{1}{C_2}$$

with:

$$\log \frac{1}{C_m} < \log \frac{1}{C_1} < \left(2 \log \frac{1}{C_m} - \log \frac{1}{C_2}\right)$$
