# Effective Therapy of Enteric Hyperoxaluria: *In Vitro* Binding of Oxalate by Anion-Exchange Resins and Aluminum Hydroxide

**M. F. LAKER** * **and A. F. HOFMANN** ˣ

Received August 11, 1980, from the *Division of Gastroenterology, Department of Medicine, University of California at San Diego Medical Center, San Diego, CA 92103.* Accepted for publication March 2, 1981. *Present address: Department of Clinical Biochemistry, Royal Victoria Infirmary, Newcastle-upon-Tyne NE1 4LP, England.

**Abstract** □ Hyperabsorption of dietary oxalate is a major factor in the pathogenesis of enteric hyperoxaluria and a frequent complication of inflammatory bowel disease and ileojejunal bypass surgery. Successful treatment requires reduction in oxalate intake or inhibition of absorption of dietary oxalate by oral ingestion of oxalate binding agents. To identify such agents, oxalate binding by anion-exchange resins, gums, and aluminum hydroxide was measured under conditions that simulated those present in the intestinal lumen. Of the agents tested, those that bound oxalate best were colestipol and aluminum hydroxide. Strongly basic anion-exchange resins readily bound oxalate only in the absence of chloride. These results suggest that colestipol and aluminum hydroxide administration might reduce dietary oxalate absorption in patients with enteric hyperoxaluria.

**Keyphrases** □ Oxalate—*in vitro* binding by various anion-exchange resins and aluminum hydroxide □ Binding agents—*in vitro* binding of oxalate by anion-exchange resins and aluminum hydroxide □ Enteric hyperoxaluria—dietary oxalate, *in vitro* binding by anion-exchange resins and aluminum hydroxide

Nephrolithiasis is a frequent complication of inflammatory bowel disease (1, 2), ileal resection (3–5), and ileojejunal bypass (6, 7). The stones are usually composed of calcium oxalate; hyperoxaluria, which often occurs in patients with ileal dysfunction, is a major predisposing factor.

Enteric hyperoxaluria is due, at least in part, to enhanced absorption of dietary oxalate (8, 9). The pathogenesis of this condition is complex and probably involves alterations in the physical state of dietary oxalate in the intestinal lumen as well as an increase in colonic permeability to the oxalate anion. In hyperoxaluric patients, malabsorbed fatty acids are thought to prevent normal precipitation of oxalate in the gut by preferentially binding intraluminal calcium to form insoluble calcium soaps (10, 11). Free oxalate then is absorbed in increased amounts, in part because the permeability of the colon to the oxalate anion is increased by abnormally elevated intraluminal concentrations of bile acids and fatty acids (12–14).

This explanation suggests that enteric hyperoxaluria can be treated successfully by decreasing dietary oxalate, the free oxalate concentration in the intestinal lumen, or the colonic permeability. To decrease intraluminal oxalate, agents capable of binding or precipitating oxalate could be administered. To decrease the concentration of fatty acids or bile acids in the colonic lumen, fat intake could be reduced or bile acid or fatty acid binding resins could be administered.

## BACKGROUND

In this study the *in vitro* binding of oxalate by a number of nonabsorbable substances was examined. Cholestyramine, a nonabsorbable ion-exchange resin already reported to bind oxalate *in vitro* (9, 15), was used successfully by some investigators (3, 9), but not others (7, 16), to reduce oxalate excretion in patients with enteric hyperoxaluria. Aluminum antacids are essentially nonabsorbable and also were reported to decrease oxalate excretion in patients with enteric hyperoxaluria (11). However, since both cholestyramine and aluminum hydroxide are potent binders of bile acids (17–20) and fatty acids (21) *in vitro*, their ability to diminish urinary oxalate excretion in patients with enteric hyperoxaluria might result from bile acid or fatty acid binding in the colon, which would diminish the enhanced mucosal permeability, thus reducing the increased oxalate absorption. This effect on mucosal permeability might contribute more to diminishing oxalate absorption than that attributable to intraluminal oxalate binding. Thus, an unequivocal interpretation of clinical investigations of agents capable of binding not only oxalate but also bile acids and fatty acids is impossible.

Information is needed on the relative affinity *in vitro* of these binding agents for oxalate. Binding studies with these and several other potential therapeutic agents for oxalate are reported here. Binding of oxalate by calcium was not studied since the solubility product of calcium oxalate is well known and since calcium administration to patients with enteric hyperoxaluria has been reported to increase urinary calcium excretion, which may be undesirable in patients at risk for nephrolithiasis (22, 23).

## EXPERIMENTAL

**Adsorbents**—The adsorbents investigated were ion-exchange resins, an uncharged hydrophobic resin, guar gum, and various types of aluminum hydroxide.

Three types of strongly basic anion-exchange resins were used. The first ($SB_r$) is a widely used bead resin with quaternary ammonium groups attached to a styrene–divinyl benzene copolymer lattice[1]. The second, cholestyramine[2], is chemically identifical to $SB_r$ but was milled to reduce its particle size; it is marketed as a hypocholesterolemic agent. The third ($SB_d$) is a resin used for ion-exchange gel permeation chromatography; it consists of dextran beads containing quaternary ammonium groups[3].

Three weakly basic anion-exchange resins also were used. The first, colestipol[4], is a synthetic ion-exchange resin prepared by cross-linking tetraethylenepentamine with epichlorohydrin; the polymer, which has primary and secondary amine groups, is marketed as a hypocholesterolemic agent. The second ($WB_r$), a widely used bead resin, contains mostly tertiary amine groups on an epoxy lattice[5]. The third ($WB_c$), diethylaminoethylcellulose containing diethylamine groups on a cellulose lattice, is used for ion-exchange chromatography of proteins[6].

The uncharged hydrophobic resin ($UH_r$) consisted of beads of divinyl–benzene styrene copolymer with a macroreticular surface[7]. Guar gum[8] is a natural gum containing primary and secondary amino groups.

Aluminum hydroxide was used both in the form of proprietary antacid preparations ($AHPF_1$[9] and $AHPF_2$[10]) and as dried powder[11]. Three types

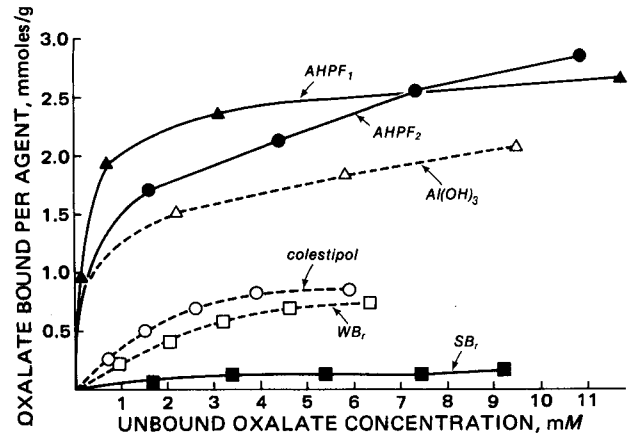

**Figure 1**—*Equilibrium isotherms for oxalate binding to anion-exchange resins and aluminum hydroxide in histidine buffer (pH 6.5, 37°; 0.15 M chloride ion).*

of aluminum hydroxide powder were studied.

Ion-exchange resins were conditioned before use by stirring with two volumes of 1 *N* NaOH, decanting the supernate, and washing the resin with distilled water. The resin was converted to the chloride form by stirring with two volumes of 1 *N* HCl. After repeated washings with glass-distilled water until the supernate was no longer acidic (pH > 6), resins were dried at room temperature.

Next, $UH_r$ was conditioned by washing with methanol followed by distilled water and then was stored in water. The dextran- and cellulose-based ion exchangers, as well as the guar gum, were preswollen in buffered saline solution (150 m*M* NaCl, 20 m*M* L-histidine, pH 6.5).

Aluminum hydroxide preparations were used without initial conditioning.

**Adsorption Studies**—Oxalate binding was studied by incubating 50 mg of adsorbent (wet weight for $UH_r$, volume containing 50 mg of aluminum hydroxide for $AHPF_1$ and $AHPF_2$, and dry weight for the other adsorbents) with 10 ml of oxalate-containing solution. The solutions contained varying amounts of unlabeled oxalic acid (2–25 m*M*), a constant amount of [$^{14}$C]oxalic acid[12] (20 μCi/liter), sodium chloride (150 m*M*), and L-histidine (20 m*M*). The pH was adjusted to 6.5 with hydrochloric acid.

Premixed solutions and adsorbents were added to 20 ml-glass serum storage vials, which were sealed with butyl rubber septa and crimped aluminum closures. The sealed bottles were kept in a 37° oven and continuously rotated. Samples were centrifuged, and the supernate was aspirated; its radioactivity was determined by liquid scintillation counting (0.2 ml was mixed with 10 ml of scintillant[13]). Each study was performed in duplicate.

The binding affinity of each adsorbent for oxalate was characterized by using adsorption isotherms to summarize the data (24). The amount of oxalate bound at equilibrium was determined for several starting

**Table I—Oxalate Binding at Equilibrium by Selected Adsorbents in the Presence of Isotonic Saline or Simulated Intestinal Content (Containing Fatty Acid and Bile Acid Anions)**

| Adsorbent | Incubation Solution Oxalate Concentration, m*M* | Oxalate Bound, mmoles/g of adsorbent: With 0.15 *M* Saline | With Simulated Intestinal Content | Reduction in Binding, % |
|---|---|---|---|---|
| $SB_r$ | 10 | 0.16 | 0.10 | 37 |
| $WB_r$ | 10 | 0.74 | 0.52 | 30 |
| Colestipol | 10 | 0.85 | 0.44 | 48 |
| $AHPF_1$ | 25 | 2.38 | 0.74 | 69 |
| Aluminum hydroxide powder | 25 | 1.84 | 0.10 | 94 |

concentrations (2–10 m*M* for resins and 5–25 m*M* for aluminum hydroxide preparations). Specimens in which adsorbent and isotope were omitted were included as controls. The kinetics of oxalate binding were studied by repeated sampling of containers with a single oxalate concentration (7.5 m*M*).

To test whether oxalate binding to $SB_r$ was influenced by the presence of chloride ion in the incubation medium, oxalate binding to $SB_r$ was defined in the absence of chloride ion. Thus, $SB_r$ was incubated with 10 ml of a solution containing 7.5 m*M* oxalic acid, [$^{14}$C]oxalic acid (20 μCi/liter), and 20 m*M* L-histidine, and the pH was adjusted to 6.5. Oxalate binding at equilibrium was determined as already described.

To determine whether bile acid or fatty acid anions that are present in intestinal content in humans might competitively inhibit oxalate binding, oxalate binding was measured in simulated intestinal content (25). The incubation solution contained 130 m*M* sodium chloride, 20 m*M* L-histidine, 7.5 m*M* glycocholic acid, 7.5 m*M* chenylglycine, 2.5 m*M* taurocholic acid, 2.5 m*M* chenyltaurine, 6.7 m*M* monoolein, and 13.3 m*M* oleic acid; the pH of the solution was adjusted to 6.5 (19). Unlabeled oxalate (10 m*M* for resins and 25 m*M* for aluminum hydroxide preparations) and [$^{14}$C]oxalic acid (20 μCi/liter) were included. Vials were sampled until equilibrium of binding was achieved.

Experiments also were carried out to determine whether substances present in the liquid component of one of the two proprietary formulations of aluminum hydroxide ($AHPF_1$) influenced oxalate binding. An aliquot was centrifuged, and the supernatant fraction was removed. The aluminum hydroxide was resuspended in water and recentrifuged, with the supernate being discarded, and this procedure was repeated three times. The initial supernate was then mixed with aluminum hydroxide powder. The equilibrium binding was studied with the dried $AHPF_1$ residue as well as the suspension of aluminum hydroxide powder, the oxalate concentration in the incubation mixture being 15 mmoles/liter.

## RESULTS

**Equilibrium Isotherms**—Colestipol and $WB_r$ had a greater affinity for oxalate than $SB_r$ (Fig. 1). Binding to $SB_d$ or $WB_c$ (not shown) was considerably less than that to $SB_r$. The weak binding of oxalate to $SB_r$ was due to the chloride ion in the medium; when chloride ion was omitted, binding increased threefold.

In addition, aluminum hydroxide, either as a proprietary antacid formulation or as a dried powder, readily bound oxalate. Binding of oxalate to $AHPF_1$ was identical whether the suspension or the washed solid phase obtained by centrifugation was used. Thus, all binding was attributable to particulate aluminum hydroxide. The binding isotherms for all aluminum hydroxide powders were similar, so only data for one of them are shown. No binding by guar gum or $UH_r$ was detected, and $WB_c$ only bound oxalate weakly (7%).

In Table I, oxalate binding by selected adsorbents in the presence or absence of simulated intestinal content is compared. Less oxalate was bound by all the adsorbents tested when constituents of intestinal content, *i.e.*, bile acid and fatty acid anions, were included. The decrease was most marked for aluminum hydroxide preparations, with $AHPF_1$ binding only 31% and aluminum powder binding only 5% of the amount of oxalate adsorbed in the absence of intestinal content. Oxalate binding to colestipol and $WB_r$ was also less in simulated intestinal content, being 52 and 70%, respectively, of that observed when chloride was the only anion present.

**Binding Kinetics**—Oxalate was adsorbed more rapidly by colestipol

and $WB_r$ (not shown) than by aluminum hydroxide (Fig. 2). The binding to aluminum hydroxide had two rates. Initially, there was rapid uptake, binding being more rapid for proprietary antacid formulations of aluminum hydroxide than for the powders. For both adsorbents, several days were required for equilibrium to be obtained.

## DISCUSSION

These results indicate that oxalate, in the presence of simulated intestinal content, binds better to aluminum hydroxide and weak anion-exchange resins (colestipol and $WB_r$) than to a strongly basic ion-exchange resin. They also show that the binding is rapid to ion-exchange resins but consists of a slow and fast component for aluminum hydroxide.

Although cholestyramine has been reported to be an effective oxalate adsorbent *in vitro* (11, 16), the data suggest that effective binding occurs only if chloride is omitted from the incubation. This could explain the findings of Caspary *et al.* (16) who demonstrated that cholestyramine did not bind oxalate *in vivo*. The data suggest that the reported efficacy of this resin in the treatment of enteric hyperoxaluria (3, 9) is due more to its binding of bile acid and fatty acids than to its binding of oxalate. Such binding should diminish colonic permeability to oxalate, which would be interpreted as reducing its absorption.

Colestipol and $WB_r$ bound less oxalate when bile acids and fatty acids were present in the incubation mixture; however, both resins were effective binding agents under experimental conditions simulating those present in the small intestinal lumen.

Aluminum hydroxide preparations had a greater capacity than colestipol or $WB_r$ for oxalate binding but required much longer for equilibrium to be reached, a factor that could diminish clinical efficacy. Although the commercial antacid preparations bound oxalate more rapidly than the dry powder preparations, similar amounts were bound by the two forms of oxalate within 30 min. Whether these differing rates of binding *in vitro* have clinical significance is unknown.

These *in vitro* binding data indicate that both aluminum antacids and weakly basic anion exchange resins might prove effective in adsorbing oxalate within the intestinal lumen and thus act to diminish the hyperoxaluria occurring in patients with intestinal disease. Preliminary clinical studies support these *in vitro* binding studies (26). Nonetheless, several recent reports (27, 28) claimed that oral calcium reduces oxalate absorption and that urinary calcium levels do not show a reciprocal increase.

Although hyperoxaluria contributes to nephrolithiasis in such patients, other factors, such as diminished urinary volume (29) and hypocitraturia (30, 31), are involved. Thus, reduction in oxalate excretion is only one of several alternative approaches for reducing the lithogenicity of urine.

# Disposition of Sulfadimethoxine in Cattle: Inclusion of Protein Binding Factors in a Pharmacokinetic Model

**D. W. A. BOURNE *§, M. BIALER *¶, L. W. DITTERT *‖, M. HAYASHI **, G. RUDAWSKY ‡, G. D. KORITZ ‡, and R. F. BEVILL ‡x**

Received June 11, 1979, from the **College of Pharmacy, University of Kentucky, Lexington, KY 40506*, and the ‡*College of Veterinary Medicine, University of Illinois, Champaign–Urbana, IL 61801.* Accepted for publication March 5, 1981. §Present address: Department of Pharmacy, University of Queensland, St. Lucia, 4067, Queensland, Australia. ¶Present address: School of Pharmacy, Hebrew University, Jerusalem, Israel. ‖Present address: School of Pharmacy, University of Pittsburgh, Pittsburgh, PA 15261. **Present address: Tokyo College of Pharmacy, Tokyo, Japan.

**Abstract** □ Sulfadimethoxine was administered intravenously and orally to four cattle, and plasma and urine samples were collected at various times postdose. Modeling these data with a linear pharmacokinetic model gave unsatisfactory fits, and the data were subsequently fitted to a one-compartment model with saturable protein binding. The saturable protein binding model included the usual linear excretion and elimination processes as well as protein binding parameters. The values obtained *in vivo* for the binding constant, $5.01 \times 10^4\ M^{-1}$, and the total protein concentration, $7.89 \times 10^{-4}\ M$, compared favorably with previously reported *in vitro* values. These results indicate that protein binding can be successfully included in a pharmacokinetic model.

**Keyphrases** □ Sulfadimethoxine—protein binding, pharmacokinetics, cattle □ Protein binding—sulfadimethoxine, pharmacokinetics, cattle □ Pharmacokinetics—sulfadimethoxine, protein binding, cattle

Sulfadimethoxine is a long-acting sulfonamide with bacteriostatic activity against a variety of organisms, and commercial preparations are available for use in chickens, turkeys, dogs, cats, horses, cattle, and humans. Because of the widespread use of sulfonamides, a problem of drug residues in edible food tissues has developed.

To understand the kinetics of sulfonamides in food-producing animals, the disposition of various sulfonamides was investigated in a number of species (1–4). The present study involves the disposition of sulfadimethoxine in cattle after intravenous and oral administration. Previous studies (5–7) investigated sulfadimethoxine kinetics in cattle; however, none of these reports included excretion of metabolites into urine or the extensive binding of sulfadimethoxine to plasma proteins.

## EXPERIMENTAL

**Animals**—Four crossbred heifers[1], 10–12 months old and 161–202 kg, were used. The four animals were weighed and placed in slot-floored metabolism units 3 days prior to drug administration. They received a grain–concentrate mixture in limited amounts and grass, hay, and water *ad libitum* during the acclimatization and experimental periods; however, feed was withheld 24 hr prior to oral dosing. To facilitate urine collection, Foley retention catheters[2] were placed in the urinary bladder of each animal 24 hr prior to drug administration.

**Drugs**—Sulfadimethoxine[3] was prepared as a 12.5% solution in sterile distilled water. Complete solution of sulfadimethoxine was aided with a sufficient quantity of sodium hydroxide.

**Dosing Procedure**—Sulfadimethoxine (107 mg/kg of body weight) was administered by rapid intravenous drip into the left jugular vein of each animal. After a washout period of ~3 months, sulfadimethoxine (107 mg/kg of body weight) was administered to each animal *via* stomach tube.

**Sample Collection**—Blood and urine samples were collected at 0, 0.5, 1, 2, 3, 4, 6, 8, 10, 12, 16, 24, 36, 48, 60, 72, 84, 96, 108, and 120 hr following drug administration. Blood samples were taken from the right jugular vein in heparinized syringes and centrifuged at 3000 rpm for 7 min. The plasma was collected and stored at 4° until assay; all plasma samples were assayed within 1 week. The total volume of urine excreted during each sampling period was recorded before aliquots were taken. Urine samples were stored at −20° until assay.

**Assay Methods**—The plasma sulfadimethoxine concentration was determined spectrophotometrically following color formation with Bratton–Marshall reagents (2, 8). The concentrations of sulfadimethoxine and metabolites in urine were determined spectrophotometrically following separation by TLC and color formation, as previously described (2).

## RESULTS AND DISCUSSION

**Analytical Data following Intravenous Administration**—The average plasma concentration *versus* time data obtained following intravenous sulfadimethoxine administration to cattle (Table I and Fig. 1) appeared to fall biexponentially with a terminal rate constant of ~0.065 $hr^{-1}$ (biological half-life of 10.7 hr). The area under the average plasma concentration *versus* time curve from 0 to 120 hr was 3030 mg hr/liter.

The average excretion rate of unchanged sulfadimethoxine into urine *versus* time data (Fig. 1) also appeared to fall biexponentially but with

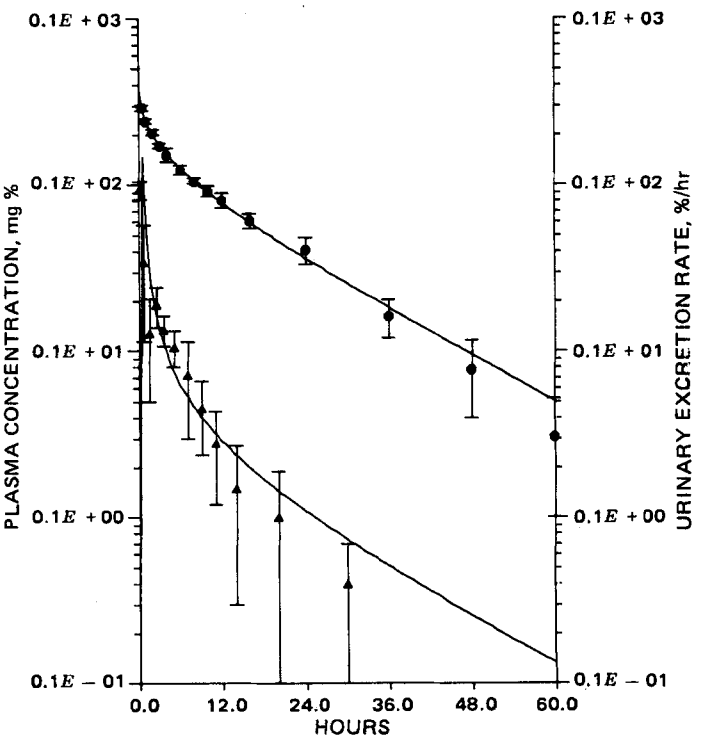

**Figure 1**—*Semilog plot of plasma concentration (●) versus time and rate of excretion of unchanged sulfadimethoxine in urine (▲) versus time following intravenous sulfadimethoxine administration. Points are the experimentally observed averages (SD as error bars) for four cattle, and lines were calculated.*

| 120.0 | —[c] | —[b] | —[d] | —[e] |

[a] One standard deviation ($n = 4$). [b] No further sulfadimethoxine was detected in urine after 48 hr. [c] Less than 0.1 mg/100 ml. [d] No further acetylsulfadimethoxine was detected in urine after 60 hr. [e] No further polar metabolite was detected in urine after 84 hr.

a slope quite different from that of the plasma data, especially at early time points. The total cumulative amounts of unchanged sulfadimethoxine, acetylsulfadimethoxine, and a polar metabolite excreted into urine were 17.9, 54.4, and 4.0% of the administered dose, respectively (Table I and Fig. 2).

Similar results were obtained for all four individual animals. Results for one animal are shown in Fig. 3.

**Analytical Data following Oral Administration**—The average plasma concentration *versus* time data obtained following oral sulfadimethoxine administration to cattle are shown in Table II and Fig. 4. The peak plasma concentration was 114 mg/liter at 10 hr, and the area under the plasma concentration–time curve from 0 to 120 hr was 4458 mg hr/liter. The total cumulative amounts of unchanged sulfadimethoxine, acetylsulfadimethoxine, and a polar metabolite excreted into urine were 6.3, 35.6, and 2.1% of the administered dose, respectively (Table II).

**Selection of Pharmacokinetic Model**—On the basis of plasma concentration data alone, a three-compartment linear model was used

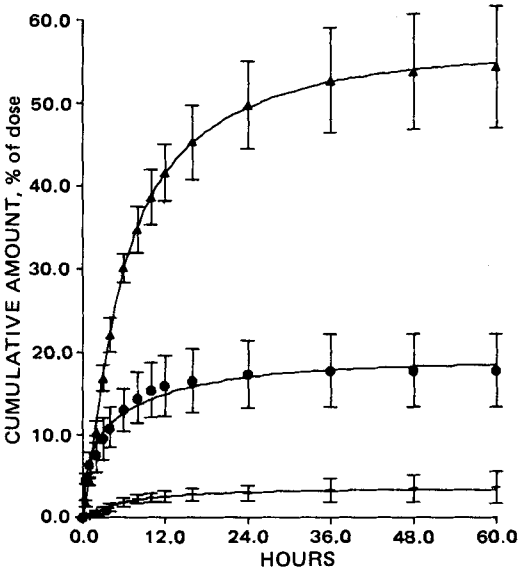

**Figure 2**—*Plot of cumulative amounts of sulfadimethoxine (●), acetylsulfadimethoxine (▲), and polar metabolite (+) excreted into urine* versus *time. Points are the experimentally observed averages for four cattle, and lines were calculated.*

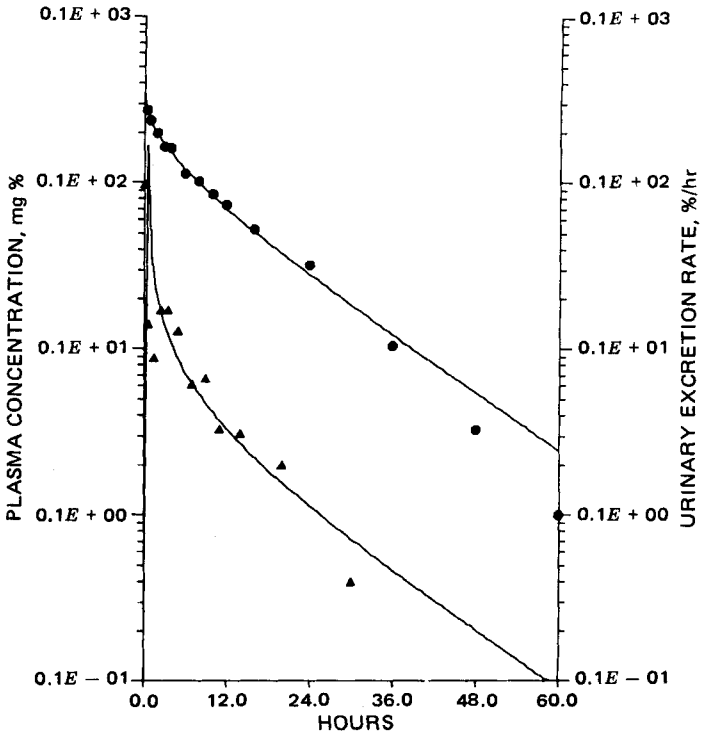

**Figure 3**—*Semilog plot of plasma concentration (●)* versus *time and rate of excretion of unchanged sulfadimethoxine in urine (▲)* versus *time following intravenous administration to one animal. Points were experimentally observed, and lines were calculated.*

to describe the elimination kinetics of sulfadimethoxine in cattle (7). However, a linear model, including the three-compartment model described previously, would predict that the plasma data and the urinary rate of excretion data would appear parallel when plotted semilogarithmically. If linear first-order kinetics apply, the rate of excretion at any time is directly proportional to the plasma concentration. The results obtained (Fig. 1) suggest that there is no constant proportionality between plasma concentration and the rate of excretion data at each time point measured so a simple linear model may not be sufficient to explain the data.

**Table II—Average Plasma Concentration of Sulfadimethoxine and Cumulative Amount of Sulfadimethoxine, Acetylsulfadimethoxine, and Polar Metabolite Excreted in Urine following Oral Sulfadimethoxine Administration**

| Hours | Plasma Concentration, mg/100 ml | Cumulative Amount Excreted in Urine, % of dose | | |

| 144.0 | —[c] | —[b] | —[d] | 2.1 ± 2.6 |

[a] One standard deviation ($n = 4$). [b] No further sulfadimethoxine was detected in urine after 84 hr. [c] Less than 0.1 mg/100 ml. [d] No further acetylsulfadimethoxine was detected in urine after 96 hr.

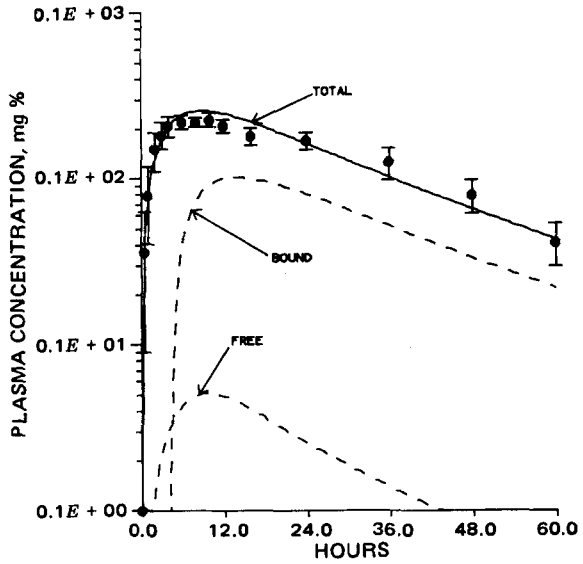

**Figure 4**—*Semilog plot of plasma concentration (●) versus time following oral sulfadimethoxine administration. Points are the experimentally observed averages for four cattle, and lines were calculated. The points and the solid line were multiplied by 2 to separate these values from the dashed lines representing free and bound drug concentrations.*

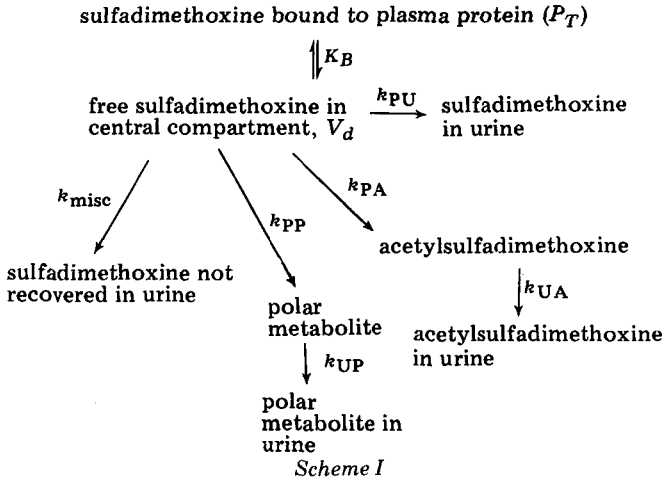
Sulfadimethoxine is extensively bound to bovine serum albumin, and the percentage of drug bound to protein decreases as the total concentration of drug in plasma increases (6). Since only free drug can be removed by the kidney or metabolized, protein binding of sulfadimethoxine should extensively affect sulfadimethoxine disposition. Kruger-Thiemer *et al.* (9) proposed a number of pharmacokinetic models involving protein binding of sulfonamides in humans. By means of computer simulations, these authors fit the plasma concentration *versus* time data to a pharmacokinetic model involving protein binding.

In view of the extensive protein binding of sulfadimethoxine in bovine plasma, it was decided that a model involving protein binding could be used to fit the data. A one-compartment model (Scheme I) was selected as the simplest model involving reversible protein binding.



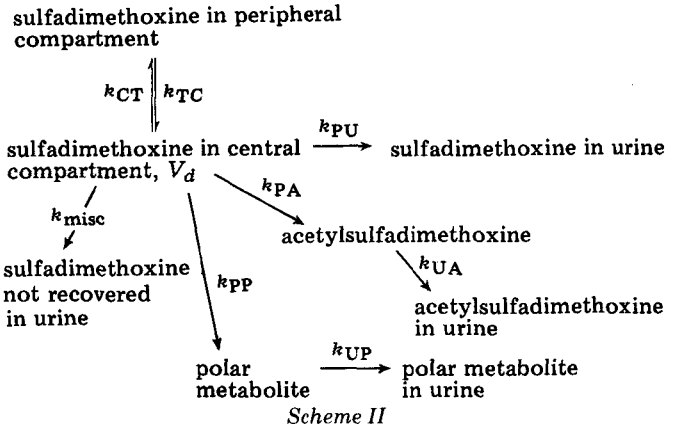
*Scheme I*

Value $K_B$ is the protein binding constant, $P_T$ is the total concentration of protein binding sites, and $V_d$ is the apparent volume of distribution.

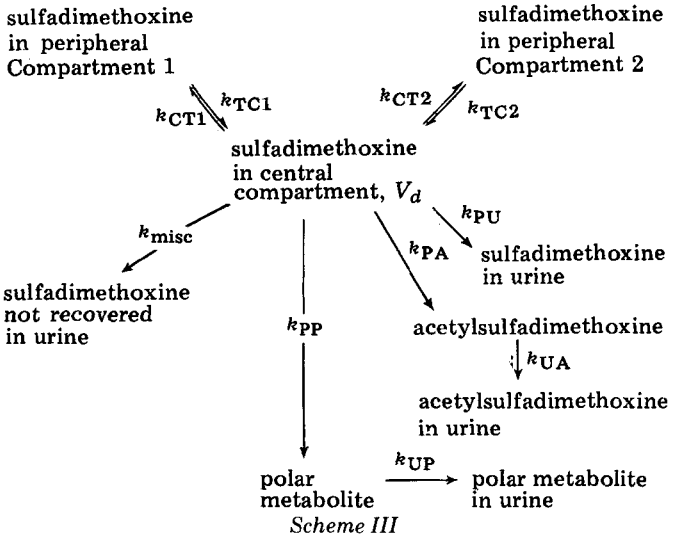
Because drug and metabolite concentrations in urine were measured, this model includes metabolism of sulfadimethoxine and excretion of the two metabolites. All transfer processes in this model are linear, obeying first-order kinetics, with protein binding described by:

$$K_B = \text{[drug bound to protein]/[free drug][free protein binding sites]} \quad \text{(Eq. 1)}$$

The data were also fitted to linear two- and three-compartment models (Schemes II and III, respectively) so that a statistical evaluation of the model shown in Scheme I could be made.



*Scheme II*



*Scheme III*

**Fitting Data to Pharmacokinetic Model**—*Intravenous Study*—The plasma and urine data obtained following intravenous administration of sulfadimethoxine were fitted simultaneously to the model shown in Scheme I and to the linear models shown in Schemes II and III using the digital computer program NONLIN.

An initial estimate of the overall elimination rate constant, $k_{el}$ ($= k_{PU} + k_{PA} + k_{PP} + k_{misc}$) (Scheme I), was obtained from the slope of the early rate of urinary excretion of unchanged sulfadimethoxine *versus* time data and the estimated concentration of free sulfadimethoxine present at zero time. This value for $k_{el}$ was separated into values for the individual rate constants ($k_{PU}$, $k_{PA}$, $k_{PP}$, and $k_{misc}$) by means of the total cumulative amounts of sulfadimethoxine excreted as unchanged drug, acetyl metabolite, or polar metabolite into urine data (1).

The free sulfadimethoxine concentration in plasma at different total concentrations was calculated from the data of Silvestri *et al.* (6) and was used to obtain initial estimates of the binding equilibrium constant, $K_B$, and the total concentration of protein binding sites, $P_T$. The initial fitting of the data was carried out with all of the parameters, except $k_{UA}$ and $k_{UP}$, held fixed at the initial estimate values. Once best fit values of $k_{UA}$ and $k_{UP}$ were obtained, the fitting was continued with progressively more of the parameters allowed to vary, *i.e.*, $k_{PU}$, $k_{PA}$, $k_{PP}$, $k_{misc}$, $K_B$, and then $P_T$. The final best fit values for all parameters of the model in Scheme I are presented in Table III. The close agreement between the model and the experimental data is shown in Figs. 1–3, 5, and 6. The lines were generated using the model shown in Scheme I with the best fit parameter values of Table III.

Initial estimates for $k_{el}$, $k_{CT}$, and $k_{TC}$ (Scheme II) and $k_{el}$, $k_{CT1}$, $k_{TC1}$, $k_{CT2}$, and $k_{TC2}$ (Scheme III) were obtained by "feathering" the plasma concentration–time data. Initial estimates for the other parameters of the linear models were obtained as already described. The fitting process was completed for each model using the average and individual animal data.

The Akaike criterion (11) was used to compare the proposed model,

incorporating protein binding parameters (Scheme I) with the linear models (Schemes II and III). In each case, the one-compartment saturable protein binding model gave a better fit than either of the two linear models (Table III). The appropriateness of the chosen model is further supported by the reasonable values obtained for $K_B$ and $P_T$. The average value of $K_B$ obtained in the present study, $5.01 \times 10^4\ M^{-1}$, compares favorably with values reported by other workers using bovine serum albumin *in vitro*, $1.5\text{–}25 \times 10^4\ M^{-1}$ (12–14). In addition, the average value of $P_T$, $7.89 \times 10^{-4}\ M$, compares well with the plasma albumin concentrations previously reported, $4.5\text{–}4.7 \times 10^{-4}\ M$ (15, 16).

*Oral Study*—The plasma and urine data obtained following oral administration of sulfadimethoxine were fitted to the model shown in Scheme I, with an added first-order absorption step. The initial estimate of the absorption rate constant, $k_a$, was determined by the method of residuals. The bioavailability was calculated as 0.59. When calculated by comparison of the total amount of drug recovered in urine following intravenous and oral administration, ~47% of the dose was absorbed. The ratio of the area under the plasma concentration–time curve could not be used in this study as a measure of bioavailability since the model was nonlinear. The model is consistent with the observed higher area under the curve following the oral dose compared with the intravenous dose. The values of the parameters of Scheme I obtained from the intravenous study were used as initial estimates in fitting the oral study data with the NONLIN computer program. The final best fit values obtained are

# Quantitative Determination of Conjugated Estrogens in Formulations by Capillary GLC

**G. K. PILLAI and K. M. McERLANE ˣ**

Received December 15, 1980, from the *Faculty of Pharmaceutical Sciences, University of British Columbia, Vancouver, British Columbia, V6T 1W5 Canada.* Accepted for publication March 4, 1981.

**Abstract** □ A rapid capillary GLC method for the analysis of conjugated estrogen tablets and injectable formulations is described. The method involves the hydrolytic cleavage of the sodium sulfate ester conjugates by sulfatase enzyme. The free phenolic steroids are reacted sequentially with hydroxylamine hydrochloride and *N,O*-bis(trimethylsilyl)trifluoroacetamide. The resulting dual derivatives are analyzed on a 15-m glass capillary column wall coated with a cyanopropylmethyl silicone phase.

**Keyphrases** □ Estrogens, conjugated—quantitative determinations by capillary GLC □ GLC, capillary—quantitative determination of conjugated estrogens □ Steroids—conjugated estrogens, quantitative determination by capillary GLC

Conjugated estrogens is the official name (1) given to a group of closely related steroids derived from the urine of pregnant mares. These naturally occurring, water-soluble salts have been used since 1942 for the treatment of estrogen deficiency symptoms associated with menopause. Only recently, however, have the structures of these steroids been collectively reported (2) and quantitative methods developed (3, 4). For many years, the accepted method of analysis was that contained in USP XVIII (5), which specified colorimetric methods and limits for the major steroids, estrone and equilin, as well as for total estrogen content. An absorbancy ratio requirement was included in the identification tests for an unspecified steroid.

Recent revisions of the USP/NF (1) included a GLC identification test based on a published method (3) but retained the iron–kober chromogenic reagent for the assay of estrone, equilin, and total estrogen content. The identification test requires a prominent peak for one steroid, 17α-dihydroequilin, and this substance probably is the steroid monitored by the previous USP (5) identification test.

## BACKGROUND

A consequence of the broad and nonquantitative specifications for the major and minor steroids is that compendial standards may not ensure pharmaceutical equivalence. More rigorous specifications for the indi-

The method involves the hydrolytic cleavage of the sodium sulfate ester conjugates by sulfatase enzyme. The free phenolic steroids are reacted sequentially with hydroxylamine hydrochloride and *N,O*-bis(trimethylsilyl)trifluoroacetamide. The resulting dual derivatives are analyzed on a 15-m glass capillary column wall coated with a cyanopropylmethyl silicone phase.

**Keyphrases** □ Estrogens, conjugated—quantitative determinations by capillary GLC □ GLC, capillary—quantitative determination of conjugated estrogens □ Steroids—conjugated estrogens, quantitative determination by capillary GLC

Conjugated estrogens is the official name (1) given to a group of closely related steroids derived from the urine of pregnant mares. These naturally occurring, water-soluble salts have been used since 1942 for the treatment of estrogen deficiency symptoms associated with menopause. Only recently, however, have the structures of these steroids been collectively reported (2) and quantitative methods developed (3, 4). For many years, the accepted method of analysis was that contained in USP XVIII (5), which specified colorimetric methods and limits for the major steroids, estrone and equilin, as well as for total estrogen content. An absorbancy ratio requirement was included in the identification tests for an unspecified steroid.

Recent revisions of the USP/NF (1) included a GLC identification test based on a published method (3) but retained the iron–kober chromogenic reagent for the assay of estrone, equilin, and total estrogen content. The identification test requires a prominent peak for one steroid, 17α-dihydroequilin, and this substance probably is the steroid monitored by the previous USP (5) identification test.

## BACKGROUND

A consequence of the broad and nonquantitative specifications for the major and minor steroids is that compendial standards may not ensure pharmaceutical equivalence. More rigorous specifications for the indi-

[a] Amount is expressed as milligrams of each steroid in a 1.0-mg aliquot. Amount of conjugated estrogens found = 1.0131 ± 0.0093 mg.

vidual steroids are needed, especially in view of the widely varying potencies of each steroid in the mixture. For example, 17β-estradiol, although a minor component, exhibits 12 times the potency of the major steroid, estrone (6). Many methods have attempted to resolve all of the components of this relatively complex mixture, including paper chromatography (7–9), TLC (10–14), high-performance liquid chromatography (15–18), and GLC (2–4, 19–23). Of these, two GLC methods were capable of resolving most of the components and were applied toward quantitation of the pharmaceutical product (3, 4). However, both methods suffer from either long chromatographic times and poor column stability (3) or the need for dual injections and lack of resolution of 17β-estradiol from 17α-dihydroequilin (4). In addition, the quantitation of the estrogens was further hindered by the presence of an impurity subsequently identified as equol (21). This impurity, if not removed prior to analysis, would interfere with both GLC methods (3, 4). This interference has necessitated the removal of this impurity by a lengthy extraction step (4).

As an alternative to packed column chromatographic analysis of the equine estrogens, capillary columns were recently used (24). However, the method did not significantly improve the resolution of estrone and equilin and did not address the problem of resolution of 17β-estradiol from 17α-dihydroequilin. Similar efforts in this laboratory resulted in the complete resolution of all known equine estrogens present in conjugated estrogens using a highly polar capillary column (25). The present study was based on the capillary column separation reported earlier (25) but included a quantitative determination of all known estrogens as well as a reported impurity, equol, in tablet and injectable formulations.

## EXPERIMENTAL

A gas chromatograph[1] equipped with a capillary inlet system, a flame-ionization detector, and a data terminal[2] was used for all measurements.

A commercial 15-m × 0.25-mm borosilicate column[3] wall coated with cyanopropylmethyl silicone liquid phase (Silar 10C) was used with a helium carrier gas flow of 0.8 ml/min through the column and a split vent flow of 40 ml/min. The column inlet pressure was 10 psi. The injector and detector temperatures were both 250°; the oven temperature was programmed from 170° for 7 min, heated at 2.3°/min to 220°, and maintained at this temperature for 5 min.

GLC–mass spectral data[4] were obtained with electron-impact ionization at 70 ev.

**Materials**—Reagent grade chloroform, acetic acid, sodium acetate, and anhydrous sodium sulfate were used. *N,O*-Bis(trimethylsilyl)trifluoroacetamide[5] and pyridine[5] were silylation grade. Sulfatase enzyme[6], ethinyl estradiol[7], hydroxylamine hydrochloride[8], and equine estrogens[9] were used as received.

**Sample Extraction and Preparation**—*Tablets*—Twenty tablets were weighed and powdered, and an amount equivalent to 1 mg of conjugated estrogens was weighed into a 50-ml, polytef-lined, screw-capped culture tube. To this tube was added 15 ml of an acetate buffer (0.02 *M*, pH 5.2), and the tube was shaken mechanically for 20 min. An amount equivalent to 2000 units of sulfatase enzyme was added, and the contents were incubated in a water bath at 45° for 30 min with occasional shaking. Then 0.2 ml of the internal standard, ethinyl estradiol, was added in 10 ml of chloroform, and the tube was shaken mechanically for an additional 30 min.

After centrifugation at 2000 rpm for 15 min, the chloroform layer was separated as completely as possible and filtered through a bed of anhydrous sodium sulfate. The filtrate, 3 ml at a time, was evaporated to dryness under a clean nitrogen stream in a 5-ml conical vial[10]. To the residue was added 200 μl of a 2% solution of hydroxylamine hydrochloride in dry pyridine. The polytef-lined screw-capped vial was heated in an aluminum block[11] at 70° for 30 min. The excess pyridine in the vial was evaporated under a gentle stream of clean, dry nitrogen, 150 μl of *N,O*-bis(trimethylsilyl)trifluoroacetamide and 50 μl of dry pyridine were added, and the vial was heated at 70° for an additional 10 min. Then 2 μl of the resulting solution was injected directly into the gas chromatograph. Peak identification was confirmed by comparison of retention times with those of pure standards.

*Injectable Formulation*—The contents of a 25-mg multiple injection vial were dissolved in an acetate buffer and brought to volume in a 50-ml volumetric flask with acetate buffer. An aliquot equivalent to 1 mg of conjugated estrogens was processed as described.

## RESULTS AND DISCUSSION

Conjugated estrogens exist in the pharmaceutical product as the sodium salts of the sulfate esters. For GLC analysis, it was necessary to hydrolyze these esters to their free phenolic forms. Two hydrolysis methods were used previously. The first method (2) involved the use of hydrochloric acid at elevated temperature, and the second consisted of

incubation with sulfatase enzyme (3). The use of hydrochloric acid to hydrolyze steroid sulfates is known to cause steroid transformations (26, 27); and since it was considered essential to measure the original components of the mixture without creating artifacts during workup, acid hydrolysis could not be used. Although optimum conditions for the use of the sulfatase enzyme were established previously (4), it was considered necessary to ascertain that phosphates, suspected to be present in one formulation, did not inactivate the enzyme. Accordingly, a series of enzyme concentrations was incubated with identical aliquots of this tablet formulation, and an optimum enzyme quantity of 2000 units was found to yield maximum estrogen quantities. Above this value, no increase in estrogen levels was noted.

A prior examination of derivative combinations and capillary column phases led to the development of an excellent separation of all known equine estrogens as a dual derivative (25). Among the derivatives evaluated, an oxime–trimethylsilyl combination was most suitable.

As shown in Fig. 1, the chromatogram obtained for the oxime–trimethylsilyl derivatives exhibited excellent resolution of the equine estrogens. The potent steroid, 17β-estradiol, was well resolved from 17α-dihydroequilin, as was estrone from equilin. These two steroid pairs presented the greatest problems in previous chromatographic methods. In addition, the total chromatographic time was shortened as compared to the values, 55 (4) and 70 (3) min, reported earlier.

The chromatographic properties of samples obtained from hydrolysis of commercial formulations of conjugated estrogens are shown in Figs.

**Figure 3**—*Chromatogram of equine estrogens as their oxime–trimethylsilyl derivatives derived from a 2.5-mg tablet. Key: 1, 17α-estradiol; 2, 17β-estradiol; 3, 17α-dihydroequilin; 4, 17β-dihydroequilin; 5, ethinyl estradiol (internal standard); 6, estrone; 7, equilin; 8, 17α-dihydroequilenin; 9, 17β-dihydroequilenin; 10, equilenin; 11, equol; and 12, ethyl phthalate.*

**Table II—Composition of Commercial Formulations Containing Conjugated Estrogens** [a]

| Component | Sample: 25-mg Multiple-Injection Vial | Sample: 2.5-mg Tablet |
|---|---|---|
| 17α-Estradiol | 2.82 | 0.66 |
| 17β-Estradiol | 1.06 | 0.12 |
| 17α-Dihydroequilin | 16.23 | 2.87 |
| 17β-Dihydroequilin | 1.11 | 0.23 |
| Estrone | 48.07 | 62.01 |
| Equilin | 22.45 | 26.95 |
| 17α-Dihydroequilenin | 1.65 | 1.12 |
| 17β-Dihydroequilenin | 0.11 | 0.12 |
| Equilenin | 6.49 | 6.51 |
| Equol | — | 3.85 |

[a] These results represent the percentage of each conjugated estrogen; each value is the average of two assays. The formulations are from two different manufacturers.

2 and 3. Unlike the chromatogram shown in Fig. 1 and those reported for the commercial products using conventional packed columns, these chromatograms exhibit evidence of several additional minor components. One may be 9-dehydroestrone; however, a reference standard for this material was not available for comparison. The two commercial formulations display significant qualitative and quantitative differences. The formulation shown in Fig. 3 contained ethyl phthalate (retention time, 7.32 min) and equol (retention time, 22.07 min). The identities of these two extraneous substances were confirmed by comparison of their GLC and mass spectral characteristics. Ethyl phthalate is a probable residue from the tablet film-coating process, while equol was previously reported (21) as a contaminant of equine estrogens in some formulations. Since the present method can resolve equol from the equine steroids, prewash of the unhydrolyzed sample with benzene (4) is unnecessary since equol will not interfere with quantitation. Elimination of this purification step further reduces the total analysis time.

The subsequent quantitation of the separated equine estrogens was accomplished by determining the relative response ratios of samples of each individual equine estrogen as compared to the internal standard, ethinyl estradiol. At least six aliquots of each steroid, at levels bracketing the anticipated quantity in the mixture, were analyzed with a constant amount of internal standard. For all determinations, the correlation between the peak area ratios and concentrations was ≥0.998. The precision of the assay was checked by duplicate injections of four aliquots taken from a single 50-ml solution prepared from a multiple-injection vial. Each of the four aliquots was separately hydrolyzed, extracted, derivatized, and assayed. The mean and standard deviation of each steroid and the total are given in Table I.

Quantitation of conjugated estrogens in some available formulations provided the data shown in Table II; unlike with previous methods (3, 4), the quantity of 17β-estradiol now can be determined with certainty. In addition, it was found that the quantity of equilenin was double the amounts reported earlier, perhaps because of the increase in sensitivity due to the shorter retention time in the present chromatographic assay.

# Thiourea and Thiosemicarbazide Derivatives Structurally Related to Hexestrol: Synthesis and Anticancer and Other Pharmacological Properties

**A.-MOHSEN M. E. OMAR ‡x, A. M. FARGHALY *, A. A. B. HAZZAI *, N. H. ESHBA *, F. M. SHARABI ‡, and T. T. DAABEES ‡**

Received May 16, 1980, from the **Department of Pharmaceutical Chemistry and the* ‡*Department of Pharmacology, Faculty of Pharmacy, University of Alexandria, Alexandria, Egypt.* Accepted for publication November 24, 1980.

**Abstract** □ Two novel series of thio compounds bearing internal structural modifications of hexestrol were synthesized as potential anticancer agents. The first contains several *N*-substituted thiourea functions, and the second contains various $N^4$-substituted-3-thiosemicarbazide moieties in place of one α-ethyl group of hexestrol dimethyl ether. The products showed no antileukemic activity in the P-388 lymphocytic leukemia system and did not exhibit any anticonvulsant or estrogenic properties.

**Keyphrases** □ Hexestrol—structurally related thiourea and thiosemicarbazide derivatives as anticancer agents □ Anticancer drugs, potential—compounds related to hexestrol, screened against P-388 lymphocytic leukemia □ Thioureas—synthesis, hexestrol derivatives, evaluation of anticonvulsant and anticancer activities □ Thiosemicarbazide—synthesis of hexestrol derivatives, evaluation of anticonvulsant and anticancer activities

Concurrent with ongoing studies of the cyclodesulfurization of thio compounds into various heterocyclic derivatives (1), related studies have been concerned with the synthesis of thio compounds derived from menadione (2), phthiocol (2), steroids (3), diethylstilbestrol (4), and theophylline (5), the biologically active nuclei, for various pharmacological purposes. Extending these studies to compounds containing thio functions as internal modifications of hexestrol, the thio derivatives IV–XI and XIV–XVIII (Scheme I) were prepared and tested for anticancer, estrogenic, and anticonvulsant activities.

## RESULTS AND DISCUSSION

**Chemistry**—1,2-Bis(*p*-methoxyphenyl)butylamine (II), required as the starting material, was prepared through conversion of α-ethyldesoxyanision (I) into the corresponding oxime (6), using hydroxylamine hydrochloride and potassium acetate in ethanol, followed by reduction of the product with aluminum amalgam in aqueous ethanol (7). The amine (II) was reacted with the equivalent amount of alkyl-, aryl-, or aralkylisothiocyanates (III) in refluxing ethanol to give *N*-[1,2-bis(*p*-methoxyphenyl)butyl]-*N'*-substituted thioureas (IV–XI) in high yields (Table I).

The treatment of the amine (II) with ethyl bromoacetate and sodium carbonate in anhydrous acetone gave the glycinate ester (XII), which was heated with excess hydrazine hydrate to yield the $N^{\alpha}$-[1,2-bis(*p*-methoxyphenyl)butyl]-α-aminoacetohydrazide (XIII). Heating equimolar amounts of this acid hydrazide and the selected isothiocyanate derivatives (III) in refluxing ethanol gave the required 4-substituted-1-{$N^{\alpha}$-[1,2-bis(*p*-methoxyphenyl)butyl]-α-aminoacetyl}-3-thiosemicarbazides (XIV–XVIII) (Scheme I and Table I). The products were identified by the appearance of four bands at 1550–1525, 1345, 1320–1305, and 945–910 $cm^{-1}$, characteristic for the –N–C=S amides of I, II, III, and IV, respectively, in the IR spectra (5, 8).

The PMR spectra of representative examples of the thiourea derivatives IV, VIII, and IX and the thiosemicarbazides XIV, XV, and XVII showed the common protons resonating at various shifts (Table II). In addition to these signals, the other NH proton of the thiourea part was identified at various shifts depending on the substituent present. It appeared as a triplet at δ 5.90 ppm for the allyl derivative (IV), as a singlet at δ 8.11 ppm for the *m*-tolyl derivative (VIII), and as a multiplet at δ 6.11 ppm for the benzyl thiourea (XI). Likewise, the $N^4$-H proton of the thiosemicarbazides appeared as a broad multiplet at δ 6.59 and 6.54 ppm for XIV and XV, respectively, and as a singlet at δ 8.57 ppm for XVII.

The mass spectrum of *N*-[1,2-bis(*p*-methoxyphenyl)butyl]-*N'*-benzylthiourea (XI) did not show the molecular ion peak at *m/z* 434. However, it indicated that the compound had undergone fragmentation through two pathways (Scheme II). The first pathway produced ions A and B at *m/z* 284 and 150, while the second pathway gave ions C and D at *m/z* 269 and 165, respectively. These four ions, on further fragmentation, produced various daughter ions (Scheme II), of which the tropylium ion at *m/z* 91 was almost as intense as the base peak at *m/z* 78. The mass spectrum of the thiosemicarbazide (XVII) did not show the molecular ion peak at *m/z* 506, but it showed the base peak at *m/z* 208 (see *Experimental*).

Extending these studies to compounds containing thio functions as internal modifications of hexestrol, the thio derivatives IV–XI and XIV–XVIII (Scheme I) were prepared and tested for anticancer, estrogenic, and anticonvulsant activities.

## RESULTS AND DISCUSSION

**Chemistry**—1,2-Bis(*p*-methoxyphenyl)butylamine (II), required as the starting material, was prepared through conversion of α-ethyldesoxyanision (I) into the corresponding oxime (6), using hydroxylamine hydrochloride and potassium acetate in ethanol, followed by reduction of the product with aluminum amalgam in aqueous ethanol (7). The amine (II) was reacted with the equivalent amount of alkyl-, aryl-, or aralkylisothiocyanates (III) in refluxing ethanol to give *N*-[1,2-bis(*p*-methoxyphenyl)butyl]-*N'*-substituted thioureas (IV–XI) in high yields (Table I).

The treatment of the amine (II) with ethyl bromoacetate and sodium carbonate in anhydrous acetone gave the glycinate ester (XII), which was heated with excess hydrazine hydrate to yield the $N^{\alpha}$-[1,2-bis(*p*-methoxyphenyl)butyl]-α-aminoacetohydrazide (XIII). Heating equimolar amounts of this acid hydrazide and the selected isothiocyanate derivatives (III) in refluxing ethanol gave the required 4-substituted-1-{$N^{\alpha}$-[1,2-bis(*p*-methoxyphenyl)butyl]-α-aminoacetyl}-3-thiosemicarbazides (XIV–XVIII) (Scheme I and Table I). The products were identified by the appearance of four bands at 1550–1525, 1345, 1320–1305, and 945–910 $cm^{-1}$, characteristic for the –N–C=S amides of I, II, III, and IV, respectively, in the IR spectra (5, 8).

The PMR spectra of representative examples of the thiourea derivatives IV, VIII, and IX and the thiosemicarbazides XIV, XV, and XVII showed the common protons resonating at various shifts (Table II). In addition to these signals, the other NH proton of the thiourea part was identified at various shifts depending on the substituent present. It appeared as a triplet at δ 5.90 ppm for the allyl derivative (IV), as a singlet at δ 8.11 ppm for the *m*-tolyl derivative (VIII), and as a multiplet at δ 6.11 ppm for the benzyl thiourea (XI). Likewise, the $N^4$-H proton of the thiosemicarbazides appeared as a broad multiplet at δ 6.59 and 6.54 ppm for XIV and XV, respectively, and as a singlet at δ 8.57 ppm for XVII.

The mass spectrum of *N*-[1,2-bis(*p*-methoxyphenyl)butyl]-*N'*-benzylthiourea (XI) did not show the molecular ion peak at *m/z* 434. However, it indicated that the compound had undergone fragmentation through two pathways (Scheme II). The first pathway produced ions A and B at *m/z* 284 and 150, while the second pathway gave ions C and D at *m/z* 269 and 165, respectively. These four ions, on further fragmentation, produced various daughter ions (Scheme II), of which the tropylium ion at *m/z* 91 was almost as intense as the base peak at *m/z* 78. The mass spectrum of the thiosemicarbazide (XVII) did not show the molecular ion peak at *m/z* 506, but it showed the base peak at *m/z* 208 (see *Experimental*).

[a] The compounds, in doses equivalent to 100 mg of meprobamate/kg, were suspended in gum acacia and orally given to albino mice (seven to 11 mice for each compound). The percent protection and percent mortality were determined as previously reported (5). [b] Not tested.

**Biological**—Compounds IV, V, VII, IX–XI, and XIV–XVIII did not exhibit any anticancer activity when tested in the P-388 lymphocytic leukemia system (9). In addition, the testing of representative examples of the products for other pharmacological properties revealed that they lacked estrogenic (Table III) and anticonvulsant (Table I) activities.

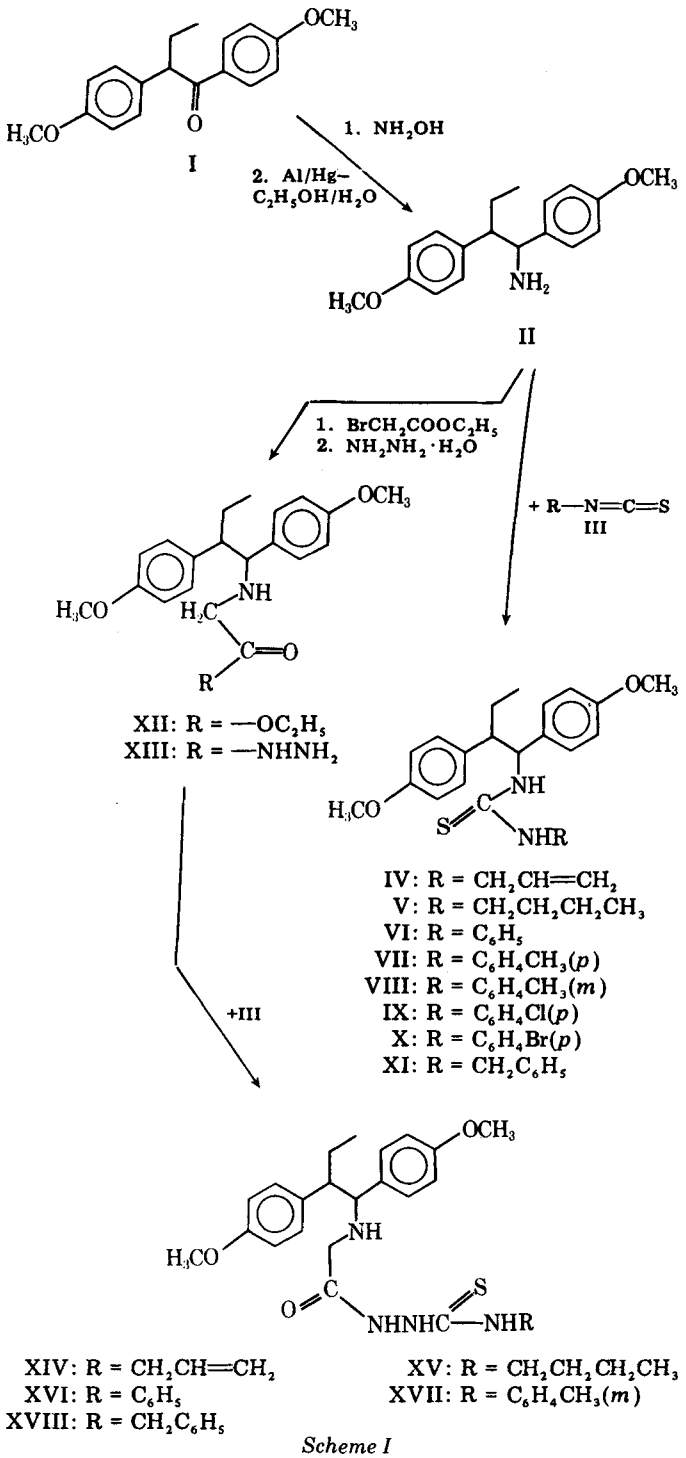
As revealed in the literature, various compounds possessing anticancer (10) and other pharmacological properties can be produced through chemical modifications involving the replacement of the one or two $\alpha$-ethyl groups of hexestrol by ethylidenyl (10–12), cyclopropyl (13), aryl (14, 15), or substituted amide (16, 17) moieties. As a supplementary modification of hexestrol, the designed compounds contained the thiourea and the thiosemicarbazide functions. The thiosemicarbazide compounds are known to produce anticancer activity when attached to certain heterocyclic compounds (18–21).

The inactivity of the products in the P-388 lymphocytic leukemia system has provided another example (9) of the inability of these thio functions, due to the variation of structures, to form the tridentate ligands (22) necessary for blocking DNA synthesis in tumor cells. The thio groups were too bulky relative to the $\alpha$-ethyl groups in hexestrol to allow IV and XIV to bind to the receptors; hence, they did not exhibit estrogenic activity (3). The results of anticonvulsant screening for XVII (5), which indicated 50% protection, confirmed the failure of related types of these compounds to fulfill the structural requirement for a proper anticonvulsant agent.

## EXPERIMENTAL[1]

**1,2-Bis(*p*-methoxyphenyl)butylamine (II)**—Aluminum amalgam, prepared from aluminum (22 g) and mercuric chloride (17.5 g) as reported (7), was treated with the solution of the oxime (12 g, 0.04 mole) in ethanol (220 ml) and distilled water (220 ml). The reaction mixture was stirred for 48 hr and filtered, and the residue was washed with ethanol (2 × 200 ml). Ethanol was distilled off from the combined filtrate and washings, and the residue was extracted with ether (4 × 100 ml). The ether extracts

[1] All melting points are uncorrected. IR spectra were measured as Nujol mulls on a Beckman 4210 IR spectrophotometer. NMR and mass spectra were measured on a Perkin-Elmer R 32 and a AEI-MS-50, respectively.

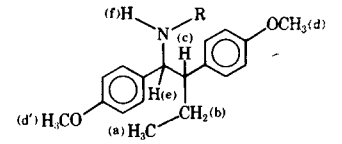


*Scheme I*

were dried (anhydrous sodium sulfate) and evaporated to leave an oil, which soon solidified. Crystallization from light petroleum (bp 60–80°) gave 8.6 g (75% yield) of white needles, mp 94–95° [lit. (23) mp 94–95.5°].

***N*-[1,2-Bis(*p*-methoxyphenyl)butyl]-*N'*-substituted Thioureas (IV–XI)**—A solution of II and the equivalent amount of the appropriate alkyl-, aryl-, or aralkylisothiocyanate (III) in ethanol was heated under reflux for 30 min. The solvent was evaporated, and the residue was scratched with drops of light petroleum (bp 40–60°) or an ether–light petroleum mixture to deposit into a solid. The products were crystallized from a benzene–light petroleum mixture and identified by elemental analysis, IR, PMR (Table II), and mass spectra; IR (mineral oil): 3400–3330 and 3310–3220 (NH), 1610, 1585, and 1510 (C=C aromatic), and 1550–1525, 1345, 1320–1305, and 945–910 $cm^{-1}$ (–N–C=S, amide I, II, III, and IV bands, respectively). Yields and physical constants of the products are recorded in Table I. The mass spectrum of XI showed

**Table II—Signals of the Common Protons in the PMR Spectra of the Thioureas IV, VIII, and XI and the Thiosemicarbazide Derivatives XIV, XV, and XVII**



| Compound | Chemical Shift[a], δ ppm ($CDCl_3$) | | | | | | |
|---|---|---|---|---|---|---|---|
| | H(a) | H(b) | H(c) | H(d) | H(d') | H(e) | H(f) |
| IV | 0.70 t | 1.54 q | 2.77 q | 3.80 s | 3.80 s | 5.00 m | 6.34 d |
| VIII | 0.70 t | 1.56 m | 2.76 m | 3.75 s[b] | 3.78 s | 5.69 t | 6.30 d |
| XI | 0.75 t | 1.55 m | 2.77 m | 3.75 s[b] | 3.87 s | 5.00 m | 6.70 m |
| XIV | 0.60 t | 1.36 m | 2.72 m | 3.88 s | 3.88 s | 3.58 m | —[c] |
| XV | 0.60 t | — | 2.74 m | 3.84 s | 3.84 s | 3.53 m | —[c] |
| XVII | 0.58 t | 1.33 m | 2.70 m | 3.72 s[b] | 3.75 s | 3.54 m | —[c] |

[a] s = singlet, d = doublet, t = triplet, q = quartet, and m = multiplet. [b] The difference in the chemical shift between the (d) and (d') group protons is due to the presence of the protons of the methoxyl group (d) in the positive shielding area caused by the anisotropic effect of the aryl substituents in the thio chains of these compounds. [c] H(f) in the thiosemicarbazides appeared between 0.90 and 1.82 ppm mixed with the methylenic protons.

*m/z* (relative abundance %) $M^{\cdot}$ at 434 absent, 284 (2), 269 (46), 240 (6), 165 (6), 150 (8), 149 (42), 136 (42), 135 (9), 134 (9), 133 (5), 121 (31), 107 (9), 106 (16), 91 (99), and 78 (100).

***N*$^{\alpha}$-[1,2-Bis(*p*-methoxyphenyl)butyl] -α- aminoacetohydrazide (XIII)**—A solution of ethyl bromoacetate (2.24 g, 0.0134 mole) in dry acetone (10 ml) was added dropwise (during 30 min) onto a well-stirred mixture of II (3.45 g, 0.012 mole) and anhydrous sodium carbonate in dry acetone (40 ml). The mixture was heated under reflux while stirring for 8 hr, allowed to cool, and then filtered. The filtrate was evaporated to leave an oily residue, which was dissolved in benzene (50 ml). The benzene solution was washed successively with 10% aqueous HCl (2 × 25 ml), sodium carbonate solution, and water. Benzene was evaporated to leave 3.78 g (84%) of a viscous oil, which was homogeneous on TLC and used directly in the subsequent experiments: IR (mineral oil): 3340 (NH), 1740 (C=O), 1610, 1585, and 1510 (C=C, aromatic), 1300 (δ NH), and 1250, 1175, and 1040 (C–O–C) $cm^{-1}$.

The mixture of ester XII (3 g, 0.0081 mole) and hydrazine hydrate (15 ml) was heated for 3 hr at 90–110° (external temperature). The mixture was poured onto excess water to separate the oil, which was extracted with benzene (2 × 50 ml). The benzene extract was washed with water, dried (anhydrous sodium sulfate), and evaporated. The oil left (2.57 g, 89%) was homogeneous on TLC and used directly for preparation of the thiosemicarbazides; IR (liquid film): 3350 (NH), 1670 (C=O), 1615, 1585, and 1510 (C=C aromatic), 1305 (δ NH), and 1250, 1180, and 1040 (C–O–C) $cm^{-1}$.

**4-Substituted -1- {*N*$^{\alpha}$-[1,2-bis(*p*-methoxy)butyl] -α- aminoacetyl}-3-thiosemicarbazides (XIV–XVIII)**—The mixture of the acid hydrazide XIII (0.71 g, 0.002 mole) and an equimolar amount of the appropriate alkyl-, aryl-, or aralkylisothiocyanate (III) in dry benzene (20 ml) was heated under reflux for 2.5 hr. The solvent was removed, and the residue was boiled in light petroleum while being scratched to deposit into solid. Crystallization from benzene–light petroleum gave the required thiosemicarbazides (XIV–XVIII) (Table I). The products were identified by microanalysis and IR, PMR (Table II), and mass spectra. The mass spectrum for the *m*-tolylthiosemicarbazide (XVII) showed *m/z* (relative abundance %) $M^{\cdot}$ at 506 absent, 325 (3), 296 (2), 269 (12), 268 (6), 208

**Table III—Results of Estrogenic Activities**

| Compound | Doses, μmoles/kg | Number of Animals | Uterine Weight, mg/100 g of body weight ± *SE* | *p* Value[a] |

## NOTES

# Pharmacokinetic Linearity of Desipramine Hydrochloride

**D. WEINER ˣ, D. GARTEIZ, M. CAWEIN, T. DUSEBOUT, G. WRIGHT *, and R. OKERHOLM**

Received July 10, 1980, from the *Merrell Dow Pharmaceuticals Inc., Subsidiary of the Dow Chemical Company, Cincinnati, OH 45215.* Accepted for publication February 2, 1981. *Present address: A. H. Robins Co., Richmond, VA 23220.

**Abstract** □ The pharmacokinetic linearity of two single oral doses of desipramine hydrochloride was examined in a parallel study involving 30 subjects. Fourteen subjects received 75 mg (3 × 25 mg) of desipramine hydrochloride, and 16 subjects received 150 mg (1 × 150 mg). An open one-compartment model with a lag time to the start of absorption was used to examine the pharmacokinetic linearity. The results of the study suggest that the kinetics are linear in the dose range studied.

**Keyphrases** □ Desipramine hydrochloride—pharmacokinetic linearity, bioavailability, comparison of two tablet dose levels, humans □ Pharmacokinetic linearity—desipramine hydrochloride, humans □ Tricyclic antidepressants—desipramine hydrochloride, pharmacokinetic linearity, bioavailability, comparison of two tablet dose levels, humans

Tricyclic antidepressants are widely used in the treatment of depression. Recent studies (1–9) showed a relationship between steady-state plasma tricyclic levels and therapeutic response. Several investigations (10–14) were undertaken to find a means of predicting steady-state plasma tricyclic antidepressant concentrations based on plasma levels obtained after a single dose, thus avoiding time-consuming dosage titration to therapeutic plasma levels. These studies indicated that steady-state plasma levels can be predicted accurately by the area under the plasma concentration curve (*AUC*) following a single dose or by a single plasma level obtained 24, 48, or 72 hr after dosing.

This study determined the pharmacokinetic linearity of two single doses of desipramine hydrochloride[1], providing additional evidence that the steady-state predictions are reasonable.

## EXPERIMENTAL

**Subjects**—Thirty healthy male volunteers were randomized into two parallel treatment groups; 14 received 75 mg (three 25-mg tablets) of desipramine hydrochloride and 16 received one 150-mg tablet. The subjects were 19–40 years of age and 47–78 kg. All subjects were within 10% of their ideal weight.

**Protocol**—Each subject received the prescribed dose at 8:00 am. A 15-ml blood sample (vacuum blood-drawing tubes[2] containing lithium heparin as anticoagulant) was drawn just prior to dosing (time zero) and at 0.5, 1, 2, 3, 4, 6, 8, 10, 12, 14, 24, 36, 48, and 72 hr postdosing. No solid food was permitted from 8:00 pm of the preceding day until 12:00 noon of the dose day, at which time a standard lunch was served. A low-fat dinner was served at 6:00 pm; after collection of the 24-hr sample, the subject resumed eating *ad libitum*. A parallel design was employed instead of a crossover design since the elimination half-life for desipramine can be long and variable (15).

**Analytical Method**—The separated plasma was kept frozen until it was assayed. Desipramine was measured using a GLC–mass spectrometric technique adapted from Pantarotto *et al.* (16). The method involved the addition of the internal standard (nortriptyline) and extraction of the alkalinized plasma with *n*-hexane. The extract was reacted with acetic anhydride and pyridine without prior evaporation. The acetylated extract then was evaporated to dryness, and the residue was dissolved in ethanol. An aliquot was injected into the apparatus with selected-ion monitoring at *m/z* 305 and 308.

**Calculations**—Pharmacokinetic parameters were computed for each dosage level corresponding to an open one-compartment model with a lag time (17) using:

$$C(t) = \frac{FD}{V}\frac{K_a}{(K_a - K_e)}\left[e^{-K_e(t-L)} - e^{-K_a(t-L)}\right] \qquad \text{(Eq. 1)}$$

where $D$ is the administered oral dose, $F$ is the fraction of the dose absorbed, $V$ is the apparent volume of distribution, $K_a$ is the apparent first-order absorption rate constant, $K_e$ is the first-order elimination rate constant, $L$ is the lag time to the start of absorption, and $t$ is the time

## NOTES

# Pharmacokinetic Linearity of Desipramine Hydrochloride

**D. WEINER ˣ, D. GARTEIZ, M. CAWEIN, T. DUSEBOUT, G. WRIGHT *, and R. OKERHOLM**

Received July 10, 1980, from the *Merrell Dow Pharmaceuticals Inc., Subsidiary of the Dow Chemical Company, Cincinnati, OH 45215.* Accepted for publication February 2, 1981. *Present address: A. H. Robins Co., Richmond, VA 23220.

**Abstract** □ The pharmacokinetic linearity of two single oral doses of desipramine hydrochloride was examined in a parallel study involving 30 subjects. Fourteen subjects received 75 mg (3 × 25 mg) of desipramine hydrochloride, and 16 subjects received 150 mg (1 × 150 mg). An open one-compartment model with a lag time to the start of absorption was used to examine the pharmacokinetic linearity. The results of the study suggest that the kinetics are linear in the dose range studied.

**Keyphrases** □ Desipramine hydrochloride—pharmacokinetic linearity, bioavailability, comparison of two tablet dose levels, humans □ Pharmacokinetic linearity—desipramine hydrochloride, humans □ Tricyclic antidepressants—desipramine hydrochloride, pharmacokinetic linearity, bioavailability, comparison of two tablet dose levels, humans

Tricyclic antidepressants are widely used in the treatment of depression. Recent studies (1–9) showed a relationship between steady-state plasma tricyclic levels and therapeutic response. Several investigations (10–14) were undertaken to find a means of predicting steady-state plasma tricyclic antidepressant concentrations based on plasma levels obtained after a single dose, thus avoiding time-consuming dosage titration to therapeutic plasma levels. These studies indicated that steady-state plasma levels can be predicted accurately by the area under the plasma concentration curve (*AUC*) following a single dose or by a single plasma level obtained 24, 48, or 72 hr after dosing.

This study determined the pharmacokinetic linearity of two single doses of desipramine hydrochloride[1], providing additional evidence that the steady-state predictions are reasonable.

## EXPERIMENTAL

**Subjects**—Thirty healthy male volunteers were randomized into two parallel treatment groups; 14 received 75 mg (three 25-mg tablets) of desipramine hydrochloride and 16 received one 150-mg tablet. The subjects were 19–40 years of age and 47–78 kg. All subjects were within 10% of their ideal weight.

**Protocol**—Each subject received the prescribed dose at 8:00 am. A 15-ml blood sample (vacuum blood-drawing tubes[2] containing lithium heparin as anticoagulant) was drawn just prior to dosing (time zero) and at 0.5, 1, 2, 3, 4, 6, 8, 10, 12, 14, 24, 36, 48, and 72 hr postdosing. No solid food was permitted from 8:00 pm of the preceding day until 12:00 noon of the dose day, at which time a standard lunch was served. A low-fat dinner was served at 6:00 pm; after collection of the 24-hr sample, the subject resumed eating *ad libitum*. A parallel design was employed instead of a crossover design since the elimination half-life for desipramine can be long and variable (15).

**Analytical Method**—The separated plasma was kept frozen until it was assayed. Desipramine was measured using a GLC–mass spectrometric technique adapted from Pantarotto *et al.* (16). The method involved the addition of the internal standard (nortriptyline) and extraction of the alkalinized plasma with *n*-hexane. The extract was reacted with acetic anhydride and pyridine without prior evaporation. The acetylated extract then was evaporated to dryness, and the residue was dissolved in ethanol. An aliquot was injected into the apparatus with selected-ion monitoring at *m/z* 305 and 308.

**Calculations**—Pharmacokinetic parameters were computed for each dosage level corresponding to an open one-compartment model with a lag time (17) using:

$$C(t) = \frac{FD}{V}\frac{K_a}{(K_a - K_e)}\left[e^{-K_e(t-L)} - e^{-K_a(t-L)}\right] \qquad \text{(Eq. 1)}$$

where $D$ is the administered oral dose, $F$ is the fraction of the dose absorbed, $V$ is the apparent volume of distribution, $K_a$ is the apparent first-order absorption rate constant, $K_e$ is the first-order elimination rate constant, $L$ is the lag time to the start of absorption, and $t$ is the time

postdosing. These calculations were performed using the computer program NONLIN (18).

The distributions of $F/V$, $K_a$, $K_e$, and $L$ for the two dose groups were compared statistically by the Mann–Whitney U test (19). The elimination half-life, $t_{1/2}$, was calculated as $0.693/K_e$. No analysis was performed on $t_{1/2}$ since the results would be identical to those reported on $K_e$ using this statistical method. If the kinetics of the compound are linear in the dose range studied, the distributions of $F/V$, $K_a$, $K_e$, and $L$ are expected to be the same for both dose groups.

The $AUC$ (nanogram hours per milliliter) was calculated using the trapezoidal rule. Statistical analysis of the $AUC$, $C_{max}$ (nanograms per milliliter), and $t_{max}$ (hours) data was performed on the logarithms of the values using a two-sample $t$-test. Homogeneity of variance was verified by Cochran's test (20). The mean $AUC$ and $C_{max}$ values for the 150-mg group were expressed as a percentage of the 75-mg group mean by taking the antilog of the difference in log means. If the kinetics are linear in the dose range studied, the expected 150-mg mean would be ~200% of the 75-mg mean for $AUC$ and $C_{max}$ but equal to the 75-mg mean for $t_{max}$.

## RESULTS

The mean plasma concentrations are displayed for the two dose groups in Fig. 1, and the relevant pharmacokinetic data are listed in Table I.

The lag time estimated for the 75-mg dose ranged from 0 to 0.78 hr, while that for the 150-mg dose ranged from 0.39 to 0.77 hr. A statistically significant longer lag time for the 150-mg group resulted. However, this result probably has no clinical significance since maintenance therapy is required with tricyclic antidepressants.

The apparent $K_a$ calculated from this data ranged from 0.210 to 1.733 hr for 29 of the 30 subjects; the other subject had an estimated apparent $K_a$ of 13.548. There was no statistically significant difference in the apparent $K_a$ values for the two groups, but the value from the one individual resulted in a relatively high mean and standard error for the apparent $K_a$ of the 75-mg dose. If the value for this subject is deleted, the corresponding values are 0.69 ± 0.13 (mean ± $SE$).

The half-lives estimated for 28 of the 30 subjects ranged from 9.76 to 34.65 hr; the other two half-lives were 4.85 and 69.30 hr. There was no statistically significant difference in the half-lives between the two groups. These half-lives agreed quite well with the previously reported half-lives of 17.1 ± 5.3 hr (mean ± $SD$, range 12.5–24.7 hr) following a 1-mg/kg dose of desipramine (29.75 ± 4.89 mg, mean ± $SD$) (11) and of 20.0 ± 1.5 hr (mean ± $SD$, range 12–30) following a 100-mg dose of desipramine (21).

There were no statistically significant differences among $F/V$, $K$, or $t_{max}$ for the two dose groups.

The 150-mg dose produced significantly higher mean $AUC$ and $C_{max}$ values than did the 75-mg dose. The mean $AUC$ for the 150-mg group, when expressed as a percentage of the 75-mg mean, was 219% with 95% confidence limits of 151–318%. The corresponding mean ratio for $C_{max}$ was 199% with 95% confidence limits of 150–263%.

These results indicate that the kinetics of desipramine hydrochloride are linear in the 75–150-mg range and provide additional evidence that the earlier steady-state predictions based on levels after a single dose are meaningful.

**Table I—Pharmacokinetic Parameters (Mean ± *SE*)**

| Parameter | 75 mg ($n$ = 14) | 150 mg ($n$ = 16) |
|---|---|---|
| $F/V$, $ml^{-1} \times 10^3$ | 0.45 ± 0.05 | 0.47 ± 0.04 |
| $K_a$, $hr^{-1}$ | 1.61 ± 0.93[a] | 0.50 ± 0.06 |
| $K_e$, $hr^{-1}$ | 0.048 ± 0.008 | 0.040 ± 0.004 |
| $t_{1/2}$, hr | 19.7 ± 4.0 | 18.4 ± 1.8 |
| $L$[b], hr | 0.46 ± 0.05 | 0.62 ± 0.03 |
| $AUC$[c], ng hr/ml | 771.7 ± 87.3 | 1854.0 ± 307.0 |
| $C_{max}$[c], ng/hr | 30.7 ± 3.2 | 60.9 ± 5.9 |
| $t_{max}$, hr | 6.1 ± 0.7 | 5.9 ± 0.5 |

[a] Values are 0.69 ± 0.13 when one subject is deleted. [b] $p < 0.02$. [c] $p < 0.001$.

# Transport in Quantitative Structure–Activity Relationships VI: Relationship between Transport Rate Constants and Partition Coefficients

**HAN van de WATERBEEMD ˣ, PAUL van BAKEL, and ADRI JANSEN**

Received October 20, 1980, from the *Department of Pharmacochemistry, Subfaculty of Pharmacy, University of Leyden, 2300 RA Leyden, The Netherlands.* Accepted for publication February 2, 1981.

**Abstract** □ The transport rate constant of a drug partitioned in a two-phase system from an aqueous to an organic phase ($k_1^{obs}$) and vice versa ($k_2^{obs}$) is a function of the partition coefficient $P$ and of a solvent system-dependent parameter $\beta$. Drug transport is shown to be independent of molecular structure for a number of arbitrary compounds.

**Keyphrases** □ Drug transport—relationship between drug transport rate constants and partition coefficients □ Partition coefficients—relationship between drug transport rate constants and partition coefficients □ Structure–activity relationships—relationship between drug transport rate constants and partition coefficients

Partition coefficients ($P$) often are used as parameters in quantitative structure–activity relationships. A quadratic log $P$ term also is necessary in many relationships to obtain good statistics. The appearance of quadratic terms has been attributed to the influence of drug transport from the site of application to the site of action (1). However, partition coefficients are equilibrium constants, and transport is kinetic in nature. Thus, the relationship between the kinetic and equilibrium parameters of partitioning is important.

## BACKGROUND

Recently, it was shown that relationships exist between transport rates and partition coefficients (2, 3). A new transport model was developed to explain these relationships (2, 3).

A kinetic approach of this interfacial drug transport model reveals the following bilinear relationships between transport rate constants ($k^{obs}$) and $P$:

$$\log k_1^{obs} = \log P - \log\left(\frac{k_{org}}{k_{aq}}P + 1\right) + \log k_{org} \qquad \text{(Eq. 1)}$$

$$\log k_2^{obs} = -\log\left(\frac{k_{org}}{k_{aq}}P + 1\right) + \log k_{org} \qquad \text{(Eq. 2)}$$

where $k_1^{obs}$ is the observed rate constant for the drug transport from water to an organic solvent, $k_2^{obs}$ is the observed rate constant for the reverse process, and $k_{org}$ and $k_{aq}$ are the diffusion rate constants of the drug through the two adjacent stagnant layers, which are assumed to be at an interface. The $\beta$ value, known from Kubinyi's bilinear model (4, 5), appears to be identical to the quotient of $k_{org}$ and $k_{aq}$ (2, 3).

Moreover, it can be understood from this theory how drug transport in a biological system can be described with partition coefficients and why bilinear and parabolic relationships are found experimentally (6). This new interfacial drug transfer model is related closely to other literature models (6).

The theoretical equations were tested with a series of 30 sulfonamide derivatives, and it was demonstrated that $\beta$ under fixed conditions is a constant for a certain two-phase solvent system (3). In the $n$-octanol–water system, and in the chosen vessel and at a certain fixed temperature and stirring rate, the experimental regression equations are:

$$\log k_1^{obs} = \log P - \log(0.412P + 1) - 3.985$$
$$n = 30 \quad r = 0.990 \quad F = 1397 \quad s = 0.045 \qquad \text{(Eq. 3)}$$

$$\log k_2^{obs} = -\log(0.411P + 1) - 3.985$$
$$n = 30 \quad r = 0.998 \quad F = 6218 \quad s = 0.046 \qquad \text{(Eq. 4)}$$

From these experimental equations, it is concluded that the transport model and the theoretically found relationships between transport rate constants and $P$ have a physicochemical reality at least for a series of congeneric compounds. It was concluded previously that the effective volumes of the compounds of this sulfonamide series are all very similar. Differences in intrinsic molecular volume and polarity of the compounds are obviously compensated by a change in solvent association of the solute (3). It is tempting to assume that a compensation mechanism of intrinsic radius, polarity, and charge distribution holds for other compounds with variations even in the molecular skeleton. The present paper describes the results of transport rate measurements of compounds with variations in structure, size, and lipophilicity, including ion-pairs and partly ionized compounds.

## EXPERIMENTAL

Transport rate constants were determined with the apparatus and method previously described (7).

Partition coefficients were taken from the literature (8) or were determined by UV detection[1] after shaking appropriate amounts of mutually saturated solvents and allowing overnight separation.

All chemicals were available commercially and were analytical grade.

## RESULTS AND DISCUSSION

The observed ($k^{obs}$) and calculated ($k^{cal}$) transport data are given in Table I. Apparent partition coefficients ($P_{app}$) were used to calculate the rate constants with Eqs. 3 and 4. The observed rate constants and apparent partition coefficients of ion-pairs and ionic compounds are dependent on the initial concentration (9). The data are plotted in Fig. 1. All points are situated very near to the curves calculated for the sulfon-

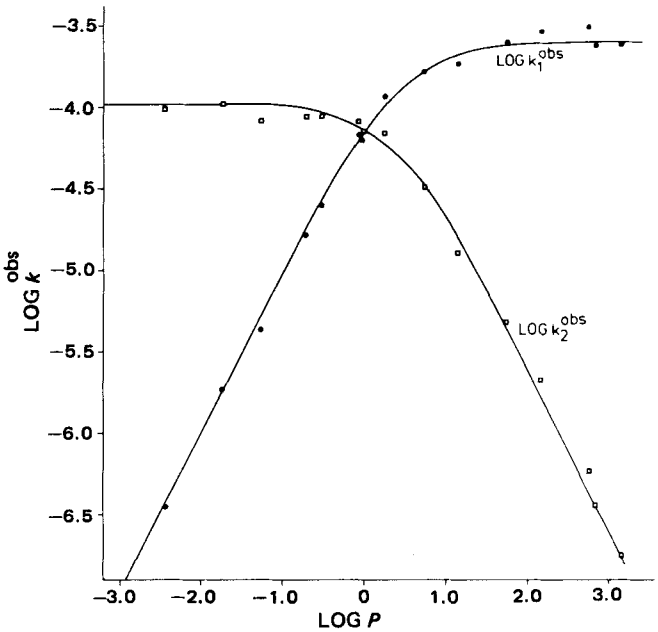

**Figure 1**—*Log* $k^{obs}$ *versus log P curves for the compounds of Table I. The plotted data are the log* $k^{obs}$ *values, and the drawn curves were calculated with Eqs. 3 and 4.*

[a] The log $k^{calc}$ calculated from Eqs. 3 and 4. [b] Stirring rate was 0.667 $sec^{-1}$, and temperature was 20 ± 0.1° (7). [c] Initial concentration in aqueous or organic phase (7). [d] Taken from Ref. 8.

amide derivatives (3) (Eqs. 3 and 4). The regression equations for the compounds of Table I are:

$$\log k_1^{obs} = \log P - \log (0.364P + 1) - 4.010 \quad \text{(Eq. 5)}$$
$$n = 15 \quad r = 0.999 \quad F = 4401 \quad s = 0.051$$

$$\log k_2^{obs} = -\log (0.358P + 1) - 4.016 \quad \text{(Eq. 6)}$$
$$n = 15 \quad r = 0.999 \quad F = 5375 \quad s = 0.051$$

When the data of the compounds of Table I are combined with the data of the sulfonamide derivatives, the regression equations are:

$$\log k_1^{obs} = \log P - \log (0.386P + 1) - 3.999 \quad \text{(Eq. 7)}$$
$$n = 45 \quad r = 0.997 \quad F = 7332 \quad s = 0.047$$

$$\log k_2^{obs} = -\log (0.385P + 1) - 4.002 \quad \text{(Eq. 8)}$$
$$n = 45 \quad r = 0.998 \quad F = 12{,}055 \quad s = 0.047$$

Because $\beta$ can only be determined with a relative standard deviation of ~10% (3, 10), it can be concluded that Eqs. 5–8 do not differ significantly and that all compounds behave as belonging to one series with regard to partitioning.

Since diffusion rate constants through the stagnant layers largely determine the overall transport rates, dependency on the radius of the molecules is expected (Stokes–Einstein relation). However, because this effect was not observed, it was concluded that the effective molecular radii of the sulfonamide derivatives all are very similar (3). This fact also holds for other compounds. These observations show that the absolute magnitude of transport rate constants in a two-phase system is not dependent on the intrinsic molecular size of a compound.

In conclusion, transport rate constants of drug partitioning in a chosen two-phase system are determined by the partition coefficient ($P$) and the solvent system parameter ($\beta$). This $\beta$ value, which equals $k_{org}/k_{aq}$, is a new parameter that can be calculated from the plateau values of a log $k^{obs}$/log $P$ curve (3).

Drug transport in biological systems includes a series of interphase aqueous environment to membrane transfers and vice versa. For each transfer process, a certain $\beta$ value can be defined; thus, it is interesting to know the factors that determine this parameter. It is assumed that the stagnant layers at an interface are more or less structured (3) and that this structuring originates from a mutual influencing of the two adjacent phases (water–organic solvent or water–membrane). Polarity and polarizability of the solvents seem to be important properties. Investigations on this subject are in progress. Studies on the partitioning kinetics of drugs will produce more knowledge of the transport properties of drugs, which then can result in improved pharmacokinetic parameters of drugs (11, 12) and the successful application of quantitative structure–activity relationships.

# Simultaneous Determination of Hydrochlorothiazide and Triamterene in Capsule Formulations by High-Performance Liquid Chromatography

G. N. MENON ˣ and L. B. WHITE

Received December 8, 1980, from the *Department of Analytical Research, Abbott Laboratories, North Chicago, IL 60064.* Accepted for publication February 20, 1981.

**Abstract** □ A stability-indicating, high-performance liquid chromatographic method is presented for the simultaneous determination of hydrochlorothiazide and triamterene in two-component capsule formulations. An aliquot of the sample is dissolved in a mixture of acetonitrile and aqueous acetic acid, mixed with *m*-hydroxyacetophenone as an internal standard, and chromatographed on octadecylsilane bonded to microparticulate silica using 80% acetate buffer (pH 5.0, 0.004 *M*)–15% acetonitrile–5% methanol as the mobile phase. The relative standard deviations are ±1.1–1.6% for hydrochlorothiazide and ±1.7–2.2% for triamterene for two formulations. Recoveries of the two drugs added to placebos ranged from 98.4 to 101.7%.

**Keyphrases** □ Hydrochlorothiazide—simultaneous determination by high-performance liquid chromatography with triamterene, capsule formulations □ Triamterene—simultaneous determination by high-performance liquid chromatography with hydrochlorothiazide, capsule formulations □ High-performance liquid chromatography—simultaneous determination of hydrochlorothiazide and triamterene, capsule formulations

A combination dosage form of triamterene and hydrochlorothiazide is indicated in the treatment and management of edema and hypertension. Several methods are available for the assay of hydrochlorothiazide, alone (1–3) or in combination with other drugs such as methyldopa (4), hydralazine (5), reserpine (5, 6), and furosemide (7), and other diuretic–antihypertensive drugs of the thiazide family (8). These methods range from nonspecific approaches such as titrimetry, spectrophotometry, and polarography to specific determinations by high-performance liquid chromatography (HPLC). Triamterene has been assayed by absorption spectroscopy, fluorescence, and TLC fluorometry (9–11).

While separation of triamterene and hydrochlorothiazide from other diuretic–antihypertensive drugs by HPLC was reported (12, 13), no details are available for the specific assay of the two drugs in a dosage form. Furthermore, there are no indications in the literature whether the HPLC separations obtained are specific for the intact drug substances only. A direct method for the simultaneous determination of triamterene and hydrochlorothiazide, used to study the dissolution rate of a tablet dosage form (14), also does not differentiate between the drugs and their respective degradation products.

This paper reports a simple, rapid, and precise stability-indicating assay for triamterene and hydrochlorothiazide in capsule formulation by HPLC.

## EXPERIMENTAL

**Instrumentation**—The chromatographic system was equipped with a dual-piston reciprocating pump[1], a universal injector[2], and a variable-wavelength detector[3]. The separation was performed on a 30-cm × 4-mm i.d. column containing microparticulate-bonded (10-μm) octadecylsilane material[4]. The chromatographic peaks were electronically integrated and recorded[5].

**Mobile Phase**—A solution of 20 ml of 0.2 *M* sodium acetate[6] adjusted to pH 5.0 with acetic acid was mixed with 780 ml of water, 150 ml of acetonitrile[7], and 50 ml of methanol[7]. The solution was filtered, degassed under vacuum, and used as the mobile phase.

**Internal Standard Solution**—A solution of *m*-hydroxyacetophenone[8] (3 mg/ml) in acetronitrile–water (1:1) was used as the internal standard.

**Standard Preparation**—A stock solution of hydrochlorothiazide was prepared using 100 mg of USP reference standard dissolved in 200 ml of acetonitrile. Stock triamterene solution was prepared by adding 25 ml of acetonitrile, followed by 4 ml of acetic acid, to 100 mg of USP reference standard, slurrying well, dissolving, and diluting to 100 ml with water.

A working standard solution was prepared by mixing 5 ml of each stock solution with 10 ml of the internal standard solution and diluting to 100 ml with water.

**Sample Preparation**—An aliquot of a powder blend from 10 capsules of a commercial formulation[9], equivalent to 50 mg of hydrochlorothiazide and 100 mg of triamterene, was slurried with 25 ml of acetonitrile followed by 4 ml of acetic acid. The mixture was shaken well for 5 min, mixed with 10 ml of internal standard solution, dissolved, and diluted to 100 ml with water. A portion of the solution was filtered through a polycarbonate membrane[10] using a filter assembly[11] and was analyzed.

**Analysis**—The chromatographic conditions used for the analysis were; flow rate, 2 ml/min; detector, 273 nm, 0.1 aufs; injection volume, 40 μl; and temperature, ambient.

Quantitative determinations were made by comparison of the peak area ratios of hydrochlorothiazide and triamterene to the *m*-hydroxyacetophenone from a sample injection to the corresponding area ratios from a standard injection.

## RESULTS AND DISCUSSION

The HPLC system described by Honigberg *et al.* (13) provided excellent separation of hydrochlorothiazide and triamterene in a commercial formulation[9]. However, when formulations degraded by acid and alkali reflux were examined, a degradation product of triamterene eluted on the shoulder of the hydrochlorothiazide peak. Therefore, the mobile phase was modified to provide for adequate resolution of the various components of degraded formulations.

Figure 1 shows a typical chromatogram from the analysis of a formulation. The detection wavelength of 273 nm was chosen so that the peak area ratios of both drugs to the internal standard were close to unity.

Triamterene is only slightly soluble in water and forms insoluble complex salts with mineral acids (15). The complexes formed with acetic acid are reportedly (15) more soluble than the inorganic acid complexes. The use of acetic acid and the order of addition of the solvents are critical in the rapid dissolution of the formulation.

Hydrochlorothiazide is susceptible to both acid and alkaline hydrolysis and yields formaldehyde and 4-amino-6-chloro-*m*-benzenedisulfonamide

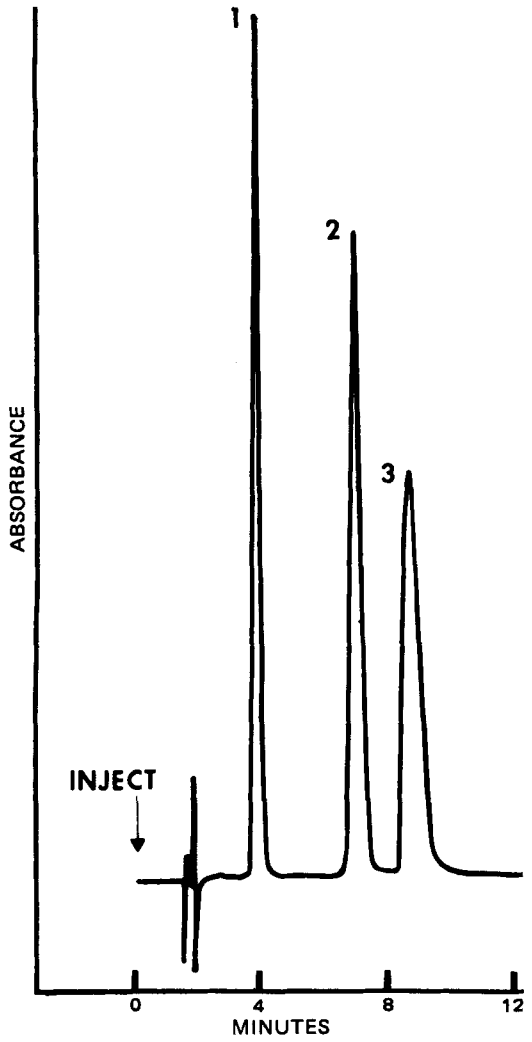

**Figure 1**—*Chromatogram of typical commercial capsule formulation. Key: 1, hydrochlorothiazide; 2, m-hydroxyacetophenone; and 3, triamterene.*

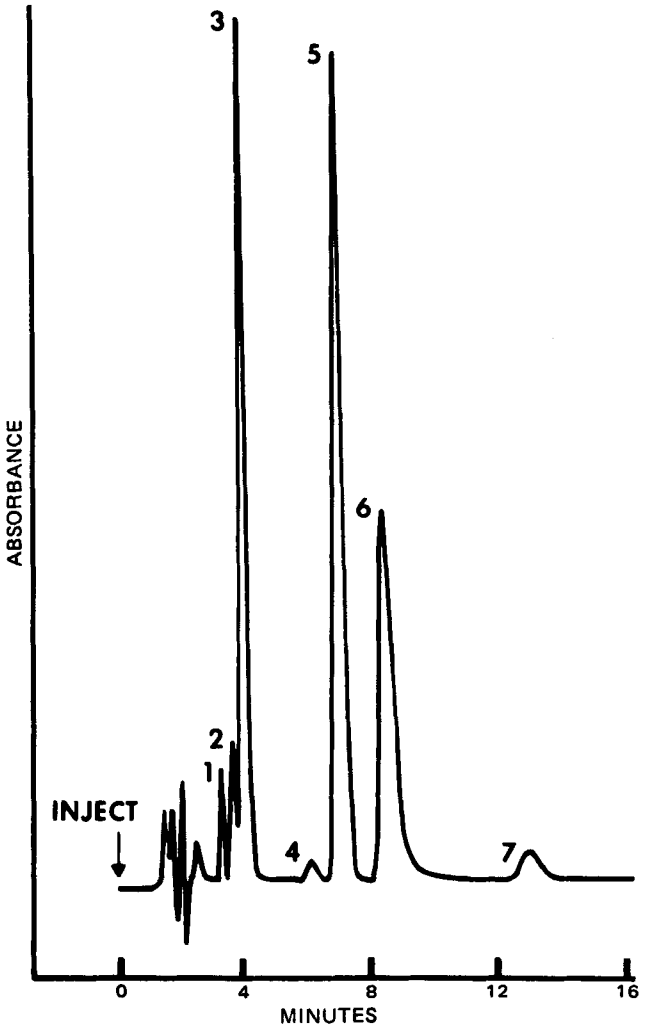

**Figure 2**—*Chromatogram of acid- and alkali-degraded commercial formulation. Key: 1, 4-amino-6-chloro-m-benzenedisulfonamide; 2, 4, and 7, degradation products of triamterene; 3, hydrochlorothiazide; 5, m-hydroxyacetophenone; and 6, triamterene.*

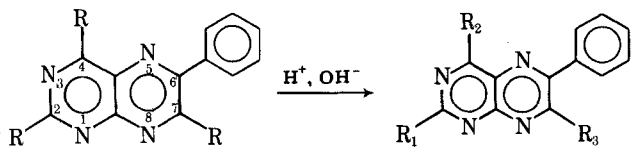
on degradation (16, 17). Although the degradation products of triamterene are not described in the literature, hydrolysis with 5 *N* HCl reportedly produced the 4-hydroxy and 7-hydroxy analogs of triamterene (18). Samples of the formulation were refluxed in 1 *N* HCl, 1 *N* NaOH, and water to observe the hydrolytic effects and resultant changes in the chromatogram. In a separate experiment, triamterene alone was subjected to similar hydrolytic stress for 3 hr. No degradation of triamterene was observed on water reflux, although total degradation resulted on base reflux and ~50% degradation occurred under acid reflux.

Figure 2 shows a chromatogram obtained from the injection of a mixture of acid- and alkali-degraded formulation. Alkali reflux of triamterene produced predominantly peak 7 with minor amounts of peak 2. Acid reflux resulted in larger amounts of peaks 2 and 4 with a trace of peak 7. The refluxed solutions were filtered and neutralized. Upon neutralization, precipitates formed in both the acid and base hydrolyzates. These precipitates were analyzed by HPLC, mass spectrometry, and spectrophotometry. By mass spectrometry, both precipitates showed *m/z* 254 but with different fragmentation patterns, suggesting that they were positional isomers of the hydroxy analogs of triamterene (Scheme I).



triamterene: R = $NH_2$
peak 7 analog: $R_1$ = OH, $R_2$ = $R_3$ = $NH_2$ in alkali
peak 4 analog: $R_2$ = OH, $R_1$ = $R_3$ = $NH_2$ in acid
peak 2 analog: $R_3$ = OH, $R_1$ = $R_2$ = $NH_2$ in acid

*Scheme I*

Based on the spectral properties in acidic and basic media and comparison to the synthetic hydroxypteridines prepared by Spickett and Timmis (18), peak 7 (the major alkaline degradation product) was identified as 4,7-diamino-2-hydroxy-6-phenylpteridine and peak 4 was identified as 2,7-diamino-4-hydroxy-6-phenylpteridine. Peak 2 probably is the 7-hydroxy analog isolated (18) upon acid hydrolysis of 2,4,7-triamino-6-phenylpteridine. Since peak 2 elutes earlier, the compound may have higher solubility than the 4- and 2-hydroxy compounds and is not precipitated on neutralization of the hydrolyzates. The major degradation pathways are represented in Scheme I.

The mass spectra of the identified compounds are in agreement with the proposed assignments. Since all components are adequately resolved from each other and the internal standard, the method indicates the

**Table I—HPLC Analysis of Hydrochlorothiazide–Triamterene Capsule Formulations**

| Parameter | Hydrochlorothiazide | | Triamterene | |
|---|---|---|---|---|
| | Product I[a] | Product II[b] | Product I[a] | Product II[b] |
| Number of analyses | 9 | 9 | 9 | 9 |
| Milligrams per capsule (mean) | 25.8 | 25.5 | 51.0 | 51.3 |
| RSD, % | ±1.6 | ±1.1 | ±2.2 | ±1.7 |

[a] Dyazide®, Smith Kline and French Laboratories, Philadelphia, Pa. [b] Abbott Laboratories, North Chicago, Ill.

stability of the drugs in the formulation. None of these degradation products was detected in a formulation subjected to high-temperature stability testing.

The linearity of the detector response was established for hydrochlorothiazide in the range of 15–30 mg/capsule ($r$ = 1.000, $y$-intercept = 0.002) and for triamterene in the range of 30–70 mg/capsule ($r$ = 1.000, $y$-intercept = 0.04). Standard addition–recovery experiments performed in two different placebos at various drug levels showed recoveries of 98.4–101.7% for hydrochlorothiazide ($n$ = 12, $CV$ = ±1.2%) and 99.5–102.0% for triamterene ($n$ = 12, $CV$ = ±0.9%).

The reproducibility of the method was demonstrated by performing replicate analyses on a commercial formulation[9] and another experimental formulation with different excipients. The statistical data generated from these analyses are presented in Table I.

In conclusion, HPLC provides a rapid and precise method for the quantitative determination of hydrochlorothiazide and triamterene in a combination oral dosage form. The method is sensitive to the degradation products of these drugs and is free from interference due to excipients in the products examined.

# Test for Reproducibility of Metered-Dose Aerosol Valves for Pharmaceutical Solutions

**A. CUTIE [§x], J. BURGER [*], C. CLAWANS [‡], D. DOLINSKY [§], W. FEINSTEIN [*], B. GUPTA [‡], A. GRUENEBERG [¶], and J. SCIARRA [§]**

Received September 8, 1980, from [§]*Arnold & Marie Schwartz College of Pharmacy and Health Sciences, Brooklyn, NY 11201*, the [*]*Whitehall International, Division of American Home Products Corporation, New York, NY 10017*, the [‡]*Schering Corporation, Bloomfield, NJ 07003*, and the [¶]*USV Laboratories Division, Tuckahoe, NY 10707.* Accepted for publication February 9, 1981.

**Abstract** □ Seven independent testing sites received metered-dose aerosols containing a standard test solution to assess a newly designed protocol for studying the reproducibility of metered-dose aerosol valves. In accordance with the rather small sampling protocol design, the amount of product dispensed per actuation was measured over the life of the aerosol at designated regions of actuation. A statistical analysis of the data collected at each testing site clearly indicated that the testing protocol is sufficiently reliable and workable for assessing the reproducibility of valve delivery for a given lot of metered-dose valves.

**Keyphrases** □ Aerosols—testing procedure for establishing the reproducibility of metered-dose valves □ Inhalation products—testing procedure for establishing the reproducibility of metered-dose aerosol valves □ Valve delivery—metered-dose aerosols, testing procedure for establishing reproducibility

Test methods, including specific gravity, net contents, vapor pressure, moisture content, spray patterns, and particulate-size determinations, have been established for determining the acceptance of metered-dose aerosol valves for pharmaceutical use (1–4). Reproducibility of the dosage delivered may be determined by assay techniques which establish the amount of active (5). Although USP XX (6) includes metered-dose inhalation products in the monographs and establishes some standards with which these metered-dose products must comply, little has been done in establishing a uniform test procedure for all metered-dose products.

The Aerosol Specification Committee[1] elected to establish a simple and uniform test method for metered-dose aerosol valves by examining the uniformity of valve delivery (amount of solution delivered by the valve) within a valve and between individual valves in any given lot. The procedure outlined in this study provides a means for manufacturers to assess the reproducibility of valve delivery for a given lot of metered-dose valves throughout the life of the product.

## EXPERIMENTAL

**Aerosol Test Solutions**—Pharmaceutical test solutions were prepared by taking 0.10% by weight of isopropyl myristate[2] and adding it to a mixture of 24.90% by weight of trichloromonofluoromethane (Propellant

11[3]), 50.00% by weight of dichlorodifluoromethane (Propellant 12[4]), and 25% by weight of dichlorotetrafluoroethane (Propellant 114[5]). This solution was prepared by the cold fill process, and a suitable metered container was used.

**Aerosol Components**—In the initial study (Protocol I), an experimental 63-μl aerosol valve[6] was used. In each subsequent study (Protocol II), a valve with a 50-μl metering chamber[6] and stainless steel stem was used. Fifteen-milliliter aluminum aerosol containers[6] and standard button actuators[6] were employed in all studies.

**Preparation of Samples**[7]—In a thermostatically controlled chill tank maintained at −32°, isopropyl myristate was mixed with trichloromonofluoromethane. By using gravity-fed metering equipment with an electrically controlled solenoid shutoff, this solution was filled by volume and time into the aluminum container. The filling machine reservoir was maintained at a constant volume and temperature, thus allowing for precise volume fills in the container *via* a predetermined timed opening of the filler tube. At a second similar filling station, at 2:1 blend of Propellants 12 and 114, maintained at −37°, was metered into the aluminum container to the appropriate volume. Aerosol valves (without diptubes) were placed on the aluminum cans and crimped. The completed cans then were tested for leaks by immersing each for 3–5 min in a water bath maintained at 55°. Cans showing evidence of leaks (production of gas bubbles) were removed and discarded.

**Sampling Procedure**—After filling, leak testing, and spray testing, the containers were packed in the inverted position (valve down) into nested cardboard shippers. In a random manner, one shipper (containing 100 cans) was sent by parcel post to each testing site[8] where the cartons were stored at ambient conditions with the cans inverted (valve down).

**Testing Procedure**—To minimize possible variation due to the multicentric nature of the studies, the following protocols were utilized at each site.

*Protocol I*—Five cans were selected from the 100 cans supplied. With the actuator kept in place, the container was weighed accurately to ±0.1 mg. The valve was actuated once, and then the container was reweighed and the weight loss was recorded. Single actuations were repeated, and the weight loss was recorded for each individual actuation up to and including 10 actuations. The time interval was recorded between each actuation. The valve was actuated again for Actuations 11–25, with 3 sec between each actuation. The container was weighed, and single actuations were repeated. The weight loss of each individual actuation was recorded up to and including Actuation 29. The valve was actuated again for Actuations 30–75, with 3 sec between each actuation. The container was weighed, and single actuations were repeated. The weight loss was recorded for each individual actuation up to and including Actuation 79. The valve was actuated again for Actuations 80–176, with 3 sec between each actuation and 1 min before dispensation of Actuations 80, 91, 101, and 111. The container was weighed, and single actuations were repeated. The weight loss of each individual actuation up to and including Actuation 180 was recorded.

*Protocol II*—Five cans were selected from the 100 cans supplied. With

the actuator kept in place, the container was weighed accurately to ±0.1 mg. The valve was actuated six times. After 30 sec, the weight of the container was recorded. Single actuations were repeated, and the weight loss was recorded for each individual actuation up to and including Actuation 10. The time interval between each actuation was recorded. The valve was actuated again at a rate of one actuation every 2 sec until one-half of the total labeled actuations minus five. (In this study, Actuation 80 was one-half of the total actuations minus five.) After 5–7 min (to allow temperature equilibrium), single actuations were repeated, and the weight loss was recorded for each individual actuation up to and including Actuation 85. The valve again was actuated at a rate of one actuation every 2 sec until five less than the total labeled actuations. (In this study, Actuation 165 was five less than the total actuations.) The wait of 5–7 min and single actuations were repeated, and the weight loss was recorded for each individual actuation up to and including Actuation 170.

In both protocols, relative humidity, temperature, condensation on can (if any), misdirected sprays, and amount accumulated on actuator (by weighing the actuator before and after rinsing with plenty of water) were reported. All actuations were performed with the cans inverted.

## RESULTS AND DISCUSSION

The means and ranges of the amount of material delivered through the metered-dose valve utilizing Protocols I and II are given in Tables I and II, respectively. Both protocols were designed to assess the amount of material actuated by a metered valve under testing during each region of product use. The regions specifically evaluated were the initial doses actuated and actuations when the aerosol container was approximately 10, 30, 50, 70, and 95% empty. No attempt was made to access the valve's performance just prior to container emptying (tail off) since it varied considerably, depending on the contents remaining in the container and the experimenter's technique (container agitation, angle of container, *etc.*).

Two separate analyses of variance were performed on the data presented in Table I to determine the influence of testing sites (laboratory conditions and technician performance) and actuation number on the amount of material actuated. The analyses were performed using two-factor analysis of variance with repeated measures on one factor (7) and a computer program[9] for repeated-measured analysis of variance. Conservative degrees of freedom were utilized in the statistical analysis of the data because of the repeated, nonindependent nature of the actuations.

| Sites × actuations | 707.72 | 52 | 13.61 | 0.063 | NS[a] |
| Actuations × cans within sites | 56,409.60 | 260 | 216.96 | | |

[a] Not significant.

The first analysis was a four-site by 22-actuation design (Protocol I) with actuations as the repeated factor. The 22 actuations outlined in Protocol I consisted of measurements of Actuations 1–10, 26–29, 76–79, and 177–180. The results given in Table III clearly indicate no significant effect for the test sites, a significant effect for actuations, and no significant interaction between sites and actuations. Therefore, there were no differences between sites, but there were differences between successive actuations.

Since the significant effect for actuation was thought to be due to the unique effects of the first actuation (valve priming), a second analysis was performed. It was identical to the previous one, except that the data for the first actuation were omitted. This procedure resulted in a four-site by 21-actuation design. The results presented in Table IV clearly indicate no significant effects for sites or actuations and no significant interactions. Therefore, when the unique first actuation was omitted, there were no differences between sites and no differences between successive actuations.

One analysis of variance was performed on the data in Table II. The data collected utilizing Protocol II (14-actuation study) when analyzed statistically indicated no difference in the milligrams of solution actuated between sites, between actuations, or in the site by actuation interaction (Table V).

## CONCLUSIONS

The statistical analysis of data clearly indicated that the protocols described are not influenced by the experimenter or the test site at which the study was conducted. The abbreviated procedure involving only 14 actuation measurements outlined in Protocol II also yielded the same results as the 21-actuation study and is practical for assessing the reproducibility of valve delivery for a given lot of metered-dose valves.

# Synthesis and Skeletal Muscle Relaxant Activity of 3-(Aminoacyl)-1-[[[5-(substituted phenyl)-2-furanyl]methylene]amino]-2,4-imidazolidinediones

**F. L. WESSELS** [x], **K. O. ELLIS, and R. L. WHITE, Jr.**

Received September 2, 1980, from the *Research & Development Department, Norwich-Eaton Pharmaceuticals, Division of Morton-Norwich Products, Inc., Norwich, NY 13815.* Accepted for publication February 17, 1981.

**Abstract** □ A series of 3-(aminoacyl)-1-[[[5-(substituted phenyl)-2-furanyl]methylene]amino]-2,4-imidazolidinediones was synthesized and evaluated for skeletal muscle relaxant activity. All compounds were active by the intravenous route, and nine of 11 were active orally. One compound was very active when evaluated by the mouse Straub tail and rotarod tests; its efficacy index ($ED_{50}$ rotarod/$ED_{50}$ Straub tail) was 2.0, while its therapeutic index ($LD_{50}/ED_{50}$ Straub tail) was >225.

**Keyphrases** □ 3-Aminoacyl-substituted 2,4-imidazolidinediones—synthesis and evaluation for skeletal muscle relaxant activity, mice □ Dantrolene sodium—related compounds synthesized and evaluated for skeletal muscle relaxant activity, mice □ Skeletal muscle relaxant activity—dantrolene sodium-related compounds synthesized and evaluated for activity, mice □ Muscle, skeletal—relaxant properties evaluated in dantrolene-related compounds, mice

Several 2,4-imidazolidinediones have skeletal muscle relaxant activity (1). One member of this series, dantrolene[1], caused skeletal muscle relaxation by a unique mechanism, acting directly on the skeletal muscle (2, 3). It has been hypothesized that dantrolene sodium induces muscle relaxation by inhibiting the release of $Ca^{2+}$ from the sarcoplasmic reticulum (4, 5).

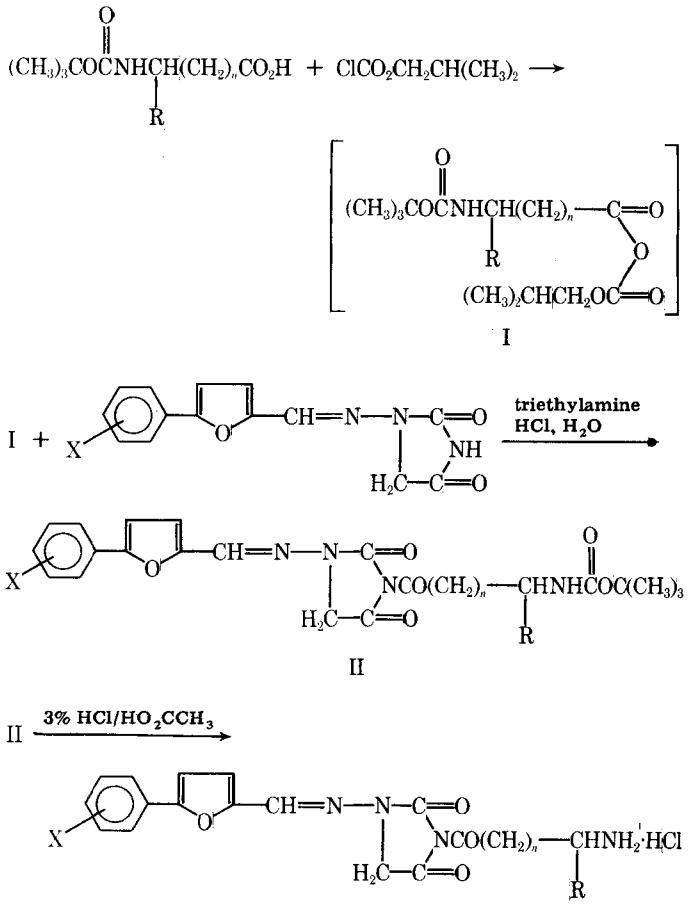
This paper presents the syntheses (6) and skeletal muscle relaxant activity of a series of 3-aminoacyl compounds related to dantrolene.

## EXPERIMENTAL[2]

The imidazolidinediones selected as starting materials were prepared by a literature method (1). The title compounds (Table I) were prepared by the general procedure shown in Scheme I and as exemplified by the following typical reaction.

**3 -(3-Aminopropionyl)-1-[[[5-(4-nitrophenyl)-2-furanyl]methylene]amino]-2,4-imidazolidinedione Hydrochloride (IIIa)**—*N-tert*-Butoxycarbonyl-β-alanine (14 g, 0.075 mole) in dimethylformamide (350 ml) was cooled to 0°, and triethylamine (21 ml, 0.15 mole) was added rapidly. The solution was maintained at from −5 to −10° while isobutyl chlorocarbonate (10.5 ml, 0.075 mole) was added. The stirred solution was kept at −5° for 10 min, and then solid 1-[[[5-(4-nitrophenyl)-2-furanyl]methylene]amino]-2,4-imidazolidinedione (21 g, 0.068 mole) was added over 5 min. The temperature was maintained at from −5 to 0° for 30 min, and then the solution was stirred for 1 hr without cooling. The dimethylformamide solution was poured into a stirred solution of ice water (3.0 liters) containing concentrated hydrochloric acid (50 ml). The resulting yellow solid was collected and air dried. Recrystallization from acetonitrile (2.5 liters) yielded 17 g (51%) of intermediate product, mp 213–214°.

The 3-[3-(*N-tert*-butoxycarbonylamino)-1-oxopropyl-1-[[[5-(4-nitrophenyl)-2-furanyl]methylene]amino]-2,4-imidazolidinedione (17 g, 0.035 mole) was added to 3% hydrochloric acid–acetic acid (400 ml) at 15°, and the mixture was stirred for 5 hr. The mixture was filtered, and the collected solid was washed with nitromethane (200 ml) and ether (100 ml). The solid was dried in a 60° oven overnight, yielding 14 g of IIIa (94%, 48% overall), mp 211–212°; IR: 2.8–4.0 (broad N–H), 5.6, 5.7, 5.8, 6.25, 6.6, and 7.5 μ.



IIIa–IIIk

*Scheme I—See Table I for specific values for X, R, and n.*

**Pharmacology**—*Gross Observation*—Groups of three unfasted male mice[3], 20–27 g, were used. The drugs were administered perorally at doses of 50–800 mg/kg as a 2% concentration suspended in 0.5% methylcellulose 4000 cps[4]. Gross observation for pharmacological effects were made for 2 hr, utilizing a rating of drug effect signs similar to that described by Irwin (7). Muscle relaxation was rated on a scale from 0 to 4: 0, no effect; 1, slight; 2, moderate; 3, marked; and 4, extreme.

*Pithed Rat Gastrocnemius Muscle Preparation*—The method used for direct stimulation of the gastrocnemius muscle in rats[5] ($n$ = 4) was the same as that described previously (8). The test drugs were administered intravenously at logarithmically spaced doses in tetrahydrofurfuryl alcohol[6] or dimethyl sulfoxide[7]. Solvent effects accounted for a <20% decrease in the twitch response at the highest volume tested.

*Rotarod Testing in Mice*—A method similar to that described by

[1] Morton-Norwich Products.

[a] Percent inhibition of electrically induced contractions of the rat gastrocnemius muscle at a cumulative dose of 36.6 mg/kg iv. The figure in parentheses is the standard error of the mean. [b] Where 1 = slight, 2 = moderate, 3= marked, and 4= severe drug effect as measured by gross observation in mice and the dose (in parentheses) at which this occurred. [c] Intraperitoneal dose of drug causing inhibition of morphine-induced Straub tail in 50% of the mice. [d] Intraperitoneal dose of drug causing loss of motor coordination (rotarod) in 50% of the mice. [e] $ED_{50}$ rotarod/$ED_{50}$ Straub tail. [f] Intraperitoneal dose of drug causing death in 50% of the mice within 72 hr. [g] $LD_{50}/ED_{50}$ Straub tail. [h] See Ref. 8. [i] The figures in parentheses are the 95% confidence limits. Muscle relaxant testing was not completed on compounds which were not effective orally (IIIh, IIIi) or in which the Rotarod $ED_{50}$ was below the Straub Tail $ED_{50}$ (IIIg).

Dunham and Miya (9) was used to test the effect of drugs on motor coordination. Male mice[3] ($n$ = 10/group) were trained to walk the revolving rod (20 rpm) for over 1 min. The test drugs were administered intraperitoneally in 0.5% methylcellulose at logarithmically spaced doses to the previously trained mice, and performance trials were conducted 30 min following drug administration. The inability of an animal to stay on the rotarod for more than 30 sec was considered a positive drug effect. The $ED_{50}$ values (rotarod) (the drug dose that caused 50% of the animals to fall off the rotarod within 30 sec) were calculated using the method of Litchfield and Wilcoxon (10).

*Straub Tail in Mice*—The method used in these experiments was similar to that reported by Ellis and Carpenter (11). Male mice[3] ($n$ = 10/group) were used for Straub tail testing. The drugs were administered intraperitoneally in 0.5% methylcellulose 20 min after morphine[8] (15 mg/kg sc) injection. The drugs were judged effective if they caused the elevated Straub tail to lay flat on the table. The compounds were administered in logarithmically spaced doses, and $ED_{50}$ values (dose of the

[8] Mallinckrodt.

drug causing the elevated tail to lay flat in 50% of the animals) were obtained by the method of Litchfield and Wilcoxon (10).

*$LD_{50}$ in Mice*—The test compounds were administered perorally in 0.5% methylcellulose to groups of unfasted male mice[3] ($n$ = 10/group). The animals were held in cages for 72 hr, and the deaths were recorded. The $LD_{50}$ values (drug dose causing death in 50% of the animals) were calculated using the method of Litchfield and Wilcoxon (10).

## RESULTS AND DISCUSSION

The synthesized compounds (6) exhibited a better absorption and solubility profile than the parent compound, dantrolene. Eleven compounds were synthesized and evaluated for skeletal muscle relaxant activity (Table II). In the pithed rat gastrocnemius muscle preparation, all compounds were effective intravenous skeletal muscle relaxants (>50% inhibition of the electrically induced twitch contraction) (Table II).

Compounds III*a* and III*f* were also potent inhibitors of the gastrocnemius twitch tension. These compounds were the most effective in that the maximal inhibition of the twitch response was 86–87% whereas dantrolene sodium and clodanolene sodium only yielded a maximal inhibition of 80%.

Gross observation in mice identified nine of the 11 compounds as orally effective muscle relaxants. Among these nine (muscle relaxant score of >1 at doses up to 800 mg/kg), III*a* and III*e* were the most effective, producing muscle relaxant scores of 4. Compounds III*b*, III*g*, III*j*, and III*k* were slightly less effective, producing muscle relaxant scores of 3; III*b* produced a 3 level of muscle relaxation at 200 mg/kg.

Lowering of the Straub tail previously was shown (11) to result from relaxation of the sacrococcygeal muscles at the base of the tail. Several different drugs can produce this muscle relaxation (11). However, the muscle relaxant properties of a drug are useful only when they can be separated in a dose-dependent manner from its neurotoxic properties (motor incoordination). Motor incoordination is an unacceptable consequence of skeletal muscle relaxant therapy and, therefore, is a limiting factor in determining muscle relaxant efficacy. In the Straub tail model, the muscle relaxant dose is identified as St $ED_{50}$; the motor incoordination dose is identified with the rotarod test (Rr $ED_{50}$). Comparing these two doses as a ratio, $ED_{50}$ rotarod:$ED_{50}$ Straub tail, gives an indication of the separation between the two dose ranges (*i.e.*, the greater the ratio, the more separation between the two doses).

Compound III*a* yielded a muscle relaxant efficacy index of 2.0, and all other compounds produced muscle relaxant efficacy indexes of <1.0. Additionally, when III*a* was evaluated for acute toxicity, no deaths were seen up to 4000 mg/kg, and the resultant therapeutic index was >225.

The difference in muscle relaxant efficacy indexes between III*a* and other muscle relaxants of this type (dantrolene sodium and clodanolene sodium), including the compounds in Table II, is small but consistent. Compound III*a* is a potent, direct-acting skeletal muscle contraction antagonist (inhibition of the directly induced gastrocnemius twitch tension). The muscle relaxant efficacy index and acute therapeutic index values reflect a high degree of efficacy and safety.

position of salicyluric acid to salicylic acid by microorganisms (3, 4). There are no reports of the methylation of salicyluric acid during its quantitation in biological fluids.

In measuring salicylic acid and its metabolites in urine by HPLC, it was observed that salicyluric acid was methylated as a consequence of sample preparation. Because similar alteration of the salicyluric acid may occur in other laboratories during quantitation, the methylated product was identified by GLC–mass spectrometry. The conditions under which this product is formed and methods to prevent its formation are described.

## EXPERIMENTAL

**Reagents**—Methanol[1], ether[2], *o*-methoxybenzoic acid[3] (*o*-anisic acid), sodium salicylate[3], salicyluric acid[3] (*o*-hydroxyhippuric acid), and gentisic acid[3] were used.

Stock standard solutions of sodium salicylate (5 mg/ml), salicyluric acid (10 mg/ml), and gentisic acid (2 mg/ml) were prepared by dissolving the compounds in small volumes of ethanol and bringing to volume with pH 7 phosphate buffer (0.1 *M*). The stock solutions were kept frozen at 0° until required. Working standards of sodium salicylate (500, 250, and 50 μg/ml), salicyluric acid (1000, 500, and 100 μg/ml), and gentisic acid (200, 100, and 20 μg/ml) were made in fresh, blank urine.

**Procedures**—Urine (1 ml), to which 1 ml of a standard solution of *o*-methoxybenzoic acid (100 μg/ml) in pH 7 phosphate buffer (0.1 *M*) had been added, was acidified with 0.6 *M* HCl (1 ml) and extracted into 5 ml of ether by shaking for 5 min. Following centrifugation, the aqueous layer was frozen in acetone–dry ice, and the ether layer was collected. The ether was evaporated to dryness at 10° with air or nitrogen. The residue was resuspended in 0.75 ml of anhydrous methanol or a mixture of 85% water containing 1.6% acetic acid and 15% methanol. Samples were placed in 1-ml capped vials[4] and injected into the HPLC system *via* an automatic sampler[5] fitted with a 20-μl injection loop. The flush time was 30 sec, and the run time was 20 min. A 15-cm × 4.6-mm i.d. reversed-phase column[6] and a 5-cm × 2.1-mm i.d. precolumn[7] were used to separate salicylic acid and its metabolites. The mobile phase of 85% water (containing 1.6% acetic acid) and 15% methanol was pumped[8] at 2.5 ml/min. Peaks were detected by a UV detector[9] (310 nm) coupled to a recorder[10] and peak integrator[11].

To determine the conditions under which salicyluric acid was altered, salicyluric acid dissolved in water was taken through the described sample preparation but with the following changes: (*a*) the evaporated ether extract was dissolved in methanol for up to 3 weeks before injection onto the column; (*b*) the ether extract was blown to dryness with air or nitrogen; and (*c*) the residue following ether evaporation was resuspended either in methanol or 85% water (containing 1.6% acetic acid) and 15% methanol.

Aliquots of water and urine samples were extracted with ether in the presence and absence of hydrochloric acid, and the ether extracts were added to test tubes containing salicyluric acid prior to drying with nitrogen or air. The resulting residues then were redissolved in methanol and allowed to stand for up to 2 weeks before analysis.

The structure of the altered salicyluric acid was identified by GLC and mass spectrometry following repeated collection and lyophilization of the unknown chromatographic peak. The trimethylsilyl derivative of this sample was prepared by dissolving the residue in an excess (0.5 ml) of pyridine–*N*,*O*-bis(trimethylsilyl)trifluoroacetamide–trimethylchlorosilane (10:10:1). The mixture then was warmed for 5 min at 90°. An aliquot of the trimethylsilyl derivative was injected onto a GLC column (2 m × 2 mm i.d.), packed with 4% OV-17 on Gas Chrom Q[12] (100–120 mesh), programmed from 80 to 300° at 10.0°/min. The altered product of salicyluric acid then was identified by mass spectrometry[13].

Preparation of the methyl esters of salicyluric acid, gentisic acid, *o*-methoxybenzoic acid, and salicylic acid was attempted by bubbling hydrogen chloride through methanolic solutions of these chemicals for 5 min. The acidified methanolic solutions then were taken to dryness, and the residues were redissolved in 1.0 ml of methanol and subjected to HPLC using the described conditions. The methyl ester of salicylic acid was not formed under these conditions; complete esterification of *o*-methoxybenzoic acid and salicyluric acid was achieved, but gentisic acid esterification was only partially complete.

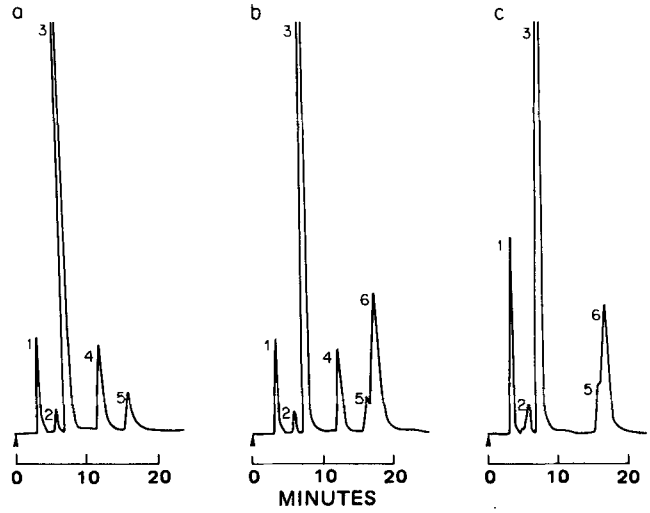

**Figure 1**—*Chromatograms of salicylic acid and its metabolites in urine under different experimental conditions: urine extract in methanol (a) immediately after the addition of methanol, (b) after allowing the methanolic extract to stand at room temperature for 8 hr, and (c) after the evaporation of ether with air. Key: 1, gentisic acid; 2, glucuronide of salicylic acid; 3, salicyluric acid; 4,o-methoxybenzoic acid; 5, salicylic acid; and 6, methyl salicylurate. The arrows indicate the points of injection.*

## RESULTS AND DISCUSSION

Quantitation of salicylic acid and its metabolites in urine gave accurate and reproducible results. Nitrogen was used to remove the ether at 10°, and the methanolic residue was immediately injected into the chromatograph. The sensitivity of the method was 5 μg/ml for salicylic acid, 5 μg/ml for salicyluric acid, and 2 μg/ml for gentisic acid. The coefficients of variation for repeated measurements of salicylic acid at 50 μg/ml, for salicyluric acid at 100 μg/ml, and for gentisic acid at 20 μg/ml were 2.6, 0.7, and 1.5%, respectively. These figures are similar to those previously reported (1, 4).

A typical HPLC tracing is shown in Fig. 1*a*. The retention times for gentisic acid, salicyluric acid, *o*-methoxybenzoic acid, and salicylic acid were 4, 8.4, 13, and 17.5 min, respectively.

The small peak that eluted between the gentisic acid and salicyluric acid peaks was probably one of the salicyl glucuronides since it disappeared following incubation of the urine with β-glucuronidase.

Occasionally, a peak that interfered with the salicylic acid peak was observed (Figs. 1*b* and 1*c*). This effect became apparent when extracted urine samples were prepared for HPLC (by the addition of methanol) well in advance of their actual injection onto the column *via* the automatic sample injector accessory. Interference also was observed if the ethereal extracts of urine were evaporated to dryness with air. The appearance and extent of this interference were variable. Sequential HPLC analysis of the salicylic acid, salicyluric acid, and gentisic acid standards in urine or water indicated that this peak was due to changes in the salicyluric acid standard.

When the salicyluric acid standard was extracted into ether from urine or water, interference occurred under the following experimental conditions: (*a*) if air or nitrogen was used to evaporate the ether; (*b*) if methanol was used to resuspend the residue from the ether evaporation; (*c*) if the residue from the ether evaporation stood in methanol for more

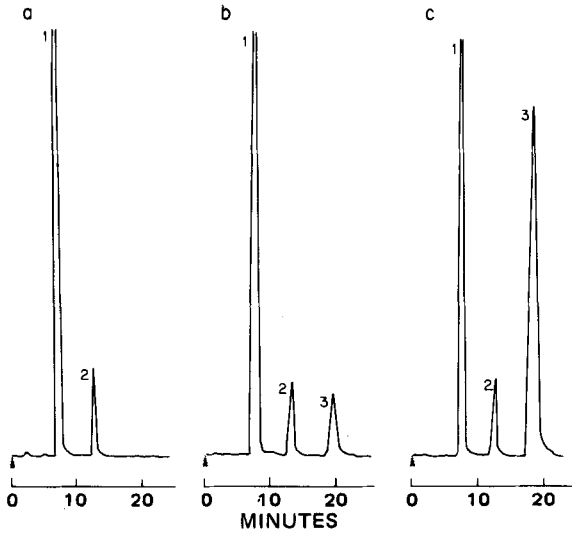

**Figure 2**—*Chromatograms of the salicyluric acid standard (1 mg/ml) under different experimental conditions: ether extract of salicyluric acid standard after standing in (a) 85% water containing 1.6% acetic acid–15% methanol for 10 days, (b) methanol for 6 hr, and (c) methanol for 21 days. The salicyluric acid concentration decreased 47%. Key: 1, salicyluric acid; 2, o-methoxybenzoic acid; and 3, methyl salicylurate. The arrows indicate the points of injection.*

than 2 hr; or (*d*) if hydrochloric acid was used to acidify the ester extract.

The time course and extent of changes in the standards were quite variable (Fig. 2*a*), but salicyluric acid levels decreased ~20% after the samples had stood in methanol for 6 hr (Fig. 2*b*). The maximum observed decrease in salicyluric acid levels was 47% after the salicyluric acid ether extract (1000 μg/ml) had stood in methanol for 21 days (Fig. 2*c*). However, there was no alteration of the salicyluric acid standard dissolved in methanol for up to 3 weeks.

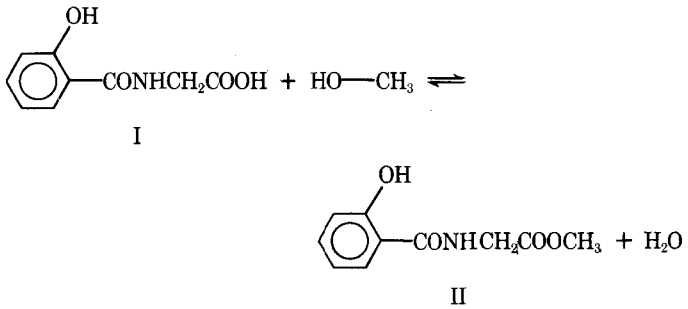
The interfering peak was collected after repeated injection and subjected to GLC–mass spectrometry for identification. Examination of the electron-impact mass spectra revealed that this peak was the methyl ester of salicyluric acid.

Like many esterification reactions, the conversion of salicyluric acid to methyl salicylurate is catalyzed by small amounts of acid. In addition, dehydration of the residue upon ether evaporation also may promote the methyl salicylurate formation. Dehydration by ether secondary to the formation of an azeotrope with water is well known. These effects favor ester formation between the carboxyl group of glycine and methanol under anhydrous conditions (Scheme I). In the ether extract, methanol is in large excess and the equilibrium is driven to the right (*i.e.*, methyl salicylurate is formed).

The formation of the ester can be prevented by adding water (which shifts the equilibrium to the left) or by adding another carbonyl group (*e.g.*, acetic acid), which competes with salicyluric acid for ester formation. Use of nitrogen gas and a limited time of exposure of salicyluric acid to methanol also help to control the ester formation with salicyluric acid.

Alternatively, salicyluric acid esterification can be circumvented if diluted urine (after centrifugation and filtration) is injected directly onto the column. However, with the HPLC column and solvent system employed, resolution of the gentisic acid peak from other endogenous substances in urine was not satisfactory without extraction.

Although some previous reports discussed precautions to prevent sublimation losses of salicylic acid and decomposition of salicyluric acid to salicylic acid by microorganisms (3, 6), there are no reports on the formation of methyl ester of salicyluric acid.



*Scheme I—Mechanism of the formation of methyl salicylurate (II) from salicyluric acid (I).*

One method (1) employed ether for urine extraction, but the ethereal residue was dissolved in methanol–water–acetic acid (50:60:1), which inhibits formation of methyl salicylurate.

Esterification of gentisic acid, salicyluric acid, and *o*-methoxybenzoic acid occurred when hydrogen chloride gas was bubbled through methanolic solutions of these compounds. The retention times of these esters were 17.3, 17.4, and 41.4 min, respectively. The methyl ester of salicylic acid was not formed under these conditions.

However, the absence of interference peaks other than the peak corresponding to methyl salicylurate and the lack of change of the gentisic acid and salicylic acid standards during the ethereal extraction of standards in urine or water indicate that esterification of gentisic acid and *o*-methoxybenzoic acid did not occur.

It is obvious from the chromatograms in which the formation of methyl salicylurate was not inhibited (Figs. 1*b* and 1*c*) that an underestimation of salicyluric acid and an overestimation of salicylic acid are possible since large amounts of methyl salicylurate can appear as a single peak of salicylic acid.

# Direct Linear Plotting Method for Estimation of Pharmacokinetic Parameters

**Keyphrases** □ Pharmacokinetics—direct linear plotting method of parameter estimation □ Direct linear plotting method—estimation of pharmacokinetic parameters

*To the Editor:*

Recently, a method was described (1) for estimating the parameters of a single-compartment linear pharmacokinetic model following intravenous bolus dose administration. This method is based on the following relationship:

$$\ln C = \ln C_0 - Kt \qquad \text{(Eq. 1)}$$

where $C_t$ is the concentration at some time, $t$, after bolus administration of a drug that results in an initial concentration of $C_0$ and $K$ is the first-order elimination rate constant. This equation may be rearranged to yield:

$$\ln C_0 = \ln C + Kt \qquad \text{(Eq. 2)}$$

For each $C$, $t$ data point, a straight line could be generated. The equation is of the general form:

$$Y = b + XM \qquad \text{(Eq. 3)}$$

where $Y$ is $\ln C_0$, $b$ is $\ln C$, $X$ is $K$, and $M$ is $t$. By using a pair of data values ($C_1$, $t_1$ and $C_2$, $t_2$), two such lines can be generated. The $X$-axis coordinate of the point of intersection of these lines provides an estimate for the $K$ parameter ($K_i$), and the $Y$-axis coordinate of this point of intersection provides an estimate of $\ln C_0$ ($\ln C_{0i}$). Thus, $K_i$ can be calculated according to:

$$K_i = \frac{\ln C_2 - \ln C_1}{t_1 - t_2} \qquad \text{(Eq. 4)}$$

and $C_{0i}$ is calculated by substituting $K_i$ into Eq. 2 and using values for either data point ($C_1$, $t_1$ or $C_2$, $t_2$), *e.g.*:

$$\ln C_{0i} = t_1 K_i + \ln C_1 \qquad \text{(Eq. 5)}$$

When more than two sets of data are available, the $K_i$ and $\ln C_{0i}$ values must be calculated for all possible combinations of data pairs. The median of all calculated $K_i$ values provides the best estimate of $K$, and the median of all calculated $\ln C_{0i}$ values provides the best estimate of $\ln C_0$. The selection of median values minimizes the effect of outliers on the parameter estimate; *i.e.*, an estimate that differed greatly from the true parameter would markedly affect the mean of all estimates but would have no greater effect on the median than would an estimate that was only slightly different than the true parameter value. This series of calculations and comparisons is readily performed by the microcomputer.

It is not the purpose of this communication to justify the use of the direct linear plotting (DLP) method of parameter estimation. Previous findings (1) indicate that this method is superior to standard nonlinear regression (with and without weighting correction) when the assumption of equal variance for all experimental data points is violated; *i.e.*, when outliers are present. However, in the absence of outliers, simple unweighted nonlinear regression performs best. Non-normal distribution of error might be expected when analytical results are periodically affected by a large magnitude. For example, a micropipet that periodically dispenses only 30–50% of the labeled volume would result in a non-normal distribution of errors. In this situation, parameter estimation using the DLP method would be favored.

**Table I—Pharmacokinetic Parameter Estimates**

| Parameter | Actual Value | Regression Estimate | Regression Percent Error | DLP Estimate | DLP Percent Error |
|---|---|---|---|---|---|
| $A$ | 50 | 81.4 | 62.8 | 56.9 | 13.8 |
| $\alpha$ | 0.8 | 1.05 | 31.2 | 0.85 | 6.2 |
| $B$ | 10 | 10.12 | 1.2 | 8.9 | −11.0 |
| $\beta$ | 0.08 | 0.078 | −2.5 | 0.073 | −8.7 |

This communication describes a program written for the microcomputer[1], using BASIC language, which facilitates the application of the DLP method of parameter estimation. In addition, the program allows for sequential parameter estimates (stripping). This program allows extension of the DLP method to polyexponential equations. As output, the program provides standard exponential (unweighted) regression values for $C_0$ and the rate constant $K$, the correlation coefficient, and estimated values for all observed concentration data. The program then provides $K_i$ and $C_{0i}$ values for all intersections already described and provides the numbers of intersection values that are

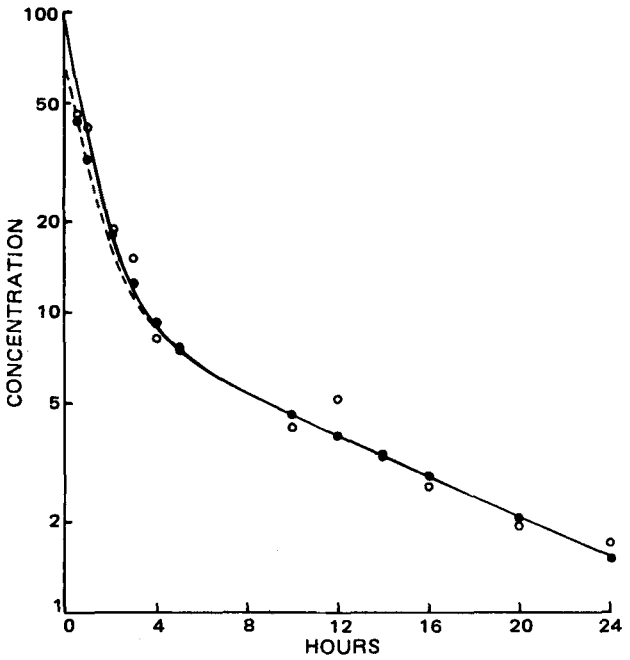

**Figure 1**—*Simulated concentration* versus *time data without error (●) and including error (○). The solid line is the best fit line obtained by stepwise unweighted nonlinear regression analysis. The broken line is the best fit line obtained by stepwise application of the DLP method.*

less than and greater than the given value. Thus, the median parameters are selected by the user. Once selected, these intersection values are used to calculate predicted concentration values for each observed value.

The performance of the DLP program is shown in the following example. Concentrations expected at time 0.5, 1, 1.5, 2.0, 3, 4, 5, 10, 12, 14, 16, 20, and 24 hr were simulated for the biexponential equation:

$$C_t = 50e^{-0.8t} + 10e^{-0.08t} \quad \text{(Eq. 6)}$$

Error with a coefficient of variation of either 5 or 20% was randomly assigned to the simulated concentrations such that four of the 12 observations were affected by the larger error. The results are shown in Fig. 1. The program was used to strip the curve. Concentrations observed between 10 and 24 hr were used for the $\beta$-phase, and those between 0.5 and 5 hr were used for the $\alpha$-phase. The results of parameter estimation using sequential regression (stripping) and the DLP method are shown in Table I. In this example, DLP produced better estimates of $A$ and $\alpha$ (13.8 and 6.2% error) than did sequential regression analysis (62.8 and 31.2% error). Estimates of $B$ and $\beta$ were somewhat better using regression (1.2 and −2.5% error) than with the DLP method (13.8 and 6.2% error). The large errors made by regression analysis in estimating $A$ and $\alpha$ indicate that DLP estimates for the entire curve were superior.

The determination of the importance of the DLP method of parameter estimation in pharmacokinetics will require further experimentation. It is hoped that the described program will facilitate this process.

## REVIEWS

**Introduction to Pharmaceutical Dosage Forms.** By HOWARD C. ANSEL. Lea & Febiger, Washington Square, Philadelphia, PA 19106. 1981. 408 pp. 18.5 × 26 cm.

The format and presentation of this third edition are the same as in the previous one, but the material has been revised to the current official compendia. The book is intended "to introduce the beginning pharmacy students to medicinal and pharmaceutic substances, the methods of their incorporation into pharmaceutical dosage forms, and the utilization of these forms in patient care."

The discussions on heritage, terminology, code of ethics, regulations, and drug substances should satisfactorily orient beginning students in their first professional course in pharmacy. The appendix defines drug categories and discusses measurements, and tables of official preparations are given. Pharmaceutical products are logically treated from the viewpoint of administration route, and the classes of pharmaceutical preparations also are discussed. Numerous photographs illustrate equipment, processing, and packaging.

However, the presentation of dosage form design in terms of biopharmacy, formulation, and practice is inadequate. Whether the curriculum of a college is arranged to present a preparations–physical pharmacy sequence or a technology series of courses, the scope of this text restricts its use to an orientation course because of its superficial presentation of theory and pharmacy principles and limited discussion of techniques and manufacturing principles.

**Pharmaceutical Calculations,** 2nd Ed. By JOEL L. ZATZ. John Wiley & Sons, 605 Third Ave., New York, NY 10016. 1981. 388 pp. 13.3 × 25 cm. Price $17.50.

Pharmaceutical calculations continues to be one of the most frustrating subjects to teach in any pharmacy curriculum. The complete accuracy required in answering many problems, the mixing of different metrology systems, the frequent use of conversions, and the simultaneous introduction of pharmaceutical terminology confound many students. This ongoing dilemma has resulted in pharmaceutical calculations being taught and evaluated in a variety of ways at different schools of pharmacy. No single textbook can solve the distress frequently associated with calculations, but Joel Zatz's second edition goes a long way to making it all more bearable.

The book is longer than the first edition by 77 pages because it now has an appendix containing instruction and problems on temperature conversion, alcohol proof strength, and sodium chloride equivalents in addition to the inclusion of alligation and a greatly expanded section on milliequivalents.

The cover of the book describes the structure of the text succinctly: "The progression of topics within each chapter and in the overall structure of the book constitutes a programmed format that permits self-paced learning and builds upon previously learned concepts to reinforce understanding. Students participate actively and are able to concentrate on calculations that are most difficult for them. Emphasis is on practical approaches to meeting accuracy requirements in filling prescriptions and manufacturing."

This book is designed to fit into the usual first general pharmacy course, to serve as a text in a calculations course or as a self-instruction text apart from the formal classroom, or to be an aid for review, and it does all of these well.

It is difficult to find much about the text to criticize. About all one can say is that it does not contain a section on commercial arithmetic which some instructors prefer to include in their course, and there are a few prescription problems for oral preparations containing amaranth (Red No. 2) which was banned in time to have been deleted from the new edition.

In conclusion, while working examples from the text, the reviewer finds it refreshing to solve for "j" (for Joel?) rather than to always hunt for the usual unknown "x."

# Solid-State Decomposition of Alkoxyfuroic Acids

**J. T. CARSTENSEN *x and ROHIT KOTHARI ‡**

Received November 10, 1980, from the **School of Pharmacy, University of Wisconsin, Madison, WI 53706*, and ‡*Ryker Laboratories, St. Paul, MN 55100.* Accepted for publication March 6, 1981.

**Abstract** □ A series of alkoxyfuroic acids with alkyl lengths of $n$ = 8–18 was synthesized, and the solid-state decomposition was studied. Bawn kinetics were adhered to, and the solid and liquid decomposition rate constants were established; they followed an Arrhenius relationship well, with energy of activations and preexponential factors being a function of the chain length. There was a break in this correlation between $n$ = 14 and $n$ = 16. The liquefaction points were of the expected correlation with inverse temperature. The isokinetic temperature ($T_i$) fell fairly well on the line demonstrated for other compound series.

**Keyphrases** □ Solid-state decomposition—alkoxyfuroic acids with alkyl chain lengths of $n$ = 8–18 □ Alkoxyfuroic acids—Arrhenius relationship, energy of activation and preexponential factors as a function of chain length □ Bawn kinetics—solid and liquid decomposition rate constants of alkoxyfuroic acids

Chemical decomposition of pure solids has been discussed sporadically in the literature, the principal publications being those of Prout and Tompkins (1) and Bawn (2). The reactions are usually dictated to a great extent by physical (*e.g.*, active site propagation) rather than chemical steps, resulting in high activation energies (300–400 kJ) when the reaction is one where:

$$\text{solid} \rightarrow \text{solid} + \text{gas}$$

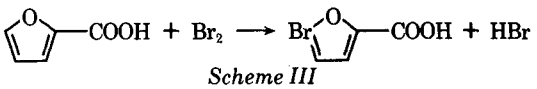
*Scheme I*

This reaction (Scheme I) was essentially covered by Prout and Tompkins, whereas the reaction (Scheme II) treated by Bawn is:

$$\text{solid} \rightarrow \text{liquid} + \text{gas}$$

*Scheme II*

Several reactions of this latter type were reported in the pharmaceutical literature (3–6). In these reactions (Scheme II), it was shown that the part occurring in the solid is not necessarily dictated by active site propagation and that chemical factors are much more prevalent (5) than when Scheme I applies. Chemical substituent effects have, for instance, been demonstrated (3–5).



*Scheme III*

The work described in this report deals with chemical substituent (chain length) effects in a series of alkyloxyfuroic acids. One of these acids (7) was previously shown to be a hypolipidemic agent.

## EXPERIMENTAL

**Synthesis**—The compounds studied were 5-alkyloxy-2-furoic acids, *i.e.*, RCOOH, where R = $C_nH_{2n+1}$–O–($C_4H_2O$)– and where $n$ = 8, 10, 12, 14, 16, and 18. The syntheses were carried out by the method described by Parker *et al.* (7) with a few modifications. Furoic acid was first brominated to give 5-bromofuroic acid, using carbon tetrachloride as a solvent (Scheme III).

A 2-liter round-bottom flask, fitted with a reflux condenser, drying tube, and magnetic stirrer, was charged with 250 g of furoic acid and 1.2 liters of carbon tetrachloride. The mixture was stirred until all of the furoic acid was dissolved. The solution was heated to 40°, and then 500 g of bromine was added slowly through a funnel directly fitted to the flask. The reaction mixture was then refluxed on a water bath for 5 hr. At the end of the refluxing period, carbon tetrachloride was distilled off.

The product of the reaction was dissolved in boiling water and filtered hot. Upon cooling, the bromosubstituted acid precipitated. It was further purified by recrystallization from hot water. To eliminate any dibromofuroic acid that might have formed, the barium salt was prepared as follows. For each gram of the product, 25 cm$^3$ of water was added and made strongly alkaline with ammonium hydroxide; 1 g of barium chloride was added with some activated charcoal. After 15 min, the solution was filtered. The filtrate was acidified with hydrochloric acid; the 5-bromofuroic acid, which precipitated out, was recrystallized from hot water. The yield was 60%, mp 186°, in agreement with the melting point obtained by Whittaker (8).

The 5-alkyloxy-2-furoic acid was next synthesized from the bromofuroic acid in two stages as shown in Schemes IV and V.

A reaction flask was charged with 1 liter of toluene, and ~0.1 liter of the solvent was distilled off to dry. The toluene remaining was cooled to 40° under nitrogen, and 0.33 mole of $n$-alkanol and 0.45 mole of sodium hydride (as a 50% dispersion in oil) were added. The mixture was refluxed

[a] $n$ = alkyl length. [b] Densities done by pycnometry. In the case of $n$ = 18, the material wets very poorly in solvents in which it is poorly soluble and density data are not available. [c] Decomposition pertubates thermogram too much in these cases to draw conclusions. [d] 5-Bromofuroic acid.

for 3 hr and then cooled under nitrogen to 40–45°. A suspension of 0.2 mole of 5-bromofuroic acid in 0.2 liter of dry toluene was added rapidly. The reaction mixture was held at 60° for ~1 hr to ensure that the balance of the sodium hydride had reacted to form the sodium salt of the acid. It was then heated at reflux temperature for 16 hr.

The mixture was cooled to 30°, and 1.2 liters of ether was added, followed by 0.3 liter of 15% acetic acid. Stirring was continued for ~30 min. The organic portion was separated with the help of a separator and then was washed three times with either distilled water or saturated sodium chloride solution. The solution was dried with calcium chloride, and then the drying agent was removed by vacuum filtration. Most of the ether was stripped off with the help of a flask-evaporator and a hot water bath held at 45°. The concentrated solution was chilled in a freezer for 12–15 hr.

The precipitated solid was filtered off and washed with cold toluene. The crude product was dissolved in hot 2-butanone or acetone, and then activated charcoal was added. The mixture was stirred for a few minutes and filtered while hot. This solution was cooled gradually to 5°, and the recrystallized product was filtered off after a few hours. Recrystallization was carried out at least three times to ensure purity. The compounds were identified with the help of NMR and mass spectra and, where possible, differential scanning calorimetry. Melting points were determined and are listed in Table I.

**Kinetic Studies**—Kinetic studies were carried out by preparing a sample *in vacuo* in a sample bulb with an attached mercury manometer such as was described previously (3, 6). The whole assembly was placed in a tall thermostatically controlled bath with either water or mineral oil as the medium; temperature control was ±0.2°. The amount of gas pressure at any time can be deduced from a knowledge of the volume, mercury height, and density of mercury at the temperature in question and can then be converted to number of moles of gas produced.

Condensation characteristics and mass spectra of the gas confirmed it to be carbon dioxide. Since, in the manner described, the decomposition takes place in a system that is evacuated but that contains mercury vapor in the headspace, several control studies were done in break-seal tubes (3) to ascertain that the mercury vapor did not affect reaction rates.

**Vapor Pressure Studies**—Since the possibility exists that the decomposition of a solid at constant volume occurs in the vapor phase, the vapor pressure of the various solids was determined. The Knudsen effusion method was used (9–12). In this method, the rate of vapor loss through a small orifice is measured gravimetrically under conditions of free molecular flow; the vapor pressure is calculated directly from the proportionality between the rate of mass loss and the vapor pressure.

The Knudsen cells used were aluminum crucibles with a lid placed on the top in conjunction with an "O" ring. A small orifice (0.5-mm diameter) was drilled in the lid. The mean value of the orifice diameter was determined microscopically. The fidelity of the method was checked by determining vapor pressures of a compound (benzoic acid) with well-established vapor pressure values (13). The cells were placed on the pan of an electrobalance in a vacuum chamber such as was described previously (14).

To determine the decomposition rate constant in the vapor phase, a 2-liter bulb was equipped with a break-seal tube. The amount of alkoxyfuroic acid necessary to (just) saturate the bulb at 95° was calculated from the vapor pressure *versus* temperature curve. This amount was then added to the bulb as a methanol solution. The solvent was then evaporated off (on the vacuum rack) at room temperature, and the nonbreak-seal end was fused off. The bulb was placed at 95°, and the amount of carbon dioxide evolved after 1 week was determined, in this case by means of a McLeod gauge with a 1:10,000 ratio of compression capacity.

## RESULTS AND DISCUSSION

The general pattern is that the solid decomposes by some means and that a liquid decomposition product is formed. There are three main feasible models that could account for this reaction.

In Model A, the solid (RCOOH) evaporates and decomposes in the vapor phase to RH and $CO_2$, and RH condenses. Decomposition in the solid state is negligible.

In Model B, the solid (RCOOH) decomposes in the solid state and, in addition to carbon dioxide, forms liquid RH in which RCOOH is insoluble. [Prout–Tompkins kinetics (1)].

In Model C, the solid (RCOOH) decomposes in the solid state and, in addition to carbon dioxide, forms liquid RH in which RCOOH is soluble [Bawn kinetics (2)].

[a] $n$ = alkyl length. [b] Number of points used. In the case of $n$ = 16, only the first 3 points were used since the point at 85° appears to be a (slight) outlier.

There is also the possibility of Model B or C in combination with Model A.

For Model A, Scheme VI applies:

$$\text{RCOOH(solid)} \rightarrow \text{RCOOH(vapor)} \rightarrow \text{RH} + \text{CO}_2$$

*Scheme VI*

If $A$ denotes the amount of intact RCOOH, then by denoting its vapor pressure as $P$:

$$dA/dt = -k'P \qquad \text{(Eq. 1)}$$

Since $P$ is simply a function of temperature, the reaction, carried out isothermally, would be zero order, with a rate constant of:

$$k_0 = k'P \qquad \text{(Eq. 2}a\text{)}$$

A typical decomposition curve is shown in Fig. 1. It is obvious from visual inspection that the decomposition is not zero order. Furthermore, the decomposition rate constants in the gas phase were found in the worst case ($n$ = 8) to be of the order of $3 \times 10^{-3}$ hr$^{-1}$ at 95°. Vapor pressure curves are shown in Fig. 2. For $n$ = 8, the pressure at 95° was $89 \times 10^{-3}$ Pa ($\sim 9 \times 10^{-7}$ atm). The headspace ($V$) of the bulb/manometer was ~100 cm$^3$, so that ($N$ denoting moles):

$$dN/dt = (V/RT)\, dP/dt = (V/RT)k'P \qquad \text{(Eq. 2}b\text{)}$$

which, with the previous figures, amounts to $0.9 \times 10^{-11}$ mole/hr or (the molecular weight for $n$ = 8 being 228) $2 \times 10^{-6}$ mg/100 hr. Hence, Model A can be ruled out.

During the decomposition as time progresses, more and more liquid is present and less and less solid exists. At a particular point, no more solid is present and the entire sample is liquid. If Model B is correct, then this point should correspond to 100% decomposition. But this is not the case; this point occurs, on the average, at 75% decomposition. Hence, the parent compound (RCOOH) has a finite solubility, $S$ moles/mole RH, and Model C seems to be a more feasible model. The mathematical consequences of the model are as follows (6). If $X$ denotes mole fraction decomposed, if $k_s$ is the decomposition rate constant of RCOOH in the solid state, and if $k_l$ is the decomposition rate constant of RCOOH in solution in RH, then:

$$\ln(1 + AX) = \alpha t \qquad \text{(Eq. 3)}$$

where $A$ is an adjustable parameter and $t$ is time. The value of $A$ is given by:

$$A = \alpha/k_s \qquad \text{(Eq. 4)}$$

and:

$$\alpha = k_l S - k_s S - k_s \qquad \text{(Eq. 5)}$$

$S$ can be determined from the time, $t_s$, at which the system becomes completely liquid. If the amount decomposed at this point is $X_s$, then the amount not decomposed is $1 - X_s$ and, hence, the solubility is

$$S = (1 - X_s)/X_s \text{ moles/mole} \qquad \text{(Eq. 6)}$$

Beyond time $t_s$, the system is a solution and should adhere to first-order kinetics, *i.e.*:

$$\ln[(1 - X)/(1 - X_s)] = -k(t - t_s) \qquad \text{(Eq. 7)}$$

For Model C to apply, it is necessary that: (*a*) the data below time $t_s$ can be linearized *via* Eq. 3; (*b*) the data above time $t_s$ can be linearized by suitable liquid kinetic schemes; and (*c*) the value of $k_l$ found from this latter scheme when inserted in Eq. 5, together with the solubility $S = (1 - X_s)/X_s$ and $k_s$ from Eq. 4, gives a value of $\alpha$ in agreement with the value of $\alpha$ from Eq. 3. If the above statements hold, then a double check of the model is established for its correctness. Of course, a model is never

[a] $n$ = alkyl lengths.

"proven"; it is simply established that the data generated do not conflict with it. Therefore, it is prudent to check the adherance in as many ways as possible to guarantee that the model is self-consistent.

It is obvious that the values of $t_s$ and $X_s$ are important, and some elaboration on this point will be made prior to testing the remaining points regarding Model C. If one considers a eutectic diagram (*e.g.*, Fig. 3), then it is obvious that at a given temperature, $T_1$, the point $(X_s, T_1)$ is part of the melting-point curve, provided the two compounds, RCOOH and RH, form a simple melting-point diagram to the left of the eutectic point without solid solution formation.

The left eutectic diagrams, constructed from $T$ *versus* $X_s$ data, are given in Table II. The heat of fusion of RCOOH should be obtainable from these curves since:

$$\ln(1 - X_s) = \frac{(-\Delta H_f)(T_0 - T_s)}{RT_0T_s}$$

$$= (-\Delta H_f/R)[(1/T_s) - (1/T_0)] \quad \text{(Eq. 8)}$$

where $T_0$ is the melting point of RCOOH and $T$ is the temperature corresponding to the particular $X_s$ in consideration; $R$ is the gas constant (8.3143 J mole$^{-1}$ degree$^{-1}$). Examples of data plotted according to Eq. 8 are shown in Fig. 4. Least-squares fit parameters are shown on the bottom of Table II. The $\Delta H_f$ value is obtained by multiplying the slope by −8.31, and $T_0$ is minus the slope divided by the intercept. It should correspond to the melting point and, except for $n$ = 8, this correlation is reasonably good.

The $\Delta H_f$ values obtained in this fashion are shown in Table I to enable comparison with data to be developed later. When differential thermal analysis (DTA) is applied, a $\Delta H$ value is obtained that is the heat of fusion for stable compounds. It is derived from the area under the endotherm. For compounds that decompose below their melting point, however, the $\Delta H$ value obtained from this area is the difference between the heat absorbed ($\Delta H_f$) due to melting and the heat evolved ($q$) due to the reaction, *i.e.*:

$$\Delta H_{DTA} = \Delta H_f - q \quad \text{(Eq. 9)}$$

Therefore, the enthalpy of reaction ($-q$) can be deduced, and values of $\Delta H_{DTA}$ and $q$ are listed in Table I. There were cases ($n$ = 10 and $n$ = 16) where the reaction taking place concurrent with or before melting made the thermograms so poorly reproducible that they are not reported here. The values for $q$ should be viewed in this light as well. For $n$ = 8, the melting point obtained from the kinetic data (Eq. 8) differs from that obtained by differential thermal analysis by several degrees. However, the latter is questionable rather than the former. The values of $\Delta H_f$ and $q$ are not germane to the further development; they are included here simply for completeness and to indicate that ancillary values obtained in the study did not conflict with the proposed model.

As an example of the fits obtained *via* Eq. 3, the data shown by direct plotting in Fig. 1 were transposed *via* Eq. 3 and are shown in Fig. 5. The fit is good. Least-squares fit parameters obtained by iteration of Model A for all of the data are shown in Table III in the form:

$$\ln(1 + Ax) = Ct + D \quad \text{(Eq. 10)}$$

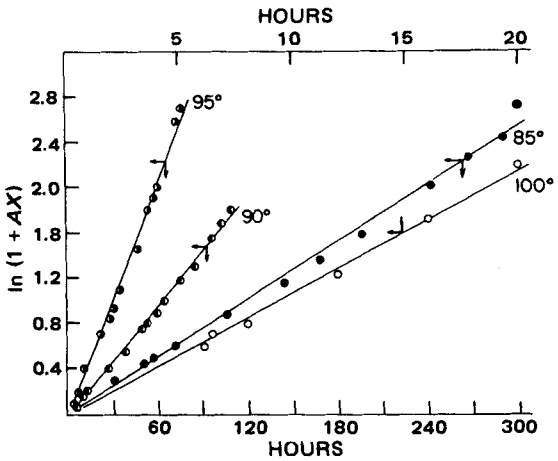

**Figure 5**—*Data from Fig. 1 plotted according to Eq. 3. Key:* ●, *85°;* ◐, *90°;* ◑, *95°; and* ○, *100°. Note dual scales.*

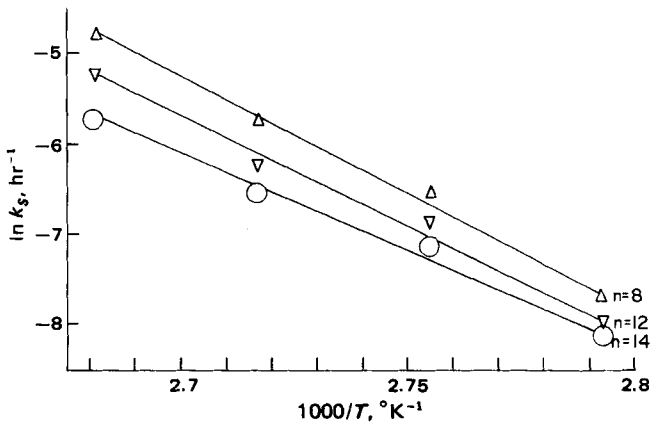

**Figure 6**—*Arrhenius plot of* $k_s$ *(hr*$^{-1}$*). For graphical clarity, only* n = *8 (*△*),* n = *12 (*▽*), and* n = *14 (*○*) are shown.*

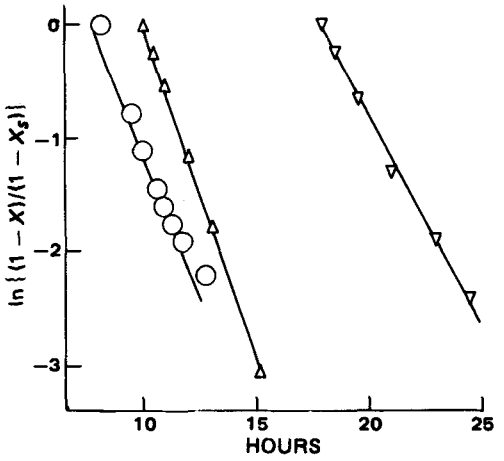

**Figure 7**—*First-order kinetics after the point where complete liquefaction has occurred. Key:* ▽, n = *10;* ○, n = *14; and* △, n = *16 (all at 100°).*

It is noted from the table that the $D$ values are small (<0.0001) at the same time as $R$, the correlation coefficient, is high (never <0.99). Hence, $C$ becomes synonymous with $\alpha$ in Eq. 3, allowing calculation of $k_s$ *via* Eq. 4. The values of $k_s$ obtained in this fashion are shown in Table III.

The temperature dependence of the $k_s$ values is, according to the Arrhenius equation:

$$\ln k_s = -(E_a/R)(1/T) + \ln Z \qquad \text{(Eq. 11)}$$

where $E_a$ is the activation energy and $Z$ is a preexponential factor. This is exemplified in Fig. 6 (linearity is obvious upon visual inspection). Least-squares fit parameters are shown in Table IV, and the high correlation coefficients are indicative of the good fits.

As mentioned, the data in Table III ($A = \alpha/k_s$ and $C = \alpha$) in conjunction with the values from Table II [$S = (1 - X_s)/X_s$] will allow calculation of the decomposition rate in solution, $k_l$ hr$^{-1}$. The parts of the curves beyond $t_s$ can be used directly to calculate the first-order decomposition rate of RCOOH in solution in RH. An example is shown in Fig. 7; the linearity is graphically obvious, supporting the assumption of first-order kinetics in solution, *i.e.*, confirming Eq. 7. The reproducibility is fair at best (±10% for the rate constants). The rate constants obtained in this fashion are denoted simply $k$ (Table V). The correlation coefficients confirm the visually observed linearity.

If the proposed model is correct, then $k$ and $k_l$ should be identical. They were plotted in linear fashion (Fig. 8); again, the linearity with a zero intercept is implied by:

$$k = A_1 k + B_1 \qquad \text{(Eq. 12)}$$

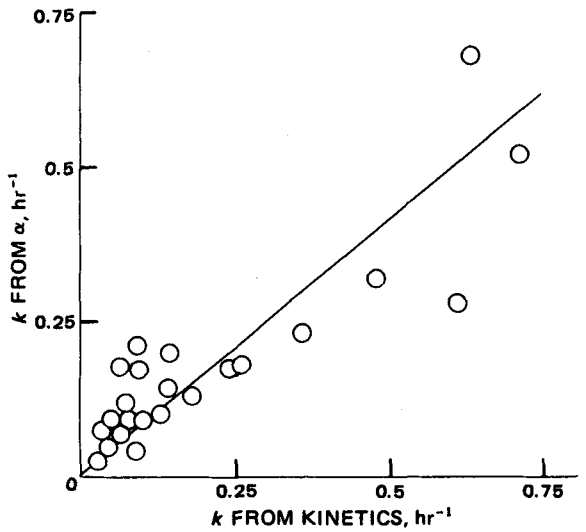

**Figure 8**—*Solution decomposition rate constants* ($k_l$) *derived from* $\alpha$ *as a function of solution decomposition rate constants* ($k$) *found experimentally.*

where $A_1$ should be unity and $B_1$ should be zero. The least-squares fit values in Fig. 8 are $A_1 = 0.83 \pm 0.22$ and $B_1 = 0.17 \pm 0.25$, so the figure does not contradict the proposed model. The overall correlation coefficient is 0.975.

The $k_l$ or $k$ values should be treatable by the Arrhenius equation (Fig. 9). The least-squares fit parameters for these relations are shown in Table V.

Pothisiri and Carstensen (4) suggested that the temperature at which $k_l = k_s$ ($T_i$) is related to the melting point ($T_m$) in log–log fashion. Data from the present study are pooled with data from Ref. 4, in Fig. 10, and the correlation seems to hold with the alkoxyfuroic acids as well as previously reported compounds. Since the furoic acids have melting temperatures close to one another, they have been averaged, as has $T_i$ (Fig. 10). With the small number of compounds at present, this is, at best, a rank-order correlation.

An attempt was made to correlate the kinetic parameters with substituent properties (chain length) in Fig. 11. Both $E_a$ and $Z$ decreased

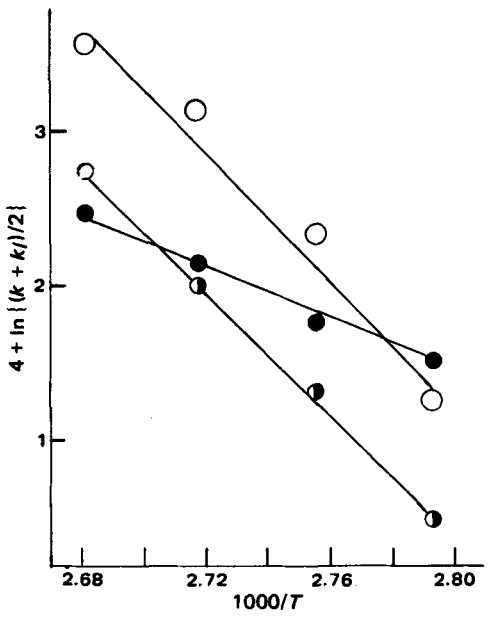

**Figure 9**—*Logarithm of the solution decomposition rate constants of RCOOH in solution in RH plotted as a function of 1000/T (°K$^{-1}$). Key:* ●, n = *8;* ◑, n = *10; and* ○, n = *14. The remainder are left out for graphical clarity.*

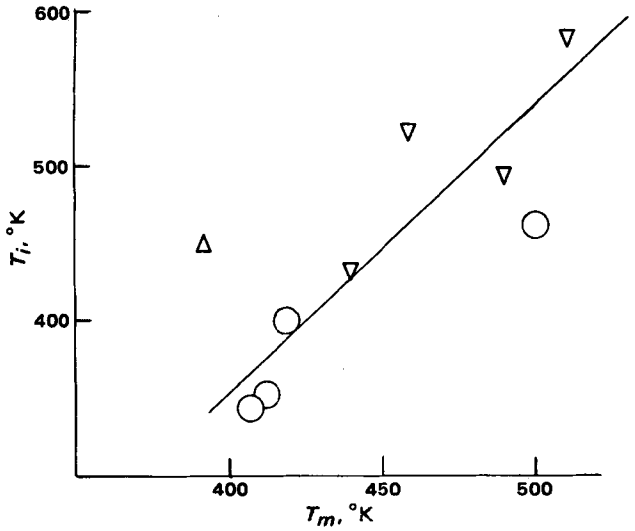

**Figure 10**—*Data from Refs. 3 (∇) and 4 (○) plotted together with the average* $T_m$ *and* $T_i$ *values (△) from this study. (Average* $T_m$ *= 394 ± 4 °K and, average* $T_i$ *= 450 ± 50 °K.)*

with increasing chain length up to $n$ = 14, after which there was an upward break in the curve. This discontinuity did not exist in other properties of the series (vapor pressures, densities, and enthalpies of fusion and reaction). No explanation is offered for this break at present.

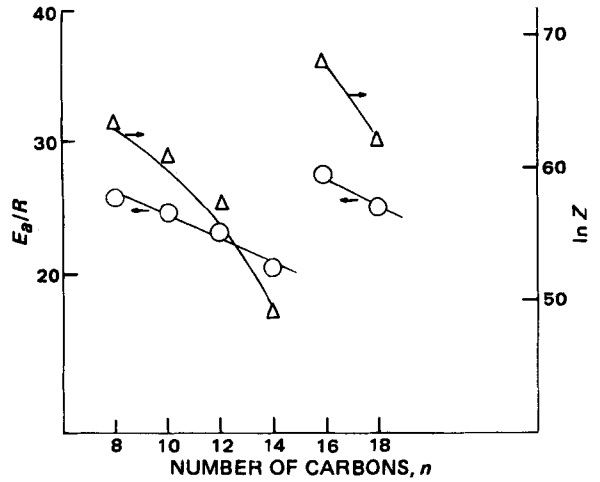

**Figure 11**—$E_a/R$ *and ln Z from Eq. 11 (Table IV) plotted* versus n. *The values for* n = *14 are slightly (4%) lower than previously reported (6) due to increased precision in this study (multiple runs).*

The effect of particle size was estimated by micronizing a sample ($n$ = 14). At 85°, this sample had a value of $k_s = 3.3 \times 10^{-4}$/hr as opposed to $3.3 \times 10^{-4}$/hr for a nonmicronized sample; therefore the effect of particle size was not pronounced. All samples tested were not milled, *i.e.*, were in the recrystallized state, and had surface areas, measured by nitrogen adsorption, of ~1 $m^2/g$.

A final note on reproducibility is in order. Data were duplicated with parameter values obtained from 10 sets that differed by no more than 5%. The effect of the use of a mercury manometer as contrasted to the use of break-seal tubes was also tested (in five cases) with duplication within the previously mentioned error.

Therefore, it is fairly conclusive that the alkoxyfuroic acids decompose as shown in Scheme II, and solid and liquid decomposition rate constants have been established. The liquefaction characteristics are in accordance with what would be expected from melting-point diagrams with a reasonable correlation. Energy of activation is a function of chain length, as is the preexponential factor. There is a break in this correlation curve at $n$ = 14/16. The isokinetic temperature ($T_i$) falls fairly well on the correlation line established for other compounds.

# Mechanism of Interaction between Polyols and Aluminum Hydroxide Gel

**DHIREN N. SHAH *, JOE L. WHITE ‡, and STANLEY L. HEM *x**

Received November 21, 1980, from the **Department of Industrial and Physical Pharmacy and the* ‡*Department of Agronomy, Purdue University, West Lafayette, IN 47907.* Accepted for publication March 6, 1981.

**Abstract** □ IR spectroscopy and changes in the rate of acid neutralization were used to study the interaction between various polyols and aluminum hydroxide. Hydrogen bonding is responsible for this interaction, although structural requirements limit the polyols that interact with aluminum hydroxide. Mannitol and sorbitol, both linear polyols, interacted with sulfate-containing aluminum hydroxide gel and aluminum hydroxycarbonate gel, while inositol, a cyclic polyol, did not interact. The adsorbed polyol has the favorable effect of inhibiting the polymerization reaction that occurs on aging and the negative effect of reducing the rate of acid neutralization. Thus, the specific polyol and concentration must be carefully selected to maximize the desired effect of stabilizing the gel structure. The presence of mannitol in the reaction medium during precipitation did not significantly enhance gel structure stability, probably because the mannitol was desorbed during the washing process as a consequence of the weak adsorption forces.

**Keyphrases** □ Aluminum hydroxide—mechanism of interaction with polyols □ Polyols—mechanism of interaction with aluminum hydroxide □ Spectroscopy, IR—mechanism of interaction between polyols and aluminum hydroxide gel □ Structure stability—mechanism of interaction between polyols and aluminum hydroxide gel

The use of a polyol such as sorbitol to improve the stability of aluminum hydroxide antacid formulations, a widely followed practice, has been the object of numerous studies and patents (1–8). Although these reports demonstrated the beneficial effects of polyols, the molecular basis of the interaction has not been described. This study examined the mechanism of interaction between polyols and aluminum hydroxide gel and the factors that affect the optimum use of polyols in antacid formulations.

## EXPERIMENTAL

Aluminum hydroxycarbonate gel was obtained commercially. A sulfate-containing aluminum hydroxide gel containing 3.4% equivalent aluminum oxide (0.33 *M*) was precipitated by the reaction of aluminum sulfate and strong ammonia solution NF (NF XV) (9). To determine the effect of the presence of mannitol at the time of precipitation, a series of precipitations of a sulfate-containing aluminum hydroxide gel containing 1.5% equivalent aluminum oxide (0.147 *M*) was carried out as described but with either 0.22 or 0.588 *M* mannitol dissolved in the aluminum sulfate solution prior to precipitation. The sulfate-containing aluminum hydroxide gel was divided into two portions. One portion was washed in the usual manner with three volumes of deionized water, and the second portion was not washed. The lower concentration of equivalent aluminum oxide was required due to the limited solubility of mannitol (0.99 *M* in water) (10).

The ease of mannitol desorption from the sulfate-containing aluminum hydroxide gel was determined by preparing a suspension containing 0.22 *M* mannitol and 0.147 *M* equivalent aluminum oxide. The mixture was centrifuged at 15,000 rpm (27,000×*g*) for 30 min. The clear supernate was decanted, weighed, and assayed for mannitol by a microcolorimetric method (11). The solid phase was resuspended in double-distilled water to the original volume, and the procedure was repeated five times.

Sorbitol, mannitol, and inositol were selected for the IR study because each is a six-carbon polyol containing one hydroxide per carbon. Sorbitol and mannitol are linear, while inositol is cyclic. The deuteration procedure of Hamill and Freudenberg (12) was adopted since the polyols are water soluble, nonvolatile, and stable in aqueous solution up to 100°. Deuterium oxide (30 g) was added to 5 g of polyol, and the solution was maintained at 70° for 72 hr followed by lyophilization[1]. The preparation of deuterated sorbitol was not successful since a glass was always obtained during lyophilization (13). The IR spectra of the deuterated mannitol and deuterated inositol were compared to those of mannitol and inositol. The OH:OD frequency ratio was 1.35 for each hydroxyl band, which confirmed that deuteration had occurred (14).

The interaction between the deuterated polyols and aluminum hydroxycarbonate gel or sulfate-containing aluminum hydroxide gel was studied by preparing a suspension containing 0.50 *M* deuterated polyol and 0.33 *M* equivalent aluminum oxide. The suspensions were allowed to mix for 1 hr, and a sample was air dried. IR spectra were recorded[2] using potassium bromide pellets (1 mg of sample/300 mg of potassium bromide). The positions of the hydroxy and deuteroxy stretching bands were determined using an abscissa expansion of 5× with a wave number marker at every 10 $cm^{-1}$ and an ordinate expansion of either 1× or 10×.

The rate of acid neutralization of suspensions containing 0.50 *M* polyol and 0.33 *M* equivalent aluminum oxide was determined by pH-stat titration[3] at pH 3.0 and 25° (15) during aging at 40°. The effect of polyol concentration on the rate of acid neutralization was studied by determining the pH-stat titrigrams of a series of suspensions containing 0.098 *M* equivalent aluminum oxide and varying molar ratios of polyol. The lower concentration of equivalent aluminum oxide was necessary due to the low solubility of inositol (0.78 *M*) (10).

The soluble aluminum content of aluminum hydroxycarbonate gels containing various amounts of mannitol was determined by centrifugation at 15,000 rpm (27,000×*g*) for 30 min and measurement of the aluminum content of the supernate by atomic absorption spectroscopy[4] (16).

## RESULTS AND DISCUSSION

Amphoteric compounds such as aluminum hydroxide usually exhibit hydroxyl stretching frequencies at 3660–2900 $cm^{-1}$ (17). The hydroxyl stretching frequencies of polyols occur at 3450–3200 $cm^{-1}$ (18). An interaction between aluminum hydroxide and a polyol that involves the hydroxyls of either the aluminum hydroxide or the polyol would be difficult to study by IR spectroscopy because the hydroxyl stretching frequencies overlap. This problem is aggravated by the occurrence of hydroxyl stretching vibrations of adsorbed water in the same region. However, the interaction between deuterated polyols and aluminum hydroxide can be directly studied by IR spectroscopy since deuteroxy stretching frequencies of deuterated polyols occur between 2550 and 2370 $cm^{-1}$. Aluminum hydroxide does not exhibit any IR absorption bands in the 2600–2400-$cm^{-1}$ region. There appears to be no hydrogen–deuterium exchange between the deuterated polyols and the aluminum hydroxycarbonate gel at these experimental temperatures. Since the preparation of the potassium bromide pellets required air drying the sample, there is the question of whether the dehydration process changes the apparent nature of the interaction. The fact that no shift was observed for the inositol–aluminum hydroxide systems suggests that the shifts observed for mannitol were not an artifact.

Figure 1 shows that both the frequency and relative intensity of the deuteroxy stretching bands of deuterated mannitol are significantly altered by the aluminum hydroxycarbonate gel. The free deuteroxyl band of deuterated mannitol occurred at the highest frequency, *i.e.*, 2525 $cm^{-1}$, and the intermolecularly bonded deuteroxyl peaks occurred at the lower frequencies, *i.e.*, 2495, 2448, and 2415 $cm^{-1}$ (19, 20). Adsorption of deu-

terated mannitol by aluminum hydroxycarbonate gel as a consequence of hydrogen bonding would be expected to cause the free deuteroxyl band to shift to a lower frequency, as observed in Fig. 1. The band at 2525 $cm^{-1}$ shifted to 2508 $cm^{-1}$, which suggests weak hydrogen bonding. However, the bands arising from intermolecular hydrogen bonds would be expected to shift to higher frequencies when monolayer adsorption occurs. From Fig. 1, it appears that the major intermolecular vibration at 2448 $cm^{-1}$ shifted upward to 2465 $cm^{-1}$ and that the 2415 band shifted to appear as a shoulder in the 2430-$cm^{-1}$ region of the deuterated mannitol–aluminum hydroxycarbonate gel system. Thus, the complex changes observed in the IR spectrum of deuterated mannitol in the presence of aluminum hydroxycarbonate gel reflect the adsorption of deuterated mannitol onto the aluminum hydroxycarbonate surface.

A similar change in the IR spectrum of deuterated mannitol occurred in the presence of sulfate-containing aluminum hydroxide gel with the deuteroxy stretching bands appearing at 2516, 2476, 2450, and 2414 $cm^{-1}$ as a consequence of adsorption.

The carbonate stretching bands of aluminum hydroxycarbonate at 1521 and 1467 $cm^{-1}$ were not affected by the presence of deuterated mannitol, suggesting that the coordinated carbonate is not involved in

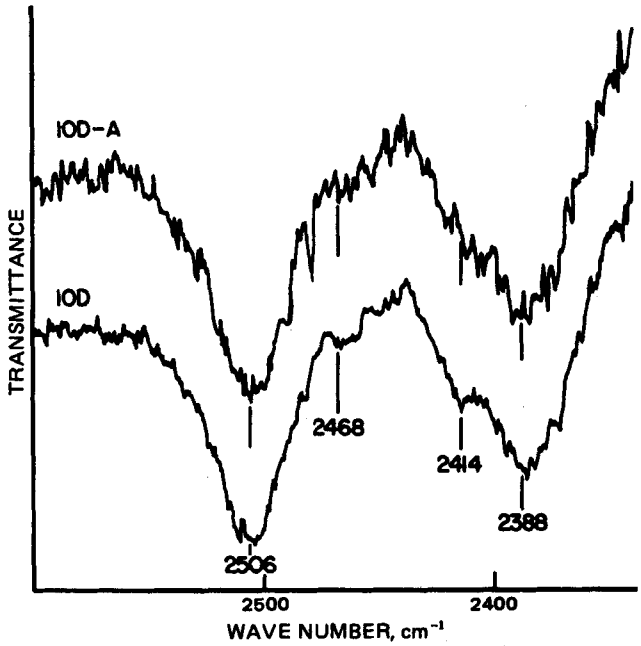

**Figure 2**—*Deuteroxy stretching bands of deuterated inositol (IOD) and deuterated inositol in the presence of aluminum hydroxycarbonate gel (IOD-A). Ordinate expansion is 10×.*

the interaction with mannitol. However, the sulfate stretching frequency of the sulfate-containing aluminum hydroxide gel shifted from 1130 to 1110 $cm^{-1}$ in the presence of deuterated mannitol. IR evidence indicates that carbonate is strongly coordinated to aluminum in aluminum hydroxycarbonate gel while sulfate is weakly coordinated to aluminum in sulfate-containing aluminum hydroxide gel (21). The apparent absence of interaction of deuterated mannitol with coordinated carbonate in aluminum hydroxycarbonate gel may be due to the strong coordination of carbonate to aluminum, which would not be substantially affected by hydrogen bonding with deuterated mannitol. The weaker sulfate–aluminum bond in sulfate-containing aluminum hydroxide gel is affected by hydrogen bonding with deuterated mannitol, and a 20 $cm^{-1}$-shift in the frequency of the sulfate bond was observed.

The hypothesis that the interaction between mannitol and aluminum hydroxide is due to hydrogen bonding is further supported by the observation that the soluble aluminum content of aluminum hydroxycarbonate gel was 0.3% and did not change when mannitol was added to the gel in a molar ratio of 0.5–4 *M* mannitol per equivalent aluminum oxide. Thus, the interaction between mannitol and aluminum hydroxycarbonate gel is not strong enough to solubilize aluminum.

The IR spectrum of deuterated inositol was not affected by the aluminum hydroxycarbonate gel (Fig. 2), thus indicating that no interaction occurs between inositol and aluminum hydroxide. However, the deuteroxy stretching frequencies of deuterated inositol (2506, 2468, 2414, and 2388 $cm^{-1}$) were all lower than those observed for deuterated mannitol (2525, 2495, 2448, and 2415 $cm^{-1}$). Thus, intermolecular association of inositol is expected to be greater than for mannitol.

IR evidence for the interaction of mannitol with aluminum hydroxide gel and the absence of an interaction with inositol is supported by the change in acid reactivity of mixtures of aluminum hydroxycarbonate gel and polyols during aging. The pH-stat titrigrams of the aluminum hydroxycarbonate gel (0.33 *M* equivalent aluminum oxide) and mixtures of the aluminum hydroxycarbonate gel containing 0.5 *M* mannitol, sorbitol, or inositol showed that all four samples reacted completely in ~60 min (Fig. 3), although the rate of acid neutralization was slightly slower in the mixtures containing sorbitol or mannitol. The pH-stat titrigrams of the aluminum hydroxycarbonate gel and the inositol-containing mixture were significantly affected by aging at 40° for 1 week. As seen in Fig. 3, ~20% of the aluminum hydroxycarbonate gel reacted very slowly at pH 3, suggesting that extensive polymerization of the aluminum hydroxy polymers had occurred (22). In contrast, the mixtures containing mannitol or sorbitol reacted completely after aging at 40° for 1 week, although the reaction rate decreased, requiring 90 min for complete neutralization. Thus, sorbitol and mannitol were effective in minimizing polymerization in aluminum hydroxycarbonate gel while inositol did not show any effect on the structural changes during aging.

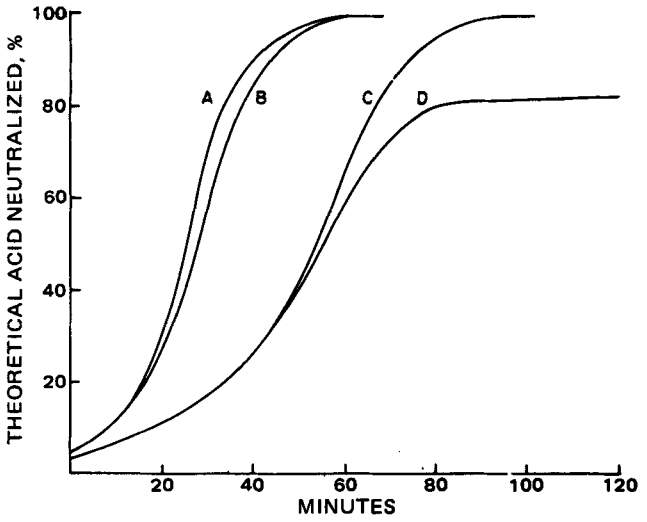

**Figure 3**—*Effect of polyols on the rate of acid neutralization of aluminum hydroxycarbonate gel (AHC). Key: A, initial pH-stat titrigram of AHC and inositol-containing AHC; B, initial pH-stat titrigram of sorbitol-containing AHC and mannitol-containing AHC; C, 1 week, 40° titrigram of sorbitol-containing AHC and mannitol-containing AHC; and D, 1 week, 40° titrigram of AHC and inositol-containing AHC.*

Therefore, the hydrogen bonding of polyols with aluminum hydroxide is an important reaction because the adsorbed polyol appears to interfere with the polymerization reaction and, consequently, the structural changes that ultimately lead to the inactive crystalline forms of aluminum hydroxide are minimized. However, the reaction between polyols and aluminum hydroxide gel is not universal. The difference in the effect of mannitol and sorbitol in comparison to inositol may be due to differences in the conformation of the polyol or in the strength of its intermolecular forces. Mannitol and sorbitol are both linear polyols, while inositol is related to cyclohexane. A linear conformation may permit more extensive hydrogen bonding to the aluminum hydroxide surface than is possible with cyclic polyols because of steric factors and the position of hydrogen

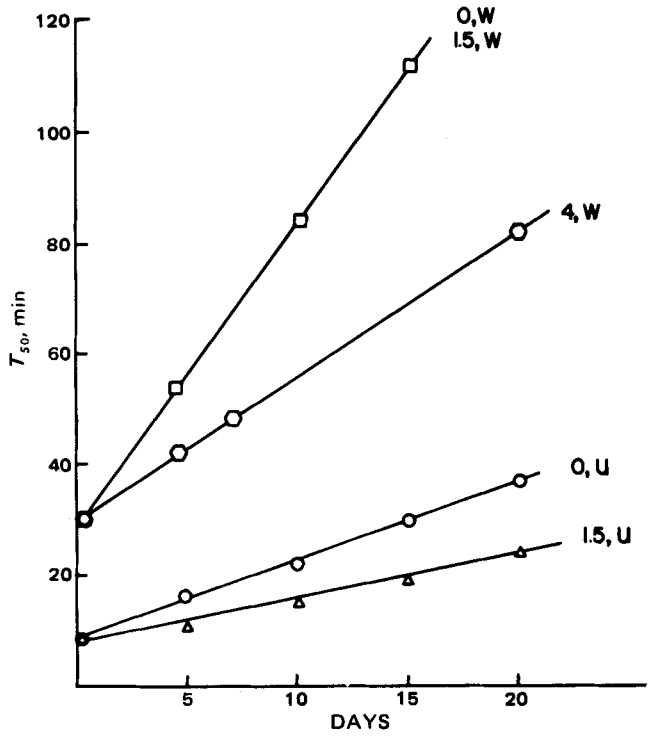

**Figure 4**—*Change in the rate of acid neutralization during aging at 25° of sulfate-containing aluminum hydroxide gels precipitated in the presence of 0, 1.5, and 4* M *mannitol per equivalent aluminum oxide. Key:* W, *washed; and* U, *unwashed.*

**Table I—Effect of Polyols on the Rate of Acid Neutralization of Aluminum Hydroxycarbonate Gel Containing 0.98 *M* Equivalent Aluminum Oxide**

| Polyol Added | $T_{50}$, min | | | |
|---|---|---|---|---|
| | 0.3 *M* polyol | 1.3 *M* polyol | 2.3 *M* polyol | 3.3 *M* polyol |
| Control[a] | 26 | 26 | 26 | 26 |
| Mannitol | 26 | 28 | 30 | 44 |
| Sorbitol | 26 | 28 | 30 | 44 |
| Inositol | 26 | 26 | 26 | 26 |

[a] Aluminum hydroxycarbonate gel.

bonding sites. The melting points of sorbitol, mannitol, and inositol are 110, 168, and 225°, respectively (10). The higher melting point and lower deuteroxy-stretching frequencies of inositol suggest the presence of strong intermolecular forces. Thus, the tendency of inositol toward self-association may be greater than the tendency toward adsorption by aluminum hydroxide.

The polyol concentration used to stabilize aluminum hydroxide must be carefully selected because the adsorbed polyol, in addition to interfering with polymerization, may also slow the rate of reaction with protons and thus reduce the rate of acid neutralization. Evidence of this effect was seen (Fig. 3) as a slight reduction in the rate of acid neutralization occurred when sorbitol or mannitol was added to the aluminum hydroxycarbonate gel. This effect is seen clearly in Table I where the rate of acid neutralization of aluminum hydroxycarbonate gel, as measured by the time required to neutralize 50% of the sample ($T_{50}$), increases in direct relationship to the concentration of mannitol or sorbitol. In the presence of high levels of mannitol or sorbitol, the $T_{50}$ increased from 26 to 44 min. In contrast, inositol did not affect the rate of acid neutralization.

Since changes in the aluminum hydroxide gel structure occur most rapidly immediately after precipitation (23), it may be advisable to incorporate a polyol in the reaction medium to achieve the maximum rate of acid neutralization. Thus, a sulfate-containing aluminum hydroxide gel was precipitated in the presence of varying amounts of mannitol. As seen in Fig. 4, the sulfate-containing aluminum hydroxide gel precipitated in the presence of a molar ratio of 1.5 *M* mannitol per equivalent aluminum oxide aged at the same rate as the control. However, the rate of loss of acid reactivity was substantially reduced when the sulfate-containing aluminum hydroxide gel was precipitated in the presence of a molar ratio of 4 *M* mannitol per equivalent aluminum oxide.

It was hypothesized, based on the hydrogen bonding mechanism indicated by the IR study, that the washing procedure removed most of the mannitol, and this hypothesis is supported by the desorption profile shown in Fig. 5. Most of the mannitol was removed by the first volume of wash water, and only ~30% of the added mannitol remained after the described washing procedure. The rate of acid neutralization of the unwashed sulfate-containing aluminum hydroxide gel was much greater

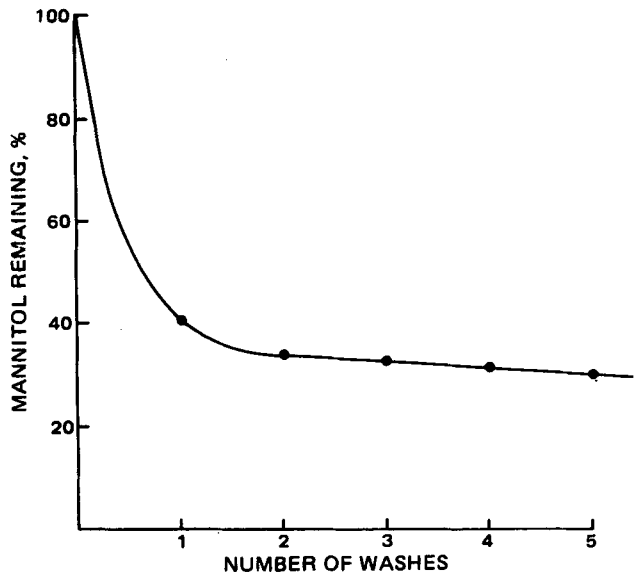

**Figure 5**—*Desorption of mannitol during washing with distilled water.*

than that of the washed portion, and the rate of loss of acid reactivity during aging was also reduced. This behavior confirms the strong stabilizing effect of anions (23). However, the unwashed portion that was precipitated in the presence of a molar ratio of 1.5 *M* mannitol per equivalent aluminum oxide showed the smallest decrease in the rate of acid neutralization during aging. The interaction between polyols and aluminum hydroxide gel apparently is too weak to recommend the incorporation of mannitol or sorbitol in the reaction medium. However, the results suggest the addition of mannitol or sorbitol immediately after washing.

# Effect of Age and Gender on Disposition of Temazepam

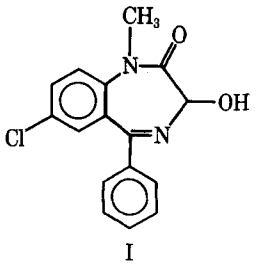
**MARCIA DIVOLL, DAVID J. GREENBLATT ˣ, JEROLD S. HARMATZ, and RICHARD I. SHADER**

Received December 12, 1980, from the *Division of Clinical Pharmacology, Departments of Psychiatry and Medicine, Tufts University School of Medicine and New England Medical Center Hospital, Boston, MA 02111.* Accepted for publication March 5, 1981.

**Abstract** □ Thirty-two male and female volunteers, 24–84 years of age, ingested single 30-mg doses of temazepam, a 3-hydroxy-1,4-benzodiazepine derivative used as a hypnotic agent. Kinetics of total and unbound temazepam were determined from multiple plasma temazepam concentrations measured during 48 hr after the dose. The temazepam elimination half-life ranged from 8 to 38 hr and was longer in women than in men (16.8 *versus* 12.3 hr, $p < 0.05$). Likewise, clearance of total temazepam (assuming complete absorption) was higher in men than in women (1.35 *versus* 1.02 ml/min/kg, $p < 0.025$). Neither half-life nor clearance was significantly related to age. The volume of distribution of total temazepam (mean 1.40 liters/kg) was unrelated to age or gender. Temazepam was extensively protein bound, with a mean free fraction of 2.6% (range 1.7–3.4%). The free fraction increased with age ($r = 0.45$, $p = 0.01$), partly due to the inverse relation of the free fraction to plasma albumin concentration ($r = -0.34$, $p = 0.06$) and the age-related decline in plasma albumin ($r = -0.49$, $p < 0.005$). After correction for individual differences in binding, clearance of unbound temazepam in men was higher than in women (50.5 *versus* 39.7 ml/min/kg, $0.05 < p < 0.1$), and it tended to decline with age in both sexes ($r = -0.44$ and $-0.43$, respectively, $p = 0.1$).

**Keyphrases** □ Temazepam—effect of age and gender on disposition and elimination □ Tranquilizers—temazepam, effect of age and gender on disposition and elimination □ Hypnotics—temazepam, effect of age and gender on disposition and elimination

Temazepam (I) is a 3-hydroxy-1,4-benzodiazepine derivative used as a hypnotic agent. The major metabolic pathway of temazepam in humans involves conjugation with glucuronic acid at position 3, yielding a water-soluble glucuronide metabolite that is excreted in the urine (1). Since the aging process may alter drug pharmacokinetics, this study was undertaken to assess the disposition and elimination of temazepam in young and elderly volunteers.



I

## EXPERIMENTAL

**Subjects**—Thirty-two healthy male and female volunteers, 24–84 years of age, participated after giving written informed consent. They were divided into four groups of young male, young female, elderly male, and elderly female subjects (Table I). All young subjects were free of any identifiable medical disease and were taking no medications. Elderly individuals were ambulatory, active, and in general good health. Five elderly subjects were taking medications for the treatment of cardiovascular disease that was clinically stable and compensated.

# Effect of Age and Gender on Disposition of Temazepam

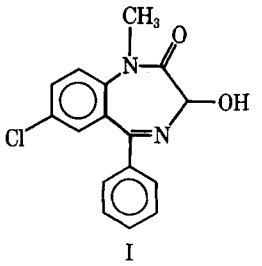
**MARCIA DIVOLL, DAVID J. GREENBLATT ˣ, JEROLD S. HARMATZ, and RICHARD I. SHADER**

Received December 12, 1980, from the *Division of Clinical Pharmacology, Departments of Psychiatry and Medicine, Tufts University School of Medicine and New England Medical Center Hospital, Boston, MA 02111.* Accepted for publication March 5, 1981.

**Abstract** □ Thirty-two male and female volunteers, 24–84 years of age, ingested single 30-mg doses of temazepam, a 3-hydroxy-1,4-benzodiazepine derivative used as a hypnotic agent. Kinetics of total and unbound temazepam were determined from multiple plasma temazepam concentrations measured during 48 hr after the dose. The temazepam elimination half-life ranged from 8 to 38 hr and was longer in women than in men (16.8 *versus* 12.3 hr, $p < 0.05$). Likewise, clearance of total temazepam (assuming complete absorption) was higher in men than in women (1.35 *versus* 1.02 ml/min/kg, $p < 0.025$). Neither half-life nor clearance was significantly related to age. The volume of distribution of total temazepam (mean 1.40 liters/kg) was unrelated to age or gender. Temazepam was extensively protein bound, with a mean free fraction of 2.6% (range 1.7–3.4%). The free fraction increased with age ($r = 0.45$, $p = 0.01$), partly due to the inverse relation of the free fraction to plasma albumin concentration ($r = -0.34$, $p = 0.06$) and the age-related decline in plasma albumin ($r = -0.49$, $p < 0.005$). After correction for individual differences in binding, clearance of unbound temazepam in men was higher than in women (50.5 *versus* 39.7 ml/min/kg, $0.05 < p < 0.1$), and it tended to decline with age in both sexes ($r = -0.44$ and $-0.43$, respectively, $p = 0.1$).

**Keyphrases** □ Temazepam—effect of age and gender on disposition and elimination □ Tranquilizers—temazepam, effect of age and gender on disposition and elimination □ Hypnotics—temazepam, effect of age and gender on disposition and elimination

Temazepam (I) is a 3-hydroxy-1,4-benzodiazepine derivative used as a hypnotic agent. The major metabolic pathway of temazepam in humans involves conjugation with glucuronic acid at position 3, yielding a water-soluble glucuronide metabolite that is excreted in the urine (1). Since the aging process may alter drug pharmacokinetics, this study was undertaken to assess the disposition and elimination of temazepam in young and elderly volunteers.



I

## EXPERIMENTAL

**Subjects**—Thirty-two healthy male and female volunteers, 24–84 years of age, participated after giving written informed consent. They were divided into four groups of young male, young female, elderly male, and elderly female subjects (Table I). All young subjects were free of any identifiable medical disease and were taking no medications. Elderly individuals were ambulatory, active, and in general good health. Five elderly subjects were taking medications for the treatment of cardiovascular disease that was clinically stable and compensated.

[a] $p < 0.005$ for young *versus* elderly of the same sex.

**Procedure**—After an overnight fast, subjects ingested a single 30-mg capsule of temazepam[1] with 100–200 ml of tap water. They remained fasting until 3 hr after drug ingestion. Venous blood samples were drawn into heparinized tubes from an indwelling butterfly cannula (kept patent by flushing with dilute heparin solution) or by venipuncture prior to the dose and at the following postdosage times: 0.25, 0.5, 0.75, 1.0, 1.5, 2, 2.5, 3, 4, 6, 8, 12, 24, 30, 36, and 48 hr. Plasma was separated and stored at −20° until the time of assay.

**Sample Analysis**—Temazepam concentrations in all plasma samples were determined by electron-capture GLC after addition of a benzodiazepine analog (3-hydroxyprazepam) as the internal standard (2).

The free fraction (percent unbound) was determined by equilibrium dialysis at 37° (3) of a single sample drawn in the nonfasting state. Since heparin may influence the free fraction of benzodiazepines, no subject received heparin systemically for at least 24 hr prior to sampling. Duplicate 2-ml plasma samples were spiked to contain 500 ng/ml of unlabeled temazepam and 20 nCi/ml of tritiated temazepam (62.5 μCi/mg). The radioactivity was determined in a liquid scintillation counter[2]. The mean coefficient of variation between duplicate samples was <6%. Binding was independent of the total plasma temazepam concentration over a range of 160–4160 ng/ml.

**Pharmacokinetic and Statistical Analysis**—Each set of data points was analyzed by iterative nonlinear least-squares regression techniques (4). Data points were fitted to the following two functions:

$$C = B(e^{-\beta t} - e^{-k_a t}) \quad \text{(Eq. 1)}$$

$$C = -(A + B)e^{-k_a t} + Ae^{-\alpha t} + Be^{-\beta t} \quad \text{(Eq. 2)}$$

where $C$ is the plasma temazepam concentration at time $t$ after dosage; $A$ and $B$ are hybrid intercept terms; and $k_a$, $\alpha$, and $\beta$ are hybrid exponents representing phases of drug absorption, distribution, and elimination, respectively. When necessary, both equations were modified by addition of a lag time prior to the start of first-order absorption. The choice between Eqs. 1 and 2 as functions of best fit was determined by scatter of actual data points about the fitted function and by comparison of weighted residual errors (5).

The hybrid exponent $\beta$ was used to calculate the apparent elimination half-life ($t_{1/2\beta}$). The area under the 48-hr plasma concentration curve was calculated using the trapezoidal rule; to this value was added the extrapolated residual area from the final concentration point to infinity, yielding the total area under the plasma concentration curve ($AUC$). The extrapolated area accounted for an average of 9.8% (range 2.6–36.8%) of the total $AUC$.

When neither Eq. 1 nor 2 provided an adequate fit of the data, $t_{1/2\beta}$ was calculated using the terminal log-linear portion of the plasma concentration curve. The total $AUC$ was calculated as described.

Although absolute bioavailability of temazepam is not known, previous studies of lorazepam, a structurally similar 3-hydroxy-1,4-benzodiazepine derivative, indicated that absolute systemic availability of orally administered drug is close to 100% (6, 7). Accordingly, it was assumed that the entire 30-mg temazepam dose reached the systemic circulation (100% bioavailability). Total clearance was calculated as the administered dose divided by the $AUC$, and the apparent volume of distribution ($V_d$) using the area method was calculated as total clearance divided by $\beta$. The volume of distribution and clearance of unbound temazepam were calculated as the quotient of total $V_d$ or clearance divided by the unbound fraction.

## RESULTS

Peak plasma temazepam concentrations ranged from 222 to 754 ng/ml. Peak concentrations were not significantly influenced by age, although they tended to be higher in women then in men and lower in elderly than in young of both sexes (Table I). After normalization for weight, peak plasma concentrations were similar among groups. Temazepam was slowly absorbed, with the time of peak concentrations ranging from 0.75 to 12.0 hr after dosage. The mean time of peak concentration among the four groups ranged from 1.8 to 4.7 hr after dosage and was not significantly influenced by age or gender. Iterative analysis provided satisfactory solutions in only 11 of the 32 subjects (Fig. 1).

The $V_d$ value for temazepam ranged from 0.7 to 2.3 liters/kg. Mean values for the four groups (1.32–1.53 liters/kg) were very close regardless of age or sex.

Within sexes, age was not significantly related to temazepam half-life or clearance (Figs. 2 and 3). However, $t_{1/2\beta}$ was significantly longer in women (mean 16.8 hr) than in men (12.3 hr) regardless of age ($p < 0.05$). Likewise, clearance of total temazepam was lower in women than in men regardless of age (1.02 *versus* 1.35 ml/min/kg, $p < 0.025$).

The free fraction of temazepam ranged from 1.67 to 4.18% and increased significantly with age ($r = 0.45$, $p < 0.02$) (Fig. 4). Elderly of both

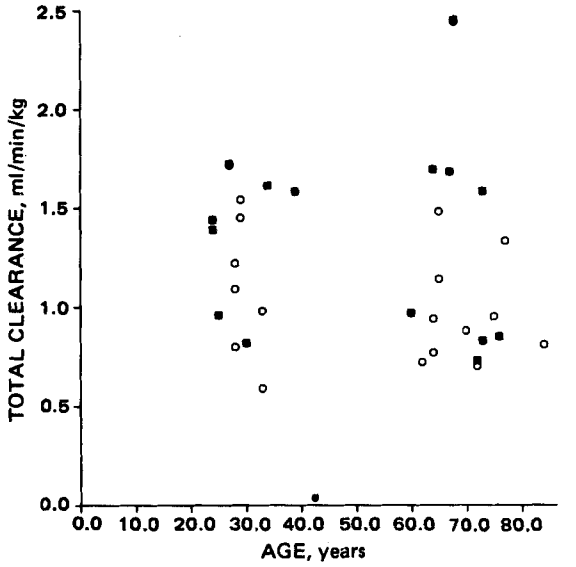

**Figure 3**—*Relation of age to clearance of total temazepam in males and females. Key:* ■, *male* (r = −0.04); *and* O, *female* (r = −0.23).

sexes had a higher free fraction than did the young subjects. The increased free fraction of temazepam in the elderly was partly explained by plasma albumin concentrations, which declined significantly with age ($r = -0.49$, $p < 0.01$).

Values of unbound $V_d$ were lower in the elderly than in the young subjects of both sexes, but the differences were not significant (Table I). Clearance of unbound temazepam declined with age in both sexes (Table I and Fig. 5), although differences did not reach statistical significance. As in the case of clearance of total temazepam, unbound clearance was higher in men than in women (50.5 *versus* 39.7 ml/min/kg, $0.05 < p < 0.1$).

## DISCUSSION

Previous studies with benzodiazepines that undergo oxidative biotransformation (such as chlordiazepoxide, diazepam, and desmethyldiazepam) suggest that metabolic clearance may be impaired among the elderly, particularly in elderly males (8–13). However, for benzodiazepines that undergo glucuronide conjugation (such as oxazepam and lorazepam), the aging process has minimal, if any, effect on metabolic disposition (6, 14–16).

In the present study, the absorption of temazepam from the GI tract was relatively slow. The time of peak concentration averaged 3 hr after dosage and was not significantly influenced by age or sex.

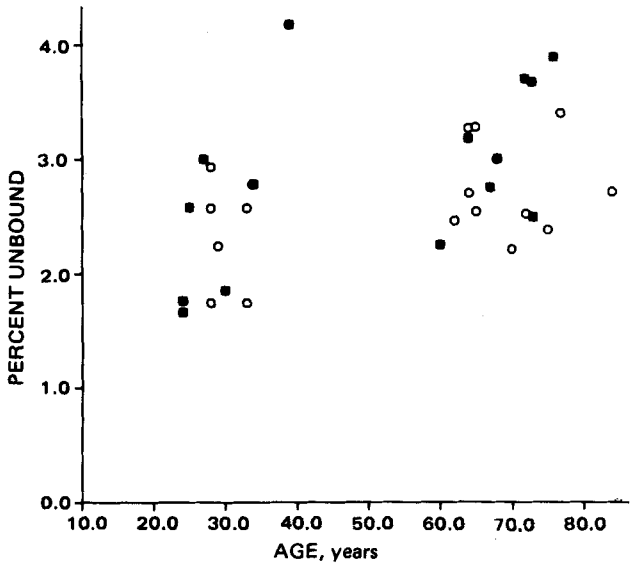

**Figure 4**—*Relation of age to temazepam protein binding in males and females. Key:* ■, *male* (r = 0.53); *and* O, *female* (r = 0.43).

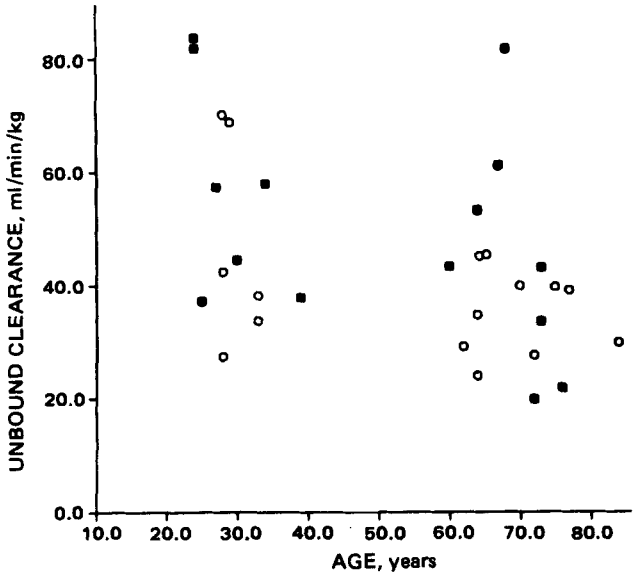

**Figure 5**—*Relation of age to clearance of unbound temazepam in males and females. Key: ■, male (r = −0.43); and ○, female (r = −0.44).*

The apparent elimination half-life of temazepam was somewhat longer than suggested by previous reports (17, 18). The mean value of $t_{1/2\beta}$ was 14.7 hr (range of 8–38 hr). Women had longer $t_{1/2\beta}$ times than men regardless of age. An essentially identical relation of gender to $t_{1/2\beta}$ was observed in a previous study of oxazepam (16).

The relation of clearance of total temazepam to age and sex also was very similar to that observed with oxazepam. Temazepam clearance was higher in men than in women and was essentially uninfluenced by age. However, the effect of age on clearance of unbound temazepam was partly obscured by an age-related increase in the free fraction. After correction for individual differences in temazepam protein binding, unbound clearance was reduced, but not significantly, in the elderly of both sexes, although it was still higher in men than in women of corresponding age. Neither age nor sex significantly influenced the volume of distribution of total or unbound temazepam, but unbound $V_d$ values tended to be smaller in the elderly than in the young of both sexes.

The effect of age and sex on temazepam distribution and clearance closely resembles the findings of previous studies of oxazepam and lorazepam, two other 3-hydroxy-1,4-benzodiazepines biotransformed by glucuronide conjugation (6, 16). The results contrast strikingly with studies of benzodiazepines transformed by oxidative pathways such as chlordiazepoxide, diazepam, and desmethyldiazepam. Clearance of these compounds declines with increasing age, and the extent of distribution increases with age. For diazepam and desmethyldiazepam, the age-related decline in clearance is more striking in men than in women (8, 13). Distribution of these two compounds is related to sex as well as age, with larger $V_d$ values associated both with increasing age and female sex.

Thus, the relation of age to benzodiazepine disposition is not easily generalized since it may be dependent on the metabolic pathway of the drug in question as well as the gender composition of the study population.

# Pharmacokinetics of Captopril in Dogs and Monkeys

**S. M. SINGHVI ˣ, A. E. PETERSON, J. J. ROSS, Jr., J. M. SHAW, G. R. KEIM, and B. H. MIGDALOF**

Received September 12, 1980, from the *Departments of Drug Metabolism and Toxicology, Squibb Institute for Medical Research, New Brunswick, NJ 08903.* Accepted for publication March 4, 1981.

**Abstract** □ [$^{14}$C]Captopril was given as a priming dose, followed by constant intravenous infusion for 4 or 6 hr, to three anesthetized dogs and three anesthetized monkeys. Blood, urine, and bile samples were collected during and after drug infusion. Pharmacokinetic evaluations were carried out exclusively on data obtained for unchanged captopril. The average total body clearance ($Cl_T$) and the renal clearance ($Cl_R$) of captopril, in milliliters per kilogram per hour, were 605 and 341 in the dog and 1135 and 944 in the monkey. The biliary clearance of captopril was negligible in both species. The greater difference between the $Cl_R$ and $Cl_T$ values in the dog compared to that in the monkey was the result of more extensive metabolism of captopril by the dog. Since almost all of the radioactive dose was recovered in urine in both species, captopril and its metabolites were almost exclusively eliminated by the kidneys. One primary reason that body and renal clearance values of captopril were much greater in the monkey than in the dog was that the net tubular secretion of captopril was about three times greater in the monkey (82%) than in the dog (28%). The volume of distribution of captopril was higher in the monkey (3.6 liters/kg) than in the dog (2.5 liters/kg); the volume of the central compartment was about the same (0.5 liter/kg) for both species. The terminal half-life value was slightly higher in the dog (2.8 hr) than in the monkey (2.2 hr).

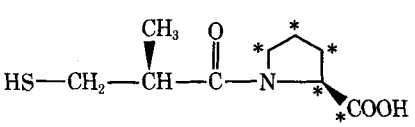
**Keyphrases** □ Captopril—pharmacokinetics in dogs and monkeys using radiolabeled drug, continuous intravenous infusion □ Pharmacokinetics—captopril in dogs and monkeys, continuous intravenous infusion □ Antihypertensives—pharmacokinetics of captopril in dogs and monkeys, continuous intravenous infusion

Captopril, 1-[(2*S*)-3-mercapto-2-methyl-1-oxopropyl]-L-proline, is a potent, orally active, specific inhibitor of the enzyme that catalyzes the conversion of angiotensin I to angiotensin II (1). It also was shown clinically to be an effective antihypertensive agent (2–4). This study determined the pharmacokinetics of captopril in dogs and monkeys using [$^{14}$C]captopril.

## BACKGROUND

Captopril, a thiol compound, is chemically unstable in biological samples and undergoes rapid autoxidation to form the disulfide dimer of the parent compound and other unidentified products (5, 6). To prevent or minimize such processes, captopril was converted to its *N*-ethylmaleimide derivative in blood, urine, and bile during or immediately after sample collection (5, 6).

In previous blood level studies in animals and humans, captopril was administered orally, and difficulty was encountered in estimating its biological half-life and other pharmacokinetic parameters. This difficulty was partly because of the lack of a sensitive specific assay and partly because of an apparent nonlinearity in the terminal portions of semilogarithmic plots of blood levels *versus* time. It was anticipated that efforts to obtain pharmacokinetic parameters following a single intravenous bolus dose of captopril would have been hampered by the same problems. Consequently, to obtain better pharmacokinetic information, it was decided to study captopril pharmacokinetics in dogs and monkeys during steady-state conditions achieved by continuous intravenous infusion.



I(* = sites labeled with carbon 14)

## EXPERIMENTAL

**Materials**—[$^{14}$C]Captopril was universally labeled with carbon 14 in the proline moiety. Radiochemical and chemical purities were each ~98%; ~2% of [$^{14}$C]captopril disulfide was present as an impurity. A nonionic surfactant[1], a tissue solubilizer[2], and *N*-ethylmaleimide[3] were used. Other chemicals were reagent grade and were obtained commercially.

**Animals**—Three male adult purebred beagles (9–11 kg) and three male adult rhesus monkeys (6–8 kg) were used.

**Procedure**—The study design was identical for dogs and monkeys. Each animal was fasted overnight, hydrated orally with water (25 ml/kg for dogs; 15 ml/kg for monkeys), anesthetized with intravenous pentobarbital sodium (30 mg/kg), intubated with an endotracheal catheter, and maintained under anesthesia by constant intravenous infusion of pentobarbital sodium (2.7 mg/kg/hr).

For determination of creatinine clearance, a priming dose of 60 mg of creatinine/kg was injected intravenously followed by 18 mg/kg/hr in the infusate. The infusate also contained phosphate-buffered 5% mannitol (pH 7.4) to maintain adequate urine flow. After the start of the infusion, the animal was surgically prepared for the collection of bile and urine. The cystic duct was ligated, and the common bile duct was cannulated near its junction with the duodenum; then both ureters were cannulated for urine collection. Urine and bile were collected for consecutive 30-min periods, and a blood sample was withdrawn at the midpoint of each collection period. After two consecutive control periods, [$^{14}$C]captopril priming and constant infusion doses were started simultaneously.

For the first dog and monkey, the priming and infusion doses (Tables I and II) were selected using data obtained from preliminary studies; the infusions were continued for 4 hr. Subsequently, the doses were determined based on results from the first animal of each species such that the steady-state concentrations of unchanged captopril in the blood of the next two animals of each species were approximately the same as the first (0.2 μg/ml). The doses for the last two dogs and monkeys were as follows: a priming dose of 0.4 mg/kg (dog) and 1.0 mg/kg (monkey) over a 1-min period and constant infusion of 0.1 mg/kg/hr (dog) and 0.2 mg/kg/hr (monkey) for 6 hr. [$^{14}$C]Captopril was infused using a constant infusion pump[4]. After the end of the infusion of [$^{14}$C]captopril, the 5% mannitol infusion was continued, and the animal was kept under anesthesia for an additional 8 hr. The 5% mannitol infusate contained creatinine and pentobarbital sodium and was infused throughout the study using another constant infusion pump[4].

Urine and bile were collected every 30 min during [$^{14}$C]captopril infusion, for 3 hr after the end of infusion, and then every 1 hr for the next 5 hr. A blood sample was withdrawn at the midpoint of each collection. All samples were treated with *N*-ethylmaleimide and analyzed for total radioactivity and unchanged captopril.

**Analytical Methods**—A thin-layer radiochromatographic assay for captopril in blood and urine was described previously (5, 6). Bile and urine samples were analyzed in an identical manner. This method is quite specific for unchanged captopril and has a limit of detection of ~10 ng/ml. The scintillation cocktail of Anderson and McClure (7) was used to count blood and bile samples. The tissue solubilizer[2] was added to solubilize whole blood and bile samples. Urine samples were counted directly in Bray's liquid scintillation counting solution[5].

All samples were counted in liquid scintillation spectrometers[6]. These counters were regularly normalized for valid utilization of automatic external standardization ratios for determination of disintergrations per minute. Known standards were counted to verify the accuracy of the instruments. Counting efficiency was determined using automatic ex-

[a] Mean of the last four (Monkey 5-31) or six (Monkeys 8-7 and 8-1) consecutive 30-min infusion periods, considered to be at steady-state. [b] Calculated using all data obtained during and after the infusion of [$^{14}$C]Captopril (see Fig. 2). [c] Represents minimum net tubular secretion since captopril protein binding was assumed to be zero (see text for details).

ternal standardization. The color and chemical quenching of the samples were corrected by using appropriately prepared quench curves. All samples were prepared and analyzed in duplicate and were counted for a minimum of 3000 counts, which resulted in a counting error of <1.8%.

**Data Analysis**—Pharmacokinetic parameters for captopril were calculated from data obtained during the infusion and postinfusion phases of the study, using relationships given in the *Appendix*.

## RESULTS

In all animals, blood pressure, heart rate, and respiration rate were monitored; no major changes were observed in any of these parameters during the infusion of [$^{14}$C]captopril. The creatinine clearance, a measure of the glomerular filtration rate, also was found to be reasonably constant during the infusion period.

Pharmacokinetic evaluations were carried out exclusively on data obtained for unchanged captopril in blood, urine, and bile during the steady-state period and the postinfusion phase. A typical semilogarithmic plot of concentrations of unchanged captopril in blood *versus* time is shown in Fig. 1. In all animals, the blood levels followed a similar pattern as a function of time; the levels were initially high due to the priming dose, steady-state levels were reached toward the end of the infusion period, and the blood levels declined biexponentially during the postinfusion period. This biexponential decline of blood captopril concentrations indicates that the drug exhibits characteristics of a two-compartment open model, with elimination occurring from the central compartment.

The priming and infusion doses of [$^{14}$C]captopril given to the first dog (H8-113) and the first monkey (5-31) were selected using limited data available from previous blood level studies, which were not designed to estimate pharmacokinetic parameters. Because of the relatively short duration of infusion and deficiencies in the priming and infusion doses initially selected, true steady-state conditions were either just approached or attained for only a limited time in the first dog and first monkey. Based on the information derived from these two animals, the priming and infusion doses of [$^{14}$C]captopril were modified to attain rapid steady-state conditions in an additional two dogs (H6-117 and H8-23) and two monkeys (8-7 and 8-1).

For the latter animals, the infusion period for [$^{14}$C]captopril was extended from the 4 hr used in the earlier study to 6 hr to maintain steady-state conditions for a longer period. As a result, good steady-state conditions were attained for the last two dogs and two monkeys. Most results for these animals were comparable to those obtained for the first animal of each species. Therefore, with few exceptions, the results of the various pharmacokinetic parameters were averaged for all three animals

**Table III—Excretion of Total Radioactivity and Unchanged Captopril in the Urine and Bile of Anesthetized Dogs and Monkeys following Infusion of [$^{14}$C]Captopril**

| Excretion | Component | Percent of Dose Excreted[a] | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| | | Dog | | | | Monkey | | | |
| | | H8-113 | H6-117 | H8-23 | Average ± *SD* | 5-31 | 8-7 | 8-1 | Average ± *SD* |
| Urine | Total radioactivity | 92.8 | 95.2 | 83.8 | 90.6 ± 6.0 | 91.7 | 99.9 | 90.6 | 94.1 ± 5.1 |
| | Captopril | 58.1 | 61.3 | 39.4 | 52.9 ± 11.8 | 80.6 | 86.7 | 75.8 | 81.0 ± 5.5 |
| Bile | Total radioactivity | 0.78 | 2.65 | 3.45 | 2.29 ± 1.37 | 0.31 | 0.49 | 0.47 | 0.42 ± 0.10 |
| | Captopril | 0.04 | 0.05 | 0.09 | 0.06 ± 0.03 | 0.01 | 0.02 | 0.02 | 0.017 ± 0.006 |
| Total (urine and bile) | Total radioactivity | 93.6 | 97.9 | 87.3 | 92.9 ± 5.3 | 92.0 | 100.4 | 91.1 | 94.5 ± 5.1 |
| | Captopril | 58.1 | 61.4 | 39.5 | 53.0 ± 11.8 | 80.6 | 86.7 | 75.8 | 81.0 ± 5.5 |

[a] Cumulative excretion for entire duration of the study (4- or 6-hr infusion period plus 8-hr postinfusion).

(Tables I and II). Since pharmacokinetic parameters calculated from both steady-state and postinfusion data were comparable for each animal, overall averages of all the parameters also were calculated.

Average clearance values (milliliters per kilogram per hour) obtained in the dog were 605 (body clearance, $Cl_T$), 341 (renal clearance, $Cl_R$), and 0.45 (biliary clearance, $Cl_B$) (Table I). Average creatinine clearance ($Cl_{Cr}$) was 253 ml/kg/hr. A comparison of the $Cl_R$ and $Cl_{Cr}$ values indicated an average minimum net tubular secretion of captopril of 28% in the dog. Net tubular secretion values were calculated by assuming no reversible (physicochemical) binding of captopril to plasma proteins and, therefore, represent minimum estimates. Since *N*-ethylmaleimide used for stabilizing captopril hemolyzes blood, plasma could not be obtained for determination of protein binding. However, *in vitro* studies done in this laboratory showed that, while captopril forms chemically reversible covalent bonds with plasma proteins, its physicochemical (noncovalent) binding to plasma proteins is negligible (8). The average volume of distribution ($V_d$) in the dog was 2.5 liters/kg, while the volume of the central compartment ($V_1$) averaged ~0.5 liter/kg. The average terminal half-life ($t_{1/2}\beta$) in blood in the dog was ~2.8 hr (Table I).

In the monkey, the average clearance values, in milliliters per kilogram per hour were 1135 ($Cl_T$), 944 ($Cl_R$), 0.2 ($Cl_B$), and 170 ($Cl_{Cr}$) (Table II). With the assumption of negligible physicochemical binding of captopril to plasma proteins, a comparison of $Cl_R$ and $Cl_{Cr}$ indicated an average minimum net tubular secretion of 82%. The average $V_d$ and $V_1$ values were 3.6 and 0.5 liters/kg, respectively. The average $t_{1/2}\beta$ value in the monkey was 2.2 hr (Table II).

Renal clearance ($Cl_R$) values for all animals also were calculated by using all data obtained and plotting the urinary excretion rate of unchanged captopril *versus* the blood concentration of captopril at the midpoint of urinary collection periods. A typical plot is shown in Fig. 2. These data provided excellent linearity, as indicated by correlation coefficient ($r^2$) values of >0.97 for all animals. The slopes of these lines represented the renal clearance values, and the intercept values were close to the expected value of zero. The values obtained for $Cl_R$ by this method were similar to those obtained using only the steady-state data (Tables I and II).

The excretion data (Table III) showed that averages of 91% (dog) and 94% (monkey) of the administered dose were recovered in urine, while biliary excretion accounted for only 2.3% (dog) and 0.4% (monkey) of the administered dose.

## DISCUSSION

The disposition of captopril in humans after oral administration of [$^{14}$C]captopril was reported recently (5); at the time the present study in animals was conducted, captopril pharmacokinetics in humans following intravenous administration of the drug had not been determined. Based on the disposition data obtained in humans after oral administration of [$^{14}$C]captopril, there was a lack of correlation between the pharmacokinetics and pharmacodynamics of the drug (5). Although unchanged captopril was not detected in the blood after 6 hr, other studies in hypertensive patients had demonstrated good control of blood pressure with a three-times-daily dosing regimen (5). Thus, this study in dogs and monkeys was initiated to gain a better understanding of captopril pharmacokinetics and to provide information for properly designing pharmacokinetic studies in humans.

Captopril appears to exhibit characteristics of a two-compartment open model in both the dog and monkey. In both species, the values for biliary clearance were negligible. Although the hepatic clearance of captopril could not be directly calculated, negligible biliary clearance of captopril indicated that the difference between the total body clearance and renal clearance of captopril in both species was primarily due to the metabolic

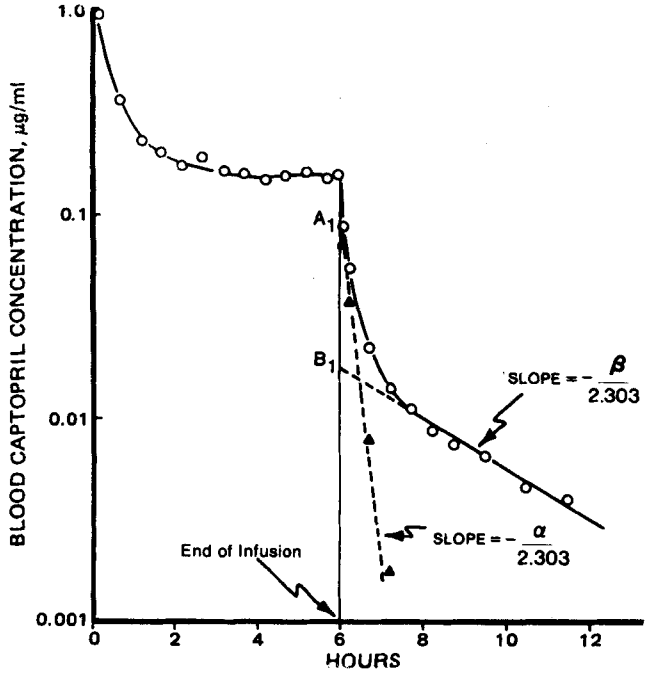

**Figure 1**—*Concentration of unchanged captopril in blood during and after infusion of [$^{14}$C]captopril into an anesthetized monkey (8-7).*

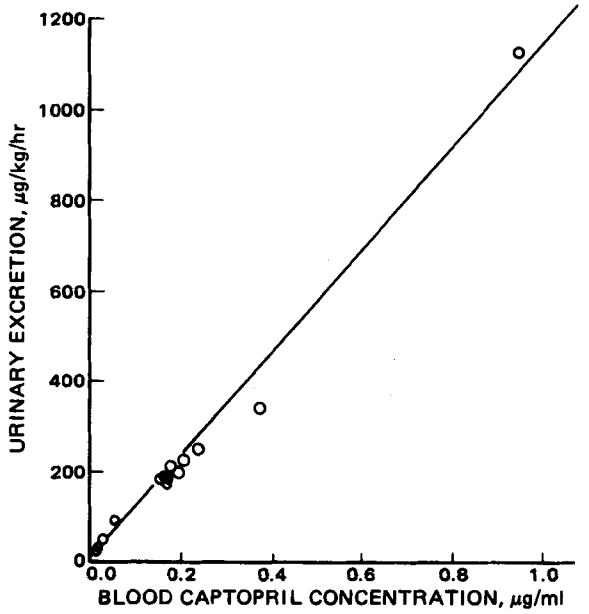

**Figure 2**—*Renal clearance of captopril in an anesthetized monkey (8-7) during and after infusion of [$^{14}$C]captopril. Slope ($Cl_R$) = 1150 ml/kg/hr, y-intercept = 1.8 μg/kg/hr, and correlation coefficient ($r^2$) = 0.990.*

clearance of captopril. Since almost all of the radioactive dose was recovered in urine in both species, captopril and its metabolites were almost exclusively eliminated by the kidneys.

A comparison of the disposition data in humans (5) and in dogs and monkeys (this study) indicated that the majority of the radioactivity excreted in urine in these species was unchanged captopril. In addition, the major elimination route of captopril in humans was *via* the kidneys. Based on a comparison of fecal excretion of radioactivity in normal subjects (5) and in patients with impaired renal function (9) after oral administration of [$^{14}$C]captopril, nonrenal elimination of captopril and its metabolites did not increase under conditions of reduced kidney function. Thus, to avoid any toxic side effects from accumulation of captopril or its metabolites, smaller doses or longer intervals between doses of captopril may be necessary in patients with renal impairment.

The volume of distribution of captopril was higher in the monkey (3.6 liters/kg) than in the dog (2.5 liters/kg); the volume of the central compartment ($V_1$) was about the same (0.5 liter/kg) for both species. The values for distribution rate constants ($k_{12}$ and $k_{21}$) were comparable for both species. However, the overall elimination rate constant ($k_{el}$) in the monkey (2.6 $hr^{-1}$) was about twice that found in the dog (1.3 $hr^{-1}$) due to the higher renal clearance in the monkey. The renal excretion rate constant ($k_e$) in the monkey (1.9 $hr^{-1}$) was also more than twice that found in the dog (0.7 $hr^{-1}$).

The body and renal clearance values of captopril in the monkey were much greater than the corresponding values for the dog, primarily because the net tubular secretion of captopril was three times higher in the monkey than in the dog. The volumes of distribution of captopril in the dog (2.5 liters/kg) and monkey (3.6 liters/kg) indicated extensive distribution of captopril throughout the body.

A comparison of the urinary excretion data between the dog and monkey (Table III) indicated that, while the average amount of total radioactivity excreted in urine during the entire experiment was approximately the same for both animals, the average amount of unchanged captopril excreted in urine was much higher in the monkey. In fact, the average ratios of $Cl_R$ and $Cl_T$ in the dog (0.56, Table I) and monkey (0.83, Table II) were in excellent agreement with the fractions of the administered dose excreted in urine as unchanged drug in these animals (0.53 and 0.81, respectively) (Table III). Thus, the greater difference between $Cl_R$ and $Cl_T$ values in the dog compared to that in the monkey can be explained by the fact that a relatively larger fraction of a given dose of captopril was eliminated by a nonrenal mechanism (metabolism) in the dog than in the monkey. Biliary excretion accounted for only 2.3% (dog) and 0.4% (monkey) of the dose (Table III). Average fecal excretion of radioactivity in unanesthetized dogs and monkeys after single intravenous doses of [$^{14}$C]captopril (2.5 mg/kg) was also <2%[7]. These data indicate that the low biliary excretion observed in anesthetized animals was not due to the administration of a general anesthetic. Thus, in both species, the major route for elimination from the body was *via* the kidneys.

The terminal half-life value was slightly higher in the dog than in the monkey. Problems in estimating the captopril half-life were encountered in previous studies in which apparent curvilinearity of semilogarithmic plots of blood concentrations *versus* time had been observed after oral administration of captopril in humans and animals (5, 10). This curvilinearity was tentatively attributed to formation of reversible disulfide bonds of captopril with proteins. By using a steady-state design for the present study, meaningful estimates of the half-life and other pharmacokinetic parameters were obtained, and the problems of curvilinearity in the semilogarithmic plots of blood concentrations *versus* time encountered after administration of single captopril doses were avoided.

## APPENDIX

**Total body clearance ($Cl_T$)** is the volume of blood cleared of drug per unit time, which is a measure of the rate at which infused compound is cleared or removed from the blood by all mechanisms:

$$Cl_T = \frac{\text{infusion rate}}{\text{blood concentration}} \qquad \text{(Eq. A1)}$$

**Renal clearance ($Cl_R$)** is the volume of blood cleared of drug by the kidney and excreted in the urine per unit time:

$$Cl_R = \frac{\text{renal excretion rate of compound}}{\text{blood concentration}} \qquad \text{(Eq. A2)}$$

Equation A2 is also used to calculate the creatinine clearance (a measure of glomerular filtration rate) when creatinine is infused along with the drug.

**Biliary clearance ($Cl_B$)** is the volume of blood cleared of drug by the bile per unit time:

$$Cl_B = \frac{\text{biliary excretion rate}}{\text{blood concentration}} \qquad \text{(Eq. A3)}$$

**Renal clearance/body clearance** reflects the contribution of renal excretion to the body clearance of drug. The deviation from 1.0 reflects the contribution of nonrenal mechanisms to the body clearance of the compound.

**Renal clearance ($Cl_R$)/creatinine clearance ($Cl_{Cr}$)** reflects the mode of drug excretion by the kidney. A ratio of <1.0 suggests glomerular filtration and net tubular reabsorption. A ratio of >1.0 suggests glomerular filtration and net tubular secretion.

**Apparent volume of distribution ($V_d$)** is the theoretical volume of water occupied by drug in the body, assuming uniform distribution and a concentration equal to that found in the blood:

$$V_d = \frac{\text{total compound in body}}{\text{blood concentration}} \qquad \text{(Eq. A4)}$$

**Terminal half-life ($t_{1/2}\beta$)** is an estimate of the time required by all mechanisms to clear half of the drug from the body:

$$t_{1/2}\beta = \frac{\text{volume of distribution}}{\text{body clearance}} \times 0.693 \qquad \text{(Eq. A5)}$$

Postinfusion blood concentration data can also be used to calculate some parameters calculated by using steady-state data as well as some parameters that cannot be calculated by using data obtained during the infusion period. The following relationships were used to calculate various pharmacokinetic parameters (with the assumption that the compound shows characteristics of a two-compartment open model):

$$C = A \exp(-\alpha t') + B \exp(-\beta t') \qquad \text{(Eq. A6)}$$

$$A = \frac{A_1 \alpha T}{1 - \exp(-\alpha T)} \qquad \text{(Eq. A7)}$$

$$B = \frac{B_1 \beta T}{1 - \exp(-\beta T)} \qquad \text{(Eq. A8)}$$

$$k_{21} = \frac{A\beta + B\alpha}{A + B} \qquad \text{(Eq. A9)}$$

$$k_{el} = \frac{\alpha\beta}{k_{21}} \qquad \text{(Eq. A10)}$$

$$k_{12} = \alpha + \beta - k_{21} - k_{el} \qquad \text{(Eq. A11)}$$

$$V_1 = \frac{\text{total dose infused}}{A + B} \qquad \text{(Eq. A12)}$$

$$V_d = \frac{\text{total dose infused}}{AUC \times \beta} \qquad \text{(Eq. A13)}$$

$$Cl_T = V_1 \times k_{el} = V_d\beta \qquad \text{(Eq. A14)}$$

$$k_e = \frac{Cl_R}{V_1} \qquad \text{(Eq. A15)}$$

$$Cl_T = Cl_R + Cl_H + Cl_0 \qquad \text{(Eq. A16)}$$

$$Cl_H = Cl_B + Cl_M \qquad \text{(Eq. A17)}$$

$$t' = t - T \qquad \text{(Eq. A18)}$$

where $A_1$ and $B_1$ are intercepts on the concentration axis at the point when the infusion is stopped (Fig. 1) and:

$C$ = concentration of drug at any time during the postinfusion period
$T$ = time of infusion
$t$ = time since the start of the infusion
$V_1$ = volume of the central compartment
$V_d$ = apparent volume of distribution
$Cl_H$ = hepatic clearance
$Cl_M$ = metabolic clearance
$Cl_0$ = clearance by other unknown routes
$AUC$ = area under the blood concentration *versus* time curve
$k_{12}$ and $k_{21}$ = distribution rate constants
$k_{el}$ = overall elimination rate constant
$k_e$ = renal excretion rate constant

[7] S. M. Singhvi and K. J. Kripalani, unpublished data.

Renal or biliary clearance can be calculated by plotting the rate of urinary excretion or biliary excretion against the blood concentration at the midpoint of each urinary or biliary collection, respectively. The resulting slopes represent each corresponding clearance value (Fig. 2 illustrates the calculation of renal clearance). However, $Cl_H$, $Cl_M$, and $Cl_0$ cannot be calculated by conventional methods.

Percent net tubular secretion can be calculated using the following relationship:

$$\text{percent net tubular secretion} = \frac{Cl_R - Cl_{cr} \times \text{fraction of unbound compound}}{Cl_R} \times 100 \qquad \text{(Eq. A19)}$$

# Quantitation of Daunorubicin, Doxorubicin, and Their Aglycones by Ion-Pair Reversed-Phase Chromatography

**A. CAROL HANEKE ˣ, J. CRAWFORD, and A. ASZALOS**

Received January 23, 1981, from the *Food and Drug Administration, National Center for Antibiotics Analysis, Washington, DC 20204.* Accepted for publication March 9, 1981.

**Abstract** □ A fast and sensitive high-pressure liquid chromatographic method was developed for the quantitation of doxorubicin, daunorubicin, and their aglycones in pharmaceutical preparations. Because its higher pH extends column life while permitting determination of impurities, this system represents an improvement over previously published methods. It utilizes a $C_{18}$ bonded silica gel column and a solvent system consisting of methanol–0.01 *M* monobasic ammonium phosphate aqueous solution (65:35) at pH 4.0 and 1600 psi of pressure. The accuracy of the doxorubicin and daunorubicin determinations, expressed as the coefficient of variation, is 1.65 and 1.27%, respectively. The aglycones can be determined with a precision of <1.3%.

**Keyphrases** □ Doxorubicin—high-pressure liquid chromatographic assay, quantitation of impurities □ Daunorubicin—high-pressure liquid chromatographic assay, quantitation of impurities □ High-pressure liquid chromatography—quantitation of doxorubicin, daunorubicin, and their aglycones □ Antibiotics—quantitation of doxorubicin, daunorubicin, and their aglycones by high-pressure liquid chromatography

Doxorubicin (adriamycin) is an anthracycline antibiotic (I) consisting of the tetracyclic quinoid aglycone doxorubicinone (adriamycinone) in a glycosidic linkage to the amino sugar daunosamine (1, 2). Doxorubicin has been shown to be effective against various human neoplasms (3, 4). Pharmaceutical preparations of doxorubicin contain several impurities such as daunorubicin, daunorubicinone, and doxorubicinone, as well as other minor contaminants. Some of these impurities, particularly daunorubicin and daunorubicinone, are present because doxorubicin is prepared from daunorubicin by chemical synthesis (5), and the parent compound and its impurities are carried through to the product during the manufacturing process.

Daunorubicin (II) is a recently approved drug used in the treatment of acute leukemia and certain solid tumors in humans (6, 7). Daunorubicin preparations contain impurities such as daunorubicinone, which may be carried through the isolation process of the drug from the fermentation broth (8). It is important that the potency of both doxorubicin and daunorubicin be determined because clinical treatment relies on an accurate dosage schedule (9). It is equally important to determine the impurities in these pharmaceutical preparations, particularly the aglycone content, because these impurities are mutagenic and have no antitumor activity (10).

Renal or biliary clearance can be calculated by plotting the rate of urinary excretion or biliary excretion against the blood concentration at the midpoint of each urinary or biliary collection, respectively. The resulting slopes represent each corresponding clearance value (Fig. 2 illustrates the calculation of renal clearance). However, $Cl_H$, $Cl_M$, and $Cl_0$ cannot be calculated by conventional methods.

Percent net tubular secretion can be calculated using the following relationship:

$$\text{percent net tubular secretion} = \frac{Cl_R - Cl_{cr} \times \text{fraction of unbound compound}}{Cl_R} \times 100 \qquad \text{(Eq. A19)}$$

Numbers given are retention times in minutes.*

## BACKGROUND

The *Code of Federal Regulations* (CFR) (11) specifies that high-pressure liquid chromatography (HPLC) be used to establish the composition of doxorubicin and daunorubicin preparations but does not require determination of the aglycones. The official method utilizes a pH 2.0 mobile phase, which can adversely affect the useful life of the chromatographic column and may also hydrolyze daunorubicin to its aglycone and daunosamine during the long analytical process.

Most previously published HPLC procedures for the analyses of these drugs are suitable only for the estimation of doxorubicin and its metabolites in plasma (12–15). Some also use a detrimental pH 2 mobile phase (12, 13). Others use a quaternary (14) or a gradient (15) solvent system and do not provide rapid quantitation of pharmaceutical preparations of doxorubicin or daunorubicin. A low pH system was used by Eksborg (16), who achieved good separations of daunorubicin, doxorubicin, and their C-13 hydroxylated metabolites by HPLC (16). Other methods were developed to determine daunorubicin and its C-13 hydroxylated metabolite in plasma (17, 18). However, none of these published methods was designed to quantitate doxorubicinone and daunorubicinone.

This report describes a new HPLC method for the quantitative determination of daunorubicin, doxorubicin, and their aglycones in pharmaceutical preparations.

## EXPERIMENTAL

**Reagents**—Spectrograde methanol and deionized water were used throughout the experiments. Monobasic ammonium phosphate[1], acetic acid[2], and heptanesulfonic acid[3] were used without further purification. Daunorubicin[4] and doxorubicin[5] were obtained commercially. Daunorubicinone and doxorubicinone were prepared as described previously (19 and 2, respectively) and checked for purity by melting-point, IR, and TLC [single spot at $R_f$ 0.92 and 0.78, respectively; methanol–chloroform–formic acid (15:85:2); silica gel] analyses.

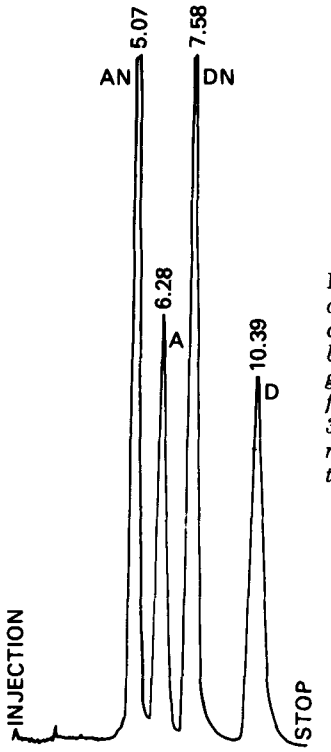

**Figure 2**—*HPLC separation profile of daunorubicin (D), doxorubicin (A), daunorubicinone (DN), and doxorubicinone (AN) with $C_{18}$ bonded silica gel, methanol–0.005 M heptanesulfonic acid aqueous solution (62.5:37.5), pH 3.5, and flow rate of 2 ml/min. Numbers indicate retention times in minutes.*

**Apparatus**—A modular high-pressure liquid chromatograph[6] was equipped with a constant-flow pump, a valve-type injector[7], and a 254-nm fixed-wavelength detector[8]. Data were recorded and reduced by a microprocessor[9] set for peak area calculations at a chart speed of 0.5 cm/min and attenuation of 128.

**Chromatographic Conditions**—A 25-cm × 4.6-mm i.d. stainless steel column, packed with 10-μm particle-size $C_{18}$ reversed-phase packing material[10], was used for all assays. The isocratic mobile phase consisted of 650 ml of methanol and 350 ml of water to which was added 1.15 g of monobasic ammonium phosphate dissolved in 5 ml of acetic acid (final pH 4.0). The mobile phase was filtered through a 0.2-μm filter and degassed by vacuum for 20 min. The flow rate was 2 ml/min, which produced a pressure of ~1600 psi. All separations were performed at ambient temperature. A 5-μl sample was injected into the chromatograph.

Before the assay was begun, a resolution factor for the system was determined at ambient temperature with a flow rate of 1.0 ml/min. To facilitate measurements of peak width, the detector was set to give at least 50% response full scale and a chart speed of 2 cm/min. The column was purged with mobile phase until a steady baseline was established. Then 5 mg of doxorubicin and 5 mg of doxorubicinone were accurately weighed into a 10-ml volumetric flask and diluted to volume with methanol. Then 5 μl of this solution was injected into the chromatograph. The retention time for the doxorubicin and the doxorubicinone peaks should be ~470 and 600 sec, respectively.

The resolution factor ($R_s$) is calculated as follows:

$$R_s = 2(t_2 - t_1)/(W_1 + W_2) \qquad \text{(Eq. 1)}$$

where $(t_2 - t_1)$ is the difference in retention times measured in centimeters at peak maxima between the doxorubicin and the doxorubicinone peaks and $W_2$ and $W_1$ are the peak widths at the base of the peaks in centimeters.

A resolution factor of 2.2 is recommended. Experiments evaluated in statistical terms were performed eight to 10 times each.

**Sample Preparation**—*Vials*—To obtain a concentration of 0.5 mg/ml, the finished products were diluted as follows: 4, 8, or 10 ml of methanol was added to a 10-, 20-, or 50-mg vial, respectively. Then 2, 2, or 1 ml of the resulting solution was transferred to a 10-ml volumetric flask and diluted to volume with methanol. Dilution factors were 20, 40, or 100 ml, respectively. A 5-μl sample size was used. Peak areas of the

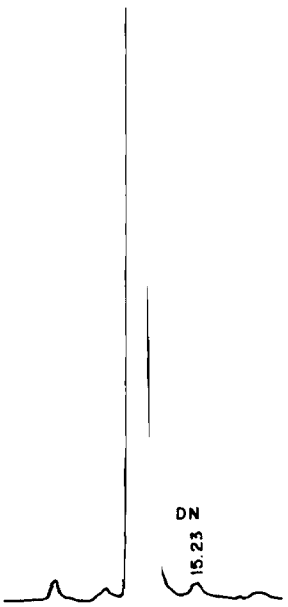

**Figure 3**—*Chromatogram of daunorubicinone estimated at 0.5% of the parent compound with the HPLC conditions given under* Experimental *for estimation of the aglycones. Numbers indicate retention times in minutes.*

samples were compared to those of the standard, and the concentrations were calculated as follows:

$$\text{mg/vial} = \frac{A_u \times W_s \times DF \times P}{A_s \times 1000\ \mu\text{g/mg}} \quad \text{(Eq. 2)}$$

where $A_u$ is area of the sample peak, $W_s$ is milligrams per milliliter of the standard, $DF$ is the dilution factor in milliliters, $P$ is purity of the standard in micrograms per milligram, and $A_s$ is area of the standard peak.

*Bulk Samples*—The standard and bulk samples were diluted with methanol to a concentration of 0.5 mg/ml, and a 5-$\mu$l sample size was used. Peak area data of the bulk samples were compared to those of the standard and calculated as follows:

$$\mu\text{g/mg} = \frac{A_u \times W_s \times P}{A_s \times W_u} \quad \text{(Eq. 3)}$$

where $W_u$ is milligrams per milliliter of the sample.

**Estimation of Aglycones**—The aglycone determination for each drug was developed for the range in which they usually occur in the preparations analyzed (0.5–3.0% of the parent compound). Because of the relatively low aglycone concentrations in the preparations and the limitations of the microprocessor in calculating relatively small areas, the attenuation was changed to 32 and the flow rate was changed to 1.0 ml/min to ensure good precision.

## RESULTS AND DISCUSSION

Optimal HPLC conditions established for this assay consisted of a mobile phase acidity of 3.5–7.0 to ensure a reasonably long column lifetime, a turnaround time of <15 min to enable high productivity, and a resolution factor of at least 2.0 for accurate quantitation.

Figure 1 shows the optimum HPLC profile achieved with the best ammonium sulfate solvent system. The pH was 4.0 and retention times for the last appearing peaks were 8 and 15 min at 2- and 1-ml/min flow rates, respectively. The resolutions for the first two peaks were 2.4 (Fig. 1*a*) and 2.7 (Fig. 1*b*) at 2- and 1-ml/min flow rates, respectively. Figure 2 shows the optimum HPLC profile achieved with the heptanesulfonic acid system. The separation time was slightly over 10 min, the pH was 3.5, and the resolution was 2.1 for the first two peaks with a 2-ml/min flow rate. No correlation between resolution and pH, flow rate (column pressure), or percent methanol could be found for either solvent system. However, the resolution was generally poorer at higher pH values.

Since the ammonium sulfate solvent system at pH 4.0 and 65% methanol gave slightly superior resolution and acidity than the heptanesulfonic acid solvent system, it was used for the rest of the study. This system was evaluated for quantitative estimation of doxorubicin, daunorubicin, and their aglycones. The aglycones were assayed at low levels relative to the parent compound since pharmaceutical preparations contain small amounts of these substances.

**Table I—Comparative Results by the Ammonium Sulfate and the CFR Methods**

| Sample | Ammonium Sulfate Method | | CFR Method | |
|---|---|---|---|---|
| | % | μg/mg | % | μg/mg |
| Standard | 100.0 | 912 | 100.0 | 912 |
| Sample A: 1 | 97.5 | 889 | 97.6 | 890 |
| 2 | 97.8 | 892 | 97.5 | 890 |
| 3 | 98.2 | 896 | 98.7 | 901 |
| Sample B: 1 | 98.7 | 900 | 98.0 | 894 |
| 2 | 97.9 | 893 | 97.7 | 891 |
| 3 | 98.1 | 896 | 99.2 | 904 |
| Sample C: 1 | 98.0 | 894 | 99.6 | 908 |
| 2 | 96.2 | 879 | 97.0 | 885 |
| 3 | 97.9 | 892 | 99.1 | 904 |

Doxorubicin was assayed in the 1–5-μg/injection range. There is a linear relation between the peak area and the quantity of doxorubicin injected within this range. A standard curve must be determined for every combination of parameters. The standard deviation of these results was 0.71%, and the coefficient of variation was 1.65%. Similar results, a standard deviation of 0.77% and a coefficient of variation of 1.27%, were obtained for daunorubicin.

Doxorubicin preparations are dispensed in 10- and 50-mg vials. Daunorubicin is obtained as a bulk preparation or in 20-mg vials. Both drugs are dissolved in methanol to obtain a 0.5-mg/ml solution, and a 5-μl sample is injected. The content of the vials can be calculated as shown in the *Experimental* section.

The precision for the estimation of doxorubicinone in the presence of a relatively large amount of doxorubicin and of daunorubicinone in the presence of a relatively large quantity of daunorubicin, expressed as standard deviation, is 1.27%. A linear relationship is shown between peak area data and the quantity of the algycones injected. Assay of these aglycones in either preparation is possible under these experimental conditions provided a standard curve is determined for each new combination of parameters. Figure 3 shows a chromatogram of the assay of daunorubicinone at 0.5% of the parent compound.

Several pharmaceutical preparations were assayed by the new ammonium sulfate method, and the results (Table I) were compared to those obtained by the CFR method, which uses an internal standard. Comparison of these data shows that results fall within a desirable range and that the proposed new method produces assay values comparable to those found by the official method. The average coefficient of variation is 0.70% for these measurements. The aglycone content was also determined for two bulk preparations used in this study; Samples A and B contained 0.34 and 0.49% daunorubicinone, respectively.

# Extended Hildebrand Solubility Approach: Methylxanthines in Mixed Solvents

**A. MARTIN *x, A. N. PARUTA ‡, and A. ADJEI ***

Received July 24, 1980, from the **Drug Dynamics Institute, College of Pharmacy, University of Texas, Austin, TX 78712*, and the ‡*College of Pharmacy, University of Rhode Island, Kingston, RI 02881.* Accepted for publication March 16, 1981.

**Abstract** □ The solubility profiles of theobromine, theophylline, and caffeine at 25° were examined in binary solvent systems including dioxane–formamide, water–polyethylene glycol 400, and glycerin–propylene glycol. Theobromine solubility was studied in dioxane–water mixtures, a solvent system that was investigated earlier for the solubility of theophylline and caffeine. Solubilities were calculated in these polar systems by a regression method, based on an extension of the Hildebrand–Scatchard equation of regular solution theory. A linear relationship between the mixed solvent solubility parameter, $\delta_1$, and dielectric constant, $\epsilon$, was introduced earlier and was confirmed in the present study. In addition, it was observed that a regression of log(activity coefficient) on $\epsilon$ in a second or higher degree polynomial provides reasonable solubility values for the methylxanthines in mixed solvents. A direct regression of molal or mole fraction (but not molar) solubility against $\delta_1$, $\epsilon$, or against volume percent of one or the other solvent in a binary solvent mixture provided a suitable measure of solubility for these crystalline drugs in mixed polar solvents. The drug's solubility parameter as determined from peak solubility in mixed polar solvents varied somewhat, depending on the specific solvent system employed. It is suggested that a drug may exhibit one (or more) solubility parameters in nonpolar solutions and multiple solubility parameters in polar systems. The extended solubility approach serves for the back-calculation of solubilities in mixed solvent systems, even though the solubility parameter of the solute may vary from one solvent system to the next.

**Keyphrases** □ Methylxanthines—solubility profiles using extended Hildebrand–Scatchard equation □ Solubility—methylxanthines in mixed solvents, extended Hildebrand–Scatchard equation □ Hildebrand–Scatchard equation—modified, solubility profiles of methylxanthines in mixed solvents

Previous reports (1–3) introduced an approach to estimate the solubility of drugs in mixed and pure solvent systems. The method employs the equation:

$$-\log X_2 = \frac{\Delta S^f_m}{R}\log\frac{T_m}{T} + \frac{V_2\phi_1^2}{2.303RT}(\delta_1-\delta_2)^2 + \frac{V_2\phi_1^2}{2.303RT}2(\delta_1\delta_2 - W) \quad \text{(Eq. 1a)}$$

or:

$$-\log X_2 = \frac{\Delta S^f_m}{R}\log\frac{T_m}{T} + \frac{V_2\phi_1^2}{2.303RT}(\delta_1^2+\delta_2^2-2W) \quad \text{(Eq. 1b)}$$

where $X_2$ is the mole fraction solubility of the drug, $\Delta S^f_m$ is the entropy of fusion, $R$ is the molar gas constant, $T_m$ is the melting point of the compound in Kelvin degrees, $T$ is the absolute temperature at which the solubility is measured, $V_2$ is the molar volume of the drug as a hypothetical supercooled liquid solute at temperature $T$, $\phi_1$ is the volume fraction of the solvent, $\delta_1$ and $\delta_2$ are the solubility parameters of the solvent and solute, and $W$ is the solute–solvent interaction energy. Subscript 1 is used for solvent and subscript 2 for solute. The $W$ value is computed for the drug in each solvent mixture, using Eq. 1*b*. It may, in turn, be back-calculated employing a power series regression in $\delta_1$ to estimate mole fraction or molal solubilities. By knowing the density of the solution at a particular temperature, it is also possible to convert these calculations to molar solubilities. The term $V_2\phi_1^2/2.303RT$ is designated in this study by the symbol $A$. The present work tests the extended Hildebrand solubility approach (as this method is called) with various binary solvent mixtures.

## EXPERIMENTAL

The sources and treatment of methylxanthines and some of the solvents used were given previously (2, 3)[1]. Additional solvents employed in the present study were propylene glycol[2], polyethylene glycol 400[2], and glycerin[2]. Pertinent physicochemical properties of the xanthine derivatives are recorded in Table I. The solubilities of the drugs were determined in a shaker bath employing 20-ml screw-capped vials containing an excess of the drug at 25 ± 0.2°. Equilibrium occurred well before 96 hr. Samples were withdrawn after 96 hr and filtered through a 0.22-$\mu$m filter, and aliquots were removed and diluted for spectrophotometric assay. Runs were carried out in quadruplicate, and the four results were averaged. Densities of the saturated solutions and of the solvent mixtures were determined in quadruplicate at 25 ± 0.2° in 10-ml pycnometers.

## RESULTS AND DISCUSSION

Theobromine was dissolved in mixtures of dioxane and water at 25°. The solubility profile is shown in Fig. 1. Table II contains the data used to plot the back-calculation line of Fig. 1, including $W_{calc}$ and $A$ values. Solution densities and dielectric constants are also recorded in Table II.

**Ideal Solubility in Relation to Maximum Solubility in Real Systems**—The ideal mole fraction solubility of theobromine at 25° is 0.0029, a value well below the ideal solubilities of theophylline (0.0190) and caffeine (0.0685) at 25° (Table I and Fig. 1) because of the greater $\Delta H^f_m$ value and high melting point (348°) of theobromine. The peak solubility of theobromine in the best dioxane–water mixture (~70% dioxane) is well below ideal solubility (Fig. 1), as observed previously for caffeine and theophylline. This phenomenon was noted by Gordon and Scott (4) and by others (5, 6). Scatchard *et al.* (7) observed that the value of $C_{12}$ (an-

[1] Reference 2 states that mean molar volumes of the binary solvent mixtures are calculated from Eq. 17, in which each molecular weight was multiplied by the mole fraction of that solvent in the mixture. This is an error; the quantity used in Refs. 2 and 3 and in the present study is volume fraction rather than mole fraction.

# Extended Hildebrand Solubility Approach: Methylxanthines in Mixed Solvents

**A. MARTIN *x, A. N. PARUTA ‡, and A. ADJEI ***

Received July 24, 1980, from the **Drug Dynamics Institute, College of Pharmacy, University of Texas, Austin, TX 78712*, and the ‡*College of Pharmacy, University of Rhode Island, Kingston, RI 02881.* Accepted for publication March 16, 1981.

**Abstract** □ The solubility profiles of theobromine, theophylline, and caffeine at 25° were examined in binary solvent systems including dioxane–formamide, water–polyethylene glycol 400, and glycerin–propylene glycol. Theobromine solubility was studied in dioxane–water mixtures, a solvent system that was investigated earlier for the solubility of theophylline and caffeine. Solubilities were calculated in these polar systems by a regression method, based on an extension of the Hildebrand–Scatchard equation of regular solution theory. A linear relationship between the mixed solvent solubility parameter, $\delta_1$, and dielectric constant, $\epsilon$, was introduced earlier and was confirmed in the present study. In addition, it was observed that a regression of log(activity coefficient) on $\epsilon$ in a second or higher degree polynomial provides reasonable solubility values for the methylxanthines in mixed solvents. A direct regression of molal or mole fraction (but not molar) solubility against $\delta_1$, $\epsilon$, or against volume percent of one or the other solvent in a binary solvent mixture provided a suitable measure of solubility for these crystalline drugs in mixed polar solvents. The drug's solubility parameter as determined from peak solubility in mixed polar solvents varied somewhat, depending on the specific solvent system employed. It is suggested that a drug may exhibit one (or more) solubility parameters in nonpolar solutions and multiple solubility parameters in polar systems. The extended solubility approach serves for the back-calculation of solubilities in mixed solvent systems, even though the solubility parameter of the solute may vary from one solvent system to the next.

**Keyphrases** □ Methylxanthines—solubility profiles using extended Hildebrand–Scatchard equation □ Solubility—methylxanthines in mixed solvents, extended Hildebrand–Scatchard equation □ Hildebrand–Scatchard equation—modified, solubility profiles of methylxanthines in mixed solvents

Previous reports (1–3) introduced an approach to estimate the solubility of drugs in mixed and pure solvent systems. The method employs the equation:

$$-\log X_2 = \frac{\Delta S^f_m}{R}\log\frac{T_m}{T} + \frac{V_2\phi_1^2}{2.303RT}(\delta_1-\delta_2)^2 + \frac{V_2\phi_1^2}{2.303RT}2(\delta_1\delta_2 - W) \quad \text{(Eq. 1a)}$$

or:

$$-\log X_2 = \frac{\Delta S^f_m}{R}\log\frac{T_m}{T} + \frac{V_2\phi_1^2}{2.303RT}(\delta_1^2+\delta_2^2-2W) \quad \text{(Eq. 1b)}$$

where $X_2$ is the mole fraction solubility of the drug, $\Delta S^f_m$ is the entropy of fusion, $R$ is the molar gas constant, $T_m$ is the melting point of the compound in Kelvin degrees, $T$ is the absolute temperature at which the solubility is measured, $V_2$ is the molar volume of the drug as a hypothetical supercooled liquid solute at temperature $T$, $\phi_1$ is the volume fraction of the solvent, $\delta_1$ and $\delta_2$ are the solubility parameters of the solvent and solute, and $W$ is the solute–solvent interaction energy. Subscript 1 is used for solvent and subscript 2 for solute. The $W$ value is computed for the drug in each solvent mixture, using Eq. 1*b*. It may, in turn, be back-calculated employing a power series regression in $\delta_1$ to estimate mole fraction or molal solubilities. By knowing the density of the solution at a particular temperature, it is also possible to convert these calculations to molar solubilities. The term $V_2\phi_1^2/2.303RT$ is designated in this study by the symbol $A$. The present work tests the extended Hildebrand solubility approach (as this method is called) with various binary solvent mixtures.

## EXPERIMENTAL

The sources and treatment of methylxanthines and some of the solvents used were given previously (2, 3)[1]. Additional solvents employed in the present study were propylene glycol[2], polyethylene glycol 400[2], and glycerin[2]. Pertinent physicochemical properties of the xanthine derivatives are recorded in Table I. The solubilities of the drugs were determined in a shaker bath employing 20-ml screw-capped vials containing an excess of the drug at 25 ± 0.2°. Equilibrium occurred well before 96 hr. Samples were withdrawn after 96 hr and filtered through a 0.22-$\mu$m filter, and aliquots were removed and diluted for spectrophotometric assay. Runs were carried out in quadruplicate, and the four results were averaged. Densities of the saturated solutions and of the solvent mixtures were determined in quadruplicate at 25 ± 0.2° in 10-ml pycnometers.

## RESULTS AND DISCUSSION

Theobromine was dissolved in mixtures of dioxane and water at 25°. The solubility profile is shown in Fig. 1. Table II contains the data used to plot the back-calculation line of Fig. 1, including $W_{calc}$ and $A$ values. Solution densities and dielectric constants are also recorded in Table II.

**Ideal Solubility in Relation to Maximum Solubility in Real Systems**—The ideal mole fraction solubility of theobromine at 25° is 0.0029, a value well below the ideal solubilities of theophylline (0.0190) and caffeine (0.0685) at 25° (Table I and Fig. 1) because of the greater $\Delta H^f_m$ value and high melting point (348°) of theobromine. The peak solubility of theobromine in the best dioxane–water mixture (~70% dioxane) is well below ideal solubility (Fig. 1), as observed previously for caffeine and theophylline. This phenomenon was noted by Gordon and Scott (4) and by others (5, 6). Scatchard *et al.* (7) observed that the value of $C_{12}$ (an-

[1] Reference 2 states that mean molar volumes of the binary solvent mixtures are calculated from Eq. 17, in which each molecular weight was multiplied by the mole fraction of that solvent in the mixture. This is an error; the quantity used in Refs. 2 and 3 and in the present study is volume fraction rather than mole fraction.

other symbol used for $W$) was 5% greater than $\delta_1\delta_2$ for benzene in methanol at 0.5 mole fraction and 8% greater than $\delta_1\delta_2$ for carbon tetrachloride in methanol, signifying strong solute–solvent interaction in these mixtures. The mole fraction solubility of theobromine in the optimum water–dioxane mixture is 0.00075 or 74% below ideal (Fig. 1) suggesting self-association of solvent, solute, or both.

The differences, Δ, between ideal and actual interaction energies of the three methylxanthines in these optimum mixtures are given in Table III. The solute–solvent interaction energy, $W$, is included together with

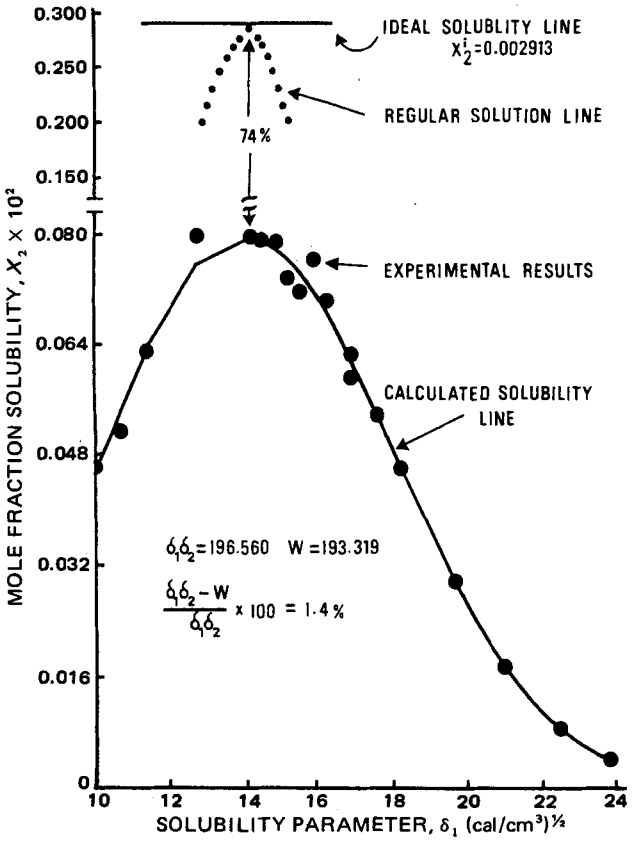

**Figure 1**—*Mole fraction solubility of theobromine in dioxane–water mixtures at 25°. Key: • • •, peak region of the regular solution curve; ●, observed solubilities; and —, back-calculated solubility using Eq. 2a of Table IV.*

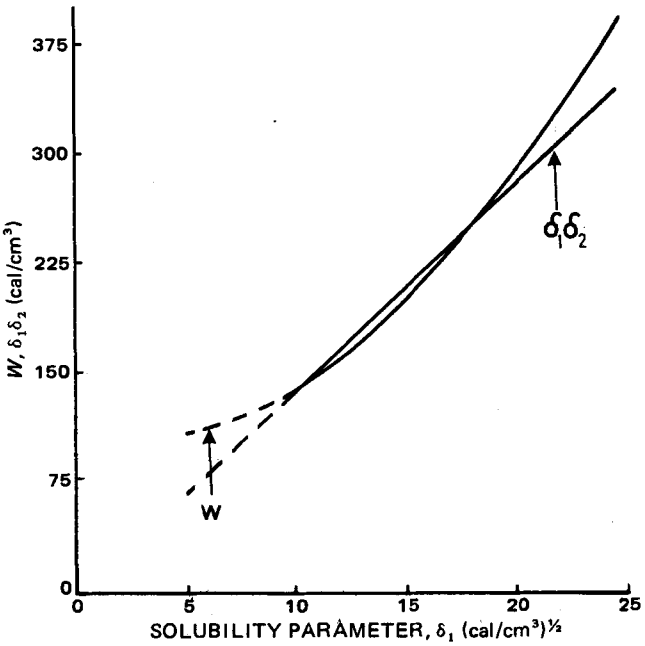

**Figure 2**—*Relationship of* W *and* $\delta_1\delta_2$, *for theophylline in dioxane* ($\delta_1$ = *10.0) and water* ($\delta_2$ = *23.5) mixture at 25°.*

$\delta_1\delta_2$, the interaction term that would be applicable if the systems behaved as regular solutions. The ratio, $K$, of $W$ to $\delta_1\delta_2$ at peak solubility is found in the last column of Table III. These data indicate that a difference of 1.4% between the geometric mean $\delta_1\delta_2$ and $W$ results in a 74% decrease in expected solubility for theobromine in dioxane–water.

Figure 2 shows the slightly curved line obtained when $W$ is plotted against $\delta_1$. The geometric mean, $\delta_1\delta_2$, is plotted on the same graph against $\delta_1$ to depict graphically the relationship of $W$ to $\delta_1\delta_2$ for theophylline across the mixtures of dioxane ($\delta_1$ = 10.0) to water ($\delta_1$ = 23.5). This small difference in interaction energy, ($\Delta = \delta_1\delta_2 - W$) of Eq. 1*a*, in xanthine–dioxane–water systems accounts for the fact that maximum solubility of the real system does not reach $X_2^i$, the ideal value of peak solubility.

The extended Hildebrand equation differs from the Hildebrand equation in the use of $W$ to replace $\delta_1\delta_2$, and Fig. 2 provides a graphical demonstration of why the original Hildebrand approach cannot be used to estimate solubilities of drugs in polar solvent mixtures. In Fig. 2, $\delta_1\delta_2$

[a] Data selected from solubilities determined at 25° using 18 solvent mixtures. [b] Calculated solubilities obtained by regressing $W$ *versus* $\delta_1$ in a third-degree power series (cubic). The cubic equation is Eq. 3*a* of Table IV. Essentially the same $X_{2_{calc}}$ values are obtained by regressing $W$ or log $\alpha_2/A$ on $\phi_w$ using Eq. 8*a* or 8*b* or by regressing $W$ or log $\alpha_2/A$ on $\epsilon_1$ (equations not shown). [c] $\delta_2 = 14.0$ (cal/cm$^3$)$^{1/2}$. [d] $X_2^i = 0.002913$, $-\log X_2^i = 2.5357$, $\Delta H_m^f = 9819$ cal/mole, $\Delta S_m^f = 15.81$ eu, and $V = 124$ ml/mole. [e] $V_2\phi_1^2/2.303RT$. [f] Solubility parameter obtained from Ref. 24 and by use of Eq. 14 of Ref. 2. [g] Experimentally determined dielectric constants of solvent mixtures at 25°.

is linear across the range of $\delta_1$ values while the correct value, $W$, produces a curve that passes through the $\delta_1\delta_2$ line. Only at two points where the straight line intersects the curve may the Hildebrand $\delta_1\delta_2$ values be used satisfactorily to predict the drug solubility.

**Predicting Solubility Using Regression Analysis**—As with theophylline and caffeine, theobromine solubility may be depicted using the extended solubility approach, *i.e.*, the regression of $W$ or log $\alpha_2/A$ on $\delta_1$ in a power series as reported earlier (1–3). The appropriate second degree (quadratic), third degree (cubic), and fourth degree (quartic) equations for theobromine in dioxane–water at 25° are given in Table IV. The solid line in Fig. 1, representing back-calculated solubilities of theobromine in dioxane–water mixtures, was obtained with Eq. 2*a* and demonstrates a good fit to experimental data. As observed in Eqs. 2*a*, 3*a*, and 4*a* of Table IV, when regressing $W$ *versus* $\delta_1$, five or six places should be retained after the decimal point for satisfactory results. In the log $\alpha_2/A$ *versus* $\delta_1$ equations (Eqs. 2*b*, 3*b*, and 4*b*), five or six places after the decimal points are also needed. The same remarks apply to Eqs. 5 and 6 of Table V. In Eqs. 8*a* and 8*b*, three places after the decimal point are adequate.

The question of when it is appropriate to use a quadratic *versus* a cubic or quartic equation is not easily answered without an analysis of variance. Statistical analysis of the solubility data will be presented in a separate report. Use of the extended solubility approach has shown that the data of some solubility studies (*e.g.*, theobromine in dioxane–water, Table II and Fig. 1) are satisfactorily reproduced with a quadratic equation. The solubility of caffeine in dioxane–water was better reproduced using a cubic equation and, for added refinement, a quartic equation (3). A fifth-degree equation was not necessary in any case studied thus far.

**Methylxanthines in Other Solvent Systems**—To examine the extended solubility approach in mixed solvents other than dioxane–water, solubilities of the three methylxanthines were measured at 25° in dioxane–formamide (Fig. 3), glycerin–propylene glycol (Fig. 4), and polyethylene glycol 400–water mixtures (Fig. 5). The quadratic regression equations of $W$ *versus* $\delta_1$ and log $\alpha_2/A$ *versus* $\delta_1$ used to obtain the back-calculated curves of Figs. 3 and 4 are found in Table V (Eqs. 5 and 6).

The original Hildebrand equation (4, 8) predicts that the solubility of a compound, the solubility parameter of which lies between the $\delta$ values of the two solvents of a binary mixture, will exhibit a peak where the solubility parameter of the mixed solvent, $\delta_1$, equals that of the solute, $\delta_2$. When $\delta_2$ of the solute is found on one side or the other of the solubility parameters of pure liquids that are combined to form the solvents, no peak is expected. For example, maximum solubility of theophylline is not found in the mixture of propylene glycol ($\delta_1 = 15.0$) and glycerin ($\delta_1 = 17.7$) since the solubility parameter of theophylline ($\delta_2 = 14.0$) does not fall between the $\delta$ values of these two solvents. However, this fact does not prevent the use of the extended Hildebrand solubility approach to calculate solubilities in solvent combinations such as glycerin and propylene glycol (Fig. 4).

**Solvation**—The solubilities of the three xanthines reach maxima below the ideal solubilities in dioxane–water mixtures. This failure to attain ideal solubility was attributed to solvent clustering (4), but a satisfactory explanation on a molecular basis has not been provided.

Solubility in excess of the ideal value is generally accepted as a manifestation of complexation between the solute and solvent and is commonly called solvation. Theophylline in the binary solvent of polyethylene glycol 400–water provides an example of solvation. Here the solubility rises to a maximum value of $X_2 = 0.0309$ (Fig. 5). In contrast to $W$ values for the xanthines in dioxane–water mixtures (Table III), $W$ for theophylline in polyethylene glycol 400–water is greater than $\delta_1\delta_2$ at maximum solubility. The $K$ value, which is equal to $W/\delta_1\delta_2$, is 1.0074 in this case.

The percent difference between maximum actual and ideal mole fraction solubility for theophylline in polyethylene glycol 400–water is 63%, whereas the difference, $\Delta = \delta_1\delta_2 - W$, is only 0.7%. Comparison of these results with the values in Table III again demonstrates that a very small difference between $\delta_1\delta_2$ and $W$ may result in a large difference between ideal and actual solubilities.

Thus, for real systems, drug solubility maxima in mixed solvents may be greater than, equal to, or less than ideal solubility, and $K = W/\delta_1\delta_2$ may have values greater than, equal to, or less than unity. When $K = 1.0$, a solution cannot necessarily be referred to as regular. In polar systems, the condition $W = \delta_1\delta_2$ may arise more or less by chance as observed in Fig. 2, where the $\delta_1\delta_2$ lines crosses $W$ at two points owing, perhaps, to a balancing of opposing intermolecular forces; thus, the conditions set forth by Hildebrand (8) for a regular solution would not obtain.

For solubilities greater than ideal, the sign of the logarithmic activity coefficients becomes negative ($\alpha_2 < 1$), and the computer program used to obtain $W_{calc}$ must take this fact into account. The $W$ calculated by regression always yields a positive log $\alpha_2$, and the computer is pro-

**Table III—Comparison of Observed Peak and Ideal Solubility Values of Caffeine, Theophylline, and Theobromine in Dioxane–Water Mixtures at 25°**

| Compound | $\delta_2$, (cal/cm$^3$)$^{1/2}$ | Ideal Solubility $X_2^i$ | Observed Peak Solubility $X_2$ | $\frac{X_2^i - X_2}{X_2^i} \times 100\%$ | $\delta_1\delta_2$ (cal/cm$^3$) | W, (cal/cm$^3$) | $\Delta$ [a] $= \delta_1\delta_2 - W$ (Percent Difference) | $K$ [a] $= W/\delta_1\delta_2$ |
|---|---|---|---|---|---|---|---|---|
| Caffeine | 13.8 | 0.0685 | 0.0282 | 59% | 193.200 | 191.715 | 1.485 (0.8%) | 0.9923 |
| Theophylline | 14.0 | 0.0190 | 0.0144 | 24% | 204.400 | 203.590 | 0.810 (0.4%) | 0.9960 |
| Theobromine | 14.0 | 0.0029 | 0.00075 | 74% | 196.000 | 193.319 | 2.681 (1.4%) | 0.9863 |

[a] The quantity $K$ was first suggested by E. Walker, J. Appl. Chem., 2, 470 (1952). The large differences between $X_2$ and $X_2^i$ resulting from very small differences $\Delta$ between $W$ and $\delta_1\delta_2$ were pointed out by Walker for polymer solutions.

grammed to reverse this sign when the calculated solubility $X_2$ is greater than $X_2^i$.

**Solubility Parameters and Dielectric Constant**—Other investigators (9–12) studied the solubility of methylxanthines and other classes of drugs as a function of the dielectric constants, $\epsilon_1$, of pure and mixed solvents. Employing 25 solvents of known $\delta_1$ and $\epsilon_1$ values, Paruta *et al.* (13) obtained:

$$\delta_1 = 7.5 + 0.22\epsilon_1 \qquad \text{(Eq. 9)}$$

to relate solvent solubility parameters to the solvent dielectric constant. The work leading to Eq. 9 (13) was repeated in the present study, regressing $\delta_1$ values of 35 liquids from various classes against dielectric constants obtained from a standard reference source (14), and the following was obtained:

$$\delta_1 = 8.3 + 0.19\epsilon_1 \qquad \text{(Eq. 10)}$$

In the particular series used in the current solubility analysis, $\delta_1$ values were regressed for each class of solvent against $\epsilon_1$ values. The resulting expression, Eqs. 11–13, with appropriate coefficients are found in Table VI. These linear expressions allow the conversion from $\delta_1$ to $\epsilon_1$ and vice versa in mixed solvent systems when studying solubility profiles expressed in terms of either solubility parameters or dielectric constants. While Eqs. 9 and 10 do not provide exact correspondence between $\delta_1$ and $\epsilon_1$ in specific solvent systems as do Eqs. 11–13, they do afford simple relationships for quick conversion between $\delta_1$ and $\epsilon_1$.

Since $\delta_1$ and $\epsilon_1$ are linearly related, it should be possible to regress log $\alpha_2/A$ or $W$ in a power series against $\epsilon_1$; $W$ and log $\alpha_2/A$ are regressed *versus* $\epsilon_1$ for theophylline in polyethylene glycol 400–water mixtures (Eqs. 7, Table V). The back-calculated solubility curve, Eq. 7b, for theophylline in this mixed solvent system is shown in Fig. 5. Figure 5 demonstrates that results showing mole fraction or molal solubility plotted against dielectric constant may be calculated using the extended solubility approach. Eq. 7b gives better results than Eq. 7a.

**Volume Fraction and Molar Volume**—However, neither $\delta_1$ nor $\epsilon_1$ are necessary to predict solubility. An earlier report (3) demonstrated that $W$, $\delta_1$, and $\delta_2$ may be by-passed and that a drug's solubility in a binary solvent may be back-calculated at a particular temperature based only on the volume fraction or percent of one solvent in another. (Molar

[a] Values in parentheses are ±1 *SE*.

volume of the solvent mixture may also be regressed against log $\alpha_2/A$ to reproduce experimental solubilities.) For theobromine in pure dioxane, pure water, and mixtures of this solvent pair, an equation relating log $\alpha_2/A$ and $\phi_w$, the volume fraction of water, is given as Eq. 8*b* in Table V. The log $\alpha_2/A$ and volume percent of water required for this calculation are found in Table II. With the value of $A$ (Table II) at a solvent volume fraction, *e.g.*, 0.40 or 40% water, log $\alpha_{2_{calc}} = 0.61427$ is obtained. This term, together with $-\log X_2^i = 2.5357$, yields $-\log X_2$. Changing the sign and taking the antilog provide the predicted solubility, $X_2 = 7.08 \times 10^{-4}$ at 25° for theobromine in water–dioxane mixtures having a $\delta_1$ value fo 15.39 and a dielectric constant of 27.46 (40% water–60% dioxane); $X_{2_{obs}}$ is equal to $6.74 \times 10^{-4}$. If one wishes to obtain the drug's solubility at another temperature, both $-\log X_2^i$ and $A$ will have new values. Densities of the solutions will also change with temperature.

If only molal or weight percent solubility data are accessible, together with volume percent of the liquids in a binary solvent, ideal solubility and $A$ values being lacking, quadratic equations can be obtained by regressing concentrations *versus* $\delta_1$, $\epsilon_1$, or $\phi_w$ to give fairly accurate back-calculations of solubility across the entire range of the solvent mixture. If the solubility is expressed in molarity, however, the method cannot be used directly. Instead, densities must be used to convert molarity to molality or mole fraction before regression *versus* $\delta_1$, $\epsilon_1$, or the solvent volume fraction can be conducted.

**Multiple Solubility Parameters of a Solute**—The peak solubility of caffeine in dioxane–formamide (Fig. 3) is found at a solvent $\delta_1$ value of 12, rather than the value of 13.8 observed for caffeine in dioxane–water systems. If the point of maximum solubility, where $\delta_1 \cong \delta_2$, is taken as a definition of $\delta_2$ for the drug molecule, then two $\delta$ values (12.0 and 13.8) must be accepted for caffeine. Other workers observed more than one solubility parameter for a solute. Hildebrand and Scott (15) found it necessary to adjust the $\delta_2$ value of iodine from 13.1 to 14.9 to account for variations in solute characteristics in some nonpolar and polar solvents; the solubility parameter ordinarily reported for iodine is 14.1. On investigating the solubility of sulfur in various solvents, Hildebrand and Scott (16) reported $\delta_2$ values for sulfur from ~11.5 to 14.5, although most of the values were in the 12–13 range.

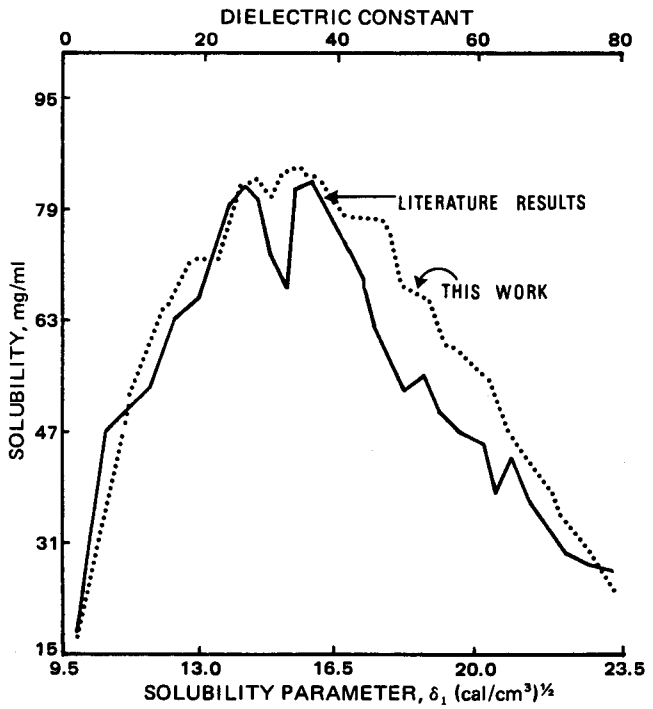

**Figure 6**—*Caffeine in dioxane–water mixtures at 25°. Solubility profiles were obtained from two studies (Ref. 2 is this work and Ref. 11 is literature results). The $\delta_2$ value at peak solubility occurs at ~$\delta_1$ = 15.*

Baker (17) found that solvents partitioned between amorphous and crystalline regions of semicrystalline polymers in solution. Based on solubility and swelling studies, he distinguished three distinct solubility parameters for a polymer. For example, the solubility parameters for butyl rubber at 25° were 7.15, 8.46, and 9.51. For atactic polypropylene at 40°, the $\delta_2$ values were 7.01, 8.07, and 9.38. Other reports (11, 12) showed that methylxanthines in various binary solvent systems exhibited peak solubilities at different solvent dielectric constants. Therefore, it is not surprising that the $\delta_2$ of caffeine obtained from peak solubilities in binary solvents varies according to the solvent mixture employed.

Although the studies reported here are preliminary, it appears from current work that drugs exhibit multiple solubility parameters (one or several for the solute in nonpolar and moderately polar solvents and multiple values in highly solvating and complexing solvents). Fortunately, multiple $\delta_2$ values for a drug do not adversely affect the extended solubility approach. The appropriate $\delta_2$ value is obtained from the method of Fedors (18), the maximum in the solubility profile for a dioxane–water system, or a regression method reported elsewhere (19, 20). The solute solubility parameter, $\delta_2$, so determined is then used with $W$ and $\delta_1$ of the solvent mixture to back-calculate solubilities.

The physicochemical phenomenon on which multiple solute values are based is difficult to explain. Hoy (21) suggested that solutes may behave in a "chameleon-like" manner, adapting to the solvent environment in which they are found. For example, carboxylic acids interact through hydrogen bonds with alcohols and water in these highly polar solvents, whereas such acids self-associate in nonpolar solvents. Therefore, the solubility parameters of these solutes would be expected to have different values in various pure and mixed solvents.

The shape and position of the peak in a solubility profile are altered when solubility is plotted as molarity or milligrams per milliliter instead of mole fraction. The solubility profile for caffeine in dioxane–water mixtures, obtained in this work and from the literature (11), is plotted against $\delta_1$ and $\epsilon_1$ in Fig. 6. The solubility values from the two studies vary somewhat but produce essentially the same profiles. The $\delta_2$ value from the peak solubility of a milligrams per milliliter *versus* $\delta_1$ plot, as seen here, would be ~15, as contrasted to a value of 13.8 obtained from a plot of mole fraction solubility of caffeine in dioxane–water mixtures.

## CONCLUSIONS

The extended solubility approach was shown to apply to three methylxanthines, theophylline, caffeine, and theobromine, in a number of binary solvent systems. It was suggested (1–3) that $W$, the solute–solvent interaction energy, may be regressed in a second, third, or fourth degree power series in terms of the pure or mixed solvent solubility parameter, $\delta_1$, to reproduce the experimental solubility curve. Direct regression of log $\alpha_2/A$ on $\delta_1$, together with a knowledge of $A$ and the drug's ideal solubility at the temperature of the experiment, provides a method for accurately reproducing solubilities of drugs in binary solvent mixtures. In an earlier study (3), it was possible to regress log $\alpha_2/A$ on $\phi_i$, where $\phi_i$ is the volume fraction of one of the two solvents in a binary solvent mixture. In the present report, the linear relationship between $\delta_1$ and $\epsilon_1$, first reported by Paruta *et al.* (13), was confirmed for various solvent systems. For the purpose of predicting solubility, it is possible to regress log $\alpha_2/A$ or $W$ directly *versus* $\epsilon_1$ in a quadratic or higher power series, as shown here. These various approaches yield back-calculated mole fraction solubility within experimental error.

The apparent success of the extended Hildebrand solubility approach to date suggests that Eq. 1, an extension of the Hildebrand equation without the restriction of the geometric mean, provides a satisfactory empirical representation for the solubility of drugs in polar binary solvent systems. In this method, $W$ is obtained from solubility data and then back-calculated by regressing $W$ against $\delta_1$, $\phi_i$, or $\epsilon_1$. This technique may not appear to be fruitful in affording *ab initio* predictions of solubilities or providing fundamental information about solvent–solute interaction since solubility data are required for the method. However, the form of the empirical equation appears to be correct for handling relatively polar

as well as nonpolar systems. An effort is being made to obtain $W$ without solubility data, with the possibility of finding a physicochemical basis for $W$ and/or a group contribution method for estimating this solvent–solute interaction term.

It is interesting to observe in Table III and in Figs. 1 and 5 that small (fractional to 1 or 2%) differences between $\delta_1\delta_2$, the geometric mean, and $W$, the correct adhesive energy density, may cause large differences (25–75%) between ideal and real solubilities. It will challenge the investigator to measure and calculate energies within 5–50 cal/mole required for an independent measure of $W$ for accurate estimation of solubilities. The prediction of solubility using $W$ from group contributions would represent a step toward a better understanding of the behavior of drug molecules in polar and nonpolar solvent systems.

# Degradation Kinetics and Mechanism of Aminocephalosporins in Aqueous Solution: Cefadroxil

**AKIRA TSUJI *x, EMI NAKASHIMA *, YOSHIHARU DEGUCHI *, KAZUNORI NISHIDE *, TAKAYOSHI SHIMIZU §, SUMIO HORIUCHI §, KIYOYASU ISHIKAWA §, and TSUKINAKA YAMANA ‡**

Received December 12, 1980, from the **Faculty of Pharmaceutical Sciences and the* ‡*Hospital Pharmacy, Kanazawa University, Takaramachi, Kanazawa 920, Japan,* and the §*Nonclinical Research Laboratories, Bristol Banyu Manufacturing Co., Ltd., Kota-cho, Nukata-Gun, Aichi 444-01, Japan.* Accepted for publication March 3, 1981.

**Abstract** □ The degradation kinetics and mechanism of a new, orally effective cephalosporin derivative, cefadroxil, in aqueous solution were investigated at pH 2.51–11.5 at 35° and ionic strength 0.5. The degradation rates were determined by high-pressure liquid chromatography. At constant pH and temperature, the degradation followed first-order kinetics and a log $k$–pH profile was presented. The shape of the rate–pH profile resembled that for cephalexin or cephradine under the same conditions. Citrate and phosphate buffers enhanced general acid and base catalysis of the degradation. In aqueous solution, cefadroxil was shown to degrade by three parallel reactions: (*a*) intramolecular aminolysis by the C-7 side-chain amino group on the $\beta$-lactam moiety, (*b*) water-catalyzed or spontaneous hydrolysis, and (*c*) $\beta$-lactam cleavage by the nucleophilic attack of hydroxide ion. In neutral and weak alkaline solutions, the main degradation products were two piperazine-2,5-diones and 3-hydroxy-4-methyl-2(5*H*)-thiophenone, the former being formed from Reaction *a*, while the latter arose *via* the degradation pathways of Reactions *b* and/or *c*.

**Keyphrases** □ Cefadroxil—degradation kinetics and mechanism, high-pressure liquid chromatography, pH–rate profile, intramolecular aminolysis to produce piperazinediones, buffer and temperature effects □ Degradation kinetics—cefadroxil, high-pressure liquid chromatography assay, pH–rate profile, intramolecular aminolysis to produce piperazinediones, buffer and temperature effects □ pH–rate profile—cefadroxil, degradation kinetics and mechanism, intramolecular aminolysis to produce piperazinediones, buffer and temperature effects □ Piperazinediones—cefadroxil degradation kinetics and mechanism, intramolecular aminolysis

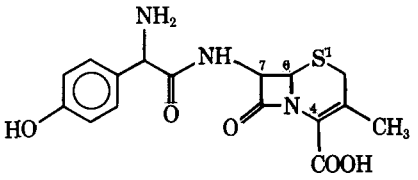
logical conditions was attributed to this phenomenon, its half-life being only ~5 hr. Although cephalexin and cephradine react similarly, they were much more stable than cephaloglycin under the same conditions. Because of the intramolecular aminolysis of these aminocephalosporins in aqueous solution, stable piperazinediones were formed (1–3, 5–7).

This paper describes the degradation kinetics and mechanisms of a new, orally effective cephalosporin antibiotic, cefadroxil (I), which shows essentially the same antibacterial spectrum as cephalexin (8). It is structurally similar to cephalexin, differing only in the hydroxylation of the phenyl side chain.



I

## EXPERIMENTAL[1]

**Materials**—Cefadroxil monohydrate (947 μg/mg) was used without further purification. Buffers and all other chemicals were reagent grade.

**Buffers**—Citrate and phosphate buffers (pH 2.51–5.82 and 6.00–7.20, respectively) were used for the kinetic study. At pH > 7.20, a pH-stat[2] was used to maintain a constant pH. All buffers of the kinetic solutions were adjusted with potassium chloride to an ionic strength of 0.5. The pH was measured[2] at the temperature of the kinetic study.

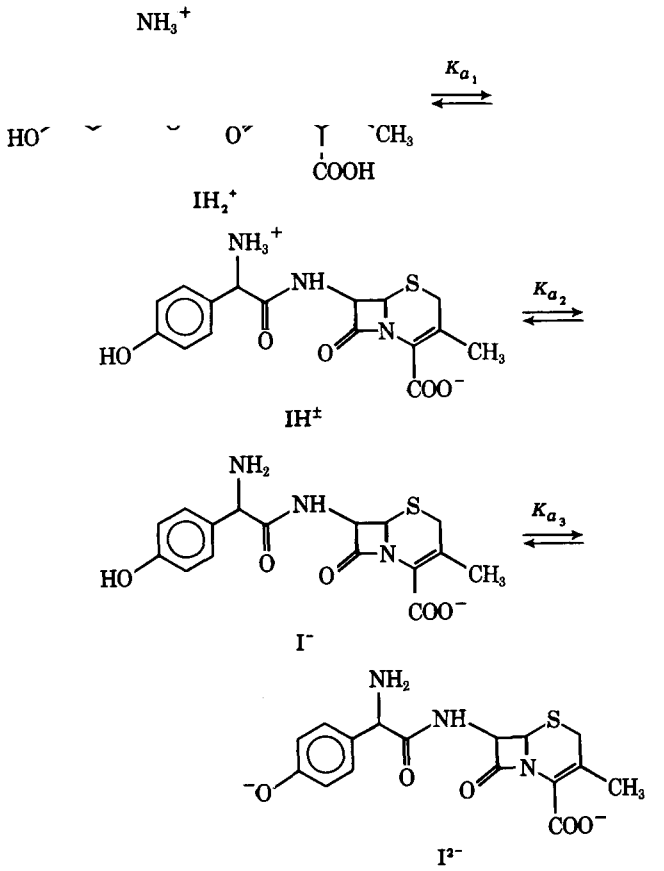
**Kinetic Procedures**—All kinetic experiments were carried out at 35 ± 0.1° and ionic strength 0.5 unless otherwise stated. Accurately weighed cefadroxil was dissolved in an appropriate buffer or 0.5 *M* potassium chloride solution preheated to the desired temperature to give an initial concentration of $5 \times 10^{-3}$ *M*. The fast reaction was performed in a glass-stoppered 100-ml volumetric flask. Where the half-life was >1 day, the degradation buffer solution was sealed in 5-ml ampuls. Samples were withdrawn at suitable intervals, cooled in an ice bath, diluted with distilled water if necessary, and analyzed.

The degradation rate of cefadroxil was followed by measuring the remaining drug concentration by a reversed-phase high-pressure liquid chromatographic (HPLC) method. In addition to the HPLC determination of the overall degradation rate of cefadroxil, the decrease in the concentration of the primary amino group in cefadroxil during the degradation was followed by a colorimetric assay.

**Analytical Procedures**—*HPLC*—The liquid chromatograph[3] was equipped with a UV detector[4] set at 254 nm and a 4.0 × 300-mm stainless steel column prepacked with octadecylsilane chemically bonded on totally porous silica gel[5]. The mobile phase was 2% (or 3%) acetonitrile–98% (or 97%) 0.01 *M* ammonium acetate aqueous solution. Chromatography was performed at ambient temperatures, and samples were eluted at a flow rate of 2 ml/min. Peak heights were measured, and the concentrations were calculated from the calibration curves obtained daily.

*Colorimetric Assay*—The primary amino group was quantitated by using the trinitrobenzenesulfonic acid assay of Satake *et al.* (9) in a modified form used previously (3) for cephalexin degradation.

A 500-μl aliquot of the degradation solution containing cefadroxil was added to 2 ml of a 0.2 *M* phosphate buffer at pH 7.6. Thereafter, 2 ml of a 0.2% (w/v) aqueous solution of 2,4,6-trinitrobenezenesulfonic acid was added; after standing for 30 min in darkness at room temperature, the absorbance of the resulting orange solution was measured[6] at 420 nm against a blank consisting of 500 μl of reaction solution without cefadroxil, 2 ml of phosphate buffer, and 2 ml of trinitrobenzenesulfonic acid solution treated similarly.



*Scheme I*

*Determination of Ionization Constants*—The apparent ionization constants, $pK_{a_1}$ and $pK_{a_2}$, for the dissociation of carboxylic acid and the α-ammonium group of cefadroxil (Scheme I) were determined to be 2.64 ± 0.03 and 7.30 ± 0.03, respectively, by the potentiometric titration of 0.01 *M* antibiotic aqueous solution at an ionic strength of 0.5 and 35°. The $pK_{a_3}$ value for the phenolic group of cefadroxil was determined spectrophotometrically (10). The calculation was made from the change in absorbance[6] at 250 nm for $5 \times 10^{-5}$ *M* cefadroxil solution adjusted to ionic strength 0.5 with potassium chloride at various pH values and 35° to give $pK_{a_3} = 9.69 \pm 0.06$.

**TLC**—TLC was conducted on precoated silica gel plates 0.25-mm thick. Developing solvents were: Solvent A, chloroform–ethyl acetate–acetic acid–water (4:4:4:1); Solvent B, methyl isobutyl ketone–acetic acid–water (7:2:1); Solvent C, toluene–butanol–acetic acid–water (4:4:3:1); and Solvent D, ethyl acetate–isopropanol–water (10:7:5). The chromatograms were visualized by exposing the plates to iodine vapor.

**Isolation and Identification of Degradation Products in Basic Aqueous Solution**—Cefadroxil (2.5 g) in 0.1 *M* disodium phosphate solution (50 ml) was kept at 60° for 1 hr at pH 9.1. The reaction mixture gave four spots on TLC. Acidification with dilute hydrochloric acid and subsequent fractionation as shown in Scheme II gave the product II (25 mg) and a mixture of IV and V slightly contaminated with III (370 mg).

*Product II*—Recrystallization from chloroform–hexane yielded the pure compound, mp 118–119.5°; IR: 3370 (OH), 1690 (thiolactone), and 1630 (olefin) $cm^{-1}$; PMR (deuterochloroform): δ 2.09 (s, 3H, $CH_3$), 3.74 (s, 2H, $CH_2$), and 6.10 (s, 1H, OH) ppm; UV (water-methanol, 9:1): $\lambda_{max}$ 246, 255 (shoulder), 246, and 304 nm (0.1 *N* NaOH added).

*Anal.*—Calc. for $C_5H_6O_2S$: C, 46.14; H, 4.65. Found: C, 45.83; H, 4.61.

[1] IR spectra were run in potassium bromide using a Hitachi 215 spectrophotometer. UV spectra were recorded with a Shimadzu UV-300 spectrophotometer. PMR spectra were obtained, unless otherwise stated, in deuterated dimethyl sulfoxide on a Hitachi R-24B (60 MHz) spectrometer with chemical shifts measured relative to tetramethylsilane. Elemental analyses were carried out at the Central Analysis Center, Nagoya City University, Japan. Preparative TLC was conducted on Merck precoated TLC plates (silica gel 60 F254, 0.5- or 2 mm thick). Visualization was done with iodine vapor. Melting points were determined on a heat block melting-point apparatus and are uncorrected.

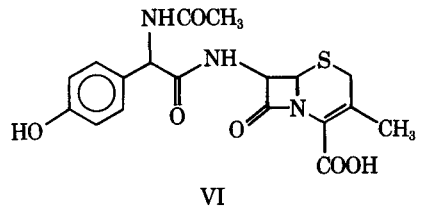
***N*-Acetylcefadroxil (VI)**—A suspension of cefadroxil (3 g) in acetic anhydride (200 ml) was stirred at ambient temperature for 15 hr. The precipitate was filtered and washed with water to yield pure VI (1.7 g, 53.3%) after recrystallization from methanol, mp 217–220° (dec.); IR: 3500–3000 (OH, NH), 1765 (β-lactam), 1735 (shoulder, carboxyl), and 1655 (amide) $cm^{-1}$; PMR: δ 1.88 (s, 3H, acetyl), 1.98 (s, 3H, 3-methyl), 3.0–3.7 (dd, $J$ = 18 Hz, 2H, 2-$CH_2$), 4.93 (d, $J$ = 5 Hz, 1H, 6-CH), 5.4–5.7 (broad, 3H, benzylic and 7-CH), 6.5–7.4 (dd, $J$ = 8 Hz, 4H, aromatic), 8.35 (d, $J$ = 9 Hz, 1H, 7-NH), 9.07 (d, $J$ = 9 Hz, 1H, NH of acetamide), and 9.3 (broad, 1H, phenolic) ppm; UV (water): $\lambda_{max}$ 228 and 263 nm.

*Anal.*—Calc. for $C_{18}H_{19}N_3O_6S$: C, 53.33; H, 4.72; N, 10.36. Found: C, 52.84; H, 4.33; N, 9.94.

## RESULTS AND DISCUSSION

**Order of Degradation and Observed Rate Constants**—The kinetics of cefadroxil degradation was followed by the HPLC method using an appropriate buffer system or a pH-stat to maintain a constant pH. Typical chromatograms of basic (pH 11.50, pH-stat) and neutral (pH 7.20, 0.15 *M* phosphate buffer) reaction mixtures, sampled at suitable time intervals, are shown in Figs. 1 and 2, indicating that the degradation products can be separated from the parent compound. Figure 3 shows the logarithmic plots of the residual cefadroxil concentration *versus* time at pH 11.50 for three different initial concentrations of 1, 5, and $10 \times 10^{-3}$ *M*. The observed pseudo-first-order rate constants were almost identical to the overall degradation of cefadroxil calculated from the slopes and were independent of initial drug concentration.



VI

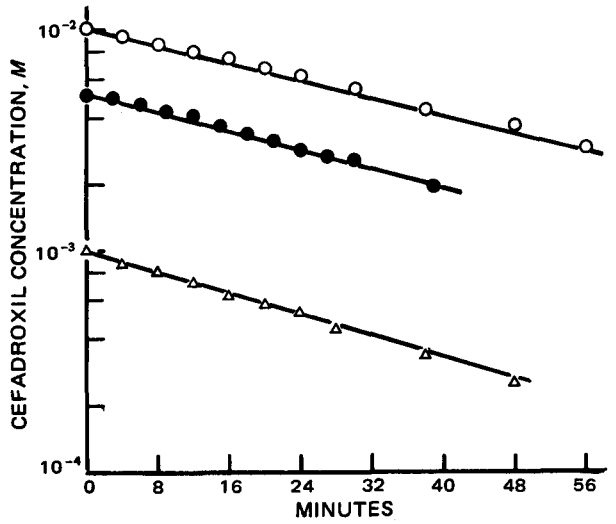


**Figure 3**—*Apparent first-order plots for cefadroxil degradation at three different concentrations (○, 1 × $10^{-2}$ M; ●, 5 × $10^{-3}$ M; and △, 1 × $10^{-3}$ M) at pH 11.50, 35°, and ionic strength 0.5, determined by HPLC assay.*

Similar semilogarithmic plots of the percent residual cefadroxil *versus* time were reasonably linear under various pH conditions (Fig. 4). These results indicate that the degradation of cefadroxil at constant pH, temperature, and ionic strength follows simple first-order kinetics with respect to cefadroxil. The observed rate constants and the buffer systems are listed in Table I.

**Catalytic Effect of Buffer Systems**—The catalytic effect of the two buffer systems used in the kinetic studies was determined at constant pH, temperature (35°), ionic strength ($\mu$ = 0.5), and drug concentration ($5 \times 10^{-3}$ *M*); only the buffer concentration was varied. This experiment was done at several pH values within the effective range for each buffer employed. The results (Figs. 5 and 6) show that the observed first-order rate constants increased linearly with an increase in the buffer concentrations at a constant pH in all cases.

Figure 5 shows the catalytic effect of citrate buffers between pH 2.51 and 5.82. The observed rate constant in the citrate buffer was actually a summation of several catalytic rate constants catalyzed by the buffer species plus the rate constant at zero buffer concentration. Accordingly, the observed rate constants, $k_{obs}$, may be expressed by:

$$k_{obs} = k_{pH} + k_{H_3A}[H_3A] + k_{H_2A^-}[H_2A^-] + k_{HA^{2-}}[HA^{2-}] + k_{A^{3-}}[A^{3-}] \quad \text{(Eq. 1)}$$

where $k_{pH}$ represents the rate constant at zero buffer concentration; other $k$ values are the second-order rate constants imposed by citrate buffer; $[H_3A]$, $[H_2A^-]$, $[HA^{2-}]$, and $[A^{3-}]$ are the concentrations of undissociated citric acid, dihydrogen citrate ion, monohydrogen citrate ion, and citrate ion, respectively.

The total citrate concentration, $[Cit]_T$, is shown as:

$$[Cit]_T = [H_3A] + [H_2A^-] + [HA^{2-}] + [A^{3-}] \quad \text{(Eq. 2)}$$

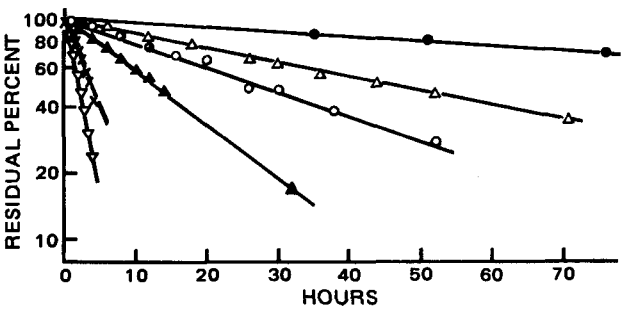

**Figure 4**—*Apparent first-order plots for the degradation of 5 × $10^{-3}$ M cefadroxil at various pH values, 35°, and ionic strength 0.5, determined by HPLC assay. Key: ●, pH 5.82 (0.11 M citrate buffer); △, pH 6.00 (0.10 M phosphate buffer); ○, pH 6.00 (0.2 M phosphate buffer); ▲, pH 7.20 (0.15 M phosphate buffer); ×, pH 10.50 (pH-stat); and ▽, pH 10.75 (pH-stat).*

| 7.00 (pH-stat) | — | — | — | — | 37.1 (50°) |
| 7.00 (pH-stat) | — | — | — | — | 92.6 (60°) |
| 7.20 (Phosphate) | 15.5 (0.03 *M*) | 25.7 (0.06 *M*) | 40.3 (0.10 *M*) | 55.7 (0.15 *M*) | 7.50 |
| 8.46 (pH-stat) | — | — | — | — | 16.0 |
| 9.00 (pH-stat) | — | — | — | — | 22.0 |
| 9.70 (pH-stat) | — | — | — | — | 60.1 |
| 10.50 (pH-stat) | — | — | — | — | 177 |
| 10.75 (pH-stat) | — | — | — | — | 361 |
| 11.50 (pH-stat) | — | — | — | — | 590 (30°) |
| 11.50 (pH-stat) | — | — | — | — | 1470 |
| 11.50 (pH-stat) | — | — | — | — | 2180 (40°) |
| 11.50 (pH-stat) | — | — | — | — | 7560 (50°) |

The dissociation constants of citric acid can be written as:

$$K_1^{cit} = \frac{[H_2A^-]a_{H^+}}{[H_3A]} \quad \text{(Eq. 3)}$$

$$K_2^{cit} = \frac{[HA^{2-}]a_{H^+}}{[H_2A^-]} \quad \text{(Eq. 4)}$$

$$K_3^{cit} = \frac{[A^{3-}]a_{H^+}}{[HA^{2-}]} \quad \text{(Eq. 5)}$$

From Eqs. 1–5, the following overall rate expression, $k_{obs}$, was obtained:

$$k_{obs} = k_{pH} + [Cit]_T \frac{k_{H_3A}(a_{H^+})^3 + k_{H_2A^-}K_1^{cit}(a_{H^+})^2 + k_{HA^{2-}}K_1^{cit}K_2^{cit}a_{H^+} + k_{A^{3-}}K_1^{cit}K_2^{cit}K_3^{cit}}{(a_{H^+})^3 + K_1^{cit}(a_{H^+})^2 + K_1^{cit}K_2^{cit}a_{H^+} + K_1^{cit}K_2^{cit}K_3^{cit}} \quad \text{(Eq. 6)}$$

In this case, no attempt was made to elucidate the catalytic constants with respect to the protonated and zwitterionic species of cefadroxil. By using the dissociation constants of citric acid, $pK_1^{cit} = 3.08$, $pK_2^{cit} = 4.75$, and $pK_3^{cit} = 5.40$ (11), the citrate catalytic constants at 35° were found from Eq. 6 and the slopes in Fig. 5 to be $k_{H_3A} = 9.70 \times 10^{-5}\ M^{-1}\ hr^{-1}$, $k_{H_2A^-} = 1.85 \times 10^{-3}\ M^{-1}\ hr^{-1}$, $k_{HA^{2-}} = 1.86 \times 10^{-2}\ M^{-1}\ hr^{-1}$, and $k_{A^{3-}} = 9.47 \times 10^{-2}\ M^{-1}\ hr^{-1}$.

Figure 6 shows the phosphate buffer effect between pH 6.00 and 7.20. Within this pH range, only the mono- and dihydrogen phosphate ions are significant. The overall rate expression can be given for the phosphate buffer effect as:

$$k_{obs} = k_{pH} + [Ph]_T \frac{k_{H_2PO_4^-}a_{H^+} + k_{HPO_4^{2-}}K_2^{Ph}}{a_{H^+} + K_2^{Ph}} \quad \text{(Eq. 7)}$$

where $k_{HPO_4^{2-}}$ and $k_{H_2PO_4^-}$ are the catalytic rate constants by mono- and dihydrogen ion species of phosphate and $[Ph]_T$ is the total phosphate concentration. By using the dissociation constant of the dihydrogen phosphate ion, $pK_2^{Ph} = 6.59$ at 35°, $\mu = 0.5$ (12), the catalytic rate constants on the degradation of cefadroxil were obtained from Eq. 7 and the slopes in Fig. 6 to be $k_{H_2PO_4^-} = 6.80 \times 10^{-2}\ M^{-1}\ hr^{-1}$ and $k_{HPO_4^{2-}} = 0.378\ M^{-1}\ hr^{-1}$.

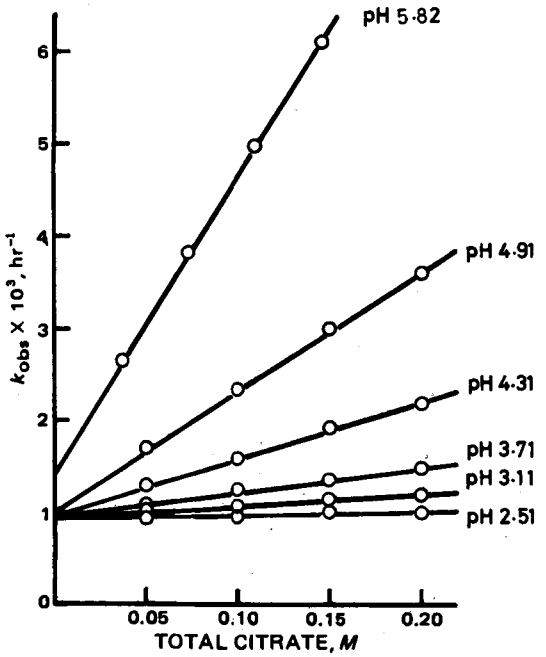

**Figure 5**—*Plots of pseudo-first-order rate constant* versus *total citrate buffer concentration for cefadroxil degradation at various pH values, 35°, and ionic strength 0.5.*

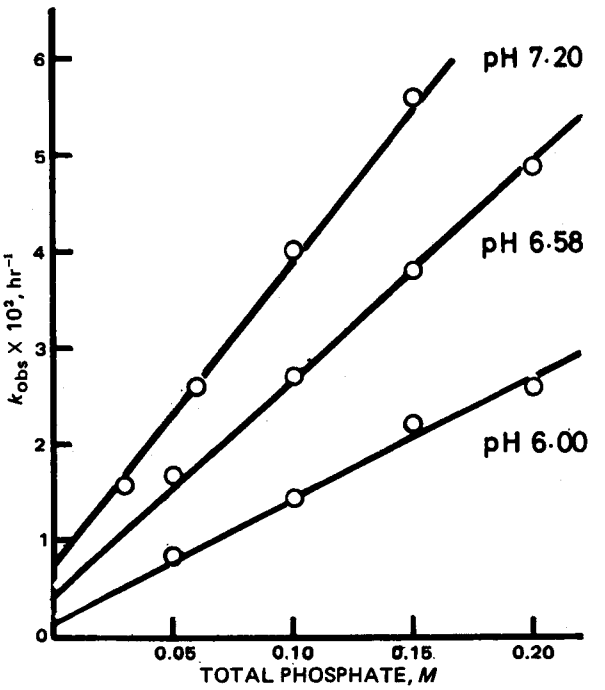

**Figure 6**—*Plots of pseudo-first-order rate constant* versus *total phosphate buffer concentration for cefadroxil degradation at various pH values, 35°, and ionic strength 0.5.*

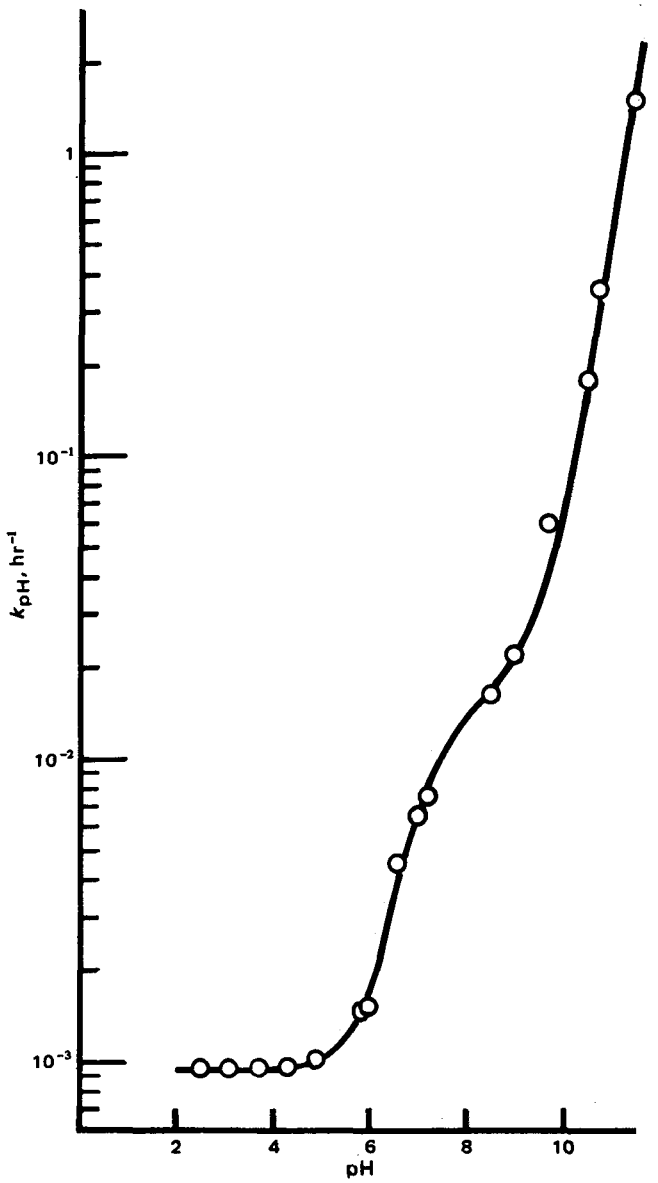

**Figure 7**—*Log $k_{pH}$–pH profile for cefadroxil degradation in aqueous solution at 35° and ionic strength 0.5, where $k_{pH}$ is the apparent first-order rate constant for the degradation in buffer-free solutions or in buffers showing no effect on the degradation rate. The line represents the curve calculated from Eq. 10 and the constants in Table II; the points are experimental values.*

**pH–Rate Profile**—The pH dependence of the overall first-order rate constant, $k_{pH}$, of cefadroxil degradation at 35° and ionic strength 0.5 is shown in Fig. 7. The rate constants used in construction of the graph were obtained from the intercepts of the graphs of $k_{obs}$ *versus* total buffer concentrations at various pH values (Figs. 5 and 6). The results from runs performed with a pH-stat were incorporated (Table I).

In the pH range studied, the amphoteric antibiotic cefadroxil exists in four different ionic forms: as a cation ($IH_2^+$), a zwitterion ($IH^\pm$), an anion ($I^-$), and a dianion ($I^{2-}$), the apparent pKa values of $IH_2^+$, $IH^\pm$, and $I^-$ being 2.64, 7.30, and 9.69, respectively (35°, $\mu$ = 0.5) (Scheme I).

Figure 7 shows that at pH > 10, the observed rate of the degradation increased rapidly and uniformly with increasing pH. Since the slope of this straight-line portion of the log $k_{pH}$ *versus* pH profile is unity, the dissociation of the phenolic moiety apparently has no effect on the $\beta$-lactam cleavage, and the specific hydroxide-ion-catalyzed reactions of anionic and dianionic cefadroxil take place at the same rate in this pH region and account exclusively for the total cefadroxil degradation.

At pH values near $pKa_2$, there was an ascending sigmoid dependence of $k_{pH}$ on pH, followed by a rapid rate decrease as the pH decreased. This inflection indicates that the dissociation equilibria of the side-chain amino group influenced the degradation rate. Below pH 5, the degradation rate of cefadroxil was pH independent and not influenced by the dissociation of the 4-carboxylic acid group ($pKa_1$ = 2.64). This observation implies that the overall degradation consists chiefly of the water-catalyzed reactions of both cationic and zwitterionic cefadroxil. The hydrogen-ion-catalyzed cefadroxil degradation was negligible compared to the water-catalyzed reaction above pH 2.5.

The total shape of the log $k_{pH}$–pH profile of cefadroxil is very similar to that for cephalexin or cephradine (1) and suggests that the rate expression given in Eq. 8 also holds true for the overall degradation of cefadroxil:

$$\frac{d[I]_T}{dt} = -[k_0(f_{IH_2^+} + f_{IH^\pm}) + (k_b + k_{OH}K_w/a_{H^+})(f_{I^-} + f_{I^{2-}})][I]_T \quad \text{(Eq. 8)}$$

where $k_0$ represents the first-order rate constant for water-catalyzed degradation of both cationic and zwitterionic cefadroxil; $k_b$ represents the first-order rate constant for the spontaneous (or water-catalyzed) degradation of the ionic and dianionic species of cefadroxil; $k_{OH}$ represents the second-order rate constant for specific hydroxide-ion-catalyzed degradation of all anionic species; $K_w$ is the autoprotolytic constant; $f_{IH_2^+}$, $f_{IH^\pm}$, $f_{I^-}$, and $f_{I^{2-}}$ represent the mole fractions of the cationic, zwitterionic, anionic, and dianionic species of amphoteric cefadroxil, respectively; and $[I]_T$ is the total cefadroxil concentration.

By introducing the first-order expression:

$$-\frac{d[I]_T}{dt} = k_{pH}[I]_T \quad \text{(Eq. 9)}$$

the following pseudo-first-order rate expression is derived since only the dissociation of the 7-side chain amino group could influence the degradation rate:

$$k_{pH} = k_0\frac{a_{H^+}}{a_{H^+} + K_{a_2}} + (k_b + k_{OH}K_w/a_{H^+})\frac{K_{a_2}}{a_{H^+} + K_{a_2}} \quad \text{(Eq. 10)}$$

The theoretical degradation rate constant of cefadroxil was calculated for the pH of 2.5–11.5 range. By employing $K_w = 2.09 \times 10^{-14}$ at 35° (13), the various rate constants listed in Table II were best satisfied. In Fig. 7, the line represents the theoretical curve calculated by substituting these $k$ values into Eq. 10 while the points show the experimental results. The good agreement indicates that this equation adequately describes the kinetics of total cefadroxil degradation.

**Degradation Products in Neutral and Alkaline Solutions**—The thin-layer chromatogram of the degradation reaction solution of cefadroxil, conducted in a basic phosphate buffer at pH 9.1 at 60° for 1 hr, revealed four spots other than cefadroxil. These spots were tentatively named products II, III, IV, and V according to their $R_f$ values on TLC. Closer inspection of the chromatogram showed the major products to be IV and V.

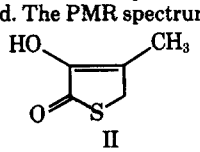
Products III, IV, and V also were detected in the degradation carried out in methanol–acetonitrile, which suggests that the main degradation process is almost identical in the two solutions, but no trace of II was observed.

Attempts to isolate and characterize the reaction mixture met with difficulties and proved only partially successful. Treatment of the mixture as shown in Scheme II yielded II and a mixture of IV and V slightly contaminated with III. Further separation of the latter mixture under repetitive chromatography was successful.

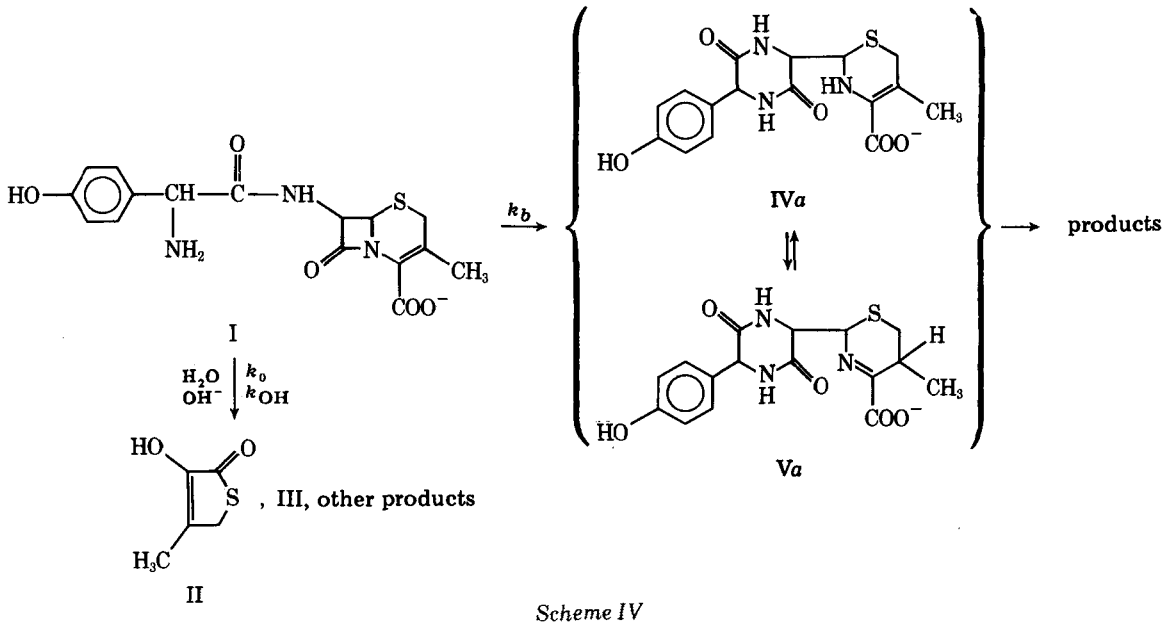
The structural elucidation of II was achieved based on spectral data. The PMR spectrum revealed simple patterns composed of three singlet signals at $\delta$ 2.09, 3.74, and 6.10 ppm, with signal areas in the ratio of 3:2:1, respectively. Furthermore, the IR spectrum exhibited three characteristic absorptions at 3370, 1690, and 1630 cm$^{-1}$, which suggests the presence of an enol lactone. The UV spectrum showed absorbances at 246 and 255 nm, the latter showing a typical bathochromic shift to 304 nm on the addition of a base. This finding led to the determination of II as the thiol lactone, 3-hydroxyl-4-methyl-2-(5*H*)-thiophenone. Elemental analysis data supported the structure.

Compound II is reported in the literature as the degradation product of cephalexin in experiments conducted at pH 7.4 (6) and 3.3 (7).

The mixture of IV and V, the major products, displayed no peaks corresponding to a $\beta$-lactam in its IR spectrum, strongly indicating that the $\beta$-lactam was cleaved. The PMR spectrum in $d_5$-pyridine revealed,



II



*Scheme IV*

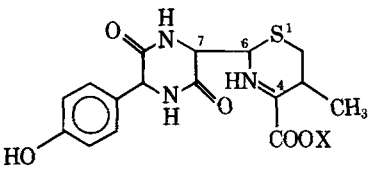
among others, two signals ascribable to methyl groups at δ 1.58 (doublet) and 2.23 (singlet) ppm, the approximate ratio of the integrated signal areas being 2:1. This finding suggests the existence of two different methyl groups in the mixture, most likely one attached to a secondary carbon atom and the other attached to a double bond. Moreover, since the mixture showed no reaction with dinitrobenzenesulfonic acid, the lack of free amino groups is evident. From these results, it was speculated that the mixture is composed of the piperazinedione derivatives, IV*a* and V*a*.

Further information on the structure of the components was gained by derivatizing the mixture to the respective methyl esters with diazomethane in methanol. Chromatographic separations as shown in Scheme III proved successful in isolating each derivative.

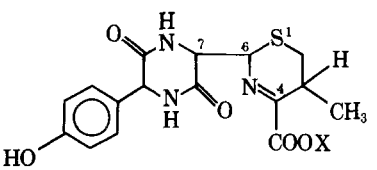
The PMR spectrum of the major product, V*b*, showed a doublet signal at δ 1.20 ppm ascribable to a methyl group on a secondary carbon atom coupling with a vicinal proton. On addition of deuterium oxide, the signals centered at δ 4.05 and 5.41 ppm showing complex coupling patterns simplify, making it reasonable to assign the former to the proton on C-7 and the latter to the proton on C-6 showing longrange coupling with protons on C-2 and/or C-3. The IR spectrum revealed peaks for ester carbonyl (1730 $cm^{-1}$) and superimposed amide carbonyls (1680 $cm^{-1}$), while the UV spectrum showed absorbances at 226 and 276 nm, assigned to the phenol group. All data proved to be consistent with the proposed structure, a piperazinedione derivative with the double bond at the C-4, C-5-position.

The minor product, IV*b*, exhibited IR and UV spectra closely resembling those of V*b*. The PMR spectrum revealed a singlet at δ 2.04 ppm, which was the decisive factor in determining its structure as the piperazinedione derivative with the double bond at the C-3, C-4-position.

Elemental analyses for the two esters supported the illustrated structures. The characterization of the methyl derivatives led to the conclusion that the major degradation products of cefadroxil in basic aqueous solution have structures IV*a* and V*a*, as illustrated in Scheme IV.



V*a*: X = H
V*b*: X = $CH_3$



IV*a*: X = H
IV*b*: X = $CH_3$

**Mechanism of Reaction Involving Side-Chain α-Amino Group**—The shape of the pH–rate profile of cefadroxil in the neutral pH region may be accounted for by the following three mechanisms (Scheme V): (*a*) intramolecular nucleophilic attack of unprotonated side-chain amino groups on the β-lactam carbonyl moiety, (*b*) intramolecular general base catalysis by the amino group inducing the attack of a water molecule on the β-lactam moiety, and (*c*) intramolecular general acid catalysis by the protonated amino group inducing the attack of hydroxide ion on the β-lactam moiety. These mechanisms are kinetically indistinguishable.

Mechanism *a* is markedly different from the other two in the formation of piperazine-2,5-dione products, whose structures are shown here as IV*a* or V*a*. Cohen *et al.* (5) reported the isolation of a piperazinedione product similar to V*a* from an aqueous sodium carbonate solution of cephradine. Recently, the piperazinedione was isolated from an aqueous phosphate solution of cephalexin kept at 35° and pH 7.6 for 24 hr (6). In this study, the structural speculation of the mixture of IV*a* and V*a* for the precipitated products from the basic solution of cefadroxil and the successful

[a] Rate constants are defined in Eq. 10. [b] Reference 1.

isolation and identification of their methyl esters (IV*b* and V*b*) supported the occurrence of Mechanism *a*.

Additional evidences for the intramolecular aminolysis reaction (Mechanism *a*) were obtained. Figure 8 shows the first-order plots of the disappearance of amino groups by following the decrease in the concentration of primary amino groups in cefadroxil solution during its degradation in 0.15 *M* phosphate buffer at pH 7.20, 35°, and $\mu = 0.5$, the plots being obtained by the Guggenheim method (14). Total disappearance followed by the HPLC method for the same samples is also shown in Fig. 8. The apparent first-order rate constants obtained from the two methods are in reasonable agreement, suggesting that the loss of cefadroxil is accompanied by a parallel loss of its amino group. Furthermore, when *N*-acetylcefadroxil (VI) was heated in a neutral phosphate buffer, no reaction was observed on TLC, indicating that the degradation required a free amino group attacking the β-lactam moiety.

These results lead to the conclusion that the degradation of cefadroxil proceeding at neutral and basic pH was dominated by a spontaneous aminolysis (Mechanism *a*) rather than water-catalyzed aminolysis to produce the piperazinediones IV*a* and V*a*.

**Equilibrium between Degradation Products**—PMR spectral studies of the mixture of IV*a* and V*a* suggested the existence of an equilibrium between them. PMR spectra in $d_5$-pyridine showed a doublet at δ 1.21 ppm which, on addition of deuterium oxide, changed to a broad singlet; no change was observed with the singlet at δ 2.01 ppm, clearly indicating the presence of an equilibrium shown in Scheme IV where the C-3 proton was easily exchanged by deuterium oxide through the migration of the double bond. Further evidence for the equilibrium was obtained when the degradation of cefadroxil in potassium carbonate–deuterium oxide solution was monitored by PMR. The spectrum showed the singlet at δ 2.01 ppm, assigned to the methyl group of cefadroxil, gradually disappearing with time while a new singlet assignable to a secondary methyl group appeared. This change indicates the double bond migration, probably to the 4,5-position, to predominantly yield V*a* and exhibits the same behavior found for cephradine (5) and cephalexin (1).

Similar migration of the double bond was also observed between the methyl esters, IV*b* and V*b*. In the PMR spectra of IV*b* in $d_6$-dimethyl sulfoxide, the addition of deuterium oxide and trifluoroacetic acid to the sample resulted in the appearance of new signal peaks, corresponding to the spectrum of V*b*, which increased in area until an apparent equilibrium was reached. Integration of peak areas showed that the equilibrium was attained at a ratio of 3:1 with IV*b* predominating.

This result was confirmed by conducting the same experiment, this time starting with V*b*, which showed the appearance and increase of small peaks corresponding to IV*b* until a similar equilibrium was reached in favor of IV*b*. Furthermore, data obtained from TLC of the esters in acidic conditions also supported the existence of an equilibrium.

**Available Evidence for Formation of II and a Possible Degradation Pathway in Aqueous Solution**—The degradation product II was isolated or confirmed from the cefadroxil degradation solutions in water and in 0.1 *M* dibasic sodium phosphate solution at pH 9.1. However, when cefadroxil was degraded in neutral organic solvents, no formation of II was observed on TLC. Bundgaard (6) reported the isolation of 3-hydroxy-4-methyl-2(5*H*)-thiophenone (II) from the degradation solution of cephalexin in 0.5 *M* phosphate buffer at pH 7.5 and proposed

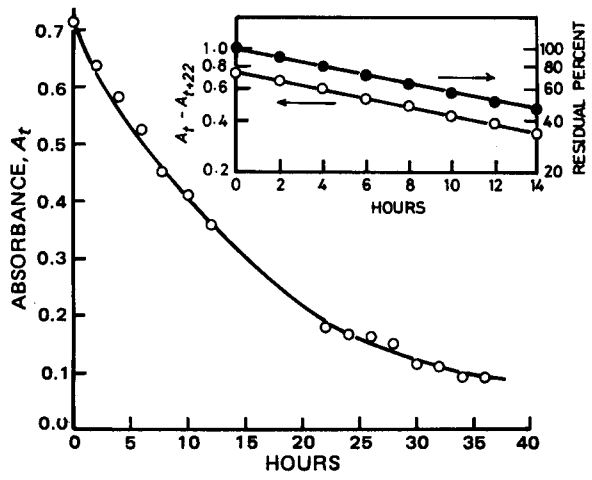

**Figure 8**—*Time courses for primary amino group disappearance during cefadroxil ($5 \times 10^{-3}$ M) degradation in 0.15 M phosphate buffer (pH 7.20) at 35° and ionic strength 0.5. Absorbance refers to the absorbances produced by subjecting equal aliquots of the reaction solution to the trinitrobenzenesulfonic acid assay. The inset shows the first-order plots of the data (○) obtained by Guggenheim treatment (22-hr intervals) in comparison with the HPLC assay (●) of the same samples.*

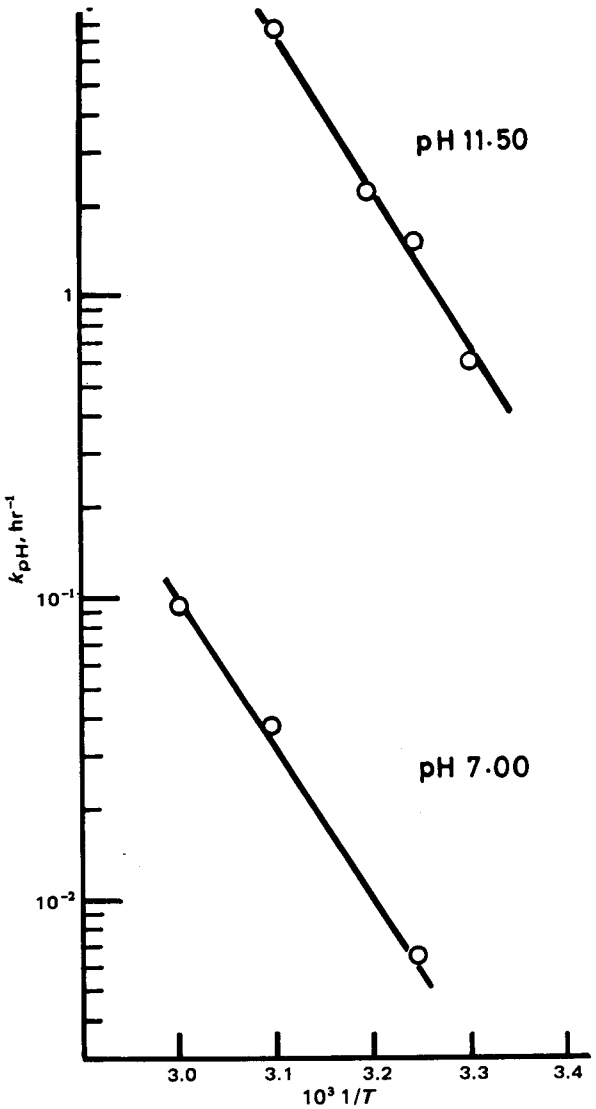

**Figure 9**—*Arrhenius plots for the apparent first-order rate constants, $k_{pH}$, for cefadroxil degradation at pH 7.00 and 11.50 and ionic strength 0.5. The pH values were maintained by a pH-stat.*

that this thiophene derivative might be transformed from the piperazinedione product.

To clarify the possible formation of II from IV*a* or V*a*, the product mixture IV*a* and V*a* was heated in an alkaline phosphate solution. Several secondary degradation products were detectable on TLC, but none had the same $R_f$ value as II. The results suggest that product II does not form *via* IV*a* and V*a* but is directly formed from cefadroxil *via* a different pathway.

Product III was difficult to isolate in amounts sufficient to characterize it; its formation was confirmed in neutral and basic degradation solutions of cefadroxil.

A possible route to account for the observed formation of II, III, IV*a*, and V*a* is shown in Scheme IV.

**Temperature Dependency**—Rate constants for the overall disappearance of cefadroxil were obtained from 35 to 60° at pH 7.00 and 11.50. The pH of the reaction solution was maintained constant by the use of a pH-stat. The Arrhenius plots are shown in Fig. 9. From these data, the apparent activation energies at pH 7.00 and 11.50 was determined to be 21.4 and 23.8 kcal/mole, respectively.

In aqueous solution at pH 7.00 and 35°, cefadroxil degraded *via* intramolecularly catalyzed reaction ($k_b$ reaction) to an extent of 83% and *via* a water-catalyzed $\beta$-lactam opening ($k_0$ reaction) to an extent of 17%.

At pH 11.50, the hydroxide-ion catalyzed degradation proceeded exclusively, the contribution of the $k_b$ reaction being only 0.1%. The apparent activation energy of 23.8 kcal/mole at this alkaline pH may include the heat of ionization of water, 13.1 kcal/mole (13). The net activation enthalpy, $\Delta H^{\neq}$, of hydroxide-ion-catalyzed degradation of cefadroxil was calculated to be 10.5 kcal/mole at 35°.

**Comparative Stability Among Aminocephalosporins**—Table II lists various rate constants defined by Eq. 10 for the degradation of cephaloglycin, cephalexin, and cephradine determined previously under the same kinetic conditions. It is apparent that the stability pattern of cefadroxil resembles that of cephalexin and cephradine over all pH regions.

A comparison of the specific rate constants of $k_0$, $k_b$, and $k_{OH}$ for the four aminocephalosporins shows that the $\beta$-lactam moiety of cephaloglycin, which has an acetoxymethyl group in the C-3 position, is about four to five times more susceptible to attack of both water and hydroxide ion and eight to 18 times more reactive to intramolecular attack by the C-7 side-chain amino group than that of cephalosporins possessing a methyl group at the C-3 position, *i.e.*, cefadroxil, cephalexin, and cephradine. The difference in reactivity between cephaloglycin and the other three antibiotics may be ascribed to the difference in the inductive ability of their C-3 substituents and/or leavability of the C-3 moiety, as suggested previously for cephalosporin degradations (1, 3, 15–18).

# Alterations in Integrity of Goldfish Membrane Induced by Edetate Disodium

**P. J. CASCELLA ˣ, E. G. HUPPLER, II, and J. D. JOHNSON**

Received October 20, 1980, from the *College of Pharmacy, South Dakota State University, Brookings, SD 57007.* Accepted for publication March 5, 1981.

**Abstract** □ The effect of the chelating agent edetate disodium on the integrity of the goldfish membrane was examined. The time to produce death in goldfish exposed to secobarbital sodium was used as a reflection of membrane integrity. Although a minimum edetate disodium concentration was necessary to induce alterations in integrity, no direct relationship between the effect and concentration of the chelating agent was evident. The chelating agent's effect appeared to be an enhancement of the transport of the ionized drug form. The change in membrane integrity existed at least 24 hr after theoretical exposure to edetate disodium, but cyclic alterations in integrity could not be ruled out. The effect on integrity was also demonstrated to be nonpermanent, and the apparent loss in integrity was partially restored by calcium but not by magnesium.

**Keyphrases** □ Permeability—effect of edetate disodium on goldfish membrane □ Edetate disodium—effect on membrane permeability, goldfish □ Chelating agents—edetate disodium, effect on membrane permeability, goldfish

Edetic acid is a chelating agent capable of changing transfer rates of certain substances across membrane barriers (1–4). It was reported (1) that the sodium salt of edetic acid was capable of enhancing the absorption of heparin and synthetic heparinoids from the GI tract of rats and dogs and that these results were consistent with another investigation (2) in the monkey, dog, cat, rabbit, and human. Feldman and Gibaldi (3) demonstrated that edetic acid was capable of affecting the transfer rate of salicylate, but not salicylamide, across the everted rat intestine. They concluded that edetic acid was capable of altering the barrier for water-soluble, but not lipid-soluble, compounds. It was also demonstrated (4) that the sodium salt of edetic acid was capable of increasing phenolsulfonphthalein absorption in rats.

Although edetic acid is capable of changing the permeability of membranes to various compounds, the exact nature of the mechanism involved is unknown. Regardless of the mechanism, numerous studies have been performed to see if the effects of the chelating agent can be reversed. Windsor and Cronheim (1) found that the magnesium and

calcium salts of edetic acid were incapable of increasing absorption, and Tidball (4) reported that rinsing with magnesium salts fully restored normal permeability. It was also reported (3) that neither calcium nor magnesium was capable of restoring normal permeability of the rat intestinal membrane.

A previous report (5) presented preliminary findings of the effect of edetate disodium on the goldfish membrane. It was considered of interest to examine the effects of edetic acid on the goldfish since they have been used in a number of studies (6–9) for the assessment of absorption and toxicity of numerous compounds. Goldfish offer an advantage over other experimental animals in that they can be exposed to chelating agents for relatively long periods of time. It also is reasonably easy to assess the effects on the membrane at different times after exposure. This report is a followup of our preliminary findings.

## EXPERIMENTAL

**Recovery Time Studies**—Goldfish (*Carassius auratus*), 1–3 g, were placed in groups of five in tanks containing 2 liters of edetate disodium[1] (0.2 mg/ml). The solutions were made with glass-distilled[2] water and were adjusted[3] to pH 7.4 using 0.1 *N* NaOH or HCl. The fish were left in the solutions for 24 hr and then were placed for varying periods in recovery tanks containing 2 liters of glass-distilled water adjusted to pH 7.4. Individual fish were then placed into beakers containing 200 ml of 0.1 m*M* secobarbital sodium[4] in a 0.05 *M* phosphate buffer, pH 7.4. Cessation of gill and mouth movements was noted, and the time to death was computed.

Controls were run for each group following the procedure for the edetate disodium-treated fish, except that the chelating agent was omitted from the treatment tank.

All investigations were performed at (20 ± 2°).

**Concentration Studies**—Five fish (1–3 g) were placed in tanks containing 2 liters of edetate disodium (varying concentrations) in glass-distilled water adjusted to pH 7.4 using 0.1 *N* NaOH or HCl. The fish were left in the tanks for 24 hr and then placed for 24 hr in a recovery tank containing 2 liters of glass-distilled water adjusted to pH 7.4. Individual fish were then placed in beakers containing 200 ml of 0.1 m*M* secobarbital sodium in 0.05 *M* phosphate buffer, pH 7.4. Cessation of gill and mouth movements was noted, and the time to death was computed.

Controls were run in the same manner as described previously. All experiments were performed at 20 ± 2°.

**pH Study**—Five fish (1–3 g) were placed in tanks containing 2 liters of 0.2 mg of edetate disodium/ml (adjusted to pH 7.4) in glass-distilled water for 24 hr. Individual fish were then immediately placed (zero recovery) in beakers containing 200 ml of 0.1 m*M* secobarbital sodium solution buffered to pH 6.4, 7.4, or 8.4 with 0.05 *M* phosphate buffer. Again, time to death was calculated.

Controls were run in the same manner as already described and all experiments were performed at 20 ± 2°.

**Calcium and Magnesium Study**—Five fish (1–3 g) were placed in tanks containing 2 liters of 0.2 mg of edetate disodium/ml (adjusted to pH 7.4) in glass-distilled water for 24 hr. Fish were then placed in recovery tanks for 24 hr. The recovery tanks contained either 2 liters of glass-distilled water or 2 liters of a 1 m*M* solution of calcium chloride or magnesium chloride. All tanks were adjusted to pH 7.4. After 24 hr, individual fish were placed in beakers containing 200 ml of a 0.1 m*M* secobarbital sodium solution buffered to pH 7.4 with 0.05 *M* phosphate buffer. Time to death was computed.

Controls were run by placing fish in glass-distilled water for 48 hr (water was changed at the end of 24 hr) and then placing individual fish in secobarbital solution as described.

All experiments were performed at 20 ± 2°.

## RESULTS AND DISCUSSION

The results of the recovery time study are summarized in Table I. As is evident from the control data, there appears to be a large amount of day-to-day variation in response. This is evident from the control segment of the table, since the controls are essentially the same procedure, one should expect similar results. However, the mean time of deaths, ranged from 18.96 to 40.23 min.

Comparisons between the treated and control fish (which were performed at the same time) were made within each block of the table using a Student *t* test. A significant difference ($p < 0.05$) existed between the treated and control fish for the 0- and 24-hr recovery studies. There was no significant difference for the 30-min and 48- and 72-hr recovery studies. Although the reason for the lack of a significant difference at the 30-min recovery study is unknown, it is consistent with previous results (5). If it is assumed that the amount of secobarbital necessary to produce death is the same between treated and control fish, then the significant difference for the 24-hr recovery study implies that alterations in membrane permeability induced by edetate disodium may exist for a substantial time after theoretical exposure of the membrane to the chelating agent, at least in the described system. The effect of the chelating agent on membrane permeability is not permanent, however, as evident from the 48- and 72-hr recovery treatments.

**Table IV—Effect of Calcium and Magnesium on Enhanced Permability Induced by Edetate Disodium**

| Group | Treatment[a] A | | | Treatment[b] B | | |
|---|---|---|---|---|---|---|
| | Mean Time of Death | *n*[c] | *SD* | Mean Time of Death | *n* | *SD* |
| I | 29.23 | 10 | 4.43 | 29.95 | 10 | 5.87 |
| II | 19.70 | 9 | 4.63 | 19.15 | 10 | 1.45 |
| III | 19.63 | 10 | 3.76 | 23.24 | 10 | 4.06 |

[a] Group III contained a 1 m*M* magnesium chloride solution. [b] Group III contained a 1 m*M* calcium chloride solution. [c] *n* = number of fish.

The results of the concentration of edetate disodium on time of death study are listed in Table II. A significant difference ($p < 0.05$) existed between each treatment and control, except for the lowest concentration of the chelating agent. To determine the effect of chelating agent concentration on time of death, the effect of day-to-day variation should be eliminated since the studies were performed on different days. This correction was made for the data in which the treatments were significantly different from the controls, *i.e.*, all but the lowest concentration of edetate disodium, by subtracting each individual observation of the treatments from the mean of each control performed at the same time as the treatment (Table III).

An analysis of variance for unequal data sets was performed on the differences for each concentration, and the result indicated a significant difference ($p < 0.05$) between the means. The means were analyzed using the Newman–Keuls method with a harmonic mean of the sample size to compensate for unequal data sets. These results indicated a difference between the treatment concentrations of 0.10, 0.15, and 0.20 mg/ml with the 0.30-mg/ml treatment. There was also a difference between the 0.2-mg/ml concentration and the 0.25- and 0.40-mg/ml treatments. A plot of the mean differences *versus* concentration of treatment (Fig. 1) shows that despite significant differences between the treatments, no direct relationship between concentration of edetate disodium and effect was apparent.

Experiments were also performed to determine if the effect of edetate disodium on membrane permeability could be reversed by exposing the fish to calcium or magnesium chloride solutions. In each experiment, the times of death of three groups of fish in secobarbital sodium were determined. The first group was the control, the second group was treated with edetate disodium and placed in a recovery tank for 24 hr, and the third group was exposed to the chelating agent and then placed in a recovery tank containing calcium or magnesium chloride for 24 hr before being placed in the secobarbital sodium solution. All groups were studied at the same time, and the results are summarized in Table IV.

An analysis of variance was performed, and the results indicated a significant difference between the means for both studies. Analysis of the means using the Newman–Keuls method indicated that, in the magnesium chloride study, the control was significantly different from the edetate disodium group and the edetate disodium/magnesium chloride group. No difference existed between the edetate disodium and the edetate disodium/magnesium chloride group. Thus, it appears that magnesium is incapable of restoring membrane integrity under these experimental conditions. In the calcium chloride study, a significant difference ($p < 0.05$) existed between all three treatments. Thus, it appears that calcium is able to restore, at least partially, the apparent loss of membrane integrity induced by edetate disodium.

In previous experiments (5) fish also were treated with edetate disodium and then exposed to secobarbital sodium buffered to varying pH values. While the treated fish seemed to fit the model proposed by Levy and Gucinski (10) for the absorption of secobarbital sodium, the controls did not. It was decided to repeat the pH study using a 24-hr treatment, zero recovery. The results of both studies are listed in Table V. Comparisons were made within each block using a Student *t* test, and there was no significant difference between treatments and control at pH 6.4 regardless of the treatment. In the 24-hr treatment, 30-min recovery, there was no significant difference at any pH. In the 24-hr treatment, zero recovery and the 24-hr treatment, 24-hr recovery, there were significant differences at pH 7.4 and 8.4.

Since secobarbital is a weak acid with a pKa of 7.9, it appears that the chelating agent changes membrane permeability to the ionized drug form since there was a significant difference between treated and control animals only at pH values (7.4 and 8.4) where the drug appreciably existed as the ionized form. The apparent increase in membrane permeability to the ionized drug form is not enough to compensate for the reduction in the absorption of the unionized form since the times to produce death increased with increasing buffer pH. Linear regression was performed on the reciprocal of the mean time of death *versus* the fraction of drug unionized for the 24-hr treatment zero recovery study and its controls.

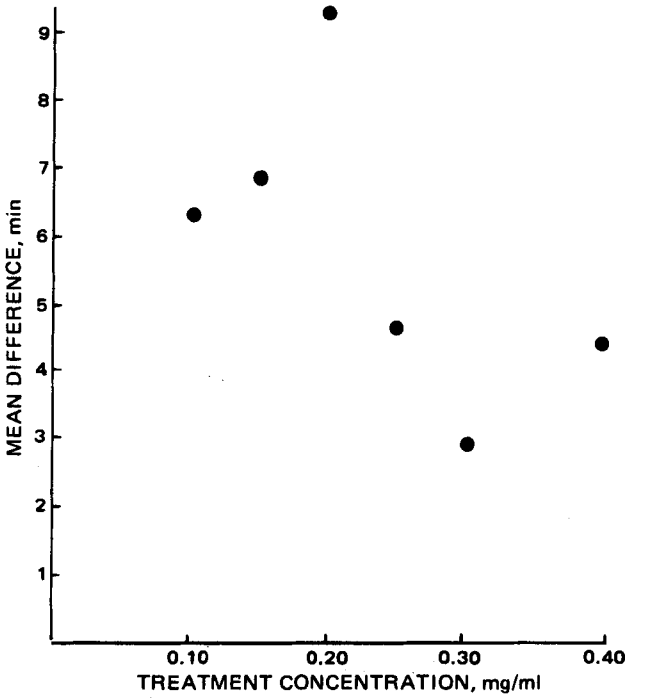

**Figure 1**—*Plot of the mean differences* versus *concentration of the chelating agent treatments.*

| Treatment[b] | 18.58 ± 3.54 | 5 | NS[c] | 18.74 ± 0.98 | 7 | $p < 0.05$ | 39.11 ± 5.93 | 3 | $p < 0.05$ |
| Control[d] | 19.76 ± 1.95 | 5 | | 21.88 ± 2.87 | 10 | | 51.77 ± 5.05 | 4 | |
| Treatment[e] | 14.88 ± 0.99 | 10 | NS | 20.21 ± 3.74 | 10 | NS | 52.29 ± 9.70 | 10 | NS |
| Control[f] | 13.49 ± 2.51 | 10 | | 23.89 ± 5.80 | 10 | | 62.30 ± 16.93 | 10 | |
| Treatment[g] | 18.73 ± 5.92 | 10 | NS | 23.03 ± 1.79 | 10 | $p < 0.05$ | 58.83 ± 17.31 | 10 | $p < 0.05$ |
| Control[h] | 15.80 ± 3.51 | 5 | | 32.27 ± 8.07 | 10 | | 97.84 ± 22.19 | 10 | |

[a] *n* = number of fish. [b] 24-hr treatment, zero recovery. [c] Not significant ($p > 0.05$). [d] 24-hr blank, zero recovery. [e] 24-hr treatment, 30-min recovery. [f] 24-hr blank, 30-min recovery. [g] 24-hr treatment, 24-hr recovery. [h] 24-hr blank, 24-hr recovery.

The predicted least-squares equations are, respectively:

$$1/t = 0.0413f_u + 0.0170 \quad (r = 0.9660) \quad \text{(Eq. 1}a\text{)}$$

and:

$$1/t = 0.0443f_u + 0.0093 \quad (r = 0.9906) \quad \text{(Eq. 1}b\text{)}$$

According to the Levy–Gucinski model (10) concerning the absorption of the ionized and unionized forms of drug in goldfish, a plot of reciprocal time of response ($1/t$) as a function of the fraction of drug unionized should be linear with a slope equal to $K_b(K_u - K_i)$ and an intercept equal to $K_bK_i$.

$$1/t = K_bK_i + K_b(K_u - K_i)f_u \quad \text{(Eq. 2)}$$

where $K_b$ is a constant equal to the quotient of the secobarbital concentration to which the fish were exposed divided by the amount of barbiturate in the fish at death; $K_i$ and $K_u$ are the first-order rate constants for the ionized and unionized drug forms, respectively. Upon inspection of the data, two discrepancies appear. The controls fit the model reasonably well while the treated animals do so to a lesser degree. In both cases, however, curvature of a form representing an inverted exponential cannot be ruled out. The intercepts of both plots are also not significantly different ($p > 0.05$) from zero. Whether these discrepancies represent a breakdown of the model or assumptions of the model as specified by Levy and Gucinski or simply a large amount of statistical variation cannot be discerned at this time. However, due to these discrepancies, the analysis as performed earlier (5), using the ratio of slope to intercept to evaluate the ratios of $K_u$:$K_i$ was not performed. Regardless of the model that characterizes the absorption of secobarbital sodium under these experimental conditions, it appears from Table V that edetate disodium changes membrane permeability to the ionized form of the drug and that the effect can be present 24 hr after theoretical exposure to the chelating agent.

# Effect of Various Vehicles and Vehicle Volumes on Oral Absorption of Triamterene in Rats

**THOMAS F. PATTON ˣ and PAMELA GILFORD**

Received October 6, 1980, from the *Department of Pharmaceutical Chemistry, University of Kansas, Lawrence, KS 66044.* Accepted for publication March 10, 1981.

**Abstract** □ The oral bioavailability of triamterene in rats was investigated after its administration as a suspension in lipid and aqueous vehicles in addition to a lactic acid solution. Triamterene is poorly soluble in both aqueous and lipid vehicles. A 1-ml oral dose volume showed that lipid vehicles may provide some enhancement of oral availability compared with aqueous suspensions. However, when the vehicle volume was reduced to a realistic dosage form volume for the rat, peanut oil and aqueous suspensions were indistinguishable from each other with respect to peak height, peak time, and overall bioavailability. For a given vehicle small vehicle volumes resulted in a better relative oral availability than did large vehicle volumes.

**Keyphrases** □ Triamterene—poor solubility in lipid and aqueous vehicles □ Vehicle volume—small *versus* large vehicle volumes in oral availability in rats □ Oral bioavailability—parameters of triamterene administered as suspensions in lipid and aqueous vehicles and lactic acid solution

The rate and extent of absorption of orally administered drugs are influenced by factors within the GI environment, such as the solubility and extent of drug ionization, gastric emptying, intestinal motility, and stimulation of bile flow. The relative contribution of each factor to oral availability is often difficult to distinguish. The vehicle into which a

drug is incorporated and the vehicle volume administered may affect all of these factors in addition to any interactions the vehicle may have with the drug itself.

## BACKGROUND

A traditional problem in oral drug delivery has been the relatively low bioavailability exhibited by many poorly water-soluble drugs. Considerable research has centered on the possible enhancement of the oral bioavailability of such drugs by their incorporation into various lipid vehicles. It is unclear whether lipid vehicles may affect oral bioavailability through some biochemical and/or physiological effects, whether solubilization of the drug is the mechanism, or a combination of these factors is operative.

Crounse (1) demonstrated an increase in griseofulvin bioavailability when administered with a high fat diet to humans. Griseofulvin bioavailability in rats also was enhanced when administered in various corn oil vehicles (2, 3). Indoxole bioavailability was increased in both humans (4) and rats (5) when administered in lipid vehicles. Sulfisoxazole (6) and dicumarol (7) are other examples of drugs whose bioavailability is enhanced in lipid vehicles.

Grisafe and Hayton (8) concluded that triglycerides had the ability to enhance the oral absorption of griseofulvin due to the enhanced dissolution and not directly to the lipid-induced increases in absorption. Solubilization of poorly water-soluble drugs as a method of improving oral bioavailability was confirmed by other investigators (9–11).

Yamahira *et al.* (12–14) recently demonstrated that the volume of vehicle in which the drug is administered can influence the results obtained in oral bioavailability studies. It was concluded that many oral bioavailability studies, particularly those with rats, used unrealistically large vehicle volumes. Yamahira *et al.* (13) developed a reproducible method of administering very small vehicle volumes (2–20 μl) to rats to eliminate the physiological effects caused by large vehicle volumes.

In the present study, the effects of various vehicles and vehicle volumes were correlated to the oral absorption of the poorly soluble, potassium-sparing diuretic, triamterene, in rats.

## EXPERIMENTAL

**Materials**—Pure triamterene powder[1] was used to prepare all drug suspensions and solutions. Five drug vehicles were studied initially: water, peanut oil[2], triolein[3], lactic acid[4], and oleic acid[5]. All solvents for chromatography were high-performance liquid chromatographic (HPLC) grade[6], and other reagents were analytical grade[6].

The suspensions used initially were at concentrations of 4.0 mg/ml. Ten-milliliter aliquots were transferred to 15-ml screw-capped tubes and shaken for 30 min on a mixer[7] with a modified shaker head. Five drops of surfactant[8] were added to the aqueous suspensions. For the solution vehicle, triamterene was dissolved in an 8% lactic acid solution. In subsequent studies, peanut oil and aqueous suspensions were prepared as described at a concentration of 45 mg/ml. The range of solubilities of triamterene in all vehicles (other than the lactic acid solutions) was $10^{-4}$–$10^{-5}$ *M*.

[a] Means calculated from four individual experiments in four different rats in a balanced incomplete block design.

**Animal Studies**—Initial studies evaluated five vehicles in a balanced incomplete block design. Ten rats were each randomly assigned to receive two of the formulations, and each formulation was tested in four rats. A 1-week washout period was allowed before a rat was used again.

Male rats[9], 250–300 g, were fasted for 12 hr prior to dosing with 10 mg of triamterene/kg, suspended or dissolved in the various vehicles. Immediately prior to dosing, suspensions were removed from the shaker and the appropriate dose was drawn into a tuberculin syringe[10]. The volume was adjusted to 1 ml with the requisite vehicle, and the syringe was shaken again.

Lightly ether-anesthetized animals were dosed with a 76-mm intubation needle[11] attached to the tuberculin syringe. Blood samples were taken by tail clipping while the animals were restrained in plexiglass cages[11]. Blood samples were obtained every 0.5 hr for 3 hr; then every hour until 6 hr, and then at 12 and 24 hr. In later studies, a 9-hr sample was added.

Whole blood (~350-μl samples) was collected in heparinized caraway capillary tubes[12], blown into 1.5-ml microcentrifuge tubes[13], and spun for 3 min[14]. Plasma aliquots (100 μl) were placed in 4-ml polypropylene tubes[15] with fitted caps. Plasma samples were frozen until analysis.

Later studies compared peanut oil and aqueous suspensions administered in a 20-μl volume in a complete crossover study in four rats. The washout period was 1 week. To administer the 20-μl volume, the procedure of Yamahira *et al.* (13) was adopted with some modifications. The suspensions were prepared at concentrations of 45 mg/ml so that each rat received 0.9 mg in the 20-μl volume. The dosing system consisted of 19-gauge flexible tubing with a luer-lock end[16] sleeved with polyethylene tubing for rigidity.

A 50-μl syringe[16] was used to draw the dose, and the tubing was calibrated to double check the volume. Each dose was followed by a small volume of air injected through the tubing to ensure that no material re-

mained on the inside. This dosing system was checked with the actual suspensions used and was found to provide reproducible doses within ±10%.

**Analytical Procedure**—The analytical procedure was a modification of the method of Sved *et al.* (15). Plasma samples were thawed, 0.2 ml of perchloric acid was added, and the sample was mixed. Methylisobutylketone[17] (0.8-ml), which had been saturated with 1 *M* $HClO_4$, was then added, and the sample was mixed again. Sample tubes were then capped and shaken for 20 min, samples were centrifuged for 10 min, and the methylisobutylketone layer was removed and refrigerated in glass vials. Standards were prepared by adding appropriate concentrations of triamterene to 100 μl of blank plasma and extracted in the same manner. This extraction procedure provided ~90% recovery when compared to standards prepared directly in methylisobutylketone in a plasma concentration range of 10–850 ng/ml.

HPLC[18] was used to analyze the extracted plasma samples. Fifty-microliter injections were made onto the column[19], and the flow rate was 2 ml/min. No attempts were made to quantitate metabolites. The system operated at 1000 psi at a fluorometer setting of 335-nm excitation and 470-nm emission. The mobile phase consisted of methylene chloride–hexane–methanol–perchloric acid (55:35:10:0.1). Concentrations were quantitated by comparing peak height to the standards developed for each set of samples.

## RESULTS

In the first series of experiments, 10 mg of triamterene/kg was administered to rats in 1 ml of the following vehicles: solution in 8% lactic acid, aqueous suspension, oleic acid suspension, triolein suspension, and peanut oil suspension. Ten rats were randomly assigned to a balanced incomplete block design in which each rat received two formulations in trials separated by 1 week. Each formulation was administered four times to four different rats.

Table I shows the mean plasma concentrations with associated standard errors for each formulation in the four rats at each sampling time. Table II shows the mean peak concentration, mean time of peak concentration, and mean area under the plasma concentration–time curve (0–24 hr) computed by trapezoidal integration from the four individual experiments with each formulation[20].

[17] Mallinckrodt, Paris, Ky.

[18] The chromatographic system consisted of a 6000 A pump and U6K universal injector (Waters Associates, Milford, Mass.) coupled to an FS 970 fluorometer (Schoeffel Instrument Corp., Westwood, N.J.).

[19] Lichrosorb Si-60-7 (250 × 4.6 mm), Chrompak, Whittier, Calif.

[20] Although the oleic acid suspension resulted in the largest *AUC*, this result is biased by the 12- and 24-hr time points in which plasma concentrations began to increase again. This observation is currently not explained and is being reevaluated.

Table IV—Mean Peak Plasma Concentration, Mean Time of Peak Concentration, and Mean *AUC* in Rats[a] following an Oral Dose of 0.9 mg of Triamterene in a 20-μl Vehicle Volume

| Vehicle | Mean Peak Plasma Concentration, ng/ml | Mean Time of Peak Plasma Concentration, hr | Mean *AUC*, ng hr/ml |
|---|---|---|---|
| Aqueous suspension | 258 (19) | 1.62 (0.47) | 2560 (169) |
| Peanut oil suspension | 251 (32) | 2.00 (0.35) | 2162 (103) |

[a] Means calculated from four individual experiments in four different rats in a complete crossover study; none of the means in any column are significantly different ($\alpha = 0.05$)..

The data of Tables I and II show a trend with peanut oil suspensions toward higher plasma triamterene levels and an overall increase in the availability of triamterene when compared to the aqueous suspensions. These findings led to a further investigation of peanut oil as a potential vehicle for enhancing the oral availability of triamterene. A second series of experiments, in a complete crossover study, was conducted in which the peanut oil suspension was compared to aqueous suspensions in four rats, also at a dose of 10 mg/kg in a 1-ml volume. The specific results of this study are not shown here; however, it confirmed the potential of peanut oil as a vehicle to enhance the oral availability of triamterene.

The third series of experiments was conducted to evaluate the oral availability of triamterene using aqueous and peanut oil suspensions in a realistic dosage form vehicle volume. In this study, 20 μl of peanut oil or aqueous suspensions of triamterene containing 45 mg of drug/ml were administered to four rats in a complete crossover design. Each rat received 0.9 mg of triamterene in a 20-μl dose volume, which represents a realistic dosage form volume when scaled to the size of the rat (13). Table III shows the individual plasma triamterene levels measured in the four rats with both aqueous and peanut oil suspensions. Figure 1 shows a plot of the mean plasma level at each time point for both the aqueous and peanut oil suspensions, and Table IV shows the mean peak concentrations, time of peak concentration, and mean *AUC* (0–24 hr).

## DISCUSSION

In the initial study with the 1-ml vehicle volume, the three lipid vehicles exhibited a trend toward a later peak time and maintained higher plasma levels for a longer time when compared to aqueous suspensions. With all formulations tested, a rather large intersubject variability was noted. This finding was consistent with what other investigators observed following triamterene administration (16). Such variability coupled with the small number of trials (four) performed with each vehicle made it difficult to evaluate statistical differences among the vehicles even though the trends were clear. Additionally, any differences among the lipid vehicles with respect to triamterene availability cannot be explained on the basis of drug solubility in the vehicles. Even with oleic acid, which was the suspension vehicle in which triamterene was most soluble, <1% of the administered drug was in solution.

The lactic acid solution clearly provided the highest plasma triamterene levels of the vehicles evaluated with a 1-ml dosing volume. As previously noted, the oleic acid vehicle resulted in the largest *AUC*, al-

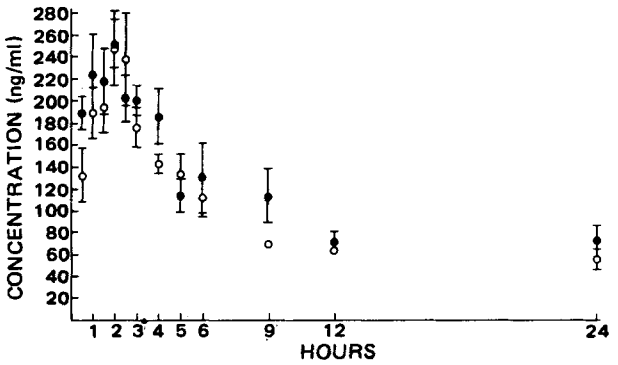

**Figure 1**—*Mean plasma levels of triamterene in rats following oral administration of 0.9 mg in a 20-μl vehicle volume in a complete crossover study. Key:* ○, *peanut oil suspension; and* ●, *aqueous suspension. Bars represent standard error of the mean.*

though this result was biased by the 12- and 24-hr time points. Oleic acid was not investigated further in this study, although Noguchi *et al.* (17) concluded that oleic acid may be a useful vehicle to sustain the release of poorly water-soluble drugs, thus, prolonging their effects.

In the last series of this study, the oral availability of triamterene was evaluated from peanut oil and aqueous suspensions in which the dosing volume was reduced to 20 $\mu$l. Peanut oil was selected for comparison with the aqueous vehicle based on results from the initial study. In that study, the peanut oil vehicle provided a similar peak plasma level as the aqueous suspension, although peak levels occurred somewhat later. The decline from peak levels was slower for peanut oil than for the aqueous suspension, resulting in a larger overall *AUC* for peanut oil suspensions. Finally, the intersubject variability in the initial study was smallest with the peanut oil suspensions. It was thus concluded that peanut oil might be a promising vehicle for formulating triamterene and improving its oral availability.

The results (Tables III and IV and Fig. 1) of the two-way crossover study, comparing peanut oil and aqueous suspensions of triamterene, did not confirm the initial optimism regarding peanut oil as a vehicle when administered in realistic dosage form vehicle volumes. A weighted unpaired $t$-test revealed no significant differences between the aqueous and peanut oil vehicles with respect to peak plasma concentration, peak time, or *AUC* ($\alpha = 0.05$). These results suggest that any enhanced availability in the peanut oil vehicle, which was suggested by the initial study, may have been due to physiological effects on the GI tract caused by the relatively large vehicle volume used. Such effects appeared to be eliminated when the dosage form vehicle volumes were used.

A further aspect of these studies is the comparison of the doses used in both the large and small volume experiments. In the 1-ml administered volume study, each rat received ~2.5 mg of triamterene; in the 20-$\mu$l volume study, the administered dose was ~0.9 mg. The $t$-test revealed that neither peak height nor peak time was significantly different between these two studies ($\alpha = 0.5$). However, with the aqueous suspension, the *AUC* for the 20-$\mu$l dose volumes was greater ($p < 0.05$) than with the 1-ml volume. With the peanut oil suspensions, the *AUC* for the 20-$\mu$l dose volume was significantly less than with the 1-ml volume ($p < 0.001$) but, in absolute terms, was reduced by one-third compared with the dosage reduction of a factor of ~3. Clearly, the larger dose volumes for both peanut oil and aqueous suspensions adversely affected the oral availability of triamterene. The precise mechanism of this effect is unexplained, although it is probably due to some alteration of physiological processes within the GI tract caused by the large vehicle volumes.

The results indicated that the methodology used to evaluate the effects of various vehicles on the GI absorption of drugs must be carefully considered. The results of *in situ* perfusion studies and those employing large vehicle volumes may not be directly applicable to an actual dosage form. With triamterene, a drug poorly soluble in both aqueous and lipid vehicles, a large volume of lipid vehicle may provide some enhancement of oral availability when compared to aqueous vehicles. At least with peanut oil, however, when the vehicle volume is reduced to a realistic dosage form volume, the potential advantage is lost. Furthermore, small vehicle volumes result in better relative oral availability for triamterene than do large vehicle volumes. Such a finding might be considered with regard to the administration of triamterene in conjunction with some foods.

# Compression Properties of Granulations Made with Binders Containing Different Moisture Contents

**Z. T. CHOWHAN** ˣ **and Y. P. CHOW**

Received June 27, 1980, from the *Institute of Pharmaceutical Sciences, Syntex Research, Palo Alto, CA 94304.* Accepted for publication March 5, 1981.

**Abstract** □ The role of the granulation moisture content on compression properties of granules made with selected binders was studied. The results suggested that, at lower pressures, higher moisture-containing granules were slightly more compressible than lower moisture-containing granules. However, at higher pressures, the reverse was true because of the water lubrication effect. At lower moisture levels, the crushing strength of the tablets was dependent on the binder; at higher moisture levels, binder differences became less significant.

to quantify the compression parameters of powders, provided that various experimental conditions are considered.

The relative density *versus* pressure plots of the granulations made with powder mixtures by wet granulation did not give a typical relationship (4), as previously explained (2). A break in the linear portion of the Heckel plots at a pressure range of ~1200–1900 kg/cm$^2$ was explained largely on the basis of the water lubrication effect at higher pressures. At lower pressures, where the water lubrication effect did not occur, the relative density–pressure plots (2) and the Cooper–Eaton plots (3) were used to calculate the apparent material constants and the coefficients of the Cooper–Eaton equation. Excellent correlation between the apparent material constant ($C_1$) of the Heckel equation and the coefficient ($k_2$) of the Cooper–Eaton equation and the tablet crushing strength suggested the usefulness of these studies for proper binder selection when designing tablet formulations.

This paper reports the role of moisture content on compression properties of granulations made with selected binders.

## EXPERIMENTAL

**Materials**—Ticlopidine hydrochloride[1] (I) was at least 98% pure. The excipients, crystalline lactose[2], starch[3], magnesium stearate[4], povidone[5], methylcellulose[6], hydroxypropyl methylcellulose[7], and pregelatinized starch[3], were all USP grade.

**Granulation**—The formulations are listed in Table I. Compound I and lactose were mixed together in a small planetary mixer for 5 min. For Formulation C, pregelatinized starch was also mixed with I and lactose and granulated with purified water by mixing for 5 min. For Formulations A, B, and D, the binder was dispersed or dissolved in the same amount of water as was used in granulating Formulation C. The I–lactose mixture (39 g) was granulated with 15 ml of the granulating solution by mixing for 5 min.

For Formulation E, the I–lactose mixture was granulated with 15 ml of purified water. The wet granulation was passed through a 1.4-mm aperture and dried in a forced-air oven at 40° until the desired moisture levels were obtained. The dried granulation was screened through a 1.2-mm aperture. Starch and magnesium stearate then were blended with the granulation for 5 min.

**Compression**—For each compression, 390 mg of the granulation was used[8]. The die and punches were 10.32 mm in diameter, and the punches were flat-faced. The contact time of the upper punch with the granulation was less than 5 sec. Immediately after compression and ejection, the height of the compact was measured accurately and the volume and density of the compact were calculated. Three determinations were made for each data point. The mean volumes of compression, along with the standard deviations at given pressures for granulations made with the selected binders, are given in Table II.

**Tablet Crushing Strength**—The compact hardness was determined[9] immediately after compression. For each hardness determination, three compacts were tested and the mean was calculated.

**Moisture Determination**—An aluminum dish was dried in a forced-air oven at 60° for 30 min. The dish was then equilibrated to room temperature, and the sample was accurately weighed into the dish and

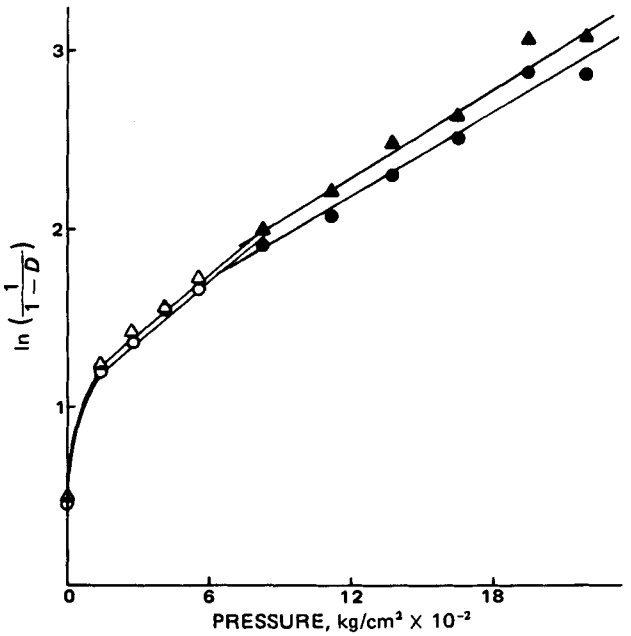

**Figure 1**—*Plots of ln[1/(1 − D)] versus pressure using granulations made with povidone (△,▲) and methylcellulose (○,●) as binders. The moisture contents at the time of compression were 1.12% for povidone granules and 0.89% for methylcellulose granules.*

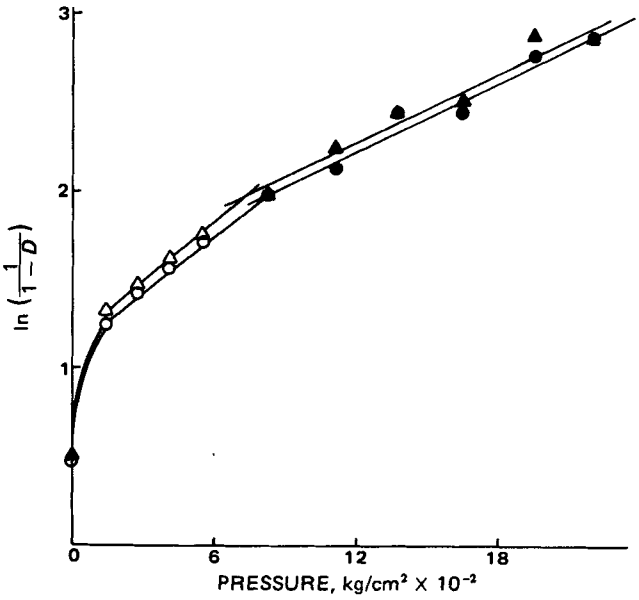

**Figure 2**—*Plots of ln[1/(1 − D)] versus pressure using granulations made with pregelatinized starch (○, ●) and without a binder (△,▲). The moisture contents at the time of compression were 0.79% for pregelatinized starch granules and 0.77% for granules made without a binder.*

[a] In cubic centimeters (mean ± *SD*).

dried in the oven at 60° until it reached a constant weight. The moisture content was calculated from the sample weight before and after drying.

**Bulk Density**—The powder was slowly sifted into a 50-ml graduated cylinder through a plastic funnel. The powder weight ($W$) and volume ($V$) were recorded to calculate the bulk density ($\gamma_b = W/V$).

**True Density**—The true density of the granules was calculated from the true density of the individual components in the formulation. The method of density matching (5) was used to determine the true density of individual components. A few milligrams of the powder was added to the test tubes containing different combinations of carbon tetrachloride and hexane mixtures. The powder–solvent mixture was shaken on a vortex mixer, centrifuged, and allowed to stand for 30 min. The true density of the powder was the same as the density of the solvent mixture in which the powder remained suspended. The density of the solvent mixture was determined with a pycnometer at 23° using water to calibrate the volume.

## RESULTS AND DISCUSSION

The relative density *versus* pressure plots of the granulations made with selected binders at different moisture levels are given in Figs. 1 and 2 (moisture content, 0.77–1.12%) and 3 and 4 (moisture content, 1.95–2.44%). The relative density *versus* pressure plots of the granulations made with hydroxypropyl methylcellulose at different moisture levels are given in Fig. 5.

As reported previously (4), the relative density *versus* pressure plots of the granulations made with powder mixtures do not give a typical relationship, as explained by Heckel (2). According to the Heckel equation (Eq. 1), plots of $\ln [1/(1-D)]$ *versus* pressure ($P$) give, on extrapolation, the material constant ($C$), which is identified with the reciprocal yield pressure of the material, and the intercept ($I$), which is identified with the movement of particles during the initial stages of compaction:

$$\ln\left(\frac{1}{1-D}\right) = CP + I \qquad \text{(Eq. 1)}$$

where $D$ (relative density of the compact) is obtained by dividing the bulk density at a given pressure by the true density (calculated). However, bulk density was determined on granules before compression (no pressure).

The break in the relative density *versus* pressure plots (Figs. 1–5) could be attributed largely to the water lubrication effect. At higher pressures, the small amount of water in the granulation is squeezed out to the surface of the die wall and thus reduces the die wall friction. However, at lower pressures, the small amount of water in the granules remains in the

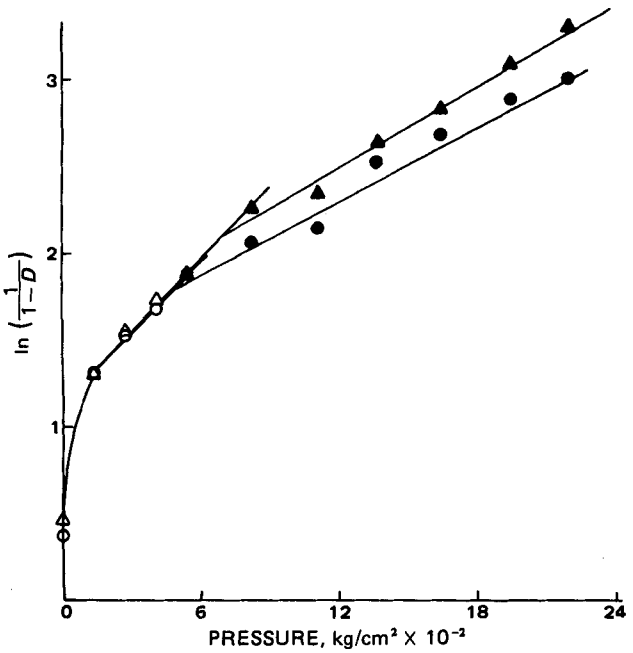

**Figure 3**—*Plots of ln[1/(1 − D)]* versus *pressure using granulations made with povidone (△,▲) and methylcellulose (○,●) as binders. The moisture contents at the time of compression were 2.23% for povidone granules and 2.44% for methylcellulose granules.*

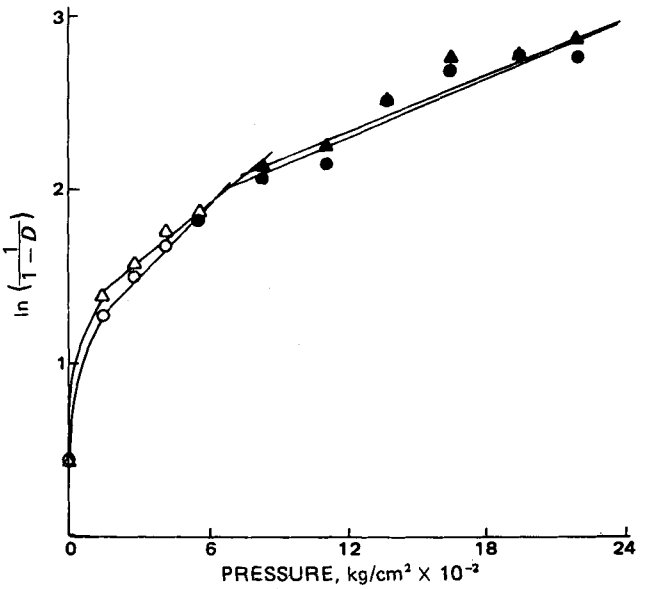

**Figure 4**—*Plots of ln[1/(1 − D)]* versus *pressure using granulations made with pregelatinized starch (○,●) and without a binder (△,▲). The moisture contents at the time of compression were 2.02% for pregelatinized starch granules and 1.95% for granules made without a binder.*

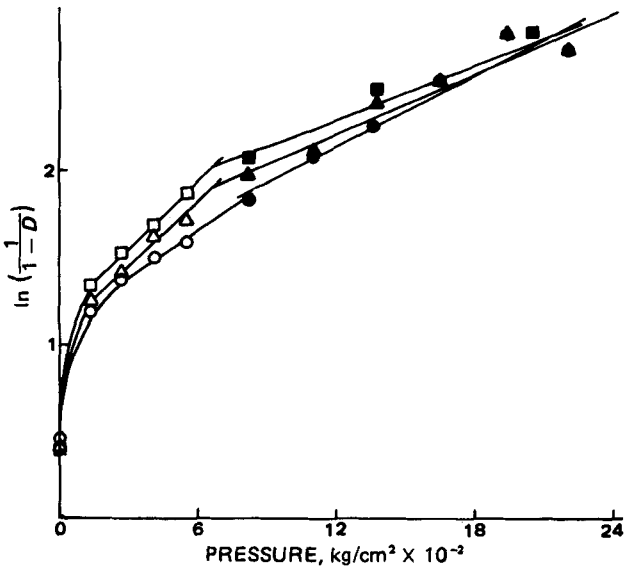

**Figure 5**—*Plots of ln[1/(1 − D)] versus pressure using granulations made with hydroxypropyl methylcellulose as a binder. The moisture contents at the time of compression were 3.35% (□,■), 2.32% (△,▲), and 0.75% (○,●).*

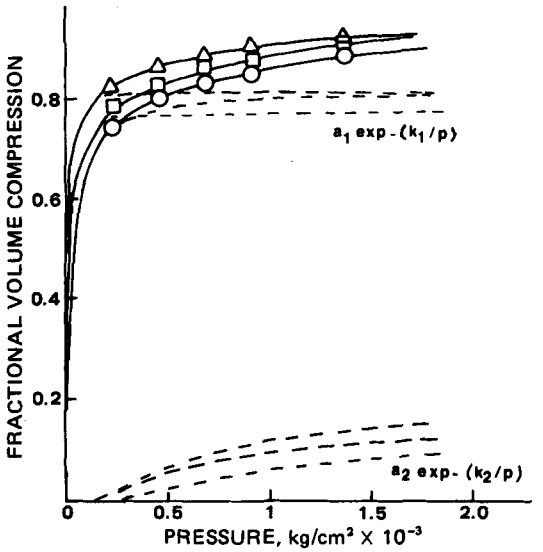

**Figure 6**—*Fractional volume compression versus pressure plots of the granulation made with hydroxypropyl methylcellulose dried to different moisture contents. Key: ○, 0.75% moisture; □, 2.32% moisture; and △, 3.35% moisture. Dotted lines indicate calculated results of Eq. 4.*

granulation and the powder mixtures behave as a single material. In view of the water lubrication effect, the first part of the relative density–pressure plots could be analyzed by the Heckel equation.

Table III gives the values of the bulk density and the calculated true density of the granules made with selected binders containing different moisture contents and the three-stage densification values, $D_0$, $D_a$, and $D_b$. These values represent the three-stage densification process that takes place: filling the die ($D_0$), individual particle movement and rearrangement ($D_b$), and particle deformation after interparticle bonding becomes appreciable ($D_a$).

The $D_a$ value was obtained from the measured intercept value, $I$ (Eq. 1), and the relationship:

$$D_a = 1 - e^{-I} \qquad \text{(Eq. 2)}$$

The $D_b$ value was obtained from the experimental bulk density, $D_0$:

$$D_b = D_a - D_0 \qquad \text{(Eq. 3)}$$

In agreement with previous results (1, 2, 4), $D_a$ values were higher than $D_b$ values, indicating that more densification occurred by granule deformation than by rearrangement and granule movement. However, these values did not show significant effect due to differences in the type of binder or the percent moisture content. The concentration of binders in these formulations was even lower than that used previously (4).

At lower moisture levels (0.75–1.12%), the values of the apparent material constant, $C_1$ (Table IV), suggest that granules made with methylcellulose, povidone, and pregelatinized starch are more compressible than granules made with hydroxypropyl methylcellulose and without a binder. However, at higher moisture levels (1.95–2.44%), the values of the ap-

parent material constant, $C_1$ (Table IV), suggest that granules made with povidone are more compressible than granules made with other binders.

The $C_2$ values, representing the slope of the second linear region (Table IV), were obtained under the assumption that the compact above a certain pressure ($P$) compresses under the water lubrication effect, thus giving a higher yield pressure. At lower moisture content, the $C_2$ values suggest that the granules made with methylcellulose and povidone are more compressible than granules made with other binders. At higher moisture contents, the $C_2$ values suggest that methylcellulose and povidone are also slightly more compressible than granules made with other binders.

In general, the $C_1$ values indicate that the granulations containing lower moisture levels are slightly less compressible than those containing higher moisture levels. However, the $C_2$ values suggest that the lower moisture-containing granules are slightly more compressible than the higher moisture-containing granules. At higher applied pressures, granules containing more moisture may exhibit a barrier to compression due to the water lubrication effect, thus making these granules more difficult to compress.

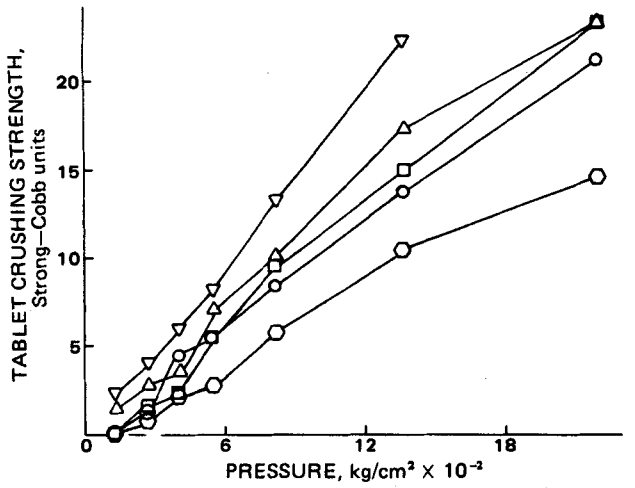

**Figure 7**—*Tablet crushing strength* versus *pressure profiles of tablets compressed from granulations made with different binders. The moisture contents of the granules at the time of compression were 0.89% (methylcellulose) (▽); 0.79% (pregelatinized starch) (△); 1.12% (povidone) (○); 0.75% (hydroxypropyl methylcellulose) (○); and 0.77% (no binder) (□).*

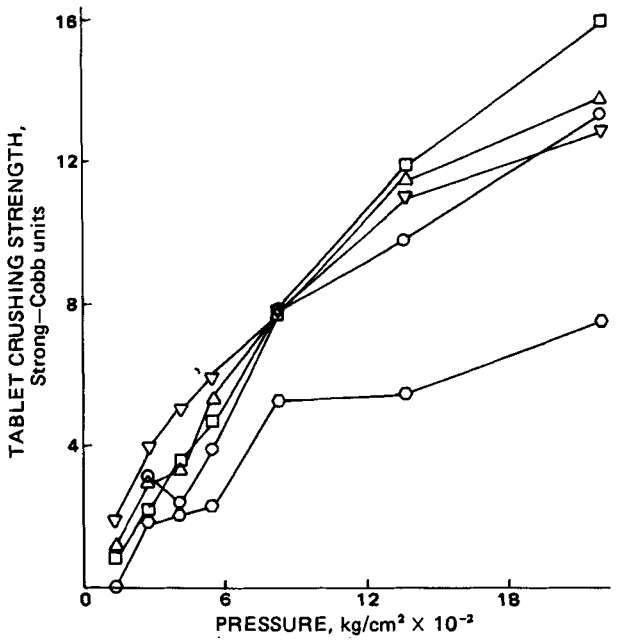

**Figure 8**—*Tablet crushing strength* versus *pressure profiles of tablets compressed from granulations made with different binders. The moisture contents of the granules at the time of compression were 2.23% (povidone) (□); 2.02% (pregelatinized starch) (△); 2.32% (hydroxypropyl methylcellulose) (○); 2.44% (methylcellulose) (▽); and 1.95% (no binder) (○).*

Cooper and Eaton (3) analyzed compression behavior of ceramic powders by assuming two largely independent probabilistic processes, the filling of large holes and the filling of small pores. The Cooper–Eaton equation (Eq. 4) relates the fractional value compression, $V^*$, to the applied pressure, $P$:

$$V^* = \frac{V_0 - V}{V_0 - V_\infty} = a_1 \exp - (k_1/P) + a_2 \exp - (k_2/P) \quad \text{(Eq. 4)}$$

where:

$V_0$ = initial total volume when no holes are filled
$V$ = compact volume
$V_\infty$ = compact volume when all holes of all types are filled
$a_1$ and $a_2$ = dimensionless coefficients indicating a fraction of the theoretical compression that would be achieved at infinite pressure by each particular process
$k_1$ and $k_2$ = coefficients with units of pressure where the particular process is most probable

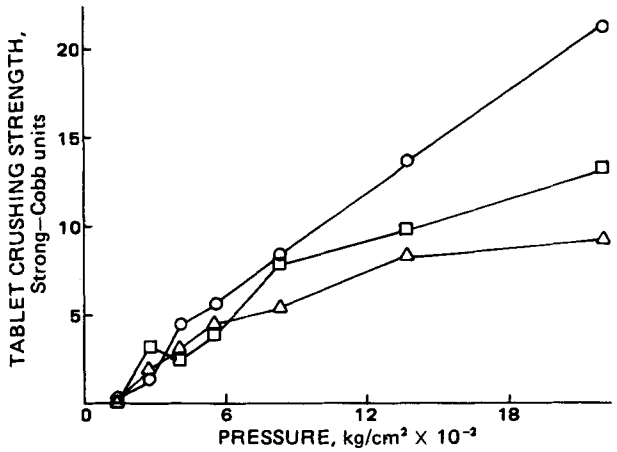

**Figure 9**—*Tablet crushing strength* versus *pressure profiles of tablets compressed from granulations made with hydroxypropyl methylcellulose. The moisture contents of the granules at the time of compression were 0.75% (○), 2.32% (□), and 3.55% (△).*

The fractional volume compression *versus* applied pressure plots up to the first linear region of the relative density *versus* pressure plots were used to calculate the coefficients of the Cooper–Eaton equation (Table V). Figure 6 gives the fractional volume compression *versus* pressure plots of the granulation made with hydroxypropyl methylcellulose and dried to different moisture contents. The experimental data were fitted to the results of the calculations using Eq. 4. The values of the coefficients were obtained from the best-fit curves.

The larger values of the dimensionless coefficient $a_1$ compared to $a_2$ (Table V) suggest that a large percentage of compression was achieved by filling large holes. The sum of coefficients $a_1$ and $a_2$ ranged from 0.97 to 1.01, indicating that compression is achieved by the two probabilistic processes of filling large and small holes by rearrangement, fragmentation, and plastic flow.

The coefficient $k_1$ gives the pressure needed to fill the large holes. This process occurs primarily by particles sliding past one another, which may require elastic deformation or even slight fracturing or plastic flow of particles. This process occurs at low pressures and is reflected in small $k_1$ values (Table V).

The coefficient $k_2$ indicates the pressure needed to fill small voids that are substantially smaller than the original particles. These voids can be filled by plastic flow or by fragmentation. This process requires high pressure, which is reflected in large $k_2$ values (Table V). Thus, $k_2$ provides more information about granulation compressibility since, during the rearrangement process, granules do not produce hard compacts. The $k_2$ values given in Table V indicate that, at lower moisture contents, methylcellulose- and povidone-containing granules are more compressible than granules made with the other binders. At higher moisture contents, methylcellulose-containing granules are more compressible than granules made with other binders. The $k_2$ values also suggest that the higher moisture-containing granules are more compressible than those of lower moisture content. This finding is in complete agreement with the $C_1$ values of the Heckel plots (Table IV), which suggest that the high moisture granules compress more easily than the low moisture ones.

The tablet crushing strength *versus* pressure profiles of granulations made with the selected binders containing different moisture contents are given in Figs. 7–9. At lower moisture contents (0.75–1.12%), methylcellulose-containing tablets gave higher crushing strengths than those made with granules containing other binders. The tablets made from granules without a binder were lower in crushing strength than the tablets made from granules containing binders.

At higher moisture levels (1.95–2.44%), differences in tablet crushing strength due to the binders were small (Fig. 8). Povidone-containing granules were better in crushing strength only at high pressure. Granules without a binder showed lower tablet crushing strengths compared to those with different binders.

Figure 9 compares the tablet crushing strength *versus* pressure profiles of the tablets compressed from granulations made with hydroxypropyl methylcellulose at different moisture levels. These results clearly show that the lower moisture-containing granules gave a higher crushing strength compared to the higher moisture-containing granules and that these differences became more pronounced as pressure was increased.

At higher moisture levels, it is important to consider the moisture-induced crushing strength increase phenomenon (6). Table VI gives the initial crushing strength and the crushing strength after a 24-hr exposure to ambient room conditions of tablets compressed at a given pressure. The crushing strength of tablets containing povidone, methylcellulose, and hydroxypropyl methylcellulose increased after overnight exposure to ambient room conditions. Pregelatinized starch-containing tablets did not show any change in crushing strength after overnight exposure to ambient room conditions. In the absence of a binder, the tablet crushing strength actually decreased after overnight exposure to ambient room conditions.

# Leaching of 2-(2-Hydroxyethylmercapto)benzothiazole into Contents of Disposable Syringes

**MARISA C. PETERSEN *, JOHN VINE ‡, JOHN J. ASHLEY ‡, and ROGER L. NATION *x**

Received November 17, 1980, from the **Perinatal Pharmacology Laboratory, Foundation 41, The Women's Hospital, Crown Street, Surry Hills, 2010 Australia*, and the ‡*Department of Pharmacy, University of Sydney, Sydney, Australia.* Accepted for publication March 6, 1981.

**Abstract** □ A contaminant was found to leach into the contents of two brands of disposable syringes. It was identified as 2-(2-hydroxyethylmercapto)benzothiazole and is believed to be formed during manufacture of the syringes as a result of a reaction between 2-mercaptobenzothiazole, a rubber vulcanization accelerator, and ethylene oxide, used for sterilization. The contaminant was isolated from the rubber plunger-seal and identified using mass, NMR, and UV spectroscopic methods. The amount of contaminant appearing in the contents of syringes was measured; up to 140 μg was found under clinically relevant conditions. This finding has important implications with respect to the use of these syringes for drug administration and for the collection of blood for drug analyses.

**Keyphrases** □ 2-(2-Hydroxyethylmercapto)benzothiazole—leaching into contents of disposable syringes, isolation, identification, and quantitation □ Syringes, disposable—leaching of 2-(2-hydroxyethylmercapto)benzothiazole, isolation, identification, and quantitation □ Contaminants—2-(2-hydroxyethylmercapto)benzothiazole, leaching from disposable syringes

Several previous reports described the problems associated with the leaching of compounds from plastic infusion bags and giving sets and from blood collection tubes. The measurement of drug levels in blood and plasma samples for toxicological, therapeutic monitoring, or pharmacokinetic purposes may be hampered by such contaminants. In addition, the accumulation of plasticizers in patients' organs after transfusion of blood from plastic storage bags was reported (1).

Recently, contamination of blood collected in evacuated

The fractional volume compression *versus* applied pressure plots up to the first linear region of the relative density *versus* pressure plots were used to calculate the coefficients of the Cooper–Eaton equation (Table V). Figure 6 gives the fractional volume compression *versus* pressure plots of the granulation made with hydroxypropyl methylcellulose and dried to different moisture contents. The experimental data were fitted to the results of the calculations using Eq. 4. The values of the coefficients were obtained from the best-fit curves.

The larger values of the dimensionless coefficient $a_1$ compared to $a_2$ (Table V) suggest that a large percentage of compression was achieved by filling large holes. The sum of coefficients $a_1$ and $a_2$ ranged from 0.97 to 1.01, indicating that compression is achieved by the two probabilistic processes of filling large and small holes by rearrangement, fragmentation, and plastic flow.

The coefficient $k_1$ gives the pressure needed to fill the large holes. This process occurs primarily by particles sliding past one another, which may require elastic deformation or even slight fracturing or plastic flow of particles. This process occurs at low pressures and is reflected in small $k_1$ values (Table V).

The coefficient $k_2$ indicates the pressure needed to fill small voids that are substantially smaller than the original particles. These voids can be filled by plastic flow or by fragmentation. This process requires high pressure, which is reflected in large $k_2$ values (Table V). Thus, $k_2$ provides more information about granulation compressibility since, during the rearrangement process, granules do not produce hard compacts. The $k_2$ values given in Table V indicate that, at lower moisture contents, methylcellulose- and povidone-containing granules are more compressible than granules made with the other binders. At higher moisture contents, methylcellulose-containing granules are more compressible than granules made with other binders. The $k_2$ values also suggest that the higher moisture-containing granules are more compressible than those of lower moisture content. This finding is in complete agreement with the $C_1$ values of the Heckel plots (Table IV), which suggest that the high moisture granules compress more easily than the low moisture ones.

The tablet crushing strength *versus* pressure profiles of granulations made with the selected binders containing different moisture contents are given in Figs. 7–9. At lower moisture contents (0.75–1.12%), methylcellulose-containing tablets gave higher crushing strengths than those made with granules containing other binders. The tablets made from granules without a binder were lower in crushing strength than the tablets made from granules containing binders.

At higher moisture levels (1.95–2.44%), differences in tablet crushing strength due to the binders were small (Fig. 8). Povidone-containing granules were better in crushing strength only at high pressure. Granules without a binder showed lower tablet crushing strengths compared to those with different binders.

Figure 9 compares the tablet crushing strength *versus* pressure profiles of the tablets compressed from granulations made with hydroxypropyl methylcellulose at different moisture levels. These results clearly show that the lower moisture-containing granules gave a higher crushing strength compared to the higher moisture-containing granules and that these differences became more pronounced as pressure was increased.

At higher moisture levels, it is important to consider the moisture-induced crushing strength increase phenomenon (6). Table VI gives the initial crushing strength and the crushing strength after a 24-hr exposure to ambient room conditions of tablets compressed at a given pressure. The crushing strength of tablets containing povidone, methylcellulose, and hydroxypropyl methylcellulose increased after overnight exposure to ambient room conditions. Pregelatinized starch-containing tablets did not show any change in crushing strength after overnight exposure to ambient room conditions. In the absence of a binder, the tablet crushing strength actually decreased after overnight exposure to ambient room conditions.

# Leaching of 2-(2-Hydroxyethylmercapto)benzothiazole into Contents of Disposable Syringes

**MARISA C. PETERSEN *, JOHN VINE ‡, JOHN J. ASHLEY ‡, and ROGER L. NATION *x**

Received November 17, 1980, from the **Perinatal Pharmacology Laboratory, Foundation 41, The Women's Hospital, Crown Street, Surry Hills, 2010 Australia*, and the ‡*Department of Pharmacy, University of Sydney, Sydney, Australia.* Accepted for publication March 6, 1981.

**Abstract** □ A contaminant was found to leach into the contents of two brands of disposable syringes. It was identified as 2-(2-hydroxyethylmercapto)benzothiazole and is believed to be formed during manufacture of the syringes as a result of a reaction between 2-mercaptobenzothiazole, a rubber vulcanization accelerator, and ethylene oxide, used for sterilization. The contaminant was isolated from the rubber plunger-seal and identified using mass, NMR, and UV spectroscopic methods. The amount of contaminant appearing in the contents of syringes was measured; up to 140 μg was found under clinically relevant conditions. This finding has important implications with respect to the use of these syringes for drug administration and for the collection of blood for drug analyses.

**Keyphrases** □ 2-(2-Hydroxyethylmercapto)benzothiazole—leaching into contents of disposable syringes, isolation, identification, and quantitation □ Syringes, disposable—leaching of 2-(2-hydroxyethylmercapto)benzothiazole, isolation, identification, and quantitation □ Contaminants—2-(2-hydroxyethylmercapto)benzothiazole, leaching from disposable syringes

Several previous reports described the problems associated with the leaching of compounds from plastic infusion bags and giving sets and from blood collection tubes. The measurement of drug levels in blood and plasma samples for toxicological, therapeutic monitoring, or pharmacokinetic purposes may be hampered by such contaminants. In addition, the accumulation of plasticizers in patients' organs after transfusion of blood from plastic storage bags was reported (1).

Recently, contamination of blood collected in evacuated

*© 1981, American Pharmaceutical Association*

tubes[1] with a compound identified as tris(2-butoxyethyl)-phosphate was reported (2). Leaching of this compound into blood causes a decrease in plasma protein binding and redistribution to the red blood cells of several drugs including propranolol (3), imipramine (4), alprenolol (4), quinidine (5), and lidocaine (6). Consequently, the measured plasma concentrations of these drugs were spuriously low. Tris(2-butoxyethyl) phosphate, leached into blood samples from collection tubes, interfered directly with the analysis of postmortem specimens (2) and with GLC analysis of theophylline (7). Another plasticizer, di(2-ethylhexyl) phthalate, also was reported to interfere with a GLC assay for disopyramide (8).

During recent work involving the development of a high-performance liquid chromatographic (HPLC) assay for blood and plasma corticosteroids (9), a large chromatographic peak interfered with the assay. The absence of the interfering compound in samples collected directly into a glass container indicated that it originated in the collection system and was not due to endogenous material or contamination of the reagents used in extraction. The compound originated in the disposable syringes used for blood collection.

The identification of the source of the compound, its isolation, and the elucidation of its chemical structure are reported here.

## EXPERIMENTAL

**Identification of Contaminant Source**—Three brands of disposable plastic syringes (A[2], B[3], and C[4]) were used. Initially, one syringe of each brand (10–12-ml capacity) was filled through a 19-gauge needle[5] with freshly distilled water (10 ml) and allowed to stand for 2 min. Another sample of water (10 ml) was allowed to stand for 2 min in a blood storage tube containing ammonium heparin (100 U/10 ml) and separation granules[6]. From each of these sources 1 ml (10%) of the water was extracted with methylene chloride[7], which was then concentrated at 45° and chromatographed as described previously for plasma samples (9). The reversed-phase HPLC column[8], with a mobile phase of methanol–water (60:40) at a flow rate of 1.25 ml/min, was coupled to a UV detector set at 254 nm. An aliquot (1 ml) of distilled water, which had been measured directly into a glass extraction tube, was also analyzed as already described.

To pinpoint the source of contamination, this procedure was repeated with three Brand A syringes, three Brand C syringes, and three samples of water measured into glass extraction tubes. In addition, the barrels of three Brand A syringes with the plungers removed and needles crimped were each filled with 10 ml of distilled water, and three rubber plunger-seals from Brand A syringes were removed and immersed in beakers containing 10 ml of distilled water. The syringes and components were in contact with the water for 2 min, and 1 ml was assayed.

To establish that the contaminant was extracted from the syringes into blood as well as into water and to confirm that the chromatographic peak observed in plasma samples was not an endogenous compound, the following experiment was performed. Blood was drawn from a single subject through a cannula[9] and three-way tap[10] using the three brands of syringes in turn. The total blood volume (15 ml) was drawn within 3 min. The blood was transferred to three heparinized plastic tubes for centrifugation; in each case, 1 ml of the resulting plasma was assayed.

**Identification of Contaminant**—To facilitate identification of the compound of interest, several syringes of each brand were allowed to stand, containing water, for 10 min. The water was subsequently extracted, the concentrated extract was chromatographed, and the fraction of the HPLC eluate corresponding to the peak of interest was collected. The fractions from each brand of syringe were pooled separately and evaporated to dryness in a 45° water bath under a nitrogen stream. The residues were dissolved in 1 ml of distilled water and extracted with methylene chloride. The extracts then were concentrated. To provide sufficient sample for NMR studies, derivatization procedures, and UV spectroscopy, ~500 μg of the contaminant was collected by pooling the HPLC fractions from 20 Brand A syringes (35-ml capacity) as already described.

GLC–mass spectrometric analyses were carried out on a chemical-ionization mass spectrometer[11] interfaced to a gas chromatograph[12]. The glass GLC column (0.91 m × 2 mm i.d.) was packed with a phenyl methyl silicone phase[13] and was programmed from 150 to 200° at 10°/min. Injection port and interface temperatures were maintained at 260°. Methane chemical-ionization mass spectra were generated by using methane as both the GLC carrier and chemical-ionization reactant gas. A flow rate of 20 ml/min generated an ion source pressure of 130 Pa. Deuterium oxide chemical-ionization mass spectra were generated by introducing deuterium oxide into the methane plasma *via* a variable leak (10). Ammonia chemical-ionization mass spectra were obtained by using helium as the GLC carrier gas at a flow rate of 20 ml/min and adding ammonia through a makeup T piece at the end of the column. The ammonia flow rate was adjusted to give an ion source pressure of 130 Pa. The electron beam energy for chemical ionization was 110 ev, and the ion source and analyzer regions of the mass spectrometer were operated at 60–100°. An interactive data system[14] was used for data acquisition and processing.

High-resolution electron-impact mass spectra were obtained[15] using the direct insertion probe inlet and an electron beam energy of 70 ev.

Derivatization reactions were carried out by dividing a methylene chloride extract from Brand A syringes into two portions and evaporating each to dryness. One portion was treated with 10 μl of a silylation reagent[16] by heating at 50° for 1 hr. The other portion was treated with excess freshly distilled ethereal diazomethane for 15 min at room temperature and then evaporated to a volume of <50 μl in a water bath at 40°.

2-(2-Hydroxyethylmercapto)benzothiazole (II) was synthesized from 2-mercaptobenzothiazole (I) and 2-chloroethanol according to the method of Sexton (11). The product, recrystallized twice from benzene, had a melting point of 56–57° [lit. (11) 56–58°].

**Quantitation of Contaminant**—Once the compound leaching from the syringes had been identified and synthesized, the recrystallized product was used as a standard to measure how much contaminant was leached from syringes under several sets of conditions. Brand A syringes were used for all three parts of this experiment.

1. Several syringes (2 and 10 ml) were filled with various volumes of distilled water and allowed to stand for 5 min before an aliquot was injected directly onto the HPLC column.

2. Seven syringes (20 ml) were each filled with 10 ml of distilled water and allowed to stand for 4–300 min before an aliquot was injected onto the column.

3. The effect of two different vehicles that are used for parenteral dosage forms was examined. A pediatric formulation, which consisted of 25 μg of digoxin/ml of propylene glycol (40%)–alcohol (10.5%)–water[17], was studied because the contaminant displayed lipophilic tendencies in its solvent extraction and HPLC characteristics and, therefore, was expected to partition more favorably into a less polar solvent than water and because the presence of the contaminant may have one of its most serious implications in infant therapy. Water (1 ml) was drawn into each of three 2-ml syringes and allowed to stand for 2, 5, or 12.5 min, and the digoxin formulation (1 ml) was drawn into each of four 2-ml syringes and allowed to stand for 1, 2, 5, or 11 min. Aliquots were injected directly into the chromatograph, and an injection also was made of the digoxin dosage form, which had not been in contact with the plastic syringes.

## RESULTS

**Source of Contaminant**—The interfering peak observed when developing an HPLC assay for plasma samples had a retention time of 6.5

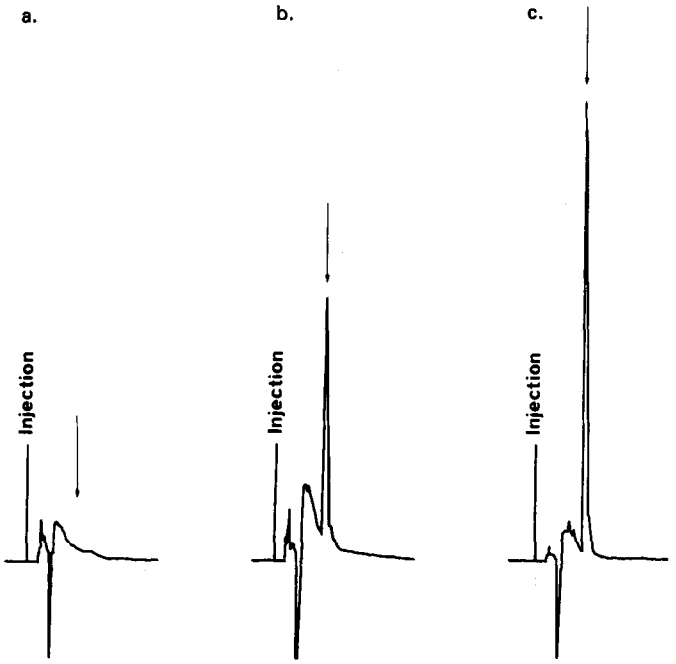

**Figure 1**—*HPLC traces of extracts of distilled water that had been standing in Brand C (sensitivity 0.05 aufs) (a), Brand B (0.02 aufs) (b), and Brand A (0.05 aufs) (c) syringes. The arrow marks retention time of 6.5 min.*

min under the chromatographic conditions described previously (9). When water was allowed to stand in the syringes and blood storage tubes for 2 min and aliquots were analyzed, a large chromatographic peak was again observed at 6.5 min in the extracts of the water from Brands A and B syringes. Extracts of the water from the blood storage tube and the Brand C syringe had chromatograms identical to that of the extract of the water that had been measured directly into the glass extraction tube.

Figure 1 illustrates the magnitude of the interfering peak observed when 10% of the water in the A–C syringes was extracted and chromatographed. Brand B syringes released less of the compound chromatographing at 6.5 min than did the A syringes. Later studies in which all of the water in the syringe was extracted showed that the A and B syringes also released into the water compounds that chromatographed with retention times of 3.8 and 4.7 min but with peak heights ~5% that of the peak at 6.5 min. These peaks were not seen in extracts of water from the C syringe.

In turn, plasma (1 ml) harvested from blood collected into the three brands of syringes was extracted and chromatographed. No peak was observed at 6.5 min when a C syringe had been used to collect the blood, but large peaks were seen in the extracts of plasma collected in A and B syringes.

The results of the experiment in which various parts of the Brand A syringe were allowed to contact the water are summarized in Table I. Although these results were semiquantitative, the severalfold differences in the heights of the peaks indicated that the contaminant was probably being leached from the rubber seal on the plunger. The average height of the peak resulting from only the syringe barrel contacting the water was <10% of the height of the peak resulting from the intact syringe being filled with water. In contrast, the peak resulting from extraction of water in which the plunger-seal had been immersed was three times greater than the peak from the intact syringe.

**Identification of Contaminant**—GLC–mass spectral analysis of the fraction collected from HPLC after extraction of the contents of Brand A syringes revealed a single GLC peak with a retention time of 2.2 min. The presence of a molecular ion at *m/z* 211 in the electron-impact mass spectrum of this GLC peak and a protonated molecular ion ($MH^+$) at *m/z* 212, together with methane adduct ions at *m/z* 240 ($M + C_2H_5^+$) and 252 ($M + C_3H_5^+$) in the methane chemical-ionization mass spectrum (Fig. 2), suggested a molecular weight of 211. Confirmation was obtained from the ammonia chemical ionization mass spectrum, which contained a single ion peak at *m/z* 212. The observation of a $MH^+$ ion in the ammonia spectrum indicated that the compound was a stronger gas phase base than ammonia (12).

The relative abundances of the isotopic ion peaks at *m/z* 212, 213, and

[a] All peak heights measured in millimeters and normalized to 0.01 aufs.

214 in the ammonia chemical-ionization mass spectrum, measured accurately using the selected ion monitoring mode, were 100, 11.81, and 9.40 (average of five measurements), respectively, which indicated the empirical formula $C_9H_9NOS_2$ (calculated isotopic abundances: 100, 11.91, and 9.44, respectively). This result was confirmed by high-resolution electron-impact mass spectrometry (measured mass 211.0128, calculated for $C_9H_9NOS_2$ 211.0125). The deuterium oxide chemical-ionization mass spectrum contained a quasimolecular ion at *m/z* 214. However, ionization of the molecule by addition of a $D^+$ ion would be expected to give an ion at *m/z* 213. Therefore, the observation of *m/z* 214 in the spectrum showed that the molecule contains one exchangeable hydrogen atom (13). The appearance of an ion peak at *m/z* 194 in both the methane (Fig. 2*b*) and deuterium oxide chemical-ionization mass spectra ($MH^+ - H_2O$ and $MD^+ - D_2O$, respectively) indicated the presence of a hydroxyl group, which would account for the exchangeable hydrogen atom.

Treatment of the compound with the silylation reagent and analysis by GLC–mass spectrometry showed a single product with a molecular weight of 283, corresponding to a monotrimethylsilylated derivative. The compound, however, failed to react with diazomethane and, therefore, must be an aliphatic alcohol rather than a phenol or carboxylic acid.

The base peak in the electron impact mass spectrum (Fig. 2*a*) was at *m/z* 167, and the relative abundances of the isotope peaks at *m/z* 168 and 169 indicated that this ion still contained the two sulfur atoms. In many respects, the spectrum below *m/z* 170 resembled that of I. The relative abundances of the ions at *m/z* 166, 140, 123, 108, 91, 69, and 45 in the spectrum of the compound were quite similar to those reported for I (14).

On the basis of the mass spectral data, II was indicated. Although the major fragment ions in both the electron-impact and chemical-ionization mass spectra could be rationalized in terms of this structure (Schemes I and II), other isomers in which the side chain was attached to the phenyl ring could not be excluded. However, these isomers can be excluded on the basis of NMR spectroscopic data.

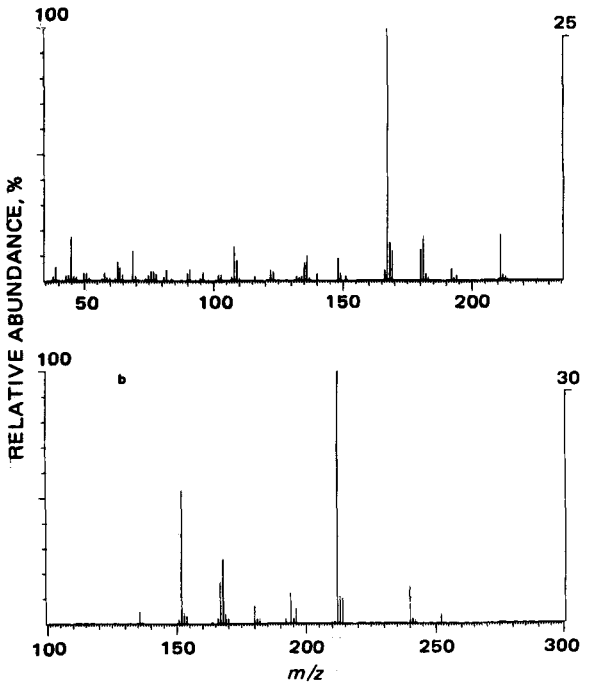

**Figure 2**—*Mass spectra of the contaminant identified as 2-(2-hydroxyethylmercapto)benzothiazole (II). Key: a, electron impact; and b, methane chemical ionization.*

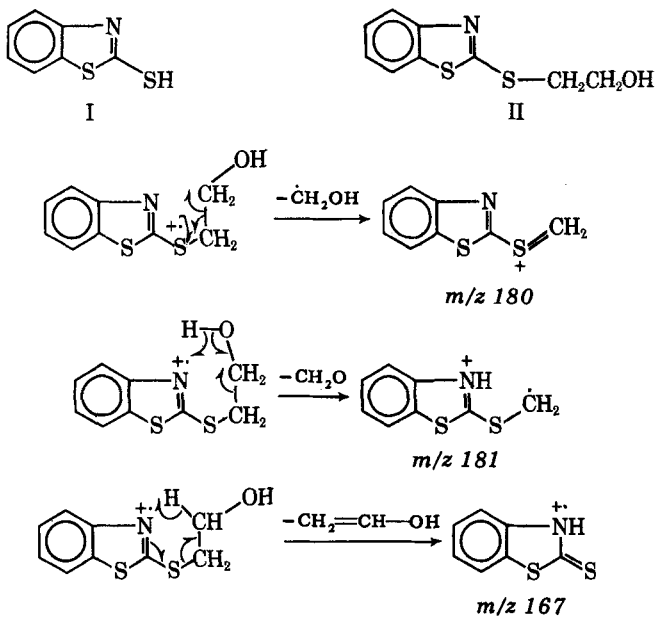

*Scheme I—Electron-impact-induced fragmentation of II.*

The NMR spectrum (recorded at 58°) contained signals at δ 7.15–7.85 (m, 4H, aromatic CH), 3.94 (m, 2H, $CH_2$–O–), 3.45 (t, 2H, $CH_2$–S–), and 3.03 (t, 1H, OH, removed by exchange in $D_2O$). Significantly, no signal could be attributed to a C-2 proton. In the NMR spectrum of benzothiazole, this signal occurred as a sharp singlet at δ 8.95. Moreover, the splitting pattern of the four aromatic protons in the spectrum of the compound extracted from syringes was very similar to that observed for the four protons on the phenyl ring of benzothiazole. Therefore, it was concluded that the side chain must be attached to C-2 of the benzothiazole ring as shown in II. In keeping with this structure, irradiation at δ 3.03 caused the signal at δ 3.94 to change to a triplet, and irradiation at δ 3.94 caused the signal at δ 3.45 to collapse to a singlet.

This structure was also supported by UV spectrophotometric data in that the observed absorption maxima ($\lambda_{max}$) at 224 and 279 nm were almost identical to the maxima reported for 2-(methylmercapto)benzothiazole ($\lambda_{max}$ 224 and 280 nm) (15).

As final proof, 2-(2-hydroxyethylmercapto)benzothiazole (II) was synthesized using the method of Sexton (11). The mass, NMR, UV, and IR spectra and chromatographic retention times (GLC and HPLC) of the authentic compound were identical to those of the compound extracted from the Brand A syringes. The mass spectra (electron-impact and chemical ionization) and GLC and HPLC retention times of the compound extracted from the A and B syringes were identical; therefore, it was concluded that both brands released II into their contents.

| Minute | II, μg |
|---|---|
| 4 | 13.8 |
| 9 | 16.1 |
| 30 | 34.0 |
| 60 | 53.2 |
| 150 | 93.0 |
| 240 | 108.7 |
| 300 | 139.5 |

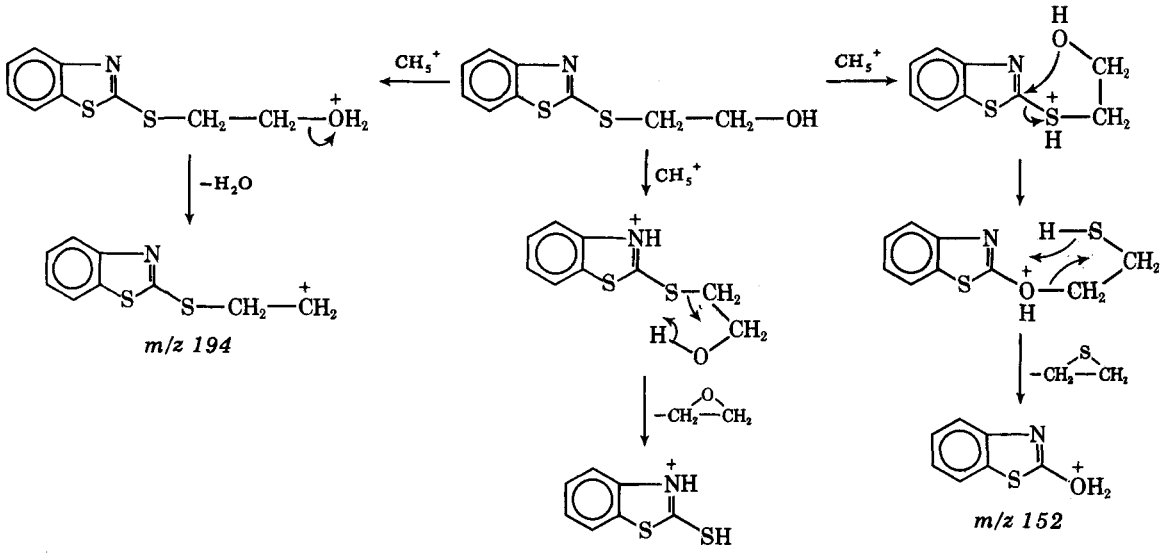
[a] Each data point represents analysis of water from a different syringe.

**Quantitation of II**—The amount of II found in the contents of the syringe after 5 min was similar for a given syringe capacity regardless of the volume of water in the barrel (Table II). As may be expected, the 10-ml syringes, with a greater surface area of rubber exposed to the liquid, released more II (mean 8.1 μg) than the 2-ml syringes (mean 1.8 μg). In a 20-ml syringe, the amount of II in the water increased as the contact time between the rubber and water increased, even up to 5 hr when 140 μg was found (Table III). Compound II moved quickly into the water from the rubber, as was shown by the presence of several micrograms of II in the syringe contents after only 4–5 min (Tables II and III). Table IV shows the amounts of II that leached into 1 ml of water and 1 ml of the digoxin formulation after various times. The results were very similar for the two solvents and followed the trends established in the previous experiments.

These data (Tables III and IV) suggest that the appearance of II in the syringe contents is not limited by the extent of its solubility in the solvent, but it is more likely to be restricted by the rate at which it can move out of the rubber matrix.

## DISCUSSION

The early experiments, designed to identify the source of the contaminant, indicated that II was coming from the rubber seal on the plunger of Brands A and B syringes. This finding was consistent with their structure since both brands have soft rubber seals while Brand C does not. Compound II is not commonly used in rubber manufacture, but



*Scheme II—Methane chemical-ionization-induced fragmentation of II.*

Table IV—Amount of 2-(2-Hydroxyethylmercapto)-benzothiazole (II) in the Contents of 2-ml Brand A Syringes Containing Different Solvents

| Distilled Water, 1 ml | | Digoxin Formulation, 1 ml | |
|---|---|---|---|
| Minute | II, μg | Minute | II, μg |
| 2 | 1.25 | 1 | 1.05 |
| 5 | 1.95 | 2 | 1.31 |
| 12.5 | 3.34 | 5 | 2.83 |
| | | 11 | 3.26 |

it has been reported to be a reaction product of I, a widely used vulcanization accelerator, and ethylene oxide (16), used in this case for sterilization of the syringes. A sample of I had the same HPLC retention time (4.7 min) as the later of the two smaller peaks found in the chromatograms of extracts from A and B syringes, supporting the view that II is formed from I.

Rubbers formulated with I were reported to present stability problems when subjected to γ-radiation (17), so syringes containing I in rubber components are likely to be sterilized with ethylene oxide. One brand of syringe that has a rubber plunger-seal and is sterilized by ethylene oxide[18] did not leach I and II into water. This brand has been reported as nontoxic to amniotic fluid cell cultures whereas other brands have been associated with cultures that fail to thrive (18, 19).

More information is available on the toxicity of I than on that of II. Compound I was identified as one of the allergens responsible for allergies to the rubber in clothing and shoes (20) and also was reported to be mutagenic in fruit flies (21) and embryotoxic in rats (22). The toxicity of I and II was studied in cell lines and in mice by Guess and O'Leary (16). Using a suggested standard of toxicity rating, they reported that both compounds would be rated as highly toxic in mice when given by the parenteral route and moderately toxic when ingested. They also suggested that care should be exercised if these compounds could gain access to the systemic circulation and reported that II was more toxic than I when administered parenterally or orally.

While II was first noticed because of its appearance in blood samples, its transfer from the rubber seal to solutions administered parenterally must be considered. Although no toxicity data are reported for II in humans, the introduction of microgram quantities of even a moderately toxic foreign compound into the body should be recognized and, if possible, avoided. The results indicate that the amount of II leaching into the syringe contents increases with the time of exposure to the rubber and with the capacity of the syringe, but it is essentially independent of the volume of liquid in the syringe. When 10 ml of water was allowed to remain in a 20-ml syringe for 5 hr, 140 μg of II was measured in the contents. This may be a cause for concern with obstetric and surgical patients undergoing epidural anesthesia since additional anesthetic solution is often left in a disposable syringe until further pain relief is required several hours later. When such relief is required, the solution containing accumulated II is injected into the epidural space, in close proximity to the cerebrospinal fluid. Compound II may also accumulate in patients who receive several injections while in the hospital or in patients who are on chronic parenteral medication, *e.g.*, diabetics.

The inadvertent administration of II may be of particular importance in hospitalized infants, especially premature infants, children, and patients with impaired elimination. Total parenteral nutrition for infants in some intensive care nurseries is administered from a disposable syringe (10 ml), which may have been filled several hours previously in the aseptic supply area. In this situation, relatively large amounts of II may be administered intravenously.

Brand A syringes were reported previously as the source of a contaminant that interfered in chromatographic assays for chlorpheniramine (23) and oxazepam (24). In this laboratory, II was first noticed as a large chromatographic peak that interfered with plasma steroid assays (9), making accurate measurement of plasma hydrocortisone and betamethasone levels impossible. Such interference results in a considerable waste of time and materials until the source of the contaminant is identified and a more suitable brand of syringe is used. Moreover, such interference may be present but not recognized if the contaminant cochromatographs with a drug, resulting in an overestimate of drug concentration (24). This situation clearly has the potential to compromise the conclusions drawn from pharmacokinetic and therapeutic monitoring data, with possible implications for clinical management. Alteration of plasma protein binding and distribution between blood components of some drugs has been caused by the contamination of blood samples (25). This more subtle effect has serious implications since it results in spuriously low plasma drug level measurements. The possibility that II could interfere in a similar way must also be considered when blood is collected in disposable syringes.

The presence of contaminants may be overlooked if the compounds do not possess characteristics that cause them to interfere with assays in general use. There may be several other compounds leaching out of syringes, closures, blood collection tubes, and other plastic and rubber apparatus which have not yet been recognized but may have similar implications toxicologically and analytically.

# Apomorphine: Bioavailability and Effect on Stereotyped Cage Climbing in Mice

ROBERT V. SMITH *x, ALLEN E. KLEIN *,
RICHARD E. WILCOX ‡, and WILLIAM H. RIFFEE ‡

Received October 6, 1980, from the *Drug Dynamics Institute and the ‡Division of Pharmacology, College of Pharmacy, University of Texas at Austin, Austin, TX 78712. Accepted for publication March 20, 1981.

**Abstract** □ Plasma levels of apomorphine and its conjugates were studied following intravenous, intraperitoneal, and oral administrations to mice. Following hydrolysis, apomorphine and its conjugates were assayed by high-performance liquid chromatography. The absolute bioavailability of apomorphine was 4%. A significant first-pass effect due to extensive conjugation in the liver was postulated based on calculated bioavailabilities and comparison of plasma levels of apomorphine and its conjugates following oral, intraperitoneal, and intravenous administrations. Apomorphine-induced stereotypical cage climbing in mice was investigated following administration of apomorphine by the three routes. Analysis of time-course data obtained from the cage-climbing experiments indicated an absolute bioavailability of 16% for apomorphine.

**Keyphrases** □ Apomorphine—bioavailability, effect on stereotyped cage climbing, mice □ Bioavailability—apomorphine, intravenous, intraperitoneal, and oral administration □ Behavior—apomorphine-induced cage climbing in mice, intravenous, intraperitoneal, and oral administration □ Emetics—apomorphine, bioavailability, effect on stereotyped cage climbing in mice

Recently, there has been considerable interest in the pharmacology and clinical utility of apomorphine (I). Its ability as an antiparkinsonian (1, 2) was noted at least 15 years before the clinical adoption of levodopa (3). More recent studies confirmed the clinical efficacy of subcutaneously administered apomorphine in the treatment of parkinsonism (4). Activity is observed when I is given to humans orally (5); however, the necessary dosage differential between these two administration routes is reportedly greater than an order of magnitude (5).

In addition to its potential use as an antiparkinsonian, I has been implicated in the treatment of Huntington's chorea (6, 7), tardive dyskinesia (8, 9), spasmodic torticollis (9), Gilles de la Tourette's syndrome (10), schizophrenia (11–13), and thalamic pain (14). The clinical application of I, however, is confounded by its apparent poor, oral absorption (5), short duration of action (4, 5), and chemical instability (15).

## BACKGROUND

Prodrugs may provide a viable alternative to the use of apomorphine (I) *per se*. Its *O,O'*-diesters, II–VI, were previously prepared and tested in mice and rats (16–20). When injected intraperitoneally, these compounds showed prolonged pharmacological effects typical of I. Furthermore, the duration of I-like effects appear to follow rank-order rates of hydrolyses expected for II–VI. However, only indirect evidence has been provided to correlate the pharmacological activity of I prodrugs with circulating blood levels of I (18–20).

The disposition of I in mice following intravenous administration was also studied (21, 22). Similarly to humans, the results in mice indicate a relatively short half-life for I. Recent studies (23) confirmed these earlier data (21, 22). Significant first-pass effects were suggested from experiments with $^3$H-labeled I and measurements of total and ethyl acetate-extracted radioactivity in mouse plasma following intravenous, intraperitoneal, and oral administrations (23).

In the present experiments, plasma analyses of I and its conjugates by high-performance liquid chromatography (HPLC) were conducted to document more carefully the bioavailability of I in mice. In addition, comparisons were made between chromatographically measured I and murine stereotyped cage climbing (24–26). The latter pharmacological test is dopaminergic in nature (27) and is possibly an effective model for predicting the antiparkinsonian activity of drugs like I (26). It was hoped that possible blood level-pharmacological correlations might be useful in future evaluations of I prodrugs.

## EXPERIMENTAL

**Reagents**—All organic solvents used in the HPLC procedures were distilled-in-glass grade[1]. Water was deionized and double distilled from glass. *R*-(−)-Apomorphine hydrochloride hemihydrate[2] [98% pure as determined by UV spectrophotometry (28)], *N*-*n*-propylnorapomorphine[3], boldine[4], [$^3$H]apomorphine[5] (specific activity 31.3 Ci/mmole), and ascorbic acid[6] were used as obtained. β-Glucuronidase (bacterial type II; 51,300 modified Fishman units/g) was used as received[7], following activation by addition of ~0.05 ml of chloroform/ml of enzyme solution. All other solvents and reagents were analytical reagent grade.

**HPLC Analyses**—HPLC assays for apomorphine (I) in plasma were performed in duplicate as previously reported (29, 30) but with the following modifications: a 7-cm × 2.1-mm i.d. guard column[8] was installed before the analytical column, and the citrate–phosphate buffer (29, 30), was replaced by 0.05 *M* acetate buffer (pH 3.25) containing 0.001 *M* sodium lauryl sulfate. Analyses of I glucuronides were accomplished after enzymatic hydrolysis. In these instances, 200-μl plasma samples were mixed with 400 μl of a pH 6.8 buffer solution (0.07 *M* phosphate buffer with 8.7 m*M* ascorbic acid) and 50 μl of a β-glucuronidase solution, equivalent to 130 Fishman units.

The enzyme solution was incubated for 30 min at 37°, and the incubation conditions were chosen since a 15-min incubation time under nearly identical conditions was reported to be sufficient for the complete hydrolysis of *N*-*n*-propylnorapomorphine glucuronide at a concentration level of 45 μg/ml (31). Incubation was terminated by the addition of 1.5 ml of acetonitrile solution containing 2 μg of boldine/ml as an internal standard. This solution was vortexed for 5 sec and centrifuged for 10 min at 1230×*g*. An 800-μl portion of the supernate was then transferred to a 1-ml siliated vial[9], evaporated, and assayed according to an earlier method (29). The amount of conjugated I in a sample was determined as the difference between the assay for free I, and the total assay, which includes I glucuronides.

[a] As determined by HPLC; average of five or six animals per data point. Values of <0.4 μg/ml (limit of assay sensitivity) were determined as zero.

**Table II—Bioavailability Parameters for Apomorphine as Determined by HPLC**

| | Parent Drug[a] | | | Conjugates[a] | | |
|---|---|---|---|---|---|---|
| Route/Dose, mg/kg | $AUC_{0-90}$, μg min/ml | $C_{max}$, μg/ml | $t_{max}$, min | $AUC_{0-90}$, μg min/ml | $C_{max}$, μg/ml | $t_{max}$, min |
| iv/15[b] | 49 | 4.0 | 3 | 94 | 2.8 | 15 |
| iv/7.5[b] | 29 | 2.7 | 3 | 31 | 2.2 | 10 |
| po/50[c] | 7 | 1.0 | 5 | 369 | 12.6 | 10 |
| ip/50[d] | 70 | 5.0 | 5 | 610 | 22.9 | 12 |

[a] Obtained from HPLC analyses of pooled plasma of five or six mice at each study time (see *Experimental*). [b] Percent parent drug circulating ($AUC$ parent drug/$AUC$ parent drug + $AUC$ conjugates × 100) = 34%. (iv/15) and 48% (iv/7.5). [c] Percent parent drug circulating = 2%. [d] Percent parent drug circulating = 10%; calculated from results with [$^3$H]apomorphine (ip/50), 10% (ether extraction), and 16% (ethyl acetate extraction).

**Assay of [$^3$H]Apomorphine in Plasma**—Two 100-μl portions of a plasma sample were each mixed with 1 ml of 0.5 *M* phosphate buffer (pH 7.0) saturated with sodium chloride. The solutions were extracted with 4.0 ml of ether or ethyl acetate by vortexing for 5 min and then were centrifuged at 1230×*g* for 20 min. A 2.0-ml portion of each organic layer was mixed with 18.0 ml of scintillation cocktail[10], and 0.5 ml of each aqueous layer was mixed with 9.5 ml of the cocktail. The solutions were counted[11] at 40% efficiency.

**Bioavailability Studies**—All investigations were conducted with experimentally naive male CD-1 albino mice[12], 20–36 g. Throughout the studies, access to food and water was provided *ad libitum*. Animals were maintained on a 12-hr light–dark cycle (lights on at 6 am and off at 6 pm), and all testing was done between 9 am and 5 pm. Only one plasma sample or one videotaping of stereotypic cage climbing was evaluated from each mouse after dosing; however, each data point was obtained by averaging analyses of pooled plasma samples or stereotyped behavior of five or six animals.

Dose levels of 50 mg of I/kg were administered orally and intraperitoneally, and 15 and 7.5 mg/kg were given intravenously. For the radiochemical study, a 50-mg of I/kg ip dose was given equivalent to ~100 Ci/kg of [$^3$H]apomorphine. Apomorphine was administered orally as an aqueous solution by intubation into the stomach *via* a suitable needle attached to a syringe; intraperitoneal and intravenous doses were given by injection.

Blood samples (400 μl) were taken from the infraorbital sinus (32) into heparanized tubes at 0, 3, 5, 10, 15, 30, 45, 60, 90, and 120 min following I administration and were immediately centrifuged. For chromatographic assay samples, 40 μl of a 150 m*M* ascorbic acid solution was added as an antioxidant to every 1–1.5 ml of plasma pooled from five or six mice per time interval following administration. For selected time periods, up to three replicate samples were collected by the pooled plasma method to evaluate the reproducibility of results. The samples were stored at −15° until analyzed. This temperature and the use of ascorbic acid prevents significant decomposition of I for up to 10 weeks (33). All chromatographic assays were completed within 2 weeks of sampling. For the radioactive samples, 100-μl portions of plasma from each mouse were immediately extracted and/or counted directly within 48 hr. Five [$^3$H]-apomorphine samples were collected for each time period.

**Stereotyped Cage Climbing**—A modification of a previous procedure (24) was used. For a 1-hr habituation period, the mice were placed into cylindrical cages, 12 cm in diameter × 14 cm high, with walls of vertical bars, 2 mm in diameter and 1 cm apart, surmounted by fine wire mesh. Immediately prior to the administration of I (2.0 and 7.5 mg/kg iv, 2.0 and 4.0 mg/kg ip, or 50 mg/kg po) or isotonic saline (intraperitoneally), behavior was videotaped to establish a baseline of activity for each animal. Beginning 3 min after drug administration, the behavior of each animal was videotaped and later rated "blind" by methods previously described (26).

**Calculations**—Bioavailability of oral and intraperitoneal doses compared to the intravenous dose was calculated as the ratios of the corresponding areas under the experimental curves ($AUC$) obtained by cutting and weighing. Areas beyond the last sampling point were initially obtained by extrapolating the apparent concentration decay phase of the individual experimental plasma concentration *versus* time curves to infinite time (34). In the final analyses (Table II), $AUC$ values for the 0–90-min period were obtained because of negligible plasma levels of drug and conjugates for most routes at 120 min. Bioavailability was calculated by dividing $AUC_{po}$ by $AUC_{iv}$ after multiplication by the intravenous–oral

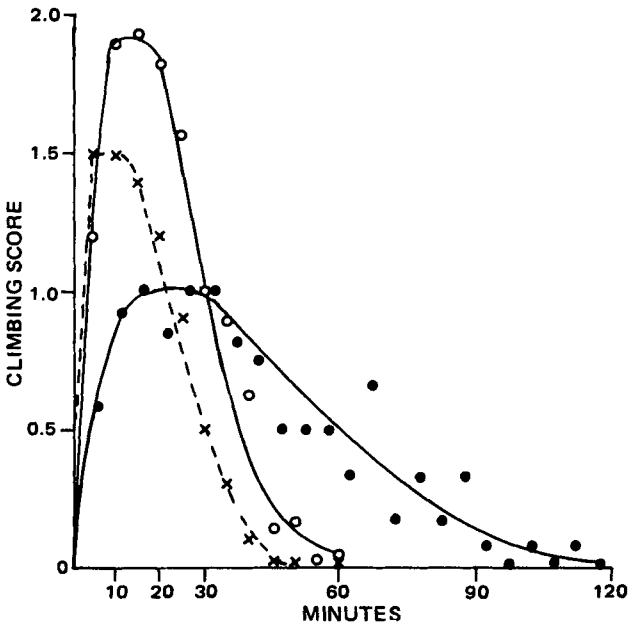

**Figure 1**—*Time course of murine cage climbing following administration of apomorphine. Key:* ○, *2.0 mg/kg iv;* ×, *4 mg/kg ip; and* ●, *50 mg/kg po.*

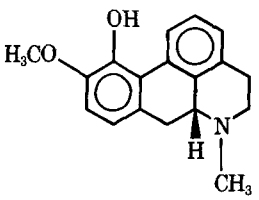
dose ratio. Peak serum concentrations ($C_{max}$), maximum cage-climbing scores, and times of the peak concentration or score ($t_{max}$) were obtained from the individual plasma level or stereotypic behavior *versus* time curves.

## RESULTS AND DISCUSSION

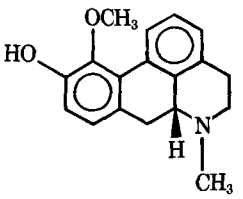
Plasma samples obtained from mice dosed with apomorphine (I) by intravenous, intraperitoneal, and oral routes were analyzed by HPLC (29, 30). Only parent drug was detected in plasma ether extracts, confirming preliminary results obtained by TLC with [$^3$H]apomorphine (23). The major metabolite(s) behaved as an *O*-glucuronide(s) from analyses of plasma fractions treated with β-glucuronidase. The importance of *O*-glucuronidation in the metabolism of I in mice was reported previously (21, 35).

The data in Tables I and II reveal that I is largely present in plasma in its conjugate form, especially after intraperitoneal and oral administrations. Furthermore, experiments utilizing [$^3$H]apomorphine and both ether and ethyl acetate extractions provided measurements of I and its apparent conjugates (following intraperitoneal administration) that were consistent with those in the HPLC determinations. In no experiments were the mono-*O*-methyl ethers of I, apocodeine (VII), and isoapocodeine (VIII) detected as metabolites.

Compounds VII and VIII are readily determined by the HPLC system utilized (36) and are formed *in vitro* when I is incubated with rat liver catechol-*O*-methyltransferase preparations fortified with *S*-adenosylmethionine (37–39). Furthermore, *in vivo* experiments (stereotyped behavior) in rats with I and catechol-*O*-methyltransferase inhibitors seem to suggest a role for VII and/or VIII in the metabolism of I (39). Indeed, Symes *et al.* (40) found elevated brain levels of I in rats pretreated with pyrogallol and tropolone, both catechol-*O*-methyltransferase inhibitors. However, these authors acknowledged that pyrogallol and tropolone may serve as inhibitors of apomorphine *O*-glucuronidation. The mono-*O*-methylation of I is perhaps species specific or is of little apparent quantitative significance in the mouse.



VII



VIII

The absolute bioavailability of I following oral administration [(*AUC* parent drug po/dose po)/(*AUC* parent drug iv/dose iv) × 100] averaged 4%, which confirms similar results obtained using [$^3$H]apomorphine (23). Thus, there appears to be a significant first-pass effect when I is administered orally to mice. The relative amount of unconjugated I found in plasma after intraperitoneal administration was higher than that observed after oral administration but was relatively lower than the levels of parent drug found after intravenous dosing. The percent of circulating parent drug followed the order intravenous > intraperitoneal > oral, and the results with intraperitoneal dosing were confirmed by experiments with [$^3$H]apomorphine (Table II). This finding probably indicates considerable portal uptake after intraperitoneal administration as suggested previously (41).

Despite the apparent rapid and extensive conjugation of I in the mouse, its bioavailability as measured by the extent of absorption of drug plus conjugates [(*AUC* parent drug po + *AUC* conjugates po/dose)/[*AUC* parent drug iv + *AUC* conjugates iv/dose) × 100] averages nearly 90%. Thus, the poor pharmacological activity observed following oral administration of I to mice is likely related to the efficient conjugation to an apparently inactive (or poorly active) conjugate. Similar conjugations and analogous first-pass effects may be the cause of reportedly poor oral activity of I in rats (16) and humans (5).

**Stereotyped Cage Climbing**—Apomorphine-induced stereotypical cage climbing was studied after intravenous, oral, and intraperitoneal administrations. Cage climbing in mice is an unusual, but apparently specific, response to certain dopaminergic agents (25–27). Treated mice respond by "verticalization" in which two or four paws remain clutching to the vertical bars of specially designed cylindrical cages (24). The cage climbing response is accurately and reproducibly rated by the videotape methodology previously described (26).

**Table III—Time Course Measurements of Apomorphine-Induced Cage Climbing in Mice**

| Route/Dose, mg/kg | $t_{max}$ | *AUC*, units/min |
|---|---|---|
| iv/7.5 | 10 | 240 |
| iv/2.0 | 15 | 86 |
| po/50 | 15 | 286 |
| ip/4 | 10 | 32 |
| ip/2 | 10 | 16 |

The time courses of I-induced cage climbing for representative doses of I are depicted in Fig. 1. Responses occurred almost immediately following administration, while maximum ratings were observed (Table III) within a few minutes of the $t_{max}$ determined for I by HPLC. Thus, the behavioral response appears to mimic the time course–blood levels of I in mice (21–23). The potentiation of I-induced stereotypical behavior in rodents by compounds that can serve as inhibitors of *O*-glucuronidation or catechol-*O*-methyltransferase also supports this proposal[13] (39, 40).

The relative *AUC* values (Table III) observed for the time course of cage climbing after different administration routes nicely parallel the data determined radiochemically and by HPLC and also by previous radiochemical assays (23). An absolute bioavailability measurement for I can be calculated using the stereotyped cage climbing data in Table III [*i.e.*, (*AUC*-cage climb po/dose po)/(*AUC*-cage climb iv/dose iv) × 100]. When averaged over the available data, the absolute bioavailability of I was calculated as 16%, which is of a similar order of magnitude as the 4% found after HPLC analyses.

As an extension of the data presented, it appears that murine cage climbing may be useful in evaluating the *in vivo* release of I from its prodrugs. Before this evaluation, however, correlations should be sought between chemical analyses of I released *in vivo* and stereotyped cage climbing produced by prodrugs. Evaluations of this type are currently being investigated and will be the subject of a future report.

# Antitumor Agents XLII: Comparison of Antileukemic Activity of Helenalin, Brusatol, and Bruceantin and Their Esters on Different Strains of P-388 Lymphocytic Leukemic Cells

**IRIS H. HALL ˣ, K. H. LEE, M. OKANO, D. SIMS, T. IBUKA, Y. F. LIOU, and Y. IMAKURA**

Received September 8, 1980, from the *Division of Medicinal Chemistry, School of Pharmacy, University of North Carolina, Chapel Hill, NC 27514.* Accepted for publication March 6, 1981.

**Abstract** □ Based on the fact that some known antineoplastic agents possess an ester moiety within their structure, the esters of helenalin, a sesquiterpene lactone, and of brusatol and bruceantin, quassinoids, were synthesized and tested for antileukemic activity in the P-388 screen. These agents gave different T/C % values dependent on the P-388 lymphocytic leukemia strain and the host strain of mice used. Later studies demonstrated that the agents caused different degrees of inhibition of nucleic acid and protein synthesis in the various P-388 strains. The higher the degree of inhibition of precursor incorporation into the nucleic acid or protein, the higher was the T/C % value obtained in a given P-388 strain. The study demonstrates the lack of consistency of P-388 lymphocytic leukemia cell lines used in various laboratories and indicates that the inbred strain of mice is a critical factor in the tolerance of drug toxicity and, thus, T/C % obtained.

**Keyphrases** □ P-388 lymphocytic leukemic cells—antileukemic activity of helenalin, brusatol, and bruceantin and their esters □ Antileukemic agents—comparison of helenalin, brusatol, and bruceantin and their esters □ Helenalin—comparison with brusatol, bruceantin, and their esters, antileukemic activity □ Brusatol—comparison with helenalin and bruceantin and their esters, antileukemic activity □ Bruceantin—comparison with helenalin and brusatol and their esters, antileukemic activity

The naturally occurring sesquiterpene lactones continue to provide numerous examples of structures exhibiting significant cytotoxic antitumor activity (1). In general, they have proven to be potent inhibitors of Walker 256 carcinosarcoma growth in rats and Ehrlich ascites carcinoma growth in mice and marginal inhibitors of P-388 lymphocytic leukemia in mice (2). For example, eupaformosanin (3), molephantinin (4), phantomolin (5), eupahyssopin (6), and helenalin (I) (7) all demonstrated highly significant inhibitory activity in the Walker 256 carcinosarcoma survival system with a T/C value of ≧300% at the low dose of 2.5 mg/kg (T/C >140% required for significant activity). However, in the P-388 murine lymphocytic leukemia screen, an *in vivo* test system currently used as a standard method by the National Cancer Institute (NCI) for evaluating compounds of natural origin, these compounds

# Antitumor Agents XLII: Comparison of Antileukemic Activity of Helenalin, Brusatol, and Bruceantin and Their Esters on Different Strains of P-388 Lymphocytic Leukemic Cells

**IRIS H. HALL ˣ, K. H. LEE, M. OKANO, D. SIMS, T. IBUKA, Y. F. LIOU, and Y. IMAKURA**

Received September 8, 1980, from the *Division of Medicinal Chemistry, School of Pharmacy, University of North Carolina, Chapel Hill, NC 27514.* Accepted for publication March 6, 1981.

**Abstract** □ Based on the fact that some known antineoplastic agents possess an ester moiety within their structure, the esters of helenalin, a sesquiterpene lactone, and of brusatol and bruceantin, quassinoids, were synthesized and tested for antileukemic activity in the P-388 screen. These agents gave different T/C % values dependent on the P-388 lymphocytic leukemia strain and the host strain of mice used. Later studies demonstrated that the agents caused different degrees of inhibition of nucleic acid and protein synthesis in the various P-388 strains. The higher the degree of inhibition of precursor incorporation into the nucleic acid or protein, the higher was the T/C % value obtained in a given P-388 strain. The study demonstrates the lack of consistency of P-388 lymphocytic leukemia cell lines used in various laboratories and indicates that the inbred strain of mice is a critical factor in the tolerance of drug toxicity and, thus, T/C % obtained.

**Keyphrases** □ P-388 lymphocytic leukemic cells—antileukemic activity of helenalin, brusatol, and bruceantin and their esters □ Antileukemic agents—comparison of helenalin, brusatol, and bruceantin and their esters □ Helenalin—comparison with brusatol, bruceantin, and their esters, antileukemic activity □ Brusatol—comparison with helenalin and bruceantin and their esters, antileukemic activity □ Bruceantin—comparison with helenalin and brusatol and their esters, antileukemic activity

failed to give T/C values higher than 147% at the maximum dose level of 25 mg/kg/day (1) (T/C >125% required for significant activity).

## BACKGROUND

In this laboratory, previous systematic investigation of the structure–activity relationships among the sesquiterpene lactones and related compounds indicated the importance of the bifunctional alkylating enone O=C—C=$CH_2$ system and the ester moiety for enhanced cytotoxic antitumor activity (1). For example, the bifunctional alkylating helenalin (I), which contains a $\beta$-unsubstituted cyclopentenone and an $\alpha$-methylene-$\gamma$-lactone, is more potent than the corresponding 2,3-dihydrohelanalin or 11,13-dihydrohelenalin (plenolin) in its *in vitro* cytotoxicity (8) and *in vivo* antitumor activity (2). Cytotoxicity is also enhanced by introduction of a lipophilic ester side chain to helenalin and related derivatives (9).

The importance of the ester group that contributes to the enhanced *in vivo* antitumor activity is also seen in many other naturally occurring antitumor agents including the germacranolides eupaformosanin, molephantinin, phantomolin, and eupahyssopin as well as the quassinoid bruceantin (10), the diterpene taxol (11), the alkaloids indicine *N*-oxide (12), homoharringtonine (13), vincristine (14), and vinblastine (14), the macrolide maytansine (15), and the fungal metabolites anguidin (16), actinomycin D (dactinomycin) (17), and mitomycin C (18). The latter compounds (19) possess high *in vivo* antileukemic activity against the P-388 lymphocytic leukemia growth.

This evidence, coupled with the fact that polyfunctionality is a common structural feature in many of the described antileukemic agents, led to the hypothesis that a polyfunctional alkylating-type compound originating from the combination of bifunctional or monofunctional alkylating active species *via* an ester linkage might be highly active as an antileukemic agent. Thus, esters of helenalin, brusatol, and bruceantin were synthesized and examined for their antileukemic activity against P-388 lymphocytic leukemia cell growth. Those results are now reported utilizing two different strains of P-388 lymphocytic leukemia cells along with the effects of these esters on key enzymes of nucleic acid and protein synthesis.

## EXPERIMENTAL

**Source of Compounds**—Helenalin (I) was isolated from *Balduina angustifolia* by the methods of Lee *et al.* (20). Treatment of I with malonyl dichloride in dry benzene by the general method gave rise to crystalline bis(helenalinyl)malonate[1] [II, $C_{33}H_{36}O_{10}$, mp 217–218°], resulting in a molecule with four alkylating centers. Brusatol (III) was obtained by treating bruceoside A, a quassinoid glycoside isolated from *Brucea javanica*, with 3 *N* $H_2SO_4$–methanol (1:1) to hydrolyze the glycosidic

linkage (21–23). Bruceantin (VI) was also synthesized from bruceoside A (24–25).

Brusatol (III) (22–24) and bruceantin (VI) were treated similarly with malonyl dichloride and succinyl chloride in dry pyridine to yield, after purification of the reaction products by preparative TLC, the corresponding bis(brusatolyl)malonate[1] [IV, $C_{55}H_{64}O_{24}\cdot H_2O$, mp 191–193°], bis(brusatolyl)succinate[1] [V, $C_{56}H_{66}O_{24}$, mp 248–250°], bis(bruceantinyl)malonate[1] [VII, $C_{59}H_{72}O_{24}$, mp 193–195°], and bis(bruceantinyl)-succinate[1] [VIII, $C_{60}H_{74}O_{24}$, mp 250° dec.][2].

**Biological**—*P-388 Lymphocytic Leukemia Antitumor Screen*—The P-388 lymphocytic leukemia-UNC tumor line was originally obtained from Mason Research Institute through NCI and has been maintained in this laboratory in DBA/2 male donor mice for ~2 years. The P-388 lymphocytic leukemia-NIH was obtained in April 1980 from the same source. The eight test compounds with the standard 5-fluorouracil were administered to both the P-388-UNC and P-388-NIH strains as follows. $BDF_1$ or CDF male mice (~20 g) were administered $10^6$ P-388 lymphocytic leukemia cells intraperitoneally on Day 0 (26). Test compounds were homogenized in 0.05% polysorbate 80–water and administered intraperitoneally daily.

*KB Tissue Cytotoxic Assay*—KB (human epidermoid carcinoma of the mouth) cells were maintained in minimum essential medium and 10% fetal calf serum containing the antibiotics penicillin and streptomycin (26). The method of Huang *et al.* (27) was utilized for the cytotoxic assay in microtest tissue culture plates.

*P-388 Lymphocytic Leukemia Cell Metabolism*—$BDF_1$ male mice (~22 g) were innoculated with $10^6$ P-388 tumor cells as previously described. On day 9, the cells were collected from the peritoneal cavity. *In vitro* incorporation studies were conducted using $10^6$ P-388-UNC or P-388-NIH cells, minimum essential medium, and 1 μCi of thymidine (6-$^3$H, 21.8 Ci/mmole), uridine (6-$^3$H, 22.4 Ci/mmole), or L-leucine [4,5-$^3$H(N) 56.5 Ci/mmole] in a total volume of 1 ml, which was incubated for 90 min at 37° (28). Compounds I and II were tested at a final concentration of 20 μmoles, and III–VIII were tested at a 10-μmole concentration.

The thymidine incorporation into DNA assays were terminated with 0.5 *N* perchloric acid containing 1% pyrophosphate. Radiolabeled DNA was collected on glass fiber paper (GF/F) by vacuum suction. RNA and protein incorporation studies were terminated with trichloroacetic acid, and the acid-insoluble macromolecule was collected on nitrocellulose membrane filters. The filter papers were placed in scintillation vials and counted in a toluene–octoxynol scintillation fluid (29).

## RESULTS AND DISCUSSION

Initially, the antileukemic activity was determined in the P-388-UNC lymphocytic leukemia screen. The T/C % value for II at 15 mg/kg/day was exceedingly high, *e.g.*, T/C % = 261 in $BDF_1$ male mice. The quassinoid esters of III were then examined and, as can be seen in Table I, IV at 0.6 mg/kg resulted in T/C % values of 272 and 197 and V resulted in a T/C % value of 217 in $BDF_1$ male mice.

Compounds I–V followed a dose–response curve against P-388-UNC lymphocytic leukemia growth in $BDF_1$ mice. The $ED_{50}$ for helenalin (I) in the KB cytotoxic assay was 0.188 compared to the literature value (28) of 0.19 μg/ml. Bis(helenalinyl)malonate (II) afforded an $ED_{50}$ of 0.08 μg/ml. The $ED_{50}$ values for the quassinoids were also impressive, with III, IV, VI, and VIII equal to 0.31, 0.025, 0.056, and 0.275 μg/ml, respectively.

In an attempt to confirm these unexpected high results, II, IV, and V were submitted to NCI for retesting and evaluation. The two contract screening agencies used by NCI were unable to obtain results >12 mg/kg in CDF mice for I and II; but at 3 and 0.39 mg/kg, T/C % values of 130[3] and 120[4], respectively, were obtained. Compound IV was also submitted to the same two contract screeners[3], whose studies resulted in T/C %

[2] Unpublished results.

[3] Southern Research.

values of 131, 135, and 131 at 3, 1.5, and 0.75 mg/kg, respectively. The second contract screener[4] found II, III, and IV totally inactive in their P-388 lymphocytic leukemia screen in CDF mice.

Since these results were somewhat baffling, a new sample of P-388 lymphocytic leukemia cells, noted as P-388-NIH, was obtained[5]. The compounds were retested against P-388-UNC and P-388-NIH leukemia growth in CDF and $BDF_1$ male mice with dosing from Days 1 to 9. These results are shown in Table II along with the data for two new compounds, *i.e.*, the malonate (VII) and succinate (VIII) ester of bruceantin. Bruceantin (VI) is a quassinoid in Phase II clinical trial. These data confirmed previous observation by this laboratory in $BDF_1$ male mice using the P-388-UNC strain, whereas data for P-388-NIH in CDF mice were comparable with the contractor's results. However, a difference could be observed between $BDF_1$ and CDF donor mice and the resulting T/C % values. Apparently, the $BDF_1$ male mice were able to tolerate the higher doses of I–III and VI, thus affording higher T/C % values than when administered to CDF mice. In fact, in a previous report (29) on DBA/2 male mice, testing above 0.5 mg/kg with III in the P-388 screen resulted in deaths. The inbred hybrid strain of mice may be a critical factor since mice used for the study in Table I were bred in this laboratory ($C_{57}B1/6$ female × DBA/2j male), whereas those used in Table II were obtained commercially[6]. When VII was tested[3] at 3, 1.5, 0.75, and 0.38 mg/kg, T/C % values of 163, 165, 146, and 128, respectively, were obtained, which were within the scope of data presented in Table II.

The two sets of conflicting data pose the question of whether P-388-UNC is a different strain of P-388 lymphocytic leukemia cells resulting from some alteration or mutation. Thus, since the sesquiterpene lactones and quassinoids were known to affect nucleic acid and protein synthesis in tumor cells, these parameters were examined in the P-388-UNC and P-388-NIH strains of cells from $BDF_1$ mice.

Table III indicates that *in vitro* DNA synthesis was affected approximately the same degree by I and II in the two strains of P-388 cells. RNA synthesis was inhibited by I and II equally in the P-388-UNC and P-388-NIH cells. Protein synthesis, however, was inhibited at a much higher rate in the P-388-UNC strain than the P-388-NIH strain (*e.g.*, compare II at 50 and 25% inhibition, respectively). Examination of II–VIII showed that the degree of inhibition of DNA synthesis was of the same magnitude in both strains of P-388 cells for a given compound. The RNA synthesis inhibition by III–VI was much higher in the P-388-UNC strain compared to the P-388-NIH strain, resulting in ~24–38% higher inhibition of RNA synthesis, with IV demonstrating the largest difference (*i.e.*, 48% in the P-388-UNC strain and 10% in the P-388-NIH strain).

Protein synthesis inhibition was also decidedly different between the two different strains for III–VI. Compound III afforded a 20% inhibition in the P-388-NIH and a 55% inhibition in the P-388-UNC strain. Compound IV demonstrated a difference of 35% compared to 83% inhibition, V showed a difference of 25% compared to 72%, and VI showed a difference of 15% compared to 42% in the respective strains. Compounds VI and VIII demonstrated approximately the same T/C % values in the two strains of P-388 cells, and the effects of the two compounds on RNA and protein synthesis was comparable in the two strains of cells. The standard emetine and pyrocatechol violet at 5 μmoles demonstrated the same degrees of protein inhibition in the two strains of P-388 cells.

These studies indicate that the P-388-UNC and P-388-NIH strains of P-388 lymphocytic leukemia cells are different in their metabolic response to certain chemical agents and the difference may be responsible for diverse values obtained in the antineoplastic screen. The P-388-UNC strain appears to be particularly sensitive to sesquiterpene lactone and quassinoid-type structure but less sensitive to 5-fluorouracil. Furthermore, the strain of mice used may be critical for the T/C % values obtained, depending on the tolerance of the mice to the particular toxic effects of the chemical agent.

# GLC Analysis of Menthol, Phenol, Benzocaine, and Pyrilamine Maleate in Aerosol Spray Lotion

**FABRIZIO DE FABRIZIO**

Received November 12, 1980, from *Adcock Ingram Laboratories Limited, P.O. Box 2368, Johannesburg 2000, South Africa.* Accepted for publication February 12, 1981. * Present address Atomic Energy Board (Chemical Division), Private Bag X256, Pretoria 0001, South Africa.

**Abstract** □ A GLC method is presented for the quantitative determination of menthol, phenol, benzocaine, and pyrilamine maleate. The propellent was exhausted from a pressurized can, and an aliquot of the alcoholic base was weighed. After the addition of the internal standard diluted with chloroform, 1 μl of the mixture was injected in the chromatograph with a flame-ionization detector and a glass column packed with 2.5% OV-225. Average recoveries were 100.3 ± 1.4, 100.0 ± 1.4, 101.3 ± 1.5, and 101.5 ± 1.5% for menthol, phenol, benzocaine, and pyrilamine maleate, respectively.

**Keyphrases** □ Aerosols—GLC analysis of menthol, phenol, benzocaine, and pyrilamine maleate □ GLC—analysis of menthol, phenol, benzocaine, and pyrilamine maleate in aerosol form □ Sprays—GLC analysis of menthol, phenol, benzocaine, and pyrilamine maleate

Menthol (I), phenol (II), benzocaine (III), and pyrilamine maleate (IV) are found in various preparations, such as creams, lotions, and dusting powders, used for the treatment of allergic conditions and analgesic applications. While analyses have been reported for the quantitation of I–III singly and in combination with other drugs in topical products, no analytical procedure was found for IV in lotion or cream form.

Douglas (1) used GLC to determine I, II, and methyl salicylate in several commercial preparations. Quantitative determinations of III by colorimetric (2), high-performance liquid chromatographic (HPLC) (3), and GLC (4) methods also were reported. Ghanekar and Gupta (5) used HPLC to determine the maleates of IV, chlorpheniramine, brompheniramine, and pheniramine. The method presented here permits the simultaneous determination and identification of the components analyzed with a single injection.

## EXPERIMENTAL

**Materials**—A gas chromatograph[1] with a flame-ionization detector was fitted with a 1.8-m × 3-mm i.d. column packed with 2.5% OV-225 on Chromosorb W, 80–100 mesh. The reagents[2] chloroform, menthol, phenol, and dichloroxylenol[3] were used.

**Solution Preparation**—The stock standard solution was prepared by dissolving, per milliliter of chloroform, 7.9 mg of menthol, 7.9 mg of phenol, 7.8 mg of benzocaine[4], and 10.9 mg of pyrilamine maleate[4]. In 50 ml of chloroform was dissolved 1000 mg of dichloroxylenol, the internal standard solution.

**Standard Preparation**—Stock standard preparation (3 ml) was pipetted into a 50-ml volumetric flask, and 2 ml of the internal standard solution was added and diluted to the mark with chloroform. Then 1 μl was injected into the chromatograph.

**Table I—Standard Preparation**

| Trial | Recovery, % I | II | III | IV |
|---|---|---|---|---|
| 1 | 100.2 | 100.6 | 100.6 | 101.0 |
| 2 | 101.6 | 101.9 | 103.2 | 103.0 |
| 3 | 100.5 | 100.5 | 99.6 | 99.1 |
| 4 | 99.5 | 100.0 | 103.4 | 101.2 |
| 5 | 101.6 | 101.3 | 99.3 | 100.2 |
| 6 | 100.9 | 100.9 | 102.5 | 100.2 |
| 7 | 99.5 | 99.0 | 102.8 | 102.9 |
| 8 | 97.9 | 98.8 | 100.7 | 103.0 |
| 9 | 100.0 | 97.8 | 101.0 | 103.5 |
| 10 | 100.6 | 100.0 | 100.3 | 100.7 |
| Mean | 100.3 | 100.0 | 101.3 | 101.5 |
| *SD* | ±1.1 | ±1.4 | ±1.5 | ±1.5 |

**Sample Preparation**—A pressurized can was cooled in the freezer of an ordinary refrigerator for 1 hr. The can was removed and pierced in the shoulder plate (valve site). The propellent ejection was regulated by holding the piercing device into the perforated hole. When the propellent[5] pressure had ceased, the top of the can was cut, and the alcoholic base[6] was poured into a 250-ml conical flask. The flask was shaken mechanically for 20 min. All operations were carried out under a semiclosed hood. An aliquot of liquid (~2.5 ml) was weighed into a 50-ml volumetric flask, and 2 ml of the internal standard solution was added and diluted to volume with chloroform. Then 1 μl was injected into the chromatograph.

## RESULTS AND DISCUSSION

The recovery study was conducted by preparing a standard solution containing the internal standard and all of the ingredients in amounts as found in the commercial product. The solution was determined 10 times. The results (Table I) show that active ingredients can be separated (Fig. 1) and analyzed by direct injection into the chromatograph. Eventual interferences from other ingredients were investigated by preparing a solution that excluded the active components. The chromatogram of this solution showed a peak of one component[7] with a retention time at ~9.15 min, which did not interfere. Peaks of less volatile compounds[8] appeared between 25 and 28 min. Therefore, it was convenient to allow the instrument to run periodically for 30 min during the analysis.

The ratios of the area per weight of substance to the area per weight of internal standard were calculated for the active components over a range of 80–120% of the label claim. Results for three solutions (80, 100, and 120%) are reported in Table II. Several liquid phases were tried to accommodate compounds of different polarity in the same chromatogram. The response factors throughout the concentration range studied attest to the usefulness of OV-225 as the liquid phase.

Since the procedure was planned only to determine the active ingredients contained in the alcoholic base, it appeared preferable to remove first the propellent from the rest of the sample at a temperature (~0°) where the alcoholic vapor tension was considerably reduced. The residual propellent was eliminated by shaking the decanted sample for 20 min. Precision also was examined by analyzing a production lot commercial preparation. Results are reproduced in Table III.

The method presented is reasonably fast, and precision is consistent with accuracy.

# Optical Characterization of a Low Solubility Organic Compound

**H. E. HUBER**

Received April 7, 1980, from *Merrell Research Center, Merrell-National Laboratories, Division of Richardson-Merrell Inc., Cincinnati, OH 45215.* Accepted for publication March 5, 1981.

**Abstract** □ The X, Y, and Z principal vibration directions along with the principal refractive indexes, optic angle, optical sign, birefringence, optical orientation, and crystal system for the low solubility compound 5-(tetradecyloxy)-2-furancarboxylic acid were determined with a polarizing microscope and spindle stage. The X and Z principal vibration directions are not coincident with the $a$ and $c$ crystallographic axes; however, the Y direction is considered to be coincident with the $b$ axis. Therefore, the crystal is assigned to the monoclinic crystal system. The bladed/lath-shaped crystals rest on one of the two large orthopinacoid (100) faces and present the microscopist with a single plane of optical symmetry. A $\beta$ refractive index of 1.555 is observed with the crystal axis of elongation parallel to the polarizer, and a $\gamma'$ of ~1.600–1.660 is observed in the contiguous extinction position. Determination of the optic angle, principal vibration directions, and principal refractive indexes was facilitated by mounting the crystals on a spindle stage for rotation about the $b$ crystallographic axis (optic normal).

**Keyphrases** □ 5-(Tetradecyloxy)-2-furancarboxylic acid—optical characterization using a polarizing microscope and spindle stage □ Optical characterization—low solubility compound, 5-(tetradecyloxy)-2-furancarboxylic acid □ Crystallography—optical characterization of a low solubility organic compound, 5-(tetradecyloxy)-2-furancarboxylic acid

Control of dosage formulation in the clinic by conventional aqueous dissolution methods was not possible with 5-(tetradecyloxy)-2-furancarboxylic acid[1] (I) because of its poor solubility in alcohol and/or water. A high concentration of surfactant and water was eventually utilized for the solvent, but other controls were necessary to ensure that changes in the crystalline structure between lots did not occur. Long-chain fatty acid compounds such as this one are well known for their polymorphic character (1).

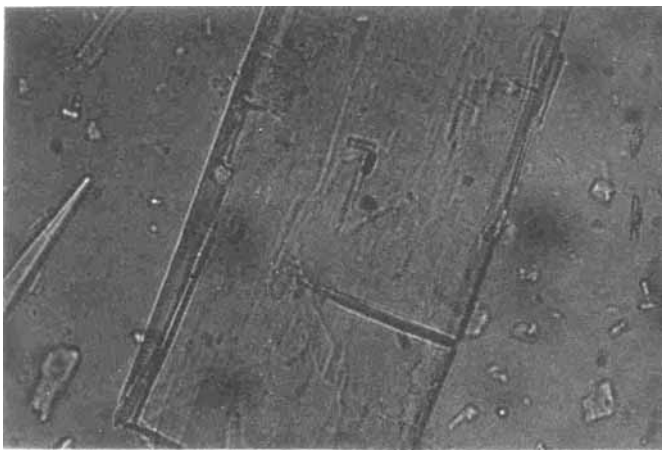

**Figure 1**—*Photomicrograph of I crystals obtained with the tungsten filament lamp at 4 amp and 0.25-sec exposure time. No filters were used. Crystals were mounted in 1.460 Cargille fluid, A 1/5 series.*

## BACKGROUND

Some investigators (2–4) attempted to control this variable with differential scanning calorimetry or related thermal methods, and others utilized X-ray diffraction. In a few isolated reports (5–7), a combination of these methods, along with optical crystallographic characterizations, was used.

Once the crystal is characterized, optical methods offer many advantages for routine identification of other lots. Optical values are quite specific for a substance, and most microscopic examinations can be performed with a minimum of time and effort. The number of discriminating optical parameters that can be used is usually numerous; consequently, one or more can be selected as conditions or limitations dictate.

An optical characterization of I is presented here and was utilized along with surface area measurements to control potential crystal changes. An X-ray diffraction profile was determined as part of the total crystal characterization; however, only optical methods are utilized for routine examination.

Geologists and chemists have long relied on optical methods for ready identification and, in some cases, composition determinations of unknown mineral or chemical samples. Each substance has a unique atomic arrangement and, therefore, unique optical properties. Optical determinative data for organic compounds are limited compared to those for inorganic materials; however, the data available indicate that the same specificity applies.

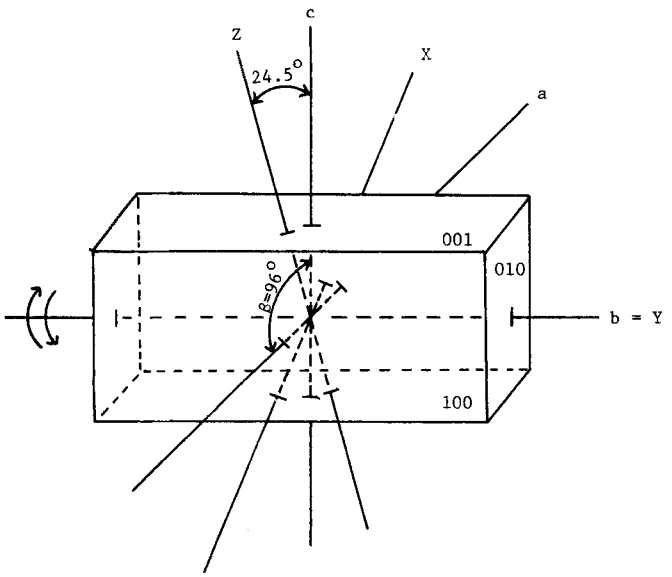

**Figure 2**—*Optical orientation of I in relation to its crystallographic axes.*

**Table I—Optical Properties Obtained for I**

| Parameter | Value |
|---|---|
| Refractive indexes (5893A – D line 25°) | |
| $\alpha$ | 1.470 ± 0.002 |
| $\beta$ | 1.555 ± 0.002 |
| $\gamma$ | 1.670 ± 0.002 |
| Birefringence | 0.200 |
| Optic axial angle (5893A – D line 25°) | $2V = 81° \pm 2.0$ |
| Optical axial plane | 010 |
| Sign of double refraction | Positive |
| Extinction | Parallel |
| Crystal system | Monoclinic |
| Elongation sign | ± |

Microscopic slide mounts of unmilled I exhibited 100–500-μm lath-shaped crystals (Fig. 1) that appeared suitable for the study. By utilizing polarizing microscopic procedures, optical crystallographic characterization of I was successfully performed.

## EXPERIMENTAL

Compound I was obtained by crystallization from methyl ethyl ketone. One lot of crystals was used for the crystal characterization study, and other lots were examined to verify that the optical data were consistent.

**Equipment**—A trinocular widefield microscope[2] was fitted with a polarizing substage condenser, an analyzer in the body tube, strain free 0.40 and 0.65 N.A. objectives, and a 12-v, 60-w tungsten filament lamp. A regulating transformer permitted the load to be varied up to a maximum of 6 amp. Photomicrographs were obtained with a 35-mm camera[2] mounted on the vertical ocular. Film[3] was 35-mm black and white with an ASA of 125. A second monocular, polarizing microscope[2] with an adjustable Bertrand lens and iris in the body tube, strain-free objectives up to 0.85 N.A., and a tungsten filament lamp with heat filters also was used.

The stage was a simple, inexpensive device described previously (8) in which a crystal is attached to a spindle and rotated about a single axis perpendicular to the microscope axis.

**Microscopic Examination**—An amount of powder adhering to the point of a dissecting needle was tapped onto the surface of a microscope slide, and the index of refraction fluid was applied with a glass applicator. The powder was mixed with fluid, and a cover slip was added. The slide was then examined with a polarized light microscope using orthoscopic and conoscopic optic conditions. (For an extensive and detailed description of microscopic procedures for optical crystallographic studies, see Refs. 9–11 or any of the numerous publications available on the

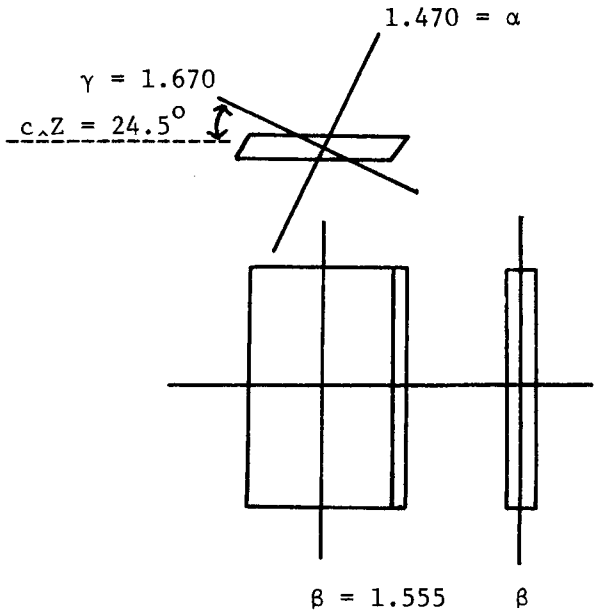

**Figure 3**—*Orthographic projection of typical crystal of I.*

[2] Leitz.
[3] Kodak PX135.

subject.) Spindle stage examination of crystals followed that described previously (8, 11).

## RESULTS AND DISCUSSION

Preliminary orthoscopic examination revealed that the lath-shaped crystals (Fig. 1) exhibited a single plane of optical symmetry from which a single $\beta$ refractive index value could be obtained. The crystals were quite thin, and most grains lay on the 100 orthopinacoid.

To obtain $\beta$ and $\gamma$ refractive index values, the crystals were mounted (Fig. 2) onto a spindle stage. The crystals were rotated on their $b$-axis to orientations that presented the principal vibration directions, and refractive index values were determined by immersion in various fluids.

Crystals could not be oriented to provide a 010 end view, and therefore, a $\beta$-angle could not be observed or measured microscopically. Subsequent data reported from X-ray diffraction methods gave a value of 96°. An orthographic projection of a typical crystal of I is shown in Fig. 3, and Table I presents the optical properties.

# Synthesis of Dehydroepiandrosterone Sulfatide and 16$\alpha$-Halogenated Steroids

**MAGID ABOU-GHARBIA, LAURA PASHKO, ARTHUR SCHWARTZ, and DANIEL SWERN** ˣ

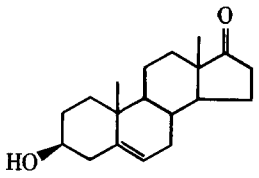
Received December 8, 1980, from the *Fels Research Institute and Department of Chemistry, Temple University, Philadelphia, PA 19122.* Accepted for publication March 5, 1981.

**Abstract** □ Dehydroepiandrosterone sulfatide was prepared in a 68% yield by the reaction of 5-androstene-3$\beta$-ol-17-one 3-sulfate (silver salt) with dipalmitoyl $\alpha$-iodopropylene glycol. The sulfatide was found to be a more potent inhibitor of human glucose-6-phosphate dehydrogenase than dehydroepiandrosterone. 16$\alpha$-Halogenated steroids also were prepared by direct halogenation of the steroid or indirect halogenation of an appropriate steroidal intermediate. Among various halogenated steroids, 16$\alpha$-bromoepiandrosterone was ~50 times as potent as dehydroepiandrosterone as an inhibitor of glucose-6-phosphate dehydrogenase.

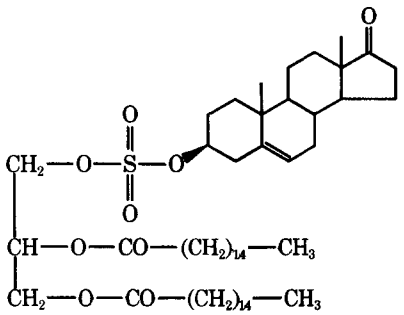
**Keyphrases** □ Dehydroepiandrosterone sulfatide—synthesis, tested as glucose-6-phosphate dehydrogenase inhibitor □ 16$\alpha$-Halogenated derivatives of epiandrosterone—synthesis, tested as glucose-6-phosphate dehydrogenase inhibitors □ Glucose-6-phosphate dehydrogenase—synthesis of dehydroepiandrosterone sulfatide and 16$\alpha$-halogenated steroids

Of the naturally occurring steroids that had been tested, dehydroepiandrosterone (I) proved to be an outstanding noncompetitive inhibitor of glucose-6-phosphate dehydrogenase (1, 2). The sulfated form of I (I$a$) is a major adrenal secretory product in humans. Approximately 99% of the plasma form of this steroid is sulfated, while the remainder is unconjugated steroid. The plasma concentration of the sulfated form of I exceeds that of any other steroidal hormone, yet its biological role is unknown. (Most investigators refer to the conjugated form as the sulfate.)

According to Oertel and coworkers (3, 4), the sulfated form of the hormone found in human plasma is I-sulfatide (II), the ester of sulfatidic acid, which must be isolated under extremely mild conditions because of its lability. In



I



II

the search for analogs of considerably higher potency than I or II in inhibiting glucose-6-phosphate dehydrogenase to diminish or eliminate undesirable side effects of high dosage dehydroepiandrosterone therapy, the sulfatide (II) and 16$\alpha$-halogenated derivatives of epiandrosterone were synthesized.

## RESULTS AND DISCUSSION

Dipalmitoyl-L-$\alpha$-iodopropylene glycol (III) was prepared in an 80% yield by facile acylation of L-$\alpha$-iodopropylene glycol with two equivalents

*0022-3549/81/1000-1154$01.00/0*

*© 1981, American Pharmaceutical Association*

subject.) Spindle stage examination of crystals followed that described previously (8, 11).

## RESULTS AND DISCUSSION

Preliminary orthoscopic examination revealed that the lath-shaped crystals (Fig. 1) exhibited a single plane of optical symmetry from which a single $\beta$ refractive index value could be obtained. The crystals were quite thin, and most grains lay on the 100 orthopinacoid.

To obtain $\beta$ and $\gamma$ refractive index values, the crystals were mounted (Fig. 2) onto a spindle stage. The crystals were rotated on their $b$-axis to orientations that presented the principal vibration directions, and refractive index values were determined by immersion in various fluids.

Crystals could not be oriented to provide a 010 end view, and therefore, a $\beta$-angle could not be observed or measured microscopically. Subsequent data reported from X-ray diffraction methods gave a value of 96°. An orthographic projection of a typical crystal of I is shown in Fig. 3, and Table I presents the optical properties.

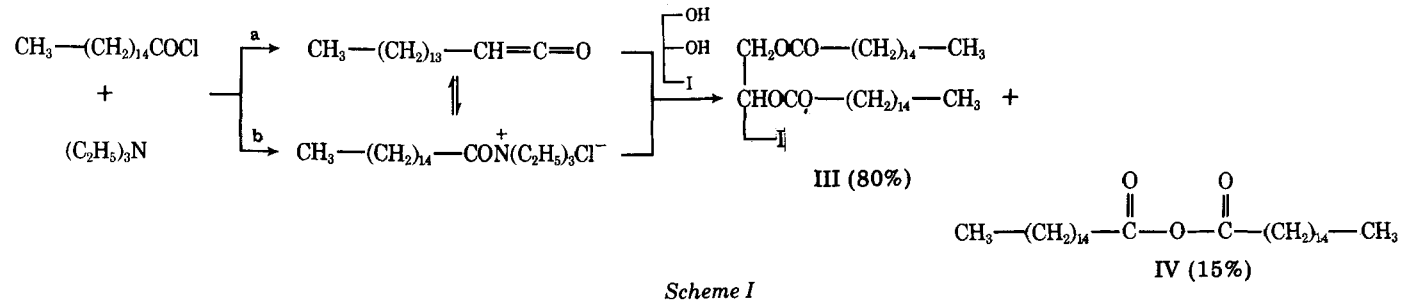
## RESULTS AND DISCUSSION

Dipalmitoyl-L-$\alpha$-iodopropylene glycol (III) was prepared in an 80% yield by facile acylation of L-$\alpha$-iodopropylene glycol with two equivalents

*0022-3549/81/1000-1154$01.00/0*

*© 1981, American Pharmaceutical Association*



*Scheme I*

of palmitoyl chloride in the presence of triethylamine (Scheme I). Reaction of carboxylic acid halides in the presence of triethylamine has been found (5, 6) to involve two pathways, an elimination pathway (a) involving a ketene intermediate and a substitution route (b) involving an acyl ammonium salt intermediate. The product palmitic anhydride (IV) also was isolated in a 15% yield. When quinoline was used instead of triethylamine, as suggested in the literature (7), only 67% of the diglyceride, in addition to 25% of palmitic acid, was formed after a reaction time of 7 days.

Dehydroepiandrosterone sulfatide (II) was then prepared in a 68% yield by alkylation of the sulfate (silver salt) (I*b*) with the iododiglyceride (III) in dry benzene (Scheme II). The sulfatide (II) was found to be a more potent inhibitor of human glucose-6-phosphate dehydrogenase than I*a* itself. It is a labile material and decomposes readily within a few days, even at −5°, to the sulfate with loss of biological activity.

The fact that $\alpha$-substitution at the C-16-position enhances biological activity of certain steroids, coupled with the intention to find more potent and stable compounds, led to the preparation of 16$\alpha$-halo derivatives of epiandrosterone (8–10). 16$\alpha$-Chloro, bromo, and fluoro derivatives were prepared from epiandrosterone according to reaction sequence shown in Scheme III.

Treatment of epiandrosterone with isoamyl nitrite in basic medium afforded 16-oximino-17-ketone (V). The observed melting point, 218–219°, does not agree with the value of 245–247° reported by Mateos *et al.* (11) but is in agreement with that reported earlier by Huffman and Lott (12). IR spectra and elemental analyses of V were consistent with the structure shown.

Treatment of V with sodium hydroxide, ammonia, and sodium hypochlorite (11, 13–15) yielded the yellow 16-diazo compound (VI), which, upon treatment with the appropriate hydrogen halide (hydrochloric, hydrobromic, and hydrofluoric acids) afforded the corresponding colorless 16$\alpha$-halo derivative. Hydriodic acid, however, reduced the diazo compound to epiandrosterone. The 16$\alpha$-configuration was established by comparing the melting points of the products with those reported in the literature (16–20) and by independent synthesis.

The 16$\alpha$-fluoro derivative was also prepared (but in only a 28% yield) by a halogen-exchange technique by refluxing the corresponding bromo derivative (VII*a*) with five equivalents of anhydrous silver fluoride in toluene–isopropanol for 48 hr. The 16$\alpha$-bromo derivative (VII*a*) was independently prepared in a 60% yield by refluxing epiandrosterone with cupric bromide in methanol for 24 hr (17).

The 16$\alpha$-iodo derivative (VII*d*) was prepared by direct iodination of the enol diacetate (VIII) with iodine in the presence of mercuric acetate or with *N*-iodosuccinimide, followed by hydrolysis of the 3$\beta$-acetoxy derivative (IX) with concentrated hydrochloric acid (Scheme IV). Overall yields of VIII to VII*d* were 89%.

16$\alpha$-Iodo steroids were first synthesized in 1973 *via* the 17-bromo-16,17-epoxy derivative or by a halogen-exchange procedure (16). The current procedure is more convenient since the starting materials are commercially available and yields are higher.

Contrary to expectation, VII*a* was the most active halogenated derivative of the four; it is ~50 times as active as dehydroepiandrosterone in inhibiting glucose-6-phosphate dehydrogenase in mouse and human red blood cells. Compound VII*a* is also ~50 times as active in antagonizing the *O*-tetradecanoylphorbol acetate-induced stimulation in the rate of DNA synthesis in mouse skin. A dose of 0.4 mg/kg ip of VII*a* is about as active as 20 mg of dehydroepiandrosterone/kg.

Compounds VII*b* and VII*d* were less active than VII*a*; VII*c* was inactive.

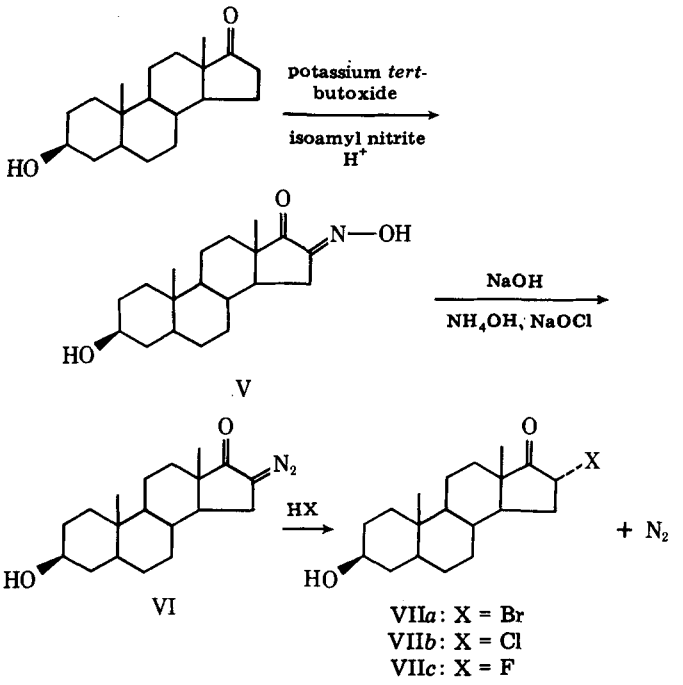
*Scheme II*

## EXPERIMENTAL[1]

**Dipalmitoyl-L-$\alpha$-iodopropylene Glycol (III)**—All apparatus was flame dried; strictly dry conditions were used throughout the study. To a stirred solution of dry, redistilled triethylamine (3.64 ml, 26 mmoles) and L-$\alpha$-iodopropylene glycol (2.7 g, 13.5 mmoles) in dry chloroform (15 ml) at 0°, a solution of palmitoyl chloride (7.42 g, 26 mmoles) in *n*-pentane (50 ml) was added dropwise. The reaction mixture was then stirred for 3 hr at 0°, and the precipitated triethylamine hydrochloride was removed by filtration. The solvent was evaporated from the filtrate under reduced pressure, and the residual solid was digested with hot absolute methanol. The insoluble material was filtered and recrystallized from acetone to afford 1.92 g (15% yield) of the by-product palmitic anhydride (IV), mp 61–63°; IR (KBr): $\nu_{max}$ 1745 and 1800 cm$^{-1}$ [–C(=O)–O–(C=O)–].

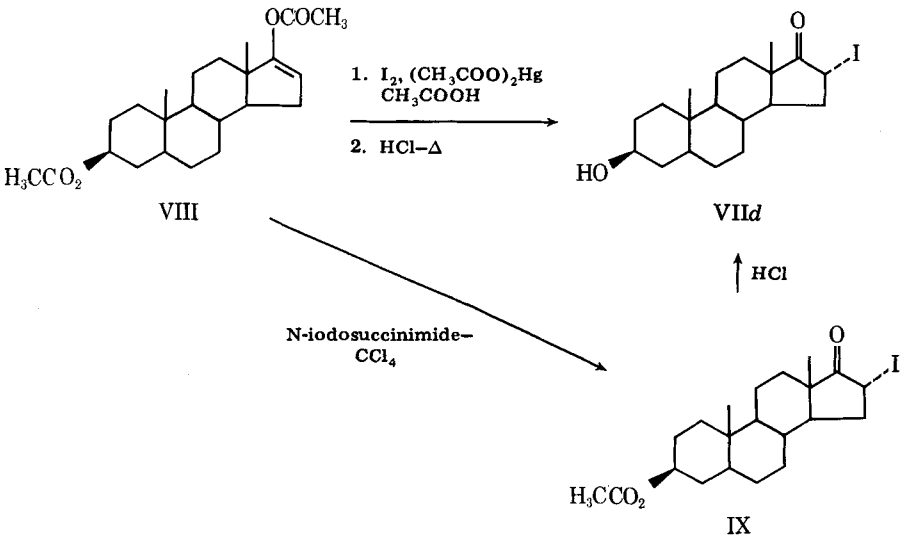
The hot methanol filtrate was cooled, and the solid that precipitated was separated by filtration and recrystallized from petroleum ether (bp 30–60°)–methanol (1:1) to afford 7.4 g (80% yield) of the diglyceride (III), mp 46–48°; IR (KBr): $\nu_{max}$ 1730 and 1745 cm$^{-1}$ [–O–C(=O)–]; $^1$H-NMR ($CDCl_3$): $\delta$ 0.65–1.10 (t, 6H), 1.1–2.00 (m, 52H), 2.20–2.45 (m, 4H), 3.30 (d, 2H), 4.2–4.35 (d, 2H), and 4.9–5.2 (q, 1H).

*Anal.*—Calc. for $C_{35}H_{67}IO_4$: C, 61.92; H, 9.94; I, 18.69. Found: C, 61.96; H, 10.04; I, 18.58.



*Scheme III*

[1] Melting points were determined on a Thomas-Hoover Unimelt apparatus and are uncorrected. IR spectra were recorded on a Unicam SP-1000 spectrophotometer. The $^1$H-NMR spectra were determined using an XL-100 instrument and tetramethylsilane as the internal standard. Elemental analyses were performed by Galbraith Laboratories, Knoxville, Tenn.



*Scheme IV*

Replacement of triethylamine by quinoline was unsatisfactory; the yield of III was only 67% after 7 days of reaction time. Palmitic acid was obtained in a 25% yield; it was separated as its sodium salt by neutralization with sodium carbonate solution. The acid was regenerated by acidification with 6 *N* HCl, mp 58–60°; IR (KBr): $\nu_{max}$ 1700 $cm^{-1}$ [–C(=O)–OH].

**Dehydroepiandrosterone Sulfatide (II)**—A mixture of the diglyceride III (0.37 g, 0.54 mole) and dehydroepiandrosterone sulfate silver salt (0.28 g, 0.860 mmole) (*Ib*) was refluxed in dry benzene (15 ml) for 2 hr. Silver iodide was separated by filtration while hot and washed with dry benzene (10 ml), and the combined benzene filtrates were evaporated to dryness under reduced pressure. The residual yellow solid was washed with cold petroleum ether and dried, mp 66–68°, yield 68%; IR (KBr): $\nu_{max}$ 1730 and 1745 $cm^{-1}$ {[–O–C(=O)–] and cyclic O=C–}; $^1$H-NMR ($CDCl_3$): absence of signal at $\delta$ 3.3 for III and appearance of signal at $\delta$ 4.45 (m, 1H, vinylic).

*Anal.*—Calc. for $C_{54}H_{90}O_9S$: C, 70.85; H, 9.90. Found: C, 70.81; H, 9.43.

**Androstan-3β-ol-16-oximino-17-one (V)**—To a fresh solution of potassium *tert*-butoxide, prepared from potassium (3.8 g, 100 mmoles) and anhydrous *tert*-butyl alcohol (120 ml), epiandrosterone (3.6 g, 12.4 mmoles) was added with vigorous stirring. The mixture was refluxed under nitrogen until a clear yellow solution was obtained and then cooled, and isoamyl nitrite (6.3 ml) was added over 2 hr. The reaction mixture was poured into water (1 liter), acidified with 6 *N* HCl, and then stored at 5° overnight. The separated crude ketooxime (V) was filtered, washed with water, and recrystallized from methanol to afford 3.0 g (68% yield) of V, mp 218–219° [lit. (11) mp 245–247° and (12) mp 218–219°]; IR (KBr): $\nu_{max}$ 1630 (C=N), 1740 (C=O), 3200 (N–OH), and 3400 (OH) $cm^{-1}$.

*Anal.*—Calc. for $C_{19}H_{29}NO_3$: C, 71.43; H, 9.15; N, 4.38. Found: C, 71.18; H, 9.32; N, 4.30.

**5α-Androstan-3β-hydroxy-16α-bromo-17-one (VII*a*)**—Compound VII*a* was prepared in a 60% yield by bromination of epiandrosterone with cupric bromide and in a 72% yield from the diazoketone (VII) following reported procedures (11), mp 158–160° [lit. (11) mp 164–165°]; IR (KBr): $\nu_{max}$ 1740 (C=O) and 3400 (OH) $cm^{-1}$.

*Anal.*—Calc. for $C_{19}H_{29}BrO_2$: C, 61.78; H, 7.79; Br, 21.69. Found: C, 61.60; H, 8.01; Br, 21.87.

**5α-Androstan-3β-hydroxy-16α-chloro-17-one (VII*b*)**—Compound VII*b* was prepared in a 70% yield from the diazoketone (VI) following a reported procedure, mp 178–180° [lit. (11) mp 170–171°]; IR (KBr): $\nu_{max}$ 1750 (C=O) and 3450 (OH) $cm^{-1}$.

**5α-Androstan-3β-hydroxy-16α-fluoro-17-one (VII*c*)**—Compound VII*c* was prepared in a 20% yield from the diazoketone (VI) and pyridine–hydrofluoric acid and in a 28% yield by refluxing VII*d* with five equivalents of anhydrous silver fluoride in toluene–isopropanol (3:1) for 48 hr, mp 177–179°; IR (KBr): $\nu_{max}$ 1760 (C=O) and 3400 (OH) $cm^{-1}$; mass spectra: *m/z* 308 ($M^+$, *m/z* calc. 308).

*Anal.*—Calc. for $C_{19}H_{29}FO_2$: F, 6.15. Found: F, 5.87.

**5α-Androstan-3β-hydroxy-16α-iodo-17-one (VII*d*)**—*Method A* (21)—To a stirred solution of the enol diacetate (VIII) (20) (496 mg, 1.3 mmoles) in acetic acid (18 ml) containing mercuric acetate (10 mg), iodine (580 mg) dissolved in acetic acid (20 ml) was added over 2 hr. Stirring was continued for an additional hour, and the mixture was then poured into cold water (50 ml) and extracted with chloroform. The extract was washed successively with aqueous potassium iodide, sodium bicarbonate, and water. Evaporation of the chloroform afforded 481 mg (89% yield) of VII*d*, mp 170–172° [lit. (16) mp 173–175°]; IR (KBr): $\nu_{max}$ 1730 (C=O) and 3450 (OH) $cm^{-1}$.

*Anal.*—Calc. for $C_{19}H_{29}IO_2$: C, 54.80; H, 7.02; I, 30.48. Found: C, 55.17; H, 7.00; I, 30.77.

*Method B*—*N*-Iodosuccinimide (0.2 g, 0.88 mmole) was added to a solution of the enol diacetate (VIII) (200 mg, 0.53 mmole) in dioxane (15 ml); after slight warming to ensure complete dissolution, the reaction mixture was left in the dark for 24 hr. Potassium iodide solution was added to the reaction mixture, followed by excess 10% aqueous sodium thiosulfate solution. The reaction mixture was extracted with chloroform, dried, and evaporated. The white solid residue was recrystallized from methanol–ether to afford 208 mg (86% yield) of the 3β-acetoxy-16α-iodo derivative (IX), mp 147–148° [lit. (16) mp 144–147°]; IR (KBr): $\nu_{max}$ 1735 [O–C(=O)–$CH_3$] and 1740 (C=O) $cm^{-1}$. To a solution of 250 mg of IX in methanol (10 ml) at room temperature, 37% HCl (1 ml) was added. After the mixture stood at room temperature overnight, VII*d* was separated by filtration, mp 170–172° (mixed melting point with sample prepared by Method A showed no depression).

# Dosage Form Design for Improvement of Bioavailability of Levodopa V: Absorption and Metabolism of Levodopa in Intestinal Segments of Dogs

**KUNIHIRO SASAHARA ˣ, TAKASHI NITANAI, TAEKO HABARA, TADASHI MORIOKA, and EIICHI NAKAJIMA**

Received November 10, 1980, from the *Product Development Laboratories, Sankyo Company, Ltd., 1-2-58, Hiromachi, Shinagawa, Tokyo, Japan.* Accepted for publication March 10, 1981.

**Abstract** □ Plasma levels of levodopa, total dopamine, and residual amounts of levodopa and its metabolites at the administered site were analyzed following administration of single 100-mg doses of levodopa in solution into isolated segments of the duodenum, jejunum, and ileum of the dog. The largest area under the plasma concentration–time curve (*AUC*) of levodopa during the 1.0-hr study was obtained following administration in the duodenum, followed by the jejunum and ileum. In addition, the residual amounts of levodopa and its metabolites detected at the administration sites were: ileum, 23%; jejunum, 7%; and duodenum, <1%. The largest *AUC* of total dopamine was obtained following administration in the jejunum, followed by the ileum and duodenum. This order was consistent with the order of levodopa decarboxylase enzyme activity reported previously. Therefore, it can be concluded that the major absorption site of levodopa in the intestine resides in the upper small intestine. Levodopa in 10-, 50-, and 100-mg doses was administered into isolated duodenal segments. The *AUC* of levodopa increased nonlinearly with increasing dose. Negligible amounts of both levodopa and its metabolites were observed in the segment at 1.0 hr after administration, indicating that the duodenal absorption of levodopa was not saturable within the dose range tested.

**Keyphrases** □ Levodopa—absorption and metabolism, intestinal segments, dogs, bioavailability, dosage form design □ Dosage form design—bioavailability of levodopa, absorption and metabolism in dog intestinal segments □ Bioavailability—levodopa, dosage form design, absorption and metabolism in dog intestinal segments

It was previously reported (1) that the reduced bioavailability of levodopa following oral administration was primarily due to levodopa metabolism by levodopa decarboxylase in the intestinal tissue, with the most enzyme activity in the jejunum and the least in the duodenum. The present investigation attempted to validate these findings by a study of levodopa absorption from intestinal segments.

## EXPERIMENTAL

**Major Absorption Site of Levodopa in Intestine of Dogs**—Nine healthy male mongrel dogs, 11.1–13.9 kg, were fasted for ~16 hr and anesthetized with 25-mg/kg iv doses of pentobarbital sodium. They were divided into three equal groups according to the segment to be ligated. After the dog was fixed on its back, a laparotomy was performed on each dog, and a 20-cm segment of the duodenum, the jejunum, or the ileum was ligated. A single 100-mg dose of levodopa was injected as a 1% solution[1] into the ligated segment of each dog. Blood samples were withdrawn with a heparinized syringe from the brachial or femoral vein.

At 0, 2, 5, 15, 30, and 60 min after dosing, blood samples were withdrawn and processed as described previously (2). The animals were killed by exsanguination at 1 hr after levodopa administration, and the ligated loop was washed with saline and then three times with 0.04 *N* $HClO_4$ solution. The irrigating solution was assayed for residual amounts of levodopa and its metabolites.

**Influence of Levodopa Dose on Absorption and Metabolism of Levodopa in Duodenum of Dogs**—Nine healthy male mongrel dogs, 10.2–13.5 kg, were fasted for ~16 hr and anesthetized as described previously. After the dog was fixed on its back, a laparotomy was performed and a 20-cm segment of the duodenum was ligated. Ten-milligram doses of levodopa in a 0.2% solution[1] were injected into the duodenal loops of the first three dogs, 50-mg doses in a 0.5% solution[1] were injected into the duodenal loops of the second three dogs, and 100-mg doses in a 1.0% solution[1] were injected into the duodenal loops of the third group.

Blood samples were withdrawn with a heparinized syringe from the hepatoportal vein at 0, 2, 5, 15, 30, and 60 min after administration. Blood samples and the irrigating solution obtained from the final wash of the ligated loops were processed as already described.

**Assay of Levodopa and Its Metabolites in Plasma and in Administered Site**—Levodopa and its metabolite in plasma were determined according to a reported method (3). Residual amounts of levodopa and its metabolites in the dosing site of the intestine were determined according to the method reported previously (1).

## RESULTS

**Major Absorption Site of Intestine of Levodopa in Dogs**—The average plasma levels of levodopa and total dopamine[2] are shown in Fig. 1 following administration of single 100-mg doses of levodopa to the duodenum, jejunum, and ileum. The highest plasma levodopa levels were obtained after duodenal administration; peak concentrations of 9.5 ± 1.9 mg/liter were observed at 5 min. Plasma levodopa levels following administration to the jejunum reached the peak levels of 5.0 ± 0.8 mg/liter at 15 min. Plasma levodopa levels following administration to the ileum were not only lowest but also increased so slowly that they reached peak levels of only 3.2 ± 0.3 mg/liter at 30 min after administration.

The average *AUC* of levodopa up to 1.0 hr after administration is shown in Fig. 2. The *AUC* of levodopa after administration to the ileum was approximately one-half that observed after duodenal administration.

[1] The 0.2, 0.5, and 1% levodopa solutions were prepared by dissolving levodopa in the buffer solution containing 0.2% sodium bicarbonate and 0.5% polyvinyl acetate (~pH 8.0).

[2] Total dopamine = unconjugated dopamine + conjugated dopamine.

# Dosage Form Design for Improvement of Bioavailability of Levodopa V: Absorption and Metabolism of Levodopa in Intestinal Segments of Dogs

**KUNIHIRO SASAHARA ˣ, TAKASHI NITANAI, TAEKO HABARA, TADASHI MORIOKA, and EIICHI NAKAJIMA**

Received November 10, 1980, from the *Product Development Laboratories, Sankyo Company, Ltd., 1-2-58, Hiromachi, Shinagawa, Tokyo, Japan.* Accepted for publication March 10, 1981.

**Abstract** □ Plasma levels of levodopa, total dopamine, and residual amounts of levodopa and its metabolites at the administered site were analyzed following administration of single 100-mg doses of levodopa in solution into isolated segments of the duodenum, jejunum, and ileum of the dog. The largest area under the plasma concentration–time curve (*AUC*) of levodopa during the 1.0-hr study was obtained following administration in the duodenum, followed by the jejunum and ileum. In addition, the residual amounts of levodopa and its metabolites detected at the administration sites were: ileum, 23%; jejunum, 7%; and duodenum, <1%. The largest *AUC* of total dopamine was obtained following administration in the jejunum, followed by the ileum and duodenum. This order was consistent with the order of levodopa decarboxylase enzyme activity reported previously. Therefore, it can be concluded that the major absorption site of levodopa in the intestine resides in the upper small intestine. Levodopa in 10-, 50-, and 100-mg doses was administered into isolated duodenal segments. The *AUC* of levodopa increased nonlinearly with increasing dose. Negligible amounts of both levodopa and its metabolites were observed in the segment at 1.0 hr after administration, indicating that the duodenal absorption of levodopa was not saturable within the dose range tested.

**Keyphrases** □ Levodopa—absorption and metabolism, intestinal segments, dogs, bioavailability, dosage form design □ Dosage form design—bioavailability of levodopa, absorption and metabolism in dog intestinal segments □ Bioavailability—levodopa, dosage form design, absorption and metabolism in dog intestinal segments

It was previously reported (1) that the reduced bioavailability of levodopa following oral administration was primarily due to levodopa metabolism by levodopa decarboxylase in the intestinal tissue, with the most enzyme activity in the jejunum and the least in the duodenum. The present investigation attempted to validate these findings by a study of levodopa absorption from intestinal segments.

## EXPERIMENTAL

**Major Absorption Site of Levodopa in Intestine of Dogs**—Nine healthy male mongrel dogs, 11.1–13.9 kg, were fasted for ~16 hr and anesthetized with 25-mg/kg iv doses of pentobarbital sodium. They were divided into three equal groups according to the segment to be ligated. After the dog was fixed on its back, a laparotomy was performed on each dog, and a 20-cm segment of the duodenum, the jejunum, or the ileum was ligated. A single 100-mg dose of levodopa was injected as a 1% solution[1] into the ligated segment of each dog. Blood samples were withdrawn with a heparinized syringe from the brachial or femoral vein.

At 0, 2, 5, 15, 30, and 60 min after dosing, blood samples were withdrawn and processed as described previously (2). The animals were killed by exsanguination at 1 hr after levodopa administration, and the ligated loop was washed with saline and then three times with 0.04 *N* $HClO_4$ solution. The irrigating solution was assayed for residual amounts of levodopa and its metabolites.

**Influence of Levodopa Dose on Absorption and Metabolism of Levodopa in Duodenum of Dogs**—Nine healthy male mongrel dogs, 10.2–13.5 kg, were fasted for ~16 hr and anesthetized as described previously. **Figure 1**—*Average plasma levels of levodopa (± SE) and total dopamine (± SE) following administration of single 100-mg dose of levodopa to dog duodenum (●), jejunum (○), and ileum (×).*

However, plasma levels of total dopamine increased slowly and reached the peak levels at 30–60 min after administration, irrespective of the administration site. The highest plasma levels of total dopamine were observed following administration to the jejunum, followed by the ileum and duodenum. This order did not correspond with the order of plasma levodopa levels.

The residual amounts of levodopa and its metabolites recovered from the segment are shown in Table I. These results showed that the residual amounts of levodopa and its metabolites were proportional to the order of plasma levodopa levels. Virtually all drug was absorbed from the duodenal segments, and negligible amounts of metabolites of levodopa were detected. Therefore, it was concluded that the major absorption site of levodopa is the duodenum.

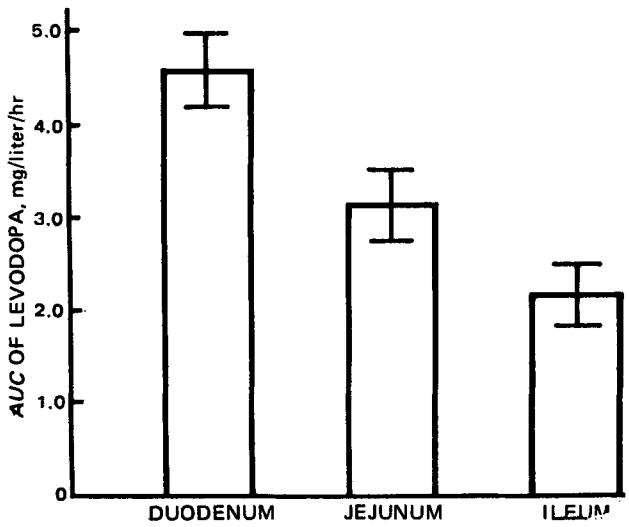

**Figure 2**—*Average* AUC *of levodopa (± SE) up to 1.0 hr after administration of single 100-mg doses of levodopa to dog duodenum, jejunum, and ileum.*

**Influence of Levodopa Dose on Absorption and Metabolism of Levodopa in Duodenum in Dogs**—The average plasma levels of levodopa and total dopamine following administration of single 10-, 50-, and 100-mg doses of levodopa to the duodenum of three dogs are shown in Fig. 3. As the administered dose increased, plasma levodopa levels in the hepatoportal vein appeared to be disproportionally high. In addition, the absorption rate from the duodenum was rapid since the peak time of plasma levodopa levels was observed at 2 min after dosing. However, total dopamine revealed an inverse situation; *i.e.*, as the dose increased, the relative plasma levels of total dopamine were progressively less. The relationship between the levodopa dose administered and the observed *AUC* of levodopa and the observed *AUC* of total dopamine up to 1.0 hr after dosing are shown in Fig. 4. These findings and the fact that levodopa obeys linear kinetics in the body after drug absorption (4) may indicate that metabolism of levodopa to dopamine by levodopa decarboxylase in the dog duodenum proceeds by a capacity-limited process.

The amounts of levodopa and its metabolites remaining at the ad-

ministered site at 1.0 hr after administration were 1% of the administered dose, indicating that levodopa is completely absorbed within 1.0 hr after administration even at the largest dose studied.

## DISCUSSION

It was previously reported (5–7) that the shorter the transit time through the stomach, the higher the observed plasma levodopa levels. These reports suggested that the upper small intestine might play an important role in levodopa absorption *via* the oral route. Analogously, the major site of oral absorption of other amino acids has been shown to be the upper small intestine (8, 9). The isolated intestinal studies carried out in the present investigation showed that the major absorption site of levodopa was the duodenum and that complete absorption occurred in the dose range studied. The inverse relationship between the observed plasma levels of levodopa and total dopamine shown in Fig. 1 is consistent with the fact that activity of levodopa decarboxylase is the lowest in the duodenum and increases in the lower sections of the small intestine (1).

However, previous studies (4) reported that levodopa bioavailability

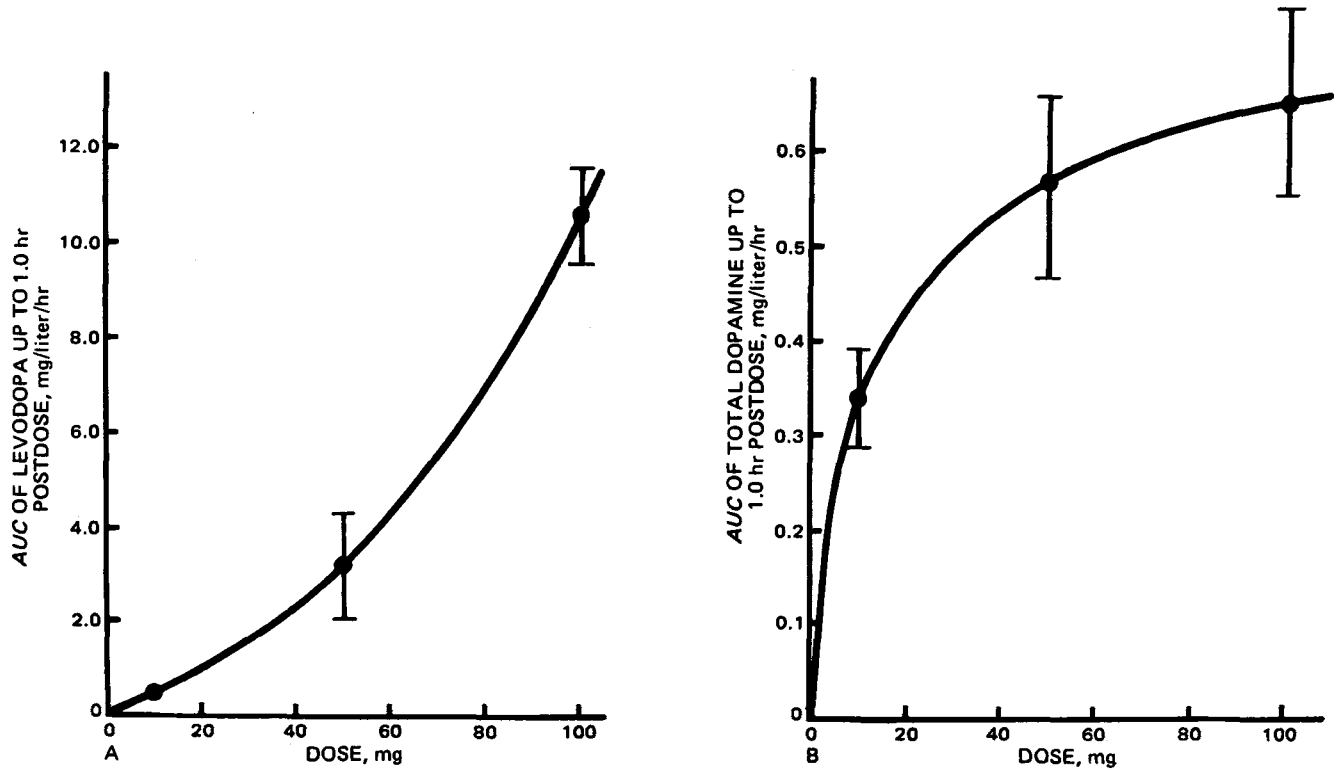

**Figure 4**—*Relationship between the levodopa dose administered and the observed* AUC *of levodopa (A) and the observed* AUC *of total dopamine (B) up to 1.0 hr after dosing.*

in the intact dog was dose dependent and that administration of 10-, 50-, and 100-mg doses of levodopa to the duodenum led to the same results shown in Fig. 3. Yet negligible amounts of levodopa remained in the duodenal segment, and plasma levodopa levels resulted from saturable metabolism of levodopa to dopamine by the levodopa decarboxylase enzyme system in the duodenal tissue. Calimlim *et al.* (10) noted that the levodopa metabolites produced in the stomach may be responsible for nausea and vomiting. Their study and the present results indicate that levodopa bioavailability might be improved with an enteric-coated preparation that releases levodopa in high concentration at the upper small intestine.

# Blood Collection Technique: No Effect on *In Vitro* Protein Binding of Prednisolone

**MARIO L. ROCCI, JR., and WILLIAM J. JUSKO** ˣ

Received November 28, 1980, from the *Clinical Pharmacokinetics Laboratory, Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo*, and the *Millard Fillmore Hospital, Buffalo, NY 14209.* Accepted for publication March 25, 1981.

**Abstract** □ The effect of the blood collection vessel and systemic heparin administration on *in vitro* protein binding of prednisolone was examined in blood collected from human subjects. No differences in the fractional binding of prednisolone were found in plasma from plain glass culture tubes, heparinized culture tubes, and two types of red- and green-top commercial vacuum tubes. Thus, these blood collection techniques do not alter serum or plasma albumin and transcortin binding of prednisolone.

**Keyphrases** □ Binding—prednisolone, effect of blood collection techniques □ Tris(2-butoxyethyl)phosphate—leached substance altering protein binding of selected drugs □ Prednisolone—protein binding in blood collection techniques

Blood collection techniques can affect the binding of ligands to serum proteins (1–7). Heparin administration stimulates lipoprotein lipase release *in vivo* (8), and this enzyme can increase the serum concentrations of nonesterified fatty acids *in vivo* (8) and *in vitro* (9). These fatty acids displace drugs from their binding sites on albumin (10). Heparin also has been shown to alter the plasma protein binding of several drugs when used to prevent blood clotting *in vitro* (6). Tris(2-butoxyethyl)phosphate, a substance leached from some stoppers, also alters the protein binding of selected drugs (1–4). Weak bases that bind to $\alpha_1$-acid glycoprotein are principally affected (2).

This study examined the effect of blood collection on the protein binding of prednisolone. This synthetic glucocorticoid is bound in serum by three proteins: transcortin, albumin, and $\alpha_1$-acid glycoprotein, although the latter contributes minimally to the overall binding of this steroid *in vivo* (11). The limited capacity of transcortin for binding prednisolone results in a nonlinear relationship between prednisolone free fraction and serum concentration, with increases in the free fraction occurring at higher concentrations. This binding pattern contributes greatly to the nonlinear disposition of this compound in humans (12). In addition, the unbound drug appears to be the pharmacologically active moiety (11). Thus, accurate binding measurements are essential when examining prednisolone pharmacokinetics.

## EXPERIMENTAL

**Study Design**—Four healthy adult males (nonsmokers), ages 24–37 years, were studied. A "scalp vein" infusion set[1] was inserted into an arm vein, and an intravenous drip of normal saline was infused at a rate of 0.5 ml/min to maintain the collection line open for 2 hr. At the end of this period, 10 ml of blood was collected into each of five tubes: (*a*) a plain glass culture tube, (*b*) a red-top commercial tube[2], (*c*) a green-top commercial tube with heparin[2], (*d*) another red-top commercial tube[3], and (*e*) a culture tube containing 0.2 ml of 1000-units/ml heparin injection[4]. Contact between the blood samples and stoppers from the two types of commercial tubes was assured through inversion of these tubes.

After initial blood collection, a dilute heparin solution in normal saline (20 units/ml) was connected to the infusion set to prevent clotting of the collection line. At 2, 2.5, 3, 3.5, and 4 hr, 5 ml of the heparin solution was flushed through the line to simulate heparin administration during intermittent blood sample collection. At 4 hr, blood was collected in various tubes as described.

All samples were maintained at 25° for 1 hr and then centrifuged; the plasma (or serum) was harvested and frozen (−20°) prior to analysis.

**Analysis**—Prednisolone containing trace quantities of [$^3$H]prednisolone[5] (specific activity 53 mCi/mmole) was added to each sample to produce concentrations of 100 ng/ml. The protein binding of prednisolone was assessed using equilibrium dialysis for 16 hr at 37° and radioactivity analysis as previously described (13).

**Statistics**—A two-way analysis of variance was performed (14) to differentiate between the effect of systemic heparin administration and the effect of the collection container on prednisolone protein binding. An interaction term was included so that the combined effects of these factors could be assessed.

## RESULTS AND DISCUSSION

The extent of prednisolone binding *in vitro* in the serum (or plasma) samples from the various collection tubes before and after systemic heparin administration is presented in Table I. There were no significant differences in the fractional binding of prednisolone in samples obtained from the various collection tubes ($F = 1.12$). In addition, heparin infusion had no significant effect on the fractional binding of prednisolone ($F = 2.84$). No dual interactions occurred between the collection vessel and heparin administration ($F = 0.67$).

Therefore, heparin administration has no effect on the *in vitro* binding of prednisolone at low steroid concentrations. A low concentration of prednisolone was chosen for these studies to reflect binding to transcortin, a protein that has not been assessed in relation to such potential binding displacement. Changes in the binding at this concentration would result in the greatest relative increase in the free fraction when compared to higher steroid concentrations where ~50–60% of prednisolone is bound (15). Elevation of free fatty acid levels by heparin increases the free fraction of drugs such as phenytoin, warfarin (10), and quinidine (5). The lipase responsible for the release of these fatty acids is active *in vitro* and can introduce a further artifact in the binding measurements *via in vitro* release of these displacing agents (9).

Heparin affects the binding of warfarin, salicylic acid, and phenytoin when used as an anticoagulant *in vitro* (6). The lack of significant differences in prednisolone binding among heparinized and nonheparinized samples obtained prior to systemic heparin administration indicates that the *in vitro* presence of heparin is not of major concern when conducting prednisolone binding and disposition studies.

The leaching of tris(2-butoxyethyl)phosphate from the stoppers of one tube[2] increased the free fraction of basic drugs including propranolol (1), alprenolol (3), and quinidine (4). Prednisolone is a neutral molecule and thus is not affected by the presence of tris(2-butoxyethyl)phosphate. Therefore, the use of heparin and commercial tubes does not appear to pose a problem when examining the protein binding of prednisolone.

[a] Top value is sodium chloride equivalent, and bottom value is freezing-point depression. [b] Isosmotic concentration, % w/v. [c] Solution foams readily.

hemolytic investigations. Results are presented in tables to supplement the previous data.

## EXPERIMENTAL

**Cryoscopic Measurements**—The method used to measure the freezing points of the solutions was the same as that already reported; all freezing-point data were obtained with a cryoscopic osmometer (4).

The freezing-point measurements were corrected for the amount of disengaged ice; −0.52° was used as the comparative freezing point for aqueous 0.9% reagent grade sodium chloride solution, which is isotonic and isosmotic with blood and tears. The materials studied were of the official grade of purity or better, and the grade of purity of the donated specialty preparations complied with the manufacturer's specifications.

**Hemolysis of Human Erythrocytes**—Colorimetric hemoglobin determinations were made to indicate the degree of hemolysis for solutions that could be made isosmotic. The method (3–6) utilized a 45-min incubation period of erythrocytes in the isosmotic solution, followed by centrifugation of the erythrocytes and ghosts and determination of absorbance *versus* a standard at 540 nm in a colorimeter.

## RESULTS AND DISCUSSION

Table I lists the sodium chloride equivalents and freezing-point depressions at various concentrations for the 29 substances investigated. To use these data, one should employ the sodium chloride equivalent that represents the concentration nearest to the desired final concentration of the medicinal substance used. Because of general interest in colligative properties of medicinal solutions, freezing-point depressions and sodium chloride equivalents are included for several substances that are not necessarily used as isotonic or isosmotic solutions. Sodium chloride equivalents and isosmotic concentrations are reported to the nearest 0.01.

Table II—Hemolysis of Erythrocytes in Isosmotic Solutions

| Substances | Isosmotic Concentration, % w/v | Hemolysis, % | Approximate pH |
|---|---|---|---|
| Carbazochrome salicylate | 2.57 | 82[a] | 9.4 |
| Cefazolin sodium | 8.77 | 0 | 4.6 |
| Cephapirin sodium | 7.80 | 3[b] | 6.7[c] |
| Dopamine hydrochloride | 3.11 | 6 | 4.6 |
| Etidocaine hydrochloride | 5.08 | 100 | 4.3 |
| Isoetharine hydrochloride | 4.27 | 8 | 4.1 |
| Ketamine hydrochloride | 4.29 | 41 | 3.3 |
| Potassium thiocyanate | 1.52 | 0 | 6.3 |
| Sodium nitroprusside | 3.30 | 50[d] | 9.1 |
| Sodium thiocyanate | 1.27 | Trace | 5.0 |
| Terbutaline sulfate | 6.75 | 11 | 4.1 |
| Ticarcillin disodium | 4.62 | Trace | 5.2 |

[a] Solution turned orange. [b] Solution turned yellow. [c] The pH was determined after addition of erythrocytes. [d] Solution turned red brown.

The percent of hemolysis found for the 12 isosmotic solutions studied, the isosmotic concentration used for each, and the solution's approximate pH before the addition of erythrocytes are listed in Table II. Any noticeable change in appearance of the erythrocytes or the solution was indicated. Of the 12 compounds studied, only four isosmotic solutions prevented hemolysis of human erythrocytes.

A compilation of the 305 substances whose isosmotic solutions were studied using the present hemolytic method shows that 144 failed to prevent hemolysis while 161 prevented hemolysis. Care must be taken not to equate isotonicity and isosmoticity without knowledge of the corresponding data whenever a biological membrane is utilized. This aspect was discussed previously (2, 4, 6–9).

Earlier studies (3–5) showed apparent aggregation of some substances in aqueous solution. In the present study, the cryoscopic graphs of cefamandole nafate and cefoxitin sodium (whose aqueous solutions foamed considerably) showed a slight discontinuity at 1%, suggesting that some aggregation may have taken place above that concentration; however, this phenomenon was not as distinct as with the previously reported drugs. Likewise, solutions of piperacillin sodium, propantheline bromide, and propranolol foamed considerably, suggesting that their surface tensions also were lowered; however, a plot of their cryoscopic graphs did not indicate aggregation. A sufficient number of compounds in the total study did tend to aggregate in solution, which suggests that this interfacial phenomenon may play a role in drug action by affecting biological activity. Associations taking place in the complex biological medium undoubtedly affect the thermodynamic activity of a given drug at the molecular level and, therefore, warrant increased study.

# Improved Liquid Chromatographic Assay for Serum Fluorouracil Concentrations in the Presence of Ftorafur

**C. L. HORNBECK *x, R. A. FLOYD ‡, J. C. GRIFFITHS *, and J. E. BYFIELD §**

Received January 5, 1981, from the * *Department of Laboratory Services and the* ‡ *Department of Pharmacy, Veterans Administration Medical Center, San Diego, CA 92161*, and the § *Division of Radiation Oncology, University of California Medical Center, San Diego, CA 92103.* Accepted for publication March 23, 1981.

**Abstract** □ An improved liquid chromatographic assay for serum ftorafur and fluorouracil is shown to be routine, sensitive, and reproducible using 200 μl of serum. Dilute ammonium acetate buffer at pH 10.2 is used for solubilization of the evaporated ethyl acetate extract for injection into the liquid chromatograph. A stability study indicated little or no *in vitro* formation of fluorouracil from ftorafur under the conditions described. Low serum fluorouracil levels were found after administration of therapeutic doses of ftorafur.

**Keyphrases** □ Liquid chromatographic assay—improved results for fluorouracil in presence of ftorafur □ Ftorafur—stability study, no *in vitro* formation of fluorouracil □ Anticancer agent—ftorafur potential for treatment of GI cancers

The recent development of an oral dosage form of the antineoplastic ftorafur [$R_1S$-*1*-(tetrahydro-2-furanyl)-5-fluorouracil] (I) has added new potential for the treatment of GI cancers on an outpatient basis. Ftorafur is generally considered to be a prodrug for fluorouracil (II), which, in turn, derives its cytotoxicity from its structural resemblance to uracil (IV). Inspection of the structure of I, II, and IV reveals the structural similarities between these molecules, and comparison of I and III indicates the unusual tetrahydrofuranyl ring of ftorafur.

## BACKGROUND

During initial human studies with bolus ftorafur, investigators reported circulating levels of fluorouracil greater than those found after continuous intravenous infusion of fluorouracil (1, 2). In addition, there is some clinical similarity between bolus ftorafur and infusional fluorouracil in terms of patient toxicity (3). These findings suggested that the cytotoxic mechanism of ftorafur was probably due to the slow release of fluorouracil into the systemic circulation.

However, in a more recent study with bolus ftorafur, very low circulating levels of fluorouracil were reported and fluorouracil was not detected in the serum 8 hr after ftorafur administration (4). This report suggested that the high fluorouracil levels reported previously were the result of *in vitro* breakdown of ftorafur or perhaps its more labile dehydro metabolite (5). This metabolite is thought to differ from ftorafur by only a double bond located in an undetermined position in the furanyl ring

Table II—Hemolysis of Erythrocytes in Isosmotic Solutions

| Substances | Isosmotic Concentration, % w/v | Hemolysis, % | Approximate pH |
|---|---|---|---|
| Carbazochrome salicylate | 2.57 | 82[a] | 9.4 |
| Cefazolin sodium | 8.77 | 0 | 4.6 |
| Cephapirin sodium | 7.80 | 3[b] | 6.7[c] |
| Dopamine hydrochloride | 3.11 | 6 | 4.6 |
| Etidocaine hydrochloride | 5.08 | 100 | 4.3 |
| Isoetharine hydrochloride | 4.27 | 8 | 4.1 |
| Ketamine hydrochloride | 4.29 | 41 | 3.3 |
| Potassium thiocyanate | 1.52 | 0 | 6.3 |
| Sodium nitroprusside | 3.30 | 50[d] | 9.1 |
| Sodium thiocyanate | 1.27 | Trace | 5.0 |
| Terbutaline sulfate | 6.75 | 11 | 4.1 |
| Ticarcillin disodium | 4.62 | Trace | 5.2 |

[a] Solution turned orange. [b] Solution turned yellow. [c] The pH was determined after addition of erythrocytes. [d] Solution turned red brown.

The percent of hemolysis found for the 12 isosmotic solutions studied, the isosmotic concentration used for each, and the solution's approximate pH before the addition of erythrocytes are listed in Table II. Any noticeable change in appearance of the erythrocytes or the solution was indicated. Of the 12 compounds studied, only four isosmotic solutions prevented hemolysis of human erythrocytes.

A compilation of the 305 substances whose isosmotic solutions were studied using the present hemolytic method shows that 144 failed to prevent hemolysis while 161 prevented hemolysis. Care must be taken not to equate isotonicity and isosmoticity without knowledge of the corresponding data whenever a biological membrane is utilized. This aspect was discussed previously (2, 4, 6–9).

Earlier studies (3–5) showed apparent aggregation of some substances in aqueous solution. In the present study, the cryoscopic graphs of cefamandole nafate and cefoxitin sodium (whose aqueous solutions foamed considerably) showed a slight discontinuity at 1%, suggesting that some aggregation may have taken place above that concentration; however, this phenomenon was not as distinct as with the previously reported drugs. Likewise, solutions of piperacillin sodium, propantheline bromide, and propranolol foamed considerably, suggesting that their surface tensions also were lowered; however, a plot of their cryoscopic graphs did not indicate aggregation. A sufficient number of compounds in the total study did tend to aggregate in solution, which suggests that this interfacial phenomenon may play a role in drug action by affecting biological activity. Associations taking place in the complex biological medium undoubtedly affect the thermodynamic activity of a given drug at the molecular level and, therefore, warrant increased study.

# Improved Liquid Chromatographic Assay for Serum Fluorouracil Concentrations in the Presence of Ftorafur

**C. L. HORNBECK *x, R. A. FLOYD ‡, J. C. GRIFFITHS *, and J. E. BYFIELD §**

Received January 5, 1981, from the * *Department of Laboratory Services and the* ‡ *Department of Pharmacy, Veterans Administration Medical Center, San Diego, CA 92161*, and the § *Division of Radiation Oncology, University of California Medical Center, San Diego, CA 92103.* Accepted for publication March 23, 1981.

**Abstract** □ An improved liquid chromatographic assay for serum ftorafur and fluorouracil is shown to be routine, sensitive, and reproducible using 200 μl of serum. Dilute ammonium acetate buffer at pH 10.2 is used for solubilization of the evaporated ethyl acetate extract for injection into the liquid chromatograph. A stability study indicated little or no *in vitro* formation of fluorouracil from ftorafur under the conditions described. Low serum fluorouracil levels were found after administration of therapeutic doses of ftorafur.

**Keyphrases** □ Liquid chromatographic assay—improved results for fluorouracil in presence of ftorafur □ Ftorafur—stability study, no *in vitro* formation of fluorouracil □ Anticancer agent—ftorafur potential for treatment of GI cancers

The recent development of an oral dosage form of the antineoplastic ftorafur [$R_1S$-*1*-(tetrahydro-2-furanyl)-5-fluorouracil] (I) has added new potential for the treatment of GI cancers on an outpatient basis. Ftorafur is generally considered to be a prodrug for fluorouracil (II), which, in turn, derives its cytotoxicity from its structural resemblance to uracil (IV). Inspection of the structure of I, II, and IV reveals the structural similarities between these molecules, and comparison of I and III indicates the unusual tetrahydrofuranyl ring of ftorafur.

## BACKGROUND

During initial human studies with bolus ftorafur, investigators reported circulating levels of fluorouracil greater than those found after continuous intravenous infusion of fluorouracil (1, 2). In addition, there is some clinical similarity between bolus ftorafur and infusional fluorouracil in terms of patient toxicity (3). These findings suggested that the cytotoxic mechanism of ftorafur was probably due to the slow release of fluorouracil into the systemic circulation.

However, in a more recent study with bolus ftorafur, very low circulating levels of fluorouracil were reported and fluorouracil was not detected in the serum 8 hr after ftorafur administration (4). This report suggested that the high fluorouracil levels reported previously were the result of *in vitro* breakdown of ftorafur or perhaps its more labile dehydro metabolite (5). This metabolite is thought to differ from ftorafur by only a double bond located in an undetermined position in the furanyl ring

(5, 6). In view of these divergent results and the importance of determining whether serum fluorouracil levels resulting from ftorafur administration could be related to patient efficacy and toxicity as indicated with infusional fluorouracil (7), levels of circulating fluorouracil were determined in patients on bolus ftorafur protocols (6).

In initial attempts to adopt existing liquid chromatographic assays for ftorafur and fluorouracil in this laboratory, great difficulty was experienced in obtaining results either routinely or reproducibly for fluorouracil. These problems were caused mainly by interfering peaks of varying sizes from serum to serum and partly by peak broadening with the use of methanol as the injection solvent. To overcome these difficulties, an assay originally developed by other researchers (8) was modified. The modified assay is very sensitive and reproducible and is readily adaptable to routine therapeutic drug monitoring of fluorouracil in the presence of ftorafur and its labile metabolite, dehydroftorafur. A stability study revealed little or no formation of *in vitro* fluorouracil during assay or storage, and patient serum data confirm low levels of circulating fluorouracil with ftorafur doses as high as 5 g/m$^2$.

## EXPERIMENTAL

**Subjects and Clinical Protocols**—Blood samples were taken from five patients with various GI carcinomas during 15 treatment cycles of a Phase I clinical trial of combined ftorafur and radiation therapy. Each cycle consisted of total daily ftorafur doses of 1.5–2.0 g/m$^2$ for 5 days and concurrent daily radiation doses of 250 rads starting on the 2nd day for 4 days. Each cycle was followed by 9 days of rest before the next treatment cycle. Ftorafur was administered orally three times daily with meals, and the serum samples were drawn 1–4 hr after the midday dose. One patient was given a single intravenous 2-hr infusion of 5.0 g of ftorafur/m$^2$. Blood samples were taken periodically during and for up to 24 hr after the infusion. All serum samples were frozen at −20° until analysis.

**Reagents and Apparatus**—Analytical standards of ftorafur[1], fluorouracil[2], and thymidine[2] were used as supplied. All solvents were nanograde quality.

The analysis of serum fluorouracil, ftorafur, and dehydroftorafur was performed on a microprocessor-controlled high-performance liquid chromatograph[3] equipped with a variable-wavelength detector, automatic sampling system, and a 4-mm × 30-cm reversed-phase column[4]. The column was run at ambient temperatures at a flow rate of 2 ml/min. The elution solvent varied from 3 to 6% methanol in 0.01 *M* aqueous sodium acetate (pH 4.0), yielding retention times of 2.9, 23, and 27 min for fluorouracil, ftorafur, and dehydroftorafur, respectively. The variable UV

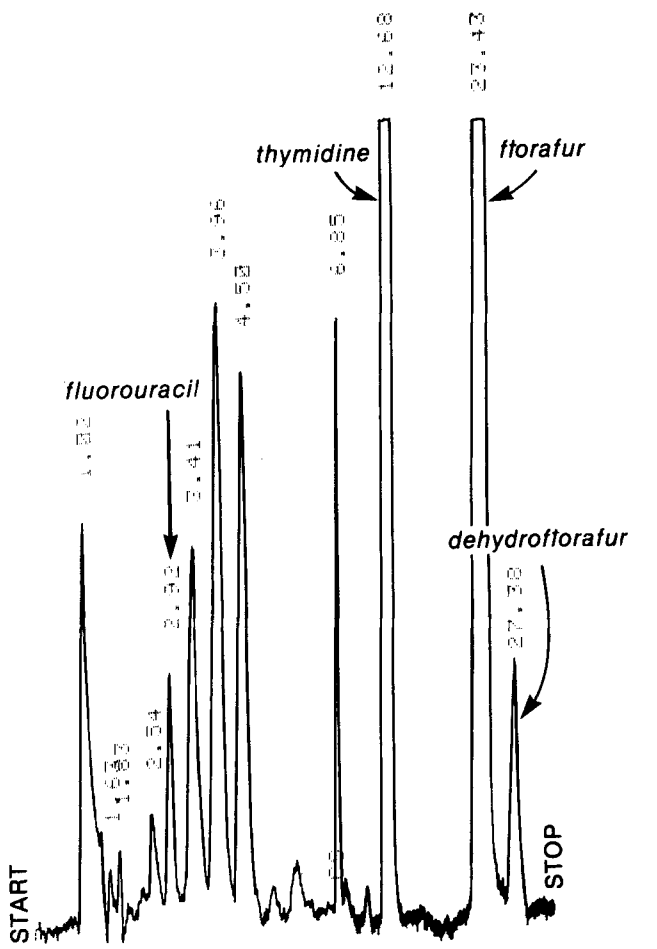

**Figure 1**—*Liquid chromatographic profile of a patient serum using 100 μl of 0.01* M *ammonium acetate (pH 10.2) as the injection solvent for the evaporated ethyl acetate extract of 200 μl of serum. Chart speed was changed from 0.8 to 0.15 cm/min at 6.5 min.*

detector was set at a sample wavelength of 270 nm and a reference wavelength of 330 nm with full-scale absorbance set at 0.003 unit.

**Extraction Procedure**—To a 10-ml screw-capped disposable glass tube were added 200 μl of serum; either 100 μl of water, fluorouracil, or ftorafur solution; 40 μl of thymidine internal standard (100 μg/ml serum); 40 μl of 0.5 *M* sodium phosphate buffer; and 6 ml of ethyl acetate. The tubes were shaken vigorously for 3 min and centrifuged at 2000 rpm for 15 min (1000×*g*). The organic phase was transferred to a second 10-ml tube and evaporated to dryness under nitrogen at 50°. Then 100 μl of 0.01 *M* ammonium acetate (pH 10.2) was added to the dried extract, and the tube was sonicated for 30 min. The extract was transferred to a microvial and capped, and 25 μl was injected into the liquid chromatograph.

Along with patient samples and the control, each assay included two duplicate reference standards for fluorouracil at concentrations of either 50 or 100 ng/ml and two ftorafur reference standards at concentrations of 50 and 100 μg/ml for quantitation of both ftorafur and dehydroftorafur. When filtration was used as a substitute for extraction and concentration, serum was passed through centriflow-membrane filters[5] before injection into the liquid chromatograph.

## RESULTS AND DISCUSSION

The most important modification to the original assay (8) is the use of 0.01 *M* ammonium acetate at pH 10.2 instead of methanol to take up the dried ethyl acetate extract. This approach leads to other modifications by taking advantage of the anionic form of the fluoropyrimidines occurring at alkaline pH. Many materials extracted by ethyl acetate are not soluble in the aqueous pH 10.2 solvent. With the modified procedure, the

extraction ratio of ethyl acetate to serum can be increased from 8:1 to 16:1; this change increases the recovery of fluorouracil from ~50 to 70% and still eliminates interferences with the fluorouracil peak.

Figure 1 is a typical serum profile. When methanol is used as the injection solvent, mixing occurs more slowly, which effectively broadens peaks not well retained by the column. These faster eluting peaks are much sharper with the use of the aqueous solvent. This increased peak definition, combined with cleaner spectra and greater fluorouracil recovery, results in a lower and constant serum requirement of 200 μl from which concentrations as low as 10 ng/ml of fluorouracil can be reliably and routinely detected. Many blank serum samples as well as patient serum samples have been tested with this procedure, and none produced interfering peaks.

The procedure offers two other benefits that are not clearly demonstrated in Fig. 1. Thymidine in microgram amounts was proven to be a reliable internal standard for the fluoropyrimidines after numerous runs showed that very few peaks of any size other than ftorafur and dehydroftorafur eluted after ~7–8 min from injection. Naturally occurring thymidine appears in low nanogram amounts in serum and contributes <1% to the much higher amounts of thymidine spiked into serum. Another advantage is a decrease in solubilization of less polar and more strongly retained compounds extracted by ethyl acetate. These materials are soluble in methanol and often become interferences in subsequent injections into the liquid chromatograph. This decrease in slowly eluting peaks allows a far more reliable use of automated injection capabilities. Ten to 20 samples can be processed for injection in 2–3 hr, and the liquid chromatograph can be programmed to inject automatically day or night.

To determine truly representative systemic fluorouracil levels in the presence of ftorafur, it is important to demonstrate that the fluorouracil concentration measured is not a result of the breakdown of ftorafur or the more labile dehydroftorafur during storage or assay. Briefly, ftorafur and dehydroftorafur did not contribute *in vitro* to fluorouracil concentrations in serum when stored at −20° for up to 6 weeks or when stored for up to 10 hr in 0.01 *M* ammonium acetate (pH 10.2) at room temperature. No fluorouracil could be detected after extraction and chromatography of purified ftorafur spiked into blank serum. A negligible fluorouracil concentration was detected after extraction and chromatography of dehydroftorafur spiked into blank serum; however, the dehydroftorafur had been concentrated by lyophilization during which conversion of dehydroftorafur to fluorouracil previously was demonstrated.

Storage and reproducibility were conveniently checked by monitoring the control samples included in daily assays. These samples were from a ftorafur patient serum, which had been divided into 200-μl aliquots and frozen at −20° until assayed. Day-to-day variations in the fluorouracil levels of 10 of these aliquots were small and random, indicating that no measurable fluorouracil originated from ftorafur and dehydroftorafur for up to 6 weeks of storage at −20°. The coefficient of variation for the control samples was 4.8% for fluorouracil at a mean concentration of 44 ng/ml. The mean and coefficient of variation for ftorafur were 64 μg/ml and 5.8%, respectively, while the corresponding values for dehydroftorafur were 1.1 μg/ml and 9.4%.

The contribution to fluorouracil from ftorafur at a concentration of ~100 μg/ml was negligible during extraction and chromatography. This result was determined by injecting a very concentrated aqueous solution of ftorafur into the liquid chromatograph to separate it from any contaminating fluorouracil. The ftorafur peak was collected, and an aliquot of the unconcentrated and fluorouracil-free ftorafur solution was spiked into a blank serum to give a concentration of ~100 μg/ml. The spiked serum was extracted and chromatographed as usual; no measurable fluorouracil peak was found in the elution profile.

Since a purified and concentrated form of dehydroftorafur was not available, it was not possible to repeat an identical experiment with the metabolite. Therefore, dehydroftorafur had to be isolated from fluorouracil and ftorafur by liquid chromatography of patient serum. For isolation of dehydroftorafur, the column elution buffer was changed from sodium acetate to ammonium acetate; the collected dehydroftorafur fraction was immediately titrated to pH ~10 for concentration by lyophilization. The reconstituted dehydroftorafur was spiked into a blank serum to give an approximate concentration of 1 μg/ml. Extraction and chromatography of the spiked serum resulted in a small 5-fluorouracil concentration of 15 ng/ml. However, it previously had been shown that similar lyophilization of ftorafur resulted in measurable fluorouracil formation. Since dehydroftorafur is even more labile, this would indicate that the formation of fluorouracil was a result of the lyophilization step, which is not part of the routine assay. In addition, serum dehydroftorafur concentrations have been typically <5% of ftorafur serum concentrations.

**Table I—Mean and Standard Deviation of the Serum Concentrations for the Three Fluoropyrimidines Monitored in Five Patients on Oral Ftorafur Chemotherapy [a]**

| Patient | Total Daily Dose, g/m² | Ftorafur, μg/ml | Dehydroftorafur, μg/ml | Fluorouracil, ng/ml | n [b] |
|---|---|---|---|---|---|
| BH | 1.5 | 76 ± 14 | 0.87 ± 0.35 | 70 ± 15 | 6 |
| RJ | 1.5 | 50 ± 14 | 0.76 ± 0.31 | 63 ± 17 | 8 |
| RW | 1.5 | 96 ± 35 | — | 45 ± 36 | 9 |
| FT | 2.0 | 79 ± 15 | — | 64 ± 22 | 7 |
| NR | 2.0 | 73 ± 23 | 1.6 ± 0.45 | 76 ± 30 | 10 |

[a] Ftorafur range = 34–147 μg/ml. Fluorouracil range = 9–133 ng/ml. [b] Number of serum samples monitored.

If the instrument is used unattended in the automatic injection mode, the last sample to be injected will sit in the pH 10.2 solution for up to 10 hr more than the first sample injected. To test this situation, multiple extractions were performed on another patient serum having a ftorafur concentration of 124 μg/ml and a dehydroftorafur concentration of 1.5 μg/ml. The dried extracts were brought up in the pH 10.2 buffer, and the samples were injected so that 10 hr elapsed from the first to last injection. The initial concentration of fluorouracil measured in this sample was 53 ng/ml, and only small random changes (coefficient of variation of 4.3%) were seen over the 10-hr period in the three fluoropyrimidine concentrations. These results were routinely confirmed several times by placing the first sample injected behind the last sample for automatic reinjection.

Table I shows the average serum levels for five patients treated with several cycles of concurrent radiation and oral ftorafur chemotherapy. On a molar basis, the dosages are approximately equivalent to the 5-day dosage of fluorouracil given during direct intravenous infusion of 25 mg/kg/24 hr. This dosage of fluorouracil generates serum fluorouracil levels starting near 100 ng/ml to >500 ng/ml (9). The highest serum fluorouracil concentrations achieved in the ftorafur patients were comparatively low, and only three of the 40 values exceeded 100 ng/ml. In a different protocol, Patient BH was given a single intravenous bolus dose of 5.0 g/m² of ftorafur and serum levels of the three fluoropyrimidines were monitored for 24 hr after the dose. This dose was more than three times this patient's daily 1.5 g/m² of oral ftorafur given during the regular 5-day cycle. The ftorafur level at 2 hr was 250 μg/ml with a fluorouracil level of 150 ng/ml. At 24 hr, the ftorafur concentration had dropped to 90 μg/ml with a fluorouracil level of only 85 ng/ml.

Serum fluorouracil concentrations in the 1–2-μg/ml range were reported for up to 24 hr after a ftorafur intravenous bolus dose of 5 g/m² (2). However, the latter data were acquired using a somewhat different method. The serum had been filtered through a 50,000 molecular weight cutoff filter and injected directly into the liquid chromatograph with water as the column eluant. As a check on methodological differences, the 2- and 24-hr serum samples from Patient BH were repeated using the filtration method with 0.1 *M* sodium acetate, 5% methanol (pH 4.0), or water as the column eluant. Both 200- and 1000-ng/ml fluorouracil standards were run concurrently with these samples, which demonstrated fluorouracil peaks smaller than the 200-ng/ml standard with both column eluants.

The assay is sensitive and reproducible, and there appears to be little or no *in vitro* formation of fluorouracil during storage or assay under the conditions described. With just minor variations, the assay is now routinely used to monitor fluorouracil serum and cerebrospinal fluid concentrations in fluorouracil infusion patients instead of the more complex GLC–mass spectrometric assay used previously (7, 10). Ftorafur patient data indicate that ftorafur does not release fluorouracil into the serum in concentrations comparable to levels seen during fluorouracil infusion regimens. Furthermore, the data indicate that fluorouracil does not accumulate in the serum to infusional fluorouracil levels during repeated 5-day oral administration of therapeutic doses of ftorafur.

# High-Performance Liquid Chromatographic Assay of Tolbutamide and Carboxytolbutamide in Human Plasma

**GURSHARAN RAGHOW and MARVIN C. MEYER ˣ**

Received October, 10, 1980, from the *Division of Biopharmaceutics and Pharmacokinetics, Department of Pharmaceutics, College of Pharmacy, University of Tennessee Center for the Health Sciences, Memphis, TN 38163.* Accepted for publication March 4, 1981.

**Abstract** □ A high-performance liquid chromatographic method was developed for the simultaneous measurement of tolbutamide and its major metabolite, carboxytolbutamide, in plasma. The assay involves the ether extraction of 1 ml of plasma, using chlorpropamide as an internal standard. The extract is dried, the residue is taken up in acetonitrile, and 5 μl is injected into a reversed-phase column. The mobile phase consisted of 35% acetonitrile and 65% 0.05 *M* phosphoric acid buffer (pH 3.9). A fixed-wavelength detector was set at 254 nm. The sensitivity limits for the tolbutamide and carboxytolbutamide assay were 2 and 0.1 μg/ml, respectively. The ratio of carboxytolbutamide to tolbutamide in plasma obtained from a subject given a 500-mg tolbutamide tablet was ~1:20.

**Keyphrases** □ Tolbutamide—simultaneous high-performance liquid chromatographic assay with carboxytolbutamide, human plasma □ Carboxytolbutamide—simultaneous high-performance liquid chromatographic assay with tolbutamide, human plasma □ High-performance liquid chromatography—simultaneous assay of tolbutamide and carboxytolbutamide

Tolbutamide is an oral hypoglycemic agent used for the chronic treatment of diabetes mellitus of the maturity-onset type. After oral administration to humans, ~85% of the dose is excreted in the urine as the carboxy metabolite (1-butyl-3-*p*-carboxyphenylsulfonylurea) and the hydroxymethyl metabolite (1-butyl-3-*p*-hydroxymethylphenylsulfonylurea) (1), both inactive.

## BACKGROUND

The pharmacokinetics of tolbutamide in patients is highly variable, with apparent half-lives ranging from ~2 to 25 hr (2, 3). Because of this variability, it was suggested that plasma tolbutamide concentrations should be determined in patients receiving this drug (2, 4). The bioavailability of tolbutamide after oral administration was shown to be influenced by the salt form (5), the surface area (6), and the excipients present in the formulation (7). These observations are particularly significant since changes in the serum glucose concentrations show a good relationship to the time course of tolbutamide in plasma (5, 7). Therefore, an assay method for tolbutamide and its metabolites would be useful in pharmacogenetic studies, therapeutic drug monitoring, and bioavailability studies.

Colorimetric (8–12) and UV (13) methods lack sensitivity and specificity. Methods involving GLC (14–17) require derivatization of the drug. More recently, high-performance liquid chromatographic (HPLC) methods were developed (18, 19). One method (18) is suitable for the determination of tolbutamide and its major metabolite, carboxytolbutamide, but does not use an internal standard and is not sensitive enough to quantitate the low metabolite levels reported previously (20). Another method (19) uses chlorpropamide as an internal standard but does not measure carboxytolbutamide simultaneously.

## EXPERIMENTAL

**Reagents and Chemicals**—Tolbutamide[1], carboxytolbutamide[1], chlorpropamide[2], ether[3], acetonitrile[3], hydrochloric acid[4], and phosphoric acid[5] were used.

**HPLC**—Deionized water (1 ml) and 1 ml of chlorpropamide internal standard (30 μg/ml) were added to 1 ml of plasma in a 20-ml centrifuge tube with a polytef-lined screw cap. After mixing, 0.1 ml of 1.3 *N* HCl was added; the mixture was extracted with 10 ml of ether for 15 min by gentle shaking on a platform shaker. After centrifugation at −10° for 15 min at 3000 rpm, the ether layer was transferred to a 15-ml conical tube and evaporated under nitrogen at 40°. The residue was taken up in 100 μl of acetonitrile and vortexed for 30 sec, and 5 μl was injected into the HPLC system.

The HPLC system consisted of a sample injector[6], a mobile phase pump[7] operated at 2.5 ml/min (2000 psi), a reversed-phase column[8], a fixed-wavelength UV absorbance detector[9] at 254 nm (aufs 0.01), and a recorder[10] operated at 0.5 cm/min. The mobile phase consisted of 35% acetonitrile and 65% 0.05 *M* phosphoric acid buffer (pH 3.9). Column temperature was maintained at 28°. After each use, the column was washed with water followed by methanol to avoid damage by the buffer in the mobile phase.

**Preparation of Standard Curves**—A standard solution was prepared to contain 100 μg of tolbutamide/ml and 5 μg of carboxytolbutamide/ml in 0.1 *N* NaOH. Aliquots of this solution were diluted with deionized water to yield standards containing 2, 5, 10, 20, 40, 60, and 80 μg of tolbutamide/ml and 0.1, 0.25, 0.5, 1, 2, 3, and 4 μg of carboxytolbutamide/ml. The internal standard solution contained 30 μg of chlorpropamide/ml in 0.0005 *N* NaOH. One milliliter of the tolbutamide–carboxytolbutamide solution and 1 ml of the chlorpropamide solution were added to 1 ml of pooled human plasma, and the mixture was assayed. Standard curves were prepared using duplicate samples at each concentration by plotting peak height ratio (tolbutamide to internal standard or carboxytolbutamide to internal standard) *versus* drug or metabolite concentration.

**Stability Studies**—Three 20-ml samples of pooled plasma were spiked with 20 ml of water, 20 ml of an aqueous standard containing 10 μg of tolbutamide/ml and 0.5 μg of carboxytolbutamide/ml, or 20 ml of an aqueous standard containing 80 μg of tolbutamide/ml and 4 μg of carboxytolbutamide/ml. Each portion of spiked plasma was separated into individual 8-ml portions and stored frozen at −10° for subsequent assay after 1, 2, and 4 weeks. A sample of each also was assayed immediately after preparation.

# High-Performance Liquid Chromatographic Assay of Tolbutamide and Carboxytolbutamide in Human Plasma

**GURSHARAN RAGHOW and MARVIN C. MEYER ˣ**

Received October, 10, 1980, from the *Division of Biopharmaceutics and Pharmacokinetics, Department of Pharmaceutics, College of Pharmacy, University of Tennessee Center for the Health Sciences, Memphis, TN 38163.* Accepted for publication March 4, 1981.

**Abstract** □ A high-performance liquid chromatographic method was developed for the simultaneous measurement of tolbutamide and its major metabolite, carboxytolbutamide, in plasma. The assay involves the ether extraction of 1 ml of plasma, using chlorpropamide as an internal standard. The extract is dried, the residue is taken up in acetonitrile, and 5 μl is injected into a reversed-phase column. The mobile phase consisted of 35% acetonitrile and 65% 0.05 *M* phosphoric acid buffer (pH 3.9). A fixed-wavelength detector was set at 254 nm. The sensitivity limits for the tolbutamide and carboxytolbutamide assay were 2 and 0.1 μg/ml, respectively. The ratio of carboxytolbutamide to tolbutamide in plasma obtained from a subject given a 500-mg tolbutamide tablet was ~1:20.

**Keyphrases** □ Tolbutamide—simultaneous high-performance liquid chromatographic assay with carboxytolbutamide, human plasma □ Carboxytolbutamide—simultaneous high-performance liquid chromatographic assay with tolbutamide, human plasma □ High-performance liquid chromatography—simultaneous assay of tolbutamide and carboxytolbutamide

Tolbutamide is an oral hypoglycemic agent used for the chronic treatment of diabetes mellitus of the maturity-onset type. After oral administration to humans, ~85% of the dose is excreted in the urine as the carboxy metabolite (1-butyl-3-*p*-carboxyphenylsulfonylurea) and the hydroxymethyl metabolite (1-butyl-3-*p*-hydroxymethylphenylsulfonylurea) (1), both inactive.

## BACKGROUND

The pharmacokinetics of tolbutamide in patients is highly variable, with apparent half-lives ranging from ~2 to 25 hr (2, 3). Because of this variability, it was suggested that plasma tolbutamide concentrations should be determined in patients receiving this drug (2, 4). The bioavailability of tolbutamide after oral administration was shown to be influenced by the salt form (5), the surface area (6), and the excipients present in the formulation (7). These observations are particularly significant since changes in the serum glucose concentrations show a good relationship to the time course of tolbutamide in plasma (5, 7). Therefore, an assay method for tolbutamide and its metabolites would be useful in pharmacogenetic studies, therapeutic drug monitoring, and bioavailability studies.

Colorimetric (8–12) and UV (13) methods lack sensitivity and specificity. Methods involving GLC (14–17) require derivatization of the drug. More recently, high-performance liquid chromatographic (HPLC) methods were developed (18, 19). One method (18) is suitable for the determination of tolbutamide and its major metabolite, carboxytolbutamide, but does not use an internal standard and is not sensitive enough to quantitate the low metabolite levels reported previously (20). Another method (19) uses chlorpropamide as an internal standard but does not measure carboxytolbutamide simultaneously.

## EXPERIMENTAL

**Reagents and Chemicals**—Tolbutamide[1], carboxytolbutamide[1], chlorpropamide[2], ether[3], acetonitrile[3], hydrochloric acid[4], and phosphoric acid[5] were used.

**HPLC**—Deionized water (1 ml) and 1 ml of chlorpropamide internal standard (30 μg/ml) were added to 1 ml of plasma in a 20-ml centrifuge tube with a polytef-lined screw cap. After mixing, 0.1 ml of 1.3 *N* HCl was added; the mixture was extracted with 10 ml of ether for 15 min by gentle shaking on a platform shaker. After centrifugation at −10° for 15 min at 3000 rpm, the ether layer was transferred to a 15-ml conical tube and evaporated under nitrogen at 40°. The residue was taken up in 100 μl of acetonitrile and vortexed for 30 sec, and 5 μl was injected into the HPLC system.

The HPLC system consisted of a sample injector[6], a mobile phase pump[7] operated at 2.5 ml/min (2000 psi), a reversed-phase column[8], a fixed-wavelength UV absorbance detector[9] at 254 nm (aufs 0.01), and a recorder[10] operated at 0.5 cm/min. The mobile phase consisted of 35% acetonitrile and 65% 0.05 *M* phosphoric acid buffer (pH 3.9). Column temperature was maintained at 28°. After each use, the column was washed with water followed by methanol to avoid damage by the buffer in the mobile phase.

**Preparation of Standard Curves**—A standard solution was prepared to contain 100 μg of tolbutamide/ml and 5 μg of carboxytolbutamide/ml in 0.1 *N* NaOH. Aliquots of this solution were diluted with deionized water to yield standards containing 2, 5, 10, 20, 40, 60, and 80 μg of tolbutamide/ml and 0.1, 0.25, 0.5, 1, 2, 3, and 4 μg of carboxytolbutamide/ml. The internal standard solution contained 30 μg of chlorpropamide/ml in 0.0005 *N* NaOH. One milliliter of the tolbutamide–carboxytolbutamide solution and 1 ml of the chlorpropamide solution were added to 1 ml of pooled human plasma, and the mixture was assayed. Standard curves were prepared using duplicate samples at each concentration by plotting peak height ratio (tolbutamide to internal standard or carboxytolbutamide to internal standard) *versus* drug or metabolite concentration.

**Stability Studies**—Three 20-ml samples of pooled plasma were spiked with 20 ml of water, 20 ml of an aqueous standard containing 10 μg of tolbutamide/ml and 0.5 μg of carboxytolbutamide/ml, or 20 ml of an aqueous standard containing 80 μg of tolbutamide/ml and 4 μg of carboxytolbutamide/ml. Each portion of spiked plasma was separated into individual 8-ml portions and stored frozen at −10° for subsequent assay after 1, 2, and 4 weeks. A sample of each also was assayed immediately after preparation.

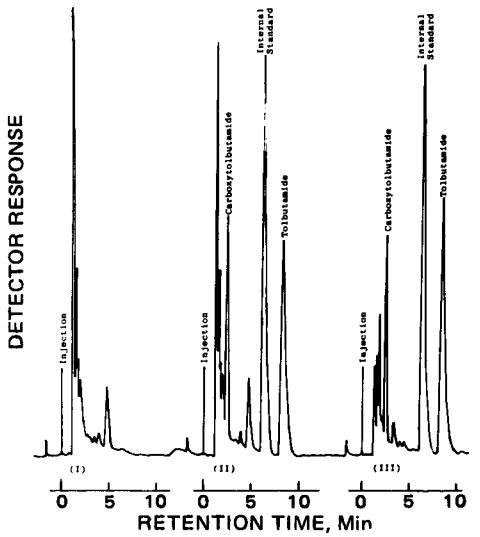

**Figure 1**—*Chromatograms for plasma extracts. Key: I, blank pooled plasma; II, pooled plasma spiked with 40 μg of tolbutamide/ml, 2 μg of carboxytolbutamide/ml, and 30 μg of chlorpropamide/ml as the internal standard; and III, plasma sample obtained from human subject 4 hr after a 500-mg oral dose of tolbutamide, with chlorpropamide added as internal standard.*

**Human Study**—A healthy male volunteer received a single commercially available 500-mg tolbutamide tablet. Blood samples (10 ml) were obtained just before and at 0.5, 1, 2, 3, 4, 6, and 24 hr after drug administration. These samples were assayed for tolbutamide and carboxytolbutamide levels using the described procedures.

## RESULTS AND DISCUSSION

Tolbutamide, carboxytolbutamide, and chlorpropamide each exhibited a 235-nm wavelength of maximum absorbance when present in the mobile phase. A wavelength of 254 nm was selected to permit utilization of a fixed-wavelength detector. The absorptivities of tolbutamide, carboxytolbutamide, and chlorpropamide in the mobile phase were 3.2, 27.9, and 9.3 liters/g cm, respectively, at 254 nm.

Typical chromatograms for extracted plasma are shown in Fig. 1 for a pooled plasma sample containing no drug, a pooled plasma sample containing 40 μg of tolbutamide/ml and 2 μg of carboxy metabolite/ml, and a plasma sample obtained from a subject 4 hr after a 500-mg oral dose of tolbutamide. Chlorpropamide (30 μg/ml) was added to the latter two samples. The metabolite, internal standard, and drug peaks were well resolved with retention times of 1.8, 5.6, and 7.8 min, respectively. A peak with a retention time of 4.0 min appeared in extracts of pooled plasma but did not interfere in the assay, provided the mobile phase was carefully maintained at pH 3.9. This peak did not appear in the plasma samples freshly obtained from a human subject. The recoveries of tolbutamide, the carboxy metabolite, and chlorpropamide were ~99, 80, and 60%, respectively, relative to a direct HPLC assay of aqueous standards. Thus, the greater sensitivity of the assay for carboxytolbutamide was due to absorptivity differences rather than extraction efficiency.

Standard curves prepared for both tolbutamide and the carboxy metabolite exhibited excellent linearity over the concentration ranges employed for each material. The least-squares slope, intercept, and correlation coefficient for the tolbutamide calibration curve were 0.0140, 0.0052, and 0.9999, respectively. The same values for the carboxy metabolite were 0.303, −0.013, and 0.9999, respectively. The precision of the assay for tolbutamide and carboxytolbutamide was determined by the analysis of six replicate samples at each of three concentrations. Plasma samples containing 10, 40, and 80 μg of tolbutamide/ml exhibited relative standard deviations of 1.8, 0.5, and 0.4%, respectively. Plasma samples containing 0.5, 2.0, and 4.0 μg of carboxytolbutamide/ml exhibited relative standard deviations of 7.9, 2.2, and 1.4%, respectively. The lower limits of sensitivity were 2 μg/ml for tolbutamide and 0.1 μg/ml for the carboxy metabolite. Analysis of the spiked pooled plasma samples that had been stored frozen for 1, 2, and 4 weeks indicated no significant loss of tolbutamide or the carboxy metabolite over that period.

Figure 2 summarizes the tolbutamide and carboxy metabolite concentrations determined in a subject who received a 500-mg of tolbutamide

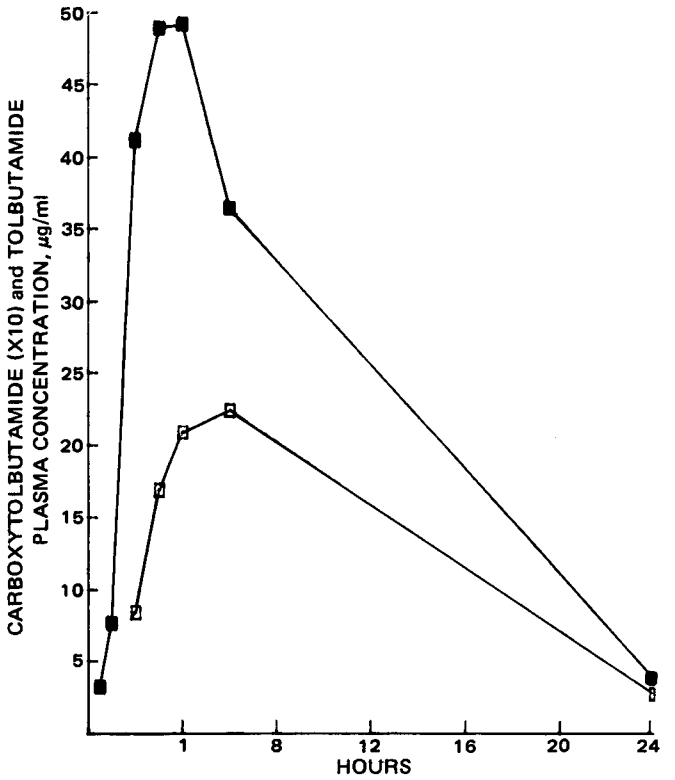

**Figure 2**—*Plasma concentrations of tolbutamide (■) and carboxytolbutamide (□) following administration of a 500-mg oral dose of tolbutamide to a human subject.*

tablet. The peak plasma tolbutamide concentration of 49 μg/ml was in the range of peak levels reported in other studies with human subjects who received 500-mg oral doses of the drug (17, 21). The peak plasma carboxy metabolite concentration was 2.2 μg/ml, which was ~1/20 the tolbutamide concentration. Matin and Knight (20) found a ratio of ~50:1 for tolbutamide to the carboxy metabolite after administration of a 1-g iv dose to a diabetic patient. They also reported the presence of a hydroxymethyl metabolite in this patient. The concentration of the metabolite paralleled that of the carboxy metabolite but was ~50% that of the major metabolite. Since an authentic sample of the hydroxymethyl metabolite was unavailable, it was not possible to determine the potential for this compound to interfere in the present assay or to be quantitated by the assay. However, chromatograms obtained with the assay did not reveal any evidence of an additional peak that could be attributed to this metabolite.

Based on these data, the reported method exhibits adequate sensitivity and specificity for single-dose bioavailability studies as well as for the monitoring of plasma tolbutamide concentrations in patients. In addition, the method is applicable to pharmacokinetic studies of the drug and its primary metabolite. It also should be applicable to the determination of plasma chlorpropamide concentrations with tolbutamide as the internal standard.

# Human Blood Preservation: Effect on *In Vitro* Protein Binding

**ANDRÉ J. JACKSON ˣ, ANN K. MILLER, and PREM K. NARANG**

Received September 8, 1980, from the *Clinical Pharmacokinetics Laboratory, School of Pharmacy, University of Maryland, Baltimore, MD 21201.* Accepted for publication March 23, 1981.

**Abstract** □ *In vitro* plasma protein binding for phenytoin, meperidine, and bretylium tosylate was affected by the type of preserved human blood used for its estimation. Fresh heparinized plasma and serum gave equivalent fractions bound at the concentrations studied for all three drugs. However, the *in vitro* plasma binding of phenytoin and meperidine decreased ~9–50% when estimated in fresh citrated plasma or commercially available lyophylized human serum at the concentration levels investigated. The fraction of bretylium tosylate bound to plasma protein decreased ~30–40% when estimated in fresh citrated plasma but was unchanged when estimated in the lyophylized human serum.

**Keyphrases** □ Binding, plasma protein—effect of blood preservation, humans □ Blood—preservation, effect on *in vitro* plasma protein binding □ Pharmacokinetics—effect of human blood preservation on *in vitro* protein binding

The influence of plasma protein binding on the distribution and elimination of drugs was recently reviewed (1). Accurate evaluation of the fraction of drug bound is essential for a thorough understanding of a drug's pharmacokinetics. Plasma/serum protein binding is normally estimated using several *in vitro* techniques such as equilibrium dialysis, ultrafiltration, gel filtration, differential spectrophotometry, and electrophoresis (2). Several investigators determined plasma protein binding in fresh plasma from subjects participating in pharmacokinetic studies (3, 4), and other sources of blood were utilized in other studies. A frequently reported source is fresh blood bank plasma (5, 6). Blood bank plasma is normally preserved with a standard anticoagulant/preservative, citrate phosphate dextrose USP. However, the presence of preservative has been implicated in lowering the protein binding of quinidine (5). Therefore, it is important that the effect of blood constituents and preservatives be evaluated.

The purpose of this investigation was to determine if a standard anticoagulant/preservative would interfere with the binding of other drugs and the suitability of a commercially available lyophilized serum[1] as a substitute for blood bank plasma when large volumes of plasma/serum are required. The drugs studied, phenytoin, meperidine, and bretylium tosylate, are chemically different and have been reported[2] to exhibit a binding of 90, 60, and 10%[2], respectively (3, 7).

## EXPERIMENTAL

Blood was obtained from one healthy male volunteer, 27 years of age, who was not using any medication. Blood was collected in a clean glass flask containing either 400 IU of heparin/20 ml of blood or 63 ml of citrate phosphate dextrose/450 ml of blood. The blood to be used as serum was collected in clean glass test tubes and allowed to clot. Lyophilized serum[1], reconstituted according to the manufacturer's suggestion, was used as the commercial source of lyophilized human serum.

**Table I—Effect of Blood Preservation Procedure on Fraction of Drug Bound** [a]

| Drug | Concentration, μg/ml | Fresh Plasma Heparin | Fresh Plasma Citrate | Fresh Serum | Lyophilized Serum |
|---|---|---|---|---|---|
| Phenytoin | 15.0 | 0.89 (0.90, 0.88) | 0.80 (0.76, 0.84) | 0.89 (0.89, 0.89) | 0.80 (0.79, 0.81) |
| | 5.0 | 0.90 (0.89, 0.90) | 0.81 (0.79, 0.83) | 0.90 (0.91, 0.89) | 0.80 (0.80, 0.80) |
| Meperidine | 0.98 | 0.58 (0.56, 0.60) | 0.25 (0.23, 0.27) | 0.54 (0.52, 0.56) | 0.26 (0.22, 0.30) |
| | 0.12 | 0.60 (0.58, 0.62) | 0.27 (0.22, 0.28) | 0.58 (0.52, 0.62) | 0.23 (0.18, 0.28) |
| Bretylium | 1.2 | 0.13 (0.14, 0.12) | 0.04 (0.04, 0.04) | 0.10 (0.12, 0.09) | 0.12 (0.12, 0.12) |
| tosylate | 0.3 | 0.11 (0.12, 0.11) | 0.06 (0.06, 0.05) | 0.11 (0.10, 0.12) | 0.10 (0.08, 0.12) |

[a] Mean of two determinations; individual values are given in parentheses.

A standard solution of [$^{14}$C]meperidine, [$^{14}$C]bretylium tosylate, or [$^{14}$C]phenytoin was added to plasma at two concentrations within the respective therapeutic ranges. Protein binding was then determined by equilibrium dialysis. The samples were dialyzed across a cellophane membrane against phosphate buffer (0.067 *M*, pH 7.4) at 37° using a dialysis cell. Equilibrium was achieved for each drug by 24 hr. A control

dialysis was run at each concentration. Following equilibration, aliquots of the buffer and plasma compartments were sampled and analyzed by liquid scintillation spectrometry. Sample efficiency was estimated by external standardization.

## RESULTS AND DISCUSSION

Data presented in Table I indicate agreement of the binding values in fresh serum and heparinized plasma with those reported earlier[2] (3, 7). However, the binding of all three drugs significantly decreased in the fresh blood bank plasma, thereby indicating drug displacement from binding sites by the citrate phosphate dextrose preservative. The decreased binding was not due to a change in pH since the pH was maintained at 7.4 after addition of the preservative. The binding of phenytoin and meperidine was also lowered in lyophilized serum while that of bretylium tosylate was not affected. The manufacturer reports that salicylates are added to lyophilized serum. Therefore, a possible explanation may be a change in protein conformation due to freezing and reconstitution, which would affect the more heavily bound drugs (phenytoin and meperidine) or competitive interaction with the salicylates. Bretylium tosylate would be least affected since it is only 10% bound.

Based on these results, studies done with commercial lyophilized serum should be verified by binding studies in fresh plasma/serum. Furthermore, when blood bank plasma is used for binding studies, the type of preservative used should be stated to allow rigorous evaluation of the pharmacokinetic parameters related to the free fraction and to facilitate duplication of protein binding studies.

# Acyclic Puromycin Analogs: 9-[(2-Phenylalanylamidoethoxy)methyl]adenine and 9-(3-Phenylalanylamidopropyl)adenine

**JAMES L. KELLEY[x], CARL A. MILLER, and HOWARD J. SCHAEFFER**

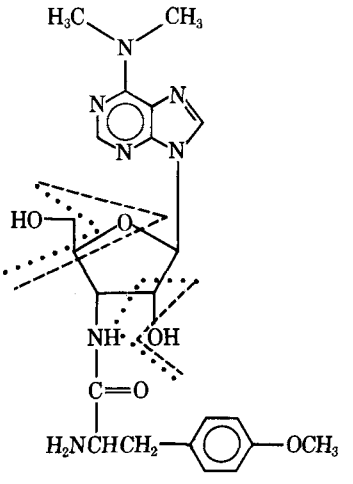
Received January 29, 1981 from *Wellcome Research Laboratories, Research Triangle Park, NC 27709.*
Accepted for publication April 1, 1981.

**Abstract** □ Two acyclic puromycin analogs, in which the 2′- and 5′-hydroxymethyl groups or the 2′-hydroxyl and 5′-hydroxyethoxy portions of the cyclic carbohydrate ring were excised, were synthesized and evaluated for inhibition of an *in vitro* protein-synthesizing system and for antiviral and antibacterial activity. No puromycin-like activity was seen with these conformationally free compounds.

**Keyphrases** □ Puromycin—acyclic analogs, synthesis and analysis, evaluation for inhibition of protein synthesis and antiviral and antibacterial activity □ Analogs—of puromycin, acyclic, synthesis and analysis, evaluation for inhibition of protein synthesis and antiviral and antibacterial activity □ Antineoplastics—puromycin, synthesis and analysis of acyclic analogs, evaluation for inhibition of protein synthesis and antiviral and antibacterial activity

A program initiated to synthesize nucleoside analogs, in which the cyclic carbohydrate moiety is replaced by an acyclic side chain, led to the discovery of the potent antiherpetic drug acyclovir, 9-[(2-hydroxyethoxy)methyl]-guanine[1] (1). This approach to nucleoside modification has been extended to the synthesis of two acyclic analogs of the broad spectrum antibiotic puromycin (I). This nucleoside antibiotic, which is an inhibitor of protein biosynthesis, has not been useful in the treatment of human disease because of its nephrotoxicity (2). It was shown (3–5), however, that toxicity could be alleviated by removal of the 5′-hydroxy group.

This paper reports an approach to separation of toxicity from activity involving the synthesis of distinct fragments of puromycin in which parts of the cyclic carbohydrate moiety are excised. Elimination of the 2′- and 5′-hydroxymethyl groups (dotted lines in I) or the 2′-hydroxyl and 5′-hydroxyethoxy portions (broken lines) would leave side chains as in II*a* or II*b*, respectively[2]. Both II*a* and II*b* can assume a conformation that is superimposable on puromycin, but they lack the 5′-hydroxyl group implicated in puromycin toxicity (3, 6). Open chain analogs similar to



I

[1] Zovirax.

[2] In this work, the readily available DL-phenylalanine was used since the phenylalanyl analog of puromycin is nearly as active as puromycin (7, 8). In addition, the *N* 6-methyl groups of puromycin were shown to be unnecessary for puromycin-like activity (9).

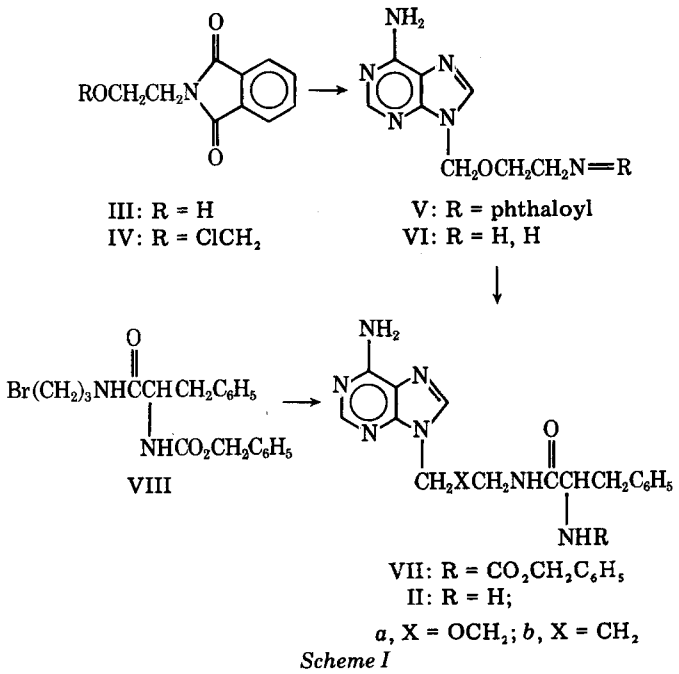

*Scheme I*

IIb but containing a 2′-hydroxyl group were reported to have powerful (10) or moderate (11, 12) puromycin-like activity. Evidence on the importance of a 2′-hydroxyl group for puromycin-like activity is conflicting (13–16).

The present paper reports the synthesis of two acyclic analogs of puromycin that lack the 5′- and 2′-hydroxyl groups. These compounds were tested for inhibition of an *in vitro* protein-synthesizing system and for antiviral and antibacterial activity.

## RESULTS AND DISCUSSION

The acyclic puromycin analogs IIa and IIb were synthesized as outlined in Scheme I. Chloromethylation (17) of III gave IV, which was reacted with adenine to give V. Identity of the product as a 9-substituted adenine was indicated from the UV spectrum (18). Cleavage of the phthaloyl group gave VI, which was coupled with DL-*N*-carbobenzoxyphenylalanine using the mixed anhydride method (19) to give VIIa. Hydrogenolysis of VIIa gave the acyclic puromycin analog IIa. For preparation of IIb, adenine was alkylated with VIII, followed by cleavage of the carbobenzoxy moiety with hydrogen bromide in acetic acid.

Both IIa and IIb were tested against an *Escherichia coli*-$f_2$-RNA protein-synthesizing system and were inactive at $10^{-4}$ *M*. Under the same conditions, puromycin showed 50% inhibition at $10^{-6}$ *M*. The lack of puromycin-like activity in IIa or IIb further substantiates the earlier conclusion that a conformationally rigid system, such as that provided by a cyclopentane ring, is necessary for puromycin-like activity (4, 11, 20).

All six of the 9-substituted adenines, V, VI, VIIa, VIIb, IIa, and IIb, were tested by means of plaque inhibition tests against three DNA viruses (vaccinia virus, adenovirus type 5, and herpes simplex virus type 1) and six RNA viruses (influenza NWS, measles, Bunyamwera, Semliki Forest, rhino 1B, and corona) (1, 21, 22). Compounds IIb, VIIa, and VIIb showed weak activity at 50 μg/disk against one DNA virus, herpes simplex type 1, although none were sufficiently active to warrant secondary testing. None of the compounds was active at 50 μg/disk against the RNA viruses.

The six adenines were also tested for *in vitro* antibacterial activity (23) against *Streptococcus pyrogenes* (CN10), *Streptococcus faecalis* (CN478), *Staphylococcus aureus* (CN491), *E. coli* (CN314), *Salmonella typhosa* (CN512), *Shigella dysenteriae* (CN1513), *Klebsiella pneumoniae* (CN3632), *Enterobacter aerogenes* (2200/86), *Enterobacter cloacae* (2200/87), *Citrobacter freundii* (2200/77), *Proteus vulgaris* (CN329), *Proteus mirabilis* (S2409), *Pseudomonas aeruginosa* (CN200), and *Candida albicans* (CN1863). None of the compounds was inhibitory at 100 μg/ml.

## EXPERIMENTAL

***N*-[(2-Chloromethoxy)ethyl]phthalimide (IV)**—A stirred dispersion of 19.12 g (0.10 mole) of III and 3.00 g (0.10 mole) of paraformaldehyde in 250 ml of ethylene dichloride was saturated with dry hydrogen chloride at −10°. After 4 hr, the solution was dried with calcium chloride, filtered, and spin-evaporated *in vacuo* to afford a white solid (21.94 g, 91%), mp 69–72°. Recrystallization from ether gave the analytical sample, mp 69–70°; NMR ($CDCl_3$): δ 7.80 (m, 4H, aromatic H), 5.45 (s, 2H, $ClCH_2O$), and 3.95 (s, 4H, $CH_2CH_2$).

*Anal.*—Calc. for $C_{11}H_{10}ClNO_3$: C, 55.1; H, 4.21; N, 5.85. Found: C, 55.9; H, 4.34; N, 5.84.

**9-[(2-Phthalimidoethoxy)methyl]adenine (V)**—This compound was prepared from adenine and IV as described for VIIb on a 100-mmole scale, except that the reaction solution was poured over 2 liters of ice water; the product was collected by filtration to yield 20.0 g (59%), mp 252–256°. A portion was recrystallized twice from 2-methoxyethanol and once from dimethylformamide to give the analytical sample, mp 256–258°; UV: $\lambda_{max}^{0.1\ N\ HCl}$ 258 nm (ε 10,800); UV: $\lambda_{max}^{0.1\ N\ NaOH}$ 259 nm (ε 15,000); NMR (trifluoroacetic acid): δ 9.20 (s, 1H, purine H), 8.70 (s, 1H, purine H), 7.98 (s, 4H, aromatic H), 6.03 (s, 2H, $NCH_2O$), and 4.17 (s, 4H, $CH_2CH_2$).

*Anal.*—Calc. for $C_{16}H_{14}N_6O_3$: C, 56.8; H, 4.17; N, 24.8. Found: C, 56.8; H, 4.28; N, 24.7.

**9-[(2-Aminoethoxy)methyl]adenine (VI)**—A mixture of 3.38 g (10 mmoles) of V, 1.0 ml (20 mmoles) of hydrazine hydrate, 250 ml of ethanol, and 75 ml of 2-methoxyethanol was refluxed with stirring for 4 hr. The cooled reaction mixture was spin-evaporated *in vacuo*. The residual solid was dispersed in 100 ml of 1 *N* HCl, stirred at ambient temperature for 0.5 hr, and then left overnight at 0°. The mixture was filtered and thoroughly washed with water. The combined filtrates were spin-evaporated *in vacuo* to give a residue, which was dissolved in 100 ml of water and stirred with ion-exchange resin[3] until a negative silver nitrate test was obtained. The mixture was filtered and spin-evaporated *in vacuo* to give a white powder (1.25g, 60%), mp 168–170°. Recrystallization from 2-propanol gave analytically pure material (0.80 g, 38%), mp 170–171°; UV: $\lambda_{max}^{0.1\ N\ HCl}$ 256 nm (ε 13,900); UV: $\lambda_{max}^{0.1\ N\ NaOH}$ 259 nm (ε 14,100); NMR (dimethyl sulfoxide-$d_6$): δ 8.31 (s, 1H, purine H), 8.22 (s, 1H, purine H), 7.34 (broad s, 2H, purine $NH_2$), 5.60 (s, 2H, $NCH_2O$), 3.48 (t, 2H, $OCH_2CH_2$), 2.64 (t, 2H, $CH_2CH_2N$), and 1.60 (broad s, 2H, aliphatic $NH_2$).

*Anal.*—Calc. for $C_8H_{12}N_6O$: C, 46.1; H, 5.81; N, 40.4. Found: C, 46.3; H, 5.86; N, 40.2.

**9 - [(2 - *N* - Carbobenzoxyphenylalanylamidoethoxy)methyl]-adenine (VIIa)**—To a stirred, ice bath cooled solution of 7.78 g (26.0 mmoles) of DL-*N*-carbobenzoxyphenylalanine and 2.62 g (26.0 mmoles) of triethylamine in 100 ml of tetrahydrofuran was added 2.70 g (25.0 mmoles) of ethyl chloroformate. A precipitate formed within a few minutes; after 1 hr, 2.70 g (13.0 mmoles) of VI was added. After 2 hr at ambient temperature, 20 ml of water was added and the reaction was spin-evaporated *in vacuo*. The residue was dissolved in 250 ml of chloroform and washed with four 50-ml portions of water, four 50-ml portions of 5% aqueous sodium bicarbonate, 50 ml of water, and 50 ml of brine. Then it was dried and spin-evaporated *in vacuo*.

The product was slurried in 2-propanol and collected (5.25 g, 82%), mp 207–208°. The analytical sample was recrystallized from 2-propanol, mp 208–210°; UV: $\lambda_{max}^{0.N\ HCl}$ 257 nm (ε 14,000); UV: $\lambda_{max}^{0.1\ N\ NaOH}$ 259 nm (ε 14,600); NMR (dimethyl sulfoxide-$d_6$): δ 8.26 (s, 1H, purine H), 8.17 (s, 1H, purine H), 8.10 (t, 1H, $CH_2NH$), 7.45 (d, 1H, CHNH), 7.28 and 7.23 (s, 12H, aromatic H, $NH_2$), 5.53 (s, 2H, $NCH_2O$), 4.93 (s, 2H, $OCH_2C_6H_5$), 4.19 (m, 1H, CH), 3.47 (m, 2H, $OCH_2CH_2$), 3.22 (m, 2H, $CH_2CH_2NH$), and 2.90 and 2.70 (m, 2H, $CHCH_2C_6H_5$).

*Anal.*—Calc. for $C_{25}H_{27}N_7O_4$: C, 61.3; H, 5.56; N, 20.0. Found: C, 61.5; H, 5.62; N, 20.0.

**9- [(2-Phenylalanylamidoethoxy)methyl]adenine Fumarate (IIa)**—A mixture of 0.98 g (2.0 mmoles) of VIIa dissolved in 50 ml of acetic acid and 0.30 g of 10% palladium-on-carbon was shaken in the presence of hydrogen at 2–3 atm for 3 hr. The mixture was filtered and spin-evaporated *in vacuo*. The residual oil was combined with 0.232 g (2.0 mmoles) of fumaric acid in 10 ml of ethanol, warmed to effect solution, and allowed to cool (0.660 g, 93%), mp 188–189° (effervescent). The analytical sample was recrystallized from ethanol, mp 190–191° (effer-

[3] Melting points were taken in capillary tubes on a Mel-Temp block and are uncorrected. NMR data were recorded on Varian XL-100-15-FT and T-60 spectrometers with tetramethylsilane as an internal standard. UV spectra were obtained on a Unicam SP 800 spectrophotometer. Each analytical sample had spectral data compatible with its assigned structure and moved as a single spot on TLC.

vescent); UV: $\lambda_{max}^{0.1N\ HCl}$ 257 nm ($\epsilon$ 12,000); UV: $\lambda_{max}^{0.1\ N\ NaOH}$ 259 nm ($\epsilon$ 12,200); NMR (dimethyl sulfoxide-$d_6$): $\delta$ 8.26 (s, 1H, purine H), 8.17 (s, 1H, purine H), 8.11 (t, 1H, $CH_2NH$), 7.29 (s, 2H, purine $NH_2$), 7.21 (s, 5H, aromatic H), 6.51 (s, 1H, fumarate CH), 5.52 (s, 2H, $NCH_2O$), ~5.5 (broad s, $CHNH_2$, fumarate OH), 3.54 (m, 1H, CH), 3.44 (m, 2H, $OCH_2CH_2$), 3.19 (m, 2H, $CH_2NH$), and 2.91 and 2.71 (m, 2H, $CH_2C_6H_5$).

*Anal.*—Calc. for $C_{17}H_{21}N_7O_2 \cdot 0.5\ C_4H_4O_4$: C, 55.2; H, 5.61; N, 23.7. Found: C, 54.9; H, 5.73; N, 23.5.

**3 - *N* - Carbobenzoxyphenylalanylamidopropyl Bromide (VIII)**—To a stirred, ice–salt bath cooled solution of 29.93 g (0.10 mol) of DL-*N*-carbobenzoxyphenylalanine and 10.12 g (0.10 mole) of triethylamine in 325 ml of chloroform was added 10.85 g (0.10 mole) of ethyl chloroformate in 20 ml of chloroform. After 0.25 hr, a solution of 21.89 g (0.10 mole) of 3-bromopropylamine hydrobromide in 70 ml of water was added, followed by 25 ml of 4 *N* NaOH with vigorous stirring. After 96 hr at ambient temperature, the two layers were separated. The chloroform layer was washed with two 50-ml portions of 0.1 *N* HCl, two 50-ml portions of water, and once with brine. It then was dried and spin-evaporated *in vacuo*. The residual solid was slurried with hexane and collected (22.25 g, 53%), mp 123–125°. A portion was recrystallized from ethyl acetate–hexane to give the analytical sample, mp 125–126° (resolidified and remelted 129–130°).

*Anal.*—Calc. for $C_{20}H_{23}BrN_2O_3$: C, 57.3; H, 5.53; N, 6.68. Found: C, 57.3; H, 5.46; N, 6.60.

**9-(3-*N*-Carbobenzoxyphenylalanylamidopropyl)adenine Hydrochloride (VII*b*)**—To a stirred, ice bath cooled dispersion of 1.81 g (45.2 mmoles) of sodium hydride (60.2% dispersion in mineral oil) in 70 ml of dimethylformamide was added 6.08 g (45.0 mmoles) of adenine. After 10 min, the cold bath was removed and the mixture was stirred at ambient temperature for 1 hr, when salt formation was complete. A solution of 19.08 g (45.5 mmoles) of VIII in 100 ml of dimethylformamide was added; after 42 hr at ambient temperature, the reaction was filtered and spin-evaporated *in vacuo*. The residue was partitioned between 600 ml of 5% methanol in chloroform and 50 ml of water, and the layers were separated.

The organic phase was washed with two 100-ml portions of water and once with brine. It then was dried and spin evaporated *in vacuo*. The residue was dissolved in ethanol and diluted with hydrogen chloride-saturated ethanol to give a crystalline product (14.20 g, 62%), mp 195–197°. The analytical sample was obtained from ethanol, mp 196–197°; UV $\lambda_{max}^{0.1\ N\ HCl}$ 262 nm ($\epsilon$ 12,200); UV: $\lambda_{max}^{0.1\ N\ NaOH}$ 262 nm ($\epsilon$ 12,200); NMR (dimethylsulfoxide-$d_6$): $\delta$ 8.45 (s, 2H, purine H), 8.20 (t, 1H, $CH_2NH$), 7.57 (d, 1H, $CHNH$), 7.26 (s, 10H, aromatic H), 4.95 (s, 2H, $OCH_2C_6H_5$), ~4.2 (m, 5H, $NH_2$, purine $CH_2$, CH), 3.0–2.8 (m, 4H, $CH_2NH$, $CHCH_2C_6H_5$), and 1.92 (m, 2H, $CH_2CH_2CH_2$).

*Anal.*—Calc. for $C_{25}H_{28}ClN_7O_3$: C, 58.8; H, 5.53; N, 19.2. Found: C, 59.2; H, 5.61; N, 19.1.

**9-(3-Phenylalanylamidopropyl)adenine (II*b*)**—To a stirred solution of 8.16 g (16.0 mmoles) of VII*b* in 100 ml of acetic acid was added 30 ml of 30–32% hydrogen bromide in acetic acid. After 18 hr, the reaction mixture was diluted with 500 ml of ether, the solvent was decanted, and the solids were washed with ether. The crude hydrobromide was dissolved in water and passed through a column containing an excess of ion-exchange resin[3]. The eluates were spin-evaporated *in vacuo* to give a syrup, which crystallized under ether and was recrystallized from 2-propanol (2.57 g, 47%), mp 143–145°. The analytical sample had a melting point of 145–146°; UV: $\lambda_{max}^{0.1\ N\ HCl\ +\ 10\%\ C_2H_5OH}$ 259 nm ($\epsilon$ 13,700); UV: $\lambda_{max}^{0.1\ N\ NaOH\ +\ 10\%\ C_2H_5OH}$ 261 nm ($\epsilon$ 13,700); NMR (dimethyl sulfoxide-$d_6$): $\delta$ 8.13 (s, 1H, purine H), 8.10 (s, 1H, purine H), 7.96 (t, 1H, $CH_2NH$), 7.22 (s, 7H, aromatic H and purine $NH_2$), 4.04 (t, 2H, purine $CH_2$), 3.39 (q, 1H, CH), 3.03 (q, 2H, $CH_2NH$), 2.92 and 2.65 (m, 2H, $CH_2C_6H_5$), 1.88 (m, 2H, $CH_2CH_2CH_2$), and 1.65 (s, 2H, $CHNH_2$).

*Anal.*—Calc. for $C_{17}H_{21}N_7O$: C, 60.2; H, 6.24; N, 28.9. Found: C, 60.0; H, 6.23; N, 28.8.

**Inhibition of Protein Synthesis Assay**—For measurement of protein synthesis, extracts were prepared from cells of *E. coli* D10 by the method of Nirenberg (24) as modified by Godson and Sinsheimer (25). RNA was prepared from bacteriophage-$f_2$ as described previously (26). Reaction mixtures (0.1 ml) were prepared as described (24) with [4,5-$^3$H]-L-leucine[4] as the radioactive amino acid. Compounds to be tested were added as neutral solutions. The reaction was started by addition of 10 $\mu$g of $f_2$-RNA. After incubation at 37° for 10 min, the reaction was stopped by the addition of sodium hydroxide to a final concentration of 0.1 *M*. After a further 15 min at 37°, 10 volumes of 10% trichloroacetic acid were added; then the mixture was heated at 85° for 20 min and cooled. The precipitates were collected on filters[5] and washed with 5% trichloroacetic acid, and the precipitated radioactivity was counted as described previously (27). In each trial, puromycin[6] was tested as a standard inhibitor and gave 50% inhibition at ~$10^{-6}$ *M*.

# Phenobarbital Solubility in Propylene Glycol–Glycerol–Water Systems

**MAMDOUH A. MOUSTAFA, ABDULLA M. MOLOKHIA ˣ, and M. WAFIK GOUDA**

Received January 5, 1981, from the *Department of Pharmaceutics, College of Pharmacy, University of Riyadh, Riyadh, Saudi Arabia.* Accepted for publication March 20, 1981.

**Abstract** □ Phenobarbital solubility in various binary and ternary propylene glycol–glycerol–water solvent systems was determined. Phenobarbital concentrations several times those of the ethanol-containing USP and BPC elixirs were obtained. From log solubility–solvent composition plots, a general equation was developed for phenobarbital solubility prediction in propylene glycol–water, glycerol–water, and propylene glycol–glycerol–water solvent systems. Solubility predictions using another equation, based on linear log solubility–dielectric constant relationships, were limited by the need to use different constants for different solvent blends. Heats of solution for phenobarbital determined in selected solvent blends as well as in USP and BPC elixirs varied within a very narrow range, suggesting similar solute–solvent interactions.

**Keyphases** □ Phenobarbital—solubility in various binary and ternary solvent systems □ Solubility—phenobarbital in binary and ternary solvent systems □ Solvent systems—various binary and ternary, phenobarbital solubility

Ethanol-free liquid preparations of phenobarbital and other drugs are needed for the treatment of alcoholic patients, children, the elderly, and peptic ulcer patients. Furthermore, ethanol is not a pharmacologically inert solvent, and its interactions with various drugs are well known (1). Ethanol is used in many prescription and nonprescription liquid preparations in proportions up to 90% (2, 3). It is used in drug products as a solvent, preservative, and stabilizer and for its pharmacological effects. Other compounds may be used in place of ethanol except when it is used as a solvent.

Various formulas were suggested as alternatives to official formulas for phenobarbital elixir (4–9). Most formulas, however, contained ethanol in proportions varying from 15 to 40%. Some solubilized systems of phenobarbital also were prepared and tested for stability and *in vitro* availability (10, 11). In the present study, phenobarbital solubility was determined in binary and ternary propylene glycol–glycerol–water systems, and solubility data were correlated to physicochemical properties of solvents and the solute. This study should provide a model for the development of ethanol-free pharmaceutical solutions of drugs that currently include ethanol in their formulations.

## EXPERIMENTAL

**Materials**—Phenobarbital[1], propylene glycol[2], and glycerin[2] were used as supplied.

**Solubility Studies**—Excess quantities of phenobarbital were placed in 50-ml glass-stoppered flasks with 30 ml of the solvent system. The flasks were shaken in a thermostatically controlled water bath[3] until saturation. Four different temperatures were used; the temperature control was better than ±0.2°. Samples of the saturated solutions were pipeted, filtered through a 0.8-μm membrane filter[4], suitably diluted with the same solvent, and assayed for phenobarbital. In all solvent systems, 0.01 *N* HCl was used instead of water to suppress phenobarbital ionization.

**Assay**—Phenobarbital was assayed spectrophotometrically[5] according to a previously described method (12). A calibration curve was established for phenobarbital in every solvent blend.

## RESULTS AND DISCUSSION

Equilibrium solubility data of phenobarbital in aqueous solvent blends containing different proportions of glycerol and/or propylene glycol are shown in Fig. 1. Phenobarbital concentrations up to 45 mg/ml (~10 times the concentration of USP or BPC elixirs) were obtained. The contribution of propylene glycol to the increase in phenobarbital solubility was greater than that of glycerol. Log solubility–solvent composition plots for both propylene glycol–water and glycerol–water systems (Fig. 2) were straight lines. Literature data (13) indicate that, in a propylene glycol–water system, the logarithm of the solubility of some drugs is linearly related to the fraction of propylene glycol present by:

$$\log S_t = \log S_0 + \alpha f \qquad \text{(Eq. 1)}$$

where $S_t$ is the drug solubility in the solvent mixture, $f$ is the volume fraction of propylene glycol, $S_0$ is the drug solubility in water, and $\alpha$ is a constant characteristic of the system under study.

Results in Fig. 2 show that Eq. 1 applies to the solubility of phenobarbital in glycerol–water and propylene glycol–water. Values for the constants ($\alpha$) for propylene glycol and glycerol as calculated from the

slopes of the lines (Fig. 2) were 19.88 and $10.88 \times 10^{-3}$, respectively. In an attempt to extend the approach to the solubility of phenobarbital in propylene glycol–glycerol–water, the following equation was developed:

$$\log S_t = \log S_0 + \alpha_1 f_1 + \alpha_2 f_2 + \beta f_1^2 f_2 \qquad \text{(Eq. 2)}$$

where $\alpha_1$ and $\alpha_2$ are the constants for propylene glycol and glycerol, respectively, and $f_1$ and $f_2$ are the volume fractions of both solvents. The term $\beta f_1^2 f_2$ was determined from the fitting of some experimental solubility data to Eq. 2. It accounts for the increase in solubility due to solvent

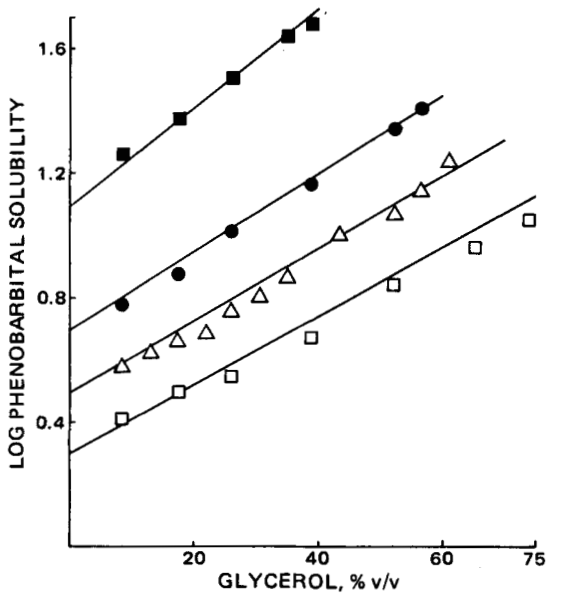

**Figure 3**—*Agreement of experimental solubility of phenobarbital in propylene glycol–glycerol–water (PG–G–W) ternary systems with values predicted from Eq. 2. Key: —, theoretical; □, 10% PG; △, 20% PG; ●, 30% PG; and ■, 50% PG.*

interactions. When $f_1$ and $f_2$ are equal to zero, Eq. 2 reduces to:

$$\log S_t = \log S_0 \qquad \text{(Eq. 3)}$$

which is the logarithm of phenobarbital solubility in 0.01 $N$ HCl.

When $f_1$ is variable and $f_2 = 0$, Eq. 2 is reduced to:

$$\log S_t = \log S_0 + \alpha_1 f_1 \qquad \text{(Eq. 4)}$$

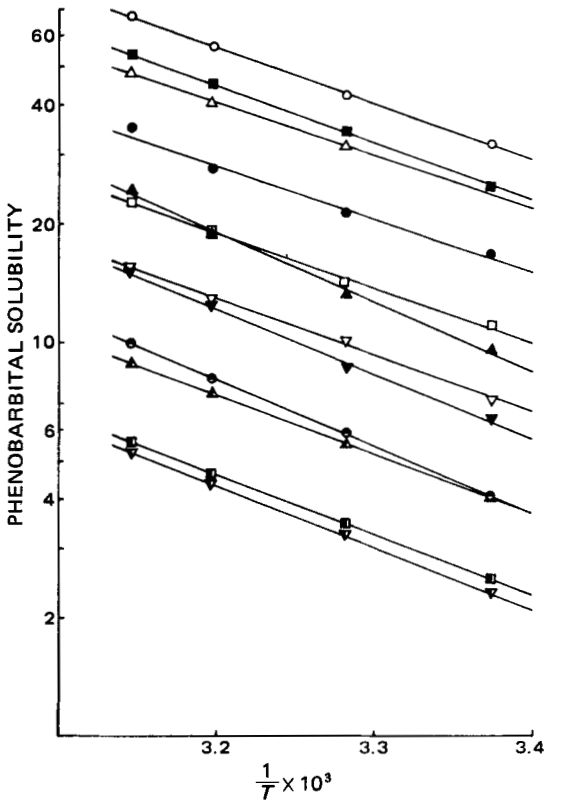

**Figure 5**—*Effect of temperature on phenobarbital solubility (propylene glycol, PG; glycerol, G; and water, W). Key: ○, BPC elixir; ■, 50% polyethylene glycol 400–50% W; △, 50% PG–26% G–24% W; ●, 30% PG–52% G–18% W; □, 30% PG–39% G–31% W; ▲, 50% PG–50% W; ▽, 30% PG–26% G–44% W; ▼, USP elixir; ◓, 30% PG–9% G–61% W; ◭, 20% PG–26% G–54% W; ◧, 10% PG–26% G–64% W; and ▼, 44% G–56% W.*

which describes the solubility of phenobarbital in propylene glycol–water.

When $f_1 = 0$ and $f_2$ is variable, Eq. 2 reduces to:

$$\log S_t = \log S_0 + \alpha_2 f_2 \qquad \text{(Eq. 5)}$$

which describes the solubility of phenobarbital in glycerol–water binary systems. Figure 3 shows the fitting of theoretical lines calculated on the basis of Eq. 2 to experimental points determined in the present study. The good fit suggests the possible use of such an equation for solubility predictions in ternary propylene glycol–glycerol–water systems.

Gorman and Hall (14) reported a linear relationship between the logarithm of secobarbital solubility and the dielectric constant of the binary solvent systems which have similar bonding characteristics: ethanol–water, glycerol–water, and propylene glycol–water. In the present investigation, the log solubility–dielectric constant (calculated) relationship for phenobarbital in propylene glycol–water and glycerol–water was also linear (Fig. 4). When this approach was extended to phenobarbital solubility in propylene glycol–glycerol–water, an essentially linear relationship was observed (Fig. 4). However, this linearity does not seem to extend to solvent systems containing high proportions of water since the line does not intersect with the other two lines at 100% water solvent composition. This result does not allow for solubility predictions over a wide range of solvent compositions as is possible when Eq. 2 is utilized.

The effect of temperature on phenobarbital solubility in 12 selected solvent systems was studied. Equilibrium solubilities were determined at 23, 32, 40, and 45 ± 0.2°, and the log solubility–$1/T$ relationships were plotted (Fig. 5). The heats of solution calculated from Fig. 5 varied in the relatively narrow range of 6–8 kcal/mole for the different solvent systems. The relatively nonpolar phenobarbital molecule is believed to dissolve in the relatively polar solvent blends through hydrogen bonding of the electronegative oxygen of the phenobarbital carbonyl groups to the hydrogen of hydroxyl groups in water, glycerol, or propylene glycol. The close values of heats of solution suggest similar types of solution mechanism and bonding.

Results of the present investigation showed that phenobarbital solubility can be effected through the use of mixed ethanol-free solvents to produce concentrations well above those required to formulate a phenobarbital elixir. The correlation of solubility data to specific solvent contributions enabled solubility predictions from a knowledge of solvent composition. Evaluation of the stability and bioavailability of phenobarbital in these solvent systems will be reported later.

## Single-Point Maintenance Dose Prediction: Role of Interindividual Differences in Clearance and Volume of Distribution in Choice of Sampling Time

**Keyphrases** ☐ Pharmacokinetics—single-point maintenance dose prediction, theoretical analysis ☐ Single-point maintenance dose prediction—pharmacokinetics, theoretical analysis

*To the Editor:*

Experimental observations of very strong correlations between a single determination of concentration after the first dose of a drug and the eventual steady-state concentration have been observed experimentally for lithium, nortriptyline, imipramine, and desipramine (1–5). Such a relationship also exists for drugs with short half-lives based on simulations and clinical studies of chloramphenicol and theophylline (6–8).

If a single determination of concentration after the first dose of drug correlates with the eventual steady-state concentration, then, over the linear range, this correlation provides the basis for the prediction of maintenance dose necessary to achieve a desired steady-state concentration. In an attempt to clarify this very powerful method of maintenance dose prediction, a theoretical analysis of the relationship was carried out to determine the: (*a*) source

## Single-Point Maintenance Dose Prediction: Role of Interindividual Differences in Clearance and Volume of Distribution in Choice of Sampling Time

**Keyphrases** ☐ Pharmacokinetics—single-point maintenance dose prediction, theoretical analysis ☐ Single-point maintenance dose prediction—pharmacokinetics, theoretical analysis

*To the Editor:*

Experimental observations of very strong correlations between a single determination of concentration after the first dose of a drug and the eventual steady-state concentration have been observed experimentally for lithium, nortriptyline, imipramine, and desipramine (1–5). Such a relationship also exists for drugs with short half-lives based on simulations and clinical studies of chloramphenicol and theophylline (6–8).

If a single determination of concentration after the first dose of drug correlates with the eventual steady-state concentration, then, over the linear range, this correlation provides the basis for the prediction of maintenance dose necessary to achieve a desired steady-state concentration. In an attempt to clarify this very powerful method of maintenance dose prediction, a theoretical analysis of the relationship was carried out to determine the: (*a*) source

*0022-3549/81/1000-1174$01.00/0*

*© 1981, American Pharmaceutical Association*

and magnitude of the error involved with the estimate, (*b*) general applicability of the method to other drugs, and (*c*) limits of the method's application (9). It was observed that the method yielded a good estimate of clearance in an individual which did not seem to be affected by interindividual variation in the volume of distribution (10).

The analysis described the inverse relationship between the concentration ($C^*$) observed at some time ($t^*$) after the first dose ($D^*$) and the maintenance dose ($D_m$) required to obtain a desired steady-state drug concentration ($\overline{C}_{ss}$):

$$1/D_m = \Psi C^* \qquad \text{(Eq. 1)}$$

where:

$$\Psi = \frac{e^{Kt^*}}{\overline{C}_{ss} K \tau D^*} \qquad \text{(Eq. 2)}$$

where $K$ is the elimination rate constant of the drug in an individual patient and $\tau$ is the dosing interval. It was previously noted (9) that $\Psi$ (the proportionality factor in Eq. 1 as defined by Eq. 2) would vary among individuals but in such a manner that, at a certain $t^*$, the variability would not allow estimates of $D_m$ that would yield $\overline{C}_{ss}$ values within 10–20% of the target value.

The purpose of this communication is to extend this analysis into areas not completely dealt with previously:

1. Since $K$ is a function of clearance ($Cl$) and volume of distribution ($V$), how does $\Psi$ vary as a function of interindividual variability in these independent parameters?
2. Why is $\Psi$ relatively constant throughout a population?
3. What factors determine the optimum value of $t^*$?

To answer these questions, it is first necessary to recast $\Psi$ as a function of clearance and volume of distribution through the relationship:

$$K = Cl/V \qquad \text{(Eq. 3)}$$

Therefore:

$$\Psi = \frac{V e^{(Cl/V)t^*}}{Cl \overline{C}_{ss} \tau D^*} \qquad \text{(Eq. 4)}$$

The portion of $\Psi$ that varies among the population is $(V/Cl)e^{(Cl/V)t^*}$. Ideally, $\Psi$ would not vary from one individual to another, but since $Cl$ and $V$ vary throughout the population, $\Psi$ will vary among individuals. However, $\Psi$ is minimally affected by interindividual differences in $Cl$ and $V$ when its partial first derivatives with respect to these independent variables are simultaneously close to zero. The partial first derivatives are equal to zero when:

$$(Cl/V)t^* = 1 \qquad \text{(Eq. 5)}$$

or:

$$t^* = V/Cl = 1/K \qquad \text{(Eq. 6)}$$

Thus, $\Psi$ is insensitive to interindividual differences in $Cl$ and $V$ when $(Cl/V)t^*$ is in the neighborhood of 1.

It is important to remember that $\Psi$ does not vary simply as a function of $Cl$ or $V$ among individuals but actually varies as a function of their ratio, $K$. Therefore, it is appropriate to consider the intersubject variability of $\Psi$ as a function of $K$ and to consider the influence of interindividual variability in $K$ on the value of $\Psi$ as defined by Eq. 2.

Since $K$ varies among individuals, the true value of $\Psi$ also varies throughout the popultion. However, under certain conditions, $\Psi$ varies much less than $K$. The variability in $K$ causes minimum fluctuations in $\Psi$ if $K$ and $e^{Kt^*}$ vary in proportion to one another (Eq. 2). When the exponent ($x$) of $e^x$ is in the neighborhood of 1, the value of $e^x$ varies in rough proportion to $x$. As seen in Table I, a fourfold variation in $x$ centered around 1 produces less than a 15% variation in the function $e^x/x$ about its mean value.

**Table I—Effect of Varying the Value of $x$ about 1 on the Value of the Function $e^x/x$**

| $x$ | $e^x$ | $e^x/x$ | Ratio[a] |
|---|---|---|---|
| 0.50 | 1.65 | 3.30 | 1.01 |
| 1.25 | 2.79 | 2.79 | 0.86 |
| 2.00 | 7.39 | 3.69 | 1.13 |
| Mean | | 3.26 | |

[a] Ratio of $e^x/x$ for each value of $x$ to the mean value.

Equation 2 is of the form $e^x/(x/t^*)$ where $x = (Cl/V)t^* = Kt^*$. When the value of $t^*$ in Eq. 6 is substituted into Eq. 2, the value of the exponent is 1. When $x$ increases, $e^x$ increases in rough proportion, and the value of the ratio in Eq. 2 does not change greatly. Therefore, $\Psi$ does not vary greatly with $K$ as long as $Kt^*$ remains in the neighborhood of 1.

In addition, from the steps leading to Eq. 6, it is seen that the value of $\Psi$ is insensitive to interindividual changes in $Cl$ and $V$ when $(Cl/V)t^*$ (*i.e.*, $Kt^*$) is in the neighborhood of 1. Since $t^*$ is chosen and fixed in the single-point method of maintenance dose prediction and since $K$ varies among individuals, changes in $Cl$ and $V$ increasingly affect $\Psi$ as $Kt^*$ moves away from 1. If the influence of interindividual differences in $Cl$ and $V$ are to be kept at a minimum for the majority of the population and if the mathematical properties of Eq. 2 are to be taken advantage of, $t^*$ should be chosen as the mean (or mode) value of $1/K$.

When $t^*$ is chosen in this manner, $\Psi$ varies minimally with changes in $K$ and the method gives estimates of maintenance doses based on a population average value of $\Psi$ that are minimally affected by interindividual variability in $Cl$ and $V$. These considerations can be extended to any one-compartment drug for which a clinically acceptable value of $t^*$ (perhaps not >24 hr) can be chosen such that $Kt^*$ can be kept in the neighborhood of 1 throughout the population. This approach is presently being extended to multicompartment drugs and the prediction of steady-state concentrations of metabolites of therapeutic interest.

# Correlation of Water Solubility with Octanol–Water Partition Coefficient

**Keyphrases** □ Solubility—water, correlation with octanol–water partition coefficient □ Partition coefficient—octanol–water, correlation with water solubility □ Melting-point effect—correlation between water solubility and octanol–water partition coefficient

*To the Editor:*

Yalkowsky and Valvani (1) made a valuable analysis of the melting-point effect on the solubility of solid compounds and discussed the correlation between water solubility ($S$) and the octanol–water partition coefficient ($P$). Regression equations between log $S$ and log $P$ were constructed using log $P$ values calculated primarily from molecular fragment constants developed by Nys and Rekker (2).

We have found several points relevant to the Yalkowsky–Valvani analysis (1). First, part of their conclusions for a particular class of compounds was based on a linear regression between the values of log $S_{obs}$ and log $P_{estim}$ obtained from the correlation equation for that class of compounds. Regression of this kind must, in principle, yield log $S_{obs}$ = 1.0 log $S_{estim}$ with an intercept equal to 0.0. The correlation coefficient will then be a measure of how well log $S_{obs}$ fits log $S_{estim}$. For reasons unspecified, this condition was not met in their Eqs. 32–36.

Second, the calculated values of log $P$ for some low solubility compounds are highly imprecise. For instance, the values of log $P$, 5.05, 5.79, and 6.53, estimated for 1,2,3,5-tetra-, penta-, and hexachlorobenzene, respectively, in their Table VI, are considerably greater than the corresponding experimental values of 4.46 (3), 4.94 (3), and 5.50 (4). It is surprising that the molar solubilities (log $S$) predicted from these calculated log $P$ values and the solute melting points ($MP$) fall into close agreement with the experimental log $S$. If experimental log $P$ values are entered into the correlation derived by Yalkowsky *et al.* (5) for the compounds in Table VI, *i.e.*, log $S = -0.9874 \log P - 0.0095(MP) + 0.7178$, the estimated $S$ values then deviate appreciably from the experimental data.

It is understood that log $P$ values calculated by various fragment approaches are only as accurate as the values used to define each fragment. At this time, the rules to calculate log $P$ values are empirically derived. This approach has led to numerous correction factors for such things as branching, flexibility, chain length, bond unsaturation, and substituent polarity. In general, the fragment approach works reasonably well for simple low molecular weight molecules. It tends to be less accurate for more complex molecules.

Third, Yalkowsky and Valvani assumed that the effect of octanol–water mutual saturation on the partition coefficient was small and thus ignored it in their treatment. Banerjee *et al.* (3) also reported no observable effect of octanol–water mutual saturation. Although this effect is expected to be small for compounds with relatively high solubilities in both octanol and water, it becomes significant for solutes with limited solubilities. Consequently, it would be a factor in the correlation of log $S$ *versus* log $P$ at the low $S$ (high $P$) region.

The significance of octanol–water mutual saturation may be evaluated by comparing experimental $P$ values with those calculated from solute solubilties in octanol and water for some high melting solid compounds. Because of the high melting-point effect, solids have limited solubilities in both solvents and their partition coefficients can be determined directly from the ratios of solute solubilties in the two solvents. Note that at low (mole fraction) concentrations, solute activity coefficients are essentially constant and the log $P$ of a solute would be practically constant at all concentrations.

We selected *p,p'*-dichlorodiphenyltrichloroethane (I)[1], hexachlorobenzene (II)[2], and anthracene (III) for illustration. The experimental and estimated octanol–water partition coefficients and the determined solubilities in water, octanol, and water-saturated octanol for these compounds are given in Table I. If it is assumed that mutual saturation has no effect on solute partitioning, the partition coefficients should be equal to the ratios of solute solubilties in pure octanol and water ($S_o/S_w$); *i.e.*, log $P$ = 6.88 for I, 5.85 for II, and 4.73 for III. These calculated $P$ values are larger than the experimental values by factors of 3.3, 2.2, and 1.9 for I, II, and III, respectively. The difference between experimental and calculated $P$ values results presumably from an alteration of the solute solubilities in the two solvents due to their mutual saturation.

**Table I—Solubilities and Octanol–Water Partition Coefficients of I, II, and III**

| Compound | Melting Point | $S_w$ (μg/liter)[a] | $S_o$ (g/liter) | $S_{o/w}$ (g/liter) | log $S_o/S_w$ | log $P_{exp}$ | log $P_{est}$[b] |

Water (2.3 $M$) dissolved in octanol (6) reduces solute solubility in octanol, while octanol ($4.5 \times 10^{-3}$ $M$) in water (9) enhances solute solubility in water. To support this point, the solubilities of these three compounds in water-saturated octanol are shown to be reduced by ~10–30% because of water saturation. These results suggest that octanol in water promotes water solubility by ~75% for III, 70% for II, and 150% for I.

Based on these findings, the use of experimental partition coefficients probably would improve the reliability of the log $S$–log $P$ correlation at the high $P$ region.

## Correlation of Water Solubility with Octanol–Water Partition Coefficient: A Response

**Keyphrases** □ Solubility—water, correlation with octanol–water partition coefficient, response □ Partition coefficient—octanol–water, correlation with water solubility, response □ Melting-point effect—correlation between water solubility and octanol–water partition coefficient, response

*To the Editor:*

The preceding paper (1) raised three concerns about our recent paper (2) which we shall now attempt to alleviate.

The first concern of Chiou *et al.* (1) is that Eqs. 32–36 of Ref. 2 do not have slopes of unity and intercepts of zero. The reason for this apparent discrepancy was mentioned briefly in the paragraph preceding Eq. 37 of Ref. 2 but will be discussed more completely here.

**Table I—Aqueous Molar Solubility ($S_w$) and Octanol–Water Partition Coefficients ($PC$) of Tetra-, Penta-, and Hexachlorobenzenes**

| Compound | Melting point | Experimental log $PC$ | log $S_w$ Observed[a] | log $S_w$ Predicted by Eq. 2 |
|---|---|---|---|---|
| 1,2,3,5-Tetrachlorobenzene | 54° | 4.46[b] | −4.79 | −4.46 |
| Pentachlorobenzene | 86° | 4.94[b] | −5.65 | −5.35 |
| Hexachlorobenzene | 230° | 5.50[c] | −7.76 | −7.67 |

[a] Reference 2. [b] Reference 3. [c] Reference 1.

Equation 30 of Ref. 2 was developed on the basis of the theoretical relationships between solubility, partition coefficient, melting point, and entropy of fusion. Solubility data for five classes of compounds were compared to the predictions based on:

$$\log S_w \cong -\log PC - 0.01MP + 1.05 \qquad \text{(Eq. 1)}$$

Only if this theoretical equation perfectly predicted all of the solubilities would the slope be unity and the intercept zero.

In most cases, the slopes were not significantly different from unity; however, the intercepts tended to be slightly negative rather than zero. This trend shows a systematic overestimation of solubility by a factor of ~3. This finding indicated that while the theoretical equation was not perfect, it did provide a basis for assessing the role of the partition coefficient and the melting point in controlling aqueous solubility.

Each of the five classes of compounds represents a fairly small data set (in most cases covering only a few orders of magnitude in solubility). The slopes and intercepts are thus more subject to errors in the log $S_w$ measurements and/or the log $PC$ estimation than is the whole data set, which covers almost nine orders of magnitude. The empirical equation for rigid molecules (Eq. 39 of Ref. 2) is:

$$\log S_w = -1.05 \log PC - 0.012MP + 0.87 \qquad \text{(Eq. 2)}$$

When Eq. 2 is used to estimate solubilities, it gives a slope and intercept of unity and zero, respectively. This final equation rather than the ones based on the smaller data sets should be used to estimate aqueous solubilities.

Second, Chiou *et al.* (1) point out that log $PC$ calculations tend to be imprecise for low solubility compounds and seem surprised that the calculated values work better for estimating aqueous solubility than their own experimentally determined values. The reason for this situation is again statistical. For the reasons already described, it is best to use Eq. 2 to estimate solubility. When this is done, the experimental log $PC$ values of Chiou *et al.* (1) will yield calculated solubilities that are in excellent agreement with the observed values as shown in Table I.

The regression equations were obtained by correlating aqueous solubility with melting points and calculated values of log $PC$. If experimental log $PC$ values were available, the regression coefficient of log $PC$ as well as the intercept probably would be somewhat altered. Thus, systematic errors in estimating log $PC$ are compensated for by the choice of the coefficient of log $PC$.

Water (2.3 $M$) dissolved in octanol (6) reduces solute solubility in octanol, while octanol ($4.5 \times 10^{-3}$ $M$) in water (9) enhances solute solubility in water. To support this point, the solubilities of these three compounds in water-saturated octanol are shown to be reduced by ~10–30% because of water saturation. These results suggest that octanol in water promotes water solubility by ~75% for III, 70% for II, and 150% for I.

Based on these findings, the use of experimental partition coefficients probably would improve the reliability of the log $S$–log $P$ correlation at the high $P$ region.

## Correlation of Water Solubility with Octanol–Water Partition Coefficient: A Response

**Keyphrases** □ Solubility—water, correlation with octanol–water partition coefficient, response □ Partition coefficient—octanol–water, correlation with water solubility, response □ Melting-point effect—correlation between water solubility and octanol–water partition coefficient, response

*To the Editor:*

The preceding paper (1) raised three concerns about our recent paper (2) which we shall now attempt to alleviate.

The first concern of Chiou *et al.* (1) is that Eqs. 32–36 of Ref. 2 do not have slopes of unity and intercepts of zero. The reason for this apparent discrepancy was mentioned briefly in the paragraph preceding Eq. 37 of Ref. 2 but will be discussed more completely here.

**Table I—Aqueous Molar Solubility ($S_w$) and Octanol–Water Partition Coefficients ($PC$) of Tetra-, Penta-, and Hexachlorobenzenes**

| Compound | Melting point | Experimental log $PC$ | log $S_w$ Observed[a] | log $S_w$ Predicted by Eq. 2 |
|---|---|---|---|---|
| 1,2,3,5-Tetrachlorobenzene | 54° | 4.46[b] | −4.79 | −4.46 |
| Pentachlorobenzene | 86° | 4.94[b] | −5.65 | −5.35 |
| Hexachlorobenzene | 230° | 5.50[c] | −7.76 | −7.67 |

[a] Reference 2. [b] Reference 3. [c] Reference 1.

Equation 30 of Ref. 2 was developed on the basis of the theoretical relationships between solubility, partition coefficient, melting point, and entropy of fusion. Solubility data for five classes of compounds were compared to the predictions based on:

$$\log S_w \cong -\log PC - 0.01MP + 1.05 \qquad \text{(Eq. 1)}$$

Only if this theoretical equation perfectly predicted all of the solubilities would the slope be unity and the intercept zero.

In most cases, the slopes were not significantly different from unity; however, the intercepts tended to be slightly negative rather than zero. This trend shows a systematic overestimation of solubility by a factor of ~3. This finding indicated that while the theoretical equation was not perfect, it did provide a basis for assessing the role of the partition coefficient and the melting point in controlling aqueous solubility.

Each of the five classes of compounds represents a fairly small data set (in most cases covering only a few orders of magnitude in solubility). The slopes and intercepts are thus more subject to errors in the log $S_w$ measurements and/or the log $PC$ estimation than is the whole data set, which covers almost nine orders of magnitude. The empirical equation for rigid molecules (Eq. 39 of Ref. 2) is:

$$\log S_w = -1.05 \log PC - 0.012MP + 0.87 \qquad \text{(Eq. 2)}$$

When Eq. 2 is used to estimate solubilities, it gives a slope and intercept of unity and zero, respectively. This final equation rather than the ones based on the smaller data sets should be used to estimate aqueous solubilities.

Second, Chiou *et al.* (1) point out that log $PC$ calculations tend to be imprecise for low solubility compounds and seem surprised that the calculated values work better for estimating aqueous solubility than their own experimentally determined values. The reason for this situation is again statistical. For the reasons already described, it is best to use Eq. 2 to estimate solubility. When this is done, the experimental log $PC$ values of Chiou *et al.* (1) will yield calculated solubilities that are in excellent agreement with the observed values as shown in Table I.

The regression equations were obtained by correlating aqueous solubility with melting points and calculated values of log $PC$. If experimental log $PC$ values were available, the regression coefficient of log $PC$ as well as the intercept probably would be somewhat altered. Thus, systematic errors in estimating log $PC$ are compensated for by the choice of the coefficient of log $PC$.

The third concern raised by Chiou *et al.* (1) is the lack of a correction for the mutual miscibility of water and octanol. They show three examples that indicate an error as high as 0.3–0.5 in log *PC* for very nonpolar solutes. This magnitude of error is not of particular concern. It is well within the error normally encountered in determining experimental values for both log $S_w$ and log *PC* for hydrophobic compounds and certainly within the limitations of Eq. 2.

The conclusion of Chiou *et al.* (1) is that experimental values for log *PC* should be used to improve the reliability of the log $S_w$ − log *PC* correlation in the high log *PC* region. While this may be true, it is somewhat impractical. The value of Eq. 2 is that it provides a simple means of estimating log $S_w$ from nothing more than a knowledge of the melting point of the solute and a group contribution estimate of its partition coefficient. The measurement of accurate partition coefficients greater than 10,000 (log *PC* > 4) is far more difficult and subject to error than the measurement of log $S_w$.

## REVIEWS

**Controlled Release Technologies: Methods, Theory, and Applications.** Edited by AGIS F. KYDONIEUS. CRC Press, 2000 N.W. 24th St., Boca Raton, FL 33431. 1980. Vol. I, 261 pp., and Vol. II, 273 pp. 17 × 26 cm. Price U.S. $69.95 each (Foreign $79.95).

*Controlled Release Technologies* is contained in two volumes, with a contributors list that reads like a "who's who" in the field of controlled-release products. In the prefix, the editor indicates that "technologies described in these two volumes depend almost exclusively on the use of polymers and polymer technology" and that, although "applications, advantages and fundamental concepts of controlled release have been the subject of many symposia and several books dealing with formulations, all known delivery systems have not been assembled for consideration as they are in these volumes." The editor is entirely correct on this point.

Volume I contains six chapters dealing with fundamental concepts of controlled release, monolithic polymer devices, monolithic elastomeric material, membrane systems, multilayered laminated structures, and controlled release from ultramicroporous triacetate. Volume II contains 13 chapters including topics on erodible matrixes and biodegradative controlled release of pesticides from polymeric substances, polymers containing pendent pesticide substituents, microencapsulation using coacervation phase separation techniques with pharmaceutical and agricultural applications, the Wurster process, microencapsulation using physical methods, controlled-vapor release from hollow fibers, delivery of active agents by osmosis, starch and other polyols as encapsulating matrixes for pesticides, pine craft lignin as a pesticide delivery system, and other controlled-release technologies and applications.

Most chapters provide a brief description of the theory of preparing controlled-release devices but omit specific examples of formulations or preparation techniques which the "novice" could employ to make the products described. This may be because much of such information is proprietary, or it may be because the authors have assumed that the average reader will already have some knowledge in this area. Chapter 3 in Volume I is an exception in that many interesting product formulations have been presented. The volumes were published in 1980, and the editor's introductory comments were signed and dated 1978. Thus, most chapters do not contain references more recent than 1976, but the literature prior to this time is well covered and a large number of excellent references are provided with each chapter.

In addition, Chapter 13 of Volume II, which deals with "other controlled release technologies and applications," contains a series of tables listing U.S. patent numbers, companies holding the patents, titles of controlled-release systems, applications for the controlled-release systems, active agents involved, and the controlled-release method employed. These tables are quite informative.

The authors have done a good job of presenting polymeric controlled-release technology for drugs, insecticides, pesticides, herbicides, and antifouling formulations. Many chapters contain a brief mathematical description for active ingredient release theory followed by an

The third concern raised by Chiou *et al.* (1) is the lack of a correction for the mutual miscibility of water and octanol. They show three examples that indicate an error as high as 0.3–0.5 in log *PC* for very nonpolar solutes. This magnitude of error is not of particular concern. It is well within the error normally encountered in determining experimental values for both log $S_w$ and log *PC* for hydrophobic compounds and certainly within the limitations of Eq. 2.

The conclusion of Chiou *et al.* (1) is that experimental values for log *PC* should be used to improve the reliability of the log $S_w$ − log *PC* correlation in the high log *PC* region. While this may be true, it is somewhat impractical. The value of Eq. 2 is that it provides a simple means of estimating log $S_w$ from nothing more than a knowledge of the melting point of the solute and a group contribution estimate of its partition coefficient. The measurement of accurate partition coefficients greater than 10,000 (log *PC* > 4) is far more difficult and subject to error than the measurement of log $S_w$.

## REVIEWS

**Controlled Release Technologies: Methods, Theory, and Applications.** Edited by AGIS F. KYDONIEUS. CRC Press, 2000 N.W. 24th St., Boca Raton, FL 33431. 1980. Vol. I, 261 pp., and Vol. II, 273 pp. 17 × 26 cm. Price U.S. $69.95 each (Foreign $79.95).

*Controlled Release Technologies* is contained in two volumes, with a contributors list that reads like a "who's who" in the field of controlled-release products. In the prefix, the editor indicates that "technologies described in these two volumes depend almost exclusively on the use of polymers and polymer technology" and that, although "applications, advantages and fundamental concepts of controlled release have been the subject of many symposia and several books dealing with formulations, all known delivery systems have not been assembled for consideration as they are in these volumes." The editor is entirely correct on this point.

Volume I contains six chapters dealing with fundamental concepts of controlled release, monolithic polymer devices, monolithic elastomeric material, membrane systems, multilayered laminated structures, and controlled release from ultramicroporous triacetate. Volume II contains 13 chapters including topics on erodible matrixes and biodegradative controlled release of pesticides from polymeric substances, polymers containing pendent pesticide substituents, microencapsulation using coacervation phase separation techniques with pharmaceutical and agricultural applications, the Wurster process, microencapsulation using physical methods, controlled-vapor release from hollow fibers, delivery of active agents by osmosis, starch and other polyols as encapsulating matrixes for pesticides, pine craft lignin as a pesticide delivery system, and other controlled-release technologies and applications.

Most chapters provide a brief description of the theory of preparing controlled-release devices but omit specific examples of formulations or preparation techniques which the "novice" could employ to make the products described. This may be because much of such information is proprietary, or it may be because the authors have assumed that the average reader will already have some knowledge in this area. Chapter 3 in Volume I is an exception in that many interesting product formulations have been presented. The volumes were published in 1980, and the editor's introductory comments were signed and dated 1978. Thus, most chapters do not contain references more recent than 1976, but the literature prior to this time is well covered and a large number of excellent references are provided with each chapter.

In addition, Chapter 13 of Volume II, which deals with "other controlled release technologies and applications," contains a series of tables listing U.S. patent numbers, companies holding the patents, titles of controlled-release systems, applications for the controlled-release systems, active agents involved, and the controlled-release method employed. These tables are quite informative.

The authors have done a good job of presenting polymeric controlled-release technology for drugs, insecticides, pesticides, herbicides, and antifouling formulations. Many chapters contain a brief mathematical description for active ingredient release theory followed by an

abundance of practical examples. There are many useful illustrations in graphical and tabular form as well as numerous high quality photographs. All art work is top quality. These volumes will be useful to scientists and students involved in controlled-release technologies.

**Recent Developments in Mass Spectrometry in Biochemistry and Medicine, 6.** Edited by ALBERTO FRIGERIO and MALCOLM McCAMISH. Elsevier, 52 Vanderbilt Ave., New York, NY 10017. 1980. 553 pp. 16 × 24 cm. Price $83.00.

This volume is a compilation of the papers from the *Proceedings of the 6th International Symposium on Mass Spectrometry in Biochemistry and Medicine*, Venice, June 1979. It contains 52 papers from a variety of mass spectrometric applications. Similar to the previous series, this volume attempts to bring together the latest information on the application of mass spectrometry and research development and methodology of mass spectrometry. This objective is met in the area of the latest applications in biochemistry and medicine.

This book discusses various applicational aspects from experts in the field and is quite up-to-date. Examples of its applications in lipids, prostaglandins, protein sequencing, biogenic amines, metabolite identification, pharmacokinetics, placental drug transfer, and physiological exchange of endogenous substances are of interest to readers at intermediate to advanced levels in mass spectrometry. It is particularly useful to less sophisticated readers who want to get a glimpse of the field without purchasing the previous volumes of the proceedings. Perhaps disappointing to some experienced researchers is the deficiency in certain aspects of applications such as the use of stable isotopes in pharmacology and pharmacokinetics. This may reflect a lack of participation of certain segment of the biomedical researchers in the symposium.

In the area of latest developments in instrumentation and methodology, it has somewhat short-changed the reader. Several areas such as mass spectrometry–mass spectrometry (multiple mass spectrometry), ion-cyclotron mass spectrometry, and high-pressure liquid chromatography–mass spectrometer interface are not covered. Nonetheless, several chapters in this area are quite valuable, *e.g.*, the description of the Kratos MS 80, the laser microprobe mass analyzer and its applications, low- and high-pressure negative chemical-ionization mass spectrometry, and the disposable surface probe.

This book is divided into six general classifications, including qualitative and quantitative studies of endogenous and exogenous compounds, instrumentation and methodology, and environmental studies. These classifications, although somewhat artificial, are quite helpful in locating quickly a particular area of interest. However, it is not understood why a paper that discusses the application of the electron-capture detector in liquid chromatography without any reference to mass spectrometry was included in this book (pp. 317–330).

This book contains an author index but not a subject index. The former does not serve much purpose because no affiliations of the authors are provided in this index and the name of the author can already be found in the table of contents. The latter, if available, is usually more useful in helping readers locate the subject of interest. However, this book is a reasonably up-to-date reference book on mass spectrometry.

**Applied Biopharmaceutics and Pharmacokinetics.** By LEON SHARGEL and ANDREW B. C. YU. Appleton-Century-Crofts, 292 Madison Ave., New York, NY 10017. 1980. 253 pp. 16 × 24 cm. Price $18.50.

This book, intended primarily for undergraduate students in pharmacy and allied health professions, emphasizes pharmacokinetic principles rather than biopharmaceutics. The first two chapters review elementary mathematics and kinetics, and the next three chapters introduce one-compartment and multicompartment pharmacokinetic models. Chapter 6 briefly discusses biopharmaceutics, including absorption mechanisms and dosage form dissolution. Chapters 7–11 deal with absorption kinetics, bioavailability, clearance, hepatic elimination, and protein binding. Chapters 12, 13, and 14 consider intravenous infusions, multiple-dose administration, and nonlinear pharmacokinetics, Chapters 15 and 16 discuss clinical pharmacokinetics, and Chapter 17 describes the kinetics of pharmacological effects.

The book is quite readable, with numerous illustrations. Most chapters contain practice problems, along with detailed solutions. In addition, questions are included at the end of each chapter, and answers are provided in the *Appendix*. One major attribute of the book is the step-by-step illustrations given for some of the more common pharmacokinetic manipulations (*e.g.*, method of residuals, Wagner–Nelson method, and Loo–Riegelman calculation). Only a limited number of references are provided, and they are generally in the form of a bibliography at the end of each chapter.

The text appears relatively free from errors, although several incorrect equations were found, and some generalizations were made that were not as widely applicable as the text seemed to imply. On the whole, the book provides a reasonable introduction to the material, although the somewhat superficial discussion of some topics could mislead someone utilizing the text without a thorough understanding of the limitation and pitfalls in the approaches. However, the book would be suitable as an introductory undergraduate text for a course taught by an instructor experienced in pharmacokinetics.

**Progress in Drug Metabolism, Vol. 5.** Edited by J. W. BRIDGES and L. F. CHASSEAUD. Wiley, 605 Third Ave., New York, NY 10016. 1980. 358 pp. 15 × 23 cm. Price $85.00.

This volume is the fifth in a series concerned with various aspects of drug metabolism. This volume is similar to the previous four volumes in that five to six major, current, and timely topics are reviewed. These topics are not necessarily directly related other than that they are concerned with the general topic of drug metabolism.

Chapter 1 deals with the distribution and role of cytochrome P-450 in extrahepatic organs and in prostaglandin metabolism. Steroidogenic organs also are extensively reviewed. The chapter does not include recent investigations involving cytochrome P-450 in the intestine and colon, and most references are pre-1978, although the volume was published in late 1980.

Chapter 2 addresses a topic on which relatively little information exists, namely species variations in xenobiotic metabolizing enzymes. The chapter is restricted to hepatic metabolism, primarily involving microsomal monoxygenases, epoxide hydratase, and glucuronyltransferase. No information is provided on interspecies variation within hepatic and extrahepatic tissues.

abundance of practical examples. There are many useful illustrations in graphical and tabular form as well as numerous high quality photographs. All art work is top quality. These volumes will be useful to scientists and students involved in controlled-release technologies.

**Progress in Drug Metabolism, Vol. 5.** Edited by J. W. BRIDGES and L. F. CHASSEAUD. Wiley, 605 Third Ave., New York, NY 10016. 1980. 358 pp. 15 × 23 cm. Price $85.00.

This volume is the fifth in a series concerned with various aspects of drug metabolism. This volume is similar to the previous four volumes in that five to six major, current, and timely topics are reviewed. These topics are not necessarily directly related other than that they are concerned with the general topic of drug metabolism.

Chapter 1 deals with the distribution and role of cytochrome P-450 in extrahepatic organs and in prostaglandin metabolism. Steroidogenic organs also are extensively reviewed. The chapter does not include recent investigations involving cytochrome P-450 in the intestine and colon, and most references are pre-1978, although the volume was published in late 1980.

Chapter 2 addresses a topic on which relatively little information exists, namely species variations in xenobiotic metabolizing enzymes. The chapter is restricted to hepatic metabolism, primarily involving microsomal monoxygenases, epoxide hydratase, and glucuronyltransferase. No information is provided on interspecies variation within hepatic and extrahepatic tissues.

Chapter 3 deals with the pharmacokinetics and metabolism of an extensive array of nonsteroidal anti-inflammatory agents including salicylates, arylacetic acids, arylpropionic acids, and *N*-heterocycles. The importance of understanding the basic pharmacokinetic properties of these drugs is emphasized. Some evidence is presented that nonsteroidal anti-inflammatory agents concentrate in inflamed tissues, but the underlying mechanisms and implications are poorly understood. Most references involve work completed prior to 1978.

Chapter 4 is concerned with the monitoring of drug disposition by immunoassay, providing a basic introduction to radioimmunoassays. In addition, there is an extensive discussion on enzyme immunoassays and also luminescent (fluorescent) immunoassays. An enormous amount of literature is now available on the immunoassay of drugs. The authors have provided a distillation and update of information on the background of immunoassays, including theories and applications ranging from practical to research uses.

Chapter 5 deals with the pharmacokinetics and metabolism of industrial chemicals. Because of the large scope of this topic, the authors restricted their discussion to the use of pharmacokinetics involved in toxicological evaluation of styrene, 2,4,5-trichlorophenoxyacetic acid, and 1,4-dioxane. Also discussed is the use of pharmacokinetic concepts and risk assessment using vinylidene chloride and tetrachloroethylene as model compounds. The examples used stress the importance of integrating chronic toxicity bioassay results with the pharmacokinetics and resulting macromoleculecular events in assessing the risk of exposure to chemicals.

The nature of the topics covered in this volume is extremely broad, as has been the case with previous volumes. The volume provides a useful addition to the review and evaluation of the literature concerned with drug metabolism. A major drawback of the volume is its price. However, Volume 5 certainly is an important addition to the library of these involved in the field of drug metabolism.

Twenty-one years ago, Rogoff and Kohler (1) demonstrated that the application of 100 ml of a concentrated solution of the organophosphorus insecticide crufomate (I) (Table I) to a small area of a cow's skin could control cattle grubs. Compound I is a systemic insecticide (2), and its mode of action is believed to involve its absorption across the skin into the cow's systemic circulation and, hence, distribution throughout the body, thus interacting with cattle grubs as they migrate through the tissues. Confirmation of drug absorption came from the observation that a slight depression of erythrocyte cholinesterase activity followed drug administration (1). This type of dosage form is referred to as a "pour-on" or "spot-on". It is a liquid formulation (solution, emulsion, or suspension) intended to be applied to a small area of an animal's skin to promote drug absorption into the bloodstream. The concentration of drug in a spot-on is higher than that in a pour-on; consequently, a smaller dosage is used.

The realization that drugs can be introduced topically into the bloodstream has stimulated the search for topical drug delivery systems to control internal and external parasites and to deliver nutrients, metabolic regulators, and hormonal regulators.

Systemic insecticides can be used to control external parasites if the latter are bloodsuckers (*e.g.*, sucking louse *Linognathus vituli*) or if drug is secreted onto the skin *via* sweat or sebaceous glands.

Although the goal of delivering drugs to the systemic circulation *via* the topical route has only been actively researched during the past 21 years, the farm industry has many years of experience in the application of drugs to the hair, wool, and skin of domestic animals by way of dips, dusts, and sprays. However, these dosage forms usually contain a much smaller drug concentration than dosage forms such as pour-ons that are intended to promote systemic delivery. Consequently, because the driving force for Fickian diffusion across a membrane such as skin is the concentration gradient across the membrane, these dosage forms usually act by bringing the drug into contact with an external parasite rather than by promoting absorption.

For example, it is common practice to treat cattle grubs in beef cattle with a dip containing 0.25% I or a spray containing 0.375% I. The usual strengths of the pour-ons and spot-ons of I are 8 and 12%, respectively. Similarly, it is common practice to treat horn flies (*Haematobia irritans*) in beef cattle with back rubbers[1] (burlap soaked with a mixture of an insecticide in an oil such as diesel fuel wrapped around a wire or cable) containing 1% coumafos (II) (3), dust bags[1] (doubled burlap bags containing powdered drug) containing 1 or 5% II, sprays containing 0.06%

[1] They apply drug to the animal's coat when the animal rubs against them.

II (3), or dips containing 0.06% II. The usual strength for a pour-on of II is 4%.

Another example of a drug delivery system that acts primarily by bringing drug into contact with the pest rather than promoting absorption is polyvinyl chloride strips impregnated with dichlorvos (III) and attached to the legs of cattle to control cattle grub by killing ovipositing flies, eggs, or newly hatched larvae (4).

Although these dosage forms are not necessarily intended to promote systemic absorption, they may do so with harmful effects to the animals under abnormal conditions. For example, if sheep are driven too far or too fast or are confined to a woolshed to protect them from rain after dipping, overheating can occur, thereby increasing the skin temperature sufficiently to promote the absorption of the dip chemicals (5).

Most of this review will be concerned with topical delivery of drugs into the systemic circulation rather than with delivery onto the skin to promote local contact with ectoparasites. However, an understanding of the permeability of cattle and sheep skins to drugs will provide a basis for preventing drug absorption (thus reducing toxicity to the host animal), prolonging drug action, and promoting drug delivery.

The topical route of systemic delivery is attractive to the farming industry because:

1. It is less labor intensive to apply a drug to an animal's skin than to administer more conventional dosage forms such as drenches, injections, and inocculations.
2. The drug is introduced into the bloodstream without

having to traverse the GI tract where it can be extensively metabolized or bound to proteins and other GI tract contents or where its transit time is unpredictable.

3. The dose for each animal can be regulated much more closely than when drugs are added to feed or are presented as licks.

4. When properly formulated, these systems are likely to cause less trauma and tissue damage than injections or drenches and are less likely to interfere with nutritional status.

The pour-on or spot-on dosage form is particularly attractive since it can be applied rapidly and easily to an animal's skin and the cost of equipment is much less than that required for spraying or dipping. However, it has been argued that the pour-on technique can be more expensive than spraying when large numbers of cattle are to be treated, the application lacks the shampooing effect of a shower treatment, and the operator is exposed to the grave risk of absorbing toxic materials from handling concentrated drug products that have been specifically formulated to promote absorption (6). This latter point was recently investigated (7), with the conclusion that experienced veterinarians can use commercially available organophosphorus pour-ons without absorbing enough drug to depress blood cholinesterase activity. This safety aspect may not be so high with inexperienced operators.

It has long been recognized that topical drug administration to humans has many advantages. As the result of a workable understanding of the barrier properties and transport mechanisms of human skin and of the influence of the physicochemical properties of drugs, vehicles, and other formulation excipients on the absorption process, pharmaceutical scientists can now produce topical dosage forms for humans that demonstrate well-controlled drug delivery. Some excellent reviews were written on these subjects (8–12). The discovery that the cells of the human stratum corneum, the dead keratinized epithelium that comprises the outer 0.001 cm of the skin, are the rate-determining barrier to human skin absorption has led to the design and performance of numerous *in vitro* experiments using isolated skin.

At present, the barrier properties of sheep and cattle skins are not well understood. One report (13) suggested that drugs are much more likely to traverse sheep and cattle skins by way of skin appendages (*i.e.*, hair follicles, sweat and sebaceous glands, and ducts) rather than through the cells of the stratum corneum as in humans, in spite of the fact that both sheep (14) and cattle (15) skins have a substantial stratum corneum. However, more work is necessary to clarify this point.

The next section of this review describes the gross structure of cattle and sheep skins and the physicochemical properties that these barriers are likely to present to diffusing drug molecules. This section is followed by a discussion of the possible changes in the barrier properties of skin as the result of season, temperature, age, sex, humidity, *etc.* Another section is concerned with useful parameters for understanding the permeability character-

istics of membranes and the conclusions about cattle and sheep skin permeability that can be drawn from some *in vitro* studies. The review concludes with an examination of reports of field and laboratory experiences with veterinary topical drug delivery systems (primarily pour-ons and spot-ons) and suggestions for future work.

## THE BARRIERS

**Hair and Wool**—The first absorption barrier encountered by drug molecules following their application to the skins of cattle and sheep is the hair or wool coat. There are ~2000 hair fibers/cm$^2$ in cattle (16, 17), although this number is affected by the animal's breed, sex, weight, age, and body region. Each fiber grows out of hair follicles, which, in cattle, are randomly distributed over the animal's body. Each follicle has a sweat gland, a sebaceous gland, and an arrector pili muscle associated with it. The hairs of European cattle leave the skin at an average angle of 61–62° (18), whereas those of Asian and African cattle tend to leave at an average angle of slightly less than 60° (19).

The hair and wool follicles in sheep, and consequently the hair and wool fibers, are not randomly distributed over the body but are in definite groups containing one to five primary follicles (20), which have a sebaceous gland, a sweat gland, an arrector pili muscle, and a number of secondary follicles, which have only sebaceous glands. Merino sheep were reported to have 300–400 primary follicles/cm$^2$ and 6000–10,000 secondary follicles/cm$^2$ in wool-growing regions (*i.e.*, midside, midback, and flank) of the body (21). The average density of primary follicles does not change appreciably on the hair-growing regions, but the densities of secondary follicles are markedly reduced. Differences in follicle densities and in ratios of numbers of primary and secondary follicles with breed were discussed elsewhere (20, 21).

Because hair and wool fibers are composed of the modified protein keratin, they possess chemically reactive groups such as thiol, amino, and carboxyl groups and hydrophobic regions. Thus, they can react with and change (frequently reduce) the thermodynamic activity of drugs that they contact. Many chemicals bind strongly to wool (23–28), and a similar situation must be expected with cattle hair.

However, sheep wool and, to a lesser extent, cattle hair are coated with an emulsion of sweat and sebum that is formed in the follicle infundibula where the sweat and sebaceous glands empty their secretions. Wool fibers appear to have an almost continuous coat of this emulsion (29) [frequently referred to as the yolk (30)], while only the lower parts of cattle hairs are similarly coated (29). This emulsion rapidly dissolves many chemicals that are applied to the coat or skin of animals (31, 32), and diffusion within the emulsion, either up or down the fibers, always competes with diffusion of molecules through the skin (33, 34).

Consequently, an understanding of the nature of the emulsion and the manner in which it varies with breed, sex, climate, season, and nutritional state is fundamental to an understanding of topical drug delivery.

**Skin Topography**—Scanning electron micrographs of cattle and sheep skins reveal that the surfaces consist of roughly hexagonal squama punctuated by hair or wool fibers and their associated follicle pores (29). The pores are not open and clear but are protected by a conical mass, which appears to be composed of squama and a convex amorphous material. The latter is believed to be a partially dehydrated or modified form of the emulsion of sweat and sebum that is formed in the follicle infundibula. As mentioned previously, the convex amorphous material also coats most of the wool fibers and the lower parts of cattle hairs. Globules or strips of this material are also present at the junctions of the interfollicular squama in both cattle and sheep skin; in the latter, a significant amount is present on the squama surfaces.

**Gross Structure of Cattle and Sheep Skins**—Like other mammals, the skin of cattle (35) and sheep (20, 22) consists of a cornified stratum corneum, an uncornified "living" epidermis, and a dermis differentiated in the cow and, to a much smaller extent, sheep (20) into papillary and reticular layers. The relative thicknesses of the various skin layers in different animal breeds are given in Table II.

The most reliable studies of the structure of the stratum corneum have employed cryostat sections (14, 15). This technique causes much less damage to the stratum corneum than does a histological technique, which involves dehydration and embedding in paraffin.

The stratum corneum of cattle appears to consist primarily of vertical columns of cells (15). The outer two-thirds of the stratum corneum cells, but not the lower third, the uncornified epidermis, or the sweat glands, are permeated by an emulsion believed to be the emulsified sweat mentioned earlier. It is proposed that the emulsion is formed in the follicle infundibula and oozes to the surface through the outer layers of the stratum corneum and the follicle pore (15).

The entire stratum corneum of sheep is permeated by emulsion, and an intact film of emulsion ~$0.90 \times 10^{-2}$ mm thick covers its outer surface (14). The lower half of the stratum corneum ($1.6 \times 10^{-2}$ mm) consists of vertical columns of densely packed flattened cells, whereas the outer half consists of a loosely knit structure.

The papillary layer of the dermis has a depth of 1–2 mm in cattle (Table II) but is much thinner in sheep (20). It is composed of fine collagenous fibers interwoven with fine elastic and reticular fibers. The reticular layer is a broad zone of coarse collagenous fibers. Goldsberry and Colhoun (38) suggested that the transition zone between the papillary and reticular layers of dermis in cattle occurs around the hair follicle bulb, whereas Jenkinson (35) suggested that the two layers meet in the region of the sebaceous gland. In any case, in both sheep and cattle, the sebaceous gland is associated with the upper portions of the hair follicle and the sweat glands are below the follicle bulb (22, 35). In both species, the ducts of the sweat glands open into the infundibula of the hair follicles (primary follicles in sheep) slightly above the entry point of the sweat ducts (22, 35, 38).

The blood supply to the skin is particularly important to drug delivery because once the drug comes into contact with a capillary network, it has the opportunity of entering the blood and being carried away from the skin. Entry into the blood is likely to be rapid unless the drug molecule is very hydrophobic (39).

Blood supply to mammalian skin was reviewed previously (35). Briefly, the hair bulb, the sebaceous gland, the

sweat gland, and especially the hair follicles are richly supplied by blood in both cattle and sheep. These blood vessels also permeate the papillary layer of the dermis.

**Emulsion**—It was previously stated that the hair and wool fibers, the infundibula of the hair and wool follicles, the junctions of squama of the stratum corneum, and all (in the case of sheep) or part (cattle) of the stratum corneum are permeated by an emulsion which oozes up from the follicle infundibula. The chemical components of the emulsion vary from animal to animal and with such factors as the time of year and climate, but most lipids in the emulsion arise from the secretions of the sebaceous glands (14, 15, 40). Minor components are likely to arise from desquamating squama (*i.e.*, keratin), cell debris, bacterial excreta, and blood. The likely components of the emulsion are listed in Table III (41–43). Thus, the solvent properties of the emulsion and its ability to solubilize and modify the thermodynamic activity of topically applied drugs will be determined by the relative concentrations of the various constituents.

In addition, the viscosity of the emulsion and thus its ability to support molecular diffusion will vary with its water content. This latter parameter will be influenced by the activity of the sweat gland, but it also has been inferred (29) that the emulsion may lose water by evaporation as it permeates through the layers of the stratum corneum. Future physicochemical studies must elucidate the solubility characteristics of skin emulsions under conditions likely to be encountered by sheep and cattle.

## BARRIER VARIABILITY

**Exposure to Solvents**—Lloyd *et al.* (44) showed that cattle skin can be clipped coarsely or finely without removing more than four cell layers of the stratum corneum. However, washing the skin with ether removed all but three stratum corneum layers (44). This effect is almost certainly involved in the marked erythema that ether causes on bovine skin (45), and it predisposes the skin to infection by *Dermatophilus congolensis* (46). Methanol washing of cattle skin had a much smaller effect on stratum corneum thickness (44) and on the incidence of infection (46). The susceptibility of cattle skin to infection also was increased by washing with light petroleum (47) or following intense water spraying (48); in sheep skin, it was increased by heavy rain (49).

The development of erythema and susceptibility to infection probably are caused by removal of the outer squama of the stratum corneum and, in particular, removal of the emulsion from the skin surface, from the junctions of squama, and from hair pores. Consequently, treatment of skin with these solvents, as well as with detergents, is likely to affect its permeability, and the extent to which this occurs is worthy of investigation.

Lipid solvents and dimethyl sulfoxide treatment of cattle and sheep skin at 20° apparently stimulates the secretory cells of the sweat glands and promotes cutaneous water loss (50). Hence, as well as removing skin lipids, the application of organic solvents to the skin is likely to lead to increased hydration of the stratum corneum and changes in the composition and viscosity of any emulsion that remains associated with the skin.

The resistance of cattle skin to infection returned 24 hr after washing with ether (46), although only one lipid layer (*i.e.*, layer of stratum corneum cells) had been replaced in that time (44). It is thus likely that replacement of emulsion in the junctions between the squama is well underway by 24 hr (46).

**Table III—Major Constituents of Skin Emulsion**

| Source | Constituents |
|---|---|
| Sebaceous gland | Monoester waxes, diester waxes, squalene, cholesterol, cholesterol esters, phospholipids, triglyceride esters of fatty acids, free fatty acids, corticosteroids |
| Sweat gland | Water, sodium ions, potassium ions, calcium ions, magnesium ions, chloride ions, lactate ions, free amino acids, water-soluble proteins, epinephrine |
| Blood | Albumin, transferrin, immunoglobulins IgA, G, and M |

The precise effects of these changes cannot be predicted at this stage. They will depend on the mechanism by which drug molecules are absorbed and on the chemical properties of each drug.

**Skin Temperature**—Elevation of temperature increases the molecular diffusion rate by lowering its activation energy. However, temperature changes also influence skin permeability by changing the activity of sweat glands and the composition of their secretions. The results of these changes are expressed as changes in the composition and viscosity of the skin emulsion and in the degree of skin hydration.

The temperature of sheep and cattle skins is influenced by ambient temperature, radiation, convection, evaporation, shivering, and exercise (43). The skin surface temperature of cattle in the shade does not vary appreciably from one area of the body to another (43). However, the coat type and skin color are important when the animal is in sunlight. Thus, an 8° temperature difference has been reported between black-haired (heat-absorbing) and white-haired (heat-reflecting) regions (51).

The effect of ambient temperature on domestic animal skin permeability is likely to be more profound than it is on human skin. This difference arises partly because humans, especially those receiving dermal treatment, are unlikely to expose their skin to the wide range of temperatures (*e.g.*, 0–50°) that animal skins may be exposed to. In addition, animal skin temperatures tend to change much more dramatically with changing environment than do human skin temperatures. For example, the surface temperature of cattle was observed (52) to vary from 34.5 to 40° when ambient temperature was increased from 15 to 40°. The temperature of the skin of sheep varied from 31 to 38.5° when ambient temperature was varied from 20 to 40°. Rectal temperatures varied from 38.2 to 40.2° throughout the same range of ambient temperatures.

The greater efficiency of the human skin thermoregulatory process could arise because of the greater rate of human sweating (2000 $g^{-2}$/hr) as against sheep (32 $g^{-2}$/hr) or cattle (588 $g^{-2}$/hr) (53).

Increases in ambient temperature increase the rate and volume of secretion of sweat in cattle (54, 55) and in shorn (53, 56) and unshorn (56) sheep. This factor may profoundly affect the aqueous content and viscosity of the emulsion because heat has only a minor effect on the output or composition of sebum (57) unless it is prolonged for >3 days (57, 58).

In addition to the higher output of sebum when high

temperatures were maintained for long periods, the relative concentration of linoleic acid (and other free fatty acids) in the sebum increased (57, 58). The importance of this finding to dermal drug delivery results from the fact that linoleic acid reduced the increased water loss from the skin of rats that was induced by fatty acid deficiency (59, 60) and is thus likely to affect skin permeability to other compounds.

Low humidity at a constant temperature caused an increase in the concentrations of palmitic and myristic acids in sebum of cattle (57).

**Season**—Most changes observed in the structure and anatomy of animal skins as a result of seasonal changes follow a predictable pattern. Smith and Jenkinson (45) found that the sebum output by Ayrshire cattle in Ayre was slightly lower in winter than at other times of the year. However, the situation may be different in hot climates because it was reported (61) that sebum secretion in cattle (Shorthorns, Friesans, and Egyptian cattle) in Egypt was greater in winter than in summer. Similarly, Nay and Hayman (62) reported that the sweat gland volume, as well as the papillary layer and skin thickness of cattle, was greater in winter than in summer. The increased size of the sweat gland indicates that it is less active in winter than in the summer (63). Amakiri (64) reported that the thickness of the total skin, the stratum corneum, and the epidermis of cattle in Nigeria was slightly thicker during the rainy season than during the dry season. The direct relationship between sweat gland volume and papillary layer thickness observed for cattle appears to be quite general (62).

**Breed**—Table II reveals differences in both total skin thickness and thickness of various skin layers for cattle of different breeds.

Differences also occur in the density of hair follicles with different breeds of cattle and sheep. The hair follicle density of a large number of breeds of cattle with different body weight, age, sex, and growth rate follows the rule (65):

$$D = kW^{-0.67} \quad \text{(Eq. 1)}$$

where $D$ is the density of hair follicles and $W$ is the animal weight. The constant $k$ varies slightly with breed. It was observed that the density of hair follicles for Hereford and Shorthorn cattle was similar to those of Africander crossbreeds provided all the animals had similar weights (65). However, Brahman cattle had 20% more follicles per unit area than animals of the other breeds with similar weights.

The rule expressed in Eq. 1 accounts for the observations that cattle between 1 and 2 years of age had denser coats than older cattle of the same breed and that coats were densest in times of drought (*i.e.*, when the animals were lighter) (66).

Differences in follicle densities and in ratios of the number of primary to secondary follicles in different breeds of sheep have been studied (20, 21). Jenkinson and Nay (18, 19) found that the ratio of length ($L$) to diameter ($D$) of sweat glands ($L/D$) and the depths of the hair follicle ($FD$) varied in a regular manner between breeds of cattle. These authors characterized three skin types: Type 1, where $L/D < 8.0$ and $FD < 1.5$ mm (Jersey cattle and most Asian and African cattle); Type II, where $L/D > 12$ and $FD > 2$ mm (many Scottish highland breeds); and Type III, where $L/D > 12$ and $FD < 1.5$ mm (some South American breeds).

Tropical cattle (*e.g.*, Asian, African, and South American breeds) frequently have smaller sweat gland volumes than European breeds (19, 64), perhaps because the glands are more active. Values of various average parameters for cattle from different continents are given in Table IV.

The complexity of this topic is illustrated by the observation that Hereford × Shorthorn cattle sweated at a higher rate than Brahman × Shorthorns under mild conditions but at a lower rate when under stress (67).

**Body Region**—The hair and wool follicle densities and types of fibers in sheep and cattle vary significantly with the region of the body examined. The body of a sheep can generally be divided into wool-growing regions and hair-growing regions. The approximate location of these regions in numerous breeds is described in Table V (20). The epidermis of the skin is thinner on wool-growing areas (30 μm) than in hair-growing regions (500 μm) (20). Similarly, while there is an area of uniform skin thickness in the middle of a sheep's back on either side of and parallel to the vertebral column (22), there is also a steep dorsoventral gradient in skin thickness on either side of the medial dorsal line. The thicker skin is over the vertebral column, near the tail along the back of the sheep and towards the neck in older sheep.

As already mentioned, the wool follicles can be primary (with a sweat gland and a sebaceous gland) or secondary (with a sebaceous gland only). It was reported (20) that the sebaceous and sweat glands are larger in the hair- than in the wool-growing regions.

These observations suggest that whether drugs cross sheep skin *via* the cells of the epidermis or *via* the skin appendages, the permeability of the skin of wool-growing areas (thinner epidermis and more follicles) would be greater than that of haired skin. One factor that could reverse this expectation would be the greater potential of the dense wool coat, relative to the thinner hair coat, to react with applied drugs.

A study of the density of sweat glands and, thus, of hair follicles of Ayrshire cattle (16) indicated that the highest density (2500 $cm^{-2}$) was in skin of the axilla and neck and that the lowest was in the lower limbs (1000 $cm^{-2}$). Table VI describes the areas that had above or below average density of sweat glands and area of secretory surface per square centimeter of skin.

The thickest epidermis on Hereford and Aberdeen Angus cattle was found to be where the follicle density was lowest (*e.g.*, the epidermis of the muzzle was 150–200 cells thick (38). The thinnest epidermis in Herefords was located laterally on the thorax, neck gluteal region, and upper forelegs. In three of four Aberdeen Angus, the thinnest epidermis was on the dorsal part of the body. Such information is useful for predicting the best area of an animal's body for appropriate drug application.

**Other Factors**—Various additional factors are likely to influence skin permeability, and more factors probably will be revealed by carefully controlled studies of skin absorption.

The influence of sex has not been explored, although it was reported that sebum output was greater in castrated male Ayrshire calves than in females (45) and that male

**Table IV—Sweat Glands and Hair Follicles of Cattle [a]**

| Parameter | European | Asian | African | South American |
|---|---|---|---|---|
| Sweat gland length, μm | 928 ± 276 | 738 ± 87 | 695 ± 223 | 972 ± 394 |
| Sweat gland diameter, μm | 107 ± 21 | 87 ± 18 | 85 ± 18 | 90 ± 15 |
| L/D [b] | 8.8 ± 2.5 | 8.6 ± 3.1 | 8.4 ± 3.0 | 10.8 ± 3.9 |
| Sweat gland volume, $\mu m^3 \times 10^{-6}$ | 9.0 ± 5.2 | 4.9 ± 3.7 | 4.3 ± 2.5 | 6.7 ± 4.3 |
| Follicle length, mm | 2.0 ± 0.3 | 1.5 ± 0.3 | 1.6 ± 0.2 | 1.7 ± 0.2 |
| Follicle diameter, μm | 44.2 ± 8.1 | 47.3 ± 8.0 | 53.5 ± 7.3 | 54.2 ± 8.1 |
| Follicle depth, mm | 1.8 ± 0.3 | 1.3 ± 0.2 | 1.4 ± 0.2 | 1.5 ± 0.2 |
| FL/FDM [c] | 46.4 ± 9.7 | 32.4 ± 9.1 | 30.2 ± 6.6 | 32.5 ± 5.9 |

[a] Data from Refs. 18 and 19. [b] Sweat gland length/sweat gland diameter. [c] Follicle length/follicle diameter.

Aberdeen Angus cattle had thicker skins than females (38).

The nutritional status of the animal is also likely to be important. Thus, when wheat-fed sheep had their diet supplemented abomasally with methionine, there was a thickening of the epidermis, poor formation and improper keratinization of wool fibers, and, subsequently, a gross thickening of the outer root sheath (68). Similarly, it was reported (69) that vitamin A deficiency in cattle resulted in hyperkeratosis, leading to substantial skin thickening in the upper two-thirds of the animal's body. The vitamin A deficiency in this case was believed to be caused by ingestion of chlorinated naphthalenes, which were used as lubricants in animal food-processing equipment.

## ABSORPTION MECHANISMS

There is abundant evidence (Table VII) that many chemicals are transported across sheep and cattle skins in sufficient amounts and at sufficient rates to bring about expected pharmacological responses. However, none of the studies involving topical drug delivery to live animals provided solid evidence about absorption mechanisms. In addition, while some data are available on drug transport across excised sheep (70) and cattle (13, 71–74) skins in *in vitro* experiments, few reliable correlations were found between *in vitro* permeability parameters and *in vivo* behavior. Consequently, any speculations about absorption mechanisms at this time are highly tenuous. However, such speculations are useful in that they may create guidelines for the design and execution of needed investigations into this subject.

The speculations that follow are based mainly on knowledge of the mechanisms of drug transport across human skin (10–12, 76, 77), knowledge of the comparative anatomy and physiology of cattle and sheep skins, and conclusions drawn from a limited number of *in vitro* measurements of skin permeability (13, 70–74). The major speculations or hypotheses about cattle and sheep skin penetration are:

1. Bulk transport of neutral molecules with small to medium size molecular weights occurs largely *via* skin appendages (hair or wool follicles and associated ducts and glands) rather than the transcellular pathway which predominates in human skin penetration.

2. The rate and extent of drug absorption across the skin is significantly influenced by the composition and physical properties of the sebum–sweat emulsion associated with the skin.

**Table V—Wool- and Hair-Growing Regions in Sheep**

| Regions | Body Area |
|---|---|
| Wool growing | Midside, midflank, flank |
| Hair growing | Inguinal junction, inguen, axilla, scrotum, cheek, chin, dorsal nose, manus (proximal and distal), pes, pinna |

Most neutral molecules cross human skin by passive diffusion through cells of the interfollicular region rather than through the skin appendages (hair follicles and sweat ducts) (10, 12), even though neutral molecules with small to medium molecular weights have greater diffusivity in the appendages than in the stratum corneum. [The diffusion constants for water were reported to be $0.3–1.2 \times 10^{-5}$, $6–12 \times 10^{-5}$, and $2 \times 10^{-10}$ $cm^2$/min in human hair follicles, sweat ducts, and stratum corneum, respectively (10).] It is believed that bulk transport across human skin occurs *via* the skin cells rather than the appendages because the surface area occupied by the latter is only $10^{-3}$ of the surface area of the skin (12).

It seems reasonable that transappendagial transport would be more important in transport across cattle and sheep skins because they contain a higher density of appendages than human skin. While a square centimeter of human skin contains an average of 40–70 hair follicles and 200–250 sweat ducts, the same area of cattle skin contains ~2000 hair follicles (16, 17) with their associated sweat and sebaceous glands and ducts; sheep skins can contain up to 10,000 follicles with their associated ducts (20, 21).

The resistance to penetrating molecules, $R$, offered by multilayered human skin that consists of a stratum corneum (with resistance $R_S$), a viable epidermis (with resistance $R_E$), and a dermis (with resistance $R_D$) is given by (10):

$$R = R_S + R_E + R_D \qquad \text{(Eq. 2)}$$

Equation 2 can be restated as:

$$R = \frac{1}{k_p} = \frac{\delta S}{D_S K_S} + \frac{\delta E}{D_E K_E} + \frac{\delta D}{D_D K_D} \qquad \text{(Eq. 3)}$$

where:

$k_p$ = permeability constant of skin
$\delta_i$ = thickness of $i$th layer
$D_i$ = diffusion constant of penetrant in $i$th layer
$K_i$ = $i$th layer–vehicle partition coefficient of penetrant

Studies on the penetration of excised human skin by small to medium molecular weight molecules (10, 12) revealed that the first terms in Eqs. 2 and 3 describe the process. Thus, for a homologous series of straight-chain aliphatic alcohols with one to eight carbon atoms, the stratum corneum was the rate-determining barrier. Variations in the thickness or other properties of the viable epidermis or dermis had no effect on the rate of penetration. A similar situation applied to the penetration of levamisole (IV) through excised human skin specimens

**Table VI—Relative Density of Sweat Glands and Area of Secretory Surface per Square Centimeter of Skin for Ayrshire Cattle [a]**

| | Density of Sweat Glands, $cm^{-2}$ | Area of Secretory Surface per Square Centimeter of Skin, $cm^{-2}$ |
|---|---|---|
| Above average | Neck ventral, neck lateral, axilla | Neck ventral, axilla, upper hindleg |
| Below average | Back sacral, gluteus, lower hindleg | Forehead, back sacral, lower foreleg, gluteus, lower hindleg |

[a] From Ref. 16.

whose thicknesses varied from 1.3 to 0.8 mm (13). The average thickness of the human stratum corneum is 0.001 mm (11); therefore, all skin specimens in this experiment contained a uniform thickness of stratum corneum and varying thicknesses of viable epidermis and dermis.

However, the rate of penetration of IV through excised cattle (13) and sheep (71) skins with thicknesses that varied from 1.7 to 0.7 mm was dependent on the total skin thickness. The stratum corneum of cattle (15) and sheep (14) skin was reported to be 3.09 and $3.14 \times 10^{-2}$ mm, respectively, so all skin samples examined in these studies had their stratum corneums intact.

This evidence suggests that the rate-determining barrier to cattle and sheep skin penetration is not the stratum corneum but the whole skin. In the case of sheep skin penetration, it is known that the entire stratum corneum is penetrated by an emulsion of sebum and sweat (14). Hence, in this case, it may be argued that molecules indeed penetrate the stratum corneum *via* lipid regions in which they have similar diffusivity to that in the medium surrounding the cells in the epidermis and dermis. However, it was noted that the lower one-third of the stratum corneum of cattle skin (~0.01 mm) is not permeated by the emulsion (15), thus presenting a similar barrier to penetration as that of the human stratum corneum.

Another possible explanation is that levamisole passes rapidly through the stratum corneum and its rate of clearance into the lower skin layers is rate determining. Higuchi (77) estimated that very lipophilic molecules (*i.e.*, those with activity coefficients of $10^3$ or $10^5$) in infinitely dilute solutions in water would encounter rate-determining clearance from the stratum corneum into the more aqueous

**Table VII—Summary of Dermal Drug Delivery Studies**

| Study | Animal | Drugs | Purpose | Comments | Reference |
|---|---|---|---|---|---|
| 1 | Cattle | I, II, VIII, IX, X, XI, XII, XXI, XXII | Pour-on against southern cattle tick | VIII and IX superior | 78 |
| 2 | Cattle | VII | Bioavailability | | 79 |
| 3 | Cattle | I | Pour-on against GI parasites | Poor against abomasal parasites; erratic against intestinal parasites | 80 |
| 4 | Cattle | I | Pour-on versus spray, intramuscular and intraperitoneal injections against *Hypoderma* spp. | All dosage forms >93% effective | 84 |
| 5 | Cattle | XIX | Pour-on against cattle lice | 62.3–97.8% effective | 88 |
| 6 | Cattle | IX | Pour-on against cattle lice | Effective | 89 |
| 7 | Cattle | VIII, IX, XIV, XV | Pour-ons against long-nosed sucking lice | Most effective for a short term | 6 |
| 8 | Cattle | XIII | Pour-on versus intramuscular injection against cattle grub | Equivalent | 90 |
| 9 | Cattle | I | Pour-on against nematodes | Erratic results except against *H. placei* | 91 |
| 10 | Cattle | 44 compounds | Screen for systemic activity | Variable | 92 |
| 11 | Cattle | I | Spray *versus* pour-on against cattle grub | Pour-on superior | 1 |
| 12 | Cattle | XIII, XIV, XIX | Comparison of XIV with XIII and XIX against cattle lice | XIV at 4 mg/kg equivalent to XIII at 16.5 mg/kg, XIX at 4.5 mg/kg | 93 |
| 13 | Cattle | II | Comparison of pour-on and intramuscular injection *via* spray | Pour-on and intramuscular injection superior | 94 |
| 14 | Cattle | I | Pour-on anthelmintic | Effective against five nematodes, ineffective against four nematodes | 95 |
| 15 | Cattle | II | Bioavailability of spray | Little absorbed | 83 |
| 16 | Cattle, sheep | VII | Bioavailability | — | 96 |
| 17 | Cattle | I, II, VI, VII, VIII, XVIII, *etc.* | Comparison of pour-ons against cattle grub | Variable results | 97 |
| 18 | Cattle | I, VI, VIII | Spray and pour-on of VIII *versus* sprays of I and VI against cattle grub | All exceed $LD_{90}$ | 98 |
| 19 | Cattle | I, II, VI | Pour-ons *versus* dusts and sprays against horn flies | Dusts and pour-ons superior to sprays | 99 |
| 20 | Cattle, sheep | 10 compounds | Saturated sprays and pour-ons against cattle ticks | Maximum protection: sheep, 3 weeks, cattle, 1 day | 100 |
| 21 | Cattle | XX | Bioavailability from 1% suspension | No absorption | 101 |
| 22 | Cattle | XXIII | Pour-on for estrus synchronization | Equivalent to oral | 102 |
| 23 | Cattle | IV | Toxicity study | All complications corrected in 1–4 weeks | 103 |
| 24 | Cattle | IV | Anthelmintic trial of pour-on | Variable results but comparable to orthodox methods | 104 |
| 25 | Cattle | IV | Spot-on against round worms | Effective | 105 |
| 26 | Cattle | IV | Spot-on against lung and GI worms | Effective | 85 |
| 27 | Cattle | IV | Pour-on against nematodes | Equivalent to oral and subcutaneous dosage forms | 80 |
| 28 | Cattle, sheep | IV | Pour-on against nematodes | Effective | 86 |
| 29 | Sheep, goats | XIX | Pour-on against lice and keds | Effective against goats, hairy and wool/hair sheep; less effective against wool sheep | [a] |
| 30 | Sheep | XXIII | Pour-on against *Fasciola hepatica* | Worms in liver reduced 99–100% in 3 weeks | 87 |

[a] H. J. J. Terblanche, Bayer, South Africa (Pty.) Ltd. personal communication.

skin layers (*i.e.*, epidermis and dermis). This situation, which is essentially the same as one where the last two terms in Eqs. 2 and 3 predominate, was discussed by other investigators (10, 12, 39). However, it is unlikely that IV, which has a partition coefficient of only 5.2 between water and toluene (70), is sufficiently lipophilic to experience rate-determining clearance from the stratum corneum. The data on human skin penetration (13), where the stratum corneum was established to be the rate-determining barrier, also suggest that IV is not highly lipophilic. Thus, these *in vitro* results support the conclusion that IV penetrates cattle skin *via* skin appendages.

Further confirmation comes from the value calculated for the diffusion constants for IV in cattle skin ($2.1 \times 10^{-5}$ $cm^2$/min) (13) and sheep skin ($2.5 \times 10^{-5}$ $cm^2$/min) (71). These values are much closer to those reported for water diffusing through human hair follicles ($0.3–1.2 \times 10^{-5}$ $cm^2$/min) (10) or sweat ducts ($6.0–12.0 \times 10^{-5}$ $cm^2$/min) (10) than to the value calculated for water ($3–4 \times 10^{-8}$ $cm^2$/min) (10) or IV ($1.9 \times 10^{-9}$ $cm^2$/min) (13) penetrating through the stratum corneum.

Additional support comes from considering the effect that dimethyl sulfoxide has on penetration through cattle skin (71), sheep skin (70), and human skin (11). The dramatic accelerating effect that dimethyl sulfoxide has on the penetration of many molecules through human skin is in marked contrast to its effect on levamisole penetration through excised cattle and sheep skins where it slightly decreased penetration rates relative to those from aqueous solvents. Because this accelerating effect has been ascribed to dimethyl sulfoxide's ability to alter temporarily the structure of the stratum corneum, it can be concluded that drugs do not penetrate cattle and sheep skins by this route. The decrease in penetration rate through cattle and sheep skins caused by dimethyl sulfoxide is believed to result from its reduction of the thermodynamic activity of the drug in the applied formulation (70).

If the transappendagial route is the major means of bulk transport through cattle and sheep skins, it does not necessarily follow that the total skin thickness, depth of follicle, or length of sweat or sebaceous ducts would greatly influence penetration rates in live animals as they apparently do in excised skin. The hair follicles and ducts are richly supplied by blood, and drug molecules are likely to pass rapidly through the capillary walls and be carried away by the blood as they diffuse through the appendages.

If transappendagial penetration predominates in cattle and sheep skins and transcellular penetration predominates in human skin, some procedures that have been adopted to promote human skin penetration will not necessarily be effective in promoting cattle and sheep skin penetration. The procedures in question were well reviewed (10–12, 76), and they include hydration of the skin and the use of stratum corneum modifiers such as dimethyl sulfoxide or surfactants.

However, other procedures such as maximization of the concentration gradient or, more accurately, the thermodynamic activity gradient of a drug across the rate-determining barrier and of the rate-determining barrier–vehicle partition coefficient will be equally important in promoting cattle and sheep skin penetration as in promoting any Fickian diffusion process (77). Thus, if molecules diffuse through the skin appendages and these present a homogeneous barrier, the flux $J$ is given by:

$$J = \frac{D_A K_A}{\delta_A} \Delta C_S = k_{P,A} \Delta C_S \qquad \text{(Eq. 4)}$$

where:

$D_A$ = diffusion constant of penetrant molecules in appendages
$K_A$ = appendage–vehicle partition coefficient of penetrant
$\delta_A$ = thickness of appendages that must be traversed
$\Delta C_S$ = external concentration difference
$k_{P,A}$ = permeability constant of penetrant molecules in appendages

Poulsen (76) and others (10–12) discussed how an understanding of the density of the stratum corneum (because $D \propto 1/\text{viscosity}$) and its solvent and physicochemical properties have been utilized to control dermal delivery to humans. Similar approaches are necessary to promote dermal delivery to cattle and sheep but will necessitate an understanding of the viscosity and physicochemical properties of the appendagial pathways.

Anatomical and physiological studies of cattle and sheep skins, discussed earlier, indicate that the nature of the skin emulsion formed from sebum and sweat holds the clue to skin permeability. The emulsion forms in the infundibula of the follicles and, in oozing through follicle pores and through all (in sheep) or the upper layers (in cattle) of the stratum corneum, results in the deposition of emulsified sebum around the emerging fibers and, to a greater (in sheep) or lesser (in cattle) extent, on the wool and hair fibers. This emulsion probably is the medium through which molecules must pass to reach a point where they can diffuse through capillaries into the blood.

If this conclusion is correct, seasonal changes in the composition of the emulsion that result from previously discussed seasonal changes in sweat and sebum output are the reason why drugs appear to penetrate cattle skin faster in summer than in winter. *In vitro* studies on penetration of levamisole (IV) through excised cattle skin revealed that the drug penetrated 10 times faster through skin harvested in summer than through skin harvested in winter (71). A similar conclusion was drawn from measurements of blood levels of IV in cattle following application of trial pour-on formulations in summer and winter (71). Another possible example of reduced skin permeability in winter as compared to summer was the report (78) that a pour-on phosmet (VIII) at 40 mg/kg gave excellent control of Southern Cattle Tick when applied to cattle in Australia in March (early fall) or September or October (spring) but poor control in May (winter).

Preliminary results indicate that the penetration barrier (*i.e.*, in all probability, the emulsion) is a relatively polar solvent for penetrant molecules. Thus, studies of the penetration of IV through excised cattle skin (71) indicated that the partition coefficient of IV from aqueous solutions where it existed primarily as a neutral molecule was 0.84. The substitution of water by less polar solvents (*i.e.*, better solvents for IV) resulted in an apparent reduction in the skin–solvent partition coefficients. Dedek (72) concluded that polar organophosphorus compounds (*i.e.*, those with

relatively high water solubility) penetrate cattle skin most rapidly from solvents with low polarity, whereas nonpolar Compounds penetrate most rapidly from polar solvents.

Before a definitive correlation of these results with the solvent properties of the barrier can be made, it must be established (77) that diffusion in the barrier rather than clearance from it into an aqueous environment is rate determining for the organophosphorus compounds. Nevertheless, Dedek and coworkers (72–74) set out useful guidelines for formulation of topical drug delivery systems. The solubilities of some insecticides are given in Table I. Values of 738 compounds are in Ref. 75.

An additional problem arises if diffusion through the emulsion is the preferred pathway for drug absorption. Hence, if a dosage form is designed so that the drug has a favorable emulsion–vehicle partition coefficient, the drug will also have a strong tendency to diffuse up the emulsion coat on the hair and wool fibers in competition with its diffusion into the lower skin layers. This phenomenon could reduce the rate of skin penetration, but it could also lead to relatively sustained release of a drug over an extended period because the surface emulsion would act as a drug depot.

It must be reemphasized that the foregoing discussion is highly speculative and is included to stimulate experimental approaches towards elucidation of absorption mechanisms.

## POUR-ON AND SPOT-ON FORMULATIONS

Table VII lists some trials performed with pour-on or spot-on formulations on cattle and sheep. While there is a substantial body of evidence that topical drug delivery can be effective, the studies provided little information on the absorption mechanism and thus little information that could be used as a basis for designing future topical drug delivery systems. Some of the reasons for this sorry state of affairs are:

1. Failure to report the solvents used in trials. All but three of the reports tabulated in Table VII failed to mention the solvents used. Words such as "a suitable solvent," "a rapidly evaporating solvent," "a slowly evaporating solvent," or "an emulsifiable solvent" were used. Therefore, it is not possible to ascertain whether the failure of certain trials arose because the partition coefficient between the penetration barrier and the solvent or vehicle was so unfavorable that the rate and extent of absorption (*i.e.*, the bioavailability) were unacceptably low or because the drug was not active systemically. Furthermore, it is known that many organic solvents damage skin. This effect could increase drug bioavailability to a point where it gave an acceptable therapeutic response but produced unacceptable inflammation or lesions due to bacterial proliferation.

Without knowing the solvent used, it is also impossible to separate skin damage caused by residual drug from that possibly caused by the solvent. An example of the problems caused by failure to specify the solvents used in the formulations is provided by a report (78) of a comparison of nine pour-on formulations of organophosphorus insecticides against the Southern Cattle Tick in Australian Illawarra Shorthorns (Study 1 in Table VII). Because the solvents were not mentioned, it was impossible to evaluate why phosmet (VIII) at 40 mg/kg and chlorpyrifos (IX) at 60 mg/kg gave better tick control than the other seven products or why IX caused severe hair loss and skin burns while the VIII formulation did not.

2. Failure to restrain animals so that they cannot lick themselves or other animals. Drugs applied to the skin of animals can enter the systemic circulation by transdermal absorption or orally if the animals ingest the drug by licking. In many cases, drugs were applied to animals in such a way that they could not lick them off themselves (*e.g.*, drugs applied to cattle on the dorsal midline extending backward from the withers), but frequently no steps were taken to prevent the animals from licking drug from other animals.

The danger of this latter event leading to erroneous results is illustrated by a study (79) (Study 2 in Table VII) in which ronnel (VII) was applied on the dorsal midline of cattle from the hip forward and drug concentrations in the blood and other tissues were monitored as a function of time. The animals were yoked and their tails were tied for the first 10 days to prevent any oral ingestion; they were then allowed to run free. The blood levels of VII passed through a maximum after 36 hr and then fell away exponentially until about Day 11 when there was a dramatic increase in blood levels, eventually reaching a blood concentration that was 50% higher than the initial maximum. This phenomenon resulted from oral ingestion of drug after the animals were allowed to run free.

No difference in efficiency of a levamisole pour-on against nematodes in cattle was observed between restrained and free cattle (80). This result could arise because levamisole, as would be expected from the *in vitro* skin permeability studies (13), is very rapidly absorbed.

While it is appreciated that commercially useful pour-on formulations will be applied to free running animals, care must be exercised in judging the effectiveness of a formulation on the basis of trials where oral ingestion of topically applied drugs is possible.

3. The use of imprecise end-points to evaluate products. The ideal end-point for the evaluation of a drug delivery system is the therapeutic or pharmacological response that it is intended to elicit. However, as illustrated by Poole and Dooley (81) (Study 3 in Table VII), great care must be exercised in selecting the correct end-point. These authors discussed the effectiveness of a crufomate pour-on as an anthelmintic against GI parasites in cattle on the basis of both the egg count per gram of feces and the helminth counts at necropsy. The latter parameter indicated that the dosage form had no anthelmintic effect on abomasal helminths and had eratic efficacy on intestinal parasites. This finding was in contrast to an earlier report (82) that concluded, on the basis of egg counts per gram of feces only, that the treatment was effective against a variety of GI parasites in cattle. The authors (81) pointed out that ova in the feces indicated only the presence of an ovulating female helminth and should be used only as a diagnostic tool.

Because it is wasteful and often not possible to carry out necropsies to evaluate anthelmintic activities of pour-on formulations, it seems highly desirable to obtain blood level *versus* time profiles for drugs following dermal application and to use this information as a basis for developing new formulations.

These points illustrate the need to use caution in interpreting currently available reports on the effectiveness of pour-on formulations.

**Retention of Drugs on Skin**—Some reports indicated that a number of topically applied drugs persist on the skin or coat of animals for long periods and that only a fraction of the applied dose is absorbed (poor bioavailability). For example, the application of a 4% formulation of $^{32}P$-labeled VII in paraffin oil to cattle (Study 2 in Table VII) resulted in the appearance in the blood of an organosoluble fraction (undegraded drug and an oxygen analog) and water-soluble breakdown products (79). The maximum concentration of the organosoluble fraction was reached in 48 hr in restrained animals and had fallen to zero by Day 9. However, an appreciable amount of radioactivity was still present on the skin and hair after 10 weeks.

Although only very small amounts of $^{32}P$-labeled II were absorbed by cattle following the use of a dilute spray solution (in 20% xylene–octoxynol[2]), high levels of unchanged drug could still be detected on the skin after several weeks (83) (Study 4 in Table VII). Similarly, high levels of I were present on the skin of cattle 30 days after treatment with both a spray and pour-on made by diluting an emulsifiable concentrate of drug with water (84) (Study 5 in Table VII). These phenomena presumably result from chemical interactions of the drugs with the hair fibers or the skin proteins as discussed previously.

The ways in which these phenomena are likely to vary with the chemical properties of the drug are illustrated by reports that the bioavailability of IV from a pour-on (80) and spot-on (85) formulation was as good as or better than that from an oral formulation (Studies 6 and 7 in Table VII).

**Solvent Systems and Methods of Application**—Although many investigators have failed to report the exact solvent systems used in individual studies, there are frequent references to generic solvents. Pour-on formulations often consist of a suspension of a wettable powder in water or light mineral oils. Manufacturers do not usually reveal the formulation of the wettable powders, but they are generally composed of a wetting agent, a dispersing agent, and a clay or other inert carrier together with the drug. The wettable powder is employed to maximize the rate of dissolution of solid drug following its application to the skin.

Suspensions are also sometimes prepared in light liquid paraffin or other light mineral oils or oil-based water-immiscible drug solutions.

Light mineral oils are usually poor solvents for drugs, but they are often included in suspensions or solutions to hold the drug on the animal's skin. Some other solvent systems that have been described are 10% dimethyl sulfoxide-aromatic hydrocarbon (86), 10% cyclohexanol–aromatic hydrocarbon (86), dimethyl sulfoxide–amyl alcohol (1:4) (87), and various isopropanol-based solvents that contain light mineral oils, surfactants, or aromatic and nonaromatic solvents.

Water-insoluble compounds are often formulated as an emulsifiable concentrate. The emulsifiable concentrate contains one or more surfactant and produces an emulsion or micellar solution, with the water-insoluble drug in the nonaqueous phase, when mixed with water.

Various methods have been described for applying topical drug delivery systems. The simplest and most commonly used method is to pour the drug solution from a beaker or similar vessel onto the skin of the animal. Application of drugs to sheep skin has been achieved by parting the wool and dispensing the formulation from a needleless syringe (86).

One study (104) reported that the area of cattle skin to which IV had been applied was kept damp for several days. However, the effect of this procedure on penetration rates was not recorded.

One report (96) highlighted the fact that VII was absorbed more effectively from shorn than from unshorn areas of sheep skin.

## FUTURE WORK

There is an urgent need to establish firmly whether a relationship exists between the permeability of excised cattle and sheep skins to drug formulations in *in vitro* experiments and the permeability of the skins in live animals. Such relationships have been established (10, 12) for human skin penetration, and this fact has led to the production of a vast amount of quantitative information about the process.

If no direct relationship is found, it will suggest that such factors as the rate of production of sebum or sweat, the rate of blood flow, and even the rate at which keratinized epithelial cells are shed by the skin of live animals may be involved in the dermal drug delivery process. If this is the case, experiments must be carried out on live animals under various conditions to permit a rational approach to controlled dermal delivery. These experiments must be performed under conditions where applied drugs cannot be ingested and where their chance of being removed by rain or other environmental forces is minimized.

If the permeability of excised skin is directly related to *in vivo* behavior, the task of characterizing the absorption mechanism will be easier. The experimental methods already developed to study human skin penetration (13) can be applied to obtain quantitative information about the effects of breed, season, climate, age, nutritional status, and formulation on the transdermal delivery process.

# Pharmacokinetics of Sustained Serum Methotrexate Concentrations Secondary to Gastrointestinal Obstruction

**WILLIAM E. EVANS ˣ, ANASTASIOS TSIATIS, WILLIAM R. CROM, GARRETT M. BRODEUR, THOMAS C. COBURN, and CHARLES B. PRATT**

Received October 14, 1980, from the *Clinical Pharmacokinetics Laboratory, Biostatistics Section, Department of Diagnostic Imaging*, and the *Department of Hematology-Oncology, St. Jude Children's Research Hospital, Memphis, TN 38101.*
Accepted for publication March 30, 1981.

**Abstract** □ A physiological pharmacokinetic model for methotrexate was refined and used to simulate serum methotrexate concentrations after high dose (5000 mg/m$^2$) intravenous infusions with fixed normal values for all model parameters except the GI transit rate. There was good agreement between simulated and measured values when model simulations with the normal GI transit rate were compared to values measured following 109 doses administered to 27 patients with normal GI function. When model simulations were performed using GI transit rates representing 75, 50, and 10% of normal, there was a marked prolongation of the terminal serum methotrexate half-life, which was directly related to the reduction in the transit rate. When simulations were performed with GI transit reduced by 50%, the maximum amount of methotrexate in the GI lumen was 25% higher and occurred 4 hr later. Model simulations of serum methotrexate concentrations, using a GI transit rate reduced by 50%, were also in good agreement with serum concentrations measured in two patients with partial GI obstruction. These data establish a pharmacokinetic basis for previous clinical observations indicating sustained serum methotrexate concentrations in patients with GI obstructions and exemplify the utility of physiological pharmacokinetic models in assessing the potential effects of clinical variables on drug disposition.

**Keyphrases** □ Methotrexate—sustained serum concentrations in patients with GI obstruction, pharmacokinetics □ Pharmacokinetics—sustained serum methotrexate concentrations in patients with GI obstruction □ Model simulations—sustained serum methotrexate concentrations in patients with GI obstruction, pharmacokinetics

High dose methotrexate with leucovorin rescue is widely used as adjuvant therapy for osteosarcoma and in the treatment of acute leukemia, non-Hodgkin's lymphoma, head and neck carcinoma, and other solid tumors. However, the administration of high dose methotrexate leucovorin rescue carries with it the risk of severe toxicity, which may be fatal. A national survey (1) conducted prior to 1977 revealed a 6% incidence of mortality attributed to high dose methotrexate. For this reason, efforts have been made to identify factors that predispose to toxicity and to establish guidelines that reduce the risk of morbidity and mortality associated with high dose methotrexate therapy.

Previous studies indicated that certain clinical characteristics such as renal dysfunction, dehydration, pleural effusions, and ascites (2–7) are associated with a higher risk of toxicity following high dose methotrexate leucovorin rescue, presumably due to delayed methotrexate plasma clearance. One study (6) reported slower methotrexate elimination from plasma of two patients who had GI obstruction, in the absence of any previously described clinical features associated with delayed clearance. The present study was undertaken to establish the pharmacokinetic basis for sustained serum methotrexate concentrations in patients with GI obstruction.

## EXPERIMENTAL

**Pharmacokinetic Model**—The flow-limited physiological pharmacokinetic model of Bischoff *et al.* (8) (Scheme I) was used to simulate methotrexate concentrations in serum and tissues following high dose methotrexate intravenous infusions. Volume terms, flow rates, distribution ratios, rate constants, and transit times (*Appendix*) were those previously described by Bischoff *et al.* (8), unless otherwise stated. The volume terms and plasma flow rates were scaled to patient weight or body surface area by the equations shown in the *Appendix*, which were derived from previously published data (8, 9).

Previously published human studies (10–13) characterizing the renal clearance of methotrexate in patients with normal renal function established that the net renal clearance of methotrexate is serum concentration dependent. Glomerular filtration, tubular secretion, and tubular reabsorption are all components of methotrexate renal clearance (12), establishing the basis for saturable processes at high serum concentrations with the resulting lower net renal clearance. Therefore, net clearance probably is determined by both first-order (filtration) and saturable (secretion, reabsorption) processes. However, the rate constants ($V_{max}$ and $K_M$) for tubular secretion and reabsorption of methotrexate have not been established in humans. Therefore, net renal clearance of methotrexate was calculated from the least-squares linear regression of net renal clearance on log serum concentrations, using the published data summarized in Table I. The regression line was described by the equation $Cl_R$ (milliliters per minute per meter$^2$) = 92.0 − (13.8)(ln $C_p$), where $r^2$ = 0.81.

Secretion of methotrexate into bile from the liver was modified to represent a saturable process with $V_{max}$ = 1000 μg/min and $K_M$ = 5 μg/ml. Therefore, the ratio of $V_{max}$ to $K_M$ (200) was the same as that used by Bischoff *et al.* (8), but the differential equation permitted saturation of biliary secretion at high serum concentrations. As described in the original model-development work by Bischoff *et al.* (8), the biliary ex-

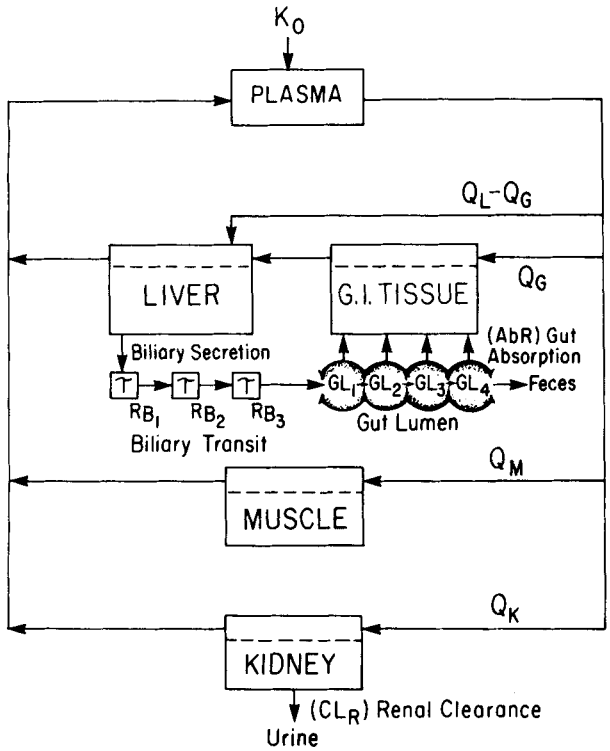

*Scheme I—Scheme of physiological pharmacokinetic model for methotrexate simulations (modified from Ref. 8).*

cretion parameter is a conjectural value to create the best fit to data from normal subjects. The assignment of $V_{max}$ and $K_M$ values in the present study represents a conservative approach by limiting the maximum velocity of drug entry into the GI compartment. GI blood flow ($Q_G$) was reduced from 82% of liver blood flow (as used by Bischoff) to 66% of liver blood flow. This value is more physiological since only ~80% of portal blood flow originates in the GI tract (14) and total portal blood flow is ~82% of hepatic blood flow (*i.e.*, 0.80 × 0.82 = 0.66). All other model parameters, including strong specific tissue binding constants, multicompartment models of biliary transit and gut lumen transit, and zero-order gut absorption, were the same as previously described (8).

A set of differential equations (*Appendix*) describing the mass balances of each model compartment was used to simulate the methotrexate concentration in each compartment as a function of time. These differential equations were simultaneously solved by a numerical method using the Runge–Kutta (15) algorithm.

Simulations of methotrexate serum and tissue concentrations were made using the previously described ("normal") values for all model parameters except GI transit time. To assess the influence of GI obstruction on serum disposition of methotrexate, model simulations were made using GI transit rates ($K_f$) of 0.001, 0.00075, 0.0005, and 0.0001 $min^{-1}$, representing 100, 75, 50, and 10% of the normal transit rate, respectively. All model simulations were for a 6-hr constant-rate intravenous infusion of 5000 mg of methotrexate/$m^2$.

For comparison, serum methotrexate concentrations measured following 109 infusions administered to 27 patients (6–30-hr concentrations) and 38 infusions administered to 21 of these patients (36–78-hr concentrations) are shown with model simulations. All of these patients had normal renal, hepatic, and GI function and had none of the previously described clinical features that predispose to toxicity. The clinical and laboratory evaluations of these patients were previously described in detail (6). Serum methotrexate concentrations measured in two patients with GI obstruction are also shown for comparison. The clinical and laboratory findings in these two patients were previously described (6). Both patients had partial small bowel obstructions secondary to tumor compression at the time of high dose methotrexate administration. Roentgenographic documentation of these GI obstructions is presented in Fig. 1.

Methotrexate serum concentrations for all of these patients were determined in duplicate by at least two methods: a radioenzymatic assay using dihydrofolate reductase (New England Enzyme) and an enzyme immunoassay (SYVA). These assays were shown to produce results comparable to a high-pressure liquid chromatographic assay and to cross-react <4% with the major methotrexate metabolite, 7-hydroxymethotrexate (16).

**Table I—Net Renal Clearance of Methotrexate**

| Net Renal Clearance, ml/min/$m^2$ | Mean Serum Concentration, $\mu M$ |
|---|---|
| 118 | 0.45[a] |
| 103 | ~0.2[b] |
| 78 | ~1.0[c] |
| 65 | 10.0[a] |
| 59 | ~10.0[d] |
| 20–50 | ~100.0[e] |

## RESULTS

As shown in Fig. 2, there was good agreement between simulated and measured serum methotrexate concentrations in patients with normal renal, hepatic, and GI function, using normal model parameters. Figure 2 also shows simulations with GI transit rates reduced by 25, 50, and 90%. These model simulations demonstrate a marked decrease in the rate of decline in serum concentrations beginning ~24–30-hr postinfusion. The prolongation of methotrexate half-life during this time interval was directly related to the reduction in the GI transit rate (Table II). These simulations also demonstrate that the GI transit rate has little influence on serum methotrexate half-life during the first 24 hr postinfusion. This finding is not surprising since most methotrexate is eliminated *via* renal clearance during this time interval and the amount of methotrexate undergoing enterohepatic circulation is relatively small.

There was good agreement between serum methotrexate concentrations measured in the two patients with GI obstruction and model simulations with the GI transit rate reduced by 50% (Fig. 3).

The simulated amounts (milligrams) of methotrexate in the GI lumen at selected times postinfusion, calculated as:

$$A_{MTX_{GL}} = \frac{(C_{GL_1} + C_{GL_2} + C_{GL_3} + C_{GL_4})}{4} V_{GL} \qquad \text{(Eq. 1)}$$

are summarized in Table III for model simulations using the normal GI transit rate and a transit rate reduced by 50%. As shown, the maximum amount of methotrexate in the GI lumen was ~25% higher and occurred 4 hr later when the GI transit rate was reduced by 50%. More importantly, the amount of methotrexate in the GI lumen declined more slowly when GI transit was reduced. By 48 hr, the amount of methotrexate was approximately four times higher when the GI transit was reduced 50% and more than 10-fold higher by 96 hr. Moreover, the amount of methotrexate in the GI lumen at 72 hr (with reduced transit) was comparable to conventional (25 mg/$m^2$) oral doses of methotrexate, although it represents <1% of the administered dose.

## DISCUSSION

A previous study (6) suggested that GI obstruction could result in a prolonged serum methotrexate half-life following administration of high dose methotrexate. Since prolongation of methotrexate elimination places patients administered high dose methotrexate at increased risk for severe toxicity (6, 7, 17), it is important to establish the clinical variables that may alter methotrexate disposition. This has been done for clinical features such as renal dysfunction (11, 18), pleural effusion (2, 5), and ascites (5). Although an earlier report described (6) previous clinical observations of sustained serum methotrexate concentrations in patients with GI obstruction, the theoretical basis for these observations had not been established.

In the present study, a previously described physiological pharmacokinetic model (8) for methotrexate disposition was used to assess the effect of the GI transit rate on methotrexate disposition. The original model assumes that methotrexate is not metabolized. However, subsequent studies have established that methotrexate is metabolized to 7-hydroxymethotrexate and studies in this laboratory[1] indicate that nonrenal clearance of methotrexate in children is ~15 ml/min/$m^2$. Metabolic clearance was assumed to be negligible for the present study, and was the same for all model simulations (0 ml/min/$m^2$).

By using model parameters that were refined from the original model

[1] W. E. Evans *et al.*, unpublished data.

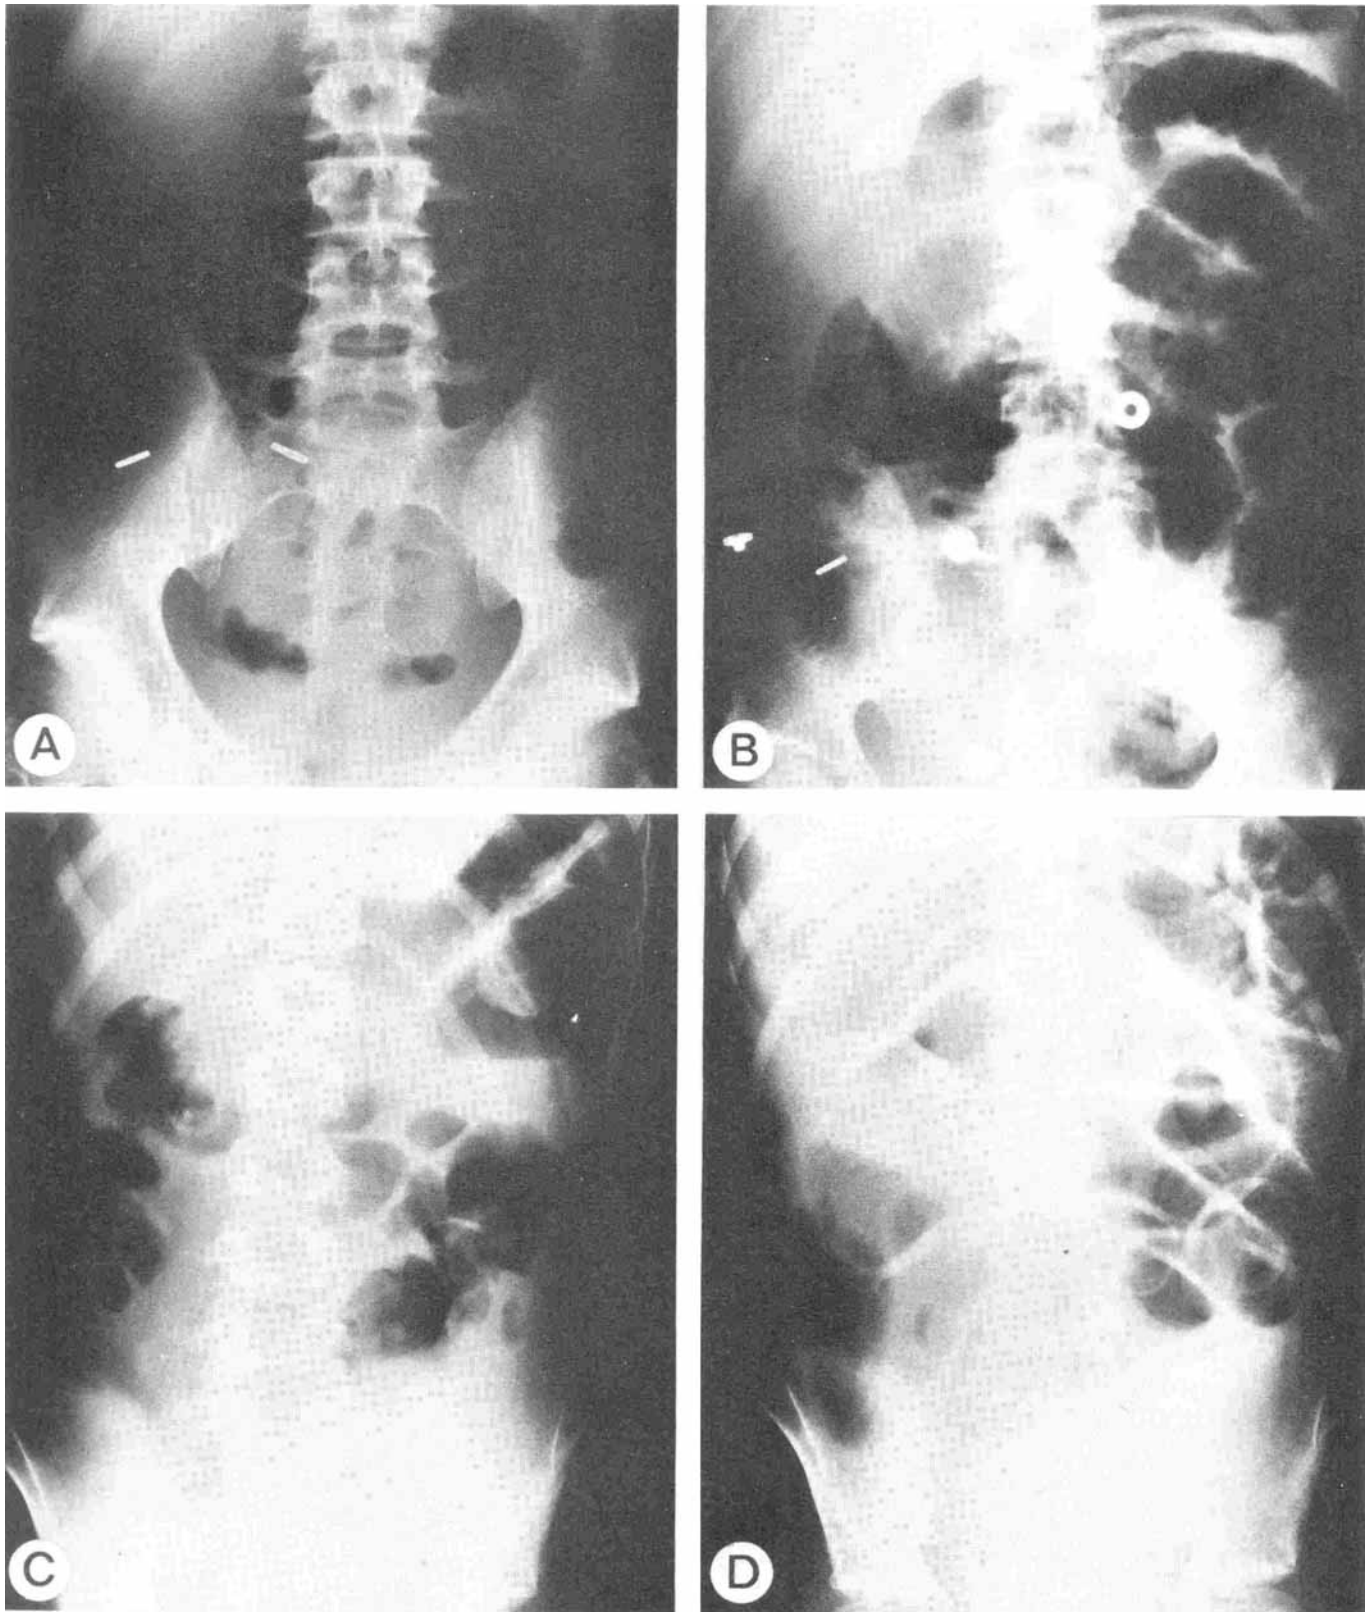

**Figure 1**—*Abdominal roentgenograms of the two patients with partial GI obstructions. Key: A, Patient 1, 9 days prior to high dose methotrexate; B, Patient 1, 6 days following methotrexate; C, Patient 2, 2 days prior to high dose methotrexate; and D, Patient 2, 19 days following methotrexate. Both sets of roentgenograms demonstrate partial GI obstruction during the evaluation period.*

(8), simulations were produced with all model parameters held constant except for the GI transit rate. These simulations demonstrated that greater amounts of methotrexate accumulate in the intestinal lumen when GI transit is reduced. The simulated amount of methotrexate in the GI lumen decreased more slowly when GI transit was reduced such that the amount in the lumen was more than 10-fold higher at 96 hr when transit was reduced by 50%. Moreover, the reduction of the GI transit rate and the resulting increased accumulation of methotrexate resulted in a prolongation of the terminal serum methotrexate half-life, which was directly related to the extent of reduction in GI transit. Model simulations

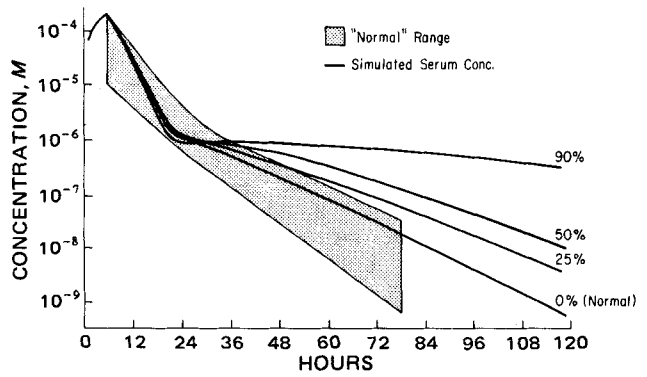

**Figure 2**—*Simulation of methotrexate serum concentrations* versus *time (solid line) by physiological pharmacokinetic model using normal GI transit rate and transit rate reduced by 25, 50, and 90% from normal. Shaded area represents range of serum concentrations measured following 109 doses administered to 27 patients (6–24-hr measurements) and 38 doses administered to 21 patients (25–78-hr measurements).*

with GI transit rate reduced by 50% were comparable to serum concentrations measured in two patients with partial GI obstructions.

These data indicate that the prolongation of serum methotrexate half-life produced by GI obstruction can result in serum methotrexate concentrations being sustained at cytotoxic levels beyond the period of conventional leucovorin rescue. These data also provide the theoretical basis for previously described (19) changes in methotrexate disposition in a patient with vincristine-induced ileus. The observed difference in simulated serum methotrexate concentrations when the GI transit rate was reduced 25% suggests that only a modest compromise in GI function could affect methotrexate disposition and provides a potential mechanism for other drug interactions.

The importance of altered GI function for a drug such as methotrexate, which is eliminated <5% in the feces, is related to the fact that the high dosage of methotrexate administered (*i.e.*, 5000 mg/m$^2$) produces serum concentrations (*i.e.*, $10^{-3}$ *M*) exceeding the minimum cytotoxic concentration (*i.e.*, $\sim 10^{-8}$ *M*) by ~100,000-fold. Thus, perturbation of an excretory pathway that eliminates only a small percentage of the administered dose becomes important. Moreover, reduction in GI transit would result in a more localized accumulation of methotrexate presented to the GI lumen, which produces more rapid saturation of the limited absorptive sites and thereby prolongs reabsorption. Thus, fecal elimination is retarded and reabsorption is delayed, resulting in sustained serum methotrexate concentrations.

The importance of the actual site of GI obstruction was not addressed in the present study, which assumed a consistent reduction in transit rate throughout the GI tract. It is conceivable that partial or complete obstruction in the upper portion of the small bowel might result in a greater localization of methotrexate (*versus* colonic obstruction), while complete obstruction at any site may lead to other clinical complications that could alter methotrexate disposition (*i.e.*, vomiting, malnutrition, *etc.*). These

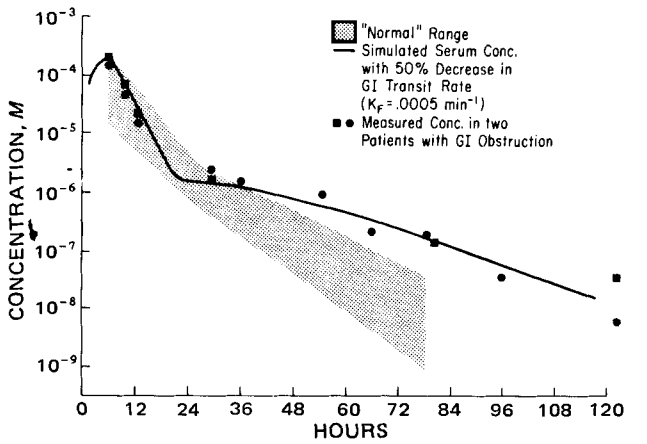

**Figure 3**—*Simulations of methotrexate serum concentrations* versus *time (solid line) by physiological pharmacokinetic model when GI transit rate is reduced by 50% from normal. Shaded area is as described in Fig. 2.*

**Table II—Terminal Serum Half-Life of Methotrexate from Simulated Data**

| GI Transit, min$^{-1}$ (Percent of Normal) | Half-Life, hr |
|---|---|
| 0.001 (100%) | 8.4 |
| 0.00075 (75%) | 9.8 |
| 0.0005 (50%) | 14.0 |
| 0.0001 (10%) | 39.0 |

questions await further study, as does the clinical significance of potential drug-induced alterations in GI motility.

## APPENDIX

The symbols used are:

$AbR$ = absorption rate, micrograms per minute
$aR$ = strong specific binding, micrograms per gram
$C$ = concentration, micrograms per milliliter or micrograms per gram
$Cl_R$ = renal clearance, milliliters per minute
$K_f$ = transit rate in gut lumen, minute$^{-1}$ (reciprocal of transit time)
$K_M$ = Michaelis–Menten constant, micrograms per milliliter
$K_{0(t)}$ = drug infusion rate, micrograms per minute
$Q$ = plasma flow rate, milliliters per minute
$R$ = tissue-to-plasma equilibrium distribution ratio for linear binding
$r$ = drug transport rate in bile, micrograms per minute
$t$ = time, minutes
$V$ = volume, milliliters
$V_{max}$ = maximum rate of saturable process, micrograms per minute
$Wt$ = body weight, kilograms
$\tau$ = nominal residence time in bile transit subcompartments, minutes

The subscripts used are:

$G$ = GI tissue
$GL$ = gut lumen
$K$ = kidney
$L$ = liver
$M$ = muscle
$P$ = plasma
1, 2, 3, 4 = gut lumen or bile subcompartments

The differential equations for the physiological model are as follows.

For plasma:

$$\frac{dC_P}{dt} = \frac{K_{0(t)} + Q_L\frac{C_L}{aR_L} + Q_K\frac{C_K}{aR_K} + Q_M\frac{C_M}{R_M} - (Q_L + Q_K + Q_M)C_P}{V_P} \quad \text{(Eq. A1)}$$

For kidneys:

$$\frac{dC_K}{dt} = \frac{Q_K\left(C_P - \frac{C_K}{aR_K}\right) - Cl_R\frac{C_K}{aR_K}}{V_K} \quad \text{(Eq. A2)}$$

For the liver:

$$\frac{dC_L}{dt} = \frac{(Q_L - Q_G)\left(C_P - \frac{C_L}{aR_L}\right) + Q_G\left(\frac{C_G}{aR_G} - \frac{C_L}{aR_L}\right) - \frac{V_{max_L}C_L/aR_L}{K_{M_L} + C_L/aR_L}}{V_L} \quad \text{(Eq. A3)}$$

For muscle:

$$\frac{dC_M}{dt} = \frac{Q_M\left(C_P - \frac{C_M}{R_M}\right)}{V_M} \quad \text{(Eq. A4)}$$

For GI tissue:

$$\frac{dC_G}{dt} = \frac{Q_G\left(C_P - \frac{C_G}{aR_G}\right) + AbR_{GL}}{V_G} \quad \text{(Eq. A5)}$$

**Table III—Amount of Methotrexate Accumulated in GI Lumen from Simulated Data for 1.0-m² Patient**

| Hours | GI Transit Rate, $min^{-1}$: 0.001 (Normal), mg | 0.0005 (50% Normal), mg |
|---|---|---|
| Peak[a] | 444 | 553 |
| 24 | 319 | 496 |
| 48 | 37 | 148 |
| 72 | 5 | 36 |
| 96 | 0.7 | 8 |

[a] Sixteen hours for normal GI transit and 20 hr for 50% reduced GI transit.

For the gut lumen:

$$\frac{dC_{GL_1}}{dt} = \frac{4r_{B_3} - (4\,K_f V_{GL} C_{GL_1}) - AbR_{GL_1}}{V_{GL}} \quad \text{(Eq. A6}a\text{)}$$

$$\frac{dC_{GL_2}}{dt} = \frac{4K_f V_{GL}(C_{GL_1} - C_{GL_2}) - AbR_{GL_2}}{V_{GL}} \quad \text{(Eq. A6}b\text{)}$$

$$\frac{dC_{GL_3}}{dt} = \frac{4K_f V_{GL}(C_{GL_2} - C_{GL_3}) - AbR_{GL_3}}{V_{GL}} \quad \text{(Eq. A6}c\text{)}$$

$$\frac{dC_{GL_4}}{dt} = \frac{4K_f V_{GL}(C_{GL_3} - C_{GL_4}) - AbR_{GL_4}}{V_{GL}} \quad \text{(Eq. A6}d\text{)}$$

The gut absorption rate is given by

$$AbR_{GL_i} = \frac{V_{\max_{GL}} C_{GL_i}}{K_{M_{GL}} + C_{GL_i}} \qquad i = 1, \ldots, 4 \quad \text{(Eq. A7}a\text{)}$$

$$AbR_{GL} = \frac{AbR_{GL_1} + AbR_{GL_2} + AbR_{GL_3} + AbR_{GL_4}}{4} \quad \text{(Eq. A7}b\text{)}$$

The biliary transit rate is given by:

$$\frac{dr_{B_3}}{dt} = \frac{r_{B_2} - r_{B_3}}{\tau} \quad \text{(Eq. A8}a\text{)}$$

$$\frac{dr_{B_2}}{dt} = \frac{r_{B_1} - r_{B_2}}{\tau} \quad \text{(Eq. A8}b\text{)}$$

$$\frac{dr_{B_1}}{dt} = \frac{\dfrac{V_{\max_L C_L/aRL}}{K_{M_L} + C_L/aR_L} - r_{B_1}}{\tau} \quad \text{(Eq. A8}c\text{)}$$

Renal clearance is given by:

$$Cl_R = BSA92.0 - (13.8)\,(\ln C_P) \quad \text{(Eq. A9)}$$

where:

$V_{\max_L} = 1000\ \mu g/min$
$K_{M_L} = 5\ \mu g/ml$
$V_{\max_{GL}} = 1900\ \mu g/min$
$K_{M_{GL}} = 200\ \mu g/ml$
$\tau = 10$
$R_K = 3.0$
$R_G = 1.0$
$R_L = 3.0$
$R_M = 0.15$

$$aR_K = R_K + \frac{0.3}{C_P}$$

$$aR_G = R_G + \frac{0.1}{C_P}$$

$$aR_L = R_L + \frac{0.4}{C_P}$$

$K_f = 0.001\ min^{-1}$ (normal value)

Volume equal:

$$V_P = 44 \cdot Wt^{0.99}\ \text{(plasma)} \quad \text{(Eq. A10}a\text{)}$$

$$V_K = 7.5 \cdot Wt^{0.85}\ \text{(kidneys)} \quad \text{(Eq. A10}b\text{)}$$

$$V_L = 34 \cdot Wt^{0.87}\ \text{(liver)} \quad \text{(Eq. A10}c\text{)}$$

$$V_G = 49 \cdot Wt^{0.94}\ \text{(GI)} \quad \text{(Eq. A10}d\text{)}$$

$$V_{GL} = 49 \cdot Wt^{0.94}\ \text{(GI lumen)} \quad \text{(Eq. A10}e\text{)}$$

$$V_M = 500 \cdot Wt\ \text{(muscle)} \quad \text{(Eq. A10}f\text{)}$$

where $V$ is in milliliters and $Wt$ is in kilograms.

Organ plasma flow equals:

$$Q_K = 24.5 \cdot Wt^{0.792}\ \text{(kidneys)} \quad \text{(Eq. A11}a\text{)}$$

$$Q_L = 29.96 \cdot Wt^{0.767}\ \text{(liver)} \quad \text{(Eq. A11}b\text{)}$$

$$Q_G = 0.66 \cdot Q_L\ \text{(GI)} \quad \text{(Eq. A11}c\text{)}$$

$$Q_M = 18.17 \cdot Wt^{0.738}\ \text{(muscle)} \quad \text{(Eq. A11}d\text{)}$$

where $Q$ is in milliliters/minutes and $Wt$ is in kilograms.

# Concentration of Perfluorohexyl Bromide in Dog Plasma and Selected Tissues

**MAUREEN SCRIME and JEROME EDELSON** ˣ

Received February 19, 1981, from the *Department of Drug Metabolism and Disposition, Sterling-Winthrop Research Institute, Rensselaer, NY 12144.* Accepted for publication April 2, 1981.

**ABSTRACT** □ Beagle dogs received single perfluorohexyl bromide doses, either 30.2 g/kg po or 3.8 g/kg intratracheally. The apparent first-order plasma half-life during the terminal elimination phase was ~8 hr after oral treatment and >8 hr after intratracheal administration. Tissue analysis showed the highest mean concentration of the compound in abdominal fat 1 week after intratracheal administration. One dog had detectable levels in abdominal fat 4 weeks after treatment by either administration route.

**Keyphrases** □ Perfluorohexyl bromide—tissue and blood plasma levels in dogs after oral and intratracheal administration □ Fluorocarbons—perfluorohexyl bromide, tissue and blood plasma levels in dogs after oral and intratracheal administration □ Radiopaque contrast agents—perfluorocarbons, perfluorohexyl bromide, tissue and plasma levels in dogs after oral and intratracheal administration

Perfluorocarbon compounds were recently investigated for their potential use as radiopaque diagnostic agents. Perfluorooctyl bromide and perfluorohexyl bromide (I) are the least toxic of these compounds (1–11). Among the most frequently performed radiodiagnostic procedures with these two compounds are bronchography, alveolography (4, 5), and gastroenterography (4, 7).

## BACKGROUND

One desirable property in contrast agents used in bronchography and alveolography is rapid elimination from the lungs. Radiopaque agents currently available for bronchography and alveolography are retained in the lungs for long periods; thus, they may irritate pulmonary tissues and cause varying degrees of damage (5). Vaporization of the perfluorocarbons at body temperature (4), a property not characteristic of other radiopaque agents, predisposes them to efficient elimination from the lungs. Although mucocilliary clearance is involved in elimination of the "neat" perfluorocarbons, evaporation plays the major role in elimination from the lungs (4, 5). Radiographic measurements demonstrated the elimination time from the lungs to be 30–60 min for I, as compared to 3–6 hr for the octyl derivative (4).

Good quality radiogastroenterograms have been obtained with these compounds since low viscosity and low surface tension allow them to flow freely into tiny folds and orifices (4, 6, 7). Visualization and delineation were similar for the two compounds (4). However, by vaporizing in the bowel, I provided a unique gas-contrast resolution, which allowed exceptional mucosal definition (4, 7, 8).

Elimination of the octyl derivative after oral and intratracheal administration to beagle dogs was reported (11). High concentrations of this compound were found in abdominal fat 4 weeks after medication. The present study presents elimination characteristics of I in plasma and selected tissues after oral and intratracheal administration to beagle dogs.

## EXPERIMENTAL

**Animal Procedure**—Two groups of beagle dogs, six males and six females in each group, received either a 30.2-g/kg po dose or a 3.8-g/kg intratracheal dose of I[1]. A gastric tube was used for oral administration. The intratracheal dose was instilled under light thiopental[2] anesthesia (35 mg/kg iv); a gastric tube was inserted into the trachea until it reached a point several centimeters above the bifurcation of the right and left bronchi.

Blood samples were drawn at various intervals from the femoral vein. Potassium oxalate was used as the anticoagulant. The blood was promptly centrifuged at 2500 rpm for 10 min, and the plasma was separated and stored until analysis.

Two males and females from each group were anesthetized and killed by pentobarbital sodium[2] overdose (45 mg/kg iv) 7, 14, and 28 days after treatment. Samples of the abdominal fat, gonads, adrenals, mesenteric and thoracic lymph nodes, and lungs were stored in glass jars at −4° until assay. Previous studies showed that the highest levels of the octyl derivative were found in these tissues (5, 11). Bile samples were collected from the intratracheally tested group only.

**Extraction Procedure**—Plasma samples, 1 ml each, were extracted with 1 ml of isooctane containing 0.25 μg of tetrachlorodifluoroethane[3], the internal standard for the assay. The mixture was mechanically shaken for 10 min and centrifuged for 10 min at 2500 rpm. A sample of the organic phase, 2.5 μl, was analyzed by GC.

Tissue samples, up to 2 g of frozen tissue depending on the sample size, were minced with a scalpel and placed into a 5-ml polyethylene homogenization vessel[4]. A known volume of isooctane containing the internal standard, approximately two volumes per gram of tissue, was added, and the mixture was homogenized for 1 min. The homogenization vessel was submerged in an ice bath during homogenization. The homogenate was centrifuged at 2500 rpm for 10 min, and 2.5 μl of the organic phase was assayed.

Known amounts of I were added to samples of normal, control dog plasma and tissue; these samples were freshly prepared and used as standards. They were extracted and assayed as described.

**GC**—All samples were analyzed using a gas chromatograph equipped

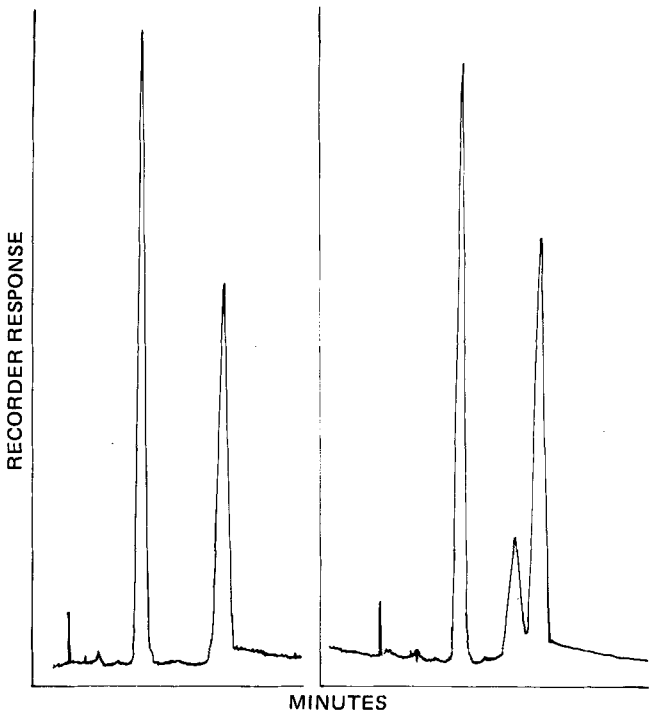

**Figure 1**—*Chromatogram of extracted dog plasma containing the internal standard (left) and the same sample containing 190 ng of I/ml (right).*

with a $^{63}$Ni-electron-capture detector[5], an automatic sampler, and an integrator. The silanized glass column, 1.8 m × 3 mm i.d., was packed with 80–100-mesh, porous polymer beads[6]. The oven was operated in the isocratic mode at 175°; both the injection port and detector temperatures were 250°. The flow rate of the carrier gas, a mixture of 7% methane in argon[7], was 40 ml/min. Under these conditions, the retention times of I and the internal standard were 6.5 and 7.8 min, respectively.

## RESULTS AND DISCUSSION

Figure 1 shows typical chromatograms of plasma extracted by the described procedure. The relationship between the relative peak area ratio and the concentration of I was linear up to 200 ng/ml; the computer estimated the standard line by a least-squares method. The concentration in the unknown sample was calculated from the equation for the extracted standards line. The minimum quantifiable level, defined as that value whose 80% confidence limit just encompassed zero, was 10 ng/ml or gram of tissue.

The mean plasma concentrations of I following oral and intratracheal administration are shown on Figs. 2 and 3, respectively. The apparent first-order terminal elimination half-life following oral administration of I was ~8 hr, as determined by linear regression on the logarithm of the plasma concentration and sample time data ($r$ = 0.993). By the intratracheal route, the decline in plasma I concentration did not appear to follow first-order kinetics (Fig. 3); plasma levels were higher than observed after oral treatment, indicating greater absorption by this administration route.

In the orally dosed group, the only tissue in which I was detected beyond the 1st week was abdominal fat (Table I). No detectable level of I was found in the gonads, and only one low level was found in a 1-week lung sample. The tissue values were highly variable. In the intratracheally dosed dogs, the highest levels of I were seen in the abdominal fat (Table II); I was not detected in bile or ovaries, and only one low level was found in the testes. After 1 week, detectable levels of I were found only in abdominal fat and lymph nodes. Only one dog still had low levels of I in abdominal fat, by either treatment route, 4 weeks after medication. The octyl derivative, which was administered at similar doses in the previous study (11), also was detected in abdominal fat 4 weeks after medication.

The level of I detected in the one beagle 4 weeks after oral medication was 2% of the mean level of the octyl derivative detected in the eight animals in the previous oral study. Similarly, the level of I detected in the one dog 4 weeks after intratracheal administration was 1% of the mean level of the octyl derivative detected in the four animals that were treated by intratracheal administration of the octyl derivative in the previous study. Levels of I in abdominal fat of the remaining dogs, 4 weeks after treatment, were below the minimum quantifiable level of the assay.

Thus, detectable levels of both the octyl- and hexylperfluorocarbon compounds were seen 4 weeks after oral and intratracheal administration to beagle dogs. Levels of I observed were 1–2% those of the octyl derivative, indicating that the higher vapor pressure of I facilitated elimination from the body.

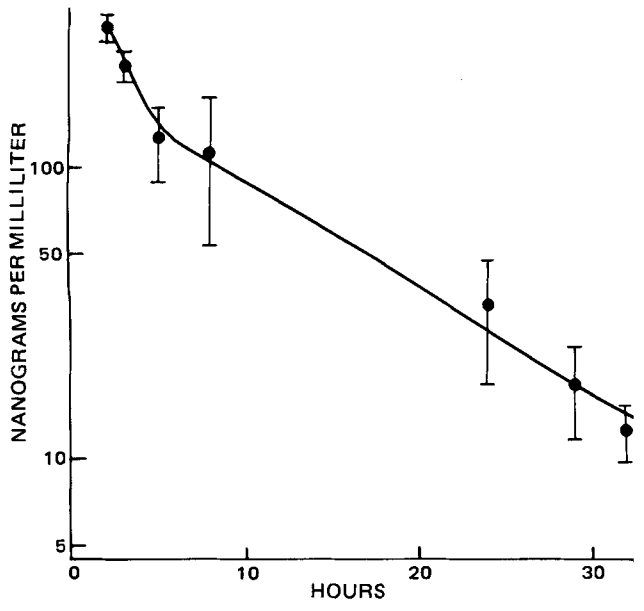

**Figure 2**—*Plasma concentrations in beagle dogs after oral administration of 30.2 g of I/kg;* n = *12. The vertical bar represents 2* SE.

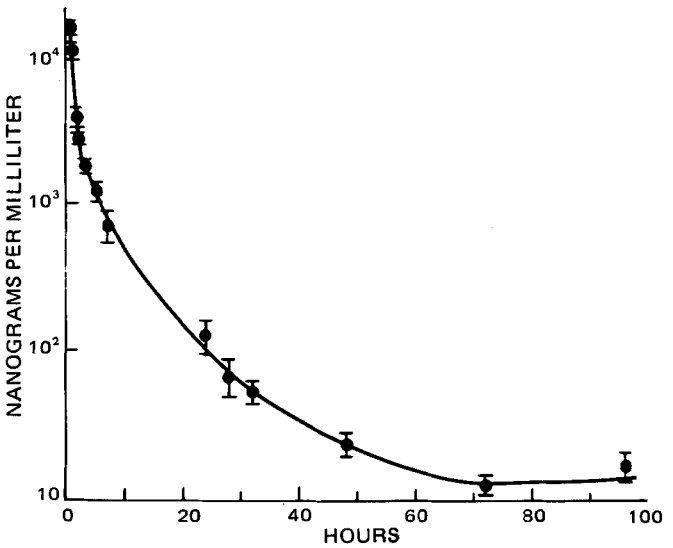

**Figure 3**—*Plasma concentrations in beagle hounds after intratracheal administration of 3.8 g of I/kg;* n = *12. The vertical bar represents 2* SE.

# Dose-Dependent Protein Binding and Disposition of Prednisolone in Rabbits

**MARIO L. ROCCI, Jr., and WILLIAM J. JUSKO** ˣ

Received November 28, 1980, from the *Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Amherst, NY 14260.* Accepted for publication March 25, 1981.

**Abstract** □ An animal model was sought that would mimic humans with regard to the dose-dependent pharmacokinetics of prednisolone. Four rabbits were each given 0.5 and 10 mg iv of prednisolone, and timed blood samples were obtained. Plasma prednisolone and prednisone concentrations were assayed by high-performance liquid chromatography, and protein binding was assessed using equilibrium dialysis at 37°. Increases in the systemic clearance, volume of distribution at steady state, mean residence time (in three of four rabbits), and variance of residence time occurred as dose was increased. As in humans, prednisolone was partly converted to prednisone in the rabbit. Transcortin and albumin concentrations and their affinity constants for binding prednisolone were also similar to humans.

**Keyphrases** □ Prednisolone—dose-dependent protein binding and pharmacokinetics, rabbits □ Binding, protein—prednisolone, pharmacokinetics, rabbits □ Pharmacokinetics—prednisolone, protein binding, rabbits

Prednisolone and its pharmacologically inactive prodrug, prednisone, are synthetic glucocorticoids widely used in the treatment of various disease entities including asthma, shock, and nephrotic syndrome. Jusko and Rose (1) demonstrated nonlinear pharmacokinetics of these compounds in humans, characterized by increases in their total plasma clearance with increases in dose. Furthermore, the serum protein binding of prednisolone is nonlinear at therapeutic serum concentrations owing to the existence of two binding proteins (2). This binding appears to explain most, but not all, of the nonlinearity in prednisolone pharmacokinetics in humans (1).

To assess mechanisms contributing to this nonlinear disposition, an animal model is needed that mimics humans with regard to the serum protein binding and disposition of prednisolone. The serum protein binding of prednisolone was previously examined in rat, rabbit, canine, and human serum (3), with the rabbit being most like the human in type and degree of nonlinear binding. This study further evaluated the rabbit as an animal model for dose-dependent disposition of prednisolone.

## EXPERIMENTAL

**Methods**—Four New Zealand White rabbits, 3.0–3.9 kg, received 0.5- and 10-mg iv equivalent doses of prednisolone as the sodium succinate.

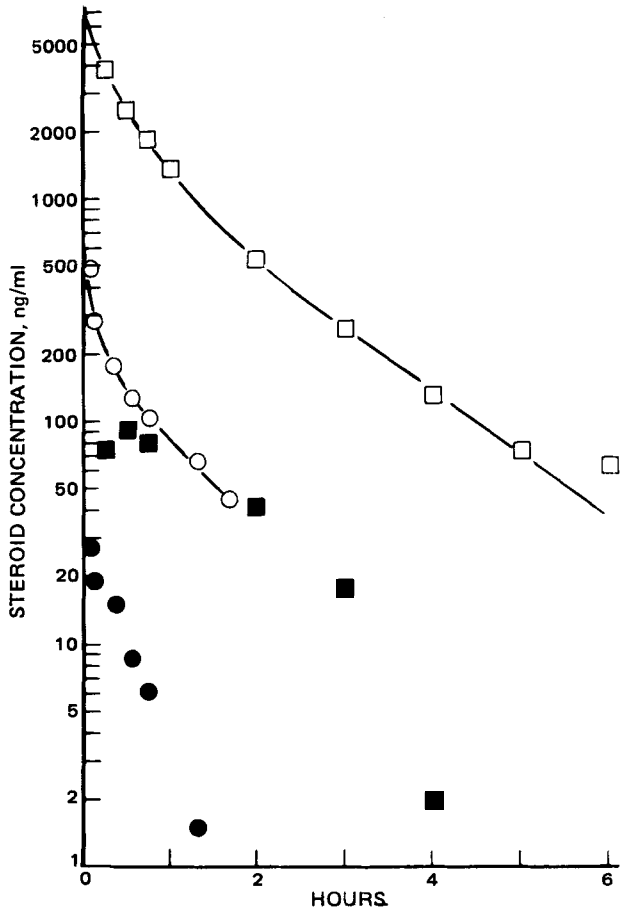

**Figure 1**—*Serum concentration* versus *time profiles of prednisolone (○,□) and prednisone (●,■) after 0.5 mg of prednisolone (○,●) and 10 mg of prednisolone (□,■) intravenously in Rabbit 2.*

A balanced crossover design was used, with 2 weeks between crossover. Rabbit body weight did not change appreciably over the experimental period. The drug was administered into the lower left marginal ear vein over 15 sec. Blood samples (~3 ml) were obtained from the right lower marginal ear vein just prior to dosing and at 0.08, 0.17, 0.25, 0.5, 0.75, 1, 2, 3, 4, 6, and 8 hr following drug administration.

**Sample Analysis**—Serum samples were analyzed for prednisolone and prednisone using the high-performance liquid chromatographic (HPLC) technique described earlier (4). Serum protein binding of prednisolone was evaluated at 37° by equilibrium dialysis with [$^3$H]-prednisolone. Details of the protein binding technique and data analysis were presented previously (3).

**Pharmacokinetics**—The area under the curve for prednisone ($AUC_P$) and prednisolone ($AUC_{Pn}$), the systemic clearance ($Cl_T$), mean residence time ($MRT$), variance of the residence time ($VRT$), and volume of distribution at steady state ($V_D^{ss}$) were obtained through use of the LAGRAN computer program, which provides model-independent estimates of these pharmacokinetic parameters based on area/moment analysis[1].

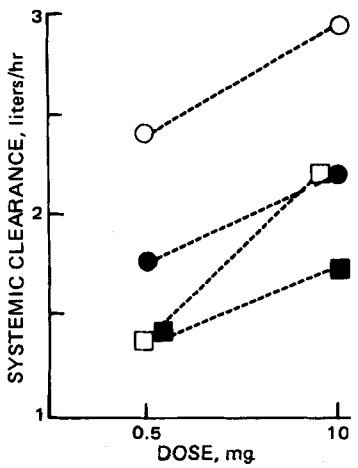

**Figure 2**—*Systemic clearance ($Cl_T$) of prednisolone as a function of dose. The stippled lines connect $Cl_T$ values from the same rabbit.*

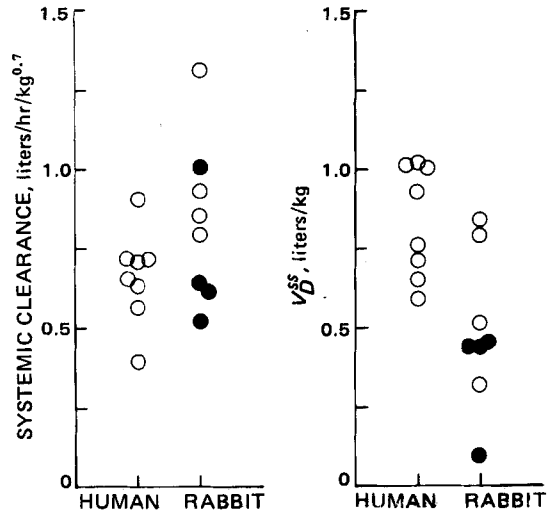

**Figure 3**—*Rabbit $Cl_T$ values (animal scale-up) and $V_D^{ss}$ values compared to those observed in humans. The solid and open symbols in the rabbit data represent values from the low and high dose studies. Human data are from Rose* et al. *(6).*

The free drug clearance ($Cl_{T,free}$) and the transcortin (CBG) free drug clearance ($Cl_{T,CBG\text{-}free}$) of prednisolone were computed using:

$$Cl_{T,free} = \text{dose}/AUC_{Pn,free} \quad \text{(Eq. 1)}$$

$$Cl_{T,CBG\text{-}free} = \text{dose}/AUC_{Pn,CBG\text{-}free} \quad \text{(Eq. 2)}$$

where $AUC_{Pn,free}$ and $AUC_{Pn,CBG\text{-}free}$ are the areas under the serum concentration *versus* time curves of free and CBG-free prednisolone.

Approximate extraction ratios of prednisolone by kidney ($E_K$) and liver ($E_L$) tissues were obtained as the ratio of $Cl_T$ to kidney plasma flow ($Q_K$) and liver plasma flow ($Q_L$). The values of $Q_K$ and $Q_L$ used in the computation were 55 and 70 ml/min (5).

## RESULTS

**Prednisolone Disposition**—Typical serum concentration–time profiles for prednisolone and prednisone after low and high doses of prednisolone are presented for Rabbit 2 in Fig. 1. Prednisolone disposition was biphasic in nature, with metabolism of prednisolone to prednisone occurring at each dose. The systemic clearance of prednisolone ($Cl_T$) at the two doses is shown in Fig. 2. A significant increase ($p < 0.02$) in $Cl_T$ occurred with the increase in dose. The mean ($\pm SD$) $Cl_T$ values after low and high intravenous doses were 1.72 (±0.48) and 2.25 (±0.52) ml/min, respectively. The approximate $E_K$ and $E_L$ values obtained using the mean $Cl_T$ values were 0.036 and 0.028, respectively. There was no dose dependence in prednisolone clearance when corrected for albumin and

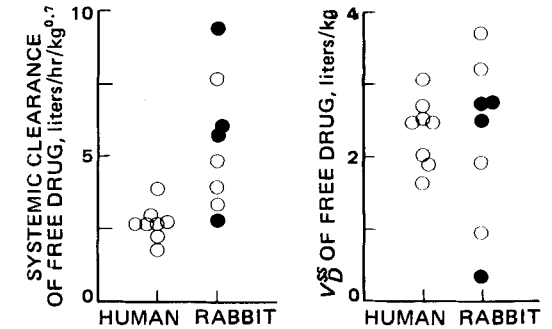

**Figure 4**—*Rabbit $Cl_T$ and $V_D^{ss}$ values for unbound prednisolone compared to human values (corrected for animal scale-up). The solid and open symbols in the rabbit data represent values from the low and high dose studies. Human data are from Rose* et al. *(6).*

| | 3.0 | 10.0 | 0.56 | 2.8 | 0.63 | 0.076 | 0.51 | 0.91 | 1.51 |
| Significance[a] (between doses) | | — | $p < 0.02$ | NS[a] | NS | — | $p < 0.05$ | NS | $p < 0.02$ |

[a] NS = not significant.

transcortin binding ($Cl_{T,free}$) nor in the clearance corrected for only transcortin binding ($Cl_{T,CBG\text{-}free}$) (Table I).

Significant increases in the volumes of distribution at steady state ($V_D^{ss}$) and the variance of residence time ($VRT$) were observed at the higher prednisolone dose. In contrast, the mean residence time ($MRT$) increased with dose in only three of four rabbits. This total change in $MRT$ was not statistically significant (Table I).

Figure 3 illustrates $V_D^{ss}$ and $Cl_T$ using animal scale-up corrections (5) for the rabbit compared to the human (6). There was no significant difference in the $Cl_T$ values between species. In contrast, $V_D^{ss}$ values were significantly higher in the human than in the rabbit ($p < 0.01$). Comparison of $Cl_T$ and $V_D^{ss}$ for unbound prednisolone between humans and rabbits using animal scale-up corrections demonstrated no significant species difference in $V_D^{ss}$, while the $Cl_T$ values for free prednisolone were significantly higher in the rabbit ($p < 0.05$) (Fig. 4).

**Protein Binding**—A plot of percent bound *versus* postequilibrium dialysis serum prednisolone concentrations for a rabbit is presented in Fig. 5. The mean (±$SD$) serum albumin concentration and the binding affinity constant obtained from computer fitting of the binding data (2) were 5.51 (±0.46) × $10^{-4}$ $M$ and 6.24 (±1.5) × $10^3$ $M^{-1}$, respectively. The mean (±$SD$) transcortin concentration and binding affinity constant, also obtained through computer fitting, were 4.70 (±2.4) × $10^{-7}$ $M$ and 2.84 (±2.16) × $10^7$ $M^{-1}$, respectively. The binding parameters obtained in each rabbit are compared in Figs. 6 and 7 with values obtained from a study (6) performed in normal healthy volunteers.

## DISCUSSION

The pharmacokinetic parameters derived from these disposition studies are dose and time average values since the disposition of prednisolone is nonlinear, as indicated by the increase in $Cl_T$, $V_D^{ss}$, $MRT$, and $VRT$ with dose. Interconversion between these corticosteroids occurs as well, providing an additional confounding influence on the pharmacokinetic parameters obtained in the present investigation. Such interconversion of prednisone and prednisolone was demonstrated in humans (1, 6) and in the isolated perfused rat kidney (7). The increases in $Cl_T$ and $V_D^{ss}$, as well as the formation of prednisone after intravenous doses of prednisolone, are all characteristic of the disposition of this steroid in humans (1). Corrections of $Cl_T$ for total protein binding and transcortin binding partially eliminates the differences in $Cl_T$ between low and high doses of prednisolone. This result also was observed in the human and suggests that nonlinear protein binding largely produces dose-dependent changes in $Cl_T$ (6).

The dose-dependent increase in $V_D^{ss}$ is consistent with the changes in protein binding that occur as a function of serum prednisolone concentration (Fig. 4). High prednisolone doses produce higher initial serum concentrations. The reduced binding of prednisolone at these high concentrations (Fig. 4) results in increased distribution of prednisolone to tissues, as reflected by an increase in $V_D^{ss}$.

Further support for the importance of protein binding in prednisolone disposition is provided by the low extraction ratios of prednisolone by the kidney and liver, suggesting that only drug not bound to serum proteins is available to these tissues (*i.e.*, restrictive clearance). The extraction ratios calculated in the present investigation are overestimates of the true extraction ratios since total and not individual organ clearances were used. The $E_K$ value, however, agrees very well with those (mean = 0.044) obtained during prednisolone perfusion in isolated rat kidneys (7).

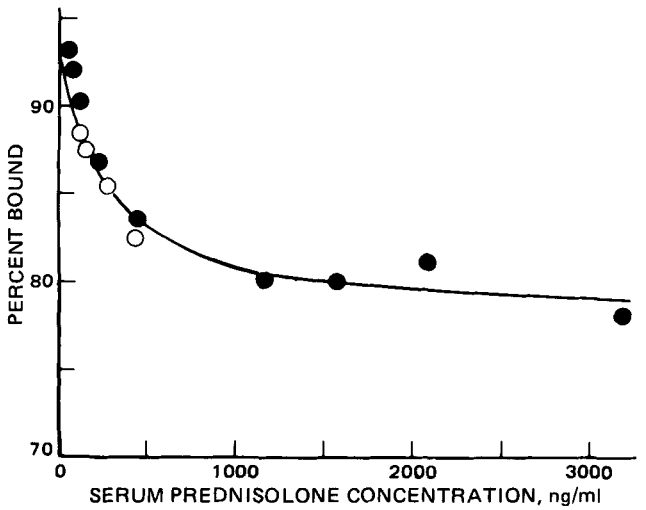

**Figure 5**—*Percent of prednisolone bound* versus *postdialysis serum prednisolone concentration after low (○) and high (●) intravenous prednisolone doses. The solid line represents the nonlinear least-squares regression line for the protein binding data using a modified Rosenthal relationship for two classes of binding sites (see Ref. 2).*

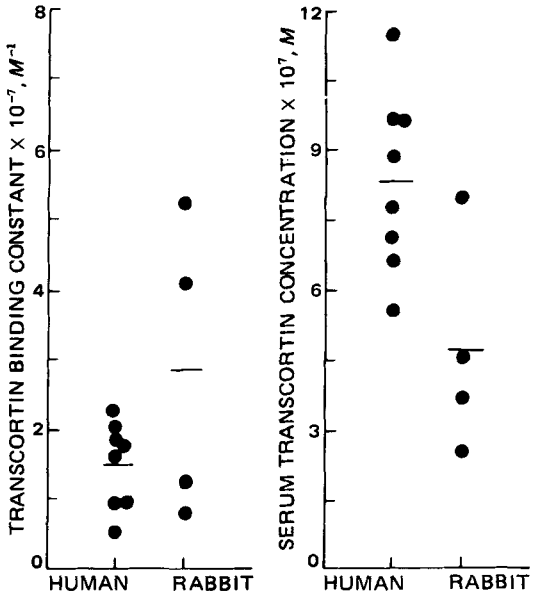

**Figure 6**—*Serum transcortin concentrations and binding affinity constants for prednisolone in the rabbit and in normal healthy human volunteers (from Ref. 6).*

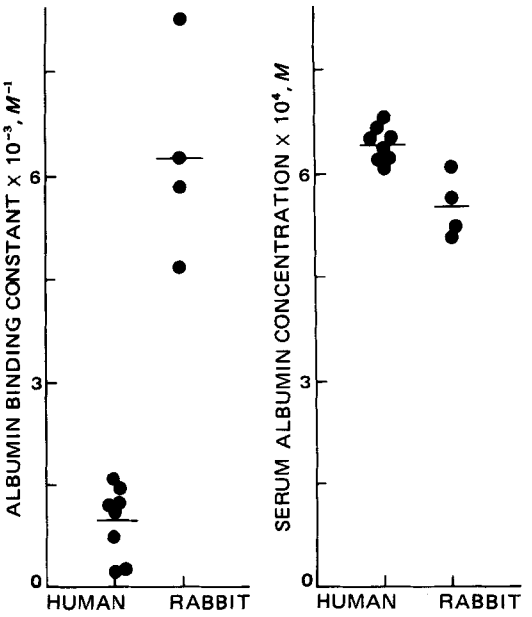

**Figure 7**—*Serum albumin concentrations and binding affinity constants for prednisolone in the rabbit and in normal healthy volunteers (from Ref. 6).*

Adolph (8) demonstrated that many metabolic and physiological properties among mammals are proportional to some exponential power of their body weight, and Dedrick (9) indicated that the exponent is usually in the 0.7–0.8 range. Excellent agreement between humans and rabbits was observed in the $Cl_T$ values normalized for weight raised to the 0.7 power (Fig. 3). In addition, $V_D^{ss}$ values, although significantly different between species, are in the same general range. The absence of significant interspecies differences in $V_D^{ss}$ for unbound prednisone (corrected for animal scale-up) (Fig. 4) suggests that differences in binding between species accounts for the differences in $V_D^{ss}$ observed for total drug. The significantly higher free $Cl_T$ in the rabbit (Fig. 4) should not be a major complication in its use as a model since the interspecies difference in this parameter is not large. While the doses used for these comparisons are not equivalent, the dose range examined in the rabbit (0.15–2.98 mg/kg) encompasses the dose (0.52 mg/kg) employed in the human studies (6). This comparison establishes that the normalized $Cl_T$ and $V_D^{ss}$ values in the rabbit are reasonably similar to those observed in humans and further demonstrates the applicability of the rabbit in mimicking prednisolone disposition in humans.

The relative changes in $Cl_T$ and $V_D^{ss}$ with prednisolone dose are greater in the human than in the rabbit. Rose *et al.* (6) observed that both $Cl_T$ and $V_D^{ss}$ approximately doubled over an eightfold dose range. The relative increases in $Cl_T$ and $V_D^{ss}$ with dose in the present study averaged 33 and 102%, respectively. These increases were observed over a 20-fold dose range. The lesser magnitude of the changes in $Cl_T$ and $V_D^{ss}$ in the rabbit may be due to less pronounced nonlinearity of prednisolone plasma binding (2).

The apparent increase in *MRT* (in three of the four rabbits studied) at the higher dose directly reflects an increase in the average persistence time of prednisolone in the body. The fractional increase in $V_D^{ss}$ at the higher dose exceeds the relative increase in $Cl_T$ that occurs as the dose is increased. Since $MRT = V_D^{ss}/Cl_T$, the net effect of these changes is an increase in *MRT*. The increase in *VRT* with dose indicates a wider spread of residence time of the mass of drug molecules at the higher dose. This finding appears to be congruous with the enhanced $Cl_T$ and the larger $V_D^{ss}$ that occur at the higher dose. Increases in $Cl_T$ serve to diminish the residence time of prednisolone, while more extensive tissue distribution of prednisolone prolongs the residence time. Concomitant increases in each of these processes would increase the variance (spread) of the residence times of the drug molecules.

The transcortin and albumin serum concentrations and affinity constants for prednisolone binding in rabbits are in the same general range as those determined in normal healthy volunteers after the 40-mg iv dose of prednisolone phosphate (Figs. 6 and 7). This finding confirms the similarity in prednisolone binding between human and rabbit reported previously (3). The apparent superposition of the binding data after low and high prednisolone doses suggests that prednisolone does not compete with prednisone or other metabolites for protein binding sites on transcortin and albumin. The concentrations of these potential displacers is higher after larger prednisolone doses. Competitive binding studies are required, however, to definitively ascertain whether such competition actually occurs.

In conclusion, the rabbit appears to be a suitable model for prednisolone disposition in humans. This species is also desirable from a technical standpoint in that blood samples are easily obtainable and may be taken in sufficient volume to permit examination of serum prednisolone protein binding in addition to HPLC assay for total serum prednisolone and prednisone concentrations.

# High-Pressure Liquid Chromatographic Determination of Anthralin in Ointments

**JEAN-CLAUDE CARON** ˣ **and BRAHAM SHROOT**

Received January 9, 1981, from the *Centre International de Recherches Dermatologiques, Sophia Antipolis, F-06565 Valbonne, France.* Accepted for publication March 23, 1981.

**Abstract** □ Anthralin concentration was determined in different ointments by high-pressure liquid chromatography, and results were compared with those of the USP assay technique. Significant differences existed between the claimed and the actual levels of anthralin in some preparations. Varying quantities of anthralin breakdown products were found, and their concentrations appear to be related to the nature of the formulation.

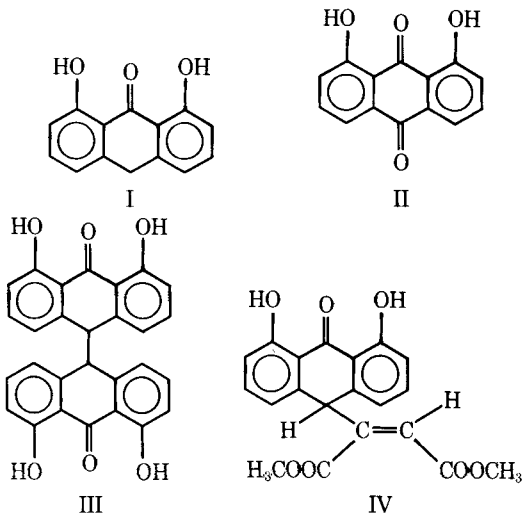
**Keyphrases** □ Anthralin—high-pressure liquid chromatographic determination in ointments □ High-pressure liquid chromatography—determination of anthralin in ointments □ Ointments—high-pressure liquid chromatographic determination of anthralin

Anthralin, applied percutaneously in various formulations, has been used in the treatment of psoriasis for over 100 years (1). This reactive chemical entity can undergo predictable chemical changes in the vehicle, depending on the presence of basic ingredients and/or oxygen. The end-products are claimed to be inactive in the chemotherapy of psoriasis (2). Ponec-Waelsch and Hulsebosch (3) postulated that anthralin and zinc hydroxide interact in zinc oxide pastes (Lassars' paste). These workers, however, used UV spectrophotometry for the assay and, as discussed recently (4), quantification of the breakdown products can only be estimated following prior separation of the compounds by TLC.

High-pressure liquid chromatography (HPLC), a selective, sensitive, reproducible, and rapid assay procedure, seemed a better choice for this assay and is compared in the present study to the standard USP method (5).

## EXPERIMENTAL

**Materials**—Acetic acid[1] was analytical reagent grade; isooctane, isopropyl ether, methanol, chloroform, and *n*-hexane were HPLC grade[2] and were used as received after filtration and degassing.



[1] Prolabo Normapur.
[2] Merck.

1,8-Dihydroxy-9-anthrone (anthralin, I) was purified by column chromatography. Its chemical derivatives, 1,8-dihydroxy-9,10-anthraquinone (quinone, II) and 1,8,1′,8′-tetrahydroxy-10,10′-dianthrone (dimer, III) (6), and the internal standard, 1,8-dihydroxy-9-anthron-10-yl maleic acid dimethyl ester (IV) (7), were synthesized[3] following published procedures.

**Instrumentation**—Two high-pressure liquid chromatographs were used. One was equipped with a septumless injector[4], a reciprocating pump[5], a normal-phase 25-cm column[6], a UV-visible detector[7] set at 254 nm, and a strip-chart recorder[8]. The other chromatograph[9] was equipped with a reversed-phase 25-cm column[10] also set at 254 nm (referenced at 500 nm). The mobile phases compositions and conditions used are listed in Table I. Under these conditions, the response of each compound was linear in the working range (1–50 μg/ml).

**Products Investigated**—Commercially available samples were used, except in one case where the formulation was obtained directly from the

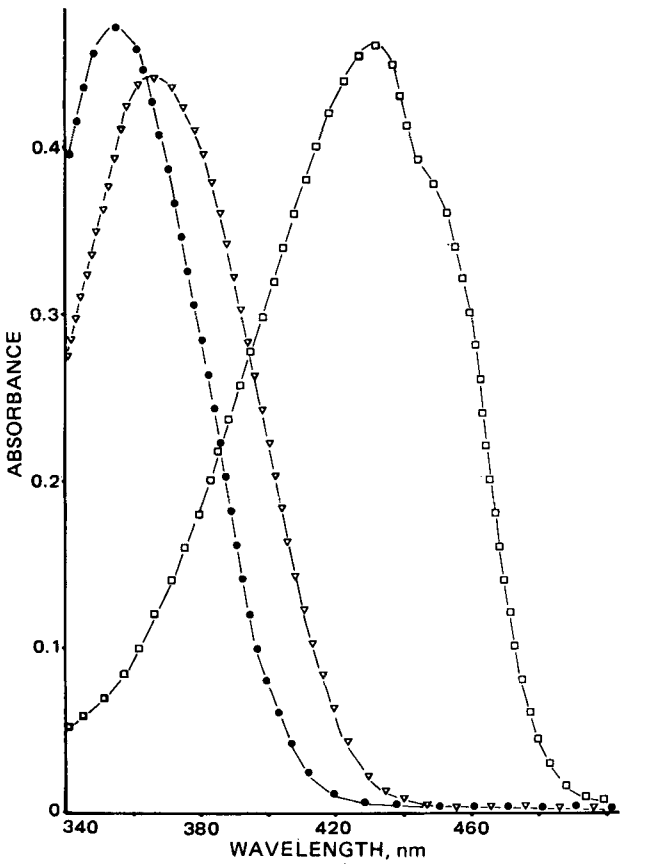


**Figure 1**—*Visible spectra at 10 μg/ml in chloroform of anthralin (●), the dimer (▽), and the quinone (□). Molar absorptivities (ε) at 345 and 432 nm are, respectively, 10,650 and 100 for anthralin, 16,970 and 220 for the dimer, and 1680 and 10,890 for the quinone.*

pharmacy of a local hospital. The ointment bases and theoretical concentrations of anthralin are given in Table II.

**Analytical Procedure**—Ointment theoretically corresponding to ~200 μg of anthralin was weighed and spiked with exactly 200 μg of internal standard in the appropriate solvent (chloroform or *n*-hexane) from a freshly prepared (1 mg/ml) stock solution.

The extraction was performed by shaking the mixture for 15 min on a vortex mixer in the presence of 5 ml of chloroform or *n*-hexane and filtering the resulting solution through a solvent-resistant filter[11]. An aliquot (1 ml) of this solution was then evaporated to dryness under nitrogen at room temperature, and the residue was redissolved in the same amount of the elution solvent and subjected to HPLC analysis.

## RESULTS AND DISCUSSION

The USP describes an assay procedure for the quantification of anthralin as the starting material for the preparation of ointments or in the ointment itself. This method is based on the absorbances at 354 and 432 nm but suffers from overlapping and interference between the absorption maxima of anthralin, dimer, and quinone (Fig. 1). In contrast, the described method allows the quantification of anthralin and its major oxidation products in the presence of each other (Fig. 2).

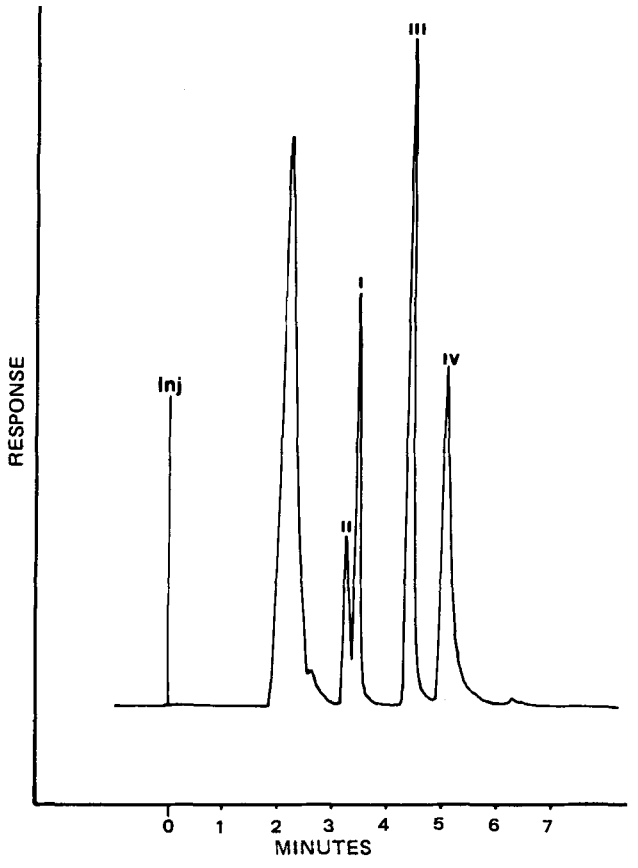

**Figure 2**—*Example of the chromatogram of a formulation extract (Sample 11) obtained on a silica gel phase.*

[11] Millipore FHLP 013, 0.5 μm.

Table III lists the results obtained by HPLC and USP techniques for the percentages of anthralin in the formulations studied.

Table IV lists the results obtained for anthralin, the quinone, and the dimer, with chloroform as the extraction solvent, on the two chromatographic systems; for solubility reasons, *n*-hexane is unsuitable as an extraction solvent for the dimer.

In nine out of the 12 formulations studied, 100 ± 5% of the material could be accounted for. Since the possible variation in the original anthralin used by the manufacturers could not be estimated, in cases where significantly less products was found, the extraction procedure was verified by adding increasing amounts of pure anthralin standard to the ointment before extraction.

The possibility of anthralin decomposition during extraction can be rejected since the standard deviation in the results obtained by the two extraction procedures was the same as the error in the analytical procedures itself. Decomposition during chromatography on either system can also be rejected since the normal and reversed-phase results are in good agreement.

Consequently, the difference between the theoretical and actual concentrations of anthralin in the ointment is related to the vehicle itself, in particular the zinc oxide pastes (Base D, Table III). Three out of the four such preparations (Samples 9, 11, and 12) contained <40% of the theoretical amount of anthralin; in two cases, a marked tendency towards the formation of the corresponding dimer (81 and 91%) was noted.

For Base C (Sample 10), low overall recovery was obtained with the highest amount of quinone. This low recovery can be explained by the

**Table II—Composition of Vehicles and Theoretical Anthralin Concentration of Ointments**

| Cream Base | Anthralin Concentration, % | Code |
|---|---|---|
| Powder-in-cream urea | 0.1 | A |

formation of high molecular weight materials, and an HPLC method is currently being developed for the analysis of these products.

The surprising disparity between the USP and HPLC assay results can be rationalized when the data in Table IV are considered. Although both methods rely on UV absorption, the USP technique cannot quantify the dimer and merely includes it with the anthralin level. However, a discrepancy between the results is still evident after correcting the USP data for the presence of dimer.

The majority of these ointments contained ~70% (range 44–92%) of the theoretical amount of anthralin, the remaining 30% being various quantities of the dimer, quinone, and, perhaps, high molecular weight materials.

The need to check anthralin and its preparations must be emphasized, and the danger of further decomposition of samples in use cannot be ignored.

# High-Performance Liquid Chromatographic Determination of Stereoselective Disposition of Carprofen in Humans

**J. K. STOLTENBORG *, C. V. PUGLISI ‡, F. RUBIO *, and F. M. VANE *x**

Received January 26, 1981, from the **Department of Biochemistry and Drug Metabolism and the* ‡*Department of Pharmacokinetics and Biopharmaceutics, Hoffmann-La Roche Inc., Nutley, NJ 07110.* Accepted for publication March 25, 1981.

**Abstract** □ A high-performance liquid chromatographic (HPLC) assay was developed for the determination of the ratios of the (*S*)-(+) and (*R*)-(−) enantiomers of the anti-inflammatory drug carprofen in blood, urine, and feces. The procedure relies on: (*a*) extraction and purification of carprofen from biological fluids, (*b*) reaction of carprofen with (*S*)-(−)-α-methylbenzylamine to form the two diastereomeric (S)-(−)-α-methylbenzylamides *via* the 1,1′-carbonyldiimidazole intermediate, (*c*) purification of the reaction mixture by extraction of the diastereomeric derivatives into hexane at pH 11, and (*d*) analysis of the diastereomeric derivatives by HPLC with UV detection. The (*S*)-(+):(*R*)-(−) ratios in the blood of three subjects receiving single 100-mg oral doses of carprofen were greater than unity up to 16 hr after dosing. The mean ± *SD* of the ratios in the early blood samples (0.5, 1, and 2 hr) was 1.21 ± 0.09, while the mean of the ratios in the later blood samples (4, 6, 8, 12, and 16 hr) was slightly higher (1.48 ± 0.17). The blood level fall-off curves for the (*S*)-(+) and (*R*)-(−) enantiomers were similar in each of the three subjects for the 4–16-hr period. The carprofen enantiomers were excreted stereoselectively by humans. An excess of the (*S*)-(+) enantiomer relative to the (*R*)-(−) enantiomer was excreted in the urine as the ester glucuronide, while unchanged (*R*)-(−) enantiomer predominated in the feces. The total urinary plus fecal excretion of the enantiomers (0–96 hr) revealed only a slight excess of the (*S*)-(+) enantiomer over the (*R*)-(−) enantiomer, which amounted to 2.1–4.9% of the dose. Since the amount of carprofen (free and glucuronide) excreted in 96 hr by the three subjects only accounted for 62–72% of the dose, no definitive statement could be made relative to the possible inversion of the carprofen chiral center.

**Keyphrases** □ Carprofen—stereoselective disposition determination in humans using high-performance liquid chromatography □ Anti-inflammatory agents—carprofen, metabolism in humans, and rats, high-performance liquid chromatography □ High-performance liquid chromatography—determination of stereoselective disposition of carprofen in humans

Carprofen [(D,L)-6-chloro-α-methylcarbazole-2-acetic acid] is presently undergoing extensive clinical evaluation as a nonsteroidal anti-inflammatory agent. The possible stereoselective disposition of carprofen is of interest since it is a racemic compound with a chiral center at the α-carbon position. Other α-methylarylacetic acids have been shown to undergo stereoselective disposition and inversion at the α-carbon (1–5).

A TLC procedure was previously developed (6) for the quantitation of the enantiomers of [$^{14}$C]carprofen as their diastereomeric (*S*)-(−)-α-methylbenzylamides. This TLC procedure has been used to study stereoselective elimi-

nation of [$^{14}$C]carprofen in rats (6) and humans (7). In the rat, the (*R*)-(−) enantiomer is eliminated from the blood and secreted in the bile as the ester glucuronide at a rate approximately twice that of the (*S*)-(+) enantiomer. Concurrently, the (*S*)-(+) isomer, the pharmacologically more active enantiomer (8), persists longer in rat blood. Preliminary data suggested a preferred urinary elimination of the (*S*)-(+) enantiomer as the ester glucuronide and a preferred fecal elimination of the (*R*)-(−) enantiomer in humans (7).

This report describes a high-performance liquid chromatographic (HPLC) assay for the determination of the (*S*)-(+):(*R*)-(−) ratios of carprofen in biological fluids by measuring the diastereomeric (*S*)-(−)-α-methylbenzylamide derivatives of carprofen. Whereas the radio-TLC stereospecific assay depends on labeled carprofen for quantitation, the HPLC assay can be used to evaluate clinical specimens from studies using nonlabeled drugs. This stereospecific HPLC assay, in conjunction with other assays (9, 10) for total carprofen, was used to study the stereoselective disposition of carprofen in humans.

## EXPERIMENTAL

**Materials**—The procedure relies on the reaction of racemic carprofen with (*S*)-(−)-α-methylbenzylamine[1] to form the (*R,S*) and (*S,S*) diastereomers (Scheme I). However, the synthetic analytical standards, I and II, were prepared by reacting the carprofen enantiomers with (*R*)-(+)-α-methylbenzylamine. Therefore, standards I and II are the antipodes, respectively, of the (*R,S*) and (*S,S*) diastereomers formed in the carprofen reaction procedure. A solution of 32.5 mg of 1,1′-carbonyldiimidazole[1]/ml of chloroform was prepared daily.

*Carprofen*—Carprofen ($C_{15}H_{12}ClNO_2$) has a molecular weight of 273.72. A stock solution of 1 mg/ml in ethanol was prepared. Carprofen[2] labeled with carbon 14 in the α-position was used in certain experiments as indicated. The original specific activity of 9.91 μCi/mg was diluted in solution with appropriate amounts of unlabeled compound.

For the (*S*)-(+) enantiomer the specific rotation in methanol was $[\alpha]_D^{23}$ +53.7°; for the (R)-(−) enantiomer, the specific rotation in methanol was $[\alpha]_D^{23}$ −54.2°.

*Standard I*[3] [(S,R)-N-(*2-Phenethyl*)-α-*methyl*(*6-chloro-9H-carbazol-2-yl*)*acetamide*]—Standard I ($C_{23}H_{21}ClN_2O$) has a molecular weight of 376.88, mp 238–239°. It dissolved slowly in the HPLC solvent system (0.75% $CH_3OH$ in methylene chloride) at concentrations greater than 0.5 mg/ml.

*Standard II*[3] [(R,R)-N-(*2-Phenethyl*)-α-*methyl*(*6-chloro-9H-carbazol-2-yl*)*acetamide*]—Standard II ($C_{23}H_{21}ClN_2O$) has a molecular weight of 376.88, mp 191–193°. It was soluble in the HPLC solvent system at concentrations of 1.0 mg/ml.

*Reagents*—The following analytical reagent grade chemicals were used: 1 and 0.6 *N* NaOH, 0.1 and 6 *N* HCl, 1 and 0.2 *M* sodium acetate buffer (pH 5), 1 *M* potassium phosphate buffer (monobasic) (pH 7), 0.2 *N* $NH_4OH$ (pH 11), acetic acid, formic acid, methanol, ethanol (anhydrous), chloroform (stabilized with 0.75% ethanol), methylene chloride, UV quality hexane, and ether[4] (anhydrous).

*TLC*—TLC plates were precoated with silica gel 60F-254[5]. Filter paper[6] was used for lining the TLC tanks. A shortwave UV lamp was used for visualization of spots.

**Extraction and Purification of Carprofen from Biological Samples**—*Blood*—Five-milliliter aliquots of blood were adjusted to pH 5 with 2 ml of 1 *M* acetate buffer and extracted twice with 12 ml of ether. The blood–ether mixtures were shaken for 10 min in a reciprocating shaker[7] at 60–80 strokes/min and centrifuged[8] at 2400 rpm for 5 min at room temperature. The combined ether layers were evaporated to dryness with nitrogen in a 30–40° water bath[9]. The extract residues were dissolved

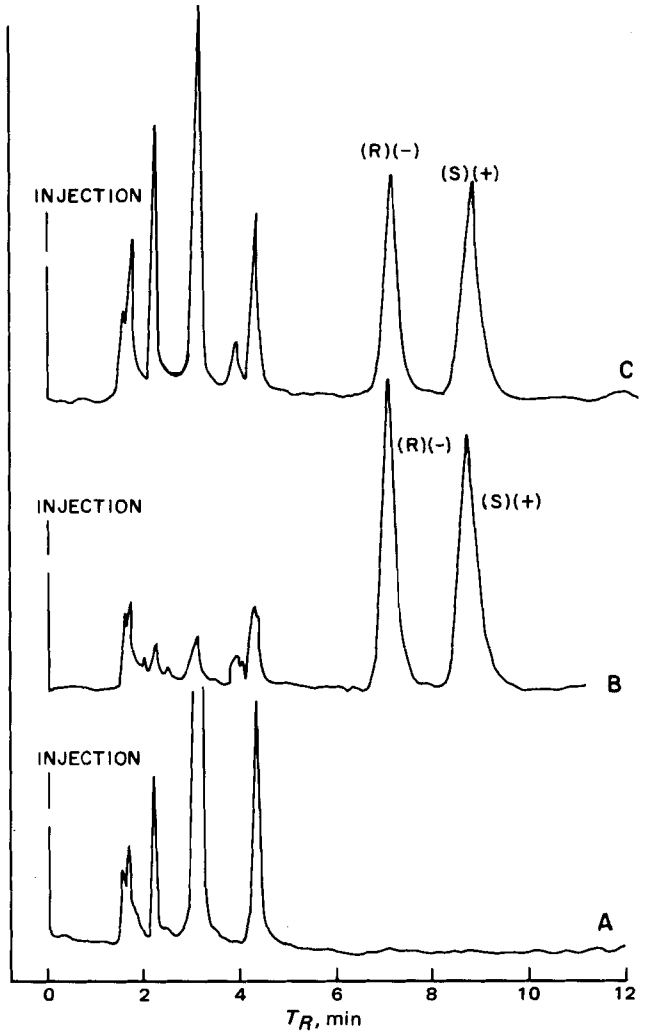

**Figure 1**—*HPLC (UV detection) of the products from the reaction with (S)(−)-α-methylbenzylamine. Key (A), reagent blank; B, standard carprofen; and C, control human urine spiked with carprofen. Peaks labeled (R)-(−) and (S)-(+) are the diastereomeric amides of the (R)-(−) and (S)-(+) enantiomers of carprofen, respectively.*

[a] Number of separate reactions on different days.

in 100 μl of ethanol and spotted on the TLC plate as 3-cm wide streaks.

The plate was developed with chloroform—acetic acid (90:10) until the solvent reached 14 cm from the origin. The UV-absorbing band corresponding to carprofen ($R_f$ 0.54) was well separated from biological impurities ($R_f$ 0.61). The silica gel containing carprofen was scraped off the plate and, after addition of 3 ml of 0.2 *M* acetate buffer (pH 5), was extracted twice with 5 ml of ether. The combined ether layers were evaporated to dryness.

*Urine*—Aliquots of 2–5 ml of urine were adjusted to pH 11 by the addition of 1 ml of 1 *N* NaOH. After standing 2 hr at room temperature to cleave the ester glucuronides, the solution was adjusted to pH 5 and the deconjugated carprofen was extracted twice with 10 ml of ether as already described. The ethanolic extract was spotted on a TLC plate, and the plate was developed using chloroform–ethanol–formic acid (90:10:5). Carprofen ($R_f$ 0.50) was extracted from the silica gel as previously described. When it was necessary to extract 10 ml of urine, two 5-ml aliquots were extracted in separate tubes and the extracts were combined before TLC analysis.

*Feces*—Feces were homogenized in ~10 volumes of ethanol–water (70:30), and a 10-ml aliquot of each homogenate was diluted with 5 ml of 1 *M* acetate buffer (pH 5). The resulting ethanolic suspension was extracted once with 20 ml of hexane–ether (3:2). The supernatant fraction was back-extracted with 5 ml of 0.6 *N* NaOH. After centrifugation, the hexane–ether phase was discarded. The alkaline layer was washed with 10 ml of ether and, after centrifugation, the ether was discarded. Then 0.5 ml of 6 *N* HCl and 2 ml of 1 *M* phosphate buffer (pH 7) were added to the alkaline extract. This solution was extracted twice with 10 ml of ether.

The residue of this ether extract was dissolved in 7.5 ml of ethanol–0.1 *N* HCl (4:1). This solution was washed twice with 10 ml of hexane, and the hexane was discarded after each washing. The ethanol–hydrochloric acid layer was diluted with 7.5 ml of water and extracted once with 15 ml of hexane–ether (3:2). The residue of the hexane–ether extract was dissolved in ethanol and spotted on a TLC plate. The plate was developed using chloroform–ethanol–acetic acid (90:10:1). Carprofen ($R_f$ 0.40) did not resolve from endogenous biological impurities in this system, necessitating redevelopment in another solvent system; chloroform–methanol–concentrated ammonium hydroxide (70:30:1) separated carprofen ($R_f$ 0.12) from the biological impurities. Carprofen was extracted from the silica gel as already described.

**Derivatization Procedure (Scheme I)**—The derivatization procedure is based on the method used by VanGiessen and Kaiser (11) for the GLC determination of the enantiomers of ibuprofen, an α-methylarylacetic acid. Carprofen standards were processed in duplicate with each series of unknowns in concentrations comparable to the expected carprofen concentrations in the unknowns (1.4–30 μg). The reaction was performed in 15-ml conical glass-stoppered centrifuge tubes. To the dried residues of the standards and the unknowns, 0.1 ml of the 1,1′-carbonyldiimidazole solution was added. Each tube was rotated to permit the reactant to contact the residue completely. The mixture was allowed to stand at room temperature for 5 min, then 10 μl of acetic acid and 25 μl of (*S*)-(−)-α-methylbenzylamine were added stepwise, and the solution was mixed well with a vibrating mixer. The solution was centrifuged briefly and then was allowed to react at room temperature for 20 min.

After completion of the reaction, 3 ml of 0.2 *N* $NH_4OH$ (pH 11) and 5 ml of hexane were added. The tubes were stoppered tightly, shaken for 10 min in a reciprocating shaker at 60–80 strokes/min, and centrifuged for 5 min. A 4.5-ml aliquot of the hexane extract was transferred to a 15-ml conical centrifuge tube and evaporated to dryness under nitrogen in a 30–40° water bath. After drying thoroughly for 5 min in a desiccator *in vacuo*, the residue was dissolved in 0.5– 2.0 ml of the HPLC mobile phase and a 10-μl aliquot was injected into the liquid chromatograph.

[a] Average (*S*)-(+):(*R*)-(−) values are based on duplicate determinations of each specimen by each method.

**HPLC Analysis of Diastereomeric Derivatives of Carprofen**—*Column*—A 25-cm × 4.6-mm i.d. stainless steel column containing 10-μm silica gel[10] was used along with a guard column[11]. To maintain good performance, the column was sequentially washed (2.0 ml/min) with 200 ml of methanol, 200 ml of methylene chloride, 200 ml of *n*-heptane, and 60 ml of methylene chloride.

*Instrumental Parameters*—The liquid chromatograph[12] was equipped with a UV absorbance detector[13] operated at 254 nm and a solvent delivery system[14]. A fluorescence detector[15], operated at 240 nm for excitation and at wavelengths greater than 350 nm[16] for emission, was used for a limited number of HPLC analyses. The isocratic mobile phase was a mixture of 0.75% $CH_3OH$ in methylene chloride at a head pressure of 450 psi and at a constant flow rate of 2.0 ml/min. Solvents were routinely filtered and degassed[17] immediately before use.

The UV detector sensitivity was $1 \times 10^{-2}$ aufs, and the fluorescence detector sensitivity was 0.1 μA.F.s. The chart speed on the recorder[18] was 2.5 cm/min. A full-scale pen response was obtained with an injection of 75 ng of each diastereomer when operating in either detection mode. Under these conditions, the (*R*,*S*) diastereomer and standard I had the same retention time of 6.4 min with $k' = 5.1$. The (*S*,*S*) diastereomer and standard II had the same retention time of 7.6 min with $k' = 6.7$.

*Analytical Standards*—Separate stock solutions of standards I and II were prepared by dissolving 5.000 mg of the former and 5.041 mg of the latter in 500 ml of 0.75% $CH_3OH$ in methylene chloride. The stock solutions were diluted with this same solvent to prepare solutions of 5, 10, 25, 50, and 75 ng/10 μl. Ten-microliter aliquots of these solutions were injected as external standards for establishing the HPLC parameters. The computed UV peak areas, as well as peak heights, were plotted *versus* concentration, and the UV detector was shown to respond linearly and equivalently to both diastereomers.

*Quantitation and Calculations*—Free and total carprofen concentrations were determined in urine and feces of subjects given [$^{14}$C]carprofen by the radiometric method (6). Free carprofen in blood was quantitated by HPLC (9). UV detection and computer integration of the areas under the (*S*,*S*) and (*R*,*S*) diastereomer peaks were used to determine the (*S*)-(+):(*R*)-(−) ratios, which were applied to the carprofen concentrations to determine the concentrations of the individual carprofen enantiomers.

## RESULTS AND DISCUSSION

**Characteristics of Stereospecific Carprofen Assay**—Typical chromatograms for a reagent blank, standard carprofen, and spiked human urine are shown in Fig. 1. To minimize the presence of UV-absorbing impurities and to obtain adequate HPLC separation of the diastereomers, it was necessary to modify the procedures described in the original radio-TLC method (6). Extraction of the reaction product into hexane from an alkaline aqueous phase (instead of ether at pH 5) removed certain acidic and more polar by-products and provided a product sufficiently pure for direct HPLC analysis. The concentration of early eluting UV-absorbing impurities that interfered with the (*R*)-(−)-carprofen diastereomeric amide peak could be reduced satisfactorily by reacting carprofen with half the amount of each reagent used previously (6).

[$^{14}$C]Carprofen was used to determine the overall formation of the diastereomeric amides. The radioactivity determined in the reaction extract indicated that the reaction yield was 62.3 ± 2.9% (*SD*), equivalent to the yield found with the original procedure (6).

The overall percent recovery of carprofen from urine after extraction, preparative TLC, a second extraction, derivatization, and final extraction was 39.3 ± 2.3% (*SD*) with a detection limit of 0.6 μg/ml when 10 ml was extracted. The feces assay had a recovery of 29.2 ± 3.75% with a detection limit of 0.6 μg/ml of homogenate when a 10-ml aliquot of homogenate was extracted. The blood assay had a recovery of 41.5 ± 8.3% with a limit of detection of 0.27 μg/ml when a 5-ml aliquot was extracted.

Table I presents the statistical evaluation of the (*S*)-(+):(*R*)-(−) values found for carprofen reacted over a range of concentrations. The results show that the method is reproducible. Therefore, modification of the derivatization and extraction procedure did not affect overall yield and reproducibility.

To check the accuracy and precision of the method, biological samples spiked with carprofen were analyzed. The following mean (*S*)-(+):(*R*)-(−) ratios (±*SD*) were found at the indicated concentrations of carprofen: 0.27 μg/ml in blood, 1.03 ± 0.05 ($n = 4$); 0.83 μg/ml in blood, 0.98 ± 0.04 ($n = 9$); 1.0 μg/ml in urine, 0.99 ± 0.02 ($n = 7$); 2 μg/ml in urine, 0.99 ± 0.01 ($n = 3$); and 22 μg/ml of fecal homogenate, 1.02 ± 0.03 ($n = 3$). In addition, blood and urine were spiked with synthetic mixtures of carprofen enantiomers with varying (*S*)-(+):(*R*)-(−) ratios. The coefficients of variation of the ratios found were ≤2.7% (Table II). These results indicate that the method is accurate and precise.

Fluorescence detection was used for determining the (*S*)-(+):(*R*)-(−) values in a limited number of samples. Carprofen standards of 10 and 20 μg were reacted, and the diastereomers were quantitated by computer-integration of the peak areas or by measurement of peak heights. The (*S*)-(+):(*R*)-(−) values had a mean of 0.987 ± 0.012 (± *SD*) ($n = 22$). Fluorescence detection shows promise as an alternative detection mode, especially when UV contaminants are present.

**Application to Biological Specimens**—To compare the radio-TLC and HPLC methods, urine samples from a subject who had ingested 50 mg of [$^{14}$C]carprofen (0.5 μCi/mg) were analyzed by both methods. The (*S*)-(+):(*R*)-(−) ratios obtained by the two methods were nearly identical (Table III).

Blood specimens were obtained from three human subjects who were

**Table IV—Determination of (*S*)-(+):(*R*)-(−) Values in Human Blood following a Single 100-mg Oral Dose of Carprofen [a]**

| Subject | Hours after Administration | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| | 0.5 | 1.0 | 2.0 | 4.0 | 6.0 | 8.0 | 12.0 | 16.0 |
| III/14 | 1.23 | 1.40 | 1.16 | 1.45 | 1.46 | 1.52 | 1.41 | 1.40 |
| V/41 | 1.19 | 1.22 | 1.15 | 1.51 | 1.35 | 1.77 | 1.65 | 1.92 |
| V/42 | NA[b] | 1.08 | 1.22 | 1.35 | 1.31 | 1.38 | 1.40 | 1.36 |

[a] Ratios for Subjects III/14 and V/41 were determined by the HPLC method, and the ratios for Subject V/42 were determined using a fluorometric TLC procedure. For the latter subject, carprofen was extracted by the standard procedure from 9–11 ml aliquots of blood containing 0.2–1.8 μg of carprofen. After cleanup of carprofen by extraction with sodium hydroxide and by TLC, the diastereomeric derivatives were formed, separated by TLC, and extracted from the silica gel bands with 2.5 ml of ethanol–1% acetic acid. Comparison of the fluorescence intensities measured at 370 nm (emitting wavelength) after activating at 295 nm resulted in the fluorescence (*S*)-(+):(*R*)-(−) ratios for racemic carprofen of 0.986 ± 0.002. [b] Not analyzed.

[a] Free carprofen plus ester glucuronide. [b] The (*S*)(+):(*R*)-(−) values were determined for the excretion periods 0–2, 2–4, 4–6, 6–9, 9–12, and 12–24. The mean (*S*-)(+):(*R*)-(−) values for 0–24 hr are presented. The standard deviation was ±0.1 in each case. [c] Not analyzed. [d] These sums for carprofen and its enantiomers are minimum values because not all samples over the time period were analyzed. However, the samples not analyzed contained little radioactivity so their absence should not significantly affect the total excretion values. [e] Not detected.

each administered a single oral dose of 100 mg of carprofen[19]. Intact carprofen had been shown by Rubio *et al.* (10) to be the predominant component in human plasma during the first 12 hr after single-dose administration. Data on the enantiomeric ratios in the blood are presented in Table IV. The (*S*)-(+) enantiomer exceeded the (*R*)-(−) enantiomer at all time points, which is consistent with previous results (7). In addition, there was a small increase in the (*S*)-(+):(*R*)-(−) ratios with respect to time. The mean (± *SD*) of the ratios in the 4–16-hr blood samples was 1.48± 0.17, which was significantly higher ($p < 0.001$, Student *t* test) than the mean (± *SD*) of 1.21 ± 0.09 found for the early blood samples (0.5–2 hr). The relatively constant (*S*)-(+):(*R*)-(−) ratios in the 4–16-hr blood samples from the three human subjects resulted in parallel fall-off curves for the two enantiomers (Fig. 2). This finding suggests that assays for total carprofen would reflect the concentration of the pharmacologically more active (*S*)-(+) enantiomer, at least during this time period.

Previously a larger increase in (*S*)-(+):(*R*)-(−) ratios was seen in the blood of two rats given carprofen intravenously (6). The 1-hr blood samples had ratios of 1.14 and 1.21, while the 6-hr blood samples had ratios of 2.09 and 2.39. In these rats, the (*R*)-(−) enantiomer was eliminated from the blood at a rate approximately twice that of the (*S*)-(+) isomer. Therefore, the stereoselective disposition of carprofen is more pronounced in rats than in humans.

Rubio *et al.* (10) reported that three human subjects administered single oral 50-mg doses of [$^{14}$C]carprofen excreted (0–120 hr) a mean (± *SD*) of 2.8 ± 0.5% of the dose in the urine as free carprofen and 63.1 ± 10.8% as carprofen ester glucuronide. In the feces, a mean of 7% of the dose was recovered as directly extractable intact carprofen. Similar results were obtained by Ray *et al.* (12) after administration of single 100-mg doses of [$^{14}$C]carprofen to three human subjects.

Urine and fecal samples from the Rubio *et al.* study (10) were analyzed by the stereospecific assay (Table V). In all urine samples collected between 0 and 24 hr, the (*S*)-(+) enantiomer exceeded the (*R*)-(−) enantiomer; after 24 hr, urinary (*S*)-(+):(*R*)-(−) values were close to unity with the exception of the 48–72-hr urine of Subject I where the ratio was 0.7. The (*R*)-(−) enantiomer of free carprofen predominated in all fecal samples between 24 and 96 hr. These data demonstrate the stereoselective excretion of carprofen by humans.

Other α-methylarylacetic acids that are structurally related to carprofen undergo stereoselective inversion. Cicloprofen undergoes (*R*)-(−) to (*S*)-(+) inversion in rats (2, 3), monkeys (2), and dogs (4), and both ibuprofen (1) and benoxaprofen (5) undergo (*R*)-(−) to (*S*)-(+) inversion in humans. In each case, inversion was unequivocally demonstrated by the administration of the (*R*)-(−) enantiomer. Only the racemic mixture of carprofen has been given to humans. The amount of the (*S*)-(+) enantiomer of carprofen in the total urinary and fecal excretion exceeded the amount of the (*R*)-(−) enantiomer by only 2.1–4.9% of the dose (Table V). The data did not show any significant amount of stereoselective inversion of carprofen. However, since excreted carprofen accounted for only 62–72% of the administered dose, stereoselective inversion cannot be excluded as a possibility.

[19] Three normal volunteers, each receiving a single 100-mg dose of carprofen, were part of a study conducted by Dr. James D. Moore, University of Montana Foundation, Deer Lodge, Mont.

# Hydration and Percutaneous Absorption II: Influence of Hydration on Water and Alkanol Permeation through Swiss Mouse Skin; Comparison with Hairless Mouse

**CHARANJIT R. BEHL *x and MICHAEL BARRETT**

Received January 5, 1981, from the *College of Pharmacy, University of Michigan, Ann Arbor, MI 48109.* Accepted for publication March 16, 1981. *Present address: Pharmaceutical Research, Roche Laboratories, Hoffmann–La Roche Inc., Nutley, NJ 07110.

**Abstract** □ *In vitro* permeation studies with biological membranes often involve long, aqueous maceration of the tissue. The present investigation examined the possible effects of hydration on barrier integrity of Swiss mouse skin, using water, methanol, ethanol, and butanol as permeants and a previously developed procedure involving multiple, sequential permeation runs on each piece of skin. The permeation rate of water increased almost linearly up to 30 hr of hydration and then tended to level off. Transport rates of methanol and ethanol increased asymptotically and then plateaued at ~15 hr. These results contrast with earlier findings on hairless mouse skin where the permeabilities of these three compounds were unaffected by aqueous immersion. The permeation rate of butanol also increased during the first 15 hr of hydration but gradually declined over the next 25 hr. This result again contrasts with the hairless mouse species in which butanol permeability doubled in 10 hr and then plateaued. The species differences in the hydration profiles appear related to the vastly dissimilar pellages and, in the Swiss mouse, may indicate greater involvement of the transfollicular pathway.

**Keyphrases** □ Hydration—effect on water and alkanol permeation through Swiss mouse skin, comparison with hairless mouse □ Absorption, percutaneous—effect of hydration on water and alkanol permeation through Swiss mouse skin, comparison with hairless mouse □ Permeability—effect of hydration on water and alkanol absorption through Swiss mouse skin, comparison with hairless mouse

A previous study (1) on the influence of long aqueous immersion (hydration) on the permeability properties of hairless mouse skin used a method involving sequenced, *in vitro* diffusional experiments on each skin membrane. Hydration-related alterations of the permeation behaviors of a series of compounds were systematically investigated, and the observed effects were related to the physicochemical properties of the permeants and mass transport mechanism. The permeabilities of water, methanol, and ethanol were not affected by immersion of the skin in normal saline. The permeabilities of butanol and hexanol doubled and reached asymptotes in 10 hr of hydration. The permeation rate of heptanol only increased by ~50%, while octanol showed an initial 50% increase followed by a 25% decline to assume an invariant rate with a net 25% hydration-induced alteration.

In view of the experimental and possible mechanistic significance of the hydration-induced permeability alterations, the present study compared the influence of hydration on the skin permeability of the Swiss mouse, to that of the hairless mouse. The results obtained proved the skins of the two species to be exceedingly different in their chemical barrier properties, both in terms of absolute rates of permeation of the low molecular weight alcohols and in their hydration sensitivities.

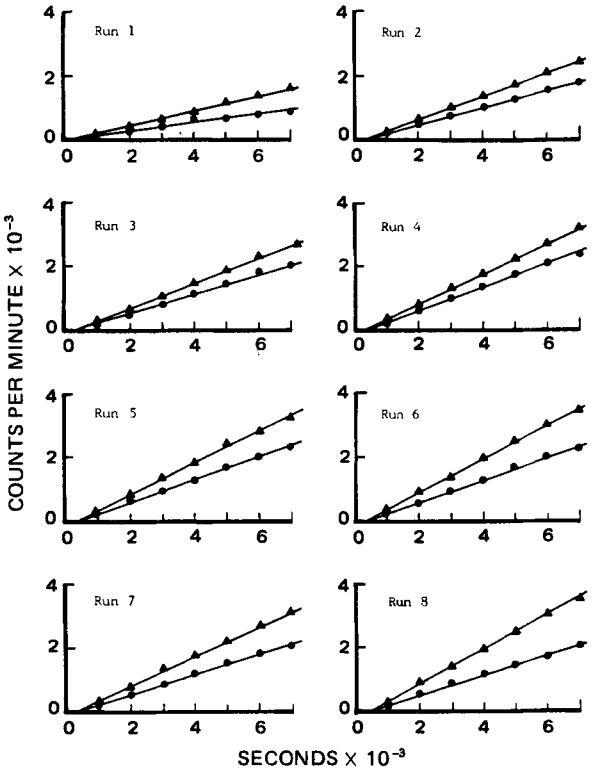

**Figure 1**—*Series of receiver concentration* versus *time profiles for eight sequential permeation runs on a single skin. This figure is one set of data from the methanol (▲)–butanol (●) series detailed in the text. Key: Run 1, $t_0$ = 0 hr; Run 2, $t_0$ = 5 hr; Run 3, $t_0$ = 10 hr; Run 4, $t_0$ = 15 hr; Run 5, $t_0$ = 20 hr; Run 6, $t_0$ = 25 hr; Run 7, $t_0$ = 30 hr; and Run 8, $t_0$ = 43 hr.*

**Keyphrases** □ Hydration—effect on water and alkanol permeation through Swiss mouse skin, comparison with hairless mouse □ Absorption, percutaneous—effect of hydration on water and alkanol permeation through Swiss mouse skin, comparison with hairless mouse □ Permeability—effect of hydration on water and alkanol absorption through Swiss mouse skin, comparison with hairless mouse

A previous study (1) on the influence of long aqueous immersion (hydration) on the permeability properties of hairless mouse skin used a method involving sequenced, *in vitro* diffusional experiments on each skin membrane. Hydration-related alterations of the permeation behaviors of a series of compounds were systematically investigated, and the observed effects were related to the physicochemical properties of the permeants and mass transport mechanism. The permeabilities of water, methanol, and ethanol were not affected by immersion of the skin in normal saline. The permeabilities of butanol and hexanol doubled and reached asymptotes in 10 hr of hydration. The permeation rate of heptanol only increased by ~50%, while octanol showed an initial 50% increase followed by a 25% decline to assume an invariant rate with a net 25% hydration-induced alteration.

In view of the experimental and possible mechanistic significance of the hydration-induced permeability alterations, the present study compared the influence of hydration on the skin permeability of the Swiss mouse, to that of the hairless mouse. The results obtained proved the skins of the two species to be exceedingly different in their chemical barrier properties, both in terms of absolute rates of permeation of the low molecular weight alcohols and in their hydration sensitivities.

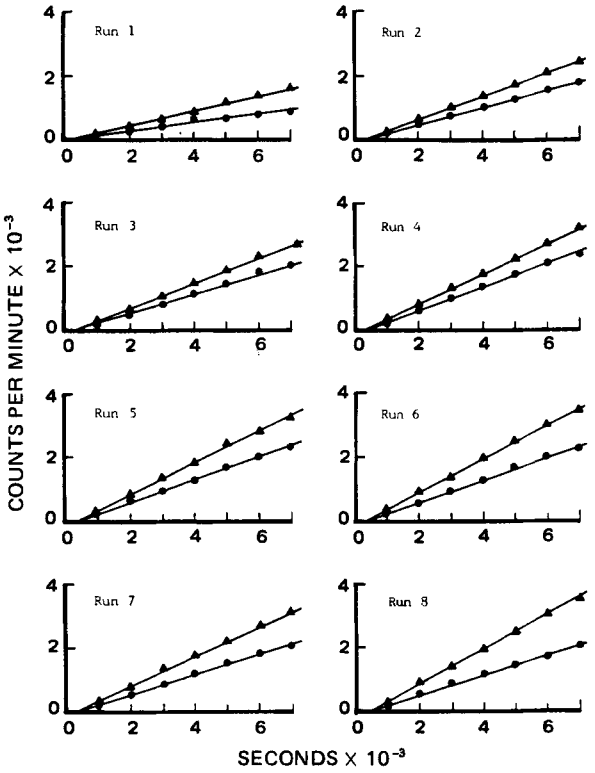

**Figure 1**—*Series of receiver concentration* versus *time profiles for eight sequential permeation runs on a single skin. This figure is one set of data from the methanol (▲)–butanol (●) series detailed in the text. Key: Run 1, $t_0$ = 0 hr; Run 2, $t_0$ = 5 hr; Run 3, $t_0$ = 10 hr; Run 4, $t_0$ = 15 hr; Run 5, $t_0$ = 20 hr; Run 6, $t_0$ = 25 hr; Run 7, $t_0$ = 30 hr; and Run 8, $t_0$ = 43 hr.*

## EXPERIMENTAL

**Chemicals**—[$^3$H]Water[1], [$^3$H]methanol[1], [$^{14}$C]ethanol[2], and [$^{14}$C]-butanol[2] were used as received. The radiochemicals were diluted into 0.9%

sodium chloride irrigation solution[3] (saline) for permeation experiments. The final chemical concentration in the diffusional medium was $\leq 10^{-4}$ *M*.

**Animals**—Male Swiss mice[4], albino out bred of Skh:Icr strains, had free access to food and water, and bedding was changed at least once a week.

**Hair Removal**—All skins used in the diffusion experiments were denuded of hair. Usual depilation methods, *i.e.*, shaving and chemical depilation, were avoided because they might seriously alter the barrier properties (2, 3). Hair from the abdominal surface of the freshly sacrificed mouse was removed by the nondestructive and nonirritating procedure of close cropping with a pair of surgical scissors.

**Permeation Procedure**—Two-compartment glass diffusion cells (1) were employed to determine skin permeability. All membranes sandwiched between the half-cells were full-thickness skin sections excised from the abdominal surfaces of Swiss mice, freshly sacrificed by spinal cord dislocation. Mouse age was tightly confined (~180 days) to avoid age-related effects (4). The external medium of the diffusion cell was saline, and the half-cell contents were stirred at 150 rpm. All experiments were carried out at 37°. The concentration in the receiver chamber (dermis side) was monitored with time for ~2 hr.

Complete hydration profiles were obtained on each skin by carrying out eight sequential experiments, with rinsing between runs (1). The

permeant concentration was determined radioisotopically using a liquid scintillation counter[5] with Aquasol[1] as the cocktail. A technique of dual labels was employed to study the permeation of $^3$H- and $^{14}$C-labeled penetrants simultaneously (4).

**Data Analysis**—The data were plotted as the receiver compartment concentration as a function of time. Each permeability coefficient was calculated from (1):

$$P = \frac{V}{A}\frac{(dC/dt)}{\Delta C} \qquad \text{(Eq. 1)}$$

where

$P$ = permeability coefficient (centimeters per hour)
$A$ = diffusional area (~0.6 cm$^2$)
$\Delta C$ = concentration difference across the membrane, which was taken to be equal to the donor concentration (counts per minute per cm$^3$)
$V$ = receiver half-cell volume (1.4 ml)
$dC/dt$ = steady-state slope (counts per minute per cubic centimeter per hour)

## RESULTS AND DISCUSSION

Figure 1 contains eight subplots obtained in sequential permeation experiments carried out on one piece of skin over 43 hr with [$^3$H]methanol and [$^{14}$C]butanol as the dual permeants. Under the experimental conditions, the linear relationship between the receiver concentration and time (which develops in each run) is representative of a quasi steady-state

transport process. Slopes of these linear segments were used to compute the permeability coefficients (Eq. 1).

Five mice were used for each of the four penetrants, and eight sequential experiments were run on each skin, yielding a total of 160 diffusion experiments. Permeability coefficients computed from 20 figures analogous to Fig. 1 are reported in Tables I–IV for water, methanol, ethanol, and butanol, respectively. Rather large animal-to-animal variations in the permeability coefficients were found for all four permeants. Similar variability was observed in earlier studies with the hairless mouse skin (1, 4). However, within a given piece of skin, permeabilities changed systematically and stereotypically for a given compound. The "percent hydration effect" was calculated from:

$$\text{percent hydration effect} = \frac{P\text{ (at a given hydration time)} - P\text{ (at zero hydration)}}{P\text{ (at zero hydration)}} \times 100 \quad \text{(Eq. 2)}$$

These derived numbers are given in Table V. To illustrate the hydration influences, the results (percentage changes) were plotted as a function of hydration time (Figs. 2–5).

Of all the permeants studied in the Swiss mouse skin, water experienced the largest increase in permeability during the aqueous immersion. Figure 2 shows that the percentage increase in permeability rose almost linearly up to 30 hr of immersion but then showed signs of leveling off. The hydration sensitivity for water was markedly different than that reported for the hairless species (1) where water penetration rates were not significantly altered by the soaking treatment. Methanol's permeability also increased with time of immersion but only up to ~20 hr. Beyond this point, the net hydration increase remained essentially invariant at 78.3 ± 3.8% (average of data at 20, 25, 30, and 48 hr of hydration). Ethanol exhibited similar behavior, with an asymptote value of 87.5 ± 6.7% (average of data at 20, 25, 30, and 48 hr of hydration). The close parallelism in the hydration profiles of methanol and ethanol may imply that both solutes penetrate the Swiss mouse skin *via* a common route. The results represent a great departure from hairless mouse data (1), which indicate no hydration-induced alterations for either methanol or ethanol.

Butanol's permeability through Swiss mouse skin also rose during the first 15 hr of aqueous immersion. Data gathered beyond this time are difficult to interpret since butanol's permeability appears to decline between 15 and 43 hr in an almost linear manner. The absolute permeability coefficients at 15 and 43 hr are not statistically separable. However, the lack of a statistically supported difference may be the result of interanimal variability since all five Swiss mouse skins showed an approximate 20% decline in butanol's permeability coefficient over 15–43 hr. Moreover, the butanol data were obtained using the dual-label procedure with methanol as the copermeant, and the permeability coefficient

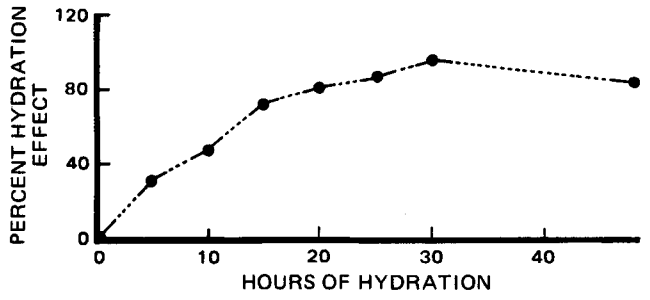

**Figure 4**—*Plot of hydration effects* versus *hydration time for ethanol.*

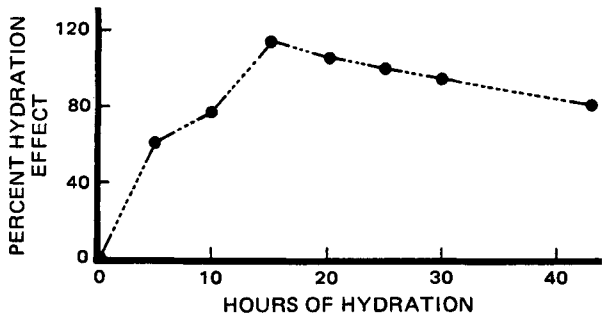

**Figure 5**—*Plot of hydration effects* versus *hydration time for butanol.*

for methanol was invariant past ~20 hr. It was tentatively concluded that when hydrating conditions are sustained past 15 hr, there is a small but real depreciation of the permeability coefficient of butanol. For hairless mouse skin, butanol's permeability coefficient doubled over the initial 10-hr immersion and then remained constant (1). Thus, with the lower alkanols and water, the skin of the Swiss species behaved qualitatively differently from that of hairless species.

**Possible Explanation of Observed Hydration Profiles**—*Water, Methanol, and Ethanol*—It was pointed out (4) that the polar solutes (water, methanol, and ethanol) do not appear to permeate the skin of the hairless mouse by the main lipoidal pathway, presumably located within the stratum corneum, but use an alternative parallel diffusional route of either transfollicular or transepidermal origin. In the mature hairless mouse, most follicles are cystic, the atrophied remains of an early coat of hair, and are not visually prominent. However, the Swiss mouse is abundantly covered with actively cycling hair follicles containing prominent hairs. Given this difference between the two species, it might be expected for a follicularly placed polar pathway that hydrophilic permeants would have greatly enhanced permeabilities through Swiss mouse skin. The permeability coefficients for water, methanol, and ethanol were indeed several times larger in the Swiss species than in the hairless species, particularly when compared in the fully hydrated states.

The qualitative differences in hydration sensitivities between the two types of mice are of even greater significance. Water gradually plasticized some critical phase of the Swiss mouse skin and opened it to more facile diffusion of the small polar solutes. In contrast, the permeabilities of water, methanol, and ethanol through hairless mouse skin were unaffected by long immersion. Quantitative considerations aside, there is obviously some fundamental difference in tissue structure and the barrier mechanism. These changes may be due to an enhanced follicular mechanism in the Swiss mouse. In this case, gradual hydration and softening of the sebaceous medium would explain the overall effects. However, the skin is integrated tissue and increased follicular density and hair prominency have been associated with a less well-formed horny layer. Thus, the critical changes possibly are associated with different degrees and qualities of cornification.

*Butanol*—Permeation of butanol was reported (1,4) to occur transepidermally by partitioning into the lipoid components of the stratum corneum of hairless mouse skin. This process is believed to occur in the Swiss species as well. Therefore, the hydration-related permeability changes in the Swiss species could be due to some modification of the lipoidal pathway in the stratum corneum. However, the exact mechanism for either species is unknown.

**Significance of Present Studies**—The influence of hydration needs to be considered in the design of skin permeation studies, and the exact state of hydration should be reported. This study suggests a possible means of factoring transepidermal and the transfollicular pathways. Given the possible association of the hair follicles and hydration-induced alterations in skin permeability, clinically different results of the occlusive dressing might be expected between hairy and nonhairy human surfaces.

# Stability-Indicating High-Performance Liquid Chromatographic Analysis of Lidocaine Hydrochloride and Lidocaine Hydrochloride with Epinephrine Injectable Solutions

**SIGMUND M. WARASZKIEWICZ ˣ, E. A. MILANO, and R. DiRUBIO**

Received December 12, 1980, from *Astra Pharmaceutical Products, Inc., Worcester, MA 01606.* Accepted for publication March 24, 1981.

**Abstract** □ A reversed-phase, high-performance liquid chromatographic (HPLC) procedure, which is specific and quantitative for lidocaine hydrochloride, epinephrine, and methylparaben, was developed for the analysis of lidocaine hydrochloride and lidocaine hydrochloride with epinephrine solutions for injection. Epinephrine sulfonic acid and adrenochrome are separated in this system. Also separated are lidocaine and methylparaben and their respective degradation products, 2,6-xylidine and *p*-hydroxybenzoic acid. The analysis requires that three detectors (two UV and one electrochemical) be connected in series. By using this arrangement, lidocaine hydrochloride and methylparaben are quantitated by UV at 254 and 280 nm, respectively, while epinephrine is quantitated electrochemically. The method is simple, accurate, precise, and rapid. No sample preparation or internal standard is necessary, and only a 2-μl sample volume is required for analysis. Chromatographic conditions include a μBondapak CN column and a mobile phase of 0.01 *M* 1-octanesulfonic acid sodium salt, 0.1 m*M* edetate disodium, 2% acetic acid, 2% acetonitrile, and 1% methanol in water.

**Keyphrases** □ High-performance liquid chromatography—specific and quantitative stability-indicating procedure for lidocaine hydrochloride, epinephrine, and methylparaben □ Lidocaine hydrochloride—injectable solutions of epinephrine using stability-indicating high-performance liquid chromatography □ Epinephrine—high-performance liquid chromatographic procedure for assaying components of injectable solutions □ Methylparaben—high-performance liquid chromatography for assaying components of injectable solutions

A literature review indicated that the various colorimetric and fluorometric methods utilized for the analysis of epinephrine in local anesthetic solutions all have problems associated with them (1, 2). The colorimetric methods generally are not stability indicating. Epinephrine sulfonic acid and bisulfite interfere with the development of the color, resulting in a lack of specificity for intact epinephrine.

A fluorometric procedure, based on the trihydroxyindole reaction first observed by Loew (3) and later modified (4, 5), is specific for epinephrine but is subject to many variables such as time, temperature, pH, presence of bisulfite, and the composition of the final alkaline/ascorbate reagent. The current USP (6) method for assaying epinephrine in lidocaine hydrochloride injectable solutions is a fluorometric procedure; although the method is specific for epinephrine, its application requires a great deal of experience and technique. The fluorometric procedure for the analysis of epinephrine in lidocaine hydrochloride injectable solutions has been automated (7) but is subject to interferences.

A high-performance liquid chromatographic (HPLC) method for epinephrine in local anesthetic solutions, which utilized a UV detector, was developed in this laboratory, but it lacked the specificity and sensitivity needed to be stability indicating. The development of electrochemical detectors for HPLC (8) and their subsequent application in the analysis of catecholamines in biological systems (9, 10) opened an entirely new possibility for the analysis of epinephrine in local anesthetic preparations. By coupling the electrochemical detector in series with a UV detector, it was possible to develop a specific, stability-indicating method that not only allowed for improved analysis of epinephrine but also permitted the simultaneous analysis of methylparaben and lidocaine hydrochloride (Fig. 1).

## EXPERIMENTAL

**Apparatus**—Analyses were performed on a liquid chromatograph[1] equipped with a 6000-psi solvent delivery system[2] and a septumless injector[3]. Detection of methylparaben and lidocaine was carried out with a dual-channel fixed-wavelength UV detector[4]. The methylparaben was quantitated at 280 nm, and the lidocaine hydrochloride was quantitated at 254 nm. Detection of epinephrine was carried out with a glassy carbon thin-layer detector cell[5] operated with an amperometric controller[6] at a potential of +0.90 v relative to a silver–silver chloride reference electrode[7]. The inlet of the electrochemical detector was connected to the outlet of the UV detector. The prepacked column[8] (30 cm × 4 mm i.d.) was operated at ambient temperature at a flow rate of 2.0 ml/min.

**Reagents**—1-Octanesulfonic acid sodium salt[9], edetate disodium[10], acetic acid[11], acetonitrile[12], methanol[13], methylparaben[14], and lidocaine hydrochloride monohydrate USP[15] were used as received. Epinephrine bitartrate USP reference standard[16] was dried in a vacuum desiccator over silica gel for at least 3 hr before use and subsequently stored in a desiccator over silica gel.

**Mobile Phase**—The mobile phase consisted of 0.01 *M* 1-octanesulfonic acid sodium salt, 0.1 m*M* edetate disodium, 2% (v/v) acetic acid, 2% (v/v) acetonitrile, and 1% (v/v) methanol in high quality distilled water. To minimize random electrical noise spikes from the electrochemical detector, the mobile phase should be degassed daily by filtering through a 0.45-μm filter[17] connected to an aspirator.

**Stock Solutions**—*Epinephrine*[18]—An appropriate quantity (Table I) of epinephrine bitartrate USP reference standard was weighed accurately into the appropriate size volumetric flask, 0.01 *N* HCl was added, and the solution was diluted to volume with 0.01 *N* HCl and mixed. The solution is stable for 1 week if refrigerated.

*Methylparaben*—In a 250-ml volumetric flask, 625 mg of methylparaben (accurately weighed) was added to 10 ml of acetonitrile and stirred until completely dissolved. The solution was diluted to volume with distilled water and mixed. Then the solution was cooled to room temperature and diluted to volume with distilled water. Occasionally, upon standing, some methylparaben crystallized out; it was redissolved by heating, but care was taken to recool to room temperature before pipetting for preparation of the standards.

*Lidocaine Hydrochloride*[18]—An appropriate quantity (Table I) of lidocaine hydrochloride monohydrate USP was weighed accurately into a 100-ml volumetric flask and distilled water was added; then the solution was diluted to volume with distilled water and mixed.

**Table I—Weight Guidelines for the Preparation of Stock Solutions and Standards for Various Lidocaine Hydrochloride–Epinephrine Products**

| Sample | Stock Solution | Recommended Dilution | Resulting Concentration |
|---|---|---|---|
| | Epinephrine[a] | | |
| 1:50,000 | ~18 mg/100 ml of 0.01 *N* HCl | 5:25 | ~20 μg/ml |
| 1:100,000 | ~23 mg/250 ml of 0.01 *N* HCl | 5:25 | ~10 μg/ml |
| 1:200,000 | ~23 mg/500 ml of 0.01 *N* HCl | 5:25 | ~5.0 μg/ml |
| | Methylparaben[b] | | |
| 1.00 mg/ml | ~625 mg/250 ml of distilled water | 10:25 | ~1.0 mg/ml |
| | Lidocaine Hydrochloride[c] | | |
| 0.5% | ~1.56 g/100 ml of distilled water | 9:25 (8:25) | ~5.3 (~4.7), mg/ml |
| 1.0% | ~3.11 g/100 ml of distilled water | 9:25 (8:25) | ~10.5 (~9.4), mg/ml |
| 1.5% | ~4.67 g/100 ml of distilled water | 9:25 (8:25) | ~15.8 (~14.1), mg/ml |
| 2.0% | ~6.22 g/100 ml of distilled water | 9:25 (8:25) | ~21.0 (~18.7), mg/ml |

[a] Epinephrine (μg/ml) = [epinephrine bitartrate (mg)/volume (ml)] × (183.21/333.30) × (5/25) × 1000. [b] Methylparaben (mg/ml) = [methylparaben (mg)/250] × (10/25). [c] Lidocaine hydrochloride (mg/ml) = [lidocaine HCl · $H_2O$ (g)/100] × (270.8/288.8) × [9(8)/25] × 1000.

**Standard Solutions**—Two standards (one at ~95% and one at ~105% of the expected lidocaine hydrochloride concentration) are required for the quantitation of the lidocaine hydrochloride if calculated utilizing peak heights. (Preliminary data indicated that only one standard is necessary if peak areas are utilized for the quantitation.)

*Standard I*—Five milliliters of the appropriate (Table I) epinephrine stock solution, 10 ml of methylparaben stock solution, and 9 ml of the appropriate (Table I) lidocaine hydrochloride stock solution were pipetted into a 25-ml volumetric flask, diluted to volume with distilled water, and mixed.

*Standard II*—Five milliliters of the epinephrine stock solution used for Standard I, 10 ml of methylparaben stock solution, and 8 ml of the lidocaine hydrochloride stock solution used for Standard I were pipetted into a 25-ml volumetric flask, diluted to volume with distilled water, and mixed.

The lidocaine hydrochloride monohydrate salt was used to prepare the stock solutions, but the final concentrations of the standards are reported as anhydrous lidocaine hydrochloride.

**Chromatography**—The column was conditioned with mobile phase for 0.5 hr at a flow rate of 2 ml/min before use. The electrochemical detector was turned on 0.5 hr before use. Standard I (2 μl) was injected repeatedly until the peak height response for all peaks of interest was reproducible to ±1–2%. The retention times of epinephrine, methylparaben, and lidocaine are ~3, ~5, and ~7 min, respectively. The flow rate was varied slightly to compensate for minor column-to-column differences. Two-microliter injections of the standards and samples were made, ensuring that each series of samples was bracketed by an injection of Standards I and II.

**Calculations**—The following calculations were used.

1. epinephrine (micrograms per milliliter) = (peak height of epinephrine in sample divided by average peak height of epinephrine in Standards I and II) × concentration of epinephrine in standards (micrograms per milliliter)

2. methylparaben (milligrams per milliliter) = (peak height of methylparaben in sample divided by average peak height of methylparaben in Standards I and II) × concentration of methylparaben in standards (milligrams per milliliter)

For lidocaine hydrochloride (milligrams per milliliter)[19], the equation of the line is determined where $Y_I$ and $Y_{II}$ are the peak heights for lidocaine hydrochloride in Standards I and II and $X_I$ and $X_{II}$ are the concentrations (milligrams per milliliter) of lidocaine hydrochloride in Standards I and II, respectively. The peak height ($Y_s$) for lidocaine hy-

drochloride in the sample is substituted into the equation, which is solved for the concentration ($X_s$).

## RESULTS

**Precision**—The precision (reproducibility), reported as the relative standard deviation, was better than ±1% for epinephrine, methylparaben, and lidocaine hydrochloride as determined on 10 replicate injections.

**Linearity**—The linearity of response was determined by preparing samples containing known quantities of the components of interest in a range from ~80–120% of the theoretical labeled quantity at each concentration[20]. All calibration curves were linear, with correlations coefficient >0.99.

**Accuracy**—Accuracy was determined by preparing simulated samples containing known quantities of the components of interest along with all excipients. The percent recoveries were determined by four different operators on two liquid chromatographs over 1 week, indicating that a day-to-day accuracy of ±1% could be obtained routinely: epinephrine, 99.9 ± 0.6% (98.1–100.9%), $n$ = 34; methylparaben, 99.8 ± 0.5% (99.0–100.6%), $n$ = 8; and lidocaine hydrochloride, 100.2 ± 0.9% (98.4–101.8%), $n$ = 30.

**Specificity**—Simulated samples to which the potential degradation products had been added were injected, and the chromatograms were recorded. The potential degradation products were separated from the components of interest (Table II), indicating that the HPLC method is stability indicating.

**Table II—HPLC Retention Values for Epinephrine, Methylparaben, Lidocaine Hydrochloride, and Their Potential Degradation Products**

| Compound | Retention Time, min | $k'$ |
|---|---|---|
| Epinephrine sulfonic acid | 1.8 | 0.29 |
| Adrenochrome | 2.2 | 0.57 |
| Epinephrine | 3.0 | 1.14 |
| *p*-Hydroxybenzoic acid | 3.2 | 1.29 |
| Methylparaben | 5.0 | 2.57 |
| 2,6-Xylidine | 4.4 | 2.14 |
| Lidocaine hydrochloride | 6.8 | 3.86 |

Further proof of this stability-indicating capability was obtained by subjecting production batches[21] of lidocaine hydrochloride with epinephrine injection to various conditions of stress[22] and assaying for epinephrine, methylparaben, and lidocaine hydrochloride. The results indicated that the major degradation products were those that had been proposed (Table II) and also that any other unknown degradation products did not interfere with the assays.

A comparison of the chromatograms obtained from analysis of the same solution[23] with the UV and electrochemical detectors clearly showed the advantages gained in specificity and sensitivity from the electrochemical detectors. Not only the degradation products but also the package extractables interfered with the accurate quantitation of epinephrine with the UV detector (Fig. 2).

An electrochemically active peak was observed that eluted from the column immediately after epinephrine (Fig. 3). This peak was identified

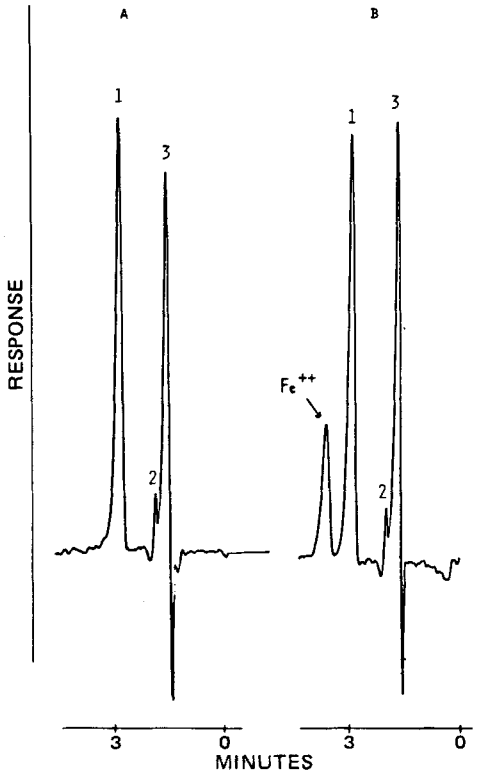

**Figure 3**—*Representative chromatograms of a 2-μl injection of a 2% lidocaine hydrochloride with 1:100,000 epinephrine solution. Key: A, with 0.1 m*M *disodium edetate in the mobile phase; B; without disodium edetate; 1, epinephrine; 2, epinephrine sulfonic acid; and 3, sodium metabisulfite.*

[20] Epinephrine concentrations were 1:50,000; 1:100,000; and 1:200,000. The methylparaben concentration was 1.00 mg/ml. The lidocaine hydrochloride concentrations were 0.5, 1.0, and 2.0%. The method was developed so that solutions containing 0.5–2.0% lidocaine hydrochloride could be assayed without any sample preparation. If the lidocaine hydrochloride concentration in a sample to be assayed is >2.0%, an appropriate dilution with distilled water should be made so that the lidocaine hydrochloride concentration is between 0.5 and >2.0%.

[22] Autoclaving for 5, 10, and 20 cycles, storage for 1 month at 80 and 110°, exposure to atmospheric oxygen, addition of 12 ppm of aluminum, and an increase in the pH of the solution.

[23] Product at its expiration date.

**Table III—Comparison of the HPLC Method with the USP XX or Current Methodology**

| Assay | Number of Batches Assayed | Percent Difference[a] |
|---|---|---|
| Epinephrine | 115 | −0.3 (USP–HPLC) |
| Methylparaben | 87 | +2.5 (UV–HPLC) |
| Lidocaine hydrochloride | 87 | −2.3 (USP–HPLC) |

[a] Mean percent difference for batches assayed.

as $Fe^{2+}$ (11) and did not interfere with the assay. However, addition of 0.1 m*M* edetate disodium to the mobile phase resulted in complete elimination of the $Fe^{2+}$ peak with no other effect on the chromatogram.

**Comparison of HPLC Method with USP or Current Methodology**—Production samples[21] of lidocaine hydrochloride with epinephrine in injectable solutions, which included vials, ampuls, and dental cartridges from batches < 1 month old to batches at their expiration date, were assayed by HPLC, fluorometry (epinephrine), titrimetry (lidocaine hydrochloride), and spectrophotometry (methylparaben). All analyses were performed on individual dosage units (if enough solution was available) or on aliquots from a pool of several dosage units (if one unit was inadequate). The results (Table III) indicate good agreement between the methods.

## DISCUSSION

The HPLC procedure provides a significant advance over existing methodology for assaying components in epinephrine-containing local anesthetic injectable solutions. Three of the major components (epinephrine, lidocaine hydrochloride, and methylparaben) of these types of dosage forms may be assayed simultaneously in one injection. The current methodology requires separate analytical procedures for each component.

The small sample size (2 μl) allows replicate analysis of the three components from individual dosage units. The current methodology in some cases requires units to be pooled to obtain a sufficient sample for analysis.

No preparation of the sample is necessary. The dosage unit is opened, a 2-μl aliquot is removed with a 10-μl syringe, and the sample is injected into the chromatograph. The current methodology requires extensive sample preparation for each component.

The HPLC method is selective and specific for all three components and is stability indicating.

Although both the HPLC and current methodology may be automated, the HPLC method offers a distinct advantage since only one setup of automated equipment is needed. The current methodology requires three separate and different automated setups since the procedure for each component is different. The HPLC methodology can be used to assay other local anesthetic injectable solutions such as prilocaine hydrochloride, etidocaine hydrochloride, mepivacaine hydrochloride, and bupivacaine hydrochloride with little or no change in the mobile phase.

# GC and GC–Mass Spectrometric Determination of *p*-Hydroxyphenobarbital Extracted from Plasma, Urine, and Hepatic Microsomes

**I. M. KAPETANOVIĆ *x and H. J. KUPFERBERG**

Received September 10, 1980, from the *Epilepsy Branch, National Institute of Neurological and Communicative Disorders and Stroke, Bethesda, MD 20205.* Accepted for publication March 19, 1981.

*Present address: Laboratory of Neurosciences, Gerontology Research Center, National Institute on Aging, Baltimore City Hospital, Baltimore, MD 21224.

**Abstract** □ Analytical methodology was developed for the quantitation of *p*-hydroxyphenobarbital extracted from plasma, urine, and hepatic microsomes. *p*-Hydroxyphenobarbital was derivatized with an appropriate *n*-alkyl iodide in the presence of a methanolic base in aprotic solvent medium. The peralkylated derivatives were stable indefinitely and were quantitated by the sensitive and selective method of GC nitrogen-selective detection and/or selected ion monitoring. The accuracy, precision, and cross verification of all methods were good. The analysis was subsequently used to study the effects of other drugs on phenobarbital biodisposition.

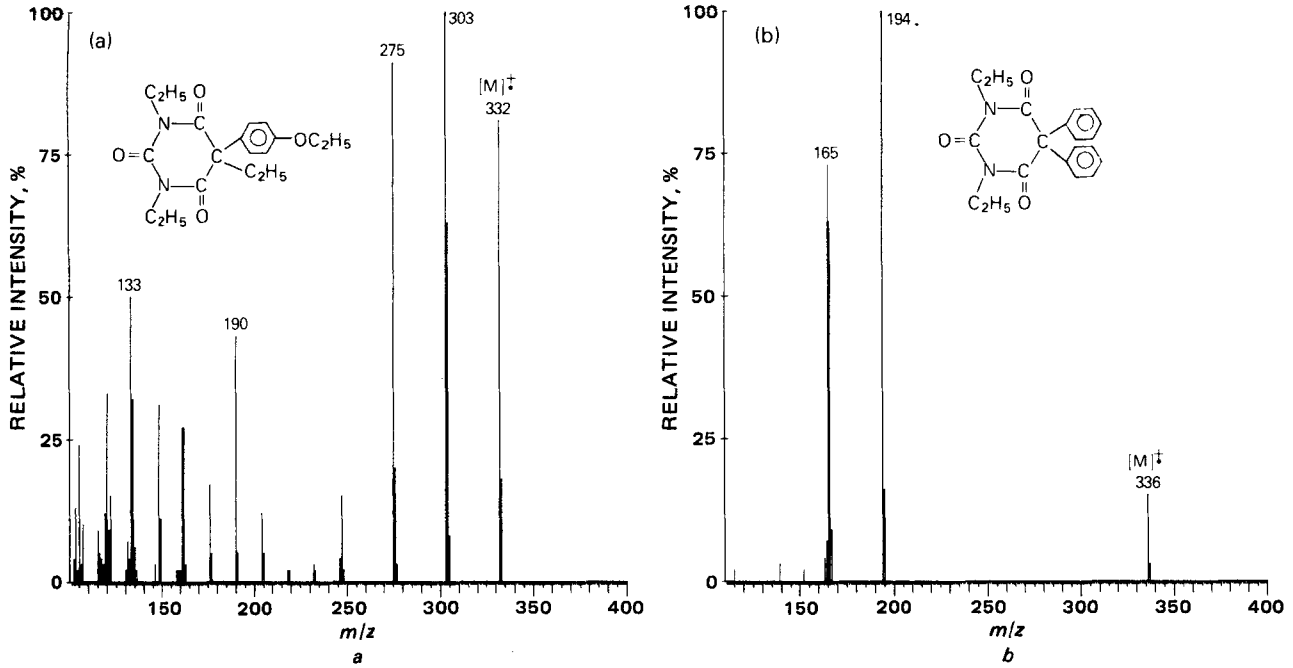

**Figure 2**—*Electron-impact spectra of ethylated* p-*hydroxyphenobarbital* (a) *and diphenylbarbituric acid* (b).

proate-caused elevation of plasma phenobarbital levels, it became necessary to quantitate *p*-hydroxyphenobarbital extracted from plasma, urine, and hepatic microsomes. The reported procedures for its quantitation lacked sensitivity or selectivity, and some methods had additional drawbacks. For example, countercurrent distribution and TLC in conjunction with liquid scintillation (1) are laborious and require the use of a radioactive tracer. TLC methods (2, 3) usually require a separate means of detection. GC methods using on-column methylation (4) can yield incomplete derivatization, and they also accelerate column degradation; furthermore, samples are not very stable once the alkylating base is added. The high-pressure liquid chromatographic method (5) has limited sensitivity due to a relatively poor extinction coefficient of unionized barbiturates.

Therefore, a GC nitrogen-selective detection method was developed for the determination of *p*-hydroxyphenobarbital. The nitrogen-selective detector is commercially available and is a reasonably priced accessory for the gas chromatograph. Its simplicity of operation is similar to that of the regular flame-ionization detector, but its sensitivity and selectivity are superior. The barbiturates were derivatized to optimize their chromatographic sep-

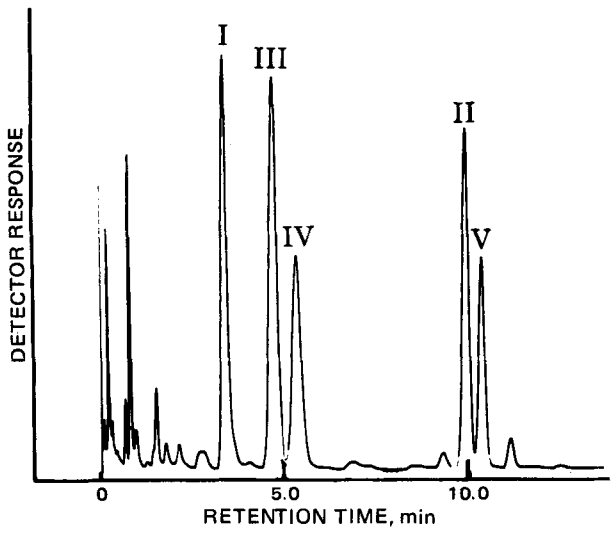

**Figure 3**—*Gas chromatogram of propylated human urine (hydrolyzed) extract using nitrogen–phosphorus flame-ionization detector. Levels of phenobarbital (I),* p-*hydroxyphenobarbital (II), and primidone (IV) were 34.6, 40.3, and 31.9 μg/ml, respectively. Diphenylbarbituric acid (V, 25 μg/ml) and* p-*methylphenobarbital (III, 50 μg/ml) were the internal standards.*

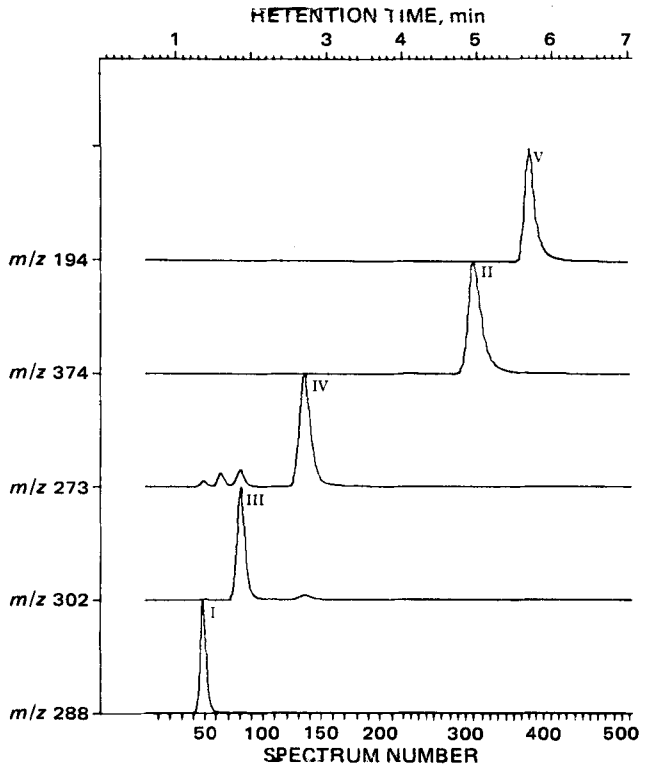

**Figure 4**—*Selected ion monitoring (electron-impact mode) tracing of propylated human urine (hydrolyzed) extract. For additional details, see Fig. 3.*

**Table I—Accuracy and Precision of Determination of Urinary *p*-Hydroxyphenobarbital (II), Phenobarbital (I), and Primidone (IV)**

| Actual II, I and IV, μg/ml | Experimental[a], μg/ml | | |
|---|---|---|---|
| | II | I | IV |
| 10.00 | 10.08 ± 0.27 | 9.12 ± 0.28 | 10.32 ± 0.24 |
| 100.00 | 100.40 ± 1.23 | 101.10 ± 1.54 | 97.60 ± 1.72 |

[a] Values expressed as mean ± *SD* of four determinations.

aration and to stabilize them. Derivatization was performed by modification of a reported alkylation procedure for barbiturates (6).

These analytical methods were satisfactorily employed for *in vitro* animal experiments and *in vivo* human studies dealing with valproate-phenobarbital interaction (7–9).

## EXPERIMENTAL

**Instrumentation**—The gas chromatograph[1] was equipped with a flame-ionization detector and a nitrogen–phosphorus flame-ionization detector. The injection port and detector temperatures were 260 and 300°, respectively. Helium was used as the carrier at a flow rate of 30 ml/min.

The dodecapole mass spectrometer[2] was equipped with electron-impact and chemical-ionization sources and was coupled to the gas chromatograph[3] by a glass-lined single-stage jet separator. Data acquisition and reduction were computer automated[4]. The temperatures of the injection port, transfer line, and ion source were 300, 300, and 180°, respectively. In the electron-impact mode, helium was used as the carrier at a flow rate of 25 ml/min; the operating pressure of the ion source was $3.7 \times 10^{-6}$ torr, and the mass spectrometer was operated with an electron energy of 70 ev. In the chemical-ionization mode, methane was used as the carrier at a flow rate of 15 ml/min and as a reagent gas. The operating pressure of the ion source was 0.4 torr, and an ionizing energy of 250 ev was used to produce the reactant ions.

**Materials**—All organic solvents[5] were used as obtained after their purity was checked. Reference compounds (phenobarbital[6], primidone[6], and *p*-hydroxyphenobarbital[7]) and internal standards (*p*-methylphenobarbital[7] and 5,5-diphenylbarbituric acid[8]) were also checked for purity before use. Methyl, ethyl, *n*-propyl, and *n*-butyl iodides[9] and tetraethylammonium hydroxide (25% methanolic solution[9]) were used as obtained.

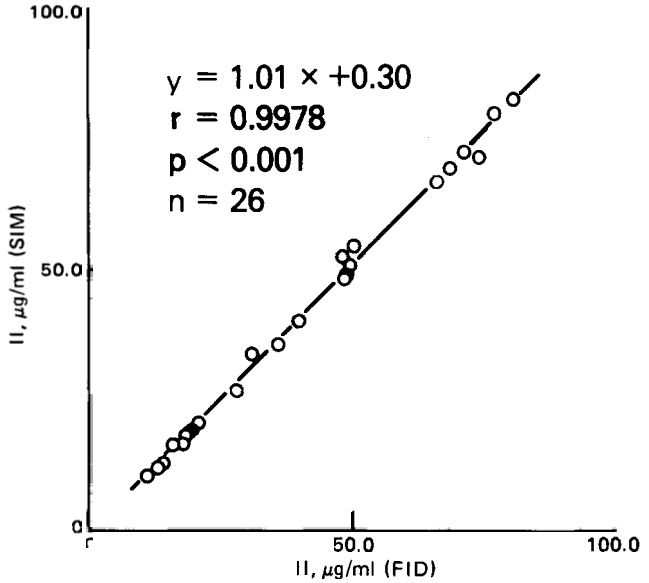

**Figure 5**—*Relationship between selected ion monitoring (SIM) at electron-impact mode and GC nitrogen–phosphorus flame-ionization detector (FID) methods for quantitation of urinary* p-*hydroxyphenobarbital (II).*

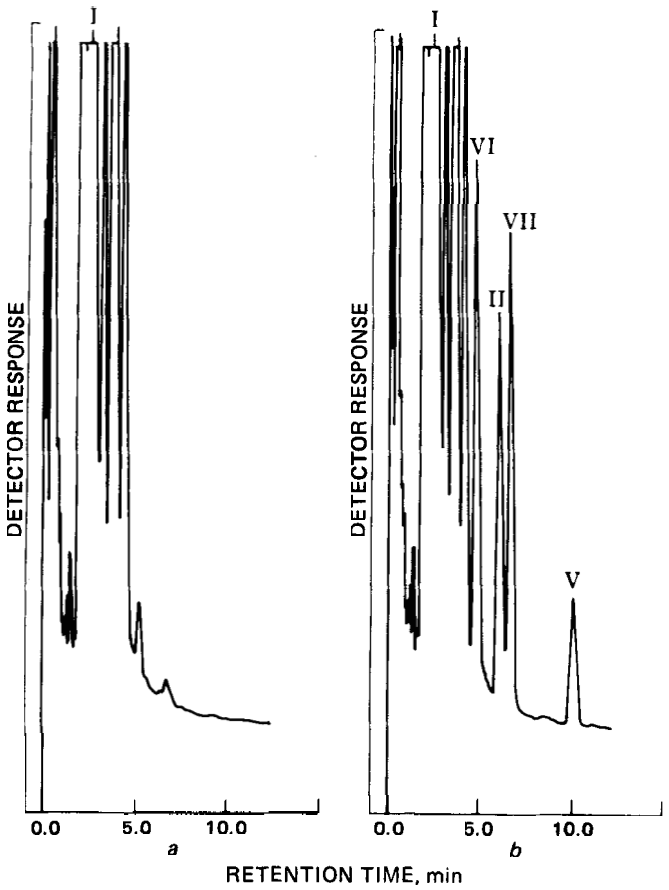

**Figure 6**—*Gas chromatogram of extract from microsomal blank (a) and microsomal phenobarbital reaction mixture containing phenobarbital (b) using nitrogen–phosphorus flame-ionization detector. The reaction occurred in the presence of 4 mM phenobarbital, and 0.875 μg of* p-*hydroxyphenobarbital was formed. Diphenylbarbituric acid (0.50 μg) was the internal standard. Peaks VI and VII represent other metabolites of phenobarbital. The microsomal blank was run parallel to the microsomal phenobarbital reaction, but NADPH was added after termination of the reaction and no internal standard was added. The chromatogram of the blank shows a lack of interferences for* p-*hydroxyphenobarbital and diphenylbarbituric acid.*

Silanized GC glass columns[10] for heated on-column injection were packed with commercially available packings[10].

Sodium salt of phenobarbital[11] was used for animal treatment.

A commercial source of β-glucuronidase–arylsulfatase and NADPH was used[12].

All other chemicals were reagent grade.

**Human Subjects**—The subjects were epileptic patients[13] who consented to participate in a clinical study of drug–drug interactions in antiepileptic therapy. Blood samples were obtained at 7 am, just prior to administration of the patients' morning medication (including phenobarbital and/or primidone); 24-hr urine samples were also collected. For the clinical study, blood and urine samples were obtained while the plasma barbiturate levels were at steady state.

**Animals**—Adult male Holtzman rats[14], ~200 g, were injected intra-

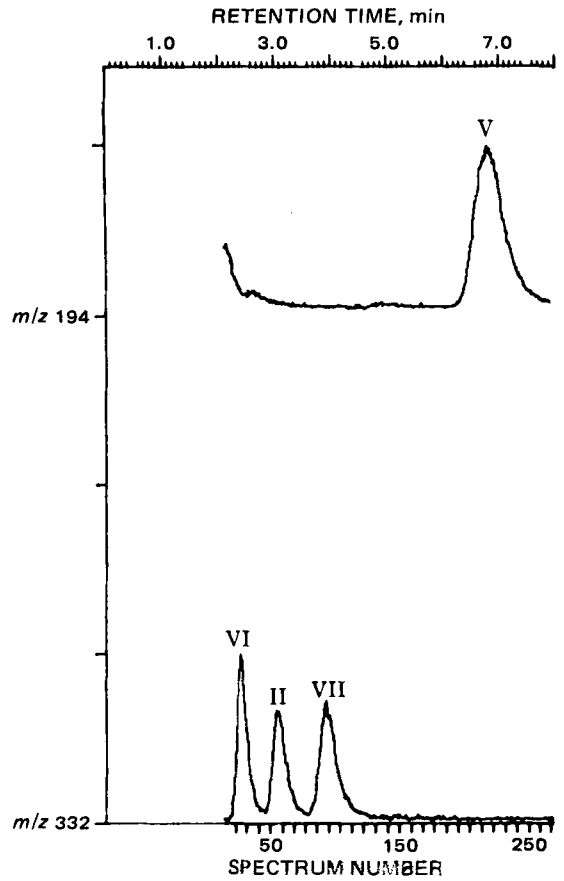

**Figure 7**—*Selected ion monitoring (electron-impact mode) tracing of ethylated extract from microsomal phenobarbital metabolic reaction. For additional details, see Fig. 6.*

peritoneally with aqueous phenobarbital sodium solution (75 mg/kg) on 3 consecutive days. The rats were then sacrificed, and hepatic microsomes were prepared as previously described (10).

**Microsomal Reactions**—Microsomal reactions were carried out in 0.1 *M* potassium phosphate buffer (pH 7.50) in the presence of 1.83 nmoles of microsomal cytochrome P-450 and various concentrations of the substrate, phenobarbital. Following preequilibration of the samples at 37° for 1 min, reaction was initiated with NADPH (final NADPH concentration in the reaction mixture was 0.25 m*M*). The samples were incubated at 37° for 8 min in 5 ml of reaction mixture.

**Plasma Extraction**—Stock methanolic solutions of reference compounds and internal standards were kept at 4° and were stable on storage. Methanolic solutions of reference compounds (10–200 μl) were added to the tubes to be used for standards, and methanolic solutions of internal standards were added to all of the tubes. Methanol was evaporated, using a rotary evaporator with aspirator vacuum[15]. Blank plasma or plasma from phenobarbital-treated subjects (1 ml) was added to the appropriate tubes. Spiked plasma standards were extracted along with the patients' samples.

For the determination of total (free plus conjugated) *p*-hydroxyphenobarbital, the samples were hydrolyzed. Free *p*-hydroxyphenobarbital was determined by omitting the hydrolysis. For determination of total *p*-hydroxyphenobarbital, 0.2 ml of 0.5 *M* sodium acetate buffer (pH 5.00) was added, followed by 50 μl of β-glucuronidase–arylsulfatase, and samples were incubated at 37° for 20–24 hr. To hydrolyzed and nonhydrolyzed samples, 1 ml of 1 *M* monobasic potassium phosphate was added; samples were then extracted with 7 ml of ethyl acetate, using a reciprocating shaker. Following centrifugation (~2000 rpm), the ethyl acetate phase was collected and washed with 2 ml of 0.1 *N* HCl and evaporated to dryness. Hexane was added to the residue, and the samples were extracted with 5 ml of acetonitrile. Hexane was used to remove endogenous lipoidal substances. The acetonitrile phase was collected and evaporated to dryness, and the residue was ready for derivatization.

**Urine Extraction**—The hydrolysis of urine samples was analogous to that of the plasma samples. Hydrolyzed and nonhydrolyzed urine samples were extracted in the same manner as the plasma samples.

[15] Buchler Instruments, Fort Lee, N.J.

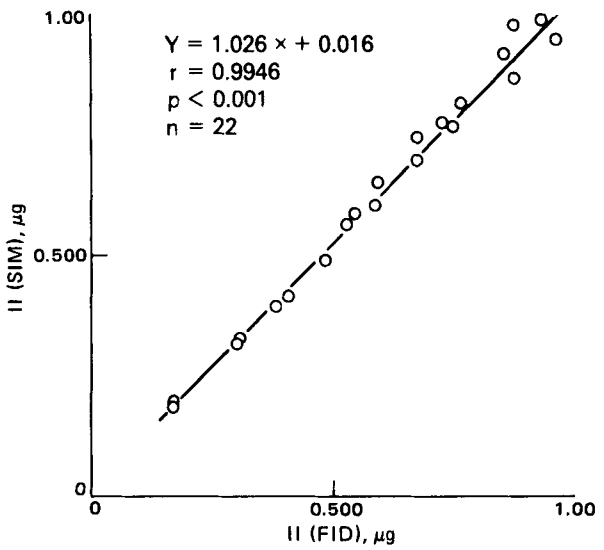

**Figure 8**—*Relationship between selected ion monitoring (SIM) (electron-impact mode) and GC nitrogen–phosphorus flame-ionization detector (FID) methods for quantitation of* p*-hydroxyphenobarbital (II) formed in microsomal reaction.*

**Microsome Extraction**—Microsomal reactions were terminated by the addition of 7 ml of cold benzene (or toluene). For consistency, phenobarbital was added such that its final concentration prior to the addition of benzene was always the same. Aqueous and organic phases were mixed by hand inversion, samples were centrifuged, and the benzene layer was discarded. The samples were then washed again with 7 ml of benzene. A double benzene wash was employed to eliminate some of the large excess of phenobarbital, which would otherwise swamp the peak corresponding to the relatively small amounts of generated *p*-hydroxyphenobarbital. *p*-Hydroxyphenobarbital was not extractable into benzene under these conditions. Following the benzene washes, diphenylbarbituric acid (the internal standard) was added, and the samples were extracted with 7 ml of ethyl acetate; the ethyl acetate phase was collected and evaporated to dryness.

**Derivatization Reactions**—The derivatization reaction was essentially the same for the extracts from plasma, urine, and microsomes. The main difference was in the choice of the *n*-alkyl iodide; the selection of alkyl iodide was made to optimize chromatographic separations. Ethyl iodide was selected for derivatization of plasma and microsomal extracts, whereas *n*-propyl iodide was used for urinary extracts. To the residue from the extract were added 200 μl of acetonitrile and 50 μl of methanolic (25%) tetraethylammonium hydroxide, and the sample was mixed well. The appropriate *n*-alkyl iodide (25 μl) was added, and the sample was mixed again and placed in a water bath at 60° for 60 min, the optimum conditions for all derivatizations.

At the end of this time, 7 ml of chloroform was added, and the sample was washed sequentially with 2 ml of 0.1 *N* HCl, 0.1 *N* NaOH, and deionized water. The washed chloroform phase was evaporated to dryness, and the residue was dissolved in methanol or isoamyl acetate for analysis. Derivatized samples were stable at 4° or at room temperature for at least 2 months.

The major modification of the reported derivatization procedure for barbiturates (6) was the use of a different aprotic solvent. Acetonitrile was selected instead of *N*,*N*-dimethylacetamide because the former is more easily removed by evaporation. It has also been shown (11) that acetone serves equally as well as *N*,*N*-dimethylacetamide in alkylation of the phenolic group; but because higher temperatures were required for propylation of *p*-hydroxyphenobarbital, the low boiling point of acetone precluded its use. It was confirmed that acetonitrile or 2-butanone serves equally as well as *N*,*N*-dimethylacetamide in the derivatization of *p*-hydroxyphenobarbital or other barbiturates, and all three were superior to a protic solvent such as methanol.

**Analysis**—The samples were analyzed on a gas chromatograph equipped with a nitrogen–phosphorus flame-ionization detector (urine and microsomes) or a gas chromatograph–mass spectrometer–computer system (plasma). Quantitation was done using peak heights (urine and microsomes) or selected ion monitoring using peak areas (plasma).

Cross-verification of the analytical methods was carried out on the gas

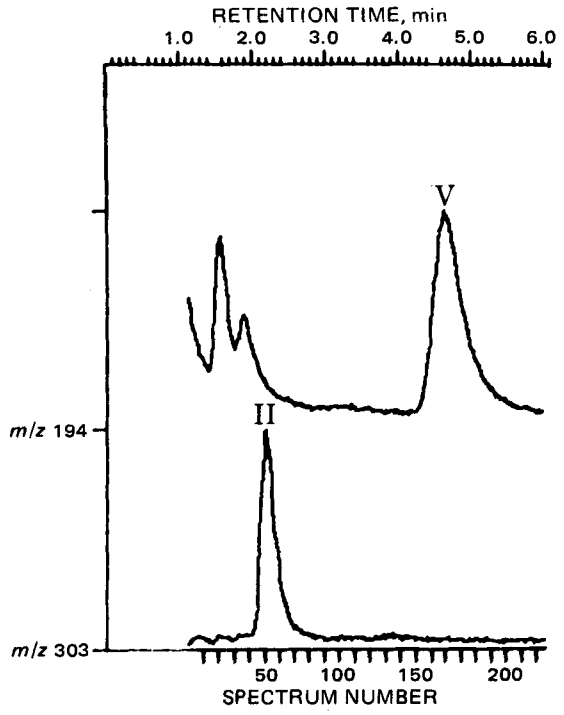

**Figure 9**—*Selected ion monitoring (electron-impact mode) tracing of ethylated human plasma (nonhydrolyzed) extract. The* p*-hydroxyphenobarbital level was 0.29 μg/ml. Diphenylbarbituric acid (0.50 μg/ml) was the internal standard.*

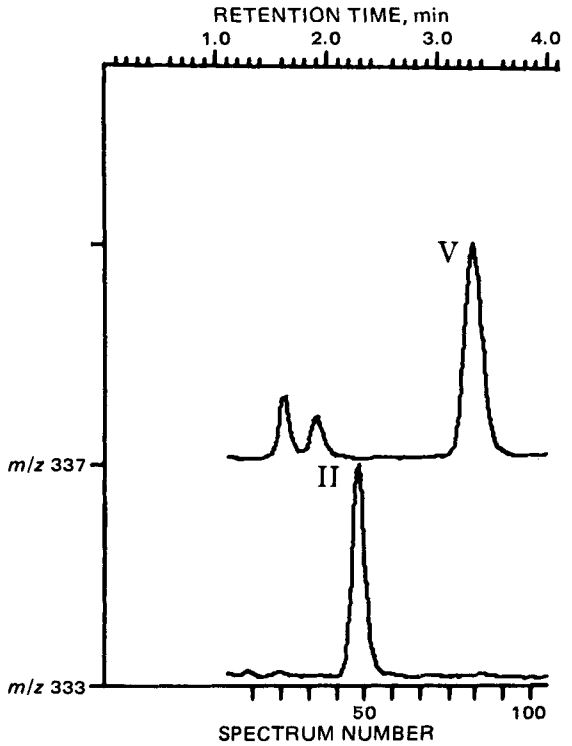

**Figure 10**—*Selected ion monitoring (chemical-ionization mode) tracing of ethylated human plasma (nonhydrolyzed) extract. For additional details, see Fig. 9.*

chromatograph–mass spectrometer–computer system. Quantitation was done by selected ion monitoring, using peak areas expressed as percent relative to internal standard. The selected ion monitoring technique was used to optimize sensitivity and specificity.

All samples, including the standards, were always injected in random order; some samples were injected in duplicate. Reproducibility between duplicate injections was always >95%. Random samples were analyzed in duplicate on the same day and on different days, and reproducibility was also >95%.

*Urine Analysis*—The gas chromatograph was equipped with a glass column (1.8 m × 2 mm i.d.) packed with 3% SE-30 on 100–120-mesh Gas Chrom Q. Oven temperature was maintained at 205° for 6 min, followed by temperature programming at 10°/min to 250°. Analysis of urinary *p*-hydroxyphenobarbital also allowed simultaneous quantitation of phenobarbital and primidone. *p*-Methylphenobarbital (III) was the internal standard for phenobarbital and primidone (IV); diphenylbarbituric acid (V) was the internal standard for *p*-hydroxyphenobarbital.

For verification of the analytical method, the gas chromatograph–mass spectrometer–computer system, operated in the electron-impact mode, was equipped with a glass column (0.9 m × 2 mm i.d.) packed with 3% SP 2250 DA on 100–120-mesh Supelcoport. Oven temperature was maintained at 200° for 4 min and then was programmed at 32°/min to 250°. The ions of *m/z* 374, 288, 273, 194, and 302 were monitored for propylated *p*-hydroxyphenobarbital (Fig. 1*a*), phenobarbital (Fig. 1*b*), primidone (Fig. 1*c*), diphenylbarbituric acid (Fig. 1*d*), and *p*-methylphenobarbital (Fig. 1*e*), respectively.

*Microsome Analysis*—The gas chromatograph was equipped with a glass column (1.8 m × 2 mm i.d.) packed with 2% OV3 on 100–120-mesh Supelcoport, and the analysis was done isothermally at 210°. Of the several packings tested, this one gave the most satisfying resolution for the peaks of interest. Diphenylbarbituric acid was the internal standard.

The gas chromatograph–mass spectrometer–computer system used for verification of the analytical method was operated in the electron-impact mode and was fitted with a glass column (0.9 m × 2 mm i.d.) packed with 3% SP 2250 DA on 100–120-mesh Supelcoport. The analysis was done isothermally at 190°. The ions of *m/z* 332 and 194 were monitored for *p*-hydroxyphenobarbital (Fig. 2*a*) and diphenylbarbituric acid (Fig. 2*b*), respectively.

*Plasma Analysis*—The gas chromatograph–mass spectrometer–computer system, operated in the electron-impact mode, was equipped with a glass column (0.9 m × 2 mm i.d.) packed with 3% SP 2250 DA on 100–120-mesh Supelcoport, and the analysis was done isothermally at 200°. Diphenylbarbituric acid was the internal standard. The ions of *m/z* 303 and 194 were monitored for *p*-hydroxyphenobarbital and diphenylbarbituric acid, respectively.

The analytical method was verified by a gas chromatograph–mass spectrometer–computer system operated in the chemical-ionization mode, using a glass column (1.2 m × 2 mm i.d.) packed with 3% OV-1 on Gas Chrom Q. The analysis was done isothermally at 220°. The ions of *m/z* 333 and 337 were monitored for *p*-hydroxyphenobarbital and diphenylbarbituric acid, respectively. The monitored ions corresponded to the quasimolecular ions for the two compounds, and they both were the base peak as well.

## RESULTS AND DISCUSSION

**Urine**—The capability of monitoring urinary phenobarbital and primidone along with *p*-hydroxyphenobarbital by this method is convenient because phenobarbital is a major metabolite of primidone, a closely related antiepileptic agent. Thus, if primidone is administered, its urinary output can be quantitated at the same time as its primary and secondary metabolites, phenobarbital and *p*-hydroxyphenobarbital, respectively. A gas chromatogram (Fig. 3) and selected ion monitoring tracing (Fig. 4) of urinary *p*-hydroxyphenobarbital, phenobarbital, and primidone are illustrated. Standard curves were set up for all three barbiturates, and the concentrations selected for all three ranged from 10 to 100 μg/ml. This range bracketed the range of experimental values for all three barbiturates.

Representative standard curves obtained from the GC nitrogen–phosphorus flame-ionization detector data exhibited the following linear least-squares regression equations and correlation coefficients ($r^2$): $y = 0.0204x + 0.006$ and $r^2 = 0.9996$ for *p*-hydroxyphenobarbital; $y = 0.0313x + 0.072$ and $r^2 = 0.9995$ for phenobarbital; and $y = 0.0167x + 0.004$ and $r^2 = 0.9965$ for primidone. Furthermore, the accuracy and precision of the method were evaluated by quadruplicate analyses of spiked samples; the results (Table I) demonstrated good accuracy and precision.

There was a good correlation between the GC nitrogen–phosphorus flame-ionization detector and selected ion monitoring methods for quantitation of urinary *p*-hydroxyphenobarbital (Fig. 5). A similar correlation was also obtained for the quantitation of phenobarbital and primidone in the urine. The 24-hr urinary output of phenobarbital, free *p*-hydroxyphenobarbital, and total (free plus conjugated) *p*-hydroxyphenobarbital from a patient on a therapeutic regimen of phenobarbital alone (180 mg/day) was 33.0 ± 4.9 μg/ml, 27.3 ± 2.7 mg, and 60.9 ± 4.1

mg, respectively (mean ± *SD* of five determinations). The urinary output of phenobarbital is reported in concentration units rather than in absolute amount of excreted phenobarbital because the amount of urinary phenobarbital is dependent on urinary volume, which is not the case for free or conjugated *p*-hydroxyphenobarbital.

**Microsomes**—A gas chromatogram (Fig. 6*b*) and selected ion monitoring tracing (Fig. 7) of *p*-hydroxyphenobarbital generated in the microsomal reaction are illustrated. A representative standard curve obtained from the GC nitrogen–phosphorus flame-ionization detector data was described by the linear least-squares regression equation as $y = 3.34x + 0.005$, $r^2 = 0.9993$. The standards ranged from 0.10 to 1.00 μg of *p*-hydroxyphenobarbital and bracketed the range of experimental values. The accuracy and precision of the method were measured by quadruplicate analyses of spiked samples. The results were 0.098 ± 0.001 and 1.04 ± 0.03 μg of *p*-hydroxyphenobarbital for samples spiked with 0.10 and 1.00 μg of *p*-hydroxyphenobarbital, respectively (mean ± *SD* of four determinations).

There was good correlation between the GC nitrogen–phosphorus flame-ionization detector and selected ion monitoring methods for quantitation of *p*-hydroxyphenobarbital in the microsomal phenobarbital metabolic reaction (Fig. 8). In the microsomal oxidative metabolism of phenobarbital, two metabolites in addition to *p*-hydroxyphenobarbital were detected (peaks VI and VII in Figs. 6*b* and 7). Compound VI was subsequently shown to correspond to *m*-hydroxyphenobarbital on the basis of the same retention times as those of the synthetic reference compound[16] in several chromatographic systems. Furthermore, ratios for the relative abundance of several ions for this metabolite were virtually identical to those of the reference compound, as determined by the gas chromatograph–mass spectrometer–computer system. Compound VII, however, could possibly be the *ortho* analog on the basis of some limited electron-impact mass spectrometric data. However, a complete mass spectrometric analysis was not performed, and the reference standard was not available. Thus, the identity of VII remains speculative. The values for $K_m$ and $V_{max}$, the kinetic parameters for *p*-hydroxylation of phenobarbital, were determined to be 1.16 m*M* and 0.325 nmole of *p*-hydroxyphenobarbital formed $min^{-1}$ $nmole^{-1}$ of P-450, respectively.

**Plasma**—Occasional interferences were encountered in the analysis of plasma *p*-hydroxyphenobarbital by the GC nitrogen–phosphorus flame-ionization detector method. Since it proved difficult to eliminate them satisfactorily with column packing phases of different polarities, a more specific selected ion monitoring method was developed. Selected ion monitoring tracings in the electron-impact mode (Fig. 9) and chemical ionization mode (Fig. 10) for the analysis of plasma *p*-hydroxyphenobarbital are illustrated. A representative standard curve obtained from the selected ion monitoring (electron-impact) data was described by the linear least-squares equation as $y = 49.68x + 0.017$, $r^2 = 0.9978$. The standards ranged from 0.25 to 1.50 μg/ml of *p*-hydroxyphenobarbital and bracketed the range of experimental values. The accuracy and precision of the method were evaluated by quadruplicate analyses of spiked samples. The results were 0.268 ± 0.014 and 1.05 ± 0.03 μg/ml of *p*-hydroxyphenobarbital for samples spiked with 0.250 and 1.00 μg/ml of *p*-hydroxyphenobarbital, respectively.

There was good correlation between the electron-impact and chemical-ionization modes of the selected ion monitoring method. For example, quadruplicate analyses of a plasma sample yielded mean (±*SD*) levels of 0.344 ± 0.008 and 0.338 ± 0.014 μg/ml of *p*-hydroxyphenobarbital in the electron-impact and chemical-ionization modes, respectively. Plasma levels of free *p*-hydroxyphenobarbital and total (free plus conjugated) *p*-hydroxyphenobarbital in a patient maintained on a therapeutic regimen of phenobarbital alone (180 mg/day) were 0.516 ± 0.022 and 0.763 ± 0.057 μg/ml, respectively (mean ± *SD* of four determinations).

# Solubility Behavior of Phenolic Compounds in Hexane–Ethyl Acetate, Hexane–Ethyl Myristate, and Hexane–Ethyl Pivalate Cosolvent Systems

**EIICHI AKAHO *, KATSUMI IGA ‡, JAN KRAAL §, and ANWAR HUSSAIN ¶ x**

Received February 1, 1980, from the *School of Pharmacy, Kobe-Gakuin University, Tarumi-ku, Kobe, Japan,* ‡*Takeda Chemical Industries, Ltd., Tokyo, Japan,* and the §*College of Dentistry and the* ¶*College of Pharmacy, University of Kentucky, Lexington, KY 40506.* Accepted for publication March 19, 1981.

**Abstract** □ Interactions of phenolic compounds 4-hexylresorcinol and 3,4-dimethylphenol with esters were studied using hexane–ester cosolvent systems by both phase solubility and partitioning methods. The data obtained by the phase solubility method were variable and could not be analyzed by any mathematical model. The data obtained by the partitioning method, however, strongly suggest that 4-hexylresorcinol forms 1:1 and 1:2 complexes with the esters in hexane, while 3,4-dimethylphenol forms only 1:1 complexes with the same esters.

**Keyphrases** □ Phenolic compounds—interaction with esters using hexane–ester cosolvent systems, phase solubility and partitioning methods □ Phase solubility—interaction of phenolic compounds with esters □ 4-Hexylresorcinol—formation of 1:1 and 1:2 complexes with esters in hexane □ 3,4-Dimethylphenol—formation of 1:1 complexes with esters

In a previous investigation (1), the permeability coefficient of 4-hexylresorcinol through an ethylene–vinyl acetate copolymer membrane varied in a nonlinear fashion as a function of the vinyl acetate content of the copolymers. In the same study, the partition coefficient of the drug in the membrane varied nonlinearly as a function of the vinyl acetate content. The results were rationalized on the basis that the dihydroxy compound forms 1:1 and 1:2 complexes with the vinyl acetate portion of the copolymers.

A study was undertaken to determine the solubility behavior of 4-hexylresorcinol in hexane–ethyl acetate cosolvent systems; hexane and ethyl acetate represent the polyethylene and the vinyl acetate portions of the copolymer, respectively. Additional data in other cosolvent systems, hexane–ethyl myristate and hexane–ethyl pivalate, also were studied. To obtain further insight on the mechanism of interaction of 4-hexylresorcinol in the described cosolvent systems, the solubility of a monohydroxy compound, 3,4-dimethylphenol, also was studied.

## EXPERIMENTAL

**Materials**—4-Hexylresorcinol[1] and 3,4-dimethylphenol[2] were crystallized from hot benzene. Ethyl myristate, ethyl acetate, and ethyl pivalate, reagent grades, were purified by distillation.

**Phase Solubility Study**—To each 1.0 g of the phenols placed in respective 10-ml volumetric flasks, a 10-ml solution containing 1.5–30 × $10^{-2}$ *M* of the esters in hexane was added. The flasks were shaken for 48 hr in a water bath shaker at 25°. The solutions were centrifuged, exactly 1 ml of supernate was pipetted into a volumetric flask, and the volume was completed to the mark with hexane. Further dilutions were carried out when necessary to obtain an absorbance range within the Beer's law region. The absorbance of the solutions was determined spectrophotometrically[3] at 277.5 nm. The solubilities of the phenols were calculated using a standard curve constructed for them in hexane. This procedure was previously reported (2).

[1] Curtin-Matheson Scientific, Cincinnati, Ohio.
[2] Aldrich Chemical Co., Milwaukee, Wis.
[3] Cary 118, Varian Associates, Palo Alto, Calif.

**Partitioning Study**—Two hundred milligrams of the phenol was dissolved in 1 liter of phosphate buffer (0.1 *M*, pH 7.5), and exactly 5 ml of the aqueous solution was pipetted into a 15-ml test tube with a stopper. Exact volumes (between 2 and 5 ml) of the solutions containing 1.5–30 × $10^{-2}$ *M* of the esters in hexane were added to the test tubes, which then were shaken for 10 min. After the test tubes were centrifuged, the aqueous layer was taken and the absorbance of the solution was determined spectrophotometrically without dilution at 277.5 nm. The partition coefficients (*PC*) were calculated from the change in UV absorbance at 277.5 nm in the aqueous layer before and after the partition:

$$PC = \frac{(\text{volume of aqueous layer})(A_0 - A)}{(\text{volume of organic layer})(A)} \qquad \text{(Eq. 1)}$$

where $A_0 - A$ is the absorbance change in the aqueous layer and $A$ is the absorbance in the aqueous layer.

## RESULTS AND DISCUSSION

Tables I, II, and III show the total solubility of 4-hexylresorcinol as a function of the ethyl acetate, ethyl myristate, and ethyl pivalate concentrations in hexane, respectively. Figure 1 shows the solubility diagrams of the drug in the three cosolvent systems and demonstrates that the solubility increased in a nonlinear fashion as a function of the added esters and that the solubility behavior was different in the three cosolvent systems.

To characterize these systems mathematically, it was first assumed that 4-hexylresorcinol forms 1:1 and 1:2 complexes with esters according

| 6.12 | 5.2 |
| 7.7 | 6.3 |
| 15.3 | 153 |
| 23.0 | — |
| 30.6 | 291 |

to Eqs. 2 and 3 (3, 4):

$$HR_0 + E_0 = HR - E \quad \text{(Eq. 2)}$$

$$HR_0 + 2E_0 = HR - E_2 \quad \text{(Eq. 3)}$$

$$K_{1:1} = \frac{[HR - E]}{[HR_0][E_0]} \quad \text{(Eq. 4)}$$

$$K_{1:2} = \frac{[HR - E_2]}{[HR_0][E_0]^2} \quad \text{(Eq. 5)}$$

where $[HR_0]$, $[E_0]$, $[HR - E]$, and $[HR - E_2]$ represent the concentrations of free 4-hexylresorcinol, free ester, the 1:1 complex, and the 1:2 complex, respectively.

The total concentration of 4-hexylresorcinol, $[HR_T]$, and the total concentration of the ester, $[E_T]$, can be written according to:

$$[HR_T] = [HR_0](1 + K_{1:1}[E_0] + K_{1:2}[E_0]^2) \quad \text{(Eq. 6)}$$

$$[E_T] = [E_0] + K_{1:1}[E_0][HR_0] + 2K_{1:2}[E_0]^2[HR_0] \quad \text{(Eq. 7)}$$

Elimination of $[E_0]^2$ from Eq. 7 by using Eq. 6 gives:

$$[E_0] = \frac{1}{1 - K_{1:1}[HR_0]}\{[E_T] - 2([HR_T] - [HR_0])\} \quad \text{(Eq. 8)}$$

The combination of Eqs. 6 and 8 to eliminate $[E_0]$ gives:

$$[HR_T] = [HR_0] + \frac{K_{1:1}[HR_0]}{1 - K_{1:1}[HR_0]}\{[E_T] - 2([HR_T] - [HR_0])\} + \frac{K_{1:2}[HR_0]}{(1 - K_{1:1}[HR_0])^2}\{[E_T] - 2([HR_T] - [HR_0])\}^2 \quad \text{(Eq. 9)}$$

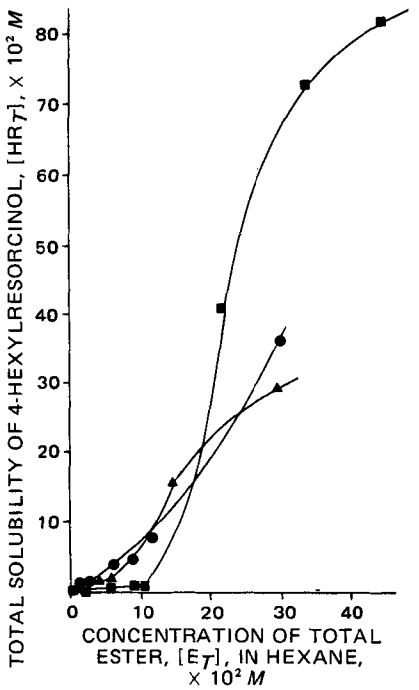

**Figure 1**—*Plot of the total solubility of 4-hexylresorinol, $[HR_T]$, as a function of the total ester concentration $[E_T]$, in hexane at 25°. Key: ■, ethyl acetate; ●, ethyl myristate; and ▲, ethyl pivalate.*

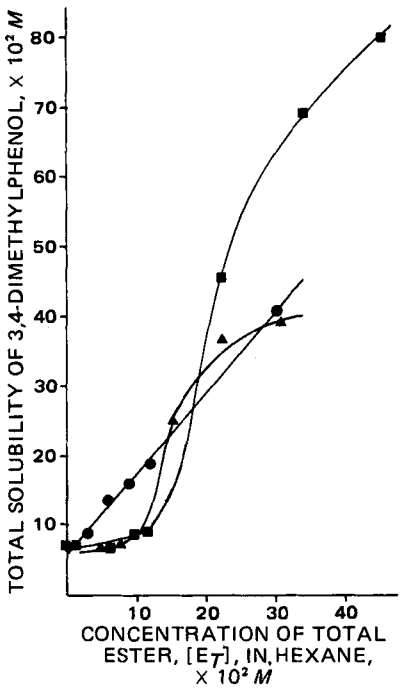

**Figure 2**—*Plot of the total solubility of 3,4-dimethylphenol as a function of the total ester concentration, $[E_T]$, in hexane at 25°. Key: ■, ethyl acetate; ●, ethyl myristate; and ▲, ethyl pivalate.*

Bringing $[HR_0]$ to the left side of Eq. 9 and dividing both sides of Eq. 9 by $[E_T] - 2([HR_T] - [HR_0])$ gives:

$$\frac{[HR_T] - [HR_0]}{[E_T] - 2([HR_T] - [HR_0])} = \frac{K_{1:1}[HR_0]}{1 - K_{1:1}[HR_0]} + \frac{K_{1:2}[HR_0]}{(1 - K_{1:1}[HR_0])^2}\{[E_T] - 2([HR_T] - [HR_0])\} \quad \text{(Eq. 10)}$$

A plot of the left-hand side of Eq. 10 *versus* $[E_T] - 2([HR_T] - [HR_0])$ should give a straight line with a positive intercept. However, the phase solubility data plotted according to Eq. 10 gave a negative intercept value, and the concentration of the free ester, $[E_0]$, calculated from Eq. 8 also gave a negative value. This result was evident from the data in Tables I–III where at $30 \times 10^{-2}$ *M* esters in hexane, the total solubility of 4-hexylresorcinol was equivalent or slightly greater than that of the ester added.

Other assumptions based on the formation of dimer or higher order complexes failed to explain the solubility behavior of 4-hexylresorcinol in these systems. Similarly, the phase solubility diagrams of 3,4-di-

methylphenol were different in the three cosolvent systems (Fig. 2). It is known that the monohydroxy compound forms a 1:1 complex with esters. If that is the case, then one should observe a linear increase in the total solubility of the phenol as a function of added esters in hexane. In Fig. 2, the increase in the solubility of 3,4-dimethylphenol as a function of added esters in hexane is nonlinear for ethyl pivalate and ethyl acetate and appears to be linear for ethyl myristate.

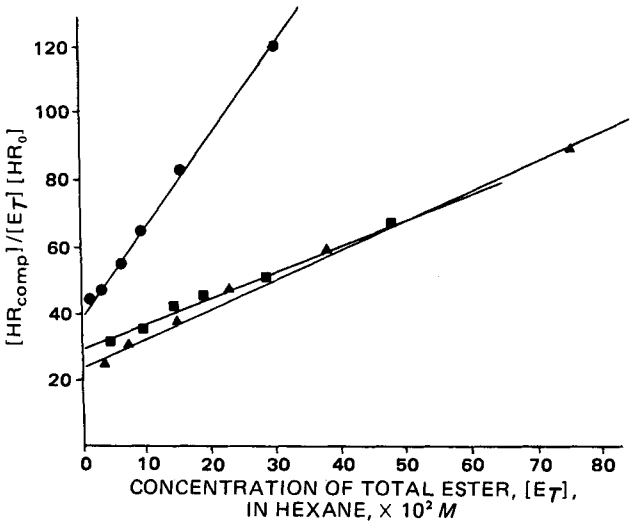

**Figure 4**—*Plot of $[HR_{comp}]/[HR_0][E_T]$ as a function of the total ester concentration, $[E_T]$, in hexane according to Eq. 16 ($[HR_{comp}] = [HR_T] - [HR_0]$). Key: ■, ethyl acetate; ●, ethyl myristate; and ▲, ethyl pivalate.*

Further examination of the equilibrated systems showed that, in addition to the supernatant and crystalline phases, an oily third phase existed. It was assumed that the abnormalities in the phase solubility diagrams of 4-hexylresorcinol and 3,4-dimethylphenol were due to the formation of a eutectic phase between the low-melting-point phenols and the esters. It is known that low-melting-point phenols form a eutectic mixture upon their interaction with a low-melting-point proton acceptor.

The irreproducibility of the phase solubility data of 4-hexylresorcinol led to a study to characterize the nature of the complexes formed using partitioning methods. The data obtained for 4-hexylresorcinol in the three cosolvent systems are shown in Tables IV–VI. The concentration of free 4-hexylresorcinol, $[HR_0]$, in hexane was obtained as follows:

$$[HR_0] = (PC \text{ at } 0\% \text{ ester})\,[HR_{H_2O}] \quad \text{(Eq. 11)}$$

where $PC$ at 0% ester is the partition coefficient of 4-hexylresorcinol at zero ester concentration, $[HR_{H_2O}]$ is the aqueous phase concentration, and the concentration of 4-hexylresorcinol in the complex is equal to $[HR_T] - [HR_0]$. A plot of $([HR_T] - [HR_0])/[HR_0]$ *versus* added ester is shown in Fig. 3 for ethyl acetate, ethyl myristate, and ethyl pivalate. As seen in Fig. 3, the increase in the total drug concentration as a function of added esters showed a positive curvature. The ratio of the free form, $[HR_0]$, and the complex form of 4-hexylresorcinol, $[HR_{comp}]$, in the organic layer is:

$$\frac{[HR_{comp}]}{[HR_0]} = \frac{[HR_T] - [HR_0]}{[HR_0]} \quad \text{(Eq. 12)}$$

$[HR_T] - [HR_0]$ is given from Eq. 6; *i.e.*,

$$[HR_T] - [HR_0] = K_{1:1}[E_0][HR_0] + K_{1:2}[HR_0][E_0]^2 \quad \text{(Eq. 13)}$$

Substituting the $[HR_T] - [HR_0]$ value from Eq. 12 in Eq. 13 gives:

$$\frac{[HR_{comp}]}{[HR_0]} = K_{1:1}[E_0] + K_{1:2}[E_0]^2 \quad \text{(Eq. 14)}$$

Dividing both sides of Eq. 14 by $[E_0]$ gives:

$$\frac{[HR_{comp}]}{[HR_0][E_0]} = K_{1:1} + K_{1:2}[E_0] \quad \text{(Eq. 15)}$$

Since the partitioning study used very dilute solutions of 4-hexylresorcinol, the concentrations of the complexes also are fairly small. Even if 100% of 4-hexylresorcinol complexes with esters, it is reasonable to replace the concentration of the free ester, $[E_0]$, by the concentration of the total ester concentration, $[E_T]$:

$$\frac{[HR_{comp}]}{[HR_0][E_T]} = K_{1:1} + K_{1:2}[E_T] \quad \text{(Eq. 16)}$$

A plot of $[HR_{comp}]/[HR_0][E_T]$ *versus* $[E_T]$ provides a straight line with a slope of $K_{1:2}$ and an intercept of $K_{1:1}$. The experiments were repeated

for various cosolvent systems, and each showed a straight-line relationship between the two parameters (Fig. 4). The stability constants, $K_{1:1}$ and $K_{1:2}$, for each ester were calculated from Fig. 4 and are shown in Table VII. It is evident from these results that 4-hexylresorcinol forms not only 1:1 but also 1:2 complexes with esters in hexane. The stability constant values obtained for ethyl myristate were somewhat higher than those for the other esters. This result is probably due to the fact that ethyl myristate has a larger hydrocarbon chain, which results in a better interaction with the hydrophobic portion of phenols.

To ascertain whether the formation of 1:2 complexes is due to the involvement of the two hydroxy groups of 4-hexylresorcinol, the partitioning study was repeated with 3,4-dimethylphenol. The data obtained from this study are shown in Tables VIII–X. A plot of $[DMP_{comp}]/[DMP_0][E_T]$ *versus* the total ester concentration is shown in Fig. 5; $[DMP_{comp}]$ is the concentration of 3,4-dimethylphenol in the complex form, and $[DMP_0]$ is the concentration of the free form.

**Table X—Extent of Complex Formation between 3,4-Dimethylphenol and Ethyl Pivalate Determined by Partitioning Study**

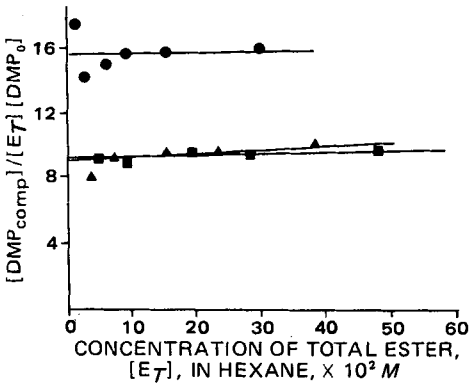

**Figure 5**—*Plot of $[DMP_{comp}]/[DMP_{free}][E_T]$ as a function of the total ester concentration, $[E_T]$, in hexane; $[DMP_{comp}]$ and $[DMP_{free}]$ represent the concentrations of complexed and free forms of 3,4-dimethylphenol, respectively. ($[DMP_{comp}] = [DMP_T] - [DMP_0]$). Key: ■, ethyl acetate; ●, ethyl myristate; and ▲, ethyl pivalate.*

As seen in Fig. 5, the monohydroxy compound forms only a 1:1 complex with the esters. The stability constants calculated from Fig. 5 are given in Table VII. The results of this study substantiate the conclusion that the diffusion of 4-hexylresorcinol through ethylene–vinyl acetate copolymers involved the formation of 1:1 and 1:2 complexes between the drug and the vinyl acetate portion of the copolymers.

# High-Performance Liquid Chromatographic Analysis of Chemical Stability of 5-Aza-2′-deoxycytidine

**KUN-TSAN LIN*x, RICHARD L. MOMPARLER*‡, and GEORGES E. RIVARD***

Received December 17, 1979, from the *Centre de Recherche Pédiatrique, Hôpital Sainte-Justine, and the ‡Département de Pharmacologie, Université de Montréal, Montréal, Québec, Canada H3T 1C5. Accepted for publication March 31, 1981.

**Abstract** □ The chemical stability of 5-aza-2′-deoxycytidine (I) in acidic, neutral, and alkaline solutions was analyzed by high-performance liquid chromatography. In alkaline solution, I underwent rapid reversible decomposition to *N*-(formylamidino)-*N*′-β-D-2-deoxyribofuranosylurea (II), which decomposed irreversibly to form 1-β-D-2′-deoxyribofuranosyl-3-guanylurea (III). The pseudo-first-order rate constants for this reaction were determined. The decomposition of I in alkaline solution was identical to that reported previously for the related analog, 5-azacytidine. However, in neutral solution (or water), there was a marked difference in the decomposition of I and 5-azacytidine. The same decomposition products were formed from 5-azacytidine in neutral solution as in alkaline solution. However, in neutral solution, I decomposed to II and three unknown compounds that were chromophoric at 254 nm. Compound I was most stable when stored in neutral solution at low temperature.

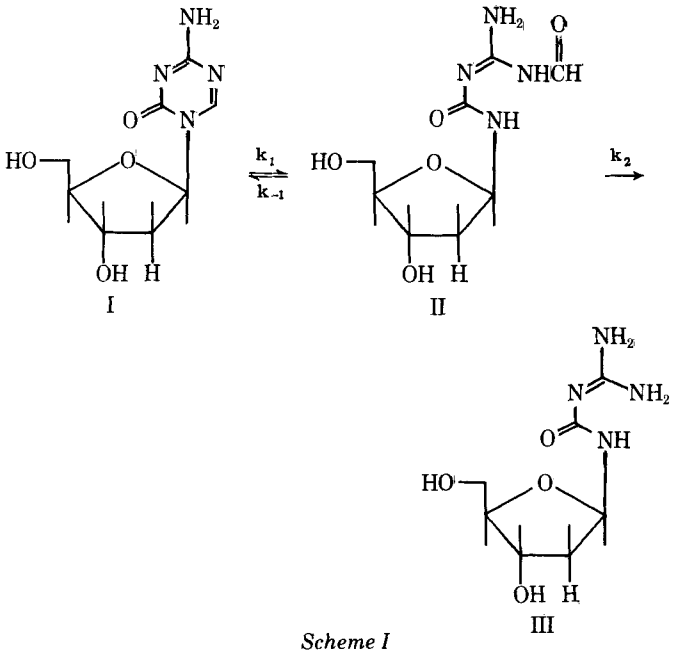

*Scheme I*

## BACKGROUND

One major problem encountered in the clinical formulation of 5-azacytidine is its chemical instability, leading to solutions of decreasing potency on storage. The chemical stability of 5-azacytidine was first studied by Píthová *et al.* (5), who demonstrated that in alkaline solution the triazine ring of 5-azacytidine opens and loses a formyl group to form 1-β-D-ribofuranosyl-3-guanylurea. These workers proposed that the intermediate compound in this reaction was *N*-(formylamidino)-*N'*-β-D-ribofuranosylurea, but they were unable to isolate it using paper chromatography because of its chemical instability. Beisler (6), using high-performance liquid chromatography (HPLC), isolated and identified this intermediate compound and showed that it could be partially converted back to 5-azacytidine.

The chemical decomposition of I at alkaline pH (Scheme I) presumably follows the same reaction steps as described previously for 5-azacytidine. In alkaline solutions, I undergoes a reversible hydrolytic reaction to form *N*-(formylamidino)-*N'*-β-D-2-deoxyribofuranosylurea (II), which, by the irreversible loss of the formyl group, forms 1-β-D-2'-deoxyribofuranosyl-3-guanylurea (III).

The present study investigated the decomposition of I in acidic, neutral, and alkaline solutions and at different temperatures to illustrate the chemical stability of this compound.

## EXPERIMENTAL

5-Aza-2'-deoxycytidine (I) was synthesized[1] by modification of an earlier method (7).

**Method of Analysis**—HPLC[2] was performed with a variable-wavelength detector by monitoring at 220 or 254 nm. Analytical and preparative work was accomplished with a 300 × 3.9-mm i.d. commercially packed octadecylsilane column[3], which was eluted at a flow rate of 2 ml/min with 10 m*M* potassium phosphate buffer (pH 6.8). For analytical and preparative work, 20- and 500-μl injector loops, respectively, were used.

Stock solutions of 10 m*M* I in water were stored at −70°. Aliquots of this solution were thawed quickly and stored at 1–2°. The following buffers were used for the pH stability studies: phosphoric acid, pH 2.2; phosphoric acid–potassium phosphate, pH 3.2; sodium acetate buffer, pH 4.5 and 5.7; potassium phosphate buffer, pH 6.4 and 7.0; and sodium borate, pH 8.5, 9.2, 9.8, and 10.4. Compound II was prepared by addition of 20 μl of 0.5 *M* sodium borate, pH 10.4, to a 1.0-ml solution of 10 m*M* I. The mixture was incubated for 2 min at 24° and then neutralized with 20 μl of 1.0 *M* $KH_2PO_4$, and a 500-μl sample was injected onto the column for isolation of II.

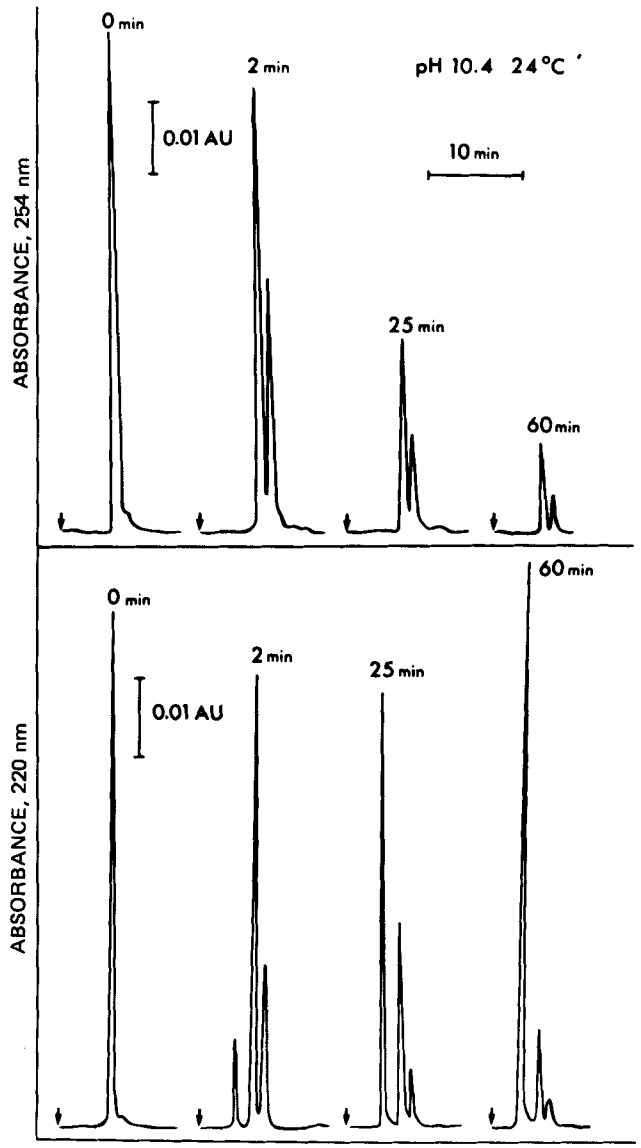

**Figure 1**—*Decomposition of I at pH 10.4 and 24°. Compound I (1.0 mM) was dissolved in 10 mM borate buffer (pH 10.4). At the indicated times, an aliquot of the solution was neutralized with phosphate buffer and analyzed by HPLC at 254 and 220 nm.*

**Kinetic Experiments**—A series of tubes containing 10 μl of 0.5 *M* stock sodium borate buffer were incubated at 37° for 10 min. Then 100 μl of isolated II (in 10 m*M* potassium phosphate, pH 6.8) was added to each tube to start the reaction. At timed intervals, an aliquot was withdrawn, and 20 μl was injected onto the column. The absorbance at 220 nm was recorded, and the relative concentration of the observed degradation products was characterized by peak heights. Similar experimental procedures were followed for the kinetic study on 5-azacytidine[4].

## RESULTS

The decomposition of I at pH 10.4 and 24° as determined by HPLC is shown in Fig. 1. Measurement of the absorbance of the column eluate at 254 nm initially showed a single major peak (I) with a $t_R$ value of 5.5 min. With time, a second peak (II) appeared with a $t_R$ value of 6.6 min. Both peaks showed a gradual decrease in peak size with time. At 220 nm, the column eluate initially showed a single major peak (I) with a $t_R$ = 5.5 min. With time, peak II ($t_R$ = 6.6 min) and peak III ($t_R$ = 3.5 min) became evident. At 60 min, most of I decomposed to peak III.

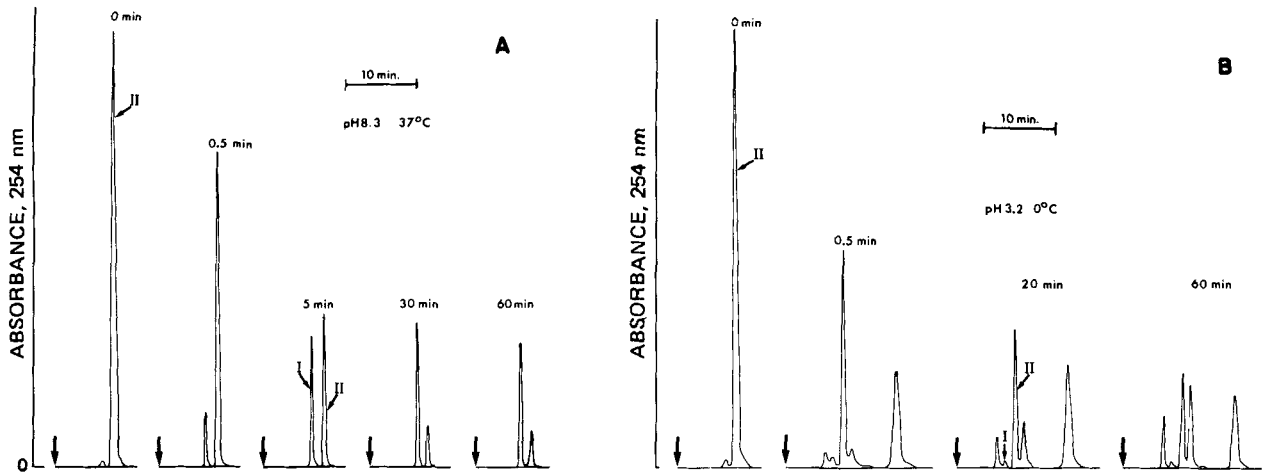

**Figure 2**—*Conversion of II to I at pH 8.3, 37° (A), and to unidentified compounds at pH 3.2, 0° (B). Peak II was isolated by HPLC and placed in 20 mM potassium phosphate buffer (at final pH 8.3 or 3.2). At the indicated times, aliquots of this solution were analyzed by HPLC.*

When II was isolated and placed at pH 8.3 and 37°, I appeared rapidly, indicating that II could be converted to I (Fig. 2A). However, when II was placed in an acidic solution (pH 3.2), it did not produce I; three unidentified peaks at 254 nm were observed. The latter reaction was very rapid, even at 0° (Fig. 2B).

The decomposition of I and 5-azacytidine when stored in water and in pH 7.4 phosphate buffer at 24° for 24 hr is compared in Fig. 3. Absorbance measurements at 254 nm of the column eluate showed five major peaks for I and two major peaks for 5-azacytidine. At 220 nm, the column eluate showed seven major peaks for I and three major peaks for 5-azacytidine.

The decomposition rates of I in acidic, neutral, and basic solutions at 24 and 37° are shown in Figs. 4A and 4B, respectively. Compound I decomposed more rapidly at pH 2.2, 8.5, and 9.2 than at pH 5.7, 6.4, and 7.0. The decomposition rate of I was the slowest at pH 7.0. At pH 2.2 a peak with the same $t_R$ value (2.3 min) as 5-azacytosine appeared on the chromatogram. The decomposition rate of I was very temperature dependent. For example, at pH 7.0, the decomposition rate was about sevenfold greater at 37 than at 24°.

A kinetic study at pH 8.1 and 9.5 was then carried out with II as the starting substance. According to Scheme I, the pseudo-first-order rate constants $k_1$, $k_{-1}$, and $k_2$ were determined using the following differential

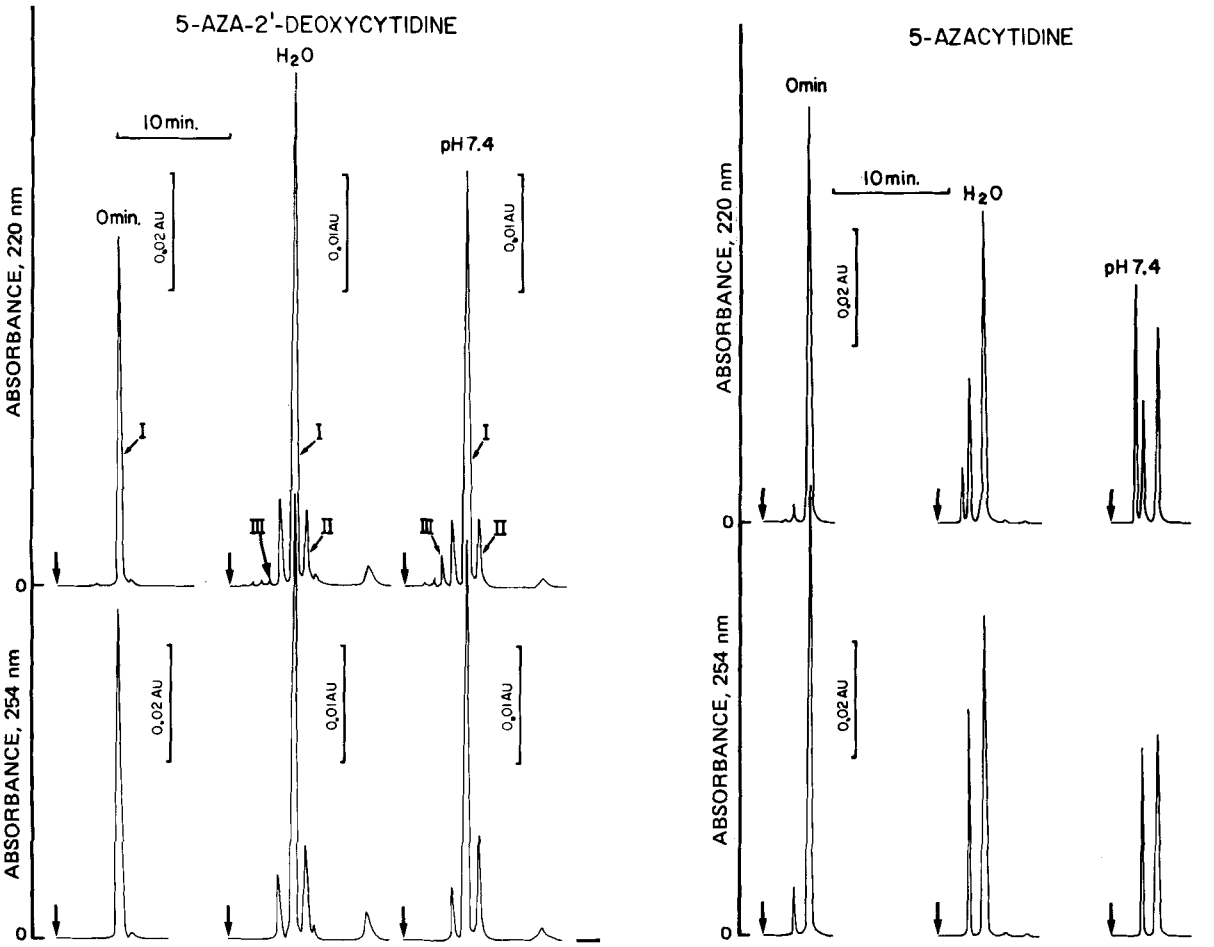

**Figure 3**—*Decomposition of I and 5-azacytidine in pH 7.4 phosphate buffer and water. 5-Azacytidine (0.5 mM) and I (0.5 mM) were dissolved in 10 mM potassium phosphate (pH 7.4) and water and incubated at 24°. At the indicated times, aliquots of these solutions were analyzed by HPLC at 254 and 220 nm.*

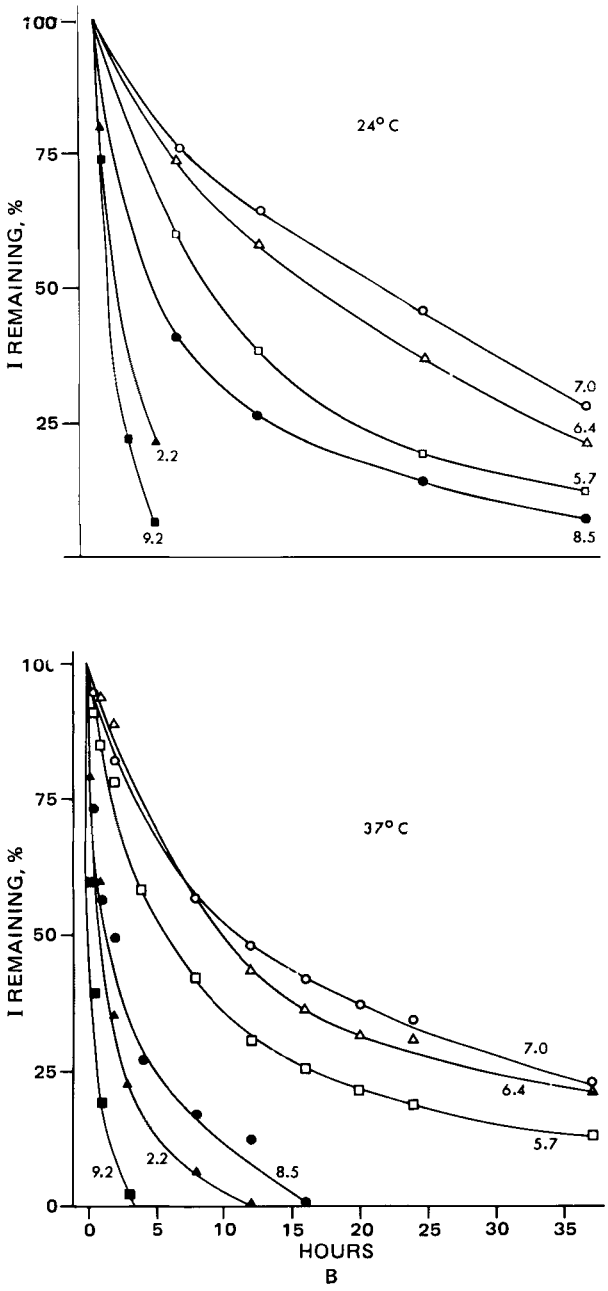

**Figure 4**—*Effect of pH and temperature on the stability of I. Compound I (1.0 mM) was dissolved in 10 mM of the appropriate buffer with the indicated pH and incubated at either 24° (top) or 37° (bottom). At the indicated times, an aliquot of the solution was neutralized with phosphate buffer and analyzed by HPLC.*

equations (8):

$$I_t = k_{-1} II_0 \left( \frac{1}{B-A} e^{-At} + \frac{1}{A-B} e^{-Bt} \right) \quad \text{(Eq. 1)}$$

$$II_t = II_0 \left( \frac{k_1 - A}{B-A} e^{-At} + \frac{k_1 - B}{A-B} e^{-Bt} \right) \quad \text{(Eq. 2)}$$

$$III_t = II_0 \left( 1 - \frac{k_2(k_1 - A)}{A(B-A)} e^{-At} - \frac{k_2(k_1 - B)}{B(A-B)} e^{-Bt} \right) \quad \text{(Eq. 3)}$$

Here $A$ and $B$ are roots of the following quadratic equation taken with the reverse signs:

$$X^2 + X(k_1 + k_2 + k_{-1}) + k_1 k_2 = 0 \quad \text{(Eq. 4)}$$

The rate constants thus obtained are presented in Table I and were used to generate time–concentration profiles for I–III. Normalized experimental data obtained by HPLC were superimposed on these generated time–concentration profiles (Fig. 5). Similar procedures were used for the kinetic study of 5-azacytidine, and the results are shown in Table I and Figs. 6 and 7.

**Table I—Rate Constants for the Alkaline Decomposition of I and 5-Azacytidine at 37°**

## DISCUSSION

The hydrolysis of 5-azacytidine in alkaline solution and water results in the opening of the triazine ring between C-6 and N-1 to form *N*-(formylamidino)-*N'*-β-D-ribofuranosylurea in a reversible reaction; when this latter compound loses the formyl group, it irreversibly forms 1-β-D-ribofuranosyl-3-guanylurea (5, 6). By using quantum chemical cal-

culations, it was shown (5) that the electron density at C-6 of 5-azacytosine is much lower than cytosine, making this position more susceptible to nucleophilic attack by a hydroxyl ion.

From the structural similarity of 5-azacytidine and I, it would seem that I would decompose in alkaline solution according to Scheme I. This study supports this reaction scheme in alkaline solution. As shown in Fig. 1, the decomposition of peak I ($t_R$ = 5.5 min) at pH 10.4 produced peak II ($t_R$ = 6.6 min) when the column eluate was monitored at 254 nm. Peak III was not observed on this chromatogram because guanylurea derivatives are nonchromophoric at 254 nm (5, 6).

However, at 220 nm, peak III ($t_R$ = 3.5 min) became apparent following the decomposition of II to III. When peak II was isolated, it had the same $UV_{max}$ of 238 nm as reported previously (6) for *N*-(formylamidino)-*N*′-β-ribofuranosylurea. The hydrolysis of I in alkaline solution produced an initial increase in absorbance[5] at 238 nm, supporting the formation of II, since the formylguanylurea derivative has a much higher extinction coefficient than 5-azacytosine derivatives at this wavelength (6). The conversion of II to I (Fig. 2A) indicates that this reaction is reversible, which is in agreement with other observations (5, 6) for 5-azacytidine.

There were marked differences in the decomposition of I and 5-azacytidine in phosphate buffer (pH 7.4) and water (Fig. 3). In these solvents, 5-azacytidine decomposed to form formylguanylurea and guanylurea derivatives, as reported previously (6). However, the decomposition of I in phosphate buffer or water was very different from that of 5-azacytidine as shown by the presence of five (254 nm) and seven (220 nm) peaks on the chromatograms of I. Two of these peaks represent I and II, whereas the other peaks were not identified. These unidentified peaks could also be produced rapidly by placing II at pH 3.2 (Fig. 2B), even at 0°. These unidentified compounds were not the intermediates that eventually formed III, since they were not converted to III when placed in alkaline buffer, as would happen to I and II under the same conditions.

Determination of the pseudo-first-order rate constants for I and 5-azacytidine at pH 9.5 and 37° demonstrated that both compounds decomposed at comparable rates, although the formylguanylurea derivative for ribose appeared to be slightly more stable than that of deoxyribose (Table I). A 22-fold decrease in the hydroxyl-ion concentration (pH 9.5–8.1) reduced all three rate constants for 5-azacytidine equally by about 11-fold. Lowering the pH from 9.5 to 8.1 also greatly reduced the conversion rate of II to I and to III (Figs. 5 and 8). The kinetic data obtained for I at pH 8.1 did not quite fit in Eqs. 1–3 because apparently some of the decomposition did not follow Scheme I precisely due to the formation of minor unidentified peaks. Thus the rate constants were not determined. These unidentified peaks became increasingly prominent as the pH was lowered, and there was virtually no conversion of II to I at pH <4.6. (Fig. 2B).

[5] R. L. Momparler, unpublished data.

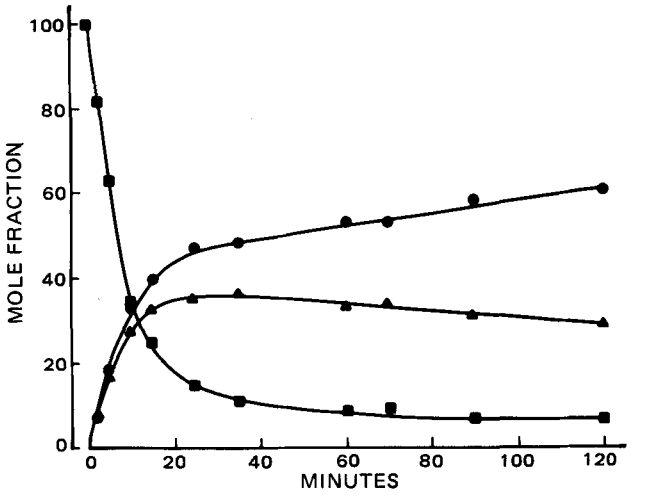

**Figure 8**—*Time–concentration profile of decomposition for I at pH 8.1 and 37°. Key: ▲, normalized data for I; ■, normalized data for II; and ●, normalized data for III.*

Comparison of the overall stability profile of I in aqueous buffer solution at various pH levels showed that I was most stable at neutral pH and at low temperature (Fig. 4). The instability of I at high pH could be explained on the basis that the opening of the triazine ring ($k_1$) and the breakage of an amide bond ($k_2$) is facilitated by a hydroxyl ion. Reduction in pH would slow down both these events and thus stabilize I. However, I became increasing unstable as the pH was gradually reduced below 7.0. This result might be due to the increase in the rate of ring opening as well as to the instability of II in acidic solutions; thus, once ring opening took place and produced II, the latter broke down to the unidentified peaks more rapidly and minimized the reversal back to I (Fig. 2B). In strong acidic solution (with pH <2.2), breakage of the glycolytic bond of I occurred, producing 5-azacytosine[6] as reported previously for I (9) and for 5-azacytidine (5, 10).

The effect of pH and temperature on the chemical stability of 5-azacytidine was studied by Chan *et al.* (11), who observed that this compound is most stable at pH 7.0 and that its rate of decomposition increases in solutions of high or low pH and with temperature.

# Distribution, Metabolism, and Elimination of Phenobarbital in Rats: Physiologically Based Pharmacokinetic Model

**J. M. ENGASSER* ˣ, F. SARHAN ‡, C. FALCOZ *, M. MINIER *, P. LETOURNEUR *, and G. SIEST ‡**

Received February 15, 1980, from the **Laboratoire des Sciences du Génie Chimique, CNRS-ENSIC, 1, rue Grandville, 54042 Nancy Cedex, France*, and the ‡*Laboratoire de Biochimie Pharmacologique, Faculté de Pharmacie, 7, rue Albert Lebrun, 54001 Nancy, France.*
Accepted for publication March 26, 1981.

**Abstract** □ The distribution, metabolism, and elimination kinetics at two different doses of phenobarbital were examined in rats. After intravenous injection, phenobarbital distributed very rapidly to the liver and kidneys, less rapidly to the muscle and gut, and much more slowly to the brain. At the higher dose, a concentration rebound was observed 1 hr after injection. In addition, phenobarbital distributed unevenly in various organs as a result of a different extent of drug binding. A physiologically based model, including enterohepatic cycling and diffusion resistances between blood and tissue, is proposed for phenobarbital pharmacokinetics. It satisfactorily describes phenobarbital distribution in rats at the two doses and allows an evaluation of fundamental physicobiochemical parameters such as drug–tissue binding constants, blood–tissue transport coefficients, metabolism, and elimination rate constants.

**Keyphrases** □ Phenobarbital—physiologically based model for distribution, metabolism, and elimination kinetics in rats □ Models, pharmacokinetic—for phenobarbital distribution, metabolism, and elimination, rats □ Pharmacokinetics—model for phenobarbital distribution, metabolism, and elimination, rats

Physiologically based models are being used more frequently in pharmacokinetic studies (1, 2). Based on anatomical and physiological characteristics and on drug physicochemical parameters, these models greatly facilitate pharmacokinetic data interpretation and allow extrapolation outside the data range and to other species. Physiological models are of greatest interest for the determination of basic physicobiochemical parameters relating to drug disposition and action and for the rational design of drug posology. Their potential was recently illustrated for anticancer drugs (2) and for digoxin (3), thiopental (4, 5), and pesticides (6).

The present study, which examined the distribution, metabolism, and elimination of phenobarbital following intravenous injection in rats, proposes a physiologically based pharmacokinetic model for phenobarbital. The drug, known to have different pharmacological action (sedative, hypnotic, and antiepileptic) depending on its concentration level in the brain, is also a powerful inducer of hepatic metabolizing enzymes (7). A physiological model considering phenobarbital diffusion to the brain, metabolism in the liver, binding to proteins and tissues, renal elimination, and intestinal resorption following biliary excretion can satisfactorily describe phenobarbital distribution and fate in rats.

## EXPERIMENTAL

Male Sprague–Dawley rats[1], 200–240 g, were injected intravenously with an isotonic sodium chloride solution of phenobarbital sodium[2]. Two doses, 30 and 50 mg/kg, were used. At different times after injection in the tail vein, the rats were decapitated, and blood and tissues were collected. After blood centrifugation at 9000 rpm, plasma was separated. Tissues and plasma were then stored at −14° until analysis.

Phenobarbital was extracted from plasma, urine, and bile using a one-step extraction procedure with chloroform; drug extraction from tissues and feces was performed with a previously described, two-step procedure with chloroform (8). Phenobarbital was then assayed in a gas chromatograph equipped with a nitrogen selective detector (9) to improve assay specificity and sensitivity. Analysis sensitivity is <1 μg of phenobarbital/sample.

For the evaluation of urinary excretion, rats were placed in metabolic cages. Urine, free from fecal contamination, was collected at timed intervals and then assayed for phenobarbital. The biliary excretion of phenobarbital was determined on bile duct-cannulated rats previously anesthetized with ether.

Drug binding to plasma proteins was measured with an equilibrium dialysis system[3]. When using 1-ml polytef[4] dialysis cells with cellulose membranes[5], binding equilibrium can be rapidly achieved. Experiments were performed with undiluted plasma adjusted to pH 7.35 by carbogen (5% carbon dioxide, 95% oxygen) bubbled on one side of the membrane and an isotonic phosphate buffer (pH 7.35), initially spiked with phenobarbital, on the other side. Phenobarbital binding to the membrane was <5%. A total plasma concentration of 10–110 μg/ml was investigated.

## RESULTS

Figure 1 shows the measured distribution of phenobarbital in the blood, liver, brain, muscle, intestine, and kidneys at the two injected doses of 50 and 30 mg/kg. Each point represents the mean obtained for five rats, with a standard deviation between 15 and 20%. The following pharmacokinetic characteristics can be observed. First, while phenobarbital distributed very rapidly in the liver and kidneys, it entered more slowly in brain, muscle, and intestine, probably because of mass transport limitations. The slowness of drug diffusion was particularly pronounced in the brain where the maximum concentration was reached only after 1 hr at the two investigated doses.

Second, a concentration rebound was observed in blood and several organs, ~1 hr after drug injection, at least at the higher dose. This phenomenon may be the result of enterohepatic cycling[6]. A biliary excretion of unchanged phenobarbital (~110 μg in the 1st hr at the high dose) was indeed observed in bile duct-cannulated rats.

Third, during the elimination phase, the concentration remained at different levels in the various organs, with the liver presenting the highest phenobarbital affinity. This result suggests different binding extents by plasma proteins and tissues.

Further insight into the kinetics of the limiting processes is obtained by plotting the ratio of the drug concentration over the administered dose. As seen in Fig. 2 for the various tissues, the points corresponding to the two doses come close together, indicating that phenobarbital pharmacokinetics can be considered dose independent at the investigated concentrations. Consequently, in a first approximation, first-order transport, metabolism, and excretion processes, as well as linear phenobarbital binding to plasma proteins and tissues, may be assumed.

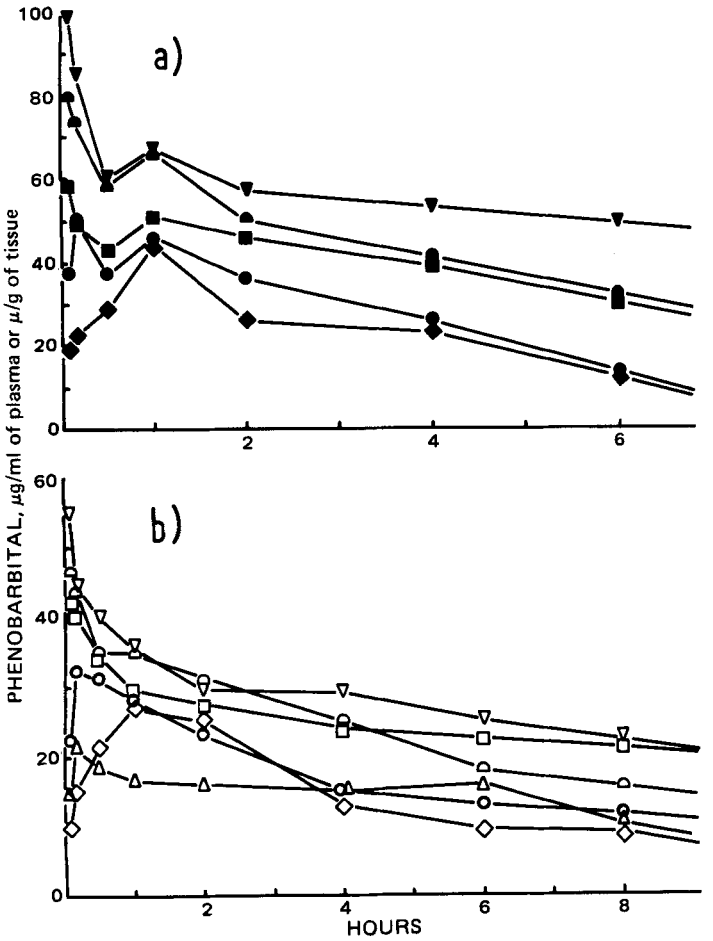

**Figure 1**—*Time evolution of phenobarbital distribution in rat tissues after intravenous injection of 50 (a) and 30 (b) mg/kg. Key (solid symbols for a and open symbols for b): ◓, ◔, plasma; ◆, ◇, brain; ▼, ▽, liver; ■, □, kidneys; and ●, ○, muscle; △, gut.*

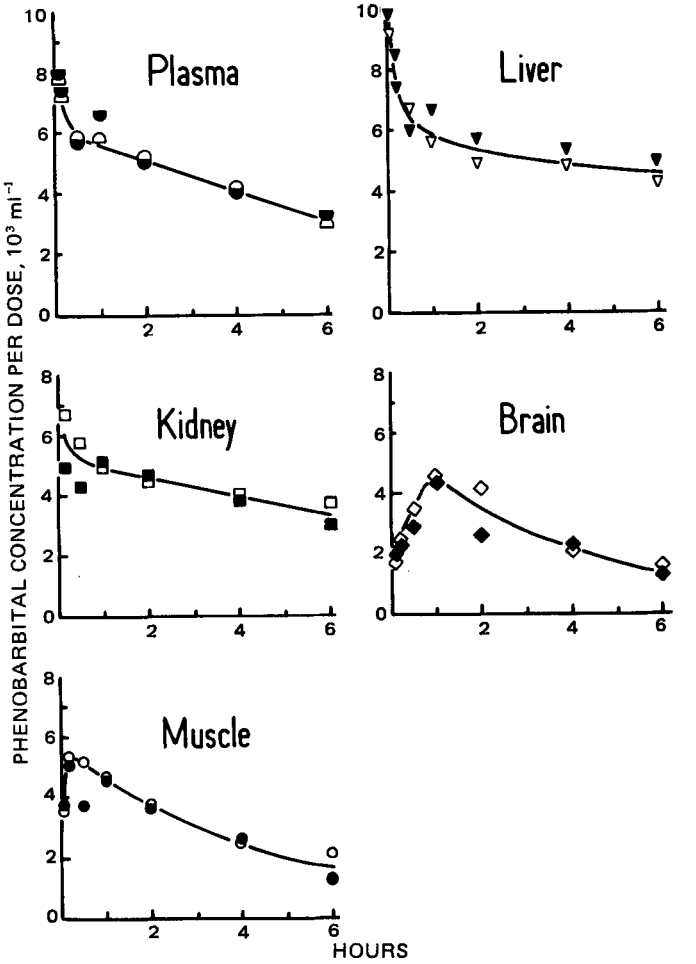

**Figure 2**—*Variation with time of the ratio of phenobarbital concentration over the administered dose in various rat tissues as calculated from Fig. 1 Key: solid symbols, 50 mg/kg; and open symbols, 30 mg/kg.*

The kinetics of urinary excretion were independently determined by simultaneously measuring the rate of urinary excretion and plotting the results as a function of drug plasma concentration. Figure 3 shows that the elimination rate was proportional to plasma concentration for concentrations of <30 μg/ml, with, however, the rate falling off at higher levels. During the first 24 hr, the total amount of excreted unchanged phenobarbital was ~10% of the administered dose.

## THEORY

**Flow-Sheet Diagram**—In its basic structure, the model in Scheme I is similar to models previously proposed for other drugs (4, 10). It depicts the main organs (brain, liver, gut, kidneys, and muscles) represented by a physiological compartment and connected by the blood network. Moreover, each organ and tissue is subdivided into the flowing blood and the tissue region. Tissues not experimentally considered are lumped into an additional compartment, called "remaining distribution volume," analogous to the distribution volume concept introduced in classical pharmacokinetics.

In view of the previous experimental results, the model also takes into account the enterohepatic cycle. The progress of the biliary-secreted drug towards the gut is handled by a plug flow compartment with a given residence time. Since the intestinal resorption of phenobarbital is relatively fast, the excreted drug is assumed to be directly transferred to the gut tissue.

In addition, this model includes some diffusional limitations between the perfusing blood and the brain, muscle, and intestinal tissues. In other organs, drug membrane transport is fast enough to assume equilibrium between blood and tissue.

To account for drug elimination, the model also considers drug metabolism in the liver tissue and urinary excretion in the kidney.

**Injection**—To represent intravenous administration of the drug, the injection function $Dg(t)$ proposed by Bischoff and Dedrick (4) was used such that:

$$g(t) = \frac{30}{\theta}\left(\frac{t}{\theta}\right)^2\left(1 - \frac{t}{\theta}\right)^2 \qquad \text{(Eq. 1)}$$

where $g(t)$ is a normalized impulse function (minutes$^{-1}$), $\theta$ is the injection duration (minutes), and $D$ is the total dose (micrograms).

**Drug Binding to Plasma Proteins**—The total blood concentration can be expressed as:

$$C^*_{Bl} = (1 - \text{HEM})\, C^*_P + \text{HEM}\, C^*_{BlC} \qquad \text{(Eq. 2)}$$

where:

$C^*_{Bl}$ = total blood concentration (micrograms per milliliter)
$C^*_P$ = total plasma concentration
$C^*_{BlC}$ = total blood cell concentration.
HEM = hematocrit (dimensionless)

It was observed experimentally that for phenobarbital the total blood concentration is equal to the total plasma concentration, *i.e.*:

$$C^*_{Bl} = C^*_P = C^*_{BlC} \qquad \text{(Eq. 3)}$$

Blood may thus be assimilated to plasma.

In the plasma, it is necessary to distinguish between the free and bound drug concentration:

$$C^*_P = C_P + C'_P \qquad \text{(Eq. 4)}$$

where $C_P$ is the free plasma concentration, and $C'_P$ is the bound plasma concentration.

According to drug binding experiments, there is a linear relationship between plasma bound and free phenobarbital concentrations, *i.e.*:

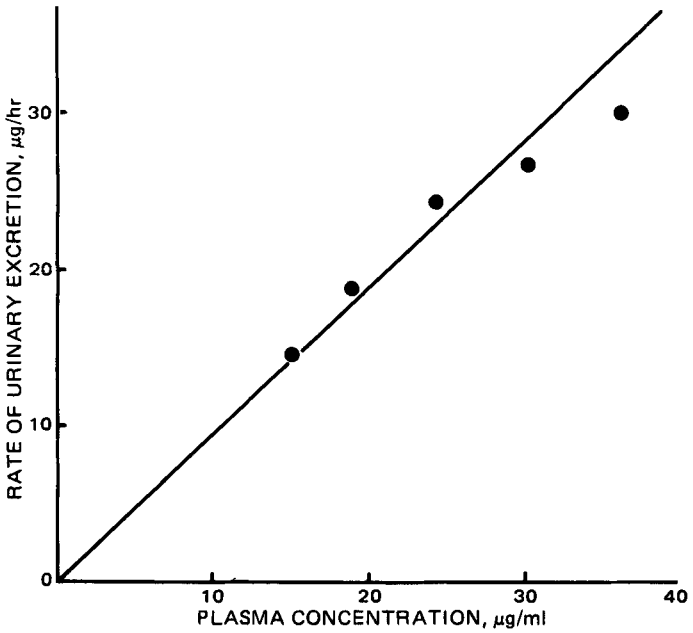

**Figure 3**—*Rate of urinary phenobarbital excretion as a function of plasma concentration after a 30-mg/kg iv dose. The rate was calculated from the quantity of phenobarbital excreted over 2 hr, and the corresponding plasma concentration is the one at the middle of the collection period. The urinary elimination rate constant was evaluated from the slope of the line drawn through the experimental points.*

$$C'_P = b_P C_P \qquad \text{(Eq. 5)}$$

where $b_P$ represents the plasma binding constant. Accordingly, the total plasma concentration is simply related to the free concentration by:

$$C^*_P = (1 + b_P)C_p \qquad \text{(Eq. 6)}$$

**Drug Binding to Tissues**—As previously proposed (4), the total tissue concentration is expressed as:

$$C^*_T = f_T C_T + (1 - f_T)C'_T \qquad \text{(Eq. 7)}$$

where:

$C^*_T$ = total tissue concentration
$C_T$ = free tissue concentration
$C'_T$ = bound tissue concentration
$f_T$ = water fraction of tissue (dimensionless)

Preliminary binding experiments with diluted muscles, as well as other results (11) with rat lung and liver slices, suggest a linear relationship for phenobarbital tissue binding, *i.e.*:

$$C'_T = b_T C_T \qquad \text{(Eq. 8)}$$

where $b_T$ is the binding constant of the tissue. Under these conditions:

$$C^*_T = [f_T + (1 - f_T)b_T]C_T \qquad \text{(Eq. 9)}$$

According to Eqs. 6 and 9, for blood and tissues the total concentration, $C^*$, is proportional to the free concentration, $C$:

$$C^* = \Phi C \qquad \text{(Eq. 10)}$$

where:

$$\Phi = f + (1 - f)b \qquad \text{(Eq. 11)}$$

The proportionality constant, $\Phi$, represents the binding ability of blood and tissues (12).

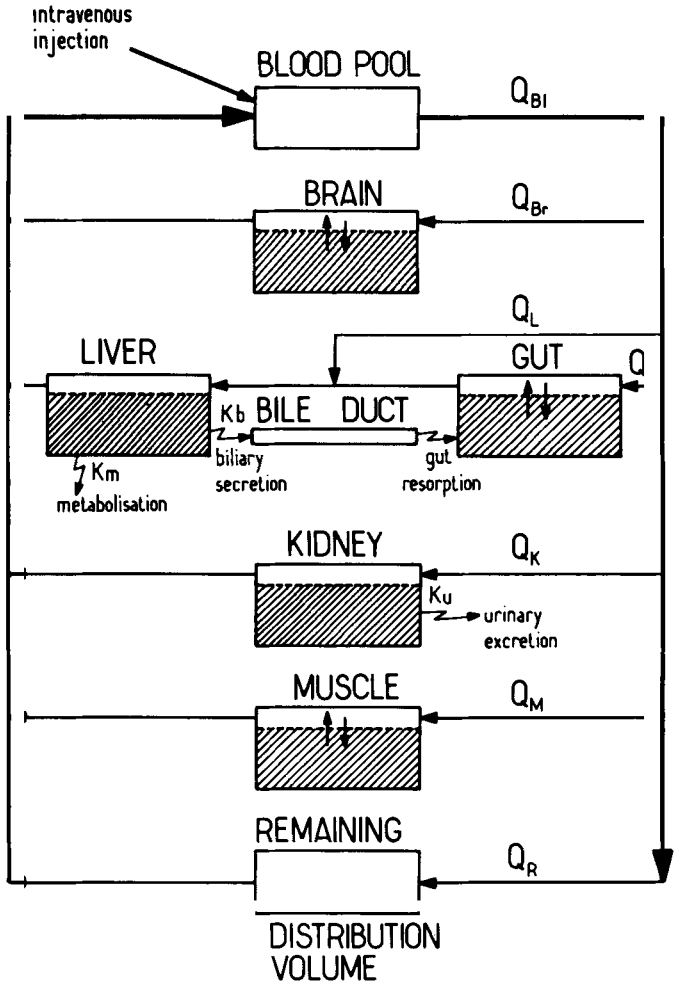
**Blood–Tissue Distribution**—In organs where the transport of drug between blood and tissue is very fast, equal free concentrations in plasma and tissue were assumed, *i.e.*:

$$C_T = C_P \qquad \text{(Eq. 12)}$$

However, in brain, muscle, and gut, drug transport between blood and tissue may represent a limiting process. Under these conditions the transport rate is expressed as:

$$r_t = H(C_P - C_T) \qquad \text{(Eq. 13)}$$

where $r_t$ is the drug transport rate from plasma to tissue (μg/min), and $H$ is the drug transport coefficient or tissue permeability (ml/min).



*Scheme I—Physiological pharmacokinetic model for phenobarbital.*

**Drug Elimination Processes**—Phenobarbital elimination by urinary excretion, hepatic metabolism, and biliary excretion is assumed to be a first-order process and thus is represented by:

$$r_e = KC_T \qquad \text{(Eq. 14)}$$

where:

$r_e$ = elimination rate (μg/min)
$K$ = elimination (excretion or metabolism) rate constant (ml/min)
$C_T$ = free concentration in elimination tissue (μg/ml)

The total amount of drug, $E$ (in micrograms), excreted in a given organ is equal to:

$$E = \int_0^t KC_T\,dt \qquad \text{(Eq. 15)}$$

where $t$ is time (minutes).

**Mass Balance Equations**—The resulting mass balance equations for the various compartments are as follows (notation is given in the *Appendix*).

For blood:

$$V_{Bl}\Phi_{Bl}\frac{dC_{Bl}}{dt} = Dg(t) + \Phi_{Bl}\,[Q_{Br}C_{Br,Bl} + (Q_L + Q_G)C_{L,Bl} + Q_K C_{K,Bl} + Q_M C_{M,Bl} + Q_R C_R - Q_{Bl}C_{Bl}] \qquad \text{(Eq. 16a)}$$

where:

$$Q_R = Q_{Bl} - Q_{Br} - Q_L - Q_G - Q_K - Q_M \qquad \text{(Eq. 16b)}$$

**Table I—Values of parameters for a Standard 200-g Male Rat [a]**

| Compartment | Physiological Parameters: Volume, ml: Tissue | Volume, ml: Blood [b] | Blood Flow, ml/min | Water Fraction [c] ($f$) | Pharmacokinetic Parameters: Binding: Constant ($b$) | Binding: Ability ($\Phi$) | Transfer Coefficient, ml/min | Elimination Constant, ml/min |
|---|---|---|---|---|---|---|---|---|
| Blood | | 13 | 58(*) | — | 1.1 | 2.1 | | |
| Brain | 2 | 0.022 | 2 | 0.80 | 1.1 | 1. | 0.15 | |
| Gut | 5.6 | 0.23 | 8.5 | 0.76 | 1.7 | 1.2 | 20 | $K_b = 1$ |
| Liver | 6.7 | 0.7 | 1 | 0.75 | 6.7 | 2.4 | | $K_m = 0.4$ |
| Kidneys | 2.3 | 0.21 | 8.5 | 0.80 | 6.1 | 2. | | $K_u = 0.04$ |
| Muscle | 93 | 0.4 | 10 | 0.78 | 3.6 | 1.6 | 50 | |
| Remaining distribution volume | | 55 | 28 [d] | | | | | |

[a] References 3, 5, and 13–23. [b] Blood permitted to ooze from tissue (13). [3] From dog values (5). [d] Calculated from difference between total cardiac output (*) and the sum of the tissue blood flows.

For brain blood:

$$V_{Br,Bl}\Phi_{Bl}\frac{dC_{Br,Bl}}{dt} = Q_{Br}\Phi_{Bl}(C_{Bl} - C_{Br,Bl}) + H_{Br}(C_{Br,T} - C_{Br,Bl}) \quad \text{(Eq. 17a)}$$

For brain tissue:

$$V_{Br,T}\Phi_{Br}\frac{dC_{Br,T}}{dt} = H_{Br}(C_{Br,Bl} - C_{Br,T}) \quad \text{(Eq. 17b)}$$

For gut blood:

$$V_{G,Bl}\Phi_{Bl}\frac{dC_{G,Bl}}{dt} = Q_G\Phi_{Bl}(C_{Bl} - C_{G,Bl}) + H_G(C_{G,T} - C_{G,Bl}) \quad \text{(Eq. 18a)}$$

For gut tissue:

$$V_{G,T}\Phi_G\frac{dC_{G,T}}{dt} = H_G(C_{G,Bl} - C_{G,T}) + K_bC_{L,T}^{(t-T_{del})} \quad \text{(Eq. 18b)}$$

where $C_{L,T}^{(t-T_{del})}$ is the free tissular liver concentration at time $(t - T_{del})$.

For liver:

$$C_{L,Bl} = C_{L,T} = C_L \quad \text{(Eq. 19a)}$$

$$(V_{L,Bl}\Phi_{Bl} + V_{L,T}\Phi_L)\frac{dC_L}{dt} = \Phi_{Bl}[Q_GC_{G,Bl} + Q_LC_{Bl} - (Q_G + Q_L)C_L] - (K_m + K_b)C_L \quad \text{(Eq. 19b)}$$

For kidney:

$$C_{K,Bl} = C_{K,T} = C_K \quad \text{(Eq. 20a)}$$

$$(V_{K,Bl}\Phi_{Bl} + V_{K,T}\Phi_K)\frac{dC_K}{dt} = Q_K\Phi_{Bl}(C_{Bl} - C_K) - K_uC_K \quad \text{(Eq. 20b)}$$

For muscle blood:

$$V_{M,Bl}\Phi_{Bl}\frac{dC_{M,Bl}}{dt} = Q_M\Phi_{Bl}(C_{Bl} - C_{M,Bl}) + H_M(C_{M,T} - C_{M,Bl}) \quad \text{(Eq. 21a)}$$

For muscle tissue:

$$V_{M,T}\Phi_M\frac{dC_{M,T}}{dt} = H_M(C_{M,Bl} - C_{M,T}) \quad \text{(Eq. 21b)}$$

For the remaining distribution volume:

$$V_R\frac{dC_R}{dt} = Q_R(C_{Bl} - C_R) \quad \text{(Eq. 22)}$$

The resulting set of nonlinear differential equations is solved simultaneously with a fourth-order Runge–Kutta method on a digital computer.

**Values of Parameters**—The various anatomic and physiological parameters, blood flow rates, tissue volumes, and water fractions for a 200-g male rat are summarized in Table I. The remaining distribution volume was determined by fitting the theoretical curves to the experimental results.

For the intravenous drug injection, a value of 0.25 min for $\theta$ is representative of the experimental conditions.

The plasma binding constant $b_P$ was experimentally determined as 1.1, which corresponds to a proportionality constant, $\Phi p$, of 2.1 between the total and free plasma concentration. The binding constants $b_T$ for the tissues as defined in Eq. 8 were obtained by curve fitting. They were most precisely determined from the different drug levels in the elimination phase, as experimentally observed in Fig. 1. The resulting values of $b_T$ and the tissue binding ability $\Phi_T$, *i.e.*, the proportionality constant between total and free concentration, are shown in Table I.

The urinary elimination constant, $K_u$, defined in Eq. 20*b* as the proportionality constant between the rate of urinary elimination and the free tissue, *i.e.*, free plasma, concentration in the kidney can be simply evaluated from the slope of the line obtained on Fig. 3 as 0.04 ml/min.

The metabolism rate constant $K_m$, which, according to Eq. 14, relates the rate of metabolism to the free liver tissue concentration, was estimated by dividing the amount of drug metabolized, ~80% of the dose, during the first 24 hr by the area under the free plasmatic concentration *versus* time curve (assuming equal free plasma and free liver tissue concentration):

$$K_m = (1 + b_P)\frac{\int_0^{24} K_mC_L\,dt}{\int_0^{24} C_P\,dt} \quad \text{(Eq. 23)}$$

This evaluation procedure yields a value of 0.4 ml/min for $K_m$.

As previously suggested (12), the passage of the drug through the enterohepatic cycle was approximated in Eq. 18*b* by a delay time, $T_{del}$, which approximates the drug travel through the bile and down the small intestine before absorption in the gut tissue. This residence time, $T_{del}$, through the enterohepatic cycle was adjusted to 55 min to obtain a concentration rebound ~1 hr after drug injection. The magnitude of the biliary excretion constant, $K_b$, which directly determines the height of the concentration rebound, was chosen as 1 ml/min.

Finally, blood–tissue transfer coefficients in brain, muscle, and gut were determined by fitting the theoretical curves to the experimentally observed tissue concentrations during the distribution phase. The corresponding values are given in Table I.

## DISCUSSION

The theoretical drug distribution curves in the various compartments obtained with the previously defined model are shown in Fig. 4. The two sets of curves corresponding to the two injected doses of 30 and 50 mg/kg were calculated with the same physiological and pharmacokinetic parameters (Table I).

Although in its present state the model does not perfectly describe the observed phenobarbital distribution, it appears satisfactory in many respects. It is the simplest possible model based on the animal anatomy and taking into account key physiological parameters such as protein and tissue binding, liver metabolism, renal excretion, bile excretion, intestinal reabsorption, and tissue diffusion. This model, which only entails simple first-order physical and chemical rate processes, can especially account for the slow drug penetration in the brain, for the concentration rebound 1 hr after injection, and for different tissue drug levels during the elimination phase. Moreover, for several tissues it adequately predicts drug levels at two different doses, at least at the lower dose.

The present model can be improved to get a close agreement with experimental observation. The model does not precisely describe, at the two doses, the relatively narrow peak or its exact height in the brain tissue. The introduction into the model of a simple reversible mass transfer process through the brain–blood barrier accounts for the relatively slow drug entry into the brain but also results in slow drug release during the elimination phase. The observed rapid phenobarbital concentration decrease in the brain may be explained and modeled by some more

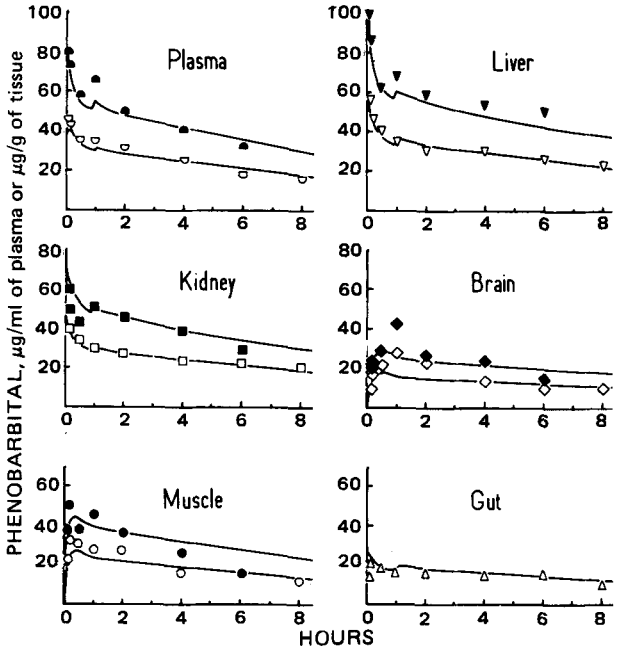


**Figure 4**—*Calculated time distribution of phenobarbital in various rat tissues, using the physiologically based pharmacokinetic model at 50 and 30 mg/kg. The corresponding experimental points are taken from Fig. 1. Key: solid symbols, 50 mg/kg; and open symbols, 30 mg/kg.*

complex asymmetric transport process, which greatly favors drug transport, at least during the elimination phase. Some active drug secretion from brain tissue to the peripheral blood was experimentally demonstrated for triamterene (24) and salicylic acid (25).

Another observation concerns the enterohepatic cycle, which was introduced in the model to explain the phenobarbital concentration rebound. Similar rebounds were observed in rats with morphine (27), phenolphthalein (28), and phenytoin metabolites (29). The lag time ranged from 4 to 6 hr, accounting, in addition to hepatic formation and biliary excretion, for the intestinal hydrolysis of the glucurono conjugate prior to reabsorption of the compound; this rebound did not occur with bile duct-cannulated rats (28, 29).

As demonstrated by the present model, despite continuous bile flow in the rat, phenobarbital biliary excretion followed by intestinal reabsorption can partly account for the concentration rebound observed at the higher dose ~1 hr after drug injection. This phenomenon can be theoretically obtained by considering a mean residence time of ~55 min of the drug through bile and intestine before reabsorption, provided the excreted drug concentration is sufficiently high. Autoradiographic studies with [$^{14}$C]phenobarbital[7] demonstrated an intensive enterohepatic recycling. On the other hand, Caldwell *et al.*[6] found that ~35% of an intraperitoneal [$^{14}$C]phenobarbital dose was excreted by the bile while only 1% was recovered in the feces during the first 24 hr. Moreover, unmetabolized phenobarbital seems to represent about one-third of the total gut content radioactivity. Personal experiments and other work (26) on bile duct-cannulated rats confirm the biliary excretion of unmodified phenobarbital.

However, according to this model based on a simple delay time through the enterohepatic cycle, an approximate 10-fold greater amount of phenobarbital than that experimentally observed has to be excreted in the bile to account for the observed peak height. Thus, further experiments are necessary to quantify the mechanism of biliary excretion. Moreover, if enterohepatic cycling is the actual phenomenon responsible for the concentration rebound, a more detailed representation of the cycle may be needed to improve model validity.

According to Fig. 4, phenobarbital elimination at the high dose is slightly faster than that predicted by simple first-order renal excretion and liver metabolism. A better quantitative understanding of the various elimination processes represents another prerequisite for better physiological modeling.

In the present model, a remaining distribution volume was introduced to represent all nonspecified organs and tissues. This distribution volume can account for the approximate 30% of the dose that distributes elsewhere than in blood, liver, brain, muscle, gut, and kidneys. According to autoradiographic results[7] for phenobarbital, the remaining distribution volume corresponds primarily to fat, lungs, and the heart, providing that in all tissues, except for the intestine and gut contents, there are no metabolites but only unchanged drug[6].

In conclusion, a relatively simple model based on the animal physiology and physicochemical drug parameters to a first approximation describes the main characteristics of phenobarbital pharmacokinetics. This model has many features similar to physiological models recently proposed for other compounds (3, 6, 10, 30).

## APPENDIX

$b$ = linear binding constant (dimensionless)
$C$ = free drug concentration (micrograms per milliliter of water)
$C'$ = bound drug concentration (micrograms per gram of dry matter)
$C^*$ = total drug concentration (micrograms per milliliter of blood or micrograms per gram of tissue)
$D$ = dose (micrograms)
$E$ = total amount eliminated by one-way metabolism, bile, or urine during a period of time (micrograms)
$f$ = fraction of water (dimensionless)
$g(t)$ = normalized impulse injection function (minutes$^{-1}$)
$H$ = transport coefficient between blood and tissue (milliliters per minute)
HEM = hematocrit (dimensionless)
$K$ = elimination constant by metabolism ($K_m$), bile ($K_b$), or urine ($K_u$) (milliliters per minute)
$r_e$ = elimination rate (micrograms per minute)
$r_t$ = drug transport rate from plasma to tissue (micrograms per minute)
$t$ = time (minute)
$T_{del}$ = step-delay time accounting for the biliary excretion (minute)
$V$ = volume (milliliter)
$\Phi$ = global binding coefficient for blood or tissue (dimensionless)
$\theta$ = injection duration (minute)
$Bl$ = blood pool
$BlC$ = blood cells
$Br$ = brain
$G$ = gut
$K$ = kidneys
$L$ = liver
$M$ = muscle
$P$ = plasma
$R$ = remaining distribution volume
$T$ = tissue
$X,Bl$ = blood compartment of the considered organ or tissue $X$
$X,T$ = tissue compartment of the considered organ or tissue $X$

# Solubility Behavior of Barbituric Acids in Aqueous Solution of Sodium Alkyl Sulfonate as a Function of Concentration and Temperature

**C. VAUTION *, C. TREINER ‡ ×, F. PUISIEUX *, and J. T. CARSTENSEN §**

Received January 5, 1981, from the *Laboratoire de Pharmacie Galénique, Faculté de Pharmacie, Rue Jean Baptiste Clément, 92290 Chatenay Malabry, France*, the ‡ *Laboratoire d'Electrochimie, Université Pierre et Marie Curie, 4 Place Jussieu, Bâtiment F, 75005, Paris, France*, and the § *School of Pharmacy, University of Wisconsin, Madison, WI 53706.* Accepted for publication March 25, 1981.

**Abstract** □ The solubility of 13 barbituric acids was determined in aqueous solutions of sodium alkyl sulfonate. The effects of concentration and temperature were investigated, and the thermodynamic functions of the solubilization process were calculated. An analysis of the location of a solubilized species within a micelle is suggested in terms of the sign and amplitude of the standard entropy of solubilization, which is strongly positive for micelle penetration and negative for adsorption. A solubilization mechanism through adsorption onto the micellar surface is suggested for most of the barbituric acids studied. The enthalpy/entropy compensation phenomenon was identical for barbituric acids in ionic and nonionic (polyoxyethylene lauryl ether) surfactant solutions with a compensation temperature of 270 °K, indicating common behavior of these compounds with respect to micellar solubilization. The concept of molecular surface area was used to correlate the free energy of solubilization of the solutes to their size and structure. A linear relationship was found with an excellent correlation factor for the alkane derivatives of the 5-ethyl-barbituric acids. The specific behavior of some of the barbituric acids investigated is discussed.

**Keyphrases** □ Solubility—barbituric acids in aqueous sodium alkyl sulfonate, thermodynamics □ Thermodynamics—solubility of barbituric acids in aqueous sodium alkyl sulfonate □ Barbituric acids—solubility in aqueous sodium alkyl sulfonate, thermodynamics

The increase in solubility of poorly soluble preservatives in water by the addition of surfactants has been the subject of a large number of studies (1, 2). This phenomenon is related to the formation of micelles in water, but the availability of the preservative as an active agent is highly dependent on the molecular attachment site, and this subject is still a controversial matter. Opposite views have been proposed for barbituric acids, such as adsorption at the micelle interface (3) or incorporation into the micelle hydrocarbon core (4). However, for simpler molecules like acetone or urea, which may be considered model compounds for barbituric acids, thermodynamic evidence shows that these molecules hardly penetrate the micelle interior, at least at the critical micelle concentration (CMC) and for ionic micelles (5, 6).

## BACKGROUND

Studies on the solubilization of barbituric acids have been mostly (7) restricted to the influence of nonionic surfactants (3, 4, 8–10). Few of these studies were concerned with the determination of thermodynamic functions such as free energy, enthalpy, and entropy (3). In fact, few papers have been published on this subject for compounds other than barbituric acids (3, 11, 12).

The present work investigated the solubilization properties of sodium alkyl sulfonate. Its biodegradability and nontoxic properties, even at high surfactant concentration, make it an interesting surfactant in formulation problems (13). The barbituric acids are useful compounds in this respect since the possibility of changing, almost at will, the radicals attached to the malonylurea ring permits the study of the influence of shape and structure on the solubilization process. Thus, previous studies (14) on the molecular surface area concept and the investigation of the effects of temperature on barbituric solutions have indicated the use of the entropy function to deduce the chemical environment of compounds solubilized by micelles.

## EXPERIMENTAL

**Materials**—Sodium alkyl sulfonate[1] was composed of 90.7% (by weight) monosulfonated detergent, 8.8% polysulfonated compound, and 0.5% unsulfonated product. The monosulfonated compound was a mixture of $C_{14}H_{29}SO_3Na$ and $C_{15}H_{31}SO_3Na$, so a molecular weight of 323 was adopted in the concentration calculations. The CMC of the detergent

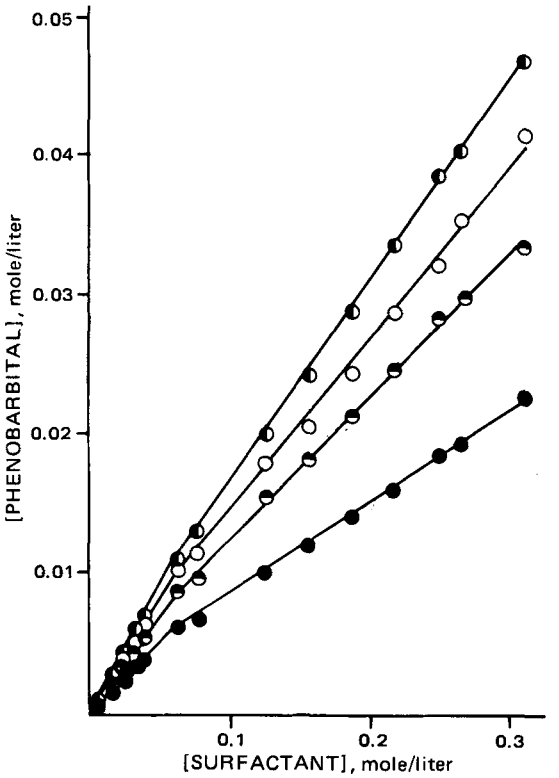

**Figure 1**—*Variation of the solubility of phenobarbital with sodium alkyl sulfonate concentration at various temperatures. Key:* ◐, *55°;* ○, *45°;* ◓, *35°; and* ●, *25°.*

used was 0.0039 mole/liter, as determined from conductivity measurements at 25°. Highly pure sodium dodecyl sulfate[2] was used without purification. Its CMC at 25° was 0.0081 mole/liter, in excellent agreement with literature values (15).

The barbituric acids were from different sources[3]. Their melting points and solubilities in water at 25° are presented in Table I, although some solubility values in water may be slightly in error due to impurities. However, since the major interest was in partition coefficients, *i.e.*, in ratio of concentrations with and without the added surfactant, the influence of the impurities on the partition coefficient values should be negligible.

**Solubility Measurements**—The barbiturate solution with the added surfactant was equilibrated for 240 hr (10 days) at a given temperature, and controlled to within ±0.1°. The suspension was filtered and diluted, and the concentration of solubilized solute was determined with a UV spectrophotometer[4].

**Solubility Calculations**—The pH of the solutions was determined and used with the pKa of each barbituric acid to correct for the variation of solubility due to the pH change of the solution, which occurs with the addition of alkyl sulfonate (16). The classic formula was used:

$$S = S_0 (1 + 10^{pH-pKa}) \qquad \text{(Eq. 1)}$$

where $S$ and $S_0$ are the total amount of barbituric acid and the intrinsic solubility of the undissociated acid, respectively.

## RESULTS AND DISCUSSION

An example of the variation of barbituric acid solubilization with the surfactant concentration is presented at several temperatures in Fig. 1. This behavior was typical of all barbituric acids studied with alkyl sulfonate but had not been observed with nonionic surfactants. It has been interpreted as the result of the presence of mixed micelles of monosulfonated and polysulfonated sodium alkyl sulfonate above the concentration $C_2$ (17). Below this value, the only micelles present are formed from monosulfonated molecules. The present report concerns only the first part of these curves, *i.e.*, the initial slope above the CMC. In Fig. 1, the maximum concentration of solubilized material is plotted for convenience as a function of the concentration of surfactant used minus the CMC.

In all cases, solubilization increased with increased surfactant concentration in water and with temperature. To quantify, the relative variation of the solubilized solute in water and in the micellar solutions, an apparent distribution coefficient such as:

$$K = \frac{S_m - S_w}{S_w C} \qquad \text{(Eq. 2)}$$

is defined where $S_m$ and $S_w$ are the saturation molarities of solubilized barbituric acid in the micellar solution and in water, respectively, and $C$ is the excess of surfactant above the CMC in moles per liter. The maximum surfactant concentration used in the determination of $K$ was ~0.04 mole/liter (1.3 g/100 ml of solution).

In each case, $K$ was calculated using at least eight experimental points with a least-squares method. As shown in Table II, $K$ decreased as temperature increased, which means that the increase in solubility was faster in water than in the micellar solution. This finding agrees with previous findings (3) for barbituric acids in nonionic polyoxyethylene lauryl ether aqueous solutions but contradicts the results of Ismail *et al.* (10) for the same solutes with the nonionic polyoxyethylene derivative surfactants used (monoalkyl ether, monostearate, and polysorbate).

**Thermodynamic Functions and Location of Solubilized Material in Micelles**—To discuss the thermodynamic properties of the solutions, the free energy of solubilization may be calculated as:

$$\Delta G_s^\circ = -RT \ln K \qquad \text{(Eq. 3)}$$

where $K$ is an apparent distribution coefficient, uncorrected for volume effects (5).

The standard enthalpy of solubilization is defined by:

$$\partial \frac{\ln K}{\partial T} = \frac{\Delta H_s^\circ}{RT^2} \qquad \text{(Eq. 4)}$$

and:

$$\Delta G_s^\circ = \Delta H_s^\circ - T\Delta S_s^\circ \qquad \text{(Eq. 5)}$$

where $\Delta S_s^\circ$ is the standard entropy of solubilization. The results of these calculations are given in Table II. The precision of $\Delta H_s^\circ$ is not very good when obtained from indirect determinations (4). Thus, $\Delta H_s^\circ$ values should be considered reliable within ±300 cal/mole, while $\Delta S_s^\circ$ values are accurate to ±1.0 entropy units.

The same thermodynamic functions are examined in more extreme cases in Table III, using the standard thermodynamic functions of hydrocarbon transfer (18) from water to an aqueous anionic surfactant solution (such as sodium lauryl sulfate of molarity $c$ = 0.06 mole/liter).

Thus:

$$\Delta G_t^\circ = -RT \frac{S}{S^\circ} \qquad \text{(Eq. 6)}$$

As expected, $\Delta G_t^\circ$ is more negative the larger the solute molecule since

[a] Throughout this paper, 1 cal = 4.184 J.

dispersion forces and the hydrophobic effect both increase in magnitude when the surface of contact between the solute and the solvent molecules (here the micelles) increases.

The standard enthalpy of transfer, $\Delta H_t^\circ$, is close to zero and is also size dependent, but the entropy of transfer is strongly positive. Since hydrocarbons dissolve in the micelle interior, the positive entropy change upon solubilization seems a good thermodynamic characteristic of the penetration of a solute from an aqueous to a nonaqueous environment. The cases of ammonium chloride and hydrochloric acid were chosen to illustrate the behavior of a polar or an ionic hydrophilic solute (19). [Methane is presented to illustrate the thermodynamics of transfer of a hydrocarbon from water to an organic component (20). It shows that all thermodynamic functions are of the same order of magnitude whether the transfer is from water to a micellar phase or to an organic solvent in the case of penetration. The same reasoning may be applied to a polar solute.] Table III shows that, for a hydrophilic solute transferred from an aqueous to an organic environment, $\Delta G_t^\circ$ is positive and $\Delta S_t^\circ$ is negative. Since ammonium chloride or hydrochloric acid prefers water to the organic phase (19), a negative entropy change is associated with nonpenetration of the solute into the organic phase (which can be a micelle). Thus, $\Delta G_s^\circ < 0$ and $\Delta S_s^\circ > 0$ are associated with the penetration into a micelle interior, and $\Delta G_s^\circ > 0$ and $\Delta S_s^\circ < 0$ are associated with an interaction of the solute with the micelle without penetration, *i.e.*, through an adsorption phenomenon.

Examination of the barbituric acids shows that $\Delta H_s^\circ$ is negative in all cases and $\Delta S_s^\circ$ is negative or zero for nine out of 13 barbiturates. Thus, it may be concluded that solubilization occurs in an environment of mixed water and nonpolar molecules, depending on the particular solute, but with a preference for a predominantly aqueous phase.

To compare solutes dissolved in sodium lauryl sulfate and alkyl sulfonate solutions, the solubilization of butethal was studied at four temperatures in very pure samples of sodium lauryl sulfate. The results were analyzed as for the alkyl sulfonate solutions (Table IV). They are similar in both surfactant solutions. The $\Delta G_s^\circ$ values are equal within experimental error, and only the dependence of $K$ with temperature is slightly different with alkyl sulfonate and sodium lauryl sulfate. The $\Delta H_s^\circ$ and $\Delta S_s^\circ$ values are both somewhat more negative in the alkyl sulfonate solutions, a good example of enthalpy/entropy compensation. In addition, the thermodynamic functions are very much the same in the nonionic polyoxyethylene lauryl ether solutions (deduced from dialysis measurements at several temperatures) and in the anionic alkyl sulfonate solutions. For example, $\Delta G_s^\circ$ is systematically more negative by only ~20% in the nonionic solution[5]. This finding should be the result of a number of compensation effects. If, as was previously suggested (3) for polyoxyethylene lauryl ether and as presently proposed for alkyl sulfonate, solubilization occurs through adsorption for barbituric acids in these surfactant solutions, the situations at each micelle surface must be quite different. In particular, the role of the adsorbed sodium counterions in the latter case should be clarified.

**Enthalpy/Entropy Compensation Phenomenon**—Ionic and nonionic surfactants as solubilizing agents also can be compared by considering the enthalpy/entropy compensation phenomenon. It occurs in most solutions but presents amazing regularities for aqueous solutions. Lumry and Rajendar (21) described the phenomenon by an equation of the type:

$$\Delta H_s^\circ = \alpha + T_c \Delta S_s^\circ \qquad \text{(Eq. 7)}$$

where $\alpha$ and $T_c$ are constants. This equation holds for a given solute in various media or for a series of different solutes in a given medium. The compensation temperature ($T_c$) is equal to an average value of 285 °K for most aqueous or predominantly aqueous systems, indicating a common mechanism in a given solution process when essentially water molecules are involved. [In organic solvents, Eq. 7 is known as the Barclay–Butler plot (22) with $T_c \approx 910$ °K.]

Figure 2 presents the correlation found for the barbituric acids used in this work and those of Ikeda *et al.* (3) with polyoxyethylene lauryl ether. If the results for barbital and reposal in the ionic solutions and for

[5] The same situation was described with phenobarbital in ionic and nonionic surfactant solutions (7). Unfortunately, the authors did not publish the actual data but only corresponding curves.

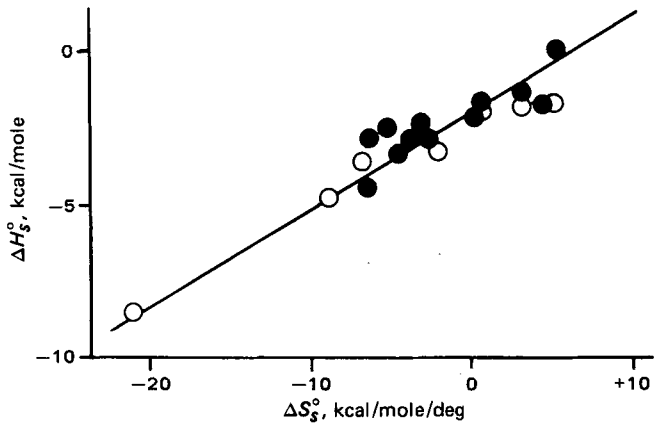

**Figure 2**—*Enthalpy/entropy compensation plot for barbituric acids in sodium alkyl sulfonate (●), ionic, and polyoxyethylene lauryl ether (○), nonionic, aqueous solutions at 25°.*

secobarbital in the nonionic solutions are discarded, a linear regression on the remaining 18 barbituric acid solutions may be represented at 25° by:

$$\Delta H_s^\circ = -2020 + 269\ \Delta S_s^\circ \qquad \text{(Eq. 8)}$$

with a correlation coefficient of $r^2 = 0.98$. The $T_c$ value of 269 °K is in agreement with the average 285 °K.

The Humphreys and Rhodes distribution coefficients at several temperatures were also analyzed for benzoic acid in aqueous solutions of *n*-alkylpolyoxyethylene surfactants. Benzoic acid is considered as being mostly adsorbed on the micelle surface (23). The derived thermodynamic functions are presented at 25° in Table V. The $\Delta H_s^\circ$ and $\Delta S_s^\circ$ values are situated on the same line as for the other systems in Fig. 3.

Although speculation on the meaning of the compensation temperature in terms of chemical compensation has been criticized (24), the fact that, for the same chemical process (*i.e.*, solubilization by adsorption onto micellar surfaces), a single line is obtained on a $\Delta H_s^\circ$ *versus* $\Delta S_s^\circ$ plot should be considered. In the case of benzoic acid, $\Delta S_s^\circ$ becomes less negative as the number of oxyethylene group increases, which may be interpreted as an increase in penetration of the benzoic molecule within the micelle mantle. However, $\Delta S_s^\circ$ remains negative for the four surfactants, indicating that adsorption still predominates for this system.

**Solubilization and Molecular Surface Area Concept**—Many approaches have been tested, from the crudest models that correlate distribution coefficients with the number of carbon atoms on the barbituric acid molecule [with corrections for the position of radicals and the malonylurea rings (25)], to the more general approach of Hansch and Anderson (26), who correlated drug activity with the distribution coefficient in octanol–water mixtures, to others who use the regular solution theory to find an index of drug activity (27). An attractive alternative to these approaches may be found in the concept of molecular surface area, as proposed by Herman (14) and extensively used in the case of slightly soluble series of organic compounds in water (28–30). It is based on the idea that, provided no specific interactions take place between solute and solvent molecules and the solute is sufficiently diluted so that solute–solute interactions are negligible, the molecular surface of contact between solute and solvent molecules is proportional to their free energy of interaction. Thus, the logarithm of solubility should be a linear function of the molecular surface area. Implicitly, it is assumed that the same correlation will not be found for any series of compounds. Thus, alkanes, alkynes, or aromatic derivatives may be found on different straight lines.

**Table V—Partition Coefficients and Thermodynamic Parameters for Benzoic Acid in Nonionic Surfactant Solutions at 25° (Molar Scale)**

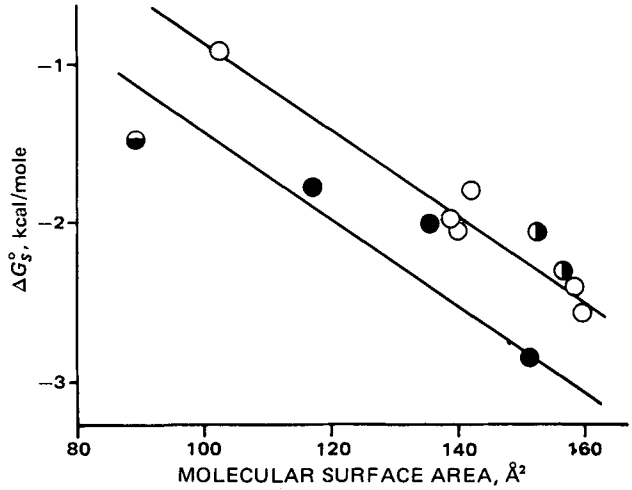

**Figure 3**—*Variation of the standard free energy of solubilization of barbituric acids with the molecular surface area of their substituted groups at 25°. Key: ○, 5-ethyl (linear); ◑, 5-ethyl (cyclic); ●, 5-allyl; and ◒, 5-diallyl.*

Valvani *et al.* (29) proposed a simplified version of the elaborate method of evaluation of molecular surface area by Herman (14), and the present study used their results whenever possible (28). The heptabarbital ring has been considered as being equivalent to that of cycloheptane (29) minus one methylene group (a quaternary carbon atom has no molecular surface area) and minus the difference between one methylene and one CH group. It was assumed that the molecular surface areas of phenobarbital and cyclobarbital were equivalent to that of a benzene ring minus one methylene group. The molecular surface area of malonylurea was not accounted for since it was assumed to play the same role for each barbituric acid. The results of these calculations are presented in Table I. (Reposal was not calculated because of too many geometrical unknowns. However, a value of ~150 Å² is plausible.)

Figures 3 and 4 correlate $\Delta G_s^\circ$ (which is proportional to the logarithm of a ratio of solubilities) and molecular surface area at 25 and 55°. For the eight 5-ethylbarbituric acids, a linear correlation is found at 25° with a standard deviation of $\sigma = 117$ and $r^2 = 0.980$. (If phenobarbital is ignored, $\sigma = 101$ and $r^2 = 0.990$.) At 55°, the correlation is even better if phenobarbital is ignored, with $\sigma = 70$ and $r^2 = 0.995$. This result is as good as the correlation found, for example, between the logarithm of the partition coefficients of alkylbenzenes in octanol–water mixtures and their molecular surface area (28). The standard deviation is of the order of magnitude of the experimental error or better. The three 5-monoallylbarbituric acids stand on a parallel to the preceding line, and the one 5-diallylbarbituric acid is at a still more negative $\Delta G_s^\circ$ value. This behavior was observed with other types of correlations, such as those involving the solubility and melting point of a given series of compounds (31).

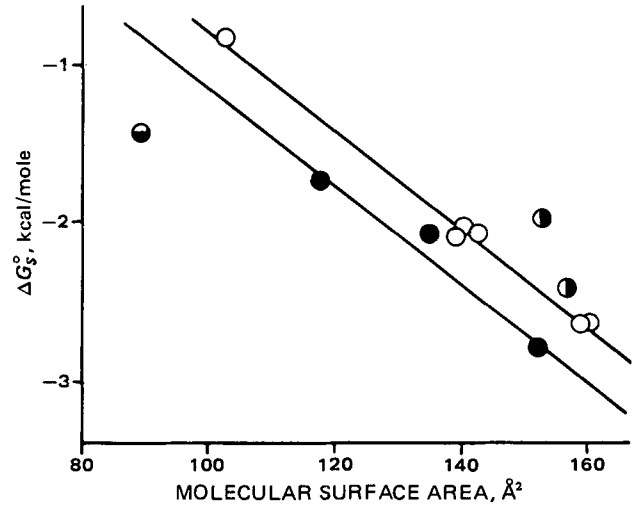

**Figure 4**—*Variation of the standard free energy of solubilization of barbituric acids with the molecular surface area of their substituted groups at 55°. See Fig. 3 for key.*

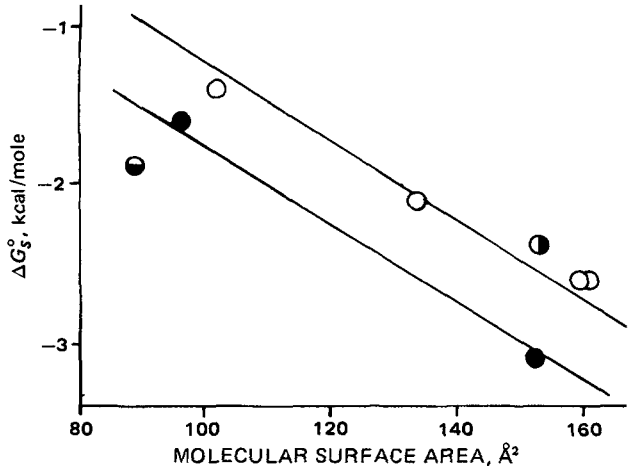

**Figure 5**—*Variation of the standard free energy of solubilization of barbituric acids with the molecular surface area of their substituted groups at 25°, polyoxyethylene lauryl ether solutions. See Fig. 3 for key.*

Comparison of these results with those of Ikeda *et al.* (3) in polyoxyethylene lauryl ether aqueous solutions (Fig. 5) shows the standard deviation of fit for the five 5-ethyl derivatives is $\sigma = 53$ with $r^2 = 0.996$. It also seems that the two monoallyl and the one diallyl derivatives are in the same position with respect to the 5-ethyl line in polyoxyethylene lauryl ether and alkyl sulfonate solutions.

Since the common behavior of these solutes in nonionic and ionic surfactant solutions has been stressed, some differences should now be pointed out. Some authors noted the specific interaction between phenobarbital and oxyethylene groups at high surfactant concentrations and low temperatures (3, 4), leading to precipitation of this barbituric acid. Such behavior is not found with alkyl sulfonate. However, some specificity is apparent with the observation that, for phenobarbital, $\Delta G_s^\circ$ moves off the line corresponding to the 5-ethyl derivatives as the temperature increases. This effect, which is small, is difficult to interpret since specific effects usually decrease as temperature increases. (The correlation between $\Delta G_s^\circ$ and molecular surface area is better at 55° than at 25° for the 5-ethylbarbituric acids.) Reposal is more soluble than one might expect from its molecular surface area, although it is the only compound for which precise molecular surface area evaluation could not be made. Finally, a rough correlation may be observed between $\Delta G_s^\circ$ and $\Delta S_s^\circ$ in a direction indicating that the micellar solubilization is favored by the penetration of the solubilized compounds in the micelle interior. Thus, barbital with the less negative $\Delta G_s^\circ$ value and reposal with the most negative $\Delta G_s^\circ$ value have the most negative and the most positive $\Delta S_s^\circ$ values, respectively. This observation again points out that micellar solubilization is essentially an entropy-related phenomenon.

In conclusion, although this study used an impure surfactant product, the self-consistency of the results, when compared with pure sodium lauryl sulfate solutions or with the nonionic solutions, and the correlations found with the molecular surface area approach justify the general conclusions proposed.

# Theoretical Comparison of Release Rates of Drugs into Sink and Nonsink Conditions

**RICHARD H. GUY *x, and JONATHAN HADGRAFT ‡**

Received October 6, 1980, from the **School of Pharmacy, University of California, San Francisco, CA 94143*, and the ‡*Department of Pharmacy, University of Nottingham, University Park, Nottingham NG7 2RD, England.* Accepted for publication March 30, 1981.

**Abstract** □ Theoretical expressions were derived that show how drug release rates are modified by sink and nonsink conditions. The effect of basic physicochemical parameters and the relevance to *in vitro* testing are discussed.

**Keyphrases** □ Theoretical release profiles—drug release rates modified by sink and nonsink conditions □ Release rates—theoretical comparison of drug release into sink and nonsink conditions

The release characteristics of formulations are often determined in sink conditions, usually produced either with a continuous supply of fresh receptor solution or by devising an experiment where there is a large receptor volume compared to the donor phase. Mathematical equations were previously derived to describe drug release into sink conditions for certain physical situations (1–6), and experimental confirmation of the results was obtained (7–12). For some cases, the assumption that drug release takes place into sink conditions is an adequate representation of the *in vivo* situation, but nonsink conditions would be more appropriate under certain circumstances. Furthermore, experimental constraints may prevent the attainment of sink conditions *in vitro* and, consequently, a mathematical description of the nonsink situation is necessary.

In this paper, drug release into sink and nonsink conditions is theoretically compared and the manner in which the volume of the receptor phase affects the drug release rate is demonstrated. The relevant diffusion equations are solved for a nonspecific general situation using the method of Laplace transformation. The style of the mathematical approach parallels that of several recent reports (13–17).

## THEORETICAL

**The Model**—The formulation is assumed to release drug at a diffusion-controlled rate into a well-stirred receptor volume. The concentration profile of drug in the formulation and the receptor compartment then have the form shown in Fig. 1.

The cumulative amount of drug that penetrates into the receptor compartment at time $t$ is given by:

$$M_t = D_d A \int_0^t (dc_d/dx)_{x=0}\, dt \qquad \text{(Eq. 1)}$$

where $D_d$ is the diffusion coefficient of the drug in the formulation and $A$ is the surface area across which release takes place.

To simplify solution of the diffusion equations, three normalized variables are defined (18):

$$U = c/c_0 \qquad \text{(Eq. 2)}$$

$$X = x/l \qquad \text{(Eq. 3)}$$

$$T = D_d t/l^2 \qquad \text{(Eq. 4)}$$

where $c_0$ is the initial drug concentration in the donor phase and $l$ is the thickness of the donor phase. With these variables, it is possible to rewrite Eq. 1 to give:

$$M_t = Alc_0 \int_0^T (\partial U_d/\partial X)_0\, dT \qquad \text{(Eq. 5)}$$

To facilitate solution of the diffusion equations, it is also assumed that diffusion occurs in only one dimension and that the diffusion coefficient is concentration independent.

Diffusion in the donor phase is then described by Fick's second law of diffusion, which, in terms of the normalized variables, is expressed as:

$$\partial U_d/\partial T = \partial^2 U_d/\partial X^2 \qquad \text{(Eq. 6)}$$

This differential equation is solved by using Laplace transforms with boundary conditions appropriate to sink and nonsink conditions.

**Sink Conditions**—For sink conditions, drug is continuously removed from the surface of the formulation, producing the boundary conditions:

$$T \geq 0 \qquad U_{d,X=0} = 0 \qquad \text{(Eq. 7)}$$

$$T = 0 \qquad U_d = 1 \qquad \text{(Eq. 8)}$$

$$(\partial U_d/\partial X)_1 = 0 \qquad \text{(Eq. 9)}$$

The physical significance of Eqs. 7–9 may be explained as follows. Equation 7 describes the sink condition. For all values of $T$ (the normalized time variable), the concentration at the surface of the formulation ($X = 0, x = 0$) is zero. Equation 8 shows that there is initially a uniform drug concentration in the donor phase (*i.e.*, at $t = 0, c = c_0$ and $U_d = 1$). Finally, Eq. 9 indicates that there is only a finite quantity of drug in the donor phase; *i.e.*, it is not being replenished by any reservoir at $x = l (X = 1)$.

The Laplace transform of Eq. 6:

$$s\bar{U}_d - 1 = \partial^2 \bar{U}_d/\partial X^2 \qquad \text{(Eq. 10)}$$

has the general solution:

$$\bar{U}_d = A \cosh s^{1/2}X + B \sinh s^{1/2}X + s^{-1} \qquad \text{(Eq. 11)}$$

By using boundary conditions Eqs. 7 and 9, the coefficients $A$ and $B$ may be eliminated to give:

$$(\partial \bar{U}_d/\partial X)_0 = s^{-1/2} \tanh s^{1/2} \qquad \text{(Eq. 12)}$$

Thus:

$$M_t = Alc_0 \mathcal{L}^{-1} (s^{-3/2} \tanh s^{1/2}) \qquad \text{(Eq. 13)}$$

which is identical to a previous problem (Eq. 15 of Ref. 14) and which has

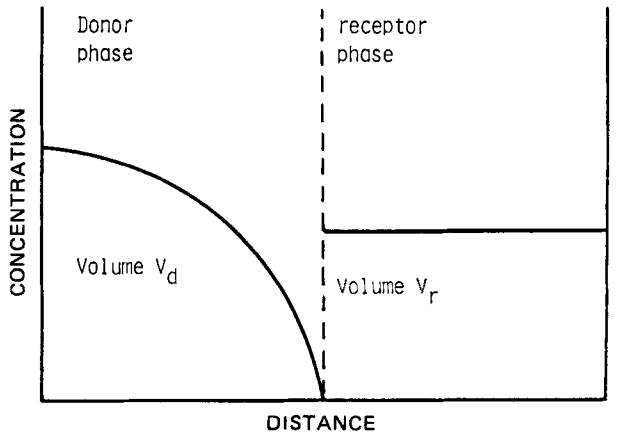

**Figure 1**—*Concentration profile of drug in the receptor and donor phases at some time t after the start of the experiment.*

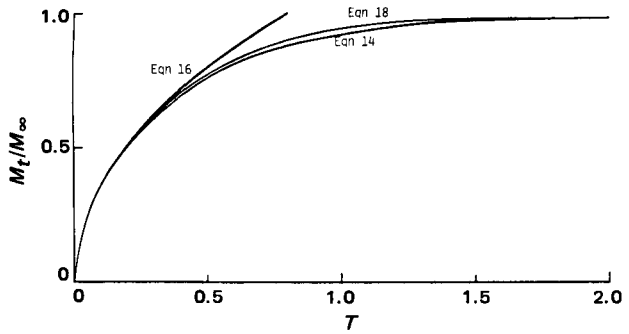

**Figure 2**—*Release profile generated from Eqs. 14, 16, and 18 for sink conditions.*

a solution:

$$M_t = M_\infty \left[1 - 8/\pi^2 \sum_{n=1}^{\infty} \{(2n-1)^{-2} \exp[-(2n-1)^2\pi^2 T/4]\}\right] \quad \text{(Eq. 14)}$$

where $M_\infty = AlC_0$ and is the initial total amount of drug.

It is also possible to derive simplified expressions by approximating the hyperbolic term in Eq. 13 and then taking the inverse transform.

For short times $T < 1$, $s > 1$, $\tanh s^{1/2} \simeq 1$ (19):

$$M_t \simeq M_\infty \mathcal{L}^{-1}(s^{-3/2}) \quad \text{(Eq. 15)}$$

$$M_t \simeq 2M_\infty T^{1/2}\pi^{-1/2} \quad \text{(Eq. 16)}$$

At long times $T > 1$, $s < 1$, $\coth s^{1/2} \simeq s^{-1/2} + s^{1/2}/3$ (19):

$$M_t \simeq 3M_\infty \mathcal{L}^{-1}[s^{-1}(s+3)^{-1}] \quad \text{(Eq. 17)}$$

$$M_t \simeq M_\infty[1 - \exp(-3T)] \quad \text{(Eq. 18)}$$

**Nonsink Conditions**—For these release characteristics, the drug concentration is allowed to build up in the receptor phase and the condition described by Eq. 7 is no longer valid. At the interface between the formulation and the receptor compartment, fast interfacial kinetics are assumed, which provide the new boundary condition:

$$K = U_{r,0}/U_{d,0} \quad \text{(Eq. 19)}$$

where $K$ is a partition coefficient.

Solution of the diffusion equation is identical to that previously described. A finite quantity of drug is still present, and the boundary condition Eq. 9 is still valid. The difference arises during the elimination of the coefficients $A$ and $B$ in the general solution, Eq. 11.

The coefficients are eliminated by considering the buildup of concentration in the receptor phase, which is related to the amount diffused at time $t$ by:

$$c_r = M_t/V_r \quad \text{(Eq. 20)}$$

Substitution of Eq. 5 gives:

$$c_r = AlC_0V_r^{-1}\mathcal{L}^{-1}[s^{-1}(\partial\overline{U}_d/\partial X)_0] \quad \text{(Eq. 21)}$$

Thus:

$$\overline{U}_{d,0} = Al(KV_r)^{-1}s^{-1}(\partial\overline{U}_d/\partial X)_0 \quad \text{(Eq. 22)}$$

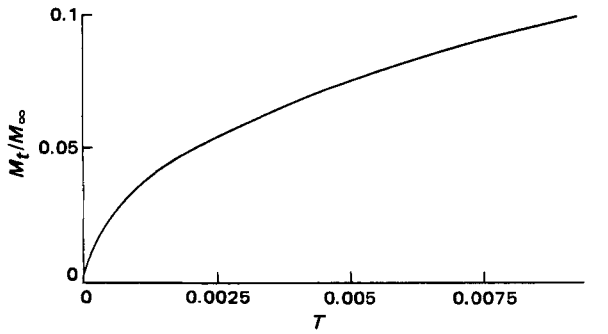

**Figure 3**—*Release profile given from Eq. 26 with* Q = *1, showing the short time pattern for nonsink conditions.*

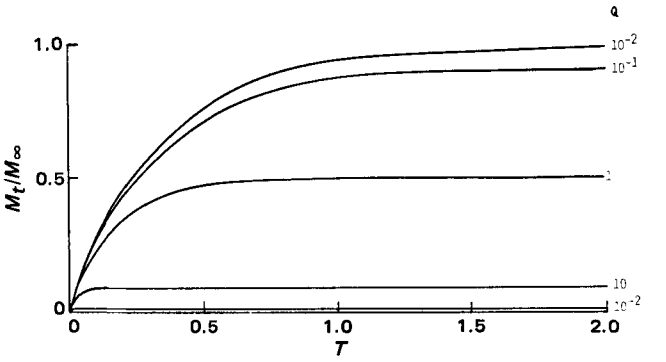

**Figure 4**—*Release profile from Eq. 28 with various values of* Q, *showing the long time pattern for nonsink conditions.*

Differentiation of Eq. 11 and use of the boundary condition Eq. 9 give:

$$(\partial\overline{U}_d/\partial X)_0 = (\overline{U}_{d,0} - s^{-1})s^{1/2}\tanh s^{1/2} \quad \text{(Eq. 23)}$$

and $(\partial\overline{U}_d/\partial X)_0$ may be eliminated by combination of Eqs. 22 and 23. Hence:

$$c_r = KAlc_0\mathcal{L}^{-1}[s^{-1}(s^{1/2}V_rK\coth s^{1/2} + Al)^{-1}] \quad \text{(Eq. 24)}$$

Simple inversion of this equation is not possible, and approximations are made for long and short time release profiles.

**Short Time Approximation**—At short times $T < 1$, $s > 1$, the coth function in Eq. 24 may be approximated (19):

$$c_r = Alc_0V_r^{-1}\mathcal{L}^{-1}[s^{-1}(s^{1/2} + Al/V_rK)^{-1}] \quad \text{(Eq. 25)}$$

This function may be most readily inverted by separation into partial fractions followed by inversion of the individual fractions (19):

$$M_t = M_\infty Q^{-1}[1 - \exp(Q^2T)\,\mathrm{erfc}\,(QT^{1/2})] \quad \text{(Eq. 26)}$$

where $Q = Al/V_rK$.

**Long Time Approximation**—For $T > 1$, $s < 1$, and $\coth s^{1/2} \simeq s^{-1/2} + s^{1/2}/3$, Eq. 24 becomes:

$$c_r = KAlc_0\mathcal{L}^{-1}\{s^{-3/2}[V_rK(s^{1/2} + s^{1/2}/3) + Als^{-1/2}]^{-1}\} \quad \text{(Eq. 27)}$$

which may be inverted:

$$M_t = M_\infty(1+Q)^{-1}\{1 - \exp[-3(1+Q)T]\} \quad \text{(Eq. 28)}$$

**Comparison of Sink *versus* Nonsink Conditions**—It is now possible to obtain a direct comparison of the two sets of conditions using the approximations at short and long times. At short times, Eqs. 26 and 16 produce:

$$\frac{M_{t,ns}}{M_{t,s}} = \frac{\pi^{1/2}[1 - \exp(Q^2T)\mathrm{erfc}(QT^{1/2})]}{2QT^{1/2}} \quad \text{(Eq. 29)}$$

and this complex expression describes the ratio of the amount released at time $t$ from nonsink compared to sink conditions.

The equivalent ratio for long times is given by combining Eqs. 28 and 18:

$$\frac{M_{t,ns}}{M_{t,s}} = \frac{1 - \exp[-3(1+Q)T]}{(1+Q)[1 - \exp(-3T)]} \quad \text{(Eq. 30)}$$

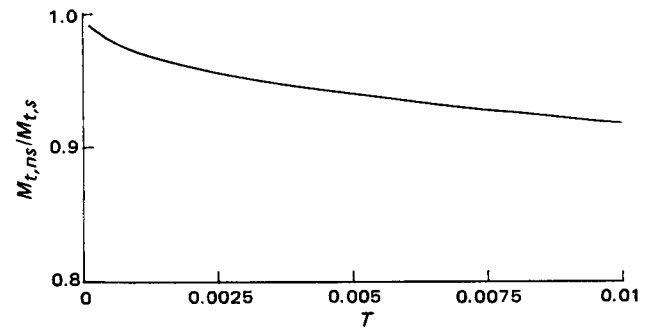

**Figure 5**—*Comparison of sink* versus *nonsink conditions at short times.*

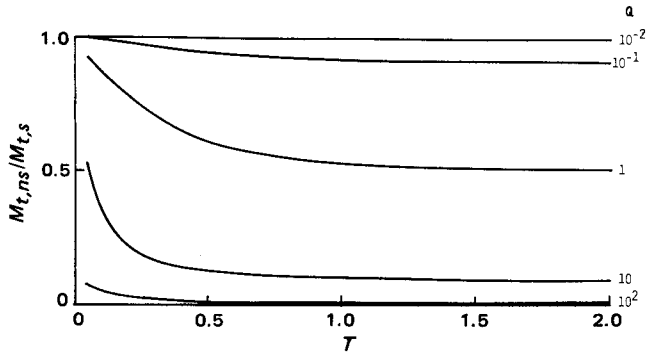

**Figure 6**—*Comparison of sink* versus *nonsink conditions at long times.*

## DISCUSSION

Figure 2 shows the release profile generated using the full solution given by Eq. 14. The figure also shows Eqs. 16 and 18, the two approximations. It is apparent that Eq. 16 is correct up to values of $T \sim 0.5$; from this time onwards, Eq. 18 is applicable.

No unique mathematical expression is obtainable to describe the nonsink conditions. Therefore, concentration is focused on long and short time approximations because it is not possible to predict accurately the release profile for $T$ values approximating to unity. Figure 3 shows the short time approximation given by Eq. 26 for $Q = 1$. The curve generated shows a smooth release pattern not unlike that given by the more simple $t^{1/2}$ approximation applicable to sink conditions. However, there are slight differences as $T$ increases, as shown in Fig. 3. This result would be expected at short periods of time since there is no appreciable concentration buildup in the receptor phase.

The long time approximation, given by Eq. 28, is plotted in Fig. 4. The variation with $Q$ is indicated, and a series of simple first-order curves is obtained. The curves approach the limit, as $T \rightarrow \infty$, of $(1 + Q)^{-1}$, as predicted by Eq. 28. When $Q < 1$, the nonsink limit approaches the long time limit for sink conditions, as expected. This situation corresponds to the experimental conditions of a large receptor volume or large partition coefficient.

Figure 5 compares sink and nonsink conditions at short times for $Q = 1$. At extremely short times, the ratio is unity, as expected. However, as $T$ increases, the deviation from unity becomes more marked and the effect of nonsink conditions becomes apparent. As expected, this general deviation is more pronounced at long times (Fig. 6) and is most noticeable for large values of $Q$ corresponding to small values of the volume of the receptor phase and low partition coefficient.

# Physicochemical and Analytical Characteristics of Itanoxone

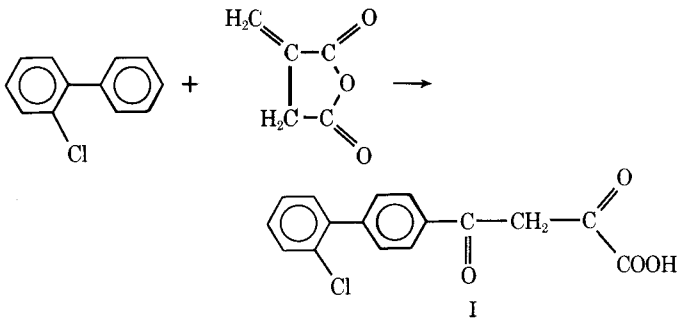
**HENRI COUSSE ˣ, GILBERT MOUZIN, JEAN-PAUL RIBET, and JEAN-CLAUDE VEZIN**

Received March 5, 1980, from the *P. Fabre S.A. Research Center, 17 Avenue Jean Moulin, 81106 Castres, France.* Accepted for publication March 27, 1981.

**Abstract** □ The analytical and spectroscopic characteristics of itanoxone were determined. These data can be used to identify or assay this new drug.

**Keyphrases** □ Itanoxone—physicochemical and analytical characteristics of itanoxone □ Spectroscopy—itanoxone, physicochemical and analytical characteristics □ Hyperlipidemic agents—itanoxone, physicochemical and analytical characteristics □ Hyperuricemic agents—itanoxone, physicochemical and analytical characteristics

Itanoxone is the internationally designated name (1) for 4-[4′-(2-chlorophenyl)phenyl]-4-oxo-2-methylenebutanoic acid (I). This compound has pharmacological and clinical properties (2) suitable for the treatment of hyperlipidemia (3–5) and hyperuricemia (6). Theoretical impurities of I (7) and an industrial purification process (8) were studied previously. This paper considers some physical and physicochemical properties of I.



*Scheme I*

## EXPERIMENTAL

**Synthesis**—Itanoxone (I) was synthetized by the Friedel–Crafts reaction between itaconic anhydride and 2-chlorobiphenyl (9, 10) (Scheme I).

# Physicochemical and Analytical Characteristics of Itanoxone

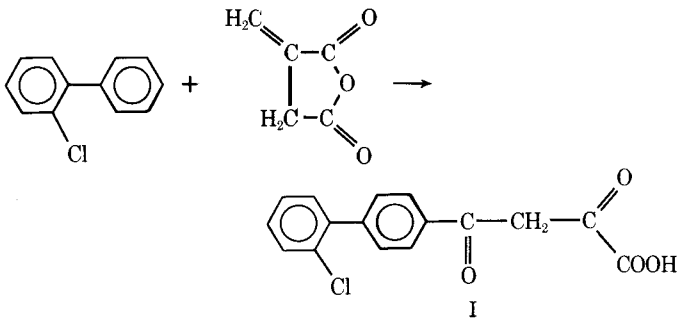
**HENRI COUSSE ˣ, GILBERT MOUZIN, JEAN-PAUL RIBET, and JEAN-CLAUDE VEZIN**

Received March 5, 1980, from the *P. Fabre S.A. Research Center, 17 Avenue Jean Moulin, 81106 Castres, France.* Accepted for publication March 27, 1981.

**Abstract** □ The analytical and spectroscopic characteristics of itanoxone were determined. These data can be used to identify or assay this new drug.

**Keyphrases** □ Itanoxone—physicochemical and analytical characteristics of itanoxone □ Spectroscopy—itanoxone, physicochemical and analytical characteristics □ Hyperlipidemic agents—itanoxone, physicochemical and analytical characteristics □ Hyperuricemic agents—itanoxone, physicochemical and analytical characteristics

Itanoxone is the internationally designated name (1) for 4-[4′-(2-chlorophenyl)phenyl]-4-oxo-2-methylenebutanoic acid (I). This compound has pharmacological and clinical properties (2) suitable for the treatment of hyperlipidemia (3–5) and hyperuricemia (6). Theoretical impurities of I (7) and an industrial purification process (8) were studied previously. This paper considers some physical and physicochemical properties of I.



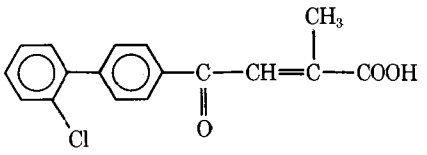
*Scheme I*

## EXPERIMENTAL

**Synthesis**—Itanoxone (I) was synthetized by the Friedel–Crafts reaction between itaconic anhydride and 2-chlorobiphenyl (9, 10) (Scheme I).

*0022-3549/81/1100-1245$01.00/0*

*© 1981, American Pharmaceutical Association*



II

**Apparatus**—A GLC chromatograph[1] was equipped with a glass 3 m × 4-mm i.d. column, packed with 10% (w/w) Carbowax 20 *M* on Chromosorb W.A.W. (60–80 mesh). The carrier gas was nitrogen at 50 ml/min, the column temperature was 130°, and the injection detector temperature was 200°. Potentiometric measurements were made with a titration device[2] fitted with a combined electrode[3]. Melting points were determined on a hot stage[4] and were not corrected.

PMR spectra were recorded at 40° on a spectrometer[5] using solutions in dimethyl sulfoxide-$d_6$ containing tetramethylsilane as the internal standard. IR spectra were measured on a spectrophotometer[6] using potassium bromide pellets at ~1% (w/w) concentration. A mass spectrometer[7] with the probe at 160° and an ionizing voltage of 70 ev, was used.

**Identification and Assay of Impurities**—Secondary products of I were described previously (7), but that report did not include tests and detection limits for impurities. The solvents used in the reaction and during recrystallization were determined by GLC. Traces of aluminum from the aluminum chloride catalyst were identified by emission spectrography[8] (low voltage alternating arc, carbon electrodes) (11).

**Determination of pKa**—The pKa values were determined by potentiometric titration using a glass electrode. A water-jacketed beaker connected to a circulating water bath maintained the temperature of the titrating vessel at 25°. Stirring was accomplished by introducing a slow nitrogen stream under the surface of the solution to be titrated.

The titrant of carbonate-free potassium hydroxide (0.100 *N* KOH) was delivered from a micrometer syringe; for each addition of titrant, the pH was measured and the pKa was determined from the half-neutralization point.

**Solubility Conditions**—The solubilities, expressed in percentage (weight/volume), were determined as follows. The solvent and solute were placed in 50-ml test tubes with a suitable amount of undissolved I. The tubes were stoppered and shaken for 1 hr at 25 ± 1° to avoid isomerization of I into II (7). The tubes were then centrifugated, and the liquid was filtered through a sintered-glass funnel. The clear liquid was diluted and spectrophotometrically[9] assayed for I.

**Partition Coefficients**—Itanoxone was partitioned between buffer solutions saturated with organic solvents and organic solvent saturated with buffer solutions. Usually 50 ml of buffer solution containing a known amount of solute was shaken with an equal volume of organic solvent. The sample was maintained at 25 ± 1° and mechanically[10] shaken for 1.5 hr until equilibrium was obtained (12, 13). After stirring, the two phases were separated by centrifugation at 3000 rpm for 30 min. The amount of I in the water layer was determined spectrophotometrically.

## RESULTS AND DISCUSSION

**Assay of Impurities**—Methylene chloride reaction solvent and dimethylformamide recrystallization solvent had retention times of 1.5 and 3.5 min, respectively. Under these conditions, solvent amounts of <0.05% (w/w) were detected in itanoxone (I). The most sensitive rays characteristic of aluminum (11) were not observed in the spectrum of I. The lower limit of detection sensitivity of metal in I is 0.02 μg.

**Melting Points**—Itanoxone occurs as a white crystalline powder in the monoclinic system (14) with an instantaneous melting point of 212 ± 1°. It is overlapped by the standard melting points of saccharin and dicyanodiamide.

**Determination of pKa**—In view of the low solubility of I in water, the pKa value was determined at 25° by extrapolation from a series of dissociation constants in water–dioxane mixtures evaluated by potentiometry. The results are expressed by introducing an experimental parameter, $g(S)$, which is characteristic of each solvent (15). This quantity takes care of all types of solvent–solute interactions, such as hydrogen bonding and structural effects, and its measurement gives the magnitude of solvent effects on acid–base reactions. Measurement of the dissociation constant of itanoxone, ${}^{S}K_I$, and of salicylic acid, ${}^{S}K_{\text{ref}}$, used as the standard compound in each $S$ medium indicates that the difference between both pKa values is a linear function of $g(S)$ according to the formula:

$$\text{p}{}^{S}K_{a\text{I}} - \text{p}{}^{S}K_{a\text{ref}} = \alpha + \beta g(S) \qquad \text{(Eq. 1)}$$

in which $\alpha$ and $\beta$ are constants dependent only on I. Itanoxone transfer between water and dioxane may be expressed by:

$$\log {}^{\text{water}}T^{\text{dioxane}}(\text{I}) = \log C_{\text{sat}}^{\text{water}}(\text{I}) - \log C_{\text{sat}}^{\text{dioxane}}(\text{I}) \qquad \text{(Eq. 2)}$$

where $C_{\text{sat}}^{\text{water}}(\text{I})$ and $C_{\text{sat}}^{\text{dioxane}}(\text{I})$ are the solubilities (weight/volume) of I in water–dioxane. Thus, $\log {}^{\text{water}}T^{\text{dioxane}}$ (I) is proportional to the solvent variable $g(S)$:

$$\log {}^{\text{water}}T^{\text{dioxane}}(\text{I}) = f(\text{I}) \times g(S) \qquad \text{(Eq. 3)}$$

where $f(\text{I})$ is a constant characteristic of I. The measurement of solubility of I in water–dioxane enables the calculation of values proportional to the solvent variable $g(S)$. The agreed convention is then expressed as:

$$g(S) = -\log {}^{\text{water}}T^{\text{dioxane}}(\text{I}) \qquad \text{(Eq. 4)}$$

For each $g(S)$ calculation, the relative water and dioxane contents of the medium must be considered.

Extrapolation to pure water gives $g(S) = 0$. Any $g(S)$ is given by:

$$g(S) = -\log {}^{\text{water}}T^{\text{dioxane}}(\text{I}) = -\log a(0.019)/b(3.9) \qquad \text{(Eq. 5)}$$

where $a$ and $b$ represent the water and dioxane contents, respectively.

The values of $g(S)$ for different percentage volumes of dioxane and the pKa values of salicylic acid (the reference compound) are shown in Table

**Table I—Dissociation Constants in Water–Dioxane Mixtures**

| Dioxane, % (v/v) | $g(S)$ | $\text{pKa}_{\text{ref}}$[a] | $\text{pKa}_{\text{I}}$[b] | $\text{pKa}_{\text{I}} - \text{pKa}_{\text{ref}}$ |
|---|---|---|---|---|
| 0.6 | 2.49 | 4.60 | 6.68 | 2.08 |
| 0.8 | 2.92 | 5.50 | 7.55 | 2.05 |
| 0.9 | 3.26 | 6.40 | 8.38 | 1.98 |

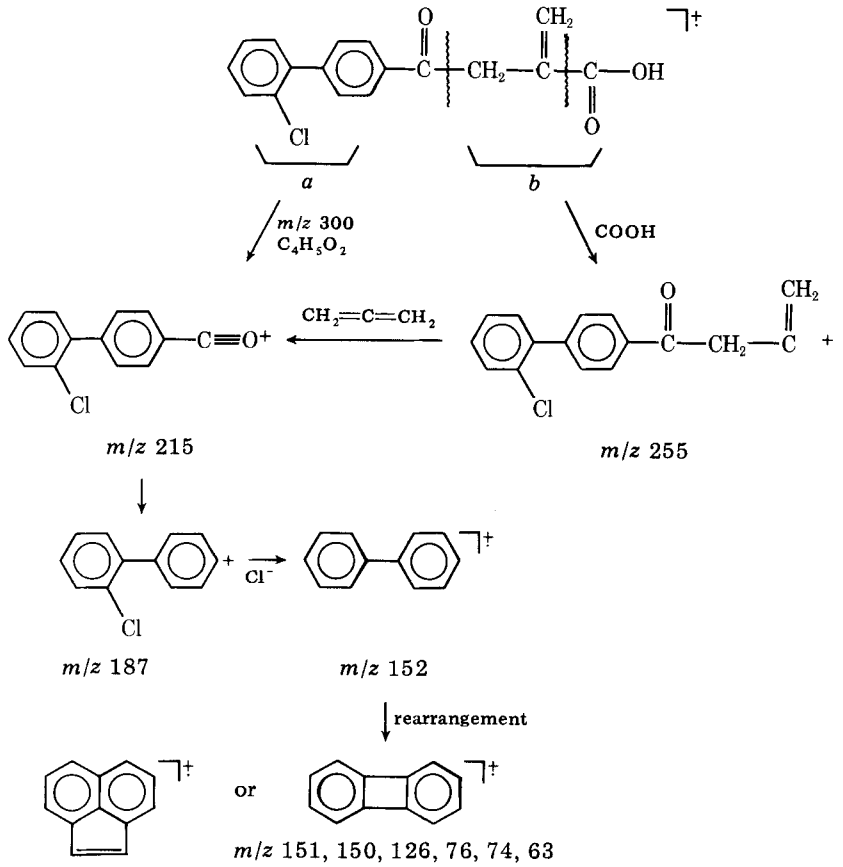

*Scheme II—Fragmentation mechanism.*

I. The difference between the two pKa values is a linear function of $g(S)$. The determination of the pKa of I in water by extrapolation of measurements made on water–dioxane mixtures is plotted *versus* $g(S)$ determined for each water–dioxane system (Fig. 1). The pKa of salicylic acid determined in water is 3.0. The pKa of I determined in water–dioxane with extrapolation of the results to zero dioxane concentration is 3.0 + 2.3 = 5.30.

**Solubility**—The maximum values are expressed in Table II as percentage (weight/volume). This technique cannot be used for ketonic solvents having absorptions in the same range.

**Partition Coefficients**—The I concentration was determined in the aqueous phase by UV spectroscopy at 265 nm. The apparent partition coefficient is calculated by the formula:

$$\text{Apparent partition coefficient} = \frac{C_{\text{octanol}}}{C_{\text{buffer}}} = \frac{(C_1 - C_2) \times a}{C_2 \times b} \quad \text{(Eq. 6)}$$

where $C_1$ and $C_2$ are the I concentrations (weight/volume) in the aqueous phase before and after equilibration, respectively, and $a$ and $b$ are the volumes of the aqueous and octanol phases, respectively. By working at a fixed pH and knowing the pKa for I, the partition coefficient can be determined using:

$$\text{Partition coefficient} = \frac{C_{\text{octanol}}}{C_{\text{buffer}}\,(1 - \alpha)} \quad \text{(Eq. 7)}$$

where $\alpha$ is the degree of ionization. Details are given in Table III.

For a good extraction yield of I from biological media such as blood and urine, it is imperative to use an acidic pH. Under these conditions, 98% of the drug is extracted from the aqueous phase during the first extraction. Ethyl acetate is recommended to reduce emulsion effects.

The TLC procedure reported previously (7) was used to demonstrate that I did not isomerize during the 1–1.5 hr needed to determine solubility or partition coefficients. In the media used to determine solubilities and partition coefficients, traces of II were detected after the 2nd hr of TLC. The amount of II ranged from 0.1 to 0.3%, depending on the solvent. Isomerization continued, but the lack of II in the first 2 hr confirmed the validity of solubility and partition data.

**IR Spectroscopy**—The IR spectrum revealed characteristic bands (16) that agreed with the suggested structure: 3000–3080 (aromatic and ethylenic CH), 2910 (aliphatic CH), 1690 (C=O acid), 1675 (C=O conjugated ketone), and 1630 (ethylenic C=C) $cm^{-1}$ (Fig. 2).

**UV Spectroscopy**—The spectrum was obtained in ethanolic solution using 1-cm quartz cells, $\lambda_{max}$ 265 ($\epsilon$ 18,350 ± 30) nm.

**PMR Spectroscopy**—Assignments (17) were: $\delta$ 4.1 (s, 2H, $COCH_2$), 5.75 (d, 1H, $J$ = 1.2 Hz, *trans*-*H*C=CCOOH), 6.3 (d, 1H, $J$ = 1.2 Hz, *cis*-*H*C=CCOOH), 7.3–7.7 (m, 6H, aromatic protons), 8.05 (d, 2H, $J$ = 8 Hz, aromatic protons *ortho* to C=O), and 11–13.5 (s, 1H, COOH) ppm.

**Table II—Solubilities at 20°, Percent (weight/volume)**

| Solvent | Solubility, g/100 ml |
|---|---|
| *n*-Hexane | 0.00025 |
| Water | 0.019 |
| Chloroform | 0.15 |
| Ether | 0.17 |
| Acetonitrile | 0.20 |
| Ethyl acetate | 0.24 |
| Methanol | 0.39 |
| Ethanol | 0.50 |
| *n*-Octanol | 0.75 |
| Dioxane | 3.9 |
| Tetrahydrofuran | 4.34 |
| Dimethylformamide | 28.5 |
| Dimethyl sulfoxide | 38.4 |

**Table III—Itanoxone Partition Coefficients between *n*-Octanol and Buffered Solutions**

| Buffer Solution | Apparent Partition Coefficient[a] | Partition Coefficient | Log $P$ |
|---|---|---|---|
| pH 10[b] | 2.12 | 2120 | 7.66 (0.021) |
| pH 7.4[c] | 16.6 | 2075 | 7.64 (0.020) |
| pH 2.2[d] | 2098 | 2100 | 7.65 (0.043) |

[a] All determinations were done in triplicate, and the average value for log $P$ was determined. Values in parentheses indicate standard deviations. [b] Ammonium chloride buffer (0.05 $M$). [c] Phosphate buffer (0.05 $M$). [d] Potassium chloride buffer (0.05$M$).

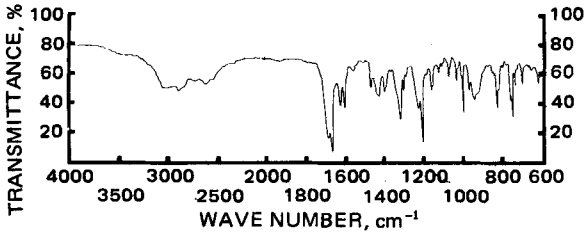

**Figure 2**—*IR spectrum of itanoxone*

The exchangeable acid proton appeared faintly in dimethyl sulfoxide-$d_6$, but a very marked singlet was obtained in pyridine-$d_5$ at 9.9 ppm.

**Mass Spectroscopy**—The molecular peak was observed at *m/z* 300, corresponding to the molecular mass of the product. The most characteristic fragments of I gave a series of peaks at *m/z* 302, 300, 277, 255, 217, 215, 152, and 76. The peak at *m/z* 302 corresponded to the chlorine 37 isotope. The isotopic peaks at p + 2 were also observed in the various fragments containing chlorine.

Fragmentation is shown in Scheme II. The $C_{12}H_8$ ion (*m/z* 152) (18, 19) was followed by the series of ions at *m/z* 151, 150, 126, 76, 75, 74, and 63. The relative intensities of these ions in the spectrum of I were very close to those in the Cornu–Massot catalog (20) for diphenylene and acenaphthene. This result indicates that the ion obtained after the removal of C=O and the chlorine atom rearranges to give a radical ion with a structure close to diphenylene or acenaphthene.

# Effect of Docusate Sodium on Drug Release from a Controlled-Release Dosage Form

**WALTER G. CHAMBLISS, ROBERT W. CLEARY, RICHARD FISCHER, ALAN B. JONES, PAUL SKIERKOWSKI, W. NICHOLES, and ARTHUR H. KIBBE** ˣ

Received December 22, 1980, from the *Department of Pharmaceutics, University of Mississippi, University, MS 38677.* Accepted for publication April 1, 1981.

**Abstract** □ This study was designed to determine the effect of a clinically used surfactant, docusate sodium, on the release of chlorpheniramine from a controlled-release dosage form (encapsulated coated pellets). *In vivo* treatments consisted of the controlled-release capsule alone or with 200 mg of docusate sodium. Plasma chlorpheniramine levels were determined, and the *AUC* was calculated. No significant difference in *AUC* values was observed between the two treatments. At a concentration below the CMC, docusate sodium enhanced the *in vitro* drug release rate. The surfactant exerted a greater effect on the release of the first one-third of the drug contained in nonwax-coated pellets. At the CMC, 0.02% (w/v), docusate sodium rapidly entrapped chlorpheniramine in micelles. The overall enhanced dissolution rate *in vivo* may have been offset by micellar drug entrapment.

**Keyphrases** □ Docusate sodium—effect on drug release from a controlled-release dosage form □ Controlled-release formulations—effect of docusate sodium on drug release □ Surfactants—effect on drug release of controlled-release dosage forms

Most long-acting oral dosage forms utilize a physical barrier to decrease the rate of drug release into the GI tract. The wax coating on the pellets of a controlled-release capsule serves as this barrier (1).

Disintegration of the wax coat is thought to be controlled by the penetration of moisture through pores (2). The pH of the medium reportedly does not affect disintegration (3) although surface tension is thought to be important. The surface tension of intestinal fluid is less than gastric fluid due to bile salts in the intestines. This lowered surface tension may lead to the release of more drug into the intestinal fluids (2). The effect of lowered surface tension in the GI tract on the release of drug from wax-coated pellets has not been reported.

## BACKGROUND

Numerous studies have been performed to determine the effect of surfactants on drug absorption, mainly with surfactants that promote oral absorption of a poorly absorbed drug. The exact mechanism by which docusate sodium and other surfactants enhance drug absorption is unknown. The most popular theory has been that surfactants directly alter membrane permeability of the GI tract (4–14). Although the mechanism of this "hyperabsorptive state" is unknown, most investigators believe that the surfactant disrupts the integrity of the epithelial membrane in a reversible fashion (4–11). The removal of proteins (12, 13) and phos-

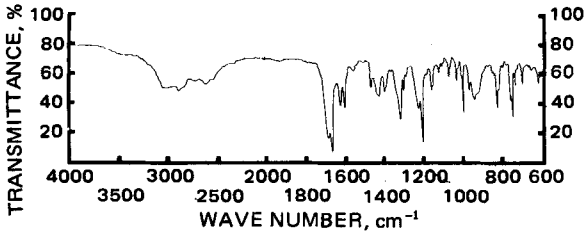

**Figure 2**—*IR spectrum of itanoxone*

The exchangeable acid proton appeared faintly in dimethyl sulfoxide-$d_6$, but a very marked singlet was obtained in pyridine-$d_5$ at 9.9 ppm.

**Mass Spectroscopy**—The molecular peak was observed at *m/z* 300, corresponding to the molecular mass of the product. The most characteristic fragments of I gave a series of peaks at *m/z* 302, 300, 277, 255, 217, 215, 152, and 76. The peak at *m/z* 302 corresponded to the chlorine 37 isotope. The isotopic peaks at p + 2 were also observed in the various fragments containing chlorine.

Fragmentation is shown in Scheme II. The $C_{12}H_8$ ion (*m/z* 152) (18, 19) was followed by the series of ions at *m/z* 151, 150, 126, 76, 75, 74, and 63. The relative intensities of these ions in the spectrum of I were very close to those in the Cornu–Massot catalog (20) for diphenylene and acenaphthene. pholipids (13, 14) from the membrane by surfactants may alter permeability. "Plasticization" of the membrane by the action of surfactant molecules in the lipoidal epithelium has also been suggested as a possible mechanism for altered permeability (7).

Gouda and colleagues (4–8) determined that the effect of docusate sodium on drug absorption was concentration related. The critical micelle concentration (CMC) was closely related to the critical concentration for the enhancement of drug absorption. The CMC for docusate sodium was reported to be 0.02–0.03% (w/v) (15). Surfactants can trap drug molecules in micelles that form in surfactant concentrations above the CMC. Since micelles are thought to be too large to diffuse across the mucosal membrane, drugs trapped by micelles are not available for absorption (16).

## EXPERIMENTAL

***In Vivo***—A 2 × 2 Latin square design was used to study the effect of coadministration of 200 mg of docusate sodium on the GI absorption of chlorpheniramine released from a controlled-release capsule[1]. Seven subjects were randomly assigned to two different groups. Study days were separated by 7 days to allow adequate drug clearance of the previous dose.

All subjects were adult males, 22–34 years of age, who were within 10% of their ideal body weight. Since the drugs were not administered on a milligram per killigram basis, only subjects weighing 72–80 kg were used. In addition, all subjects had prestudy test results within the normal laboratory limits.

Subjects fasted for 12 hr prior to drug administration and were allowed water *ad. libitum*. Blood samples were drawn through a 21-gauge heparin lock inserted into a vein on the dorsal side of the forearm. Treatment A consisted of 12 mg of chlorpheniramine in controlled-release capsule dosage form[1]. Treatment B consisted of the chlorpheniramine capsule and two 100-mg docusate sodium capsules[2]. Drugs were ingested with 240 ml of water. Blood samples (7.5 ml) were drawn at 0, 10, 20, 40, 80, 160, 240, 360, and 480 min. Plasma was immediately separated and kept frozen until assayed.

**Assay Procedure**—The procedure of Chiou *et al.* (17) was modified and used for the assay of chlorpheniramine in plasma. Samples were analyzed by a high-performance liquid chromatograph[3] equipped with a reversed-phase column[4] and a UV detector set at 264 nm[5]. The mobile phase consisted of 20% acetonitrile in phosphate buffer (0.075 *M* monobasic ammonium phosphate in 0.016 *M* phosphoric acid). Chlorpheniramine and the internal standard, brompheniramine, had average retention times of 9.64 and 12.75 min, respectively, at a flow rate of 1 ml/min.

Aliquots (200 μl) of the plasma samples were added to 5-ml centrifuge tubes containing 10 μl of brompheniramine solution (3.67 μg of brompheniramine free base/ml of 0.5% phosphoric acid). Then 200 μl of 60% methanol in 0.2 *M* sodium acetate buffer was added, followed by vortexing for 10 sec. The samples were centrifuged at 400×*g* for 10 min.

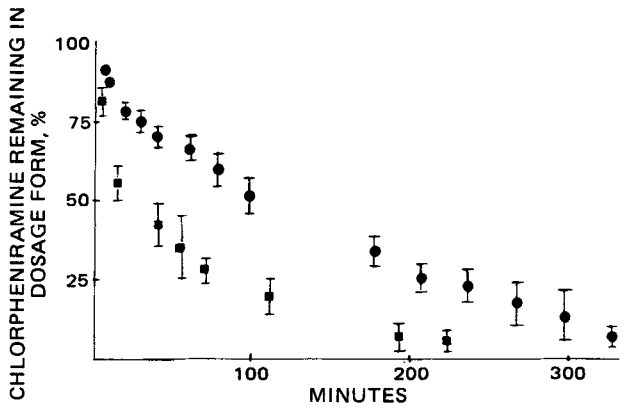

**Figure 1**—*Linear* in vitro *dissolution profile of 12 mg of chlorpheniramine released from the controlled-release dosage form into 0.1* N *HCl containing 0.01% (w/v) docusate sodium (Group II, ■) or no docusate sodium (Group I, ●).*

[2] Colace capsules, 100 mg, lot MJN73, Mead Johnson.
[3] Varian model 4200.
[4] μBondapak $C_{18}$, Waters Associates.
[5] Tracor model 970.

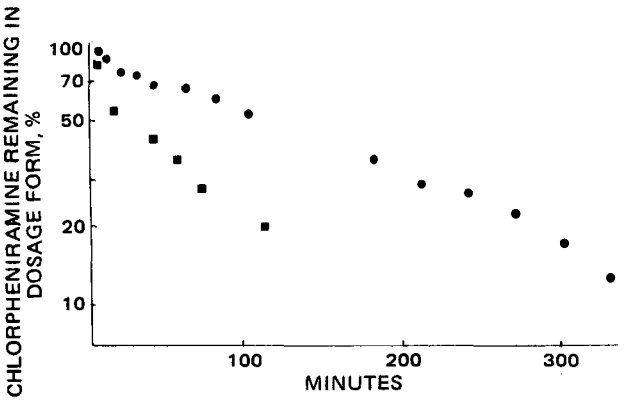

**Figure 2**—*Semilogarithmic* in vitro *dissolution profile of 12 mg of chlorpheniramine released from the controlled-release dosage form into 0.1* N *HCl containing 0.01% (w/v) docusate sodium (Group II, ■) or no docusate (Group I, ●).*

Duplicate 20-μl injections of the supernate were analyzed by high-performance liquid chromatography (HPLC).

The ratio of the area units of the chlorpheniramine peak to the area units of the brompheniramine peak was used to determine the plasma chlorpheniramine concentration from the standard curve. Linearity ($r$ = 0.992) on the standard curve was observed from 0.0088 mg to 0.352 mg/ml of pooled plasma.

***In Vitro***—A USP rotating-basket dissolution apparatus[6] was used for all dissolution studies. The controlled-release capsule was placed into the 40-mesh rotating basket and lowered into 500 ml of 0.1 *N* HCl (Group I, no docusate sodium; Group II, 0.01% (w/v) docusate sodium). The dissolution medium was maintained at 37 ± 0.2°. The basket was lowered to a position 2 cm from the bottom of the vessel and rotated at 100 rpm. Aliquots of 3.0 ml were removed from the point midway between the cylindrical edge of the basket and the wall of the vessel.

Samples from Group I were immediately transferred to a cell and analyzed for chlorpheniramine by UV spectroscopy[7] at 264 nm. Samples from Group I were drawn at 0, 5, 10, 20, 30, 40, 60, 80, 100, 180, 210, 240, 270, 300, 330, 360, 390, 420, 450, 540, and 720 min. Samples from Group II were transferred to a 5-ml centrifuge tube and centrifuged at 400×*g* for 10 min. Centrifugation was necessary because the surfactant solubilized the wax, resulting in an opaque suspension. The supernate was transferred to a cell and analyzed at 264 nm. Sampling times for Group II were 0, 5, 15, 40, 55, 70, 110, 190, 220, 250, 280, 355, 540, and 720 min. All samples were returned to the dissolution medium, but samples from Group II were first remixed with centrifuged material.

**Micellar Entrapment Study**—A single study was performed to determine the effect of surfactant concentration on chlorpheniramine availability. Chlorpheniramine powder USP (12 mg) was added to the dissolution vessel which contained 500 ml of 0.1 *N* HCl and either 0.01 or 0.02% (w/v) of docusate sodium. The solutions were agitated by the rotation of the dissolution basket at 100 rpm. Aliquots of 3.0 ml were removed at 0, 1, 3, 4, 6, 9, and 11 min. The samples were immediately transferred to a cell and the amount of free chlorpheniramine was determined by UV detection at 264 nm.

## RESULTS AND DISCUSSION

***In Vivo***—The plasma concentrations for each subject were plotted *versus* time, and the areas under the curves (*AUC*) were calculated by the trapezoidal rule. Table I shows the *AUC* for each subject at 40, 80, 160, 240, and 480 min. The mean *AUC* and the standard deviations are given in Table II. A $t$ test ($p$ = 0.1) revealed no significant difference between the mean *AUC* obtained after administration of Treatments A (no docusate sodium) or B (200 mg of docusate sodium) at each time period. A paired $t$ test was performed on the mean change in area from Treatment A to B for each time. No significant difference was observed at $p$ = 0.1.

***In Vitro* Dissolution**—Figures 1 and 2 contain graphs of the percent of total drug remaining in the dosage form *versus* time on linear and semilogarithmic graph paper, respectively. Each data point represents the average of four trials. As shown in Fig. 2, the drug was released in a first-order process in both groups. The data (percent remaining *versus* time) were analyzed by the NONLIN subroutine of the AUTOAN computer program (18) to determine if the dissolution profile was best described by a mono- or polyexponential equation. The data from both groups were best described by a biexponential equation.

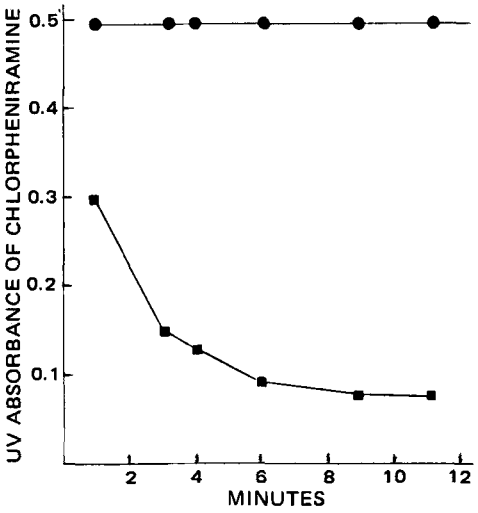

**Figure 3**—*Micellar entrapment of chlorpheniramine in 0.1* N *HCl containing 0.01% (●) or 0.02% (■) w/v of docusate sodium.*

The results of the analysis are shown in Table III. As expected, the initial dissolution rate constants, $k_1$, from both groups were greater than the corresponding terminal rate constants, $k_2$. The first phase of drug release provides the loading dose at a rapid rate. The second rate constant, $k_2$, is associated with the slower rate at which the maintenance dose is released.

The overall effect that docusate sodium had on drug release from the controlled-release capsule may be observed by comparing the dissolution rate constants calculated for each group. Both initial and terminal rates of drug release were increased by the surfactant. The initial rate constant, $k_1$, was tripled (from $1.25 \times 10^{-2}$ to $3.92 \times 10^{-2}$ $min^{-1}$) in the presence of the surfactant. The terminal rate constant, $k_2$, was doubled (from $5.85 \times 10^{-3}$ to $1.19 \times 10^{-2}$ $min^{-1}$) by the surfactant. The ratio of $k_1$ to $k_2$ was increased by the surfactant from a value of 2.14 to 3.29. This finding suggests that the surfactant exerted a greater effect on the initial drug release than on the release of the maintenance dose.

One-third of chlorpheniramine contained in the controlled-release capsule was in nonwax-coated pellets, with the remainder of the drug contained in pellets coated with varying thicknesses of wax. Table IV contains the dissolution data divided into two segments, which roughly correspond to the amounts of drug contained in these two types of pellets. The times given in Table IV were determined from regression analysis of the dissolution data using the biexponential equations described in Table III. A value of 95% released was chosen for the last group due to the difficulty of accurately determining the time at which 100% of the drug had been released from the dosage form.

The $\Delta T$ values in Table IV represent the time required for chlorpheniramine to be released from each pellet group. The $\Delta T$ value for the first one-third of the drug was simply the time required for 33.33% to be released from the dosage form. The $\Delta T$ value for the release of drug from wax-coated pellets (33.33–95%) was determined by subtracting $\Delta T$ for the first one-third from the total time required to release 95% of the drug. The surfactant decreased the required release time from both pellet groups. However, as shown by the ratio of $\Delta T$ from Group I to $\Delta T$ from Group II in Table IV, the surfactant had a greater effect on the amount

[a] Group I = 12 mg of chlorpheniramine released from a controlled-release capsule into 0.1 *N* HCl, and Group II = 12 mg of chlorpheniramine released from a controlled-release capsule into 0.1 *N* HCl containing 0.01% (w/v) docusate sodium.

Table IV—Time Required for a Fixed Amount of Chlorpheniramine to be Released from the Controlled-Release Capsule

| Percent Released | Group I[a] Time, min | Group I[a] $\Delta T$[c], min | Group II[b] Time, min | Group II[b] $\Delta T$, min | Ratio, $\Delta T_I/\Delta T_{II}$ |
|---|---|---|---|---|---|
| 33.33 | 64.22 | 64.22 | 10.62 | 10.62 | 6.05 |
| 95.00 | 502.10 | 437.88 | 218.07 | 207.47 | 2.11 |

[a] Dissolution of 12 mg of chlorpheniramine released from the controlled-release capsule into 0.1 *N* HCl. [b] Dissolution of 12 mg of chlorpheniramine released from the controlled-release capsule into 0.1 *N* HCl containing 0.01% (w/v) docusate sodium. [c] Amount of time required for chlorpheniramine to be released from each pellet group.

of time required for the first one-third of the drug to be released. This ratio decreased from 6.05 for the nonwax-coated pellet group to 2.11 for the wax-coated pellet group.

Figure 3 shows the results of the micellar entrapment study. Below the CMC, the amount of free chlorpheniramine in solution was not altered. However, in 0.1 *N* HCl containing 0.02% (w/v) docusate sodium, the amount of free chlorpheniramine decreased rapidly over a short time. This finding demonstrated that the micelles formed in the surfactant solution at the CMC apparently have a high affinity for the chlorpheniramine molecules. Drugs trapped in surfactant micelles must be released from the micelle before crossing the mucosal membrane. Therefore, micellar entrapment *in vivo* could delay or decrease drug absorption. The concentration of docusate sodium that was in contact with the controlled-release capsule in the *in vivo* study probably exceeded the CMC.

## CONCLUSIONS

The availability of chlorpheniramine maleate from a controlled-release capsule was not significantly altered *in vivo* by the coadministration of 200 mg of docusate sodium. No significant difference in the *AUC* at 40, 80, 160, 240, and 480 min was observed between the administration of the capsule alone or with docusate sodium.

Docusate sodium enhanced the *in vitro* rate of chlorpheniramine release from the dosage form. The initial drug release rate tripled and the release of the remainder of the drug doubled in the presence of the surfactant. Micelles formed in the dissolution medium at the CMC of docusate sodium were shown to bind rapidly to chlorpheniramine.

There are several possible explanations as to why the enhanced drug release rate was not observed *in vivo*. The surfactant concentration *in vivo* may have exceeded the CMC of docusate sodium. Although the drug release rate may have been enhanced, micellar entrapment of the drug molecules may have occurred. Drug molecules trapped by surfactant micelles are generally considered to be too large to be absorbed from the GI tract. The overall effect of the surfactant on drug release from the dosage form may have been negated by micellar entrapment. The surfactant also was observed to exert its major effect *in vitro* on the release of the loading dose. The nonwax-coated pellets in the controlled-release capsule are designed for the rapid release of the loading dose *in vivo*. Rapid therapeutic blood levels of chlorpheniramine were obtained in this study both in the presence and absence of the surfactant. Initial therapeutic levels of the drug were obtained so fast that any enhancement of initial drug release due to surfactant was not discernible.

The effect of docusate sodium on the absorption of a solution of chlorpheniramine maleate is not known. Investigation of this effect would show whether micellar entrapment of the drug by 200 mg of docusate sodium occurs *in vivo*. Additional insights into the *in vivo* effects of the surfactant on drug release from the dosage form would be gained by decreasing the amount of surfactant administered to the subjects. The effect of premicellar concentrations of the surfactant could be observed.

Although the *in vivo* study showed no significant difference in the *AUC* after administration of the controlled-release capsule alone or with the surfactant, generalizations should not be made. The effect of a surfactant on drug absorption is highly dependent on the drug being studied. Surfactants have been shown to increase, decrease, or have no effect on the absorption of a drug already released from the dosage form. Other drugs contained in similar long-acting oral dosage forms may show marked changes in drug absorption when exposed *in vivo* to a surfactant.

# Interaction of Povidone with Aromatic Compounds II: Evaluation of Ionic Strength, Buffer Concentration, Temperature, and pH by Factorial Analysis

**J. A. PLAIZIER-VERCAMMEN** ˣ **and R. E. De NÈVE**

Received April 28, 1980, from the *Faculteit Geneeskunde en Farmacie, Vrije Universiteit Brussel, Laarbeeklaan, 103 B-1090 Brussels, Belgium.* Accepted for publication April 1, 1981.

**Abstract** □ The interaction of a series of ligand molecules, all consisting of substituted benzoic and nicotinic acid derivatives, and povidone was studied. The influence of ionic strength, buffer concentration, and temperature was evaluated using factorial analysis. Complex formation was not affected at low ionic strength, but increased considerably at higher values due to dehydration of the macromolecule. Complex formation was enhanced in phosphate solutions, particularly in the presence of dibasic phosphate ions. A linear relationship was found between the logarithm of the percentage of bound ligand and ionic strength and buffer capacity.

Increasing the temperature lowered complex formation. Although dehydration of the macromolecule also occurred, the decrease in complex formation could be attributed to the solubility increase of the ligand molecules. The influence of the degree of dissociation of the ligand molecules was investigated by factorial analysis. The compounds mainly interacted to a lesser extent in the dissociated than in the nondissociated state. In addition, a negative effect of a pyridine ring with respect to a phenyl ring was observed. The binding tendency was markedly increased by substituting the aromatic ring structure with hydroxyl functions and by esterification of the carboxyl function attached to the ring. The results suggested that lipophilicity and hydrogen bonding played a predominant role in povidone complexation.

**Keyphrases** □ Povidone—interaction with aromatic compounds, evaluation of complex formation by factorial analysis □ Complexation—evaluation of povidone–aromatic compound interaction by factorial analysis □ Factorial analysis—evaluation of complex formation, povidone–aromatic compound interaction □ Aromatic compounds—interaction with povidone, evaluation of complex formation by factorial analysis

The influence of parameters such as ionic strength, temperature, and buffer concentration and composition on the complex formation between small ligand molecules and macromolecules such as povidone has not yet been investigated systematically (1–9). However, the influence of these parameters is important for meaningful comparisons between the complexing tendencies of related ligand molecules (10) and for understanding the binding and thermodynamic characteristics involved (11–16).

The present report deals with a factorial analysis of these parameters.

## EXPERIMENTAL

**Reagents**—Povidone[1] with a molecular weight of 700,000 was used as the macromolecule and was oven dried at 50° until a constant weight was reached. The following ligand molecules were investigated: benzoic acid[2], nicotinic acid[3], isonicotinic acid[2], salicylic acid[4], nicotinamide[2], salicylamide[2], benzoic acid hydrazide[5], nicotinic acid hydrazide[6], isonicotinic acid hydrazide[4], iproniazide phosphate[7], salicylic acid hydrazide[6], 4-hydroxysalicylic acid[8], 5-hydroxysalicylic acid[4], 5-nitrosalicylic acid[8], methyl salicylate[4], and ethyl salicylate[2].

The following buffer solutions were used: hydrochloric acid–potassium chloride buffers (17) at pH 1.0 and 1.93, McIlvaine buffers (18) at pH 2.20–5.60, a phosphate buffer (17) at pH 7.00, a boric acid–disodium tetraborate buffer at pH 7.20 (19), and a boric acid–sodium hydroxide buffer (17) at pH 9.20. The solutions were brought to a determined ionic strength with sodium chloride. [Sodium chloride does not complex with povidone (6).] The pH of the solutions was controlled with a potentiometric pH measurement[9] and adjusted if necessary.

To control the influence of buffer ions two kinds of buffer solutions were used: the normal buffers are denoted by 1 and those with half the normal capacity are indicated as 0.5.

**Methods**—*Complex Formation Using Factorial Analysis*—Complex formation of the ligand molecules and povidone was investigated by ultrafiltration as previously described (10). The povidone concentration was 4.0%, and the ligand concentrations varied from $1.33 \times 10^{-3}$ to $1.00 \times 10^{-2}$ *M*, depending on their solubility at the pH values used. The complexing tendency expressed as percent of bound ligand (*B%*) was, in the ranges used, independent of the ligand concentration. The concentration of free ligand in the filtrate was determined, after appropriate dilution, with a double-beam spectrophotometer[10] at the respective $\lambda_{max}$ of the ligands. Corrections were made for possible membrane adsorption, and the percentage of bound ligand was calculated as a measure of the complexing tendency. For each sample, these values were obtained at two levels of the three parameters studied (*i.e.*, ionic strength, buffer composition, and temperature) and investigated by factorial analysis (10, 20–22).

For the binding of ligand molecules at pH 1.0, only ionic strength and buffer composition were investigated. At pH 7.00, for 4-hydroxysalicylic acid and 5-nitrosalicylic acid, only the temperature and buffer composition were investigated.

*Complex Formation at Varying Ionic Strengths*—The effect of ionic strength was determined in a series of solutions containing $1.00 \times 10^{-2}$ *M* salicylic acid and 4.0% povidone in McIlvaine buffer (18) (pH 2.20). Ionic strength varied from 0.15 to 6.00.

*Complex Formation at Varying Buffer Concentrations*—The effect of phosphate buffer (pH 7.00) was investigated for three ligand molecules by varying the buffer concentration from 0.0500 to 0.00834 *M*, expressed as dibasic phosphate ions.

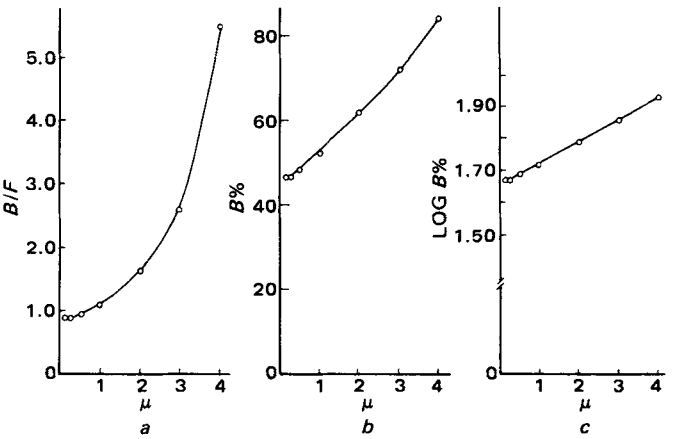

**Figure 1**—*Effect of ionic strength on the complexing tendency of salicylic acid ($1.00 \times 10^{-2}$ M) onto povidone (4.0%) at 25° and pH 2.20*

*Desolvating Effect of Temperature on Macromolecule*—Solutions of povidone in different solvents were slowly heated, and the cloud point was determined.

## RESULTS AND DISCUSSION

**Factorial Analysis**—Factorial analysis was carried out as described previously (10). The three parameters were each investigated at a low and high level: temperature, 25 and 50°; buffer concentration, 0.5 and 1.0 and low or high ionic strength, depending on the buffers used.

With the data resulting from the ultrafiltration experiments, i.e., the percentage of bound ligand, analyses of variance were carried out and the significance of the individual parameters was evaluated with an *F* test (10). Results are summarized in Tables I–III.

Interaction between parameters were not observed except for salicylic acid at pH 2.20 where a significant relative positive interaction was observed between temperature and ionic strength.

In Tables I–III, the significance value for a 99% certainty level was indicated as 0, +, or −, corresponding with a zero, positive, or negative significant influence on complex formation when the respective factor was changed from a low to a high level.

Preliminary studies found that some derivatives showed no interaction with povidone. They are included in Table IV (the effects of the parameters were not investigated with them).

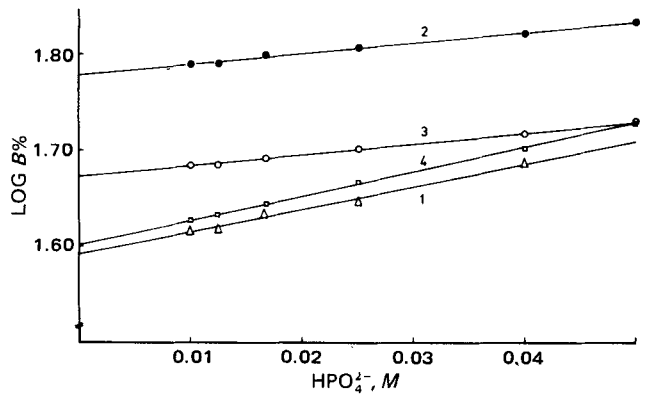

**Figure 2**—*Effect of phosphate ions (pH 7.00) on the complexing tendency of various cosolutes onto povidone (4.0%). Key: 1, salicylic acid (5.00 × 10⁻³ M), 25°, μ = 0.25; 2, 4-hydroxysalicylic acid (4.81 × 10⁻³ M), 25°, μ = 0.25; 3, 4-hydroxysalicylic acid (4.81 × 10⁻³ M), 50°, μ = 0.25; and 4, 5-nitrosalicylic acid (4.81 × 10⁻³ M), 25°, μ = 0.25.*

[a] Hydrochloric acid–potassium chloride buffer. [b] MacIlvaine buffer. [c] Phosphate buffer. [d] Boric acid–disodium tetraborate buffer. [e] Boric acid–sodium hydroxide buffer. [f] Water. [g] Since a little difference in free ligand concentration exerts a great influence on the percentage of bound ligand, the difference for the two levels is not significant.

**Theory of Multiple Equilibrium**—The principles and concepts of complex formation with macromolecules were delineated previously (11, 23–30).

**Ionic Strength**—Table I gives the results for the influence of ionic strength studied at two levels, at a temperature of 25° and a buffer concentration of half the normal buffer capacity.

With the experimental conditions used, ionic strength had no significant effect on complex formation of the cosolutes. However, for salicylic acid at pH 2.20, a significant positive effect was observed when the ionic strength was changed from 0.15 to 1.00 ($p > 0.001$). At this pH, a relative positive interaction was also noted between ionic strength and temperature ($0.01 < p < 0.001$), although this last factor exerted a negative effect when considered individually (see effect of temperature). This effect of ionic strength is represented in detail in Fig. 1.

Complex formation as a function of ionic strength is represented in three ways: the ratio of bound to free ligand concentration ($B/F$), the percentage of bound ligand ($B\%$), and the logarithm of bound ligand (log $B\%$).

Ionic strength has a great positive influence since the amount of bound ligand rose with a factor of 1.8 from $\mu = 0.15$ to 4.00. At higher ionic strength (>4.00) the macromolecule precipitated.

It was previously reported (31–38) that neutral salts enhance complex formation with nonionic macromolecules. This activity was attributed to the dehydrating effect of the salt making the water molecules less available for hydrogen bonding with the macromolecules, thereby de-

**Table III—Complex Formation of Various Cosolutes with Povidone (4.0%) as a Function of Temperature Using Low Ionic Strength and 0.5 Buffer**

[a] MacIlvaine buffer. [b] Phosphate buffer. [c] Boric acid–disodium tetraborate buffer. [d] Boric acid–sodium hydroxide buffer.

creasing the aqueous solubility of the polymer and favoring the competing ligand polymer interaction. The precipitation of povidone observed at higher ionic strength (>4.00) indicated that this parameter effectively exerted a dehydrating effect on the macromolecule.

From the results represented in Fig. 1, the following relationships could be deduced:

$$\log B\% = a\mu + b \qquad \text{(Eq. 1)}$$

or:

$$B/F = \frac{10^{(a\mu + b)}}{100 - 10^{(a\mu + b)}} \qquad \text{(Eq. 2)}$$

The values $a$ and $b$, determined from the slope and intercept of Fig. 1*c* were 0.068 and 1.655, respectively.

Together with the macromolecule dehydration, which is a logarithmic function of the ionic strength (39), the percentage of bound ligand increased as an exponential function of ionic strength until precipitation. From the log $B\%$ graph as a function of the ionic strength, it was possible to eliminate the effect of this parameter by extrapolation to the ordinate. An increasing complexing tendency at higher ionic strength was observed with hydrophobic binding and Van der Waals forces.

**Buffer Concentration**—The influence of buffer concentration, studied at two levels, is reported in Table II.

No significant effect was noted with hydrochloric acid–potassium chloride buffer (pH 1.0), boric acid–disodium-tetraborate buffer (pH 7.20), boric acid–sodium hydroxide buffer (pH 9.20), or the MacIlvaine buffer (pH 2.20–5.60).

For the compounds investigated at pH 7.00 in phosphate buffer, a large positive effect of the buffer concentration was observed. Doubling the concentration of the buffer ions considerably enhanced complex formation: 16.4% for salicylic acid, 6.4% for 4-hydroxysalicylic acid, 15.7% for 5-nitrosalicylic acid, and 2.7% for salicylic acid hydrazide at 25°.

At the investigated pH values, the MacIlvaine buffer was composed mainly of monovalent phosphate and citrate ions. The phosphate buffer (pH 7.00) consisted of monobasic (61.9%), and dibasic ions (30.1%). Thus, the dibasic phosphate ions presumably affected the complexing tendency.

This enhancement in complex formation with bivalent ions can perhaps be explained in terms of macromolecule dehydration. This presumption is supported by the fact that the salting-out effect is a function of size and the hydration state of the ions (11). The pronounced dehydrating effect of bivalent phosphate ions was emphasized in an earlier experiment (see effect of temperature).

The effect of phosphate buffer was also investigated for three ligand molecules (Fig. 2). The logarithm of the percentage of bound ligand as a function of the buffer concentration showed a linear relationship. The intercept, obtained by extrapolation to the ordinate, represented the log percentage of bound ligand at infinite dilution, thereby eliminating the

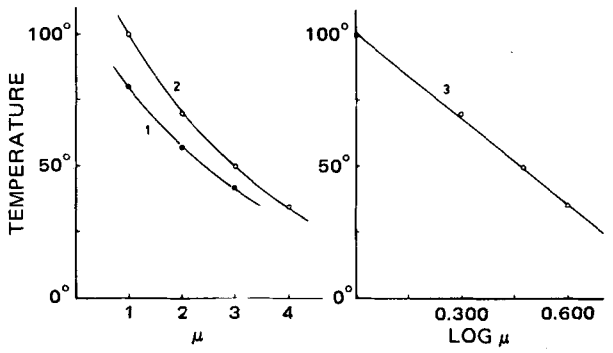

**Figure 3**—*Cloud point of the povidone (4.0%)–salicylic acid (1.00 × $10^{-2}$ M) complex as a function of temperature at pH 2.20. Key: 1, cloud point; 2, precipitation; and 3, cloud point.*

effect of the buffer. These values represented 38.8% of bound ligand for salicylic acid; 60.0 and 47.9%, respectively, at 25 and 50° for 4-hydroxysalicylic acid; and 40.6% for 5-nitrosalicylic acid. Comparison of these results with those of Table II shows that the complexing tendency of salicylic acid and 4-hydroxysalicylic acid was lowest at pH 7.00 where the two ligand molecules were fully dissociated. However, 5-nitrosalicylic acid seemed to have a higher complexing tendency onto povidone at higher pH values.

Ionic strength (Table I), had no effect on complex formation, and the effects of buffer concentration and ionic strength were compared. For both parameters, a linear relationship was found between the logarithm of the percentage of bound ligand and the ionic strength and buffer capacity.

**Temperature**—The effect of temperature was evaluated by factorial analysis carried out at 25 and 50°. Binding diminished significantly at the higher temperature (Table III). However, an exception was noted for benzoic acid at pH 3.40. The same effect was found for this compound in the nonionic state with povidone[11] (5). Methyl and ethyl salicylate also did not influence complexation.

Thermal energy would be expected to exert two antagonistic effects on complex formation. By thermal desolvation of the polymer chain, a more suitable environment for the interaction with the ligand molecules would be expected. However, thermal agitation might also decrease the association of the ligand molecules with the polymer by weakening the attractive forces between them (31, 40). It is the authors' opinion that another effect must be considered; temperature also enhances the solubility of the ligand molecules, probably decreasing the complexing tendency.

The results of the desolvating effect of temperature on povidone are given in Table V. No cloud point could be obtained with povidone solutions in water, ethanol, and 20% (v/v) ethanol when the solutions were heated to 100°. However, the solutions containing salts became clouded by temperature elevation, suggesting dehydration of povidone by salt. This effect, most pronounced with bivalent phosphate ions, could explain the positive effect of these ions on complex formation.

The same experiment was performed on the solutions represented in Fig. 1, and the results are shown in Fig. 3.

The cloud point and precipitation occurred at lower ionic strength as the temperature increased. This finding is in accordance with the relative positive interaction noted between ionic strength and temperature. When representing the logarithm of the ionic strength as a function of temperature where the solutions are clouded, a linear relationship is observed (Fig. 3). These results were also indicative of the dehydrating effect of temperature. When the clouded solutions were cooled, turbidity disappeared with the exception of the solution heated to 100° ($\mu = 1$).

**Effect of pH and Substituents**—The results obtained from factorial analysis (Tables I and II) indicated that ionic strength and buffer concentration had no influence on complex formation. Therefore, it is possible to discuss in a more meaningful way the influence of pH and dissociation of ligand molecules on complex formation. An exception was observed at pH 7.00, where the buffer effect was considerable (Table II). At this pH, the extrapolated values from Fig. 2 were used, representing the percentage of bound ligand at infinite buffer dilution and excluding the effect of the buffer.

The results for the different ligand molecules as a function of their pKa values and degree of dissociation are summarized in Table IV. The

compounds generally interacted to a lesser extent when dissociated than when undissociated. Exceptions were noted for nicotinic acid, isonicotinic acid, and 5-nitrosalicylic acid.

The low interaction tendency of the dissociated compounds could be attributed to their more hydrophilic nature. For the carboxylic acid derivatives, the complexing tendency followed the series: salicylic acid > benzoic acid > nicotinic acid ≃ isonicotinic acid. The same order was observed for the amide derivatives (salicylamide > nicotinamide) and the hydrazide derivatives (salicylic acid hydrazide > benzoic acid hydrazide > nicotinic acid hydrazide = isonicotinic acid hydrazide = iproniazide phosphate = no interaction).

A large negative influence of the pyridine ring with regard to the benzene ring was striking. Where benzoic acid, in the undissociated state (pH 1.0), showed complex formation of 34.3% and benzoic acid hydrazide (pH 7.00) showed complex formation of 11.6%, no interaction was noted for the pyridine derivatives. The introduction in the molecular structure of a hydroxyl function enhanced the complexing tendency; *e.g.*, compare salicylic acid with 47.7% of bound ligand against benzoic acid with 34.3%, and salicylic acid hydrazide with 33.1% of bound ligand against benzoic acid hydrazide with 11.6%. A second hydroxyl function enhanced complex formation considerably; *e.g.*, compare 4-hydroxysalicylic acid and 5-hydroxysalicylic acid with 72.2 and 59.0%, respectively, of bound ligand against salicylic acid with 47.7%. However, the introduction of a nitro function decreased the interaction (5-nitrosalicylic acid < 5-hydroxysalicylic acid).

The position of the substituents on the benzene ring also played an important role; *i.e.*, 4-hydroxysalicylic acid showed a higher complexing tendency than the 5-hydroxy derivative. Esterification of the carboxyl function with a methyl or ethyl function enhanced the interaction considerably. The alkyl chain length seemed to have a positive influence [ethyl salicylate (91.1 *B*%) > methylsalicylate (87.3 *B*%).] The negative effect of a nitro group as compared with a hydroxyl function was also observed by Jürgensen Eide and Speiser (5). In the case of the bulky nitro group, steric hindrance should play a role. The difference in interaction between 5-hydroxysalicylic acid and 4-hydroxysalicylic acid could be due to the higher solubility of the 5-hydroxy derivative in contrast to the 4-hydroxy derivative, accompanied by a decreased complexing tendency. However, a correlation between solubility and complex formation had exceptions. The solubility of 5-nitrosalicylic acid was much lower than that of the 5-hydroxy derivative. While the latter showed a higher complexing tendency, the same statement could be made for 5-hydroxysalicylic acid and salicylic acid, with the former showing a greater solubility and a more pronounced complexing tendency. The increasing complexing tendency of compounds in the dissociated state containing hydroxyl groups indicates that hydrogen bonding must play an important role in the interaction.

Moreover, the difference in complex formation between undissociated and respectively dissociated ligand molecules was not important; *e.g.*, for salicylic acid, the complexing tendency only decreased from 47.7 to 38.7 *B*%. Also, for 4-hydroxysalicylic acid and 5-hydroxysalicylic acid, the decrease in the percentage of ligand bound when going from the undissociated (pH 1.0) to the dissociated state (pH 7.00) was not very important. The correlation between degree of complexing tendency and pH and pKa of the drug and partition coefficients is being investigated.

# Polymorphism of Spray-Dried Microencapsulated Sulfamethoxazole with Cellulose Acetate Phthalate and Colloidal Silica, Montmorillonite, or Talc

**H. TAKENAKA, Y. KAWASHIMA ˣ, and S. Y. LIN**

Received January 8, 1981, from the *Gifu College of Pharmacy, Mitahora, Gifu 502, Japan.* Accepted for publication March 27, 1981.

**Abstract** □ Sulfamethoxazole was microencapsulated with cellulose acetate phthalate and talc, colloidal silica, or montmorillonite clay by a spray-drying technique. The surface topography of the products varied with the type of excipient used and the pH of the suspending medium. The products without the excipient were coated with flake-like crusts, while the products containing the excipient tended to become well-rounded spheres. In addition, the crystalline form of sulfamethoxazole converted from Form I to an amorphism and Form II during the spray-drying process. This polymorphic transformation was attributed to the interaction of cellulose acetate phthalate with sulfamethoxazole. Increasing the concentration of cellulose acetate phthalate in the formulation increased the attainment of amorphism. Form II was also obtained by freeze and vacuum drying. Talc was the only excipient that contributed to polymorphism, which occurred in the alkaline suspension medium. Montmorillonite products prepared from the acidic medium exhibited an exothermic differential scanning calorimetry thermogram, which might be interpreted in terms of adsorption of the fused sulfamethoxazole with the internal surface of montmorillonite.

**Keyphrases** □ Microencapsulation—sulfamethoxazole, spray drying with cellulose acetate phthalate and colloidal silica, montmorillonite, or talc, polymorphism □ Polymorphism—microencapsulation of sulfamethoxazole, spray drying with cellulose acetate phthalate and colloidal silica, montmorillonite, or talc □ Sulfamethoxazole—microencapsulated, polymorphism, spray drying with cellulose acetate phthalate and colloidal silica, montmorillonite, or talc

The appropriate selection of the most suitable polymorphic form of medicaments with high thermodynamic activities frequently is the key to improving bioavailability or preventing caking in an aqueous vehicle.

The polymorphic form of a compound depends on the nature of crystallization, *i.e.*, the type of solvent used, the temperature of crystallization, *etc.* It has been documented that polymorphism occurs during spray drying. Fell and Newton (1) produced spray-dried lactose that was a mixture of $\alpha$-monohydrate, $\alpha$-anhydrous, and $\beta$-lactose forms. Kawashima *et al.* (2) reported that spray-dried sodium salicylate was polymorphic, composed of normal crystals and amorphisms. Another study (3) showed that the crystalline form of spray-dried sulfamethoxazole with cellulose acetate phthalate converted from Form I to Form II and an amorphism.

The present study examined the effects of cellulose acetate phthalate and excipients such as colloidal silica, talc, and montmorillonite clay on polymorphism. Tests were performed by freeze drying and vacuum drying at 70° using the same formulations as for spray drying. Another microcapsule of sulfamethoxazole with cellulose acetate phthalate was prepared by the coacervation method of Merkle and Speiser (4) as a reference to test polymorphism.

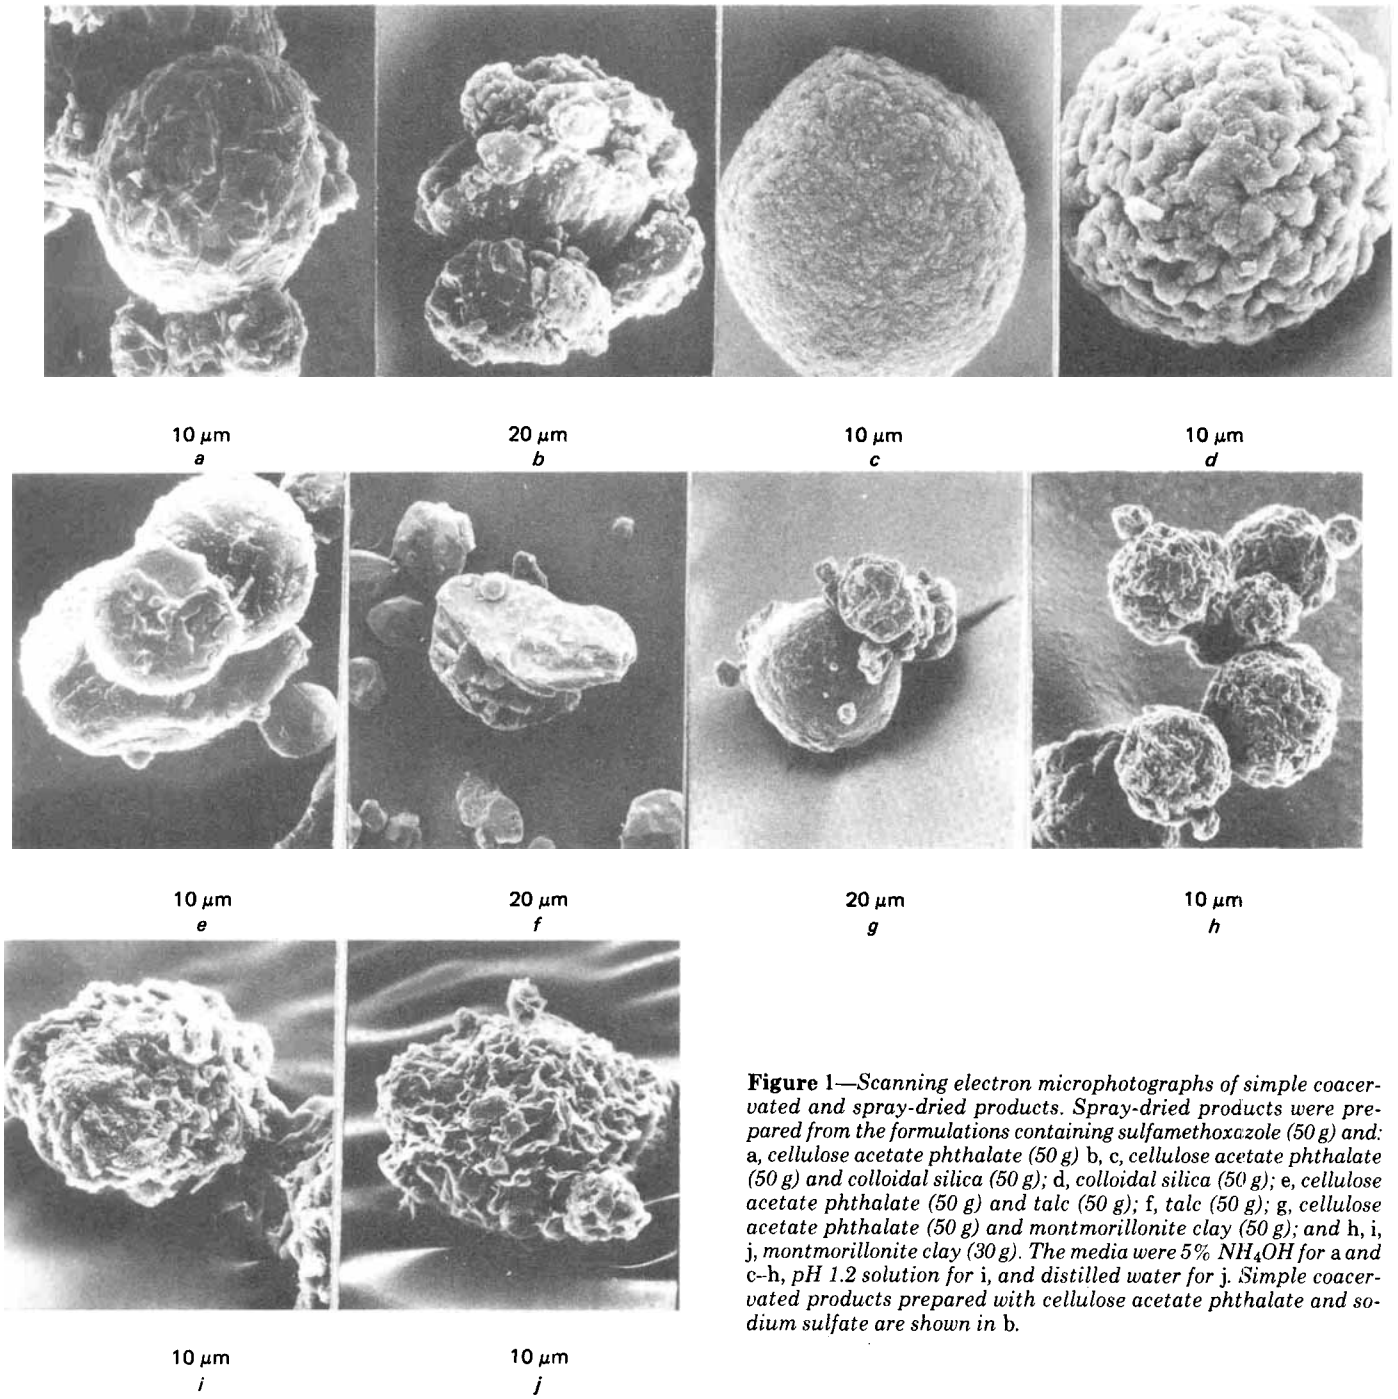

**Figure 1**—*Scanning electron microphotographs of simple coacervated and spray-dried products. Spray-dried products were prepared from the formulations containing sulfamethoxazole (50 g) and:* a, *cellulose acetate phthalate (50 g)* b, c, *cellulose acetate phthalate (50 g) and colloidal silica (50 g);* d, *colloidal silica (50 g);* e, *cellulose acetate phthalate (50 g) and talc (50 g);* f, *talc (50 g);* g, *cellulose acetate phthalate (50 g) and montmorillonite clay (50 g); and* h, i, j, *montmorillonite clay (30 g). The media were 5% $NH_4OH$ for* a *and* c–h, *pH 1.2 solution for* i, *and distilled water for* j. *Simple coacervated products prepared with cellulose acetate phthalate and sodium sulfate are shown in* b.

solved in 1 liter of 5% $NH_4OH$. To this solution was added 0, 30, or 50 g of colloidal silica[3], talc[4], or montmorillonite clay[5]. The resultant slurries were supplied for spray drying. Formulations without cellulose acetate phthalate were also prepared to test the influence of excipients alone on polymorphism. These slurries or solutions were atomized into a drying chamber by a centrifugal wheel atomizer at 40,000 rpm[6]. The drying chamber was maintained at 140 ± 10°, and the dried products were collected by a cyclone collector.

The detailed formulations for spray drying were as follows.

Spray drying for microencapsulation involved sulfamethoxazole (50 g) as the medicament, cellulose acetate phthalate (50 g) as the wall material, colloidal silica and montmorillonite clay (0, 30, and 50 g) as the excipients, and 1 liter of 5% $NH_4OH$ as the medium.

Spray drying for agglomeration involved sulfamethoxazole (50 g) as the medicament with colloidal silica, talc, and montmorillonite clay (30 and 50 g) in 1 liter of 5% $NH_4OH$; colloidal silica, talc, and montmorillonite clay (30 g) in 1 liter of pH 1.2 solution; and colloidal silica, talc and montmorillonite clay (30 g) in 1 liter of distilled water.

Evaporation at 70° in vacuum (20 mm Hg) or spray drying at 140 ± 5° involved sulfamethoxazole (50 g) as the medicament, cellulose acetate phthalate (10–50 g) as the additive, and 5% $NH_4OH$ as the medium.

Cellulose acetate phthalate microcapsules of sulfamethoxazole were prepared by the coacervation method of Merkle and Speiser (4). Sulfamethoxazole (10 g) was suspended in 100 ml of aqueous solution (pH 7.5) containing 2 g of cellulose acetate phthalate and 0.74 g of dibasic sodium phosphate. The system was maintained at 60° and agitated at 620 rpm. Then 25 ml of 20% (w/w) aqueous sodium sulfate solution preheated at 60° was added in small portions. The system was slowly cooled to 20°, and the coacervates were separated and washed with water to remove noncoacervated cellulose acetate phthalate. The coacervate wall was hardened by 2% aqueous acetic acid.

Five grams of sulfamethoxazole and cellulose acetate phthalate were dissolved in 100 ml of 5% $NH_4OH$. The solutions were vacuum freeze

The medium was 5% $NH_4OH$.*

dried at −20° ($10^{-3}$ mm Hg) in a freeze dryer[7].

One hundred milliliters of 5% $NH_4OH$ solution containing 5 g of sulfamethoxazole and cellulose acetate phthalate were evaporated at 70° in vacuum to remove ammonium hydroxide and water. The precipitated particles were supplied to test the crystalline form of sulfamethoxazole.

**Measurement of Physicochemical Properties**—The surface topography of the spray-dried particles coated with gold was investigated with a scanning electron microscope[8]. To determine the crystalline form of sulfamethoxazole, X-ray diffraction patterns, IR absorption spectra, and differential scanning calorimetry thermograms were obtained using an X-ray diffractometer[9], an IR spectrometer[10], and a differential scanning calorimetry calorimeter[11] run with a scanning rate of 5°/min, respectively.

## RESULTS AND DISCUSSION

**Surface Topography of Agglomerates and Microcapsules**—Surface topography of the agglomerates and microcapsules was investigated using scanning electron microscopy. The microcapsules with cellulose acetate phthalate prepared by spray drying and coacervation are shown in Figs. 1*a* and 1*b*, respectively. The surfaces of spray-dried microcapsules were composed of flake-like crusts. The simple coacervated microcapsules were aggregated to form an agglomerate.

When the additives were introduced to the formulations for spray drying, the resultant microcapsules became well-rounded spheres without flakes but varied in some degree, depending upon the type of additive used (Figs. 1*c*, 1*e* and 1*g*). The surface topography of agglomerates prepared by spray drying with the formulations containing only sulfamethoxazole and the excipient are seen in Figs. 1*d*, 1*f*, and 1*h*–1*j*. The agglomerates took various forms, depending on the type of excipient and the pH of the vehicle. The latter factor strongly affected the topography of agglomerates with montmorillonite clay (Figs. 1*g*–1*j*).

Key: A, Form I; B, Form II; C, physical mixture of sulfamethoxazole and cellulose acetate phthalate; D, simple coacervated microcapsule; and E–H, spray-dried products prepared from the formulations containing 50 g of cellulose acetate phthalate (E), 50 g of cellulose acetate phthalate and 50 g of colloidal silica (F), 50 g of cellulose acetate phthalate and 50 g of montmorillonite clay (G), and 50 g of cellulose acetate phthalate and 50 g of talc (H). The medium was 5% $NH_4OH$.*

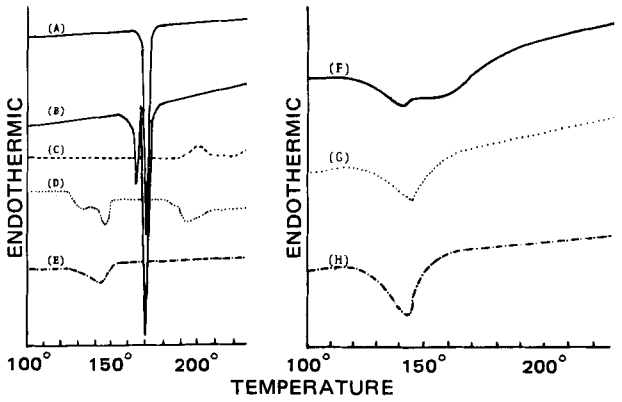

**Figure 4**—*Differential scanning calorimetric thermograms for original sulfamethoxazole, cellulose acetate phthalate, freeze-dried sulfamethoxazole, and spray-dried products containing cellulose acetate phthalate. Key: A, Form I; B, Form II; C, original cellulose acetate phthalate; E, freeze-dried sulfamethoxazole; and D and F–H, spray-dried products prepared from the formulations containing 50 g of cellulose acetate phthalate (D), 50 g of cellulose acetate phthalate and 50 g of colloidal silica (F), 50 g of cellulose acetate phthalate and 50 g of montmorillonite clay (G), and 50 g of cellulose acetate phthalate and 50 g of talc (H). The medium was 5% $NH_4OH$.*

**Effects of Cellulose Acetate Phthalate on Polymorphism**—The IR spectra of original sulfamethoxazole and spray-dried products with cellulose acetate phthalate are seen in Fig. 2. The crystalline form of original sulfamethoxazole was proved to be Form I by identification of its IR spectrum, characterized by intense bands at 3300 and 3150 $cm^{-1}$ attributed to the amide N–H stretching vibration (5). Regardless of whether the excipients were included in the formulations, all spray-dried products with cellulose acetate phthalate exhibited the characteristic absorption bands of Form II in their IR spectra, *i.e.*, weaker bands than those of Form I at 3300 and 3150 $cm^{-1}$ and additional bands at 1640, 1395, 1330, and 750 $cm^{-1}$.

Form II of sulfamethoxazole was prepared by recrystallizing its aqueous solution at dry ice–acetone temperature. It was also confirmed that the crystalline form of freeze- and vacuum-dried sulfamethoxazole always exhibited Form II when cellulose acetate phthalate was included. The sulfamethoxazole in the simple coacervated microcapsule proved to be Form I.

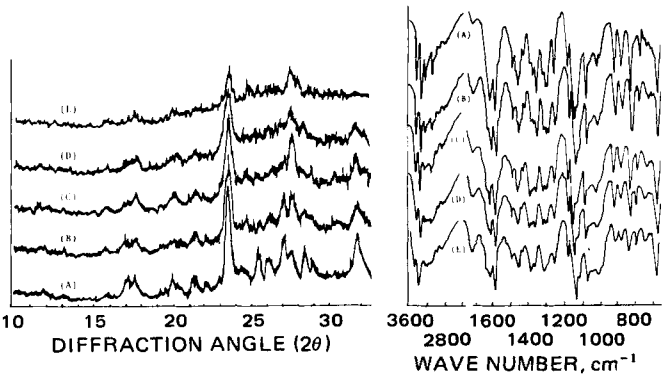

**Figure 5**—*IR spectra and X-ray diffraction patterns of spray-dried products with increasing amounts of cellulose acetate phthalate: A, 10 g; B, 20 g; C, 30 g; D, 40 g; and E, 50 g. The medium was 5% $NH_4OH$.*

Key: A, Form I; B, Form II; C–F and H, spray-dried products prepared from the formulations containing 30 g of colloidal silica (C), 30 g of montmorillonite clay (D), and 30 g of talc (E, F, and H); and G, original talc. Key for H: I, Form I; II, Form II; and T, talc. Media were 5% $NH_4OH$ (C, D, and H), distilled water (E), and pH 1.2 solution (F).*

The peaks in X-ray diffraction patterns of the excipients were less intense than those of the original crystals (Fig. 3). This finding suggests that some sulfamethoxazole crystals in the spray-dried products converted to a disordered form due to the rapid evaporation. The pattern for sulfamethoxazole in the simple coacervated microcapsule coincided with that of Form I.

In the differential scanning calorimetric thermogram of Form II, sharp endothermic peaks appeared at 166 and 171° (Fig. 4), attributed to the transition temperature from Form II to I and to the fusion temperature of Form I, respectively. Spray- and freeze-dried products containing cellulose acetate phthalate exhibited a broad peak at 140–150° in the thermogram. This characteristic discrepancy in the thermograms suggests that some sulfamethoxazole in the spray-dried products exists in amorphic form as already described.

To investigate the effect of cellulose acetate phthalate on the crystalline form, spray drying was performed with various amounts of cellulose acetate phthalate contained in the formulations. With increasing cellulose acetate phthalate concentration, the characteristic IR bands of Form II at 1640, 1395, and 1330 $cm^{-1}$ became more intense while the bands at 3300 and 3150 $cm^{-1}$ became weaker (Fig. 5). The reduced intensities of the X-ray diffraction patterns of the product with a high cellulose acetate phthalate concentration indicated increased amorphism. These findings suggested that cellulose acetate phthalate in the formulation caused polymorphism to occur. It was reported (5, 6) that sulfonamide polymorphism might be due to the formation of intermolecular hydrogen bonds. Hydrogen bonding may occur between the acetyl and hydroxyl groups of cellulose acetate phthalate and the *p*-amino and sulfonyl groups

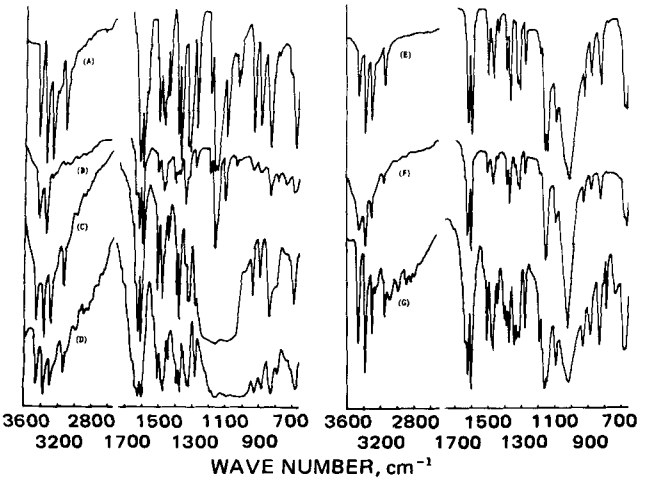

**Figure 7**—*IR spectra of original sulfamethoxazole and spray-dried products without cellulose acetate phthalate. of sulfamethoxazole. This phenomenon, and the steric hindrance of cellulose acetate phthalate, may restrict the intermolecular hydrogen bonding of sulfamethoxazole.

**Effects of Excipients on Polymorphism**—To examine the effects of excipients on the polymorphism of spray-dried sulfamethoxazole, cellulose acetate phthalate was excluded from the formulations. The X-ray diffraction patterns (Fig. 6) and IR spectra (Fig. 7) of the products with montmorillonite clay and colloidal silica suggested that the products were the polymorphic mixture of Form I and amorphisms. The products with talc exhibited a sharp X-ray diffraction pattern, characteristic of the patterns of Form I and talc (Fig. 6). Furthermore, the pattern varied with the type of medium (Fig. 6). IR spectra proved the crystalline forms of the products prepared from the aqueous and acidic slurries to be Form I. Peaks in the IR spectra and X-ray diffraction patterns of products prepared from the ammonium slurries were characteristic of both Form I and II, indicating a polymorphic mixture.

The mechanism of polymorphic transformation that occurred in the alkaline medium was not resolved in the present study. However, previous investigators (7) reported that anionic dyes were selectively adsorbed with talc from aqueous solution. In alkaline medium, the anionic form of sulfamethoxazole could be strongly adsorbed with talc, causing reduced intermolecular hydrogen bonding of sulfamethoxazole, and possibly converting crystals from Form I to Form II. In the aqueous medium, the silanol group of colloidal silica and montmorillonite clay should be hydrated, preventing the formation of hydrogen bonds between sulfamethoxazole and the silanol groups. Thus, the drug molecule adsorbed only physically might be disordered when crystallized by spray drying, leading to amorphism.

Differential scanning calorimetric thermograms of the spray-dried products were characteristic of the type of excipient and medium used. The thermogram of the talc-containing product prepared from ammonium slurries was characteristic of that of Form II (Fig. 8), thus supporting the polymorphic transformation suggested previously by X-ray and IR analyses. The product with colloidal silica exhibited a broad endothermic peak at 150–160° in the thermogram, suggesting the coexistence of amorphism.

Thermograms of the product with montmorillonite clay varied with the type of medium used. The product from distilled water was Form I since most sulfamethoxazole crystals were not dissolved but only suspended in water. With the ammonium slurries, a broad peak resembling that of the product with colloidal silica appeared in the thermogram. When the acidic medium was used, the thermogram changed to an exothermic pattern having a peak at 164°. Porubcan *et al.* (8) reported that the distance between the interlayers of montmorillonite clay in an acidic medium is larger than in an alkaline medium. Thus, when the product prepared from the acidic medium was heated, sulfamethoxazole might

interact with the internal surface of montmorillonite clay since the distance between the interlayers is wide enough for holding the molecule. This interaction might produce some heat, leading to the exothermic thermogram in Fig. 8.

# Extended Hansen Solubility Approach: Naphthalene in Individual Solvents

**A. MARTIN *x, P. L. WU *, A. ADJEI ‡, A. BEERBOWER §, and J. M. PRAUSNITZ ¶**

Received January 30, 1981, from the **Drug Dynamics Institute, College of Pharmacy, University of Texas, Austin, TX 78712,* ‡*Abbott Laboratories, North Chicago, IL 60064,* §*Energy Center, University of California at San Diego, La Jolla, CA 92093,* and the ¶ *Department of Chemical Engineering, University of California, Berkeley, CA 94720.* Accepted for publication April 3, 1981.

**Abstract** □ A multiple regression method using Hansen partial solubility parameters, $\delta_D$, $\delta_P$, and $\delta_H$, was used to reproduce the solubilities of naphthalene in pure polar and nonpolar solvents and to predict its solubility in untested solvents. The method, called the extended Hansen approach, was compared with the extended Hildebrand solubility approach and the universal-functional-group-activity-coefficient (UNIFAC) method. The Hildebrand regular solution theory was also used to calculate naphthalene solubility. Naphthalene, an aromatic molecule having no side chains or functional groups, is "well-behaved"; *i.e.*, its solubility in active solvents known to interact with drug molecules is fairly regular. Because of its simplicity, naphthalene is a suitable solute with which to initiate the difficult study of solubility phenomena. The three methods tested (Hildebrand regular solution theory was introduced only for comparison of solubilities in regular solution) yielded similar results, reproducing naphthalene solubilities within ~30% of literature values. In some cases, however, the error was considerably greater. The UNIFAC calculation is superior in that it requires only the solute's heat of fusion, the melting point, and a knowledge of chemical structures of solute and solvent. The extended Hansen and extended Hildebrand methods need experimental solubility data on which to carry out regression analysis. The extended Hansen approach was the method of second choice because of its adaptability to solutes and solvents from various classes. Sample calculations are included to illustrate methods of predicting solubilities in untested solvents at various temperatures. The UNIFAC method was successful in this regard.

**Keyphrases** □ Naphthalene—solubility study, extended Hansen, extended Hildebrand, and UNIFAC approaches compared □ Solubility—of naphthalene in various solvents, extended Hansen, extended Hildebrand, and UNIFAC approaches compared □ Extended Hansen solubility approach—compared with extended Hildebrand and UNIFAC approaches, naphthalene solubility in various solvents

The solubility parameter concept (1) was originally designed to describe nonpolar solvent–solute systems, although it recently has been extended to the realm of commercial paints, inks, plastics, insecticides, and pharmaceuticals, which may include highly polar solvents and solutes.

The problem of estimating the solubility of crystalline solids in various solvents has been particularly intractable. This report uses partial solubility parameters together with multiple regression analysis to obtain equations that predict solubilities within an error of <30% relative to experiment. Results using a partial parameter–multiple regression method, referred to here as the extended Hansen solubility approach, were compared with those obtained by the extended Hildebrand solubility approach (2) and the universal-functional-group-activity-coefficient (UNIFAC) method (3, 4).

The interaction of a solute and solvent follows either from weak van der Waals forces or from strong forces of a "chemical" nature, such as hydrogen bonding and Lewis acid–base interactions (5). For solutions of interest in the pharmaceutical and biological sciences, both physical and chemical forces are likely to be important.

## THEORY

**Partial Solubility Parameters**—Burrell (6, 7) extended the original solubility parameter concept to estimate the solubility of coating materials (mainly polymers) in polar solvents of low, medium, and high hydrogen-bonding capacity. Hansen (8, 9) partitioned the cohesive energy density, $\Delta E/V$, for a species into contributions from dispersion forces, dipolar interactions, and hydrogen bonding:

$$\frac{\Delta E}{V} = \frac{\Delta E_D}{V} + \frac{\Delta E_P}{V} + \frac{\Delta E_H}{V} \qquad \text{(Eq. 1)}$$

or:

$$\delta^2 = \delta_D^2 + \delta_P^2 + \delta_H^2 \qquad \text{(Eq. 2)}$$

where:

$$\delta = (\Delta E^v/V)^{1/2} \cong \left(\frac{\Delta H^v - RT}{V}\right)^{1/2} \qquad \text{(Eq. 3)}$$

$\Delta E^v$ is the energy of vaporization of a liquid, $\Delta H^v$ is its enthalpy of vaporization, $R$ is the gas constant, $T$ is the absolute temperature, and $V$ is the liquid molar volume. The quantity $\delta$ is the total solubility parameter, and $\delta^2$ is the cohesive density for a solvent or solute. The term $\delta_D$ stands for the dispersion component of the total solvent or solute solubility parameter, $\delta_P$ is the polar component, and $\delta_H$ is the hydrogen-bonding component. These terms are the partial solubility parameters.

[a] Molar volumes (cc/mole) and solubility parameters (cal/cm³)$^{1/2}$ are obtained at 25°. [b] The solubility parameters for *tert*-butanol and 1,1-dibromoethane are not found in the literature. The former was calculated by the group contribution method (9), and the latter was obtained by reference to the values for ethylene dichloride, ethylidene chloride, and ethylene dibromide.

As used here, hydrogen bonding is not restricted to hydrogen bonds in the classical sense but also refers to any type of highly polar, oriented interaction. Partial solubility parameters were originally calculated and adjusted to provide estimates of solubility and elastomer swelling (8, 9).

The dispersion parameter, $\delta_D$, was obtained from data for the compound's homomorph, defined as a saturated hydrocarbon having essentially the same chemical structure, size, and shape as those of the polar compound (8, 9). The polar parameter, $\delta_P$, was calculated using a modified equation from Böttcher (10, 11):

$$\delta_P^2 = \frac{12{,}108}{V^2}\frac{\epsilon - 1}{2\epsilon + n_D^2}(n_D^2 + 2)\mu^2 \qquad \text{(Eq. 4)}$$

where $V$ is the liquid molar volume, $\epsilon$ is the dielectric constant, $n_D$ is the refractive index for the D line of sodium, and $\mu$ is the dipole moment expressed in Debye units. The hydrogen bond parameter for a hydroxyl compound is obtained from an expression:

$$\delta_H = \left(\frac{\Delta H}{V}\right)^{1/2} \qquad \text{(Eq. 5)}$$

where $\Delta H$ is an average enthalpy of formation for hydrogen bonding, 4650 cal/mole, for each hydroxy group. Barton (5) reviewed various methods of calculating partial parameters.

The partial solubility parameters of Hansen are available for a large number of liquid solvents (9). Partial solubility parameters for only a few solids (represented as supercooled liquids), such as naphthalene and succinic anhydride, can be found in the literature. Hansen and Beerbower (9) presented a table of group contributions for calculating partial solubility parameters; from these data, $\delta_D$, $\delta_P$, and $\delta_H$ may be calculated for a liquid or solid (supercooled liquid).

The values can be adjusted to obtain suitable numbers that correspond well with experimental solubility results. Hoy *et al.* (12) developed an extensive compilation of partial and total solubility parameters.

One possible approach to reproducing experimental solubilities for a drug in pure solvents would be to write the solubility equation (1, 2) in terms of partial solubility parameters, followed by multiple regression analysis toward an expression for the desired solubilities. This extended Hansen solubility approach is discussed later. Since the partial solubility parameters of Hoy *et al.* (12) differ somewhat from those of Hansen and Beerbower (9), it is important to use either one system or the other rather than a combination of the two. Regression techniques employing the Hoy parameters result in different equations from those obtained with the Hansen parameters.

**Extended Hildebrand Approach**—A technique called the extended Hildebrand approach (2) was developed to reproduce the solubilities of drugs such as xanthine derivatives in mixed solvents, including dioxane and water, water and polyethylene glycol 400, glycerin and propylene glycol, and dioxane and formamide. The interaction energy, $W$, is regressed against the solvent solubility parameter, $\delta_1$, to obtain $W_{calc}$ which is then substituted into the extended solubility equation to reproduce the drug's solubility on the mole fraction scale. The derivation begins with a relation between the drug's mole fraction solubility, $X_2$, the ideal solubility, $X_2^i$, and the activity coefficient, $\alpha_2$:

$$-\log X_2 = -\log X_2^i + \log \alpha_2 \qquad \text{(Eq. 6)}$$

where $\log \alpha_2$ is expressed in terms of solute and solvent cohesive energy densities, $\delta^2$ and $\delta^1$, the solute–solvent interaction energy, $W$, and an "$A$ factor" from regular solution theory (1):

$$-\log X_2 = -\log X_2^i + A(\delta_1^2 + \delta_2^2 - 2W_{calc}) \qquad \text{(Eq. 7)}$$

$$A = V_2\phi_1^2/2.303RT \qquad \text{(Eq. 8)}$$

where $V_2$ is the molar liquid volume of the solute, $\phi_1$ is the volume fraction of the solvent, $R$ is the molar gas constant, and $T$ is the absolute temperature. A term, $[\ln(V_1/V_2) + 1 - (V_1/V_2)]$, from Flory–Higgins theory is sometimes added to solubility expressions such as Eq. 7 to account for the entropy of mixing of substances with considerably different molar volumes. The regression analyses discussed later showed that this term was statistically insignificant for the naphthalene solutions studied.

The extended solubility approach was tested with methylxanthines in binary solvent systems (2, 13, 14) and with naphthalene in some single solvents (15), but has not been explored in detail for individual solvent systems.

**UNIFAC**—A group contribution (UNIFAC) procedure was developed (3, 4) to investigate the solubilities of solids in pure and mixed liquid solvents. According to this method, the activity coefficient is separated into two parts: a combinatorial contribution, $\log \alpha^C$, which accounts for the molecular size and shape of the solute and solvent, and a residual contribution, $\log \alpha^R$, which accounts for intermolecular energies of attraction:

$$\log \alpha_2 = \log \alpha_2^C + \log \alpha_2^R \qquad \text{(Eq. 9)}$$

Details were given previously (4), and the method is briefly described in the *Appendix*.

## RESULTS AND DISCUSSION

The present study attempted to reproduce the solubility of naphthalene at 40° in solvents using three methods: (*a*) a partial solubility parameter method together with multiple regression, (*b*) the extended Hildebrand solubility approach (2, 13–15), and (*c*) the UNIFAC procedure (3, 4). Table I shows experimental solubilities reported previously (16–19), together with solvent solubility parameters (9) and molar volumes (9). Although the solubilities were obtained at 40°, $\delta_1$ and $V_1$ are customarily calculated at 25°.

Mole fraction solubilities of naphthalene, as determined (16) at 10–75°, are plotted in Fig. 1 against $\delta_1$, the solubility parameter of the pure solvent. The curves drawn through the points are more symmetrical than would be expected for an organic solid dissolved in polar and nonpolar solvents representing different solvent classes. Some polar solvents, such as acetone and butanol, yield points that are displaced from their proper temperature lines, but most points appear in an orderly arrangement on the bell-shaped curves. Figure 1 shows that the mole fraction solubilities of naphthalene, in a range of $\delta_1$ = 7.3–14.5, exhibit peaks in the curves; the peaks do not appear to shift with temperature. With increasing temperature, the naphthalene solubility curves become less peaked; at 75°, the curve is nearly horizontal, but $\delta_1 = \delta_2$ at the peak remains constant at ~9.6 over the 10–75° range. At 75°, naphthalene is only ~5° below its melting point (mp = 80.2°), and its ideal solubility $X_2^i$ (75°) is 0.9105. At this temperature, naphthalene forms nearly ideal solutions in the majority of solvents studied.

**Multiple Regression and Extended Hansen Approach**—Partial solubility parameters for naphthalene, $\delta_D$ = 9.4, $\delta_P$ = 1.0, and $\delta_H$ = 1.9 (total parameter = 9.64), were estimated from a table of group contributions currently under preparation[1]. An early version of the table is given in the literature (9). The regression subprogram[2] (20) allows a stepwise addition of independent variables, analysis of variance, and examination of the residuals by means of scatter plots. The multiple regression yielded Eq. 10 for naphthalene in 24 solvents at 40°:

$$\log \alpha_2 = 1.0488(\pm 0.1762)A(\delta_{1D} - \delta_{2D})^2 - 0.3148(\pm 0.0490)A(\delta_{1P} - \delta_{2P})^2 + 0.2252(\pm 0.0163)A(\delta_{1H} - \delta_{2H})^2 + 0.0451(\pm 0.0155) \quad \text{(Eq. 10)}$$

$$n = 24 \quad s = 0.0559 \quad R^2 = 0.9765 \quad F = 277 \quad F(3,20,0.01) = 4.94$$

Results obtained with Eq. 10 may be substituted into Eq. 6 for log $\alpha_2$ to calculate mole fraction solubility, $X_2$, as shown in Table II. When solubilities (Table II) are calculated with Eqs. 10 and 6, the procedure is referred to as the extended Hansen approach. The results compare favorably with observed solubilities: only one residual is >30% (*tert*-butanol, 53% error), and about half the results exhibit errors of <5%.

The extended Hansen approach may be used to estimate the solubility in solvents not included in the series under investigation. For example, the solubility of naphthalene in butyric acid at 40° is not found in Table II, but it may be calculated as follows. The partial parameters (9) for butyric acid are $\delta_D$ = 7.3, $\delta_P$ = 2.0, and $\delta_H$ = 5.2. Combining these terms with the values for naphthalene, one obtains $(7.3 - 9.4)^2 = 4.41$, $(2.0 - 1.0)^2 = 1.00$, and $(5.2 - 1.9)^2 = 10.89$. These values are introduced into Eq. 10: $\log \alpha^2 = 1.0488A(4.41) - 0.3148A(1.00) + 0.2252A(10.89) + 0.0451$. Value $A$ must be calculated first, using Eq. 8 with $V_2$ = 123.0, $V_1$ = 92.48, $R$ = 1.9872, and $T$ = 40° (313.15 °K). The volume fraction of the solvent, $\phi_1$, is unknown since it depends on the $X_2$ value, which is sought:

$$\phi_1 = V_1(1 - X_2)/[V_1(1 - X_2) + V_2X_2] \quad \text{(Eq. 11)}$$

Value $A$ is found by an iteration procedure (21), beginning with a value of 1.0 for $\phi_1$ and iterating until $X_2$ or $\phi_1$ no longer changes by more than some desired small value. The iteration yields $X_{2_{calc}} = 0.1959$. This result compares satisfactorily with $X_{2_{obs}} = 0.2487$, giving a calculated value within 21% of the observed mole fraction solubility.

Although calculation of the original regression equations requires an electronic computer, back-calculations (involving iteration) for estimating solubilities in various solvents can be done on a programmable hand calculator.

**Polynomial Regression and Extended Hildebrand Approach**—The term (log $\alpha_2$)/$A$ was regressed *versus* $\delta_1$ for naphthalene in the 24 solvents in a second- (quadratic) and third- (cubic) degree expression. To account for self-association of the alcohols, it was necessary to add an indicator variable, $I$, to the regression equations. In back-calculating solubilities, $I$ is given the value of 1 for alcohols and zero for all other solvents in the series. The quadratic expression did not reproduce the solubility data adequately and was omitted from further considerations.

The cubic equation, together with an indicator variable, resulted in a squared correlation, $R^2$, of 0.86:

$$\frac{\log \alpha_2}{A} = 6.1130(\pm 1.0859)I - 53.2569(\pm 19.6920)\delta_1 + 4.6506(\pm 1.8400)\delta_1^2 - 0.1290(\pm 0.0562)\delta_1^3 + 197.8011(\pm 69.0673) \quad \text{(Eq. 12)}$$

$$n = 24 \quad s = 2.0223 \quad R^2 = 0.8648 \quad F = 32 \quad F(4,19,0.01) = 4.50$$

Residuals expressed in percentages were reasonable for the solubilities of naphthalene in most solvents at 40°. However, some large errors re-

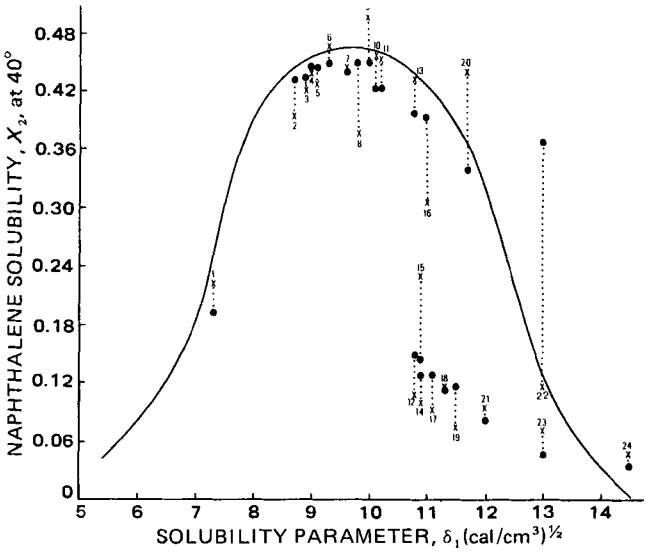

**Figure 2**—*Solubility of naphthalene in 24 individual solvents at 40°. The data is from Refs. 16–19. The curve, calculated using the Hildebrand expression, Eq. 13, rises to a maximum at $\delta_1 = \delta_2 = 9.6$, equal to naphthalene's ideal solubility, $X_2^i(40°) = 0.46594$. The experimental point (x) for each solvent is attached by a dotted line to the calculated solubility (●) obtained using Eqs. 6 and 12.*

[a] UNIFAC parameters not available for solvent functional groups.

sulted from this equation: cyclohexanol, 45%; *tert*-butanol, 40%; isobutanol, 38%; isopropanol, 53%; and acetic acid, 164%. The experimental points are shown in Fig. 2 attached by dotted lines to the solubilities predicted by use of the extended Hildebrand approach. The large error for acetic acid is unaccounted for but apparently results from the particular regression program and iteration procedure used. Alternative methods involving orthogonalization, root finding, and weighting functions are under investigation. The $X_2$ values and residuals are given in Table II, columns 5 and 6.

**UNIFAC Method**—Gmehling *et al.* (4) employed UNIFAC to estimate the solubilities of naphthalene, anthracene, and phenanthrene in several solvents. Their results were calculated, and new solvents were added in the current study; results shown in Table II, column 7, may be compared with the back-calculated mole fraction solubilities of the extended Hildebrand solubility method, column 5, and those obtained by the extended Hansen solubility approach, column 3. The extended Hansen and UNIFAC methods give remarkably similar results. As already indicated, a quantitative method for calculating solubilities in polar solvents is taken to be satisfactory if errors are no greater than ~30%. These two methods generally meet this standard. By contrast, the extended Hildebrand method gives errors of >30% for nine solvents. However, only one of these, acetic acid, produces a large error.

**Regular Solution Theory**—Column 9 of Table II shows solubilities of naphthalene in the 24 solvents at 40° calculated using the regular solution equation of Hildebrand and Scatchard for solids dissolved in liquid solvents (1). The expression is:

$$-\log X_2 = -\log X_2^i + A(\delta_1 - \delta_2)^2 \qquad \text{(Eq. 13)}$$

Equation 13 reproduces solubilities satisfactorily in nonpolar solvents (regular solutions) but fails for irregular systems with polar solvents showing self-association and solvation. The curve of Fig. 2 was plotted using the mole fractions calculated from the Hildebrand–Scatchard equation. Although the observed values are not well represented by Eq. 13 for polar solvents, the mole fraction solubility of naphthalene ($\delta_2$ = 9.64) in a range of solvents from hexane ($\delta_1$ = 7.3) to methanol ($\delta_1$ = 14.5) is at least in qualitative agreement with regular solution theory. For drug molecules having side chains and functional groups attached to the aromatic ring, the regular behavior of naphthalene solubilities is not expected to be found with single or binary solvents.

**Temperature Effects**—Several investigators (16–18, 22) plotted the mole fraction of naphthalene *versus* the reciprocal of absolute temperature; straight lines result for ideal and nearly ideal solutions. The slope of the ideal solution line provides a measure of the molar heat of fusion. For irregular solutions plotted in this manner, the lines ordinarily are curved. Chertkoff and Martin (23) evaluated solubility data employing a different plot, that of the solute mole fraction against the solubility parameter $\delta_1$ of pure or mixed solvents. In this approach, an approximately bell-shaped curve is obtained that reaches a maximum at $\delta_1 = \delta_2$ in regular systems; the mole fraction at this point corresponds to the ideal solubility. Figures 1 and 2 represent graphs plotted in this manner. They provide some information not readily evident from plots of log mole fraction *versus* $1/T$.

It would be useful to employ the solubility data of Fig. 2 at 40° to obtain solubilities at other temperatures, as shown in Fig. 1. Temperature appears in the ideal solubility term, which may be written[3] $\log X_2^i = (\Delta S^f/R) \log (T/T_m)$, and in $A = V_2\phi_1^2/2.303RT$. It might be reasoned that by use of the extended Hansen or extended Hildebrand regression equation (Eq. 10 or 12) and replacement of the temperature of 313°K by a value of 333°K, one could convert the solubility at 40° to an $X_2$ value at 60°.

The observed mole fraction solubility of naphthalene in hexane at 60° (333.15°K) is 0.547. The proper ideal solubility is used, and the temperature found in $A$ is changed from 40° (313.15°K) to 333.15°K; an iteration is then conducted (21) using the extended Hansen approach to arrive at a new $\phi_1$ value yielding $X_{2_{calc}} = 0.489$. This result represents a 10.6% error from the observed $X_2$ at 60°. The same procedure may be used to calculate the solubility of naphthalene in hexane at 20°. The error is 34%. Naphthalene forms an essentially regular solution in hexane, and the plot of log mole fraction *versus* $1/T$ for this solvent is straight, although it does not coincide with the ideal solubility line. For alcohols, plots of log $X_2$ *versus* $1/T$ are ordinarily curved, and extrapolation of naphthalene solubility in methanol at 40° to obtain $X_2$ at 60° by iteration results in an error of 313%. An attempt to extrapolate $X_2$ to 70 and 75°, however, produced errors of only 33 and 29.6%, respectively. At 20°, the result is 14.8% in error. The extended Hildebrand method yields similar results. Thus, the regression equations obtained at 40° give erratic solubility results for polar solvents at elevated temperatures. The errors are apparently due to the iteration procedure required in the extended Hansen and extended Hildebrand methods.

Hildebrand and Scott (1) discussed the influence of temperature on solubility parameters and provided $\delta$ values at various temperatures. Hansen and Beerbower (9) made estimates of the temperature coefficients of $\delta_D$, $\delta_P$, and $\delta_H$. However, as they pointed out, these estimates are needed only for the most polar or hydrogen bonded systems, since the function $V_2\phi_1^2(\delta_1 - \delta_2)^2$ is independent of temperature for near-regular solutions. The previous example of nonlinear behavior of methanol solutions could presumably be improved by using the type of temperature coefficients they suggested.

Another approach is to regress the solubility data of naphthalene from 10 through 60° (Fig. 1) using a single equation. This procedure provides a more reasonable prediction of solubilities at various temperatures and will be reported later.

[3] Ideal solubility is also calculated using the expression:

$$\log X^i = \frac{\Delta H_m^f}{2.303R}\left(\frac{T_m - T}{T_m T}\right)$$

Both forms are approximations, and it is not clear at this time which is more correct.

The UNIFAC method does not appear to suffer from the problems encountered with the regression approaches for calculating solubilities in polar solvents at elevated temperatures; it does not require an iteration procedure. In methanol at 40°, UNIFAC gives $X_{2_{calc}} = 0.0489$, a difference of 12% from $X_{2_{obs}}$; at 60°, $X_{2_{calc}}$ is 0.110, a difference of 17% from $X_{2_{obs}}$.

## SUMMARY

The work of Hildebrand and Scott (1), Scatchard (24), Hansen (8), and several other investigators has led to increased understanding of solubility phenomena. Yet, the formulation of a satisfactory approach to describe the solubility of crystalline solids in pure and mixed polar solvents has proved to be particularly difficult.

The present report applied three methods. The UNIFAC method requires only the solute's heat of fusion, the melting point, and a knowledge of the chemical structure of the solute and solvent. This method, yielding essentially the same accuracy as obtained by the extended Hansen regression method (one exception is the solubility in isobutanol) is judged far superior for predicting solubilities of naphthalene in untested solvents.

The extended Hansen method must be accepted as the second best method studied. Although it required solubility data in the initial regression step, the use of partial solubility parameters accounts for polar and hydrogen-bonding forces in the various solvents. For this reason, an indicator variable is not required in the regression equation of the extended Hansen approach. Furthermore, if new solvents are to be tested in the system under study, use of their partial solubility parameters should allow estimation of naphthalene solubility within reasonable accuracy. This expectation was found for butyric acid, where the solubility of naphthalene was predicted within 21%.

In earlier studies (2, 13, 14), the extended Hildebrand approach was successful in reproducing the solubility of solid drugs in binary solvents, both polar and nonpolar. Although it is satisfactory in the current work for most solvents studied, this method cannot be expected to apply where strong interactions exist. The predictive power of the extended Hildebrand approach is, therefore, less than that of the other two procedures.

By knowing $X_{2_{obs}}$ at a specified temperature for naphthalene in nonpolar solvents, it is possible to calculate the solubility at other temperatures using the extended Hansen or Hildebrand approach. However, for polar solvents such as methanol, this simple procedure is not successful. UNIFAC appears to be more suitable for calculating the solubility of naphthalene in polar and nonpolar solvents at various temperatures.

Naphthalene, a relatively simple molecule, is a good solute to begin a study of solubility in pure solvents; however, it is a poor model for drug solubility. Although this molecule provides $\pi$ electrons for solute–solvent interactions, its lack of functional groups and side chains renders it considerably less nonideal than those typically encountered in the pharmaceutical sciences.

Knowledge gained from these relatively simple and well-behaved systems must now be applied to real drug solutions in individual polar solvents before conclusions can be reached regarding the applicability of the extended Hansen, extended Hildebrand, and UNIFAC methods.

## APPENDIX

The UNIFAC method is based on the well-known group contribution method and was developed to estimate activity coefficients in mixtures of nonelectrolytes. As stated by Eq. 9, the logarithmic activity coefficient is divided into two parts, combinatorial ($\log \alpha_2^C$) and residual ($\log \alpha_2^R$). The combinatorial part results essentially from differences in sizes and shapes of the molecules in the mixture; the residual part is due mainly to interaction energies of species in solution.

The method involves extensive use of equations and definition of terms, but the user simply provides heats of fusion, melting points of solid solutes, and group numbers for the various atoms and chemical groups that make up the molecules. From the group numbers supplied, the computer program calculates volume, $R$, and area, $Q$, parameters as required for the combinatorial activity coefficient. Energies of interaction, $a_{mn}$ and $a_{nm}$, are calculated for the residual activity coefficient, where $m$ and $n$ are interacting groups and $a_{mn} \neq a_{nm}$. Tables of volume, area, and interaction energy parameters for some 300 groups are found in the literature (25).

# Thermodynamic Dependence of Interfacial Transfer Kinetics of Nonionized Barbituric Acid Derivatives in Two-Phase Transfer Cell

**PETER R. BYRON ˣ, ROGER T. GUEST *, and ROBERT E. NOTARI ***

Received November 28, 1980, from the *Pharmaceutics Research Group, Department of Pharmacy, University of Aston in Birmingham, Gosta Green, Birmingham, B4 7ET England.* Accepted for publication April 6, 1981. *Present address: College of Pharmacy, Ohio State University, Columbus, OH 43210.

**Abstract** □ A theory was developed to describe interfacial transport kinetics of a series of drug homologs in a two-phase transfer cell. When tested, the theory held true for 5,5-disubstituted barbituric acid derivatives in a preequilibrated octan-1-ol = (pH 5) aqueous buffer system maintained at 37° and stirred symmetrically at 50 and 100 rpm. Theoretical prediction of transfer kinetics was not possible in such a cell if the phases were stirred asymmetrically. For symmetric stirring, successful prediction of the transfer kinetics of any homolog in the series was possible from a knowledge of the partition coefficient and transfer kinetics of the parent compound, the partition coefficient of the homolog, and some easily determined system variables. The viscosity and density of the two phases and the phase-volume ratio were needed to define a system constant dependent on the solute diffusion coefficient, interfacial area, donor phase volume, and the boundary layer thickness for diffusion in the donor phase. A method is described to enable estimation of this constant from a knowledge of the transfer kinetics of the parent compound. The rank order of compounds in terms of their observed first-order transfer rate constants is shown to be dependent on the characteristics of the solvent system and stirring conditions employed, as well as on the physical chemistry of the solutes. The results are discussed in light of previously documented investigations.

**Keyphrases** □ Transfer kinetics—thermodynamics, nonionized barbituric acid derivatives in the two-phase transfer cell □ Barbituric acids—derivatives, thermodynamic dependence of interfacial transfer kinetics in the two-phase transfer cell □ Two-phase transfer cell—thermodynamic dependence of interfacial transfer kinetics of nonionized barbituric acid derivatives □ Thermodynamics—interfacial transfer kinetics of nonionized barbituric acid derivatives in the two-phase transfer cell

To exert a biological effect, a drug moiety must reach its receptor site by passing through a series of hydrophilic and hydrophobic regions. The ease with which this transfer is accomplished affects the duration and intensity of the resultant biological response.

## BACKGROUND

Two model systems used to investigate the transfer of solute from hydrophilic to hydrophobic regions are the two- and three-phase transfer cells (1, 2). Gordon and Sherwood (1) used a two-phase system of water and butanol to study the transfer of various solutes across the interface. Their studies provided data that supported the two-film theory of Lewis and Whitman (3). An aqueous *n*-octanol (pH 4.3) two-phase system was employed by Schumacher and Nagwekar (4) to study the transfer of sulfonamides. They (5) also varied the composition of the organic phase in the cell to determine the effect on the transport of the same drugs. The effect of varying the aqueous phase pH on salicylic acid transfer was also investigated (6). Since the transfer of ions through lipid membranes is fundamental to cell function, Ting *et al.* (7) used the two-phase transfer cell to investigate this transport for monovalent cations *in vitro*.

The three-phase transfer cell used (2) to study water diffusion and the transport of various salts through interfaces was modified by Perrin (8). It was used to study the transfer of solutes from an aqueous compartment of pH 2 through a lipid membrane to a second aqueous compartment at pH 7.4 to simulate gastric absorption of salicylic acid and aminopyrine. Doluisio and Swintosky (9) mimicked *in vivo* conditions using a three-phase rocking Y-tube apparatus in which the interfacial area available for drug transfer varied with respect to time. Correlations between *in vivo* drug absorption data and *in vitro* rate constants for three-phase transfer (where the pH of the aqueous compartments was varied) were also attempted for a series of sulfonamides (10).

Neither the solvent system nor the stirring arrangement associated with the respective phases of two- or three-phase transfer cells is standardized in the literature. This situation presents a problem when attempting to compare results among studies. Indeed, it was observed (11) that both the magnitude and rank order of the rate constants for drug transfer are significantly dependent on the design of the cell and the agitation conditions used.

This study demonstrates how the transport kinetics of a series of homologs may be successfully predicted from a knowledge of the transfer kinetics of the lead compound, its partition coefficient, the partition coefficients of the remaining homologs, and some simply determined system-dependent parameters in a symmetrically stirred two-phase transfer cell of known dimensions.

## THEORY

Byron *et al.* (12) used a two-phase transfer cell, containing equal volumes of a preequilibrated aqueous phase and light liquid petrolatum (Fig. 1), to study the kinetics of interfacial transport of a model solute (cyclohept-2-enone) in the presence and absence of competing degradation in the aqueous phase. Their results supported the validity of the two-film theory (3) with assumptions of no significant interfacial resistance, no thermal, electrical, and osmotic gradients, and steady-state diffusion in the two-phase transfer cell. Values for the ratio of the forward and reverse first-order rate constants for the partitioning process ($k_{12}/k_{21}$, Scheme I) from kinetic analysis agreed with equilibrium studies to determine the partition coefficient $K_D$. Thus, the cell (Fig. 1) was shown to conform kinetically to Scheme I when the stirring speed remained constant, provided that the partition coefficient of the compound was concentration independent over the concentration range studied and the compound was stable for the duration of the experiment.

The concentration $C_1$ of the solute in the donor aqueous phase was described by:

$$(C_1 - C_1^\infty) = (C_1^0 - C_1^\infty)\, e^{-(k_{12}+k_{21})t} \qquad \text{(Eq. 1)}$$

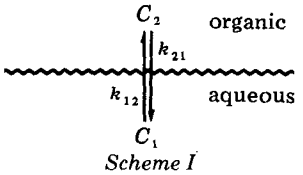
where $C_1 = C_1^0$ and $C_2 = 0$ at time $t = 0$, $C_1^\infty$ is the equilibrium concentration of the aqueous phase, and $k_{12}$ and $k_{21}$ are the first-order forward and reverse rate constants for the transfer process. Thus, a plot of $\ln(C_1 - C_1^\infty)$ *versus* time is linear with a negative slope $S$, defined by the sum of the forward and reverse rate constants ($k_{12} + k_{21}$) in Scheme I.

The partition coefficient ($K_D$) may be determined either by kinetic analysis (12) or equilibrium studies from:

$$K_D = k_{12}/k_{21} = C_2^\infty/C_1^\infty \qquad \text{(Eq. 2)}$$

where $C_2^\infty$ and $C_1^\infty$ are the equilibrium concentrations in the organic and aqueous phases, respectively. When a transfer experiment conforms to Scheme I, Eq. 1 may be rewritten in terms of $K_D$, $C_1^0$, and the observed first-order rate constant, $S$ ($= k_{12} + k_{21}$), by substituting for $C_2^\infty = (C_1^0 - C_1^\infty)$ in Eq. 2 and $C_1^\infty$ in Eq. 1 and rearranging to give:

$$C_1 = [C_1^0/(K_D + 1)][K_D e^{-St} + 1) \qquad \text{(Eq. 3)}$$



*Scheme I*

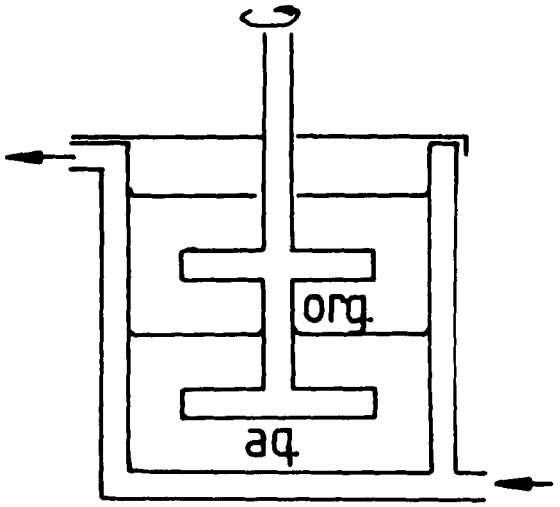

**Figure 1**—*Two-phase transfer cell with symmetric stirring.*

Equation 3 defines the $C_1$ *versus* time profile in the two-phase transfer cell given the aqueous donor phase concentration at $t = 0$, the partition coefficient, and the sum of the forward and reverse rate constants for the partitioning process.

Assuming the validity of the two-film theory (3) and Fick's first law of diffusion, Byron *et al.* (12) showed that the sum of the forward and reverse first-order rate constants in the two-phase transfer cell should be described by:

$$(k_{12} + k_{21}) = S = \frac{D_1 D_2 A(K_D V_2 + V_1)}{V_1 V_2 (D_2 K_D h_1 + D_1 h_2)} \quad \text{(Eq. 4)}$$

where subscripts 1 and 2 refer to the aqueous and organic phases, respectively, and $S$ is dependent on the solute diffusion coefficients ($D$), the phase volumes ($V$), the diffusion boundary layer thicknesses at the interface ($h$), and the solute partition coefficient ($K_D$). It follows from Eq. 4 that, if this theory and its assumptions hold true for the two-phase transfer cell given $D_1$, $D_2$, $V_1$, $V_2$, $h_1$, $h_2$, $A$, and $K_D$, the $C_1$ *versus* time profile could be predicted theoretically from Eq. 3 if an initial solute concentration $C_1^0$ were assumed.

The partition coefficients ($K_D$) of solutes in specified solvent systems at fixed temperature may be determined empirically. Alternatively, $K_D$ can be predicted for unsynthesized analogs (13, 14) from a knowledge of the partition coefficient of a lead compound and its substituents. In a transfer cell, the interfacial area and phase volumes may be kept constant throughout the experiment. The dependence of $S$ on $K_D$ (Eq. 4) for a given solvent system in the transfer cell at fixed stirring speed, however, still necessitates accurate theoretical prediction of $D_1$, $D_2$, $h_1$, and $h_2$. Theoretical predictions of absolute values for these parameters is problematic. Moreover, they will determine the nonlinear dependence of $S$ on $K_D$ and, thus, the changes in $C_1$ *versus* $t$ profiles (Eq. 3) that may be expected when an homologous series is ascended.

**Prediction of Diffusion Coefficients**—The Stokes–Einstein relationship (15) predicts the diffusion coefficient ($D_{AB}$) of a diffusing solute ($A$) in a specified solvent ($B$) as:

$$D_{AB} = \frac{RT}{6\pi\eta a N_A} \quad \text{(Eq. 5)}$$

where the coefficient is a function of the gas constant ($R$), the absolute temperature ($T$), Avogadro's number ($N_A$), the viscosity of $B$, $\eta$, and the radius ($a$) of the diffusing solute molecule. Whereas Eq. 5 has been shown to break down for solutes with molecular weights significantly less than 1000 (16), Wilke and Chang (17) developed Eq. 6 to predict $D_{AB}$ for solutes in dilute solution. The Wilke equation:

$$D_{AB} = (7.4 \times 10^{-10})\,(\psi_B M_B)^{1/2} T/(\eta \bar{V}_A^{0.6}) \quad \text{(Eq. 6)}$$

is empirical, although it is based on Eq. 5. Experimental determinations of $D_{AB}$ for numerous low molecular weight solutes ($A$) in various solvents ($B$) fall within 10% of the values predicted by Eq. 6 (17, 18). Equation 6 is written in the centimeter-gram-second system and takes into account the associating tendencies of the solvent molecules as an association parameter ($\psi_B$), their molecular weight ($M_B$), and replaces the molecular radius (Eq. 5) with $\bar{V}_A$, the molar volume of the solute (A) in cm$^3$/mole as a liquid at its normal boiling point. Typical solvent association parameters ($\psi_B$) were listed by Wilke and Chang (17).

**Prediction of Boundary Layer Thicknesses for Diffusion at Interface**—The boundary layer theory first introduced by Prandtl (19) and extended by Schlichting (20) assumes a condition of "no slip" at a solid–liquid or immiscible liquid–liquid interface due to molecular adhesion. This approach introduced the concept of a stagnant layer adjacent to an interface, where fluids are observed to behave in a nonideal fashion. If the velocity profile in one phase of the two-phase transfer cell is considered, then, provided a horizontal plane (Fig. 1) in the fluid adjacent to the stirring paddle approximates a rotating disk, Schlichting's boundary layer theory (21) predicts that the angular velocity of the fluid ($\omega$) is directly proportional to the kinematic viscosity of the fluid, $\nu(=\eta/\rho$, where $\rho$ is density), and inversely proportional to the square of the distance from the paddle ($x^2$) in the vertical direction (Fig. 1). Thus

$$\omega \propto \nu/x^2 \quad \text{(Eq. 8)}$$

such that $\omega$ will asymptotically approach zero as $x^2 \to \infty$. Moreover, it follows from Eq. 8 that in the case of symmetric stirring in a two-phase transfer cell:

$$\omega_1/\omega_2 = \nu_1/\nu_2 \quad \text{(Eq. 9)}$$

where subscripts 1 and 2 refer to the aqueous and organic phases, respectively. Equation 9 can be derived by writing Eq. 8 for each phase of the symmetrically stirred transfer cell and holding the distance $x$ from the stirring paddle constant, such that $0 < x_1 = x_2 < x_i$, where $x_i$ is the distance between the stirring paddle and the interface. It follows from Eq. 9 that for two immiscible solvents of different kinematic viscosities (Fig. 1), one solvent must move relative to the other under conditions of symmetric stirring where the angular velocities of both paddles are equal and constant.

Thus, when the condition of no slip is assumed at the interface, the bulk of the aqueous phase may be conceptualized as a disk with angular velocity ($\omega$) rotating relative to a stationary organic phase or as an organic phase with angular velocity ($-\omega$) rotating relative to a stationary aqueous phase. Schlichting's original work was based on the estimation of the boundary layer thickness as the distance from an interface required to enable the velocity of the fluid under consideration to approach that of the bulk. Marked differences occur in the types of equations used, dependent on whether velocity, thermal, or diffusive boundary layer thicknesses are to be calculated. Levich (22) introduced an equation, based on Schlichting's work, permitting the prediction of the boundary layer thickness for diffusion adjacent to a rotating-disk electrode in a stationary fluid. Levich's equation was shown to hold true for systems of the type depicted in Fig. 1 (23) and can be written for $h_1$ and $h_2$ (Eq. 4) such that:

$$h_1 = 1.62(D_1/\nu_1)^{1/3}(\nu_1/\omega)^{1/2} \quad \text{(Eq. 10)}$$

and

$$h_2 = 1.62(D_2/\nu_2)^{1/3}(\nu_2/\omega)^{1/2} \quad \text{(Eq. 11)}$$

where $\omega$ is the angular velocity of one phase relative to the other.

Prediction of absolute values for $D_1$ and $D_2$ and $h_1$ and $h_2$ remains problematic. The dimensionless ratios of the diffusion coefficients ($D_1/D_2$) and the diffusive boundary layer thicknesses ($h_1/h_2$) in the aqueous and organic phases, however, may be determined by writing Eq. 6 for $D_1$ and $D_2$ and solving for the quotient $D_1/D_2$, assuming $T$ is constant, such that:

$$D_1/D_2 = (\eta_2/\eta_1)[(\psi_1 M_1)/(\psi_2 M_2)]^{1/2} \quad \text{(Eq. 12)}$$

and dividing Eq. 10 by Eq. 11 to give

$$h_1/h_2 = (D_1/D_2)^{1/3}(\nu_1/\nu_2)^{1/6} \quad \text{(Eq. 13)}$$

Solving Eqs. 12 and 13 for $D_2$ and $h_2$ and substituting in Eq. 4 give:

$$S = [(D_1 A)/(V_1 h_1)]\{R_1(K_D + r)/[R_1 K_D + (R_1)^{1/3}(R_2)^{1/6}(\psi_1 M_1)^{1/3}(\psi_2 M_2)^{-1/3}]\} \quad \text{(Eq. 14)}$$

where $R_1 = \eta_1/\eta_2$, $R_2 = \nu_2/\nu_1$, and $r = V_1/V_2$. Equation 14 is now in a form that enables the prediction of the sum of the forward and reverse first-order rate constants ($k_{12} + k_{21}$) in Scheme I for any compound in an homologous series, provided that $S$ and $K_D$ are known for the parent compound. $K_D$ can be predicted for each compound under consideration, while the solvent system-dependent constants $R_1$, $R_2$, $r$, $\psi_1$, $\psi_2$, $M_1$, and $M_2$ may be determined easily.

The term $(D_1 A)/(V_1 h_1)$ must first be estimated experimentally for the system under consideration from a knowledge of the transfer kinetics

of the parent compound. This estimation can be made by rearranging Eq. 14 to give:

$$(D_1A)/(V_1h_1) = \{S[R_1K_D + (R_1)^{1/3}(R_2)^{1/6}(\psi_1M_1)^{1/3} (\psi_2M_2)^{-1/3}]\}/[R_1(K_D + r)] \quad \text{(Eq. 15)}$$

Viscometry and densitometry measurements on the mutually saturated binary solvent system under investigation (constant temperature) yields $R_1$ and $R_2$. The phase ratio ($r$) and molecular weights of the solvents ($M_1$ and $M_2$) are known. Wilke (17) quoted values for the association parameters $\psi_1$ and $\psi_2$, recommending values of 2.6 for water, 1.9 for methanol, 1.5 for ethanol, and 1.0 for benzene, ether, heptane, and other unassociated solvents.

The partition coefficient ($K_D$) may be determined experimentally from $C_2^\infty/C_1^\infty$ for the parent compound. The initiation of a transfer experiment by introduction of a bolus of the parent solute into the aqueous donor phase of the transfer cell and the study of its transfer kinetics at fixed temperature and stirring speed enable estimation of $S(=k_{12} + k_{21})$ according to Eq. 1. The term $(D_1A)/(V_1h_1)$ may then be determined from Eq. 15.

With fixed stirring conditions, constant temperature, and constant $V_1$, $A/(V_1h_1)$ should be independent of the solute under consideration. Moreover, it was shown (15) that the diffusion coefficients of nonassociated solutes change insignificantly within a homologous series because:

$$D \propto 1/\sqrt[3]{M_s} \quad \text{(Eq. 16)}$$

where $M_s$ is the molecular weight of the solute. The term $(D_1A)/(V_1h_1)$ can thus be considered constant within a homologous series once estimated under defined conditions for the parent compound in the two-phase transfer cell. Therefore, Eq. 14 can be used to calculate $S$ as a function of $K_D$ within a homologous series.

Given the theoretical estimation of $K_D$ for unsynthesized compounds the prediction of partitioning kinetics should be possible without exhaustive experiments. This theory was evaluated experimentally using a series of barbituric acid derivatives.

## EXPERIMENTAL

**Determination of $S$ for a Series of 5,5-Disubstituted Barbituric Acid Derivatives**—Transfer kinetics were studied for a series of 5,5-disubstituted barbituric acid derivatives (Table I) in the two-phase transfer cell shown in Fig. 1. The drugs in concentrations of $\sim 1.3 \times 10^{-4}$ $M$ were introduced as solutes into the donor aqueous phase. The cell used contained preequilibrated octan-1-ol[1] and 0.06 $M$ Sorensen's buffer (pH 5.0) (24). Preequilibration was effected by stirring for >6 hr prior to solute introduction. Phase volumes were kept constant such that $V_1 = V_2$, 90 ml ($r = 1$). During the transfer experiments, the phases were stirred[2] symmetrically (Fig. 1) with a 4-cm diameter stirring paddle positioned 1 cm from the interface in each phase, rotating at 50 or 100 (±0.5) rpm. The circular glass cell was 6.75 cm i.d.

The aqueous phase was pumped[3] through a flowcell in a spectrophotometer[4]. The concentration in the donor phase ($C_1$) was continuously monitored by automatically recording[5] the absorbance as a function of time at 222.5 nm (the isosbestic point for all the compounds) until equilibrium was attained. Control experiments monitoring 222.5 nm absorbance in the absence of the organic phase showed that Compounds I–VI were stable for the time course of a kinetic determination. Equilibrium partition coefficients determined at 37° were concentration independent in the range employed during the kinetic experiments. Plots based on Eq. 1 of $\ln(C_1 - C_1^\infty)$ *versus* $t$ were linear for >95% of the process. The terminal slope ($S$) was determined in each case by linear regression analysis.

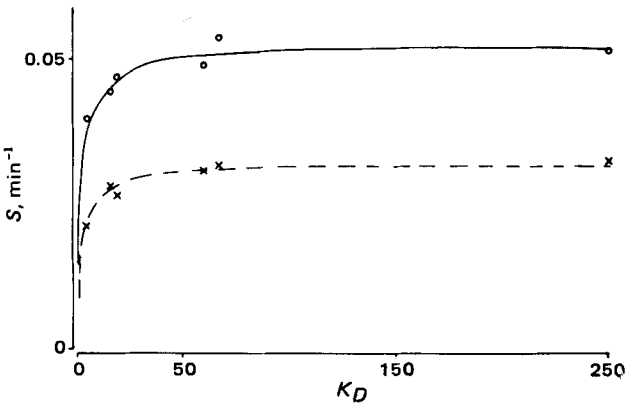

**Figure 2**—*Dependence of* S (=$k_{12}$ + $k_{21}$) *(Eq. 1; Scheme I), on* $K_D$ *for I–VI (Table I) at 50 (X) and 100 (O) rpm at 37°. The dashed (50 rpm) and solid (100 rpm) profiles are theoretical curves based on Eq. 14 after calculation of* ($D_1A$)/($V_1h_1$) *from Eq. 15.*

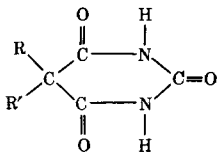
**Table I—Structures, Molecular Weight, pKa Values and Source of Barbituric Acid Derivatives Used in the Study**



| Compound | R | R′ | Molecular Weight | pKa[a] (25°) | Source |
|---|---|---|---|---|---|
| I | $CH_3CH_2$– | $CH_3$—$CH_2$– | 184.20 | 7.91 | [b] |
| II | $CH_2$=$CHCH_2$– | $CH_3CH$(–$CH_3$) | 210.23 | 7.91 | [c] |
| III | $CH_2$=$CHCH_2$– | $CH_3CHCH_2$(–$CH_3$) | 224.25 | 7.68 | [c] |
| IV | $CH_2$=$CHCH_2$– | $CH_3CH_2CH$(–$CH_3$) | 224.25 | | [d] |
| V | $CH_2$=$CHCH_2$– | $CH_3(CH_2)_2CH$(–$CH_3$) | 238.27 | 8.08 | [c] |
| VI | $CH_2$=$CHCH_2$– | $CH_2$=$CHCH_2$– | 208.21 | 7.79 | [c] |

[a] Reference 25. [b] Hopkins and Williams, Essex, England. [c] Ganes Chemical Works, Carlstadt, N.J. [d] Sterling-Winthrop Research Institute, Rensselaer, N.Y.

**Partition Coefficients**—Values of $K_D$ were estimated in triplicate by equilibrating I–VI at 37° in the solvent system previously defined. The phase ratio ($r$) was adjusted such that concentrations in the aqueous phase gave $0.1 < (\text{Abs})_{222.5\text{ nm}} < 0.9$, and $K_D$ was calculated from:

$$K_D = [(C_1^0 - C_1^\infty)r]/C_1^\infty \quad \text{(Eq. 17)}$$

where $C_1^0$ and $C_1^\infty$ are the initial and final concentrations in the aqueous phase.

**Viscometry and Densitometry**—The viscosities and densities of mutually saturated octan-1-ol and 0.06 $M$ Sorenson's buffer (pH 5.0) were determined in replicate relative to water at 37° using an Ostwald U-tube viscometer and a 10-ml specific gravity bottle. Mean values for $\eta$ and $\rho$ enabled estimation of $R_1$ and $R_2$ (Eq. 14).

**Dependence of Transfer Kinetics on $K_D$**—Values for the ratios $R_1$ and $R_2$ were determined as previously described. Molecular weights $M_2$ and $M_1$ for preequilibrated octan-1-ol and 0.06 $M$ Sorenson's buffer (pH 5.0) were assumed to be 130.23 and 18.02, respectively, as if they were pure octanol and water. The association parameters $\psi_1$ and $\psi_2$ were assigned values of 2.6 and 1.0 (17). Values for $S$ were determined from experimental data for $C_1$ *versus* $t$ for each compound at both stirring speeds. Plots of $\ln(C_1 - C_1^\infty)$ *versus* $t$ were subjected to linear regression analysis to determine the value of the linear negative slope $S(=k_{12} + k_{21})$ according to the logarithmic form of Eq. 1. Values for the coefficient $(D_1A)/(V_1h_1)$ were calculated for I–VI based on $r = 1$ and their experimentally determined values for $S$ at 50 and 100 rpm using Eq. 15. Thus, two mean values for the coefficient were calculated at the different stirring speeds. The theoretical dependence of $S(=k_{12} + k_{21})$ on $K_D$ was determined for the octan-1-ol buffer system at 37° using Eq. 14. Calculated values for $S$ were compared to those determined experimentally for I–VI.

[a] Table I. [b] Observed, mean of three determinations. [c] Equation 14; expressed in $min^{-1} \times 10^2$. [d] ($k_{12} + k_{21}$) based on kinetic analysis (Eq. 1) ($min^{-1} \times 10^2$). [e] 100 ($S_{th} - S_{obs}$)/$S_{obs}$.

## RESULTS

**Determination of $S$ for a Series of 5,5-Disubstituted Barbituric Acid Derivatives**—Plots of $\ln(C_1 - C_1^\infty)$ *versus* $t$ based on Eq. 1 were linear for >95% of the partitioning process for each compound studied at either 50 or 100 rpm. Observed terminal slopes, $S_{obs}$ ($=k_{12} + k_{21}$), are documented in Table II after determination for each of the derivatives of I–VI by linear regression (correlation coefficient $r > 0.99$, $n > 10$).

**Partition Coefficients**—Partition coefficients as mean values from triplicate determinations for I–VI at 37° in the solvent system previously described are shown in Table I, these values are based on Eq. 17, with an experimental deviation from the mean of <8%.

**Viscometry and Densitometry**—Mean viscosity and density values of the aqueous and organic phases used in the study were determined as $0.7005 \times 10^{-2}$ and $4.806 \times 10^{-2}$ poise and 1.0017 and 0.8148 g/ml, respectively, at 37°.

**Dependence of Transfer Kinetics on Partition Coefficient**—Mean values for the coefficient $(D_1A)/(V_1h_1)$ were determined for I–VI as $3.21 \times 10^{-2}$ ($\pm 0.13 \times 10^{-2}$) and $5.26 \times 10^{-2}$ ($\pm 0.21 \times 10^{-2}$) $min^{-1}$ at 50 and 100 rpm, respectively (Eq. 15). The dashed and solid curves of $S$ *versus* $K_D$ in Fig. 2 were generated using Eq. 14 for the octanol buffer system with $(D_1A)/(V_1h_1)$ held constant at these mean values for 50 and 100 rpm. They show the theoretical dependence of the sum of the forward and reverse rate constants $k_{12}$ and $k_{21}$ (Scheme I) on the equilibrium partition coefficient $K_D$. Experimental determinations of $S$ ($=k_{12} + k_{21}$), determined by kinetic analysis of $C_1$ *versus* $t$ profiles for I–VI at the two stirring speeds (from data anlysis using Eq. 1), are shown. The percentage error involved when determining $S$ from Eq. 14 ($S_{th}$) as opposed to experimentally in the two-phase cell ($S_{obs}$) at either stirring speed is shown in Table II to be ≤8%. Table II summarizes these errors and the values of $S_{th}$, $S_{obs}$, and $K_D$ at 50 and 100 rpm for I–VI.

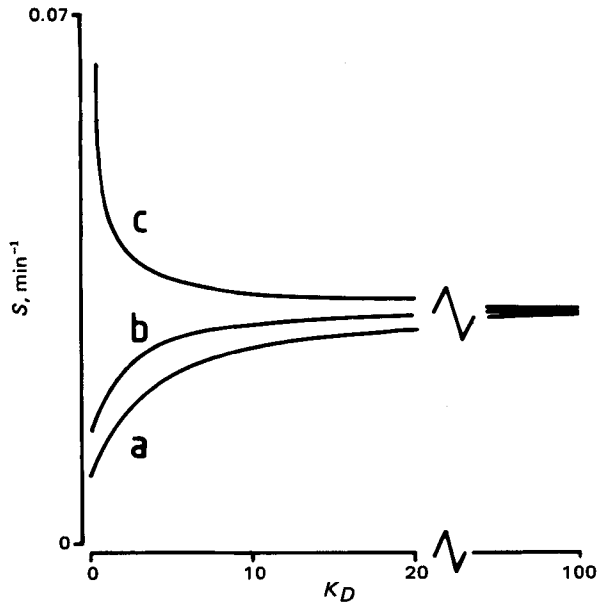

**Figure 3**—*Theoretical dependence of* S *on* $K_D$ *(Eq. 14) in the two-phase transfer cell at 50 rpm for (a) the octanol–aqueous system used in this study, (b) a butanol–aqueous system at 35°, and (c) a chloroform–aqueous system at 35°. The values of the coefficient* $(D_1A)/(V_1h_1)$ *and* r *were held constant at* $3.21 \times 10^{-2}$ $min^{-1}$ *and 1, respectively. Association parameters* ($\psi$) *were assigned values of 2.6, 1.0, 1.0, and 1.0 for water* (M = *18.02), octanol* (M = *130.23), butanol* (M = *74.12), and chloroform* (M = *119.38), respectively (17). The profile a was generated with* $R_1 = 0.149$ *and* $R_2 = 8.435$, *their experimentally determined values. For curves b and c, literature values (28, 29) were utilized for the pure solvents such that* $R_1 = 0.340$ *and 1.430 and* $R_2 = 3.522$ *and 0.480 for butanol–water and chloroform–water systems, respectively.*

## DISCUSSION

The theory describing the dependence of the sum of the forward and reverse first-order rate constants ($S$) in Scheme I on $K_D$ was derived in this study for solutes introduced into a donor phase of a stirred transfer cell (Eq. 14). For this theory to hold true, the solute must conform to Scheme I and neither dissociate nor associate in the organic or aqueous phases at experimental concentrations. An aqueous buffer (pH 5.0) was chosen to ensure that the barbituric acid derivatives were insignificantly ionized (<1%) in the aqueous phase of the cell, provided the pKa values quoted in Table I at 25° were ≥7 at 37°. These studies showed that the partition coefficients of I–VI varied insignificantly with concentration in the experimental ranges. This finding agrees with previous observations (26). Therefore, it was unlikely that these compounds existed significantly as other than unionized monomers in either phase.

The validity of the two-film theory in the two-phase transfer cell was established previously (1, 12). Experimental conditions were chosen such that both phases were mutually saturated, and the transfer cell was maintained at 37° to eliminate temperature gradients. Evaporation of water *via* diffusion through the upper organic layer was minimized by covering the cell and was negligible during 24 hr at 37°. The adequacy of Eqs. 1 and 3 in describing the experimental data, together with the absence of a visible lag time, implies rapid achievement of steady-state diffusion conditions in the transfer cell. The assumption of steady-state diffusion is involved in the derivation of Eq. 4. Similarly, the agreement between the continuous data for $C_1$ *versus* $t$ and Eqs. 1 and 3 supports the assumption of an effectively constant interfacial area, $A$, at both 50 and 100 rpm.

The remaining assumptions necessary to develop this theory and Eq. 14 require that solvent flow in each phase is essentially laminar (low Reynold's number) and that the bulk of the organic phase rotates in relation to the bulk of the aqueous phase. This approach enabled prediction of the dimensionless term $h_1/h_2$ by assuming the validity of the Levich equation (Eqs. 10 and 11) and the existence of symmetric stirring. Similarly, the validity of Wilke's equation (Eq. 6) and his solvent association parameters, $\psi_B$, were necessary for determination of $D_1/D_2$. Wilke's equation for low molecular weight nonassociating solute molecules in dilute solution enabled calculation of $(\psi_1 M_1)^{1/3}(\psi_2 M_2)^{-1/3}$ for use in Eqs. 14 and 15. The absence of significant interfacial resistance, osmotic gradients, effective constancy of diffusion coefficients within a series of drug derivatives, and the validity of these latter assumptions can only be verified by testing the dependence of $S$ on $K_D$ and by comparing the theory to empirical observations.

Figure 2 and Table II show the theoretical and experimental dependence of $S$ ($=k_{12} + k_{21}$) (Scheme I) on $K_D$ for I–VI in an octanol–aqueous system at 37°. The excellent agreement between experiment and theory (theoretical prediction of $S$ varies <8% from empirical determinations, Table II) demonstrated the validity of the assumptions for the two-phase transfer cell. Moreover, Fig. 2 and Eq. 14 demonstrate clearly how the transport kinetics of a series of drug analogs may be predicted from a knowledge of the transport kinetics of the parent compound and its partition coefficient. Given either experimental determination of the partition coefficient of subsequent analogs or its theoretical prediction for even unsynthesized compounds (13, 14), a single estimation

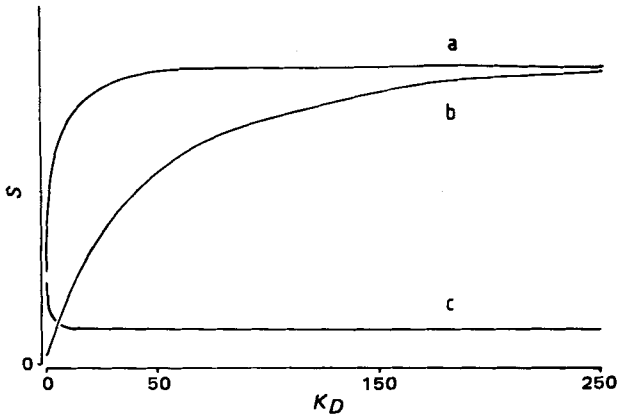

**Figure 4**—*Theoretical dependence of* S *on* $K_D$ *(Eq. 4) for conditions of symmetric (a) and asymmetric (b and c) stirring in an octanol–aqueous system at 37° in the two-phase transfer cell. The ratio of boundary layer thicknesses for diffusion,* $h_1/h_2$*, were varied such that* $h_1/h_2 = 1.12$ *(curve a; the present study with symmetric stirring), 0.1 (curve b), and 10 (curve c). Other variables were held constant (see text).*

of $(D_1A)/(V_1h_1)$ (Eq. 15), after determination of $R_1$, $R_2$, $r$, and $(\psi_1M_1)^{1/3}(\psi_2M_2)^{-1/3}$, is possible from kinetic analysis for $S$ $(=k_{12} + k_{21})$ (Eq. 1) for the parent compound in the transfer cell. The agreement between theory (Eq. 14) and experiment (Fig. 2) demonstrates that the $(D_1A)/(V_1h_1)$ estimate (Eq. 15) applies to the entire series at a fixed stirring rate. Therefore, once the system is defined, the dependence of $S$ on $K_D$ can be evaluated. Prediction of $C_1$ *versus* $t$ profiles for the remaining compounds in the series thus is possible for a given donor phase concentration at $t = 0$, $C_1^0$, using Eq. 3.

**Variation of Solvent Systems and Stirring Conditions**—Neither the solvent systems nor the stirring conditions associated with the two-phase transfer cells documented in the literature were standardized. Gordon and Sherwood (1) employed an aqueous–butanol system while Zecchi *et al.* (6) used benzene as the organic phase. Symmetric (27) and asymmetric (1) stirrers also were described. The dependence of transfer kinetics on $K_D$ in systems containing either various organic phases or asymmetric stirring methods will be different from that shown in Fig. 2 for the symmetrically stirred aqueous–octanol system.

Values for the solvent system dependent variables $R_1$, $R_2$, $\psi_1$, $\psi_2$, $M_1$, and $M_2$ were obtained for butanol–water and chloroform–water systems at 35° (17, 28, 29) and are documented (Fig. 3). The coefficient $(D_1A)/(V_1h_1)$ was held constant at $3.21 \times 10^{-2}$ min$^{-1}$. The theoretical dependence of $S$ on $K_D$ for these two systems with symmetric stirring and $r = 1$ is shown in Fig. 3 according to Eq. 14. The theoretical curve for the octanol–aqueous system used in the present study is shown for comparison. Although $K_D$ is itself a function of the solvent system employed, at a given $K_D$ value in Fig. 3 the gradient $dS/dK_D$ may be positive, negative, or zero, depending on the solvent system employed. This behavior disproves the often stated assumption that $S$ values are proportional to $K_D$ values.

To determine the effect of asymmetric stirring on the dependence of $S$ on $K_D$ for a given solvent system, it is necessary to solve Eq. 12 for $D_2$ and to substitute in Eq. 4. The value for the ratio $D_1/D_2$ was maintained at 4.032, its calculated value from Eq. 12 for the aqueous–octanol system at 37°. The phase volumes $V_1$ and $V_2$ were held constant and equal. Equation 4 was used to determine the dependence of $S$ on $K_D$ for $h_1/h_2 = 1.12$ (the ratio for symmetric stirring in the aqueous–octanol system at 37°), 0.1, and 10.0. Figure 4 illustrates the likely effect of asymmetric stirring where $h_1/h_2$ would be expected to change on the resultant dependence of $S$ on $K_D$ for a specified solvent system at fixed temperature. The gradient $dS/dK_D$ at a fixed $K_D$ value may be positive, negative, or zero, depending on the stirring conditions employed.

The results from extrapolation of the present theory are shown in Figs. 3 and 4. Studies are in progress to test these extrapolations experimentally in appropriate systems. These implications are fundamental to transport kinetic studies employing two- or three-phase transfer cells. Augustine and Swarbrick (10) used a three-phase transfer cell to rank a series of compounds dependent on a parameter proportional to $k_{12}$ (Scheme I). Other investigators (9) attempted to discriminate between compounds on the basis of their partitioning kinetics. However, it is clear from Figs. 3 and 4 that such a procedure in an unstandardized transfer cell is nothing more than a study of solvent systems and stirring paddles, provided that the present theory is correct. The observation (Figs. 3 and 4) that $dS/dK_D$ may be positive, negative, or zero at fixed $K_D$ means that $S$ $(=k_{12} + k_{21})$ and, therefore, $C_1$ *versus* $t$ profiles for a series of compounds may be ranked merely by the experimental solvent and stirring conditions.

The choice of solvent is a subject for debate in that the solvent system itself defines the partition coefficient of the compounds studied. The use of asymmetric stirring in two- and three-phase cells however, necessitates the absolute estimation of individual values for $h_1$ and $h_2$ (Eq. 4). Absolute boundary layer thicknesses can only be approximated (20). The dependence of $S$ on $K_D$ must be established empirically under asymmetric stirring conditions. The theoretical approach described in this paper, which is only applicable to symmetric stirring, utilizes the dimensionless ratio $h_1/h_2$ in the derivation of Eq. 14, which predicts the kinetics of transfer as a function of $K_D$.

# Pharmacokinetics of Isosorbide Dinitrate in Rhesus Monkey, Cynomolgus Monkey, and Baboon

**E. DOYLE ˣ and L. F. CHASSEAUD**

Received August 8, 1980, from the *Department of Metabolism and Pharmacokinetics, Huntingdon Research Centre, Huntingdon, PE18 6ES, England.* Accepted for publication May 18, 1981.

**Abstract** □ At 2 min after intravenous injection of isosorbide dinitrate (1 mg/kg), mean plasma drug concentrations were 565 ± 66 (*SD*), 586 ± 43, and 1572 ± 253 ng/ml in the rhesus monkey, cynomolgus monkey, and baboon, respectively. Following a relatively short distribution phase, mean plasma concentrations declined with half-lives of 62, 23, and 24 min in these three species, respectively. The time course of plasma concentrations could be described by a two-compartment open model, although a one-compartment open model was adequate for obtaining some pharmacokinetic parameters. Statistically significant differences among the species were observed in areas under the plasma concentration–time curves, plasma half-lives, and volumes of distribution. The pharmacokinetics of isosorbide dinitrate in baboons most closely resembled those in humans.

**Keyphrases** □ Isosorbide dinitrate—pharmacokinetics, intravenous administration compared in nonhuman primates □ Pharmacokinetics—isosorbide dinitrate, intravenous administration compared in nonhuman primates □ Vasodilators—isosorbide dinitrate, pharmacokinetics compared in nonhuman primates

Isosorbide dinitrate, an organic nitrate vasodilator, has been in clinical use for many years (1–3). This lipophilic drug is almost completely eliminated by biotransformation, being rapidly denitrated (4, 5) by the glutathione *S*-transferases (EC 2.5.1.18) (6). The urinary metabolites of isosorbide dinitrate in animals (7–10) and humans (11, 12) are the corresponding isomeric mononitrates and isosorbide, which are excreted free and probably partly conjugated with glucuronic acid. Sorbitol has also been shown to be a urinary metabolite of isosorbide dinitrate in humans (11).

Little has been reported of the pharmacokinetics of the drug in animals, probably because of the difficulty in measuring it in plasma; most early data were obtained using [$^{14}$C]isosorbide dinitrate. The recent development of adequately sensitive analytical methods now permits studies of the drug's pharmacokinetics in humans (13–15).

The present study evaluated the pharmacokinetics of isosorbide dinitrate in nonhuman primates.

## EXPERIMENTAL

**Materials**—Isosorbide dinitrate[1] solutions suitable for intravenous injection were prepared by dissolving the drug in aqueous 10% (v/v) ethanol. Solutions of nitroglycerin, 1% (w/v) in ethanol, were obtained commercially[2] and used as the internal standard.

**Animals**—Five female animals of each nonhuman primate species, ~1.5–3 years of age, were obtained commercially and maintained under conditions described previously (16). Animal body weights ranged as follows: rhesus monkey, 4–6 kg; cynomolgus monkey, 3–4 kg; and baboon, 4.5–7 kg.

**Dosage**—The animals were fasted for ~16 hr before and 7 hr after dosing, but water was provided at all times. Isosorbide dinitrate solution (1 mg/kg) was injected within 5 sec into a cephalic vein. This dose level was selected as one that might be used in chronic toxicity studies of the drug by this route. In humans, doses of 12.5 mg of isosorbide dinitrate have been infused during 2.5 hr (15).

Blood samples (2.5 ml) were withdrawn from a femoral vein before dosing and at 0.03, 0.08, 0.17, 0.33, 0.50, 0.75, 1.0, 1.5, 2.0, 3.0, and 4.0 hr (4.5 hr in the rhesus monkey) after dosing. The blood was taken into heparinized tubes, cooled in ice-cold water after mixing, and rapidly centrifuged to remove cells, which then were discarded. The plasma was stored at −20° until assayed. Isosorbide dinitrate is stable in plasma under these conditions.

**Drug Analysis**—Isosorbide dinitrate concentrations were measured in plasma by the electron-capture gas chromatographic procedure of Doyle *et al.* (17). Standard curves were prepared for three concentration ranges. Some analytical parameters are shown in Table I.

**Data Processing**—A two-compartment open model was fitted[3] to the plasma isosorbide dinitrate concentration–time data using a nonlinear least-squares curve fitting program (16). This program fits a curve to the observed data and selects a model by comparing the relative sizes of the initial and terminal phases, $\alpha$ and $\beta$, but does not allow user-defined selection of a model. A one-compartment model was fitted to the data as a possible alternative to a two-compartment model by normal regression techniques.

The criteria used to assess the data fit (obs = observed, exp = expected) from each species were: coefficient of determination, $r^2 = (G - R)/R$, where $G = \Sigma (\text{obs} - \overline{\text{obs}})^2$ and $R = \Sigma (\text{obs} - \text{exp})^2$; and residual mean square, $R/(n - 1 - p)$, where $n$ is the number of observations and $p$ is the number of parameters fitted (four parameters for a two-compartment model and two parameters for a one-compartment model). The average coefficients of determination ($r^2$) obtained were 0.9852, 0.9801, and 0.9925 in the two-compartment model and 0.9331, 0.9772, and 0.9885 in the

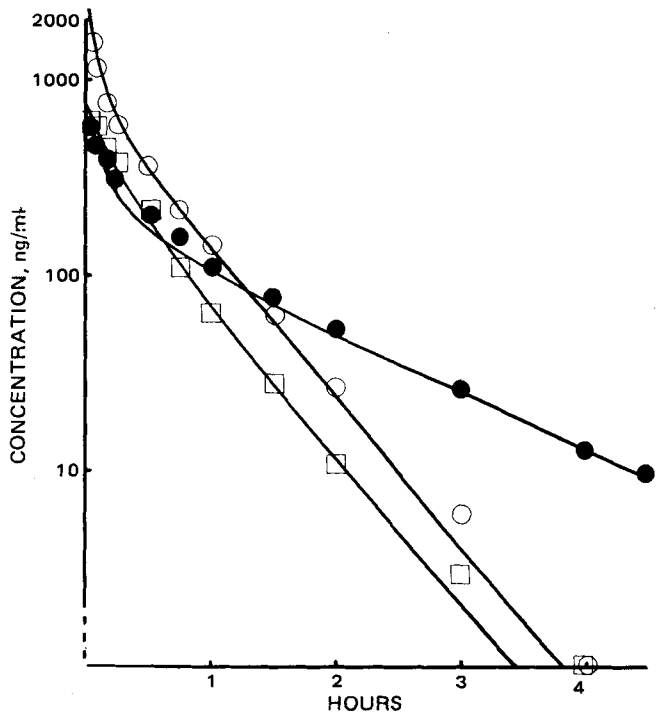

**Figure 1**—*Observed plasma concentrations of isosorbide dinitrate after a single 1.0-mg/kg iv dose to rhesus monkeys (●); cynomolgus monkeys (□); and baboons (○). Solid lines show computer-estimated concentrations.*

**Table I—Analytical Parameters for the Measurement of Isosorbide Dinitrate in the Plasma of Nonhuman Primates**

| Parameter | Concentration Range 0–10 ng/ml | 10–250 ng/ml | 100–1000 ng/ml |
|---|---|---|---|
| Regression line[a] (± *SD*) | $Y = (0.079 \pm 0.001)X$ | $Y = 0.003X - 0.028$ | $Y = 0.001X - 0.065$ |
| Accuracy[b] | ±100% at 1 ng/ml<br>±10% at 10 ng/ml | ±6% at 250 ng/ml | ±18% at 1000 ng/ml |
| Precision | ±8% at 10 ng/ml | ±5% at 250 ng/ml | ±2% at 1000 ng/ml |
| Limit of detection | 0.5 ng/ml | — | — |
| Recovery of internal standard (± *SD*) | 90 ± 4% at 5 ng/ml | 91 ± 3% at 125 ng/ml | 91 ± 3% at 500 ng/ml |
| Recovery of drug (± *SD*) | 90 ± 2% | 90 ± 4% | 83 ± 4% |

[a] $Y$ = peak height ratio; $X$ = drug concentration. [b] Defined as 95% confidence limits of the least-squares regression line.

one-compartment model for the rhesus monkey, cynomolgus monkey, and baboon, respectively. The residual mean squares obtained for the two-compartment model were 37, 87, and 73% of those obtained for a one-compartment model for the rhesus monkey, cynomolgus monkey, and baboon, respectively, indicating that the data were appreciably better fitted by a two-compartment model.

An analysis of variance was performed on each group of pharmacokinetic parameters. Group means were compared using the method of least significant differences in conjunction with the Newman–Keuls multiple comparison procedure (16). Significance testing was carried out at the 5 and 1% levels.

## RESULTS

**Plasma Concentrations**—After intravenous injection of isosorbide dinitrate (1 mg/kg), the mean plasma concentration at 2 min (the first time of blood sampling) was similar in the rhesus monkey (565 ng/ml ± 66 *SD*) and cynomolgus monkey (586 ng/ml ± 43 *SD*), whereas it was about threefold higher in the baboon (1572 ng/ml ± 253 *SD*) (Fig. 1). After a short distribution phase in the cynomolgus monkey and baboon, mean plasma concentrations declined with a half-life of ~25 min to the detection limit at ~4 hr after dosing. In the rhesus monkey, the initial and terminal phase ($t_{1/2\beta}$ ~60 min) were relatively longer than in the other two species.

**Pharmacokinetic Parameters**—The observed plasma concentrations of isosorbide dinitrate could be adequately described by a biexponential equation, $C_p = Ae^{-\alpha t} + Be^{-\beta t}$, where $C_p$ is the plasma drug concentration at time $t$; $A$ and $B$ are the zero-time intercepts of the initial and terminal phases of the concentration–time curve, respectively (Fig. 1); and $\alpha$ and $\beta$ are obtained from the slopes of these phases, respectively. Pharmacokinetic parameters were calculated using standard equations (18) for a two-compartment open model with elimination from the central compartment (Table II). Plasma concentrations predicted by this model were generally in good agreement with observed values (Fig. 1). However, since the distribution phase was short, pharmacokinetic parameters were also calculated using a one-compartment open model. There were no notable differences in parameters calculated with either of the two models, except perhaps in the elimination rate constant ($K_{el}$) (Table III). However, $K_{el}$ obtained for a one-compartment open model was almost identical to $\beta$ calculated for a two-compartment open model.

An analysis of variance of areas ($AUC$) under the plasma concentration–time curves showed that, in respect to this parameter, the cynomolgus monkey was significantly different from the other species and that the rhesus monkey was significantly different from the baboon (Table II).

**Table II—Mean Pharmacokinetic Parameters (± *SD*) for a Two-Compartment Open Model after a Single Dose of Isosorbide Dinitrate (1.0 mg/kg iv)**

| Parameter[a] | Rhesus Monkey[b] | Cynomolgus Monkey[b] | Baboon[b] |

## DISCUSSION

Relatively little data have been reported concerning the detailed pharmacokinetics of isosorbide dinitrate in animals. In dogs (9) and humans (13, 15), the plasma concentration–time course of isosorbide dinitrate appears to be adequately described by a one-compartment open model; in rats (5), a two-compartment open model appears to be more appropriate. Although a two-compartment open model seemed suitable in nonhuman primates (Table II), a one-compartment open model could be used without notable differences in calculated pharmacokinetic parameters (Table III). However, the distribution phase $A/\alpha$ contributed 14, 15, and 18% of the total area under the plasma concentration–time curve in the rhesus monkey, cynomolgus monkey, and baboon, respectively. This finding indicates that the distribution phase of isosorbide dinitrate, although short, should be considered in a pharmacokinetic analysis of the drug and that distribution of isosorbide dinitrate into a peripheral compartment is a feature of its pharmacokinetics in nonhuman primates.

The systemic clearance of isosorbide dinitrate can probably be regarded as reflecting hepatic clearance, although clearance in the intestinal mucosa also might take place after oral administration; in fact, only ~2% of an oral dose of isosorbide dinitrate appears to reach the peripheral circulation intact in the baboon[4]. Similar low absolute bioavailability of isosorbide dinitrate was reported to occur in humans (15).

In rhesus monkeys, the systemic clearance of isosorbide dinitrate was similar to the hepatic blood flow (50 ml/min/kg) reported for this species (19), as might be expected for a drug of high hepatic extraction ratio (5). By contrast, the systemic clearance of isosorbide dinitrate in humans appears to be ~10-fold lower than hepatic blood flow (15). Despite this species difference in clearance, the drug is subjected to an extensive first-pass effect in both these species, as in rats (5).

Volumes of distribution [$V_{D(ss)}$ and $V_{D(\beta)}$] and apparent half-lives of the terminal phase, $t_{1/2\beta}$, were significantly greater in the rhesus monkey than in the other species (Table II). However, clearance ($Cl$) and the apparent half-life of the initial phase, $t_{1/2\alpha}$, did not differ significantly among the species.

The mean volumes of distribution ($V_{Dss}$) represented 273, 168, and 84% of the body weight in the rhesus monkey, cynomolgus monkey, and baboon, respectively. These values presumably represent the relative extent of tissue uptake of isosorbide dinitrate in these species. In the baboon, the volume of distribution was not too dissimilar from the probable total body water volume.

Adopting the two-compartment model, the mean volume of the central compartment ($V_1$) was larger than that of the peripheral compartment ($V_2$) in all three species, the ratios being 1.2, 3.1, and 1.6 for the rhesus monkey, cynomolgus monkey, and baboon, respectively. These ratios indicate that distribution of isosorbide dinitrate into the peripheral compartment is of some importance in its disposition in the body. Indeed, simulation of the plasma concentration–time profile of isosorbide dinitrate in the central and peripheral compartments showed that equilibration between these two compartments was rapidly achieved. Peak mean isosorbide dinitrate concentrations in the peripheral compartment

were 258, 394, and 727 ng/ml in the rhesus monkey, cynomolgus monkey, and baboon, respectively. Thereafter, concentrations in both compartments were similar.

Adopting a two-compartment open model, the mean ratios of $\beta/K_{el}$ of 0.43, 0.63, and 0.51 in the rhesus monkey, cynomolgus monkey, and baboon, respectively, indicated that these fractions of isosorbide dinitrate in the body were in the central compartment and were available for elimination at any time after completion of the drug distribution phase.

The plasma half-lives of isosorbide dinitrate in nonhuman primates (rhesus monkey, 62 min; cynomolgus monkey, 23 min; and baboon, 24 min) (Table II) were longer than those observed in humans [~9 min, (15)], dogs [~7 min, (9)], and rats [~1 min, (5)]. The latter value for rats was disputed by Reed *et al.* (20) who claimed that it only represented a tissue distribution phase. The activity of the enzyme system (glutathione *S*-transferases) responsible for the denitration of isosorbide dinitrate was shown to be sex dependent in rodents, but this has not been observed in humans and would not be expected in nonhuman primates (21). In none of these species, however, would isosorbide dinitrate be expected to accumulate under the once daily dosage regimen used in chronic toxicity studies. Comparison of the relatively straightforward biotransformation of isosorbide dinitrate in different species would probably not provide the best criteria for the selection of a suitable species for chronic toxicity studies; instead, a comparison of the drug's pharmacokinetics would be more appropriate. Therefore, using pharmacokinetic criteria, the fate of isosorbide dinitrate in humans (15) appears to be more closely reflected by baboons (Tables II and III) than by either of the other two nonhuman primate species studied.

# Rapid and Specific High-Pressure Liquid Chromatographic Assay for Folic Acid in Multivitamin–Mineral Pharmaceutical Preparations

**W. H. TAFOLLA ˣ, A. C. SARAPU, and G. R. DUKES**

Received June 9, 1980, from the *Control Research and Development Laboratories, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication April 1, 1981.

**Abstract** □ A high-pressure liquid chromatographic assay for folic acid in multivitamin–mineral pharmaceutical formulations was developed. The internal standard solution used for sample extraction contained a chelating agent, pentetic acid, for prevention of metal ion-catalyzed degradation of folic acid in the prepared samples. Samples were chromatographed using a paired-ion mobile phase (water–methanol, ~76:24; 0.015 *M* phosphate buffer, pH 7.0; and 0.3% tetrabutylammonium hydroxide) on a column packed with octadecylsilane bonded to microparticulate silica gel. Sample preparation was rapid, and total chromatographic time was ~20 min. The method was accurate, precise, and highly specific. Folic acid and the internal standard, methylparaben, were separated from other tablet components and a number of potential impurities and degradation products of folic acid.

**Keyphrases** □ Folic acid—high-pressure liquid chromatography, multivitamin–mineral pharmaceutical preparations □ High-pressure liquid chromatography—folic acid, multivitamin–mineral pharmaceutical preparations □ Multivitamin–mineral formulations—high-pressure liquid chromatography, folic acid

Previous work described the use of various organic ammonium salts as ion-pairing reagents for the separation of ascorbic acid and folic acid on columns packed with octadecylsilane bonded to 5–10-μm silica gel (1–4). A high-pressure liquid chromatographic (HPLC) method for the quantitation of folic acid bulk drug is now available for common use (5, 6). However, the successful separation and quantitation of folic acid in mineral-containing multivitamin pharmaceutical formulations have not been reported.

This report describes a stability-indicating and highly specific HPLC assay for folic acid, which was applied to mineral-containing multivitamin formulations and their mineral-free counterparts.

## EXPERIMENTAL

**Reagents and Materials**—Dihydrofolic acid[1], *dl*-L-tetrahydrofolic acid[1], *dl*-*N*-5-methyltetrahydrofolic acid[1] (sodium salt), *p*-aminobenzoic acid[1], pterine[1], pterin-6-carboxylic acid[1], *N*-(*p*-aminobenzoyl)-L-glutamic acid[1], and pteroic acid[2] were used as received. Reagents used were analytical reagent grade or better. The pharmaceutical preparations analyzed are commercially available, and their compositions are described in Table I.

**Instrumentation**—The liquid chromatograph consisted of a high-pressure pump[3], a valve injector[4] equipped with a 10-μl loop, heating tape[5] and associated temperature control unit[6], and a 280-nm fixed-wavelength UV detector[7] operated at a sensitivity of 0.01 aufs. Separations were performed on a 30-cm × 4-mm i.d. column containing 10-μm silica gel with bonded octadecylsilane[8]. Chromatograms were produced on a strip-chart recorder[9]. Peak responses were measured using an electronic integrator[10].

[a] Unicap T tablets, The Upjohn Co., Kalamazoo, Mich. [b] Unicap Chewable tablets, The Upjohn Co., Kalamazoo, Mich. [c] Unicap capsules, The Upjohn Co., Kalamazoo, Mich.

**Mobile Phase**—The mobile phase was prepared by adding 650 ml of water, 7.5 ml of a 40% aqueous solution of tetrabutylammonium hydroxide[11], 2.04 g of monobasic potassium phosphate, 7.0 ml of 3.0 *N* phosphoric acid, and 240 ml of methanol to a 1-liter volumetric flask. This mixture was diluted to volume with water, adjusted to pH 7.0 with phosphoric acid or ammonium hydroxide, membrane filtered[12], and degassed prior to use. (Column variations may require alterations in the methanol and phosphate concentrations.) A flow rate of 1.5 ml/min and a pressure of ~1300 psig were used. Column temperature was maintained at 35°.

**Internal Standard Solution**—The internal standard solution was prepared by mixing together 40 mg of methylparaben, 240 ml of methanol, 650 ml of water, 12 ml of a 40% aqueous solution of tetrabutylammonium hydroxide, 2.04 g of monobasic potassium phosphate, and 30 ml of a solution containing 100 mg/ml of pentetic acid (I) in 0.75 *N* ammonium hydroxide. This preparation was diluted to 1000 ml with water.

**Standard Preparation**—Approximately 32 mg of folic acid USP reference standard was accurately weighed into a 100-ml volumetric flask, diluted to volume with the internal standard solution, and mixed well until all of the folic acid reference standard was dissolved. Then 4.00 ml of this solution was pipetted into a second 100-ml volumetric flask, diluted to volume with the internal standard solution, and mixed well. This solution was subsequently protected from prolonged exposure to light.

**Sample Preparation**—*Folic Acid Bulk Drug*—Samples of folic acid bulk drug were prepared as described for the standard preparation.

*Tablets*—Ten tablets were accurately weighed and then finely powdered. A quantity of the powder equivalent to 0.3 mg of anhydrous folic acid was accurately weighed and transferred to a 35-ml centrifuge tube. The internal standard solution (25 ml) was pipetted into the centrifuge tube, and the headspace was immediately flushed with nitrogen and then stoppered tightly. This preparation was shaken vigorously for ~5 min,

**Table II—Folic Acid Bulk Drug Assay Results**

| Lot | This Work, % | USP HPLC Assay, % |
|---|---|---|
| A | 88.8 | 89.4 |
| B | 91.9 | 91.6 |
| C | 90.9 | 90.4 |
| D | 91.5 | 91.3 |
| E | 92.3 | 90.3 |
| F | 91.0 | 93.8 |
| Mean | 91.1 | 91.1 |

after which the resulting solution was membrane filtered[13]. The headspace of the sample container was again flushed with nitrogen and capped tightly until injected.

*Soft Elastic Capsules*—Ten capsules were accurately weighed and then cut in half. The capsule filling was transferred to a glass container, and the empty capsule shells were washed with two 25-ml portions of chloroform, which were discarded. The washed capsule shells were dried and weighed to determine the average capsule fill weight. A quantity of the capsule filling equivalent to 0.3 mg of anhydrous folic acid was accurately weighed and transferred to a 35-ml centrifuge tube, and ~30 ml of hexane then was added. The contents were shaken vigorously for ~5 min and then centrifuged at ~1070×*g* for 15 min.

The hexane was carefully aspirated, and the residue was dried at 60°. The internal standard solution (25 ml) was pipetted into the centrifuge tube containing the dried residue, and the headspace was immediately flushed with nitrogen and then stoppered tightly. This preparation was shaken vigorously for ~5 min, after which the resulting solution was membrane filtered. The headspace of the sample container was again flushed with nitrogen and capped tightly until injected.

**Calculations**—The folic acid content was calculated by the following equations.

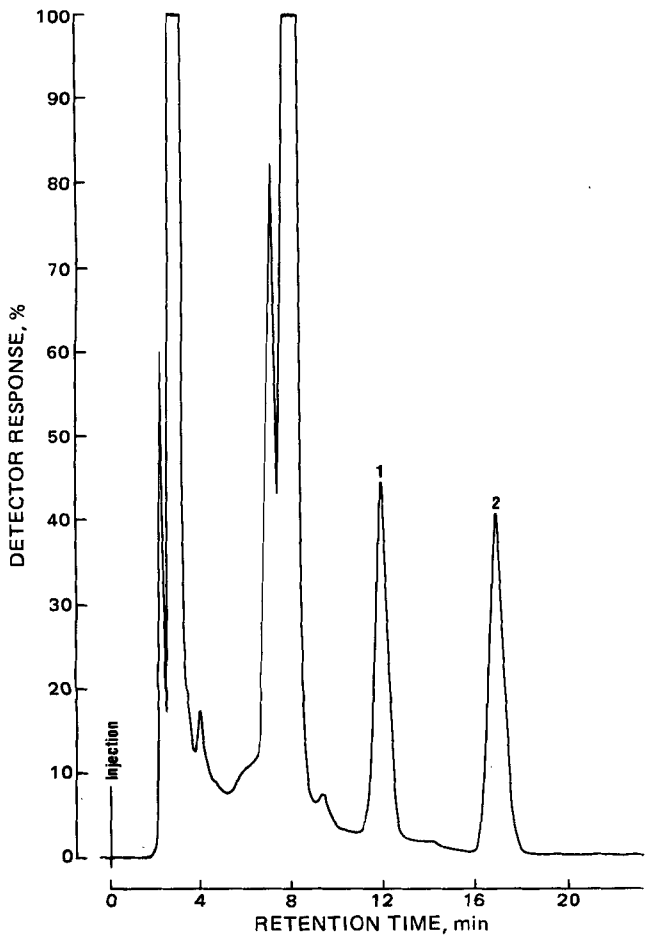

**Figure 1**—*Chromatogram of multivitamin–mineral pharmaceutical tablet preparation.*

[13] Type HA (0.45 mm), Millipore Corp., Bedford, Mass.

**Table III—Stability of Sample Preparation Solutions**

| Sample | Atmosphere | Folic Acid Remaining after 24 hrs in solution, % |
|---|---|---|
| Folic acid plus other vitamins and minerals[a] extracted in dilute sodium hydroxide without I and injected immediately | Air | 5–10[b] |
| Folic acid only in internal standard solution | Air | 100.8 |
| Folic acid plus minerals (copper, iron, potassium, manganese, and zinc) in internal standard solution | Air | 99.2 |
| Folic acid plus other vitamins and minerals[a] in internal standard solution | Air | 82.9 |
| | Oxygen enriched | 51.9 |
| | Nitrogen | 99.0 |

[a] See Table I. [b] Range of several trials. Results based on peak height approximations.

For bulk drug:

$$\frac{R_{sam}}{R_{std}} \times \frac{W_{std}}{W_{sam}} \times 100 = \% \text{ purity} \qquad \text{(Eq. 1)}$$

For tablets:

$$\frac{R_{sam}}{R_{std}} \times \frac{C_{std}}{W_{sam}} \times W_{tab} \times 25 = \text{mg/tablet} \qquad \text{(Eq. 2)}$$

For soft elastic capsules:

$$\frac{R_{sam}}{R_{std}} \times \frac{C_{std}}{W_{sam}} \times W_{sec} \times 25 = \text{mg/capsule} \qquad \text{(Eq. 3)}$$

where:

$R_{sam}$ = folic acid peak response divided by internal standard peak response of the sample preparation
$R_{std}$ = folic acid peak response divided by internal standard peak response of the reference standard preparation
$W_{std}$ = weight of folic acid (corrected for moisture) in milligrams in the reference standard preparation
$W_{sam}$ = weight of sample in milligrams
$C_{std}$ = folic acid concentration of the reference standard preparation in milligrams per milliliter (corrected for moisture)
$W_{tab}$ = average tablet weight in milligrams per tablet
$W_{sec}$ = average soft elastic capsule (sec) weight in milligram per capsule
25 = dilution volume in milliliters

## RESULTS AND DISCUSSION

**Selection of Ion-Pairing Reagent and Chromatographic Conditions**—Due to the known suitability of organic ammonium salts as ion-pairing reagents for acidic compounds, efforts were directed to the development of such a system for folic acid in multivitamin–mineral pharmaceutical formulations. Since the method was intended for routine use in a high-volume analytical laboratory, a readily available ion-pairing reagent was desirable. Possible choices included the series of organic ammonium hydroxide compounds, including tetramethylammonium hydroxide through tetrabutylammonium hydroxide.

**Table IV—Recovery of Folic Acid Added to Placebo Preparations**

| | Coated Compressed Tablet with Minerals | Compressed Tablet | Soft Elastic Capsule |
|---|---|---|---|
| Average recovery, % | 99.1 | 100.3 | 99.3 |
| Number of determinations | 8 | 5 | 7 |
| Range studied, mg/dosage unit | 0.3026–0.6972 | 0.3112–0.7130 | 0.2980–0.7178 |
| RSD, % | 1.5 | 0.9 | 1.7 |
| Correlation coefficient | 0.998 | 1.000 | 1.000 |

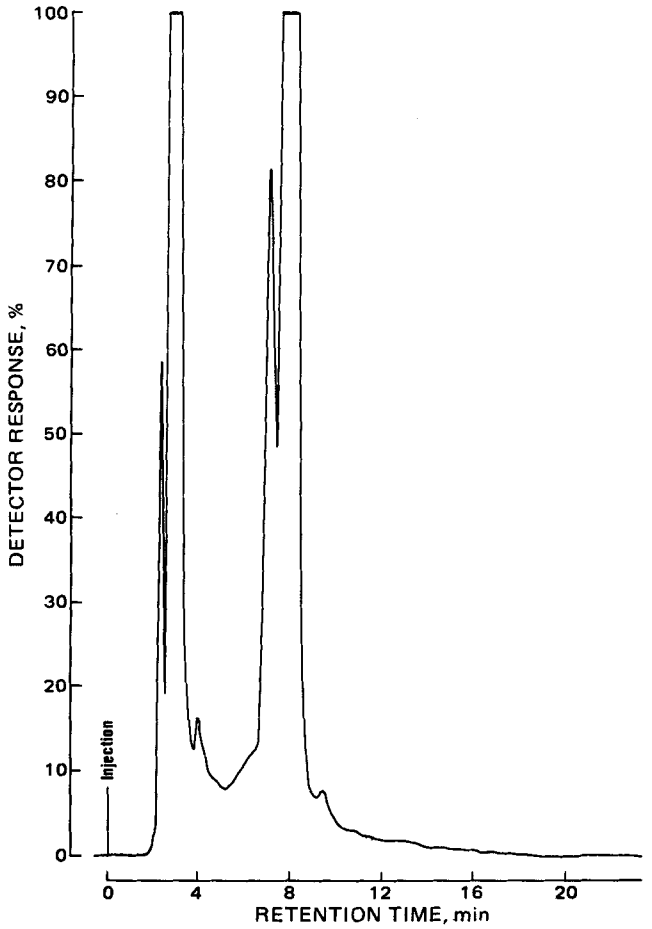

**Figure 2**—*Chromatogram of a placebo preparation containing all vitamins and minerals except folic acid.*

Tetramethylammonium hydroxide and tetraethylammonium hydroxide failed to separate folic acid from other vitamins and tablet excipients. Tetrapropylammonium hydroxide did produce adequate separation but resulted in unacceptably long chromatographic times due to retention of excipients.

The use of tetrabutylammonium hydroxide as a pairing ion provided a desirable separation and acceptable chromatographic times. Tablet excipients and other vitamins eluted rapidly, with folic acid being retained. The addition of a small quantity of monobasic potassium phosphate increased the separation of folic acid from the other vitamins and tablet excipients and provided improved efficiency. Optimum separations were usually achieved with a monobasic potassium phosphate concentration of ~0.015 *M*. The pH of the mobile phase also influenced the chromatography. Low pH values produced longer retention times for folic acid than the recommended pH 7.0, but broader peaks resulted.

Some variation of the potassium phosphate monobasic content or mobile phase pH may be required due to the chromatographic column being used. However, the chromatographic conditions described provided the best peak shapes for folic acid and the internal standard while adequate separation from other tablet constituents was maintained. The slightly elevated column temperature of 35° was employed to avoid varying the mobile phase composition to compensate for fluctuations in ambient temperature. Under these conditions, column life was comparable to that of other reversed-phase HPLC methods used for the analysis of pharmaceuticals.

**Bulk Drug Assays**—The method was tested for its comparability to the USP HPLC assay for folic acid bulk drug (4). The data presented in Table II indicate that the method yielded results for bulk drug lots that were equivalent to the official USP assay.

**Extraction of Folic Acid**—The extraction conditions used are extremely important for the successful quantitation of folic acid in mineral-containing multivitamin formulations. Under acidic conditions, folic acid has limited solubility and tends to be unstable (7). Other vitamins such as cyanocobalamin, pantothenate, riboflavin, thiamine, and ascorbic acid are unstable at high pH values (8). Furthermore, metal ion-catalyzed (particularly $Cu^{2+}$ and $Fe^{2+}$) oxidative degradation of ascorbic acid is known to occur in the presence of oxygen (9, 10). The oxidative degradation products of ascorbic acid (dehydroascorbic acid, diketogulonic acid, and oxalic acid) are powerful reducing agents. The use of ascorbic acid as a folic acid reductant is known (11).

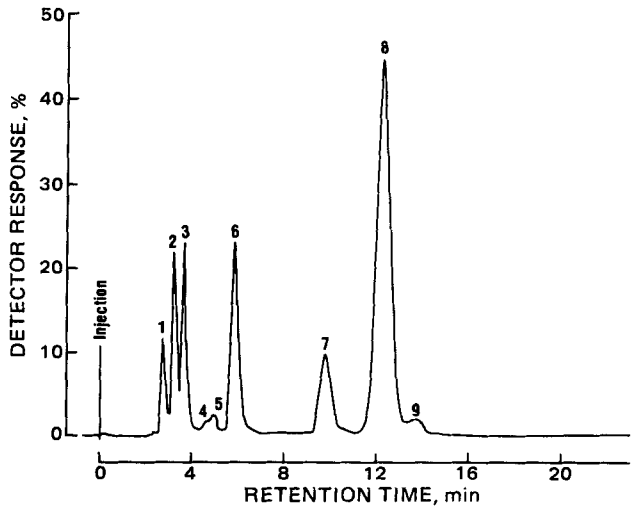

**Figure 3**—*Chromatogram of a mixture of folic acid and some known degradation products. Key: 1, pterine; 2,* p*-aminobenzoic acid; 3, pterin-6-carboxylic acid; 4 and 5, unknown; 6, pteroic acid and* N-(p*-amino-benzoyl)-*L*-glutamic acid; 7, dihydrofolic acid and tetrahydrofolic acid; 8, folic acid; and 9,* dl-N*-5-methyltetrahydrofolic acid.*

As shown in Table III, folic acid alone or in the presence of minerals did not degrade. However, when other vitamins were present and ascorbic acid was subject to metal ion-catalyzed oxidative degradation, folic acid degradation was observed. Attempts to extract folic acid from mineral-containing multivitamin formulations under high pH conditions using dilute sodium hydroxide or ammonium hydroxide resulted in only ~5–10% recovery of intact folic acid. The reversible enzymatic reduction of folic acid to dihydrofolic acid and tetrahydrofolic acid occurs in biological systems (12). However, it is believed that severely basic extraction conditions result in irreversible degradation of folic acid since these reduced folate species were not observed in chromatography of the above samples.

The internal standard solution used for extracting folic acid was designed to prevent degradation by the described pathways while still providing an efficient extraction. The internal standard solution had a pH of ~9.0–9.5, at which folic acid was readily solubilized. As folic acid and other vitamins and tablet components dissolved, the pH dropped to ~7.0–8.5, depending on the formulation. The lowered pH favors stability of other water-soluble vitamins and thus tends to limit interactions detrimental to folic acid. Metal ion-catalyzed degradation of the water-soluble vitamins was minimized by use of the chelating agent, I. Air oxidation was reduced by flushing the headspace of the extraction container with nitrogen. These extraction conditions produced excellent stability of sample solutions (Table III).

**Recovery of Folic Acid from Spiked Placebos**—The sample preparation procedure was rapid and simple. As shown in Table IV, average recoveries of 99.1–100.3% were obtained for placebo mixtures containing all of the other tablet vitamins, minerals, and excipients spiked with folic acid over a range of 0.2980–0.7178 mg/dosage unit. The relative standard deviations of the recoveries for these studies varied from 0.9 to 1.7%. Linear regression analysis of folic acid added *versus* peak area yielded correlation coefficients of 0.998–1.000.

**Specificity**—As shown in Figs. 1 and 2, folic acid and the internal standard, methylparaben, were well separated from the other ingredients contained in multivitamin–mineral formulations. The stability-indicating properties of the method were investigated by chromatographing authentic samples of known folic acid impurities and degradation products. As can be seen in Fig. 3, none of the compounds tested interfered with folic acid or the internal standard.

# Determination of Plasma Fentanyl by GC–Mass Spectrometry and Pharmacokinetic Analysis

**SHEN-NAN LIN *x, TSENG-PU F. WANG *, RICHARD M. CAPRIOLI*, and BENJAMIN P. N. MO ‡**

Received March 31, 1980, from the **Analytical Chemistry Center and the* ‡*Department of Anesthesiology, University of Texas Medical School, Houston, TX 77025.* Accepted for publication April 9, 1981.

**Abstract** □ GC–mass spectrometry was used to measure extremely low levels of fentanyl in dog plasma. Deuterated fentanyl was synthesized for use as an internal standard. Fentanyl was hydrolyzed to despropionyl fentanyl by 20% DCl in deuterium oxide. Mass spectrometric analysis of the product revealed that the molecular ion was three mass units higher than that of the authentic despropionyl fentanyl, indicating that the deuterium exchange reactions occurred at this stage. Deuterated despropionyl fentanyl was reesterified by propionyl chloride to fentanyl-$d_3$. The drug was assayed in biological fluids by extraction into ethyl acetate followed by analysis with GC–chemical-ionization mass spectrometry. The lowest measurable plasma fentanyl level is 500 pg/ml. The method is highly selective and is suitable for monitoring the time course of plasma drug levels. Evaluation of pharmacokinetic data from experiments using nine dogs revealed a triphasic phenomenon. No measurable amounts of the major metabolites, despropionyl fentanyl and norfentanyl, were detected.

**Keyphrases** □ Fentanyl—determination by GC–mass spectrometry and pharmacokinetic analysis in dog plasma □ GC–mass spectrometry—determination of plasma fentanyl, pharmacokinetic analysis □ Anesthetics—determination of plasma fentanyl by GC–mass spectrometry

Fentanyl[1], *N*-(1-phenethyl-4-piperidyl)propionanilide, is a potent narcotic analgesic widely used in clinical anesthesia. It has a rapid onset of effect and a short duration of action when compared with morphine and most other drugs of this group (1). Direct correlation between pharmacokinetic data and drug effect is difficult due to the lack of an analytical method suitable for measuring extremely small quantities of the drug in plasma (2–4). Only recently was fentanyl measurement in a subnanogram quantity made possible by radioimmunoassay (5). However, preparation of antiserum samples of fentanyl involves lengthy biological procedures. In addition, the possibility of cross interaction due to various biological components presents difficulties in using the radioimmunoassay method for specific analyses.

This report describes a sensitive and specific GC–mass spectrometric method using stable isotopically-labeled fentanyl-$d_3$ as an internal standard. The method is capable of quantitatively detecting subnanogram levels of fentanyl in plasma. After intravenous administration of 25, 50, or 100 μg of fentanyl/kg to dogs, the plasma level fell rapidly to 2.5 ng/ml within 30 min and then remained at 0.5–2 ng/ml for up to 3 hr.

## EXPERIMENTAL

**Preparation of Fentanyl-$d_3$**—After 1.2 ml of 20% DCl in deuterium oxide[2] (99 atom % deuterium) was added to 25 μg of fentanyl[3], the solution was incubated overnight at 100°. The acidity of the reaction mixture was partially neutralized by 0.2 ml of 40% NaOD in deuterium oxide[2] (99 atom % deuterium), and the unreacted fentanyl was removed by extraction twice with 2 ml of ethyl acetate. The remaining aliquot of sample was again acidified by 1.2 ml of 20% DCl solution before evaporation to dryness *in vacuo*. To the residue, 20 μl of pyridine and 1 ml of propionyl chloride[2] were added, and the mixture was incubated at 60° for 1 hr. The final product, fentanyl-$d_3$, was then purified by extraction twice with 3 ml of ethyl acetate. After evaporation to dryness by a nitrogen stream, the residue was dissolved in 0.5 ml of ethyl acetate and stored in a refrigerator at 4°.

**Instrumentation**—Combined GC–chemical-ionization mass spectrometry[4] was employed with methane as the reagent gas and an electron energy of 150 ev. GC separation was carried out isothermally at 235° with a 0.91-m × 2-mm i.d. U-shaped glass column packed with 3% SE-30 on 80–100-mesh Gas Chrom Q[5]. The temperature of the GC injector and the separator was 250°.

**Biological Samples**—Two hours before fentanyl administration, the nonselective mongrel dogs, 12–14 kg, were anesthetized with 300 mg of pentobarbital sodium. Fentanyl (25, 50, or 100 μg/kg) was introduced intravenously by 1-min infusion, and blood samples were collected into heparinized vials at 1, 2, 4, 6, 8, 10, 15, 30, 45, 62, 90, 120, 150, and 180 min after infusion was completed. Plasma was separated from red blood cells by centrifugation at 2500 rpm in the cold and stored in a freezer at −40° when necessary.

**Extraction and Quantitation**—To 2 ml of plasma, a known amount of fentanyl-$d_3$ (25 ng in 25 μl of ethyl acetate) was added as an internal standard. After rigorous mixing with the aid of an agitator[6], the plasma

was allowed to stand for 5 min before saturation with ammonium carbonate. Extractions were performed twice with 3 ml of ethyl acetate. The organic layers were pooled and dried by a nitrogen stream. To this residue, 30 μl of ethyl acetate was added and 10 μl was used for analysis. Ions selectively monitored were *m/z* 340, 337, 281, and 233 corresponding to the pseudomolecular ions of fentanyl-$d_3$, fentanyl, despropionyl, and norfentanyl, respectively. Quantitation was performed by comparison of peak area with respect to that of the internal standard.

## RESULTS AND DISCUSSION

In addition to the pseudomolecular ion, $MH^+$, which appeared as the most abundant species, the chemical-ionization mass spectrum of fentanyl showed four fragment ions at mass units greater than 100, *i.e.*, *m/z* 245, 188, 186, and 150. The mass spectrum of fentanyl-$d_3$ showed that, in addition to the pseudomolecular ion, the ion species at 248 and 153 were isotopically labeled, with *m/z* 153 resulting from cleavage of the propionyl amide bond and *m/z* 248 resulting from cleavage of the benzyl bond. Both ion species contain the phenyl ring of the propionanilide moiety of the molecule.

To obtain deuterated fentanyl, fentanyl was first hydrolyzed by 20% DCl in deuterium oxide solution to produce despropionyl fentanyl and propionic acid. Deuteration appeared to occur at this stage. After extraction with ethyl acetate, analysis of an aliquot of the reaction mixture revealed that deuterated despropionyl fentanyl was the major component. The electron-impact mass spectrum of this compound revealed a weak but detectable *m/z* 283 ion, which corresponded to the molecular ion. Three major fragment ions were observed, at *m/z* 192, 149, and 96. The mass spectrum was similar to that of the nondeuterated despropionyl fentanyl recorded previously (6), except that *m/z* 283, 192, and 149 ions contained isotopic labels. The chemical-ionization mass spectrum of the component showed a pseudomolecular ion at *m/z* 284, which was also three mass units higher than that of the nondeuterated compound. Reesterization of deuterated despropionyl fentanyl was carried out by incubating the residue with propionyl chloride. Fentanyl-$d_3$ was then purified by extraction into ethyl acetate.

During the preparation of deuterated fentanyl, two extraction processes were performed to remove the unreacted intact drug from the product. The effectiveness of the extraction is demonstrated by the results of two experiments designed to assess the purity of fentanyl-$d_3$. Table I shows the relative ion intensities of $MH^+$, $MH^+ - 1$, $MH^+ - 2$, and $MH^+ - 3$ from 70 ng of fentanyl-$d_3$ and 100 ng of fentanyl by selective ion chemical-ionization mass spectrometry. Essentially, the differences in the relative ion intensities for $MH^+ - 3$, $MH^+ - 2$, and $MH^+ - 1$ between those of fentanyl and fentanyl-$d_3$ can be regarded as the relative ion intensities contributed by the molecular ions of fentanyl, fentanyl-$d_1$, and fentanyl-$d_2$, respectively. When taking the ion intensity of $MH^+$ of fentanyl-$d_3$ as 100, it appeared that the deuterated product was a composite of 1.1% fentanyl, 2.69% fentanyl-$d_1$, 4.99% fentanyl-$d_2$, and 91.2% fentanyl-$d_3$.

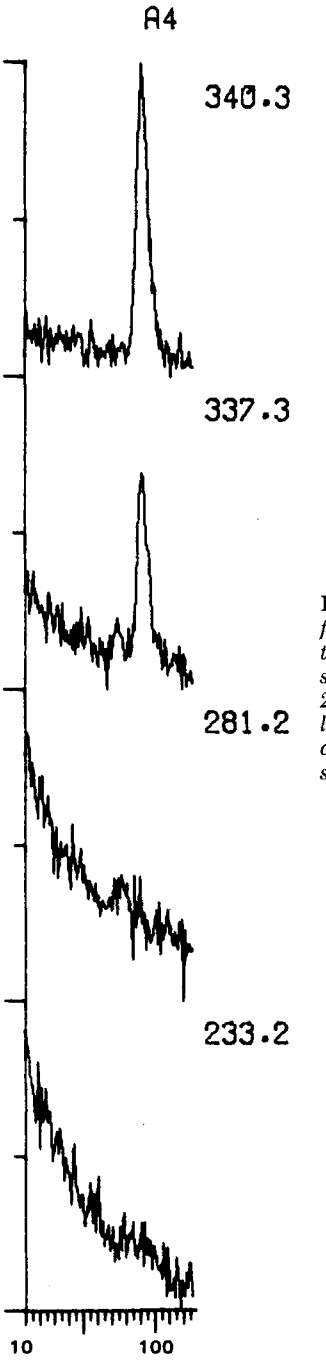

**Figure 1**—*Mass chromatogram of fentanyl in dog plasma using deuterated fentanyl-*$d_3$ *as an internal standard;* m/z *340.3, 337.3, 281.2, and 233.2 correspond to the pseudomolecular ions of fentanyl-* $d_3$*, fentanyl, despropionyl, and norfentanyl, respectively.*

To determine the percent yield of fentanyl-$d_3$ from the precursor, three separate ethyl acetate extracts corresponding to these reaction mixtures in which 25.0, 37.5, and 50.0 ng of fentanyl were used as the initial starting materials, were added with known amounts of fentanyl (5 ng/10 μl of ethyl acetate) as an internal standard. The unknown amounts of fentanyl-$d_3$ in the mixtures were then measured by chemical-ionization mass spectrometry, selectively monitoring $MH^+$ of fentanyl and fentanyl-$d_3$. The results showed that 23.2, 33.7, and 42.8 ng of the fentanyl were recovered as fentanyl-$d_3$; therefore, the percent yield of the chemical processes to obtain the deuterated compound was 89.4 ± 3.6%. The standard solution containing fentanyl-$d_3$ in ethyl acetate (1.75 μg/ml) was stored in a refrigerator at 4° and was stable after 3 months under these conditions. During this time, experiments to check the purity of fentanyl-$d_3$ were performed prior to each measurement of every batch of dog plasma.

Figure 1 shows the quantitative GC–mass spectrometric analysis of fentanyl in dog plasma, with pseudomolecular ions of fentanyl, *m/z* 337,

[a] Nonlinear estimation of triphasic pharmacokinetics of plasma fentanyl employed the NONLIN computer program from The Upjohn Co.

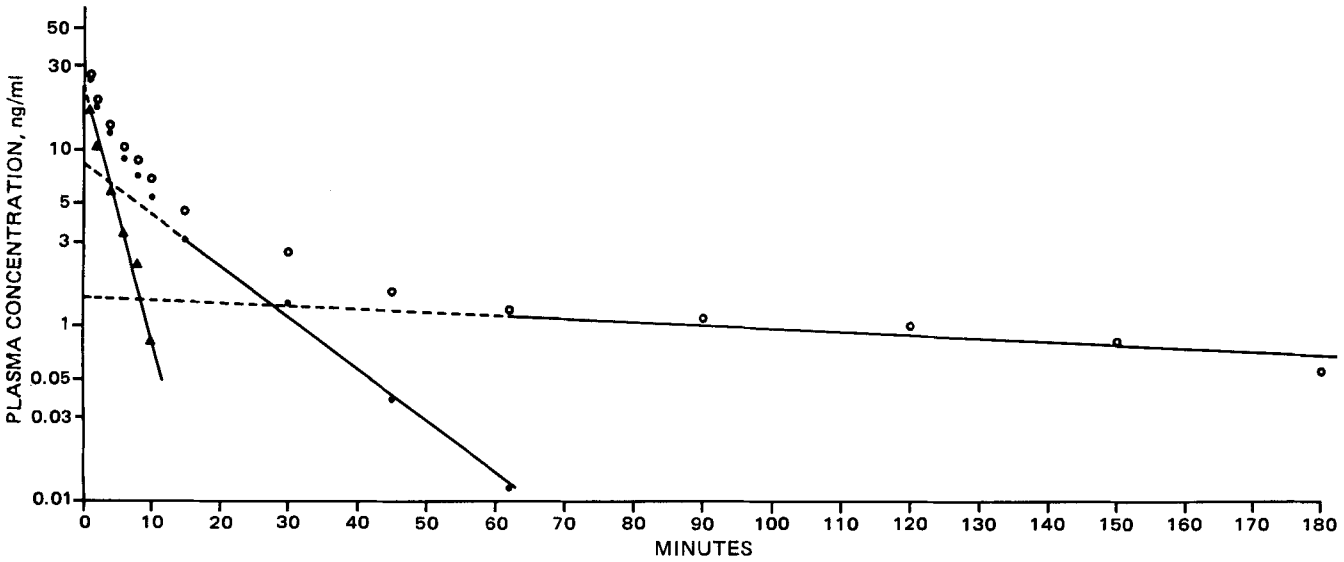

**Figure 2**—*Application of the method of residuals for nonlinear pharmacokinetic data (8) to the semilogarithmic plot of plasma fentanyl levels with respect to time. Three linear regions of first-order kinetics are shown. Key:* ○, *plasma fentanyl levels in a normal dog after 50 μg/kg iv dose; and* ▲ *and* ●, *data obtained by curve stripping.*

and fentanyl-$d_3$, $m/z$ 340, used for quantitative measurements. Since despropionyl fentanyl and norfentanyl are proposed major metabolites in the rat urine (6, 7), their $MH^+$ ions, $m/z$ 281 and 233, respectively, were also selectively monitored. In the first 28 plasma samples analyzed, these two metabolites were not found. The linear range of the calibration curve was determined by adding known amounts of fentanyl and fentanyl-$d_3$ to 2 ml of water. For standard solutions containing <5 ng of fentanyl/ml, 3.17 ng of internal standard was used; otherwise, 35.7 ng was used. Quantitative measurements were made by comparing the peak areas of fentanyl to that of the internal standard. The results from eight samples, ranging from 500 pg to 100 ng/ml of fentanyl, revealed a linear relationship between the actual and measured values determined by GC–mass spectrometry.

Table II shows plasma fentanyl levels in dogs after an intravenous bolus of 50 μg/kg. For plasma samples containing >1 ng of fentanyl/ml, the reproducibility of the analysis was within 6%; for those containing <1 ng/ml, it was ~12%. With its high sensitivity, the GC–mass spectrometric procedures allow the time course of the plasma fentanyl concentration to be followed for up to 3 hr. The lowest measured plasma concentration was 500 pg/ml. The lower limit of analysis by these methods using a signal to noise ratio of 2 was ~200 pg of fentanyl.

The plasma fentanyl concentration profile in a dog is illustrated in Fig. 2. Figure 2 also shows the results from application of the method of residuals to yield the second and third linear segments in addition to the easily recognizable terminal linear segment (8). The time course of the plasma fentanyl level appeared to follow a triphasic phenomenon. The first phase may have represented the uptake of [$^3$H]fentanyl by organs with extensive blood supplies, *e.g.*, lungs, kidneys, heart, and brain (2). The next phase was one of redistribution, especially from the lungs to the blood. Finally, the last phase represented that of metabolism and excretion. The three-compartmental pharmacokinetics of plasma fentanyl agreed with observations made by radioimmunoassay (4, 5) and radioisotope counting techniques (3).

Table III shows the pharmacokinetic parameters of plasma fentanyl of eight dogs by curve fitting with the NONLIN computer program (9). The plasma profile of fentanyl in dogs can be described by the equation $C(t) = Ae^{-\alpha t} + B^{-\beta t} + Ce^{-\gamma t}$, where $C(t)$ represents the fentanyl concentration at any time, $t$. The half-life, $T_{1/2}$, is calculated by using $0.693/\alpha$, $\beta$, or $\gamma$. The results shown in Table III indicate that the pharmacokinetic parameters vary widely among dogs. The same variability in the pharmacokinetic parameters of plasma fentanyl in humans was reported by Hull (10). Table III reveals that the half-lives of each compartment are more or less independent of the dose levels of fentanyl administered, despite the wide variation in the data. However, in contrast to other data (11), the intercepts ($A$, $B$, and $C$) are not dose dependent.

Finally, the average half-lives of the terminal linear phase (124.1 ± 57.2 min) and the middle phase (10.74 ± 7.05 min) shown in Table III are shorter than the values reported in the literature (3, 5, 10). These differences may be due to the different specificities of the techniques adapted for measuring the extremely low plasma levels of fentanyl in these two regions. The described GC–mass spectrometric technique is highly specific for several reasons. First, since selective ion monitoring measures only the pseudomolecular ions of fentanyl and fentanyl-$d_3$, the quantitative determination of plasma fentanyl was free from the interference of its own metabolites. Second, fentanyl in biological samples was repeatedly purified, first by extraction with ethyl acetate and then by GC separation. The sensitivity of measurements was extended from 500 pg/ml to 100 ng/ml, and the use of stable isotopically-labeled fentanyl as an internal standard greatly enhanced the accuracy and precision of the quantitative measurements.

## NOTES

# Plasma Protein Binding Interaction between Valproic and Salicylic Acids in Rhesus Monkeys

**C. T. VISWANATHAN** *§ **and R. H. LEVY** ‡x

Received March 12, 1981, from the *Department of Neurological Surgery, School of Medicine, and the ‡Department of Pharmaceutics, School of Pharmacy, University of Washington, Seattle, WA 98195. Accepted for publication April 7, 1981. §Present address: Biopharmaceutics Division, Food and Drug Administration, Rockville, MD 20857.

**Abstract** □ The effects of three levels of salicylic acid on the steady-state plasma concentrations of free and total valproic acid were examined in catheterized rhesus monkeys. Valproate was infused intravenously for a total of 41 hr, and salicylate was added after the first 8 hr. The three salicylate infusions were randomly assigned to each monkey. Valproate free fraction was determined by equilibrium dialysis. Statistically significant increases in valproate free fraction and total body clearance were observed after addition of salicylic acid. The increase in valproate clearance was positively correlated with the molar ratio of salicylate to valproate steady-state plasma concentrations. There was no significant change in valproate free concentration after salicylate treatment. The proposed mechanism of this *in vivo* interaction includes plasma protein binding displacement with no change in valproate intrinsic clearance.

**Keyphrases** □ Valproic acid—plasma protein binding interaction with salicylic acid, rhesus monkey □ Salicylic acid—plasma protein binding with valproic acid, rhesus monkey □ Plasma protein binding—interaction between valproic and salicylic acids, rhesus monkey

Valproic and salicylic acids are known to bind extensively to plasma proteins in humans (1–8) and rhesus monkeys (9–11). Three *in vitro* studies showed that salicylic acid decreases valproate binding to plasma or human serum albumin (12–14). However, there is no indication that such an interaction occurs *in vivo*. In addition, these two acids may interact at a metabolic level.

Epileptic patients on valproate treatment occasionally receive salicylates and, depending on its mechanism, this interaction may be of therapeutic significance. The present study was designed to investigate this interaction *in vivo* at the systemic level. Both drugs were administered by constant-rate intravenous infusion to achieve one steady-state concentration of valproic acid and three steady-state salicylic acid levels.

## EXPERIMENTAL

Four healthy male rhesus monkeys (*Macaca mulatta*) (mean weight 5.5 kg) were chair-adapted for 1 month prior to implantation of catheters. The jugular and femoral veins of each monkey were chronically catheterized to enable withdrawal of venous blood samples and drug infusion, respectively. The monkeys were maintained in three-level restraining chairs during the studies. Patency of catheters was assured by a slow, continuous saline infusion (1 ml/hr). Daily diet consisted of fresh fruit and monkey food.

Three studies were carried out in each monkey. In each study, valproic

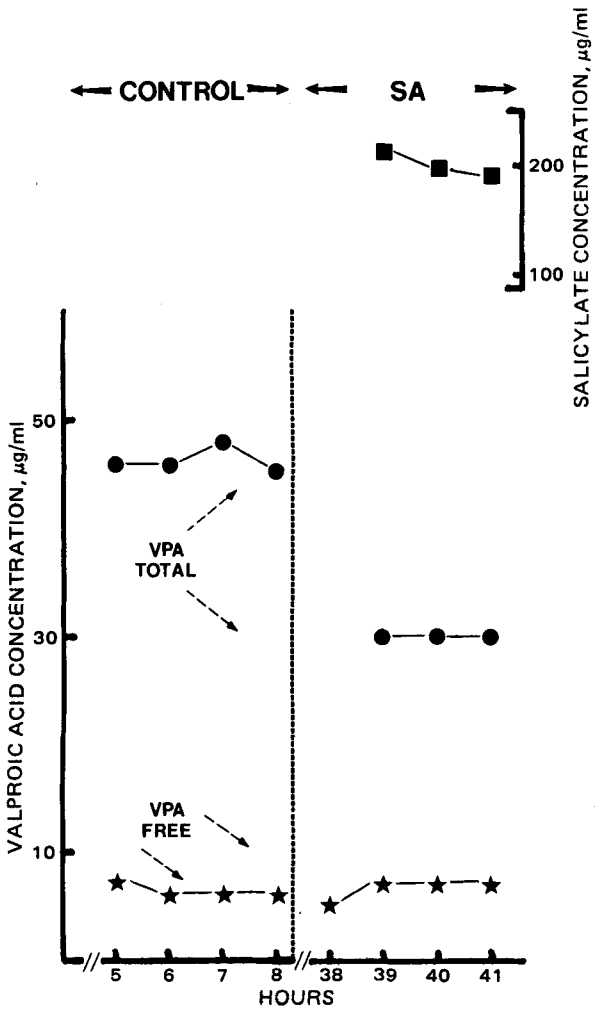

**Figure 2**—*Steady-state levels of total and free valproate (VPA) before and during salicylate (SA) infusion in Monkey 304.*

acid was infused for 41 hr (mean rate 74.4 mg/hr) and salicylic acid was added after the first 8 hr [valproic acid has a half-life of 1 hr in the monkey (15)]. The infusion rate of valproic acid was selected to yield levels in a clinically realistic range (30–80 μg/ml). The infusion rates of salicylic acid in the three studies were 55, 70, and 90 mg/hr. Study order was randomly assigned to each monkey, and a washout period of at least 2 weeks was allowed between studies.

Valproic and salicylic acids were administered as equivalents of sodium salts in sterile saline. All infusion equipment was covered with aluminum foil to protect salicylic acid from light.

Plasma samples were obtained at 5, 6, 7, and 8 hr following the start of infusion for control valproate steady-state levels and at 38, 39, 40, and 41 hr for steady-state levels of both drugs.

Valproate free fraction was determined by equilibrium dialysis. Each dialysis unit consisted of two 1-ml chambers separated by a dialysis membrane[1]. Plasma containing the drug (0.5 ml) was introduced into one chamber, and 0.5 ml of phosphate buffer (pH. 7.4) was added to the opposite chamber. The cells were kept immersed in a water bath at 37° for 24 hr. Valproate concentrations were measured from the buffer side (free drug) and plasma side (total drug) using a previously described GLC procedure (16). Plasma salicylate concentrations were determined as total salicylate by the spectrophotometric procedure of Wiseman *et al.* (17).

## RESULTS AND DISCUSSION

The effects of salicylate infusion on valproate steady-state levels are illustrated in Figs. 1 and 2 for Monkeys 201 and 304, respectively. Valproate free fraction and total body clearance before and after salicylate treatment are summarized in Table I; both increased significantly after salicylate treatment ($p < 0.05$). However, there was no significant change in the valproate free concentration ($p > 0.05$). As a result, total valproate levels decreased during valproate treatment. A significant correlation was obtained between the increase in valproate clearance and the molar ratio of salicylate to valproate ($y = 10.9x + 0.7$, $r = 0.93$, Fig. 3). Over 80% of the variability in the increase in valproate clearance can be explained by the salicylic acid concentration.

These findings indicate that salicylic acid is able to displace valproate acid from plasma protein binding sites *in vivo*. The results are consistent with the fact that valproic acid has a low extraction ratio in the rhesus monkey (15, 18). Pharmacokinetic theory predicts that the valproate free concentration should not be changed if salicylate affects valproate plasma binding without changing its intrinsic metabolic clearance (19). Several studies (12, 13) indicated that an *in vitro* plasma binding interaction exists between salicylic and valproic acids. If the interaction mechanism found in the rhesus monkey is also applicable in humans, this interaction should have little or no pharmacological consequence. However, since changes in total valproate levels would not reflect the changes in free levels, monitoring of the valproate free concentration would be indicated in patients receiving salicylates (20).

# Synthesis and Evaluation of Guanazole Prodrugs as Antineoplastic Agents

**CYNTHIA DIAS SELASSIE*, ERIC J. LIEN *x, and TASNEEM A. KHWAJA‡**

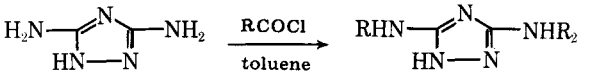
Received January 22, 1981, from the **Section of Biomedicinal Chemistry, School of Pharmacy, and the* ‡ *Department of Pathology, School of Medicine, University of Southern California, Los Angeles, CA 90033.* Accepted for publication April 16, 1981.

**Abstract** □ Nine amide derivatives of guanazole were synthesized, and eight of them were tested for antineoplastic activity *versus* L1210 cells *in vitro*. Several of these compounds exhibited activity comparable to or greater than that of guanazole.

**Keyphrases** □ Guanazole—synthesis and evaluation of prodrugs as antineoplastic agents □ Prodrugs—of guanazole, synthesis and evaluation as antineoplastic agents □ Antineoplastic agents—synthesis and evaluation of guanazole prodrugs

Guanazole (3,5-diamino-1,2,4-triazole, NSC 1895) was synthesized by Pellizzari (1) and discovered in a general screen by the National Cancer Institute. Subsequently, Brockman *et al.* (2) reported that guanazole inhibited DNA synthesis by inhibiting ribonucleotide reductase. Antitumor activity against various animal leukemias and tumors (3) and remissions in some patients with actute myelocytic leukemia (4) were reported. However, extensive clinical utilization of this drug has been limited by its high polarity and water solubility, low molecular weight, and relatively low potency, which warrants continuous intravenous infusion at frequent intervals (5).

Structure–activity relationship analysis of past and current work on guanazole derivatives established the importance of both amino groups for antineoplastic activity (2, 3). Thus, to circumvent the problem of the high elimination rate and to increase the efficacy of guanazole as an antieoplastic agent, amide derivatives with decreased polarity, water solubility, and increased molecular weight were synthesized (Scheme I). These compounds were then tested for anticancer activity *versus* L1210 cells *in vitro*.



R = $CH_3$, $C_2H_5$, $C_3H_7$, $C_6H_5$, $CF_3$, $C_2F_5$, $C_3F_7$, $p$-$NO_2C_6H_4$

*Scheme I*

The compounds and their physical properties are outlined in Table I.

## EXPERIMENTAL

**Chemistry**—All solvents were analytical grade. All melting points were taken in open capillary tubes[1] and are corrected. Elemental analysis[2] was within ±0.4% of the theoretical values. All proton NMR spectra were recorded on a 60 MHz spectrometer[3] with tetramethylsilane as the internal standard and solvents such as deuterochloroform, dimethyl sulfoxide-$d_6$, and trifluoroacetic acid. IR spectra were recorded on a spectrophotometer[4] as potassium bromide pellets or Fluorolube mulls. UV spectra were recorded on a double-beam spectrophotometer[5]. TLC was performed using Eastman-type 6060 chromatogram sheets (silica gel), and the sheets were developed in an iodine chamber to check the purity of the amides.

Most of these derivatives were synthesized by a general procedure for the acylation of amines. The appropriate acid chloride or anhydride was condensed with guanazole, usually in the presence of a nonpolar solvent. Two typical reactions for preparing the amides are described using III and VI as examples.

One gram (0.01 *M*) of guanazole and 4.2 g (0.02 *M*) of trifluoroacetic anhydride were refluxed in dry toluene for 8 hr. The white precipitate

[a] δC–H aromatic.

that formed was then washed with ether and dried *in vacuo* over phosphorus pentoxide. Drying afforded 2.26 g (78% yield) of the bis amide (III), mp 300°; IR (KBr): 1730 and 1760 ($\nu$C = 0) $cm^{-1}$.

One gram (0.01 *M*) of guanazole and 6.5 ml (1.58 g, 0.01 *M*) of heptafluorobutyric anhydride were refluxed in 10 ml of dry benzene for 4 hr. After standing overnight, the pale-yellow crystals were collected, washed with 5% ammonia, recrystallized from ethanol, and dried *in vacuo* over phosphorus pentoxide to yield 2.7 g (91% yield) of the product (VI), mp 300–301°; IR (KBr): 1725 ($\nu$C = 0) $cm^{-1}$.

**Biological Screening *versus* L1210 Cells *In Vitro***—For routine passage and during dose–response experiments, cells were maintained in asynchronous logarithmic growth at 37° in medium[6] supplemented with 10% fetal calf serum, 1% penicillin, and 1% streptomycin.

The cells were grown in a humidified incubator supplied with 95% air and 5% carbon dioxide at 37°. Stock cells were usually suspended at 6000–9000 cells/ml. The pH of the experimental flasks was adjusted to 7.4 with the addition of carbon dioxide. The drugs were solubilized with 1% dimethyl sulfoxide, diluted in phosphate-buffered saline, and added to the cell culture in 1:10 dilution to achieve the desired drug concentrations. Cell cultures were set up at 5000 cell/ml in duplicate for each drug concentration in 25-$cm^2$ flasks.

[6] Roswell Park Memorial Institute medium.

After 24, 48, and 72 hr of continuous drug exposure, the cells were harvested and counted using a Coulter counter. A control, 1% dimethyl sulfoxide-treated set of cultures, was included for each separate dose–response experiment. From the data obtained, a dose–response curve was drawn and the $ID_{50}$ value was calculated according to a reported method

| X | 0.0042 | 165.0 |

(6, 7). The $ID_{50}$ value represents the concentration of drug that halves the growth rate relative to untreated controls. Compound VII was not tested against L1210 cells *in vitro* due to insufficient quantity. The $ID_{50}$ value of VI could not be calculated due to negligible activity after 48 hr.

## RESULTS AND DISCUSSION

The amide derivatives were synthesized, and their structures were established by elemental analysis and IR, NMR, UV, and mass spectra (Tables II–IV). The hydrolysis rates of these amides are listed in Table V, and Table VI lists the calculated $ID_{50}$ values.

An assessment of the results *versus* L1210 cells revealed that, on the 1st day, VIII was substantially active. Solvolysis of this prodrug to an appreciable amount of guanazole by the medium was eliminated on the basis of the low hydrolysis rate ($t_{1/2}$ = 138 hr). Thus, VIII apparently shows activity *per se*, possibly due to its increased lipophilicity, which facilitates its transport into the cells where subsequent cytoplasmic hydrolysis may occur. However, increased interactions with the accessory binding site on the enzyme ribonucleotide reductase cannot be ruled out.

Compounds I and III showed activity comparable to that of guanazole against L1210 cells *in vitro*. Compound I, the most water soluble of the prodrugs, has a relatively short half-life ($t_{1/2}$ = 54 hr), which accounts for its activity after 48 hr. Compound III also has a short solvolytic half-life ($t_{1/2}$ = 79 hr), but its enhanced activity could be attributed to the release of trifluoroacetic acid, a well-known poison (8), as well as guanazole. The other prodrugs with extended half-lives may not have released guanazole in adequate amounts to exert the observed response. Some of the prodrugs such as VI, VIII, and IX might act as excellent depots of guanazole *in vivo*. *In vivo* testing of some of these compounds is in process.

Table VI—*In Vitro* Inhibition of L1210 by Guanazole Prodrugs

| Compound | $ID_{50}$, $M$ |
|---|---|
| Guanazole | $2.08 \times 10^{-4}$ |

# Pharmacokinetics of Intravenous Chlorpheniramine in Children

JOHN A. THOMPSON *x, DUANE C. BLOEDOW *, and FRED H. LEFFERT ‡§

Received January 30, 1981, from the *School of Pharmacy, University of Colorado, Boulder, CO 80309, and the ‡Departments of Pediatrics, National Jewish Hospital and the University of Colorado School of Medicine, Denver, CO 80206. Accepted for publication March 20, 1981. §Present address: Professional Park-on-Cleveland, 3-B Cleveland Court, Greenville, SC 29607.

**Abstract** □ The disposition of chlorpheniramine was examined in seven children, 6–14 years of age, following a 0.1-mg/kg iv dose. Postinjection serum chlorpheniramine levels in each subject declined biexponentially, with the greatest intersubject variability occurring in the initial distribution of the drug. The volume of distribution at steady state ranged from 1.20 to 5.46 liters/kg. The chlorpheniramine serum clearance varied approximately twofold (234–470 ml/hr/kg) and generally decreased with age. The chlorpheniramine elimination half-life in children (mean of 9.6 hr) appeared shorter than that in adults, probably due to higher chlorpheniramine serum clearance in children.

**Keyphrases** □ Chlorpheniramine maleate—pharmacokinetics of intravenous drug in children □ Pharmacokinetics—intravenous chlorpheniramine maleate in children □ Antihistaminics—pharmacokinetics of intravenous chlorpheniramine maleate in children

Antihistamines represent a primary pharmacological approach to therapy for conditions such as allergic rhinitis and urticaria in patients of all ages. An appropriate antihistamine and its dose are often chosen by trial and error, sometimes with marginal success. Failure of an antihistamine to provide adequate relief could be due to intrinsic limitations in the drug's effectiveness or to suboptimal dosing due to a lack of pharmacokinetic information.

Although chlorpheniramine maleate has been a widely used antihistamine for many years, only limited pharmacokinetic information on it has been reported, and no information for children is available. Studies with adults reveal inconsistencies in biological half-life, with values ranging from 2 to 43 hr. (Table I) (1–7). Recently reported longer half-lives for chlorphreniramine have been attributed to longer blood sampling periods (6).

A highly sensitive assay procedure for chlorpheniramine was recently developed (8). The distribution and elimination of chlorpheniramine following intravenous administration of the drug to children were examined using this technique. This report presents the results of these studies.

## EXPERIMENTAL

**Methods**—Seven children, 6–14 years of age and 24–63 kg (Table II), were studied. The children were participating in a study of chronic rhinitis, and all had perennial rhinitis but no other significant medical problems. None had received antihistamines or any other medication for at least 1 month prior to the study. The children were studied for a 24-hr period[1].

Chlorpheniramine maleate[2], 0.10 mg/kg, was administered intravenously over 5 min by an infusion pump[3]. Serum was obtained from venous blood samples collected immediately prior to drug administration and at 0.25, 0.5, 1, 2, 4, 6, 8, 12, and 24 hr following completion of the 5-min infusion. Serum was stored at −70° until analyzed.

Chlorpheniramine analysis was performed by GLC–mass spectrometry. A tetradeuterated analog was prepared for use as the internal standard. Each serum sample (2.0 ml) was mixed with 85 ng of the internal standard, and extractions were carried out as previously described[4] (8). Final extracts were evaporated to dryness, redissolved in 5 μl of acetonitrile, and analyzed[5]. Ion current was monitored for $m/z$ 203 (chlorpheniramine) and 207 (tetradeuterated chlorpheniramine). Peak area ratios were converted to concentrations by using a calibration curve for the chlorpheniramine concentration range of 0–160 ng/ml.

**Table I—Summary of Available Information on Chlorpheniramine Half-Life in Adults**

| Half-Life, hr | Number of Subjects | Dose, mg | Route | Blood-Sampling Period, hr | Reference |
|---|---|---|---|---|---|
| 2[a] | 6 | 4 | Oral tablet | 5 | 1 |
| 12–15 | 6 | 12 | Oral tablets | 48 | 2 |
| 28 | 2 | 4 | Intravenous | 48 | 2 |
| 4 | 3 | 4 | Oral syrup | 12 | 3 |
| 24.5–36.3 | 4 | 8 | Oral capsule | 48 | 4 |
| 18 | 4 | 4,8,12 | Oral | 24 | 5 |
| 19–43 | 5 | 8 | Oral tablet | 60 | 6, 7 |
| 22, 23 | 2 | 5 | Intravenous | 60 | 6, 7 |

[a] Estimated from Ref.

The serum chlorpheniramine concentration ($C$) *versus* time curve for each subject was computer-fitted[6] (9) to the biexponential equation:

$$C = Ae^{-\alpha t} + Be^{-\beta t} \qquad \text{(Eq. 1)}$$

where $A$, $\alpha$, $B$, and $\beta$ are constants. Coefficients of determination ($r^2$) ranged from 0.991 to 1.000, and correlation coefficients ($r$) ranged from 0.989 to 0.997, indicating that the biexponential equation adequately describes the time course of serum chlorpheniramine concentrations after short-term intravenous infusion.

Following correction of $A$ and $B$ for the 5-min injection period, the intercepts ($A$ and $B$) and slopes ($\alpha$ and $\beta$) were used to calculate the distribution of half-life ($t_{1/2,\alpha}$), the biological half-life ($t_{1/2,\beta}$), the initial dilution volume ($V_1$), the volume of distribution at steady state ($V_{ss}$), the postdistribution volume ($V_\beta$), and the serum clearance ($Cl$) (10).

## RESULTS

The biexponential decline of serum chlorpheniramine in a representative child (Subject SW) is shown in Fig. 1. Pharmacokinetic parameters describing chlorpheniramine distribution and elimination in this group of children are summarized in Table II. In this small group, no significant correlations could be shown relating absolute (not weight-adjusted) distribution volumes or serum clearance to total body surface area (11) ($V_1$, $r = -0.399$; $V_{ss}$, $r = 0.467$; $V_\beta$, $r = 0.619$; and $Cl$, $r = 0.638$). Similarly, correlations relating absolute distribution volumes or clearance to total body weight were not significant($V_1$, $r = -0.394$; $V_{ss}$, $r = 0.511$; $V_\beta$, $r = 0.654$; and $Cl$, $r = 0.695$). The distribution volumes and clearance values in Table II have been weight adjusted to facilitate comparison to available literature data for chlorpheniramine disposition in adults.

The initial distribution of the drug was quite variable, as evidenced by a large intersubject variation in the initial dilution volume ($V_1$), $\alpha$, and $t_{1/2,\alpha}$. The intersubject variability of other pharmacokinetic parameters is in the range given for other drugs in children (12).

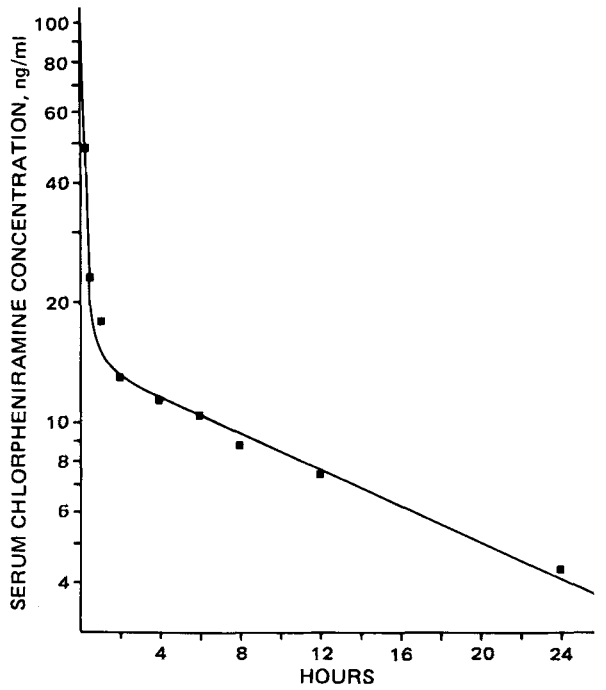

**Figure 1**—*Serum chlorpheniramine concentrations following the intravenous administration of a 0.1-mg/kg dose of chlorpheniramine maleate to Subject SW.*

## DISCUSSION

The biological half-life for chlorpheniramine in adults has been reported to be as short as 2 hr and as long as 43 hr (Table I). Recent adult studies used a sensitive liquid chromatographic method to show that the chlorpheniramine half-life was 22 and 23 hr following intravenous administration to two subjects and 19–43 hr following oral administration to five subjects (6, 7). The previously reported shorter half-lives for chlorpheniramine in adults could be attributed to shorter blood sampling periods (6) and assay differences. A comparison of the biological half-lives for chlorpheniramine in this group of children (5.2–15.7 hr, Table II) with biological half-lives reported recently for adults indicates that the drug is eliminated much more rapidly from children than from adults.

Biological half-life ($t_{1/2,\beta}$) is directly related to ($V_\beta$) and inversely related to $Cl$ according to:

$$t_{1/2,\beta} = \frac{0.693 \cdot V_\beta}{Cl} \qquad \text{(Eq. 2)}$$

Comparisons between recently reported adult data and the data from this study in children offer evidence that the shorter chlorpheniramine biological half-life in children is primarily due to a greater chlorpheniramine serum clearance in children rather than to a difference in distribution volumes. The chlorpheniramine postdistribution volume ($V_\beta$) in children averaged 4.30 liters/kg (range 2.28–5.63 liters/kg) and is similar to the postdistribution volume reported for adults (7) (3.2 and 3.6 liters/kg). The serum clearance for chlorpheniramine in children averaged 323 ml/hr/kg (range 234–470 ml/hr/kg), while plasma clearance in adults is ~100 ml/hr/kg (estimated from Ref. 7). The more rapid elimination of chlorpheniramine from children compared to adults is similar to that reported for other drugs (13). Interestingly, in this small sample of children the serum clearance of chlorpheniramine is negatively correlated with age ($r = -0.799$, $p < 0.05$) and, no correlation could be shown between serum clearance and weight ($r = -0.144$) or body surface area ($r = -0.551$).

Presently available information is insufficient for formulation of dosing recommendations for children; data on the relation between serum chlorpheniramine level and biological effect are needed. Little is known about the optimum chlorpheniramine serum concentration necessary for treatment of the clinical conditions for which the drug is used. In addition, since chlorpheniramine is commonly administered orally, an estimate of bioavailability would be necessary for formulating dosing recommendations. Studies in adults indicated that oral bioavailability is low (25 and 44% in two subjects following administration of tablets), possibly due to an extensive gut first-pass effect (7). Oral chlorpheniramine bioavailability estimates have not been reported for children.

Although optimum serum chlorpheniramine levels and bioavailability in children have not been reported, the apparent age-related differences in chlorpheniramine elimination indicate that adherence to a fixed milligram per kilogram maintenance dose may not be appropriate in all children. An oral dosage regimen of 0.35 mg/kg/day in four doses (or 0.0875 mg/kg every 6 hr) has been recommended for older infants and children (14). The desired average steady-state serum drug concentration ($\overline{C}_{ss}$) is directly related to the fraction of the oral dose absorbed ($F$) and the oral maintenance dose ($D$) and indirectly related to the serum clearance ($Cl$) and the dosing interval ($\tau$) according to:

$$\overline{C}_{ss} = \frac{F\,D}{Cl\,\tau} \qquad \text{(Eq. 3)}$$

With the assumption of no variation in bioavailability ($F$), the recommended oral dosage regimen could produce a twofold variation in average serum levels ($\overline{C}_{ss}$), based on the twofold variation in the chlorpheniramine serum clearance in the group of children studied (Table II). The data suggest that younger children may require a slightly larger milligram per kilogram dose than the older child to produce equivalent serum chlorpheniramine levels, barring age-related differences in bioavailability.

Based purely on pharmacokinetic considerations, frequent dosing of chlorpheniramine may not be necessary in adults because of the long elimination half-life (6, 7). The present study indicates that frequent dosing may be advisable in children to reduce possible widely fluctuating and perhaps excessive or subtherapeutic serum chlorpheniramine levels. Dosing frequency decisions are complicated, however, by the generally accepted statement that the therapeutic effect of chlorpheniramine is no longer than 4 hr (2). Whether this is true in children is unclear and deserving of additional study.

# Application of One-Phase End-Point Change System in Two-Phase Titration to Amine Drug Analysis

**MASAHIRO TSUBOUCHI** *x, **HIROMI MITSUSHIO** ‡, **NAKAMICHI YAMASAKI** ‡, and **KIYOSHI MATSUOKA** ‡

Received December 2, 1980, from the *Laboratory of Chemistry, Kochi Medical School, Oko, Nankoku, Kochi 781-51, Japan, and the ‡ Department of Geology, Faculty of Science, Kochi University, Asakura, Japan. Accepted for publication March 30, 1981.

**Abstract** □ A titration method was developed for the determination of diphenhydramine, quinine, neostigmine, sparteine, strychnine, homatropine, atropine, physostigmine, and procaine in aqueous solution. Tetraphenylborate was used as a titrant with tetrabromophenolphthalein ethyl ester as an indicator in the presence of organic solvent. End-point detection was based on the color change of the indicator in the organic phase without movement of the indicator from one phase to the other.

**Keyphrases** □ Amine drugs—analysis, two-phase titration □ One-phase end-point change system—two-phase titration, amine drugs □ Two-phase titration—amine drugs, one-phase end-point change system

Titration methods permit the convenient determination of organic and inorganic ions without complex instrumentation. Solvent extraction techniques are also convenient in the titration field. Two-phase titration (ion-pair extraction–titration) using methylene blue was proposed by Weatherburn (1) in 1950. However, with this two-phase dye transfer titration method, it is generally difficult to detect the end-point because a dye color in an aqueous layer reflects to the organic layer (2). Subsequently, additional reports (2–5) described two-phase dye transfer procedures involving modifications of the methylene blue method and substitutions of various dyes for methylene blue.

Titration end-point detection, however, can be a problem with the two-phase titration method due to color reflectance between phases and differences in the color shade or hue in the two phases. These problems occur because the end-point detection in the two-phase titrations is based on the transfer of the indicator dye from one phase to the other, with end-points usually taken when color intensity is judged to be equal between the two phases. The two-phase titration has been applied only to the determination of surfactants. Mohammed and Cantwell (6) recently developed a two-phase photometric titration method for the determination of drugs and surfactants.

The present paper reports a new two-phase titration method based on the change of indicator in only one phase without movement of the indicator from one phase to the other. This one-phase end-point change system provided the two-phase titration method for the determination of amines in aqueous solution. Colorimetric and nonaqueous titrimetric methods were used for the determination of alkaloids or amines.

## EXPERIMENTAL[1]

**Reagents**—The potassium salt of tetrabromophenolphthalein ethyl ester, dissolved in ethanol to make a 0.1% solution, was used as the indicator.

**Buffer Solution**—A borate–phosphate buffer was prepared by adding 2 *N* $H_2SO_4$ to a 0.2 *M* dibasic sodium phosphate solution containing 0.1 *M* sodium borate.

**Titrant**—Sodium tetraphenylborate (3.422 g), dried at 80°, was dissolved in water and diluted to 1 liter to make a 0.01 *M* solution.

**Amine Solution**—Sample solutions of diphenhydramine, quinine, neostigmine, sparteine, strychnine, atropine, physostigmine, and procaine were prepared by dissolving their hydrochlorides, bromides, or sulfates in 0.002 *N* $H_2SO_4$. The solutions were standardized by the official method (7).

**Titration Procedure**—The proposed titration methods with a one-phase end-point change system are summarized in Table I. For example, the determination of diphenhydramine was as follows: 1–10 ml of diphenhydramine solution (0.01 or 0.005 *M*), 5 ml of borate–phosphate buffer (pH 5.5–7.5), 10 ml of ethylene dichloride, and 3–4 drops of indicator solution were placed in a 300-ml erlenmeyer flask. The mixture was titrated with 0.01 *M* tetraphenylborate solution with manual intermittent shaking to ensure equilibrium between the organic solvent and the aqueous phase.

The other amines or alkaloids in Table I were treated in the same manner as described for diphenhydramine.

## RESULTS AND DISCUSSION

**End-Point Color**—The one-phase end-point change system is based on the hydrophobic indicator, which is able to react with ions in the aqueous phase. The tetrabromophenolphthalein ethyl ester indicator is a monoprotic acid and can form ion associates or charge transfer complexes with amines or alkaloids (8). The initial mixture of the amines

**Table I—Two-Phase Titration with One-Phase End-Point Change System for Determination of Amines [a]**

| Amine | pH in Aqueous Phase | Organic Solvent | Color Change in Organic Phase at End-Point |
|---|---|---|---|
| Diphenhydramine | 5.5–7.5 | Ethylene dichloride | Violet → yellow |
| Quinine | 4.5–6.0 | Nitroethane | Violet → yellow |
| Berberine | 5.0–9.5 | Chloroform | Blue → yellow |
| Neostigmine | 9.0–9.5 | Ethylene dichloride | Greenish blue → yellow |
| Sparteine | 5.0–9.0 | Ethylene dichloride | Blue → yellow |
| Alkaloids [b] | 5.5–6.5 | Ethylene dichloride | Reddish blue → greenish yellow |

[a] The indicator was tetrabromophenolphthalein ethyl ester, and the titrant was tetraphenylborate. [b] Strychnine, homatropine, atropine, physostigmine, and procaine.

or alkaloids in Table I, buffer solution, indicator, and organic solvent yields a solution with a colorless aqueous layer and a blue or violet organic phase. As the solution is titrated with tetraphenylborate, with thorough shaking after each addition of titrant, the organic solution turns green near the end-point. When 1 drop of excess is added, the organic phase turns yellow, indicating the titration end-point. The upper aqueous layer remains colorless throughout titration due to the water insolubility of the tetrabromophenolphthalein ethyl ester indicator. Amines or alkaloids cannot be determined by the two-phase dye transfer titration method with methylene blue as an indicator because the end-point is not clear.

**Effect of pH on Titration**—The effect of pH was studied by titrating a series of amines and alkaloids at various pH values. The titer was constant when the pH of the aqueous phase was within the range shown in Table I. When an amine (A) is titrated with a tetraphenylborate ion ($B^-$) solution, the $[A\text{-}H^+\cdot B^-]$ complex is formed in the organic layer. The end-point of the titration with the proposed indicator (Ind) is described by:

$$[A\text{-}H^+ \cdot Ind^-]_o + [B^-]_w + H^+ \rightarrow [A\text{-}H^+ \cdot B^-]_o + [H\text{-}Ind]_o$$

*violet or blue* — *yellow*

*Scheme I*

where $o$ is the organic phase and $w$ is the aqueous phase. The indicator in the $[A\text{-}H^+\cdot Ind^-]_o$ complex is substituted by the titrant ion to liberate the indicator in the nondissociated form.

The basic equilibria for the titration of diphenhydramine can be represented by:

$$D + B \rightleftharpoons [DB]$$

*Scheme IIa*

$$D + Ind \rightleftharpoons [DInd]$$

*Scheme IIb*

where D is the diphenhydramine. (For simplicity, charges are omitted.) The corresponding equilibrium constants are:

$$K_{DB} = [DB]/([D][B])$$

*Scheme IIIa*

$$K_{DInd} = [DInd]/([D][Ind])$$

*Scheme IIIb*

The effective stability constants ($K'$) at room temperature can be obtained by determining [DB] and [DInd] in the organic phase using spectroscopic absorption measurements at various pH values (9). A simple log $K'$–pH diagram is given in Fig. 1 for the titration. Line 1 represents pD or $-\log[D]$ at two equivalents of tetraphenylborate where $[B]_w = [BD]_o$. Line 2 corresponds to the pD or $-\log[D]$ values at which $[DInd]_o = [Ind]_o$. From the log $K'$–pH diagram, a theoretical titration curve is constructed for the 0.01 $M$ tetraphenylborate titration of 10 ml of 0.01 $M$ diphenhydramine at pH 6.5 (Fig. 2). The shaded areas indicate the region of the color change of tetrabromophenolphthalein ethyl ester indicator, with C corresponding to the point of 50% color change. A maximum color change is obtained by a minimum increment of titrant at this point. The fractional color change from 0.1 to 0.9 covers ~2 pD units. The theoretical titration curve at pH 6.5 was in good agreement with experimental values.

**Other Variables and Foreign Substances**—Larger amounts of buffer solution had no influence on titration, but amounts of <0.5 ml caused problems in phase separation. Initial volume fluctuations of the aqueous layer (5–25 ml) and the organic layer (7–15 ml) had no influence on the determination of the titration end-point. The effect of water-immiscible solvents on titration were tested: butyl acetate, benzene, carbon tetrachloride, chlorobenzene, chloroform, ethylene dichloride, $n$-hexane, isopentyl alcohol, methyl isobutyl ketone, nitrobenzene, nitroethane, and toluene. Of these solvents, the best ones for the titration are summarized in Table I.

The effect of several salts on the titration of 10 ml of 0.01 $M$ diphenhydramine solution indicated that the following ions did not interfere at the 0.01 $M$ level: $Na^+$, $Ca^{2+}$, $Mg^{2+}$, $NH_4^+$, $K^+$, $NO_3^-$, $SO_4^{2-}$, $CO_3^{2-}$, $Br^-$, $I^-$, $Cl^-$, acetate, citrate, and tannate. Amines such as thiamine and papaverine caused positive errors. Lauryl sulfate and mercury II interfered.

**Precision and Analysis of Practical Samples**—The reproducibility of the proposed method with 0.005 $M$ titrant solution was estimated from

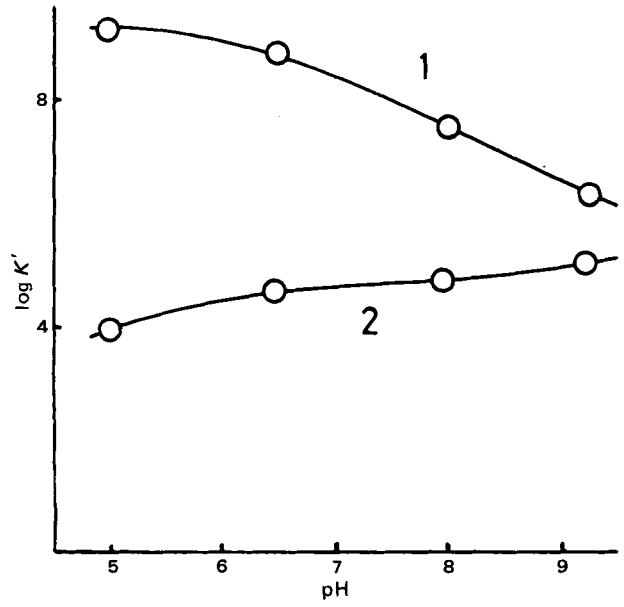

**Figure 1**—*Log K′–pH diagram. Key: 1, log $K'_{DB}$; and 2, log $K'_{DInd}$.*

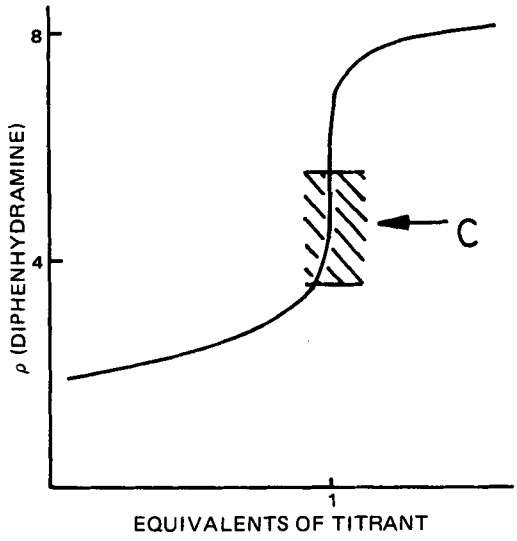

**Figure 2**—*Theoretical titration curve at pH 6.5; 10 ml of 0.01* M *diphenhydramine is titrated with 0.01* M *tetraphenylborate.*

the results of 10 sample solutions (5 ml), each with a sparteine concentration of 0.005 *M*. The mean titer was 5.02 ml, with a standard deviation of 0.05 ml. The relative error was ~2% when 5 ml of diphenhydramine solution was titrated according to the procedure.

Commercial products containing diphenhydramine (injection, 10 mg/ml; tablet, 90 mg/g; and ointment, 10 mg/g) were analyzed according to the proposed method and a spectrophotometric method (8). The results were 9.97, 91.0, and 9.90 mg of diphenhydramine/ml in the injection, tablet, and ointment, respectively, by the proposed method and 9.95, 90.7, and 9.87 mg/g, respectively, by the spectrophotometric method. Tablet samples were dissolved in dilute sulfuric acid. The solution was filtered with a glass filter. Ointment samples were dispersed with 15 ml of ether in a separator. The contents were extracted three times with 10-ml portions of 0.1 *N* $H_2SO_4$. The extracts were neutralized slightly with 0.1 *N* NaOH solution.

# Measurement of Pseudoephedrine Hydrochloride Dissolution Using Chloride-Ion Electrode

**S. T. CHEN, R. C. THOMPSON, and R. I. POUST** ˣ

Received October 24, 1980, from the *Pharmaceutical Research and Development Laboratories, Burroughs Wellcome Co., Greenville, NC 27834* Accepted for publication April 17, 1981.

**Abstract** □ Experiments were performed to determine the suitability of using a chloride-ion electrode for the measurement of pseudoephedrine hydrochloride dissolution from commercially available compressed tablets. Dissolution experiments were carried out in 500 ml of distilled water using the USP paddle method at 100 rpm. Both chloride ion and pseudoephedrine (UV spectrophotometry) were measured at six different sampling times. Percent dissolved *versus* time values were linearized on a log-normal probability basis. The slopes of individual lines obtained from the chloride and pseudoephedrine measurements were compared using a Student *t* test and did not differ significantly ($t = 0.415$, $df = 5$, $p > 0.05$). In addition to providing an efficient, inexpensive, and simple method for measuring pseudoephedrine hydrochloride dissolution rates, the chloride-ion electrode could be used in the measurement of dissolution rates for a wide variety of drugs available as hydrochloride salts.

**Keyphrases** □ Pseudoephedrine hydrochloride—measurement of dissolution using chloride-ion electrode □ Chloride-ion electrode—measurement of pseudoephedrine hydrochloride dissolution □ Dissolution—pseudoephedrine hydrochloride, measurement using chloride-ion electrode

There has been a significant increase in the use of dissolution rate testing for the development of new dosage forms as a quality assurance tool and as a predictor of bioavailability in instances where successful *in vivo–in vitro* correlations have been established. Recent activity has centered on the establishment of automated procedures and the optimization of existing methodology with emphasis on the USP rotating-basket and USP paddle methods (1). One interesting aspect has been the automation of analytical measurements, mainly through the use of flow-through cells in conjunction with various spectrophotometers (2–7). Another analytical procedure that lends itself to automation is the use of a specific ion electrode to measure directly the drug's counterion in the dissolution flask.

## BACKGROUND

A survey of the recent literature revealed limited use of selective ion electrodes for measurement of tablet or capsule dissolution rates. Mason *et al.* (8) described the use of a sodium-ion selective electrode for the measurement of dissolution rates of specially prepared sodium salicylate tablets. They found agreement between sodium-ion concentrations measured by the selective ion electrode and atomic absorption spectrophotometry. Sodium-ion concentrations agreed with salicylate concentrations measured spectrophotometrically. The method was later extended (9) to measure dissolution rates of commercial tablets containing warfarin sodium, butabarbital sodium, and sodium bicarbonate. Data obtained by selective ion electrode and spectrophotometric measurements were in agreement when both methods were utilized.

Thomas (10) used a potassium-ion specific electrode to study the release rate of potassium from several brands of slow-release potassium chloride tablets. Other investigators (11), using similar methodology, also studied the dissolution release pattern of sustained-release potassium chloride tablets. This report presents the results of similar studies using anion measurements; *i.e.*, a chloride-ion electrode was used to measure the dissolution rate of commercial pseudoephedrine hydrochloride tablets.

## EXPERIMENTAL

**Materials**—Pseudoephedrine hydrochloride tablets[1] (60 mg/tablet) and pseudoephedrine hydrochloride[2] were used as received. An ionic strength adjuster (5 *M* $NaNO_3$) was prepared by dissolving 42.5 g of sodium nitrate[3] in 100 ml of distilled water.

**Chloride-Ion Measurements**—Chloride ions were detected by a chloride-ion electrode[4] together with a double-junction electrode[5]. The electrodes were connected to an analyzer[6], which displayed direct millivolt readings of the measured potentials.

A calibration curve was constructed for pseudoephedrine hydrochloride. Standard solutions of 0.01–1.00 mg/ml were prepared. For each standard solution, 100 ml of solution and 2 ml of ionic strength adjuster were poured into a 150-ml glass beaker and thoroughly stirred. The millivolt reading was recorded once the reading stabilized. These values were then linearized by plotting them on a linear scale as a function of the logarithm of the chloride concentration.

**UV Spectrophotometric Measurements**—A Beer's law curve was constructed for pseudoephedrine hydrochloride in distilled water. The

Thomas (10) used a potassium-ion specific electrode to study the release rate of potassium from several brands of slow-release potassium chloride tablets. Other investigators (11), using similar methodology, also studied the dissolution release pattern of sustained-release potassium chloride tablets. This report presents the results of similar studies using anion measurements; *i.e.*, a chloride-ion electrode was used to measure the dissolution rate of commercial pseudoephedrine hydrochloride tablets.

## EXPERIMENTAL

**Materials**—Pseudoephedrine hydrochloride tablets[1] (60 mg/tablet) and pseudoephedrine hydrochloride[2] were used as received. An ionic strength adjuster (5 *M* $NaNO_3$) was prepared by dissolving 42.5 g of sodium nitrate[3] in 100 ml of distilled water.

**Chloride-Ion Measurements**—Chloride ions were detected by a chloride-ion electrode[4] together with a double-junction electrode[5]. The electrodes were connected to an analyzer[6], which displayed direct millivolt readings of the measured potentials.

A calibration curve was constructed for pseudoephedrine hydrochloride. Standard solutions of 0.01–1.00 mg/ml were prepared. For each standard solution, 100 ml of solution and 2 ml of ionic strength adjuster were poured into a 150-ml glass beaker and thoroughly stirred. The millivolt reading was recorded once the reading stabilized. These values were then linearized by plotting them on a linear scale as a function of the logarithm of the chloride concentration.

**UV Spectrophotometric Measurements**—A Beer's law curve was constructed for pseudoephedrine hydrochloride in distilled water. The

[a] $n = 6$.

absorbances of the standard and sample solutions were read at a wavelength of 257 nm[7].

**Dissolution Studies**—Dissolution studies were performed using the USP rotating-paddle method (1) at a stirring rate of 100 rpm. The dissolution medium consisted of 500 ml of distilled water and 10 ml of ionic strength adjuster for chloride-ion measurements. The ionic strength adjuster was omitted when UV measurements were made.

For measurements of chloride-ion concentrations, the electrodes were placed in the flask 5 cm from the bottom to permit direct measurement without sample withdrawal. Ten-milliliter samples were withdrawn with replacement and filtered through 0.65-$\mu$m membrane filters[8] for UV measurements. Direct readings and sample withdrawal were done at 2, 5, 10, 15, 30, and 60 min. These experiments were performed on two different batches of tablets. Six tablets from each batch were studied by each of the two analytical methods.

Measured concentrations were converted to amount dissolved, with correction for sample replacement where appropriate. The data was linearized using log-normal probability plots. The slopes of the resulting lines were statistically analyzed using a Student $t$ test.

## RESULTS AND DISCUSSION

The millivolt readings of the standard solutions were recorded on 3 consecutive days and indicated good reproducibility. A similar concentration range of standard solutions was prepared on 3 different days, and millivolt readings of each solution were recorded immediately after preparation with good reproducibility. A higher standard error of the mean (*SEM*) was observed at the 0.01-mg/ml concentration. Because the range of concentrations between 0.01 and 0.03 mg/ml was of minimal importance to the dissolution test, the calibration curve was established between 0.03 and 1.00 mg/ml and expressed as:

$$V = 125.62 - 53.55(\log D) \qquad \text{(Eq. 1)}$$

where $V$ is the potential (millivolts), $D$ is the drug concentration (milligrams per milliliter). Linear correlation coefficient ($r$) was 0.996.

Dissolution test results for both analytical methods are summarized in Table I for the two batches of 60-mg pseudoephedrine hydrochloride tablets. Although some differences existed at the 5-, 10-, and 15-min sampling times for both batches, no statistically significant differences were found between the dissolution rates as determined by the two methods at the 95% confidence level.

Initial attempts to use this method for the measurement of dissolution rates of sugar-coated 30-mg pseudoephedrine hydrochloride tablets resulted in large amounts (120–150% of label strength) of pseudoephedrine hydrochloride appearing in solution. Various experiments were conducted to determine the source of this considerable interference with the measurement of chloride ions. The results revealed that the major source was caused by certain unidentified ingredients in the coating material. These findings indicated that the chloride-ion electrode would be of limited use for obtaining dissolution rate profiles for such products. However, a standard could be established for the measurement of dissolution at a single time point as a quality assurance procedure.

The results of these studies demonstrate that use of a chloride-ion electrode is a rapid and effective way of generating dissolution data provided that interferences are minimal. Although this report is limited to a single drug, the method may have application for other drugs available as hydrochloride salts.

# Binding of Drugs to Human Serum Albumin XVII: Irreversible Binding of Mercaptopurine to Human Serum Proteins

**INGVAR SJÖHOLM ˣ and BRITA STJERNA**

Received January 14, 1981, from the *Department of Pharmaceutical Biochemistry, Biomedical Center, University of Uppsala, S-751 23 Uppsala, Sweden.* Accepted for publication April 23, 1981.

**Abstract** □ Studies on the binding of mercaptopurine to human serum, human serum albumin, or orosomucoid gave varying results, with binding ranging from 20 to 90%. Binding has been shown to be affected by oxidizing agents, which increase binding at low concentrations, and by reducing agents, which decrease binding. Repeated equilibrium dialyses and gel filtration experiments indicated that mercaptopurine is partly irreversibly bound to serum proteins. This binding is oxidation dependent and probably involves the sulfhydryl group of the drug.

**Keyphrases** □ Mercaptopurine—irreversible binding to human serum proteins □ Binding—irreversible, of mercaptopurine to human serum proteins □ Antineoplastics—mercaptopurine, irreversible binding to human serum proteins

Loo *et al.* (1) reported that mercaptopurine is bound 19% in human plasma. However, preliminary studies in this laboratory using equilibrium dialysis to measure the binding of mercaptopurine to serum proteins *in vitro* gave varying results. Moreover, Scatchard analyses of data obtained from experiments with serum, purifed human serum albumin, and orosomucoid gave very low $n$ values, which were not compatible with reversible binding to a specific binding site. The variance obtained with different serum samples was even greater than that seen when identical samples were compared. However, aged serum samples generally gave higher binding (up to ~90%).

Further investigation indicated that binding was influenced by the presence of reducing or oxidizing agents, *e.g.*, mercaptoethanol and hydrogen peroxide. The present paper shows that the varying binding of mercaptopurine to serum proteins *in vitro* can be explained by irreversible binding phenomena involving the reactive mercapto group of the drug.

## EXPERIMENTAL

**Drugs**—6-Mercaptopurine was used in the unlabeled[1] or $^{14}$C-labeled[2] form. Radiochemical purity (>96%) was checked by TLC.

**Serum**—Two types of serum samples were used: (*a*) pooled normal serum obtained from healthy persons and stored frozen for a long time, and (*b*) freshly prepared normal serum from three healthy persons and used within several days. The blood was collected in untreated glass tubes without any additions.

**Equilibrium Dialysis**—Serum protein binding was determined by equilibrium dialysis at 20° against an isotonic phosphate buffer (2), pH 7.4, using standard membranes[3]. Duplicate determinations were performed, and the amount of serum and buffer was 500 μl on each side of the dialysis cell. The drug was dissolved in the buffer. The equilibration time was 17–19 hr. Control experiments indicated that equilibrium was reached within 15 hr. After equilibration, radioactivity was determined in duplicate with 200 μl of sample aliquots from both sides of the dialysis cells in 5 ml of Instagel.

**Gel Filtration**—Gel filtration was performed with Sephadex G-25[4] in a 25 × 1.5-cm column and a 0.005 $M$ phosphate buffer (pH 7.4) with 0.1 $M$ potassium chloride.

## RESULTS AND DISCUSSION

**Equilibrium Dialysis**—Quantitative studies on the binding of [$^{14}$C]mercaptopurine to serum proteins by equilibrium dialysis gave varying results. The variation was particularly large between fresh and aged serum samples, and addition of reducing or oxidating agents significantly affected binding. Table I summarizes some of the results obtained. Each group of results was obtained with identical serum samples at the same time but with different treatments. Thus, the binding to freshly drawn serum was ~20–30%, while serum stored frozen for ~3 years bound ~90% of the drug. If the freshly drawn serum was exposed to air, binding significantly increased with time. In contrast, addition of reducing substances (cysteine, dithiothreitol, or mercaptoethanol) profoundly impaired the binding of both aged and fresh serums.

The difference in the binding capacity of fresh and aged serums was probably due to serum oxidation since addition of small amounts of hydrogen peroxide increased binding (Table I). However, when hydrogen peroxide was increased to millimolar concentrations, the detected binding decreased. Later experiments with gel filtrations indicated that this effect was mainly due to the oxidation of mercaptopurine to the dimeric form, which has a lower affinity for albumin.

These results suggest that the binding of mercaptopurine to the serum proteins depends on the oxidation–reduction properties of the system. Thus, the sulfhydryl group of the mercaptopurine may be involved in the binding. Such binding involving a covalently bound S-group should not be easily reversible.

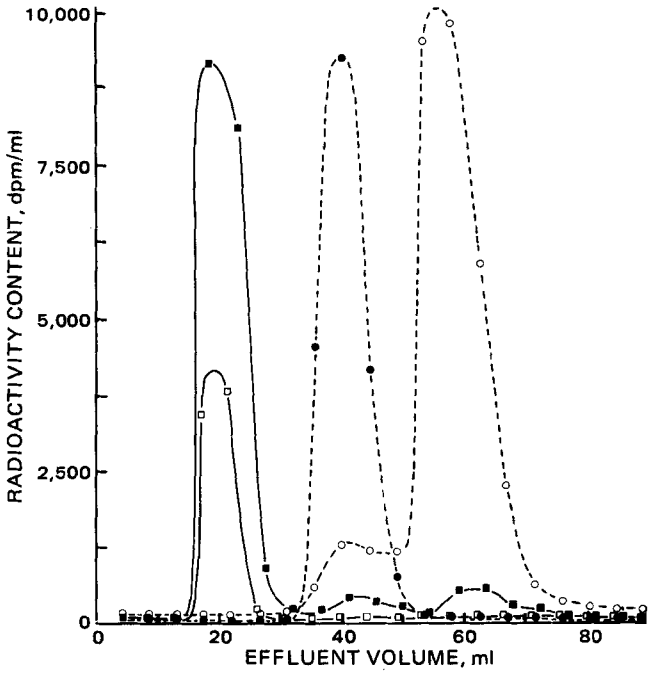

**Figure 1**—*Aged human serum with [$^{14}$C]mercaptopurine chromatographed in 0.1* M *potassium chloride with 0.005* M *phosphate, pH 7.4 (■). The protein peak fraction was rechromatographed under the same conditions (□). As controls, untreated [$^{14}$C]mercaptopurine was run alone (○) and after oxidation with hydrogen peroxide in excess (●) on the same column.*

**Table I—Binding [a] of 6-Mercaptopurine to Human Serum Proteins at Various Conditions**

| Sample | Mercaptopurine Concentration, $\mu M$ | Binding, Percent | Binding, Relative |
|---|---|---|---|
| Fresh serum | 2.5 | 30.8 | 100 |
| Fresh serum + mercaptoethanol (4.8 m$M$) | 2.5 | 6.5 | 21 |
| Fresh serum aged for 4 hr in air | 2.5 | 54.2 | 176 |
| Aged serum | 2.5 | 86.3 | 100 |
| Aged serum + mercaptoethanol (4.8 m$M$) | 2.5 | 26.0 | 30 |
| Fresh serum | 0.7 | 64.2 | 100 |
| Fresh serum + hydrogen peroxide (0.25 m$M$) | 0.7 | 95.1 | 148 |
| Fresh serum + hydrogen peroxide (2.5 m$M$) | 0.7 | 86.3 | 134 |
| Aged serum | 0.7 | 92.0 | |

[a] Binding was studied by equilibrium dialysis at 20° with an isotonic phosphate buffer (pH 7.4).

To test whether the binding is reversible or not, repeated equilibrium dialysis was performed. The buffer side of the dialysis cell was replaced with fresh buffer after equilibrium was attained. The cell was then equilibrated again. As shown in Table II, the free fraction on the buffer side reduced to about half of the original free fraction after the second equilibration. This result indicates an irreversible binding of mercaptopurine and an equal distribution of the initially unbound drug on the protein side between the two sides after buffer replacement. Nothing of the bound fraction was dissociated from the protein and redistributed to both sides of the dialysis cell. A repeated equilibrium dialysis was also performed with salicylic acid as a control. In this experiment, the original free fraction on the buffer side was recovered after the second equilibration, which indicates reversible binding as expected.

**Gel Filtration**—Another experiment was performed with gel filtration to test whether binding is reversible. A sample solution of [$^{14}$C]mercaptopurine in aged serum was run on a Sephadex G-25 column. The peak fraction containing the proteins and bound drug, *i.e.*, the first eluted peak, was run a second time. The chromatograms obtained are shown in Fig. 1. The second run gave only one peak, indicating that no free drug was present. These results support the hypothesis that binding is irreversible.

The same experiment was performed under identical conditions with salicylic acid, which is known to exhibit reversible binding to serum albumin. As expected, the second run showed that salicylic acid dissociated from the protein fraction.

When [$^{14}$C]mercaptopurine was run alone on the column, the chromatogram showed two peaks. Their relative size was directly correlated to the presence of any oxidizing agent, *e.g.*, hydrogen peroxide, which completely transferred the mercaptopurine into the dimeric form when added in excess. As shown in Fig. 1, the dimer was eluted between the protein and monomer peaks.

**Table II—Repeated Equilibrium Dialysis of [$^{14}$C]-Mercaptopurine (14,000 dpm/cell) and Human Serum**

| | Radioactivity, dpm: Protein Side | Radioactivity, dpm: Buffer Side | Fraction Bound, % |
|---|---|---|---|
| First equilibration | ND[a] | 1500 | 90.0 |
| | ND | 1317 | |
| Second equilibration after replacement of buffer | 11,727 | 817 | 93.5 |
| | 12,097 | 720 | |

[a] Not detected.

These results are compatible with the hypothesis that the sulfhydryl group of mercaptopurine is involved in an oxidation-dependent reaction with free sulfhydryl groups in proteins and/or in an oxidation-independent S–S interchange with the protein molecules. The mercaptopurine dimer does not bind or is only poorly bound to serum proteins.

Recently, similar results were found in a study on the binding of mercaptopurine to rat hepatic microsomal proteins (3). After oxidation of the labeled microsomal protein with performic acid, 75% of the radioactivity was released, suggesting that the drug was bound *via* a disulfide bond.

Binding studies *in vitro* with mercaptopurine and similar compounds should be performed with great care, excluding air and oxidizing agents. Biological samples with mercaptopurine, *e.g.* blood, plasma, or serum, should also be handled under well-controlled conditions, and results obtained under poorly defined conditions should be judged skeptically.

# Synthesis of 4,4-Ditritio-(+)-nicotine: Comparative Binding and Distribution Studies with Natural Enantiomer

**WILLIAM C. VINCEK *, BILLY R. MARTIN, MARIO D. ACETO, HEM L. TRIPATHI, EVERETTE L. MAY ˣ, and LOUIS S. HARRIS**

Received December 1, 1980, from the *Department of Pharmacology, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA 23298.* Accepted for publication April 9, 1981. * Present address: Merck Sharp and Dohme, West Point, PA 19486.

**Abstract** □ The preparation of 4,4-ditritio-(+)-nicotine (V*b*) (specific activity 10.3 Ci/mmole) from (+)-nicotine (I*b*) *via* (−)-4,4-dibromocotinine (III*b*) is described. Although I*b* is 10–30 times less potent than (−)-nicotine (I*a*) in the CNS, its binding affinity for the crude mitochondrial or nuclear fraction of whole rat brain is only three times less than that of I*a*. However, distribution studies showed that the maximum brain levels of (−)-[$^3$H]nicotine are nearly twice those of (+)-[$^3$H]-nicotine following administration of a 2-μg/kg dose. Binding affinity and disposition of the stereoisomers account for a portion of the pharmacological stereospecificity of nicotine.

**Keyphrases** □ 4,4-Ditritio-(+)-nicotine — synthesis, comparative binding and distribution with the natural enantiomer □ Stereoisomers—nicotine, binding affinity and disposition in rats □ Binding—nicotine stereoisomers, rats

The actions of nicotine on the central nervous system have been shown to be stereospecific (1–4). If nicotine's effects result from its interaction with receptors, then nicotine binding to brain tissue should reflect this selectivity. Recently (5), a synthesis and some preliminary binding data for 4,4-ditritio-(−)-nicotine (V*a*, specific activity 4.7 Ci/mmole) were presented. In those binding studies, excess (+)- and (−)-nicotine were equally effective in displacing (−)-[$^3$H]nicotine that was bound to rat brain, a finding that suggested nicotine binding lacked stereospecificity.

The stereospecificity of nicotine can be investigated further by comparing directly the binding and disposition of (+)- and (−)-[$^3$H]nicotine. The synthesis of radiolabeled (+)-nicotine, the enantiomer of V*a*, 4,4-ditritio-(−)-nicotine[1] (V*b*), prepared from (+)-nicotine according to Scheme I is reported here. An improved procedure for the hydrogenolysis of (+)-4,4- dibromocotinine (III*a*)[2], which was applied to the tritiolysis of III*b*, the enantiomer of III*a*, is also included. The resultant V*b* with a relatively high specific activity (10.3 Ci/mmole) has facilitated binding and disposition experiments with (−)- and (+)-nicotine (I*a* and I*b*, respectively).

## EXPERIMENTAL

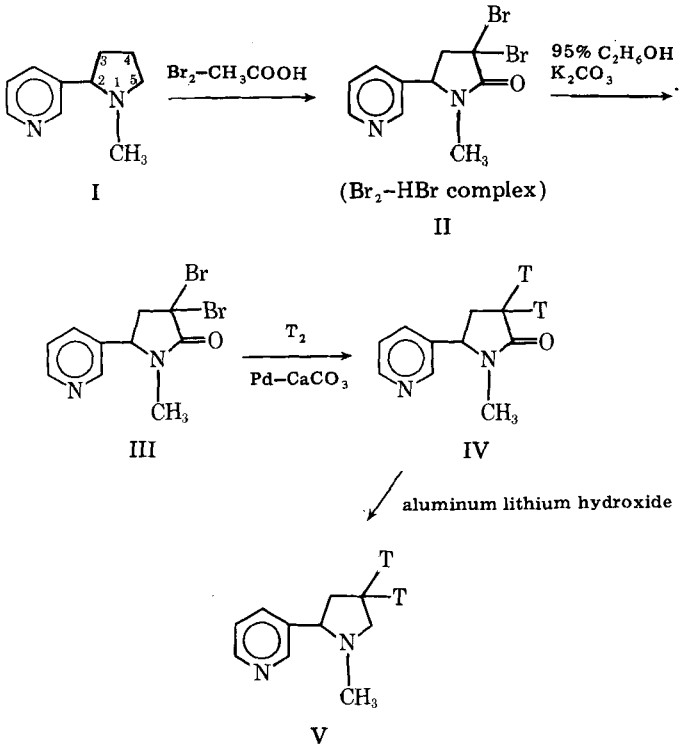
**Chemistry**—*Conversion of (+)-4,4-Dibromocotinine (III*a*) to (−)-Nicotine (I*a*)*—Compound III*a*[2] (35 mg, 0.2 mmole), $[\alpha]_D^{25}$ +33.44°, $[\alpha]_{546}^{25}$ nm +39.48° (*c*, 2.234 in methanol)[3], prepared from I*a* (5, 6), in 0.5 ml of tetrahydrofuran was added to a suspension of 30 mg of 10% palladium-on charcoal, 0.03 ml (0.2 mmole) of triethylamine, and 1.0 ml of tetrahydrofuran under hydrogen. During 45–50 min of agitation, 4.4–4.6 ml (theory, 4.4 ml) of hydrogen was consumed. Filtration and evaporation of solvent *in vacuo* (without heating) gave (−)-cotinine (6) (essentially pure by TLC)[4], which was reduced to I*a* with aluminum lithium hydride (5).

*4,4-Ditritio-(+)-nicotine (V*b*)*—Conversion of I*b* (2) to (−)-4,4-dibromocotinine (III*b*), $[\alpha]_D^{25}$ −32.74, $[\alpha]_{546}^{25}$ nm −40.12 (*c*, 0.678 in methanol) (see corresponding values for III*a*), mp 121–122°, was effected in a 50% yield as described previously for the (−)-series (5), I*a* → III*a*. The resulting III*b* was tritiolyzed[5] as described for the hydrogenolysis of III*a*. This tritiated material, IV*b*, was reduced to V*b* with aluminum lithium hydride as described for IV*a* → V*a* (5). The purity of V*b* was determined by TLC[4]. Ninety-nine percent of the radioactivity corresponded to authentic (+)-nicotine (2) and none to cotinine.

*Determination of Specific Activity of V*b—As described previously for V*a* (5), V*b* was injected into a gas chromatograph–mass spectrometer[6] for single-ion monitoring of *m/z* 84, 86, and 88, the base peaks of [$^3H_0$]-V*b*, [$^3H_1$]-V*b*, and [$^3H_2$]-V*b*, respectively. From a [$^3H_0$]-V*b* calibration curve, it was determined that each microcurie of radiolabeled material contained 111, 41, and 5 ng of [$^3H_0$]-V*b*, [$^3H_1$]-V*b*, and [$^3H_2$]-V*b*, respectively. This translates into a specific activity of 10.3 Ci/mmole for V*b*.

**Binding Studies**—Brains from Sprague–Dawley rats were homogenized in isotonic sucrose, and crude nuclear pellets were obtained by centrifuging the homogenates at 1000×*g*. The supernates were spun at 10,000×*g* to provide crude mitochondrial pellets. The crude nuclear and crude mitochondrial pellets were resuspended in Krebs–Henseleit buffer (pH 8.4) to a final protein concentration of 3 mg/ml. The resuspended fractions were pipetted into microfuge tubes; then saline, unlabeled (+)-nicotine or unlabeled (−)-nicotine was added for a 5-min incubation period at 2°. Then radiolabeled nicotine was added for an additional 5-min incubation at 2°.

Bound and free nicotine were separated by centrifugation in a micro-



*Scheme I—a (−) and b (+) series*

[1] (+)-Nicotine has the *R* configuration.

[2] Erroneously recorded as (−)-4,4-dibromocotinine in Ref. 5.

[3] E. R. Bowman, Department of Pharmacology, Medical College of Virginia (personal communication) found $[\alpha]_{546}^{25}$ nm + 35.68° (*c*, 12.5 in ethanol) for III*a*.

[4] Silica gel plates GHLF from Analtech (Newark, Delaware) were developed in acetone–ether–concentrated ammonia (4:16:0.1). Nicotine $R_f$ was 0.55.

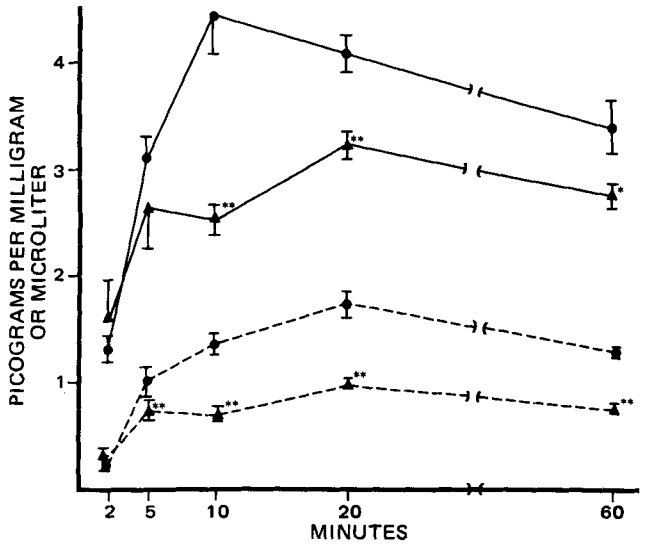

**Figure 1**—*Time course of (+)- and (−)-[$^3$H]nicotine (2 μg/kg) in rat brain and plasma. Results are expressed as mean ±SE (n = 5). Values are significantly different at p <0.005 (*) and p <0.001 (**) according to a Student t test. Key: (+)-[$^3$H]Nicotine, in brain (▲----▲) and plasma (▲—▲), and (−)-[$^3$H]nicotine, in brain (■----■) and plasma (●—●).*

fuge[7] for 3 min. The tips of the centrifuge tubes, which contained the pellets, were severed with a guillotine and vortexed with scintillation fluid (two parts of toluene containing 0.4% 2,5-diphenyloxazole and 0.01% 1,4-bis[2-(4-methyl-5-phenyloxazolyl)]benzene and one part of alkylphenoxypolyethoxyethanol[8]). Radioactivity was quantitated by liquid scintillation spectrometry, and quench was corrected by external standardization.

**Distribution Studies**—Sprague–Dawley rats were injected subcutanously with either (+)- or (−)-[$^3$H]nicotine ditartrate in saline (60 μCi/2 μg/kg, calculated as free base), and five rats were decapitated at each time point for each treatment. Blood from the cervical wound was collected in heparinized tubes, which was centrifuged at 1000×*g* to obtain plasma. Brains were homogenized[9] in five volumes of 0.5 *N* HCl. Total radioactivity was determined by counting 100 μl of plasma and tissue homogenates in aqueous counting scintillant[5]. An extraction technique that removed nicotine, but not metabolites, was used to quantitate [$^3$H]nicotine (7). Plasma (0.5 ml) and tissue homogenates (1.0 ml) were made basic with 3 drops of concentrated ammonia and 1 ml of 40% tribasic potassium phosphate. Nicotine ditartrate (1 mg/200 μl) was added as a carrier, and the samples were shaken with 10 ml of hexane. Hexane (8 ml) was removed and counted directly in 10 ml of scintillation fluid. Quench was corrected using external standardization. This extraction removed 90–95% of [$^3$H]nicotine, and no metabolites were detected in these extracts by TLC analysis[4].

## RESULTS AND DISCUSSION

**Binding Studies**—The high specific activity of (+)-[$^3$H]nicotine provided the opportunity to compare the binding characteristics and affinity of (+)-[$^3$H]nicotine to those of (−)-[$^3$H]nicotine. The physiochemical requirements for (+)-[$^3$H]nicotine binding to the crude nuclear and crude mitochondrial fractions of whole rat brain were similar to those described previously for (−)-[$^3$H]nicotine (5). Excess concentrations ($10^{-4}$ *M*) of the unlabeled stereoisomers were equally effective in displacing (+)-[$^3$H]nicotine. The quantity of saturable binding of (+)-[$^3$H]nicotine was less than that of (−)-[$^3$H]nicotine, while the amount of nonsaturable binding was similar for both. The ratio of saturable to nonsaturable binding was 1.06 and 0.64 for (−)-[$^3$H]nicotine and (+)-[$^3$H]nicotine, respectively. Scatchard plots of the saturable binding of (+)-[$^3$H]nicotine to the crude mitochondrial fraction revealed a $K_D$ value of $2.2 \times 10^{-7}$ *M*, which was approximately three times greater than that of (−)-[$^3$H]nicotine ($K_D = 6.3 \times 10^{-8}$ *M*). Binding to the crude nuclear fraction of whole rat brain was similar to that found for the crude mitochondrial fraction. The $K_D$ values for (+)-[$^3$H]nicotine and (−)-[$^3$H]nicotine were $2.6 \times 10^{-7}$ and $7 \times 10^{-8}$ *M*, respectively.

Previous reports indicated that (−)-nicotine was pharmacologically 10–30 times more potent than (+)-nicotine (2, 3). However, the *in vitro* binding of (−)-[$^3$H]nicotine to rat brain tissue appeared to lack stereospecificity in that (+)- and (−)-nicotine were equally effective in displacing (−)-[$^3$H]nicotine (5). These studies suggested that the isomers differed in efficacy rather than affinity. However, the direct comparison of (+)- and (−)-[$^3$H]nicotine binding data in the present study showed that (+)-[$^3$-H]nicotine has approximately one-third the affinity of (−)-[$^3$H]nicotine. Differences in both binding affinity and efficacy apparently account for pharmacological stereospecificity. Differences in brain levels of the stereoisomers could also contribute to potency differences that are based on dose.

**Distribution Studies**—The time course of (+)- and (−)-[$^3$H-]nicotine in rat brain and plasma is shown in Fig. 1. Maximum plasma levels of (+)- and (−)-[$^3$H]nicotine were observed at 10 and 20 min, respectively. Maximum brain levels of both stereoisomers occurred at 20 min. The brain and plasma concentrations of (−)-[$^3$H]nicotine were significantly greater than those of (+)-[$^3$H]nicotine for almost all time points. The differences in brain levels of the two stereoisomers are probably not due to binding affinity for brain or to penetration of the blood brain barrier but rather to differences in plasma levels. Levels of total radioactivity in plasma did not differ between the (+)- and (−)-[$^3$H]nicotine-treated animals at any time point.

These data suggest that both isomers are absorbed at a similar rate following subcutaneous injection. It would appear that (+)-[$^3$H]nicotine is metabolized at a faster rate than (−)-[$^3$H]nicotine, although this point needs investigation. The brain levels of total radioactivity in the (−)-[$^3$H]nicotine-treated animals were twice as high as those in the (+)-[$^3$H]nicotine treatment group, reflecting the poor penetrability of nicotine metabolites into brain. The differences in the brain levels of (+)- and (−)-[$^3$H]nicotine show that potency ratios of the stereoisomers of nicotine should be based on concentration at the target tissue rather than on dose.

# Determination of Hematoporphyrin and Protoporphyrin by Ion-Pair Extraction with Chlorpromazine

**M. R. GASCO[x] and M. TROTTA**

Received April 8, 1980, from the *Istituto di Chimica Farmaceutica e Tossicologica dell'Università de Torino, Corso Raffaello 31, Torino, Italy.* Accepted for publication April 14, 1981.

**Abstract** □ A sensitive method based on ion-pair extraction is described for the quantification of hematoporphyrin and protoporphyrin using chlorpromazine as an ion-pair-forming agent. Extraction of the ion-pair in chloroform is obtained quickly at an optimum pH of 6.5 for hematoporphyrin and of 6.5–6.8 for protoporphyrin, giving an excellent recovery of the porphyrin. A stoichiometric relationship of 1:2 betweeen porphyrin and chlorpromazine is proved. Cyanocobalamin and liver extract do not interfere with the assay.

**Keyphrases** □ Hematoporphyrin—determination by ion-pair extraction with chlorpromazine □ Protoporphyrin—determination by ion-pair extraction with chlorpromazine □ Ion-pair extraction—determination of hematoporphyrin and protoporphyrin using chlorpromazine

Hematoporphyrin[1] (I) and protoporphyrin[1] (II) have been found in human bile and in urine of patients with various porphyrias (1, 2). Compound II is present in cirrhosis, hepatic tumors, cholestasis (3), and in lead intoxication (4).

Recently, the pharmacological actions of I were reviewed (5). Compound I is used in anemia with cyanocobalamin and liver extract; I and some of its charge transfer complexes show antidepressant activity (6–8).

Analysis by direct spectrophotometry is not suitable for porphyrins in urine or when colored substances, such as liver extract and cyanocobalamin, are present in I. Ion-pair formation of I with dialkylaminoalkylphenothiazines was noted (9), and a red precipitate formed at pH 6.0–6.5. In the present study, a method based on ion-pair extraction (10–12) was applied for assaying I and II using chlorpromazine hydrochloride[2] (III) as a reagent.

## EXPERIMENTAL

**Materials**—Hematoporphyrin dihydrochloride (I), protoporphyrin disodium salt (II), chlorpromazine hydrochloride (III), cyanocobalamin[1] (IV), liver extract (4 μg/ml of cyanocobalamin)[1] (V), and chloroform BP were used.

**Reagents**—The following solutions were used: $1 \times 10^{-4}$ *M* I, $1 \times 10^{-4}$ *M* II, and $1 \times 10^{-1}$ *M* III in the required buffer. The ionic strength was not adjusted, but the solutions were prepared in $1 \times 10^{-1}$ *M* phosphate buffer at various pH values.

**Preparation of Solid Complexes between Porphyrins and Chlorpromazine**—Compound I (60 mg) was dissolved in ~250 ml of pH 6.5 buffer and was precipitated by addition of 3 ml of III ($1 \times 10^{-1}$ *M*) with continuous stirring. The mixture was set aside for 30 min, filtered through a sintered-glass funnel (porosity 4), washed with 3-ml portions of ice-cold water, and dried under vacuum. The same procedure was followed for II but with a pH 6.8 buffer. A stoichiometric relationship was proved in both cases by NMR spectroscopy[3] and by spectrophotometry[4] according to the previously described methods (9).

**Effect of Chlorpromazine on Porphyrins Recovery**—Aliquots of I (6 ml, $1 \times 10^{-4}$ *M*) and III (0.1–1.6-ml, $1 \times 10^{-1}$ *M*) in pH 6.5 buffer were diluted in a 20-ml volumetric flask with the pH 6.5 buffer and then transferred to a separator. Extraction was accomplished by adding 20 ml of chloroform and then shaking thoroughly for 2 min. Absorbance was measured against chloroform from the blank experiment at 502 nm.

The same procedure was used for II with a pH 6.8 buffer and reading of the absorbance at 505 nm (Fig. 1).

**Effect of pH on Recovery**—Aliquots of I (6 ml, $1 \times 10^{-4}$ *M*) and III (1 ml, $1 \times 10^{-1}$ *M*) in buffered solutions of pH 5.8–7.0 were introduced into dry separators and diluted with 13-ml aliquots of the appropriate buffer. Each solution was shaken thoroughly for 2 min with 20 ml of chloroform. The absorbance of the separated organic phase was measured against chloroform from the blank experiment. The same procedure was used for II.

**Calibration Curve**—Stock solutions of I ($1 \times 10^{-4}$ *M*) and III ($1 \times 10^{-1}$ *M*) were used to prepare mixed standard solutions. The mixed standards were diluted to 20 ml with the buffer in a volumetric flask to yield a series of mixed working solutions containing 1–$2.5 \times 10^{-5}$ *M* I and $5 \times 10^{-3}$ *M* III. The working solutions in the separators were gently shaken for 2 min with 20 ml of chloroform. The absorbance of the chloroform extract was measured against the chloroform extract from the blank experiment.

The mean value of three experiments was taken in to obtain the calibration curve. The molar absorptivity ($\epsilon$) was 10,000 ± 100 at 502 nm. This value was confirmed by direct measurement of the absorbance of the solid complex in chloroform.

The same procedure was used for II; the molar absorptivity ($\epsilon$) was 11,000 ± 120 at 505 nm and was also confirmed by direct measurement of the absorbance of the solid complex in chloroform.

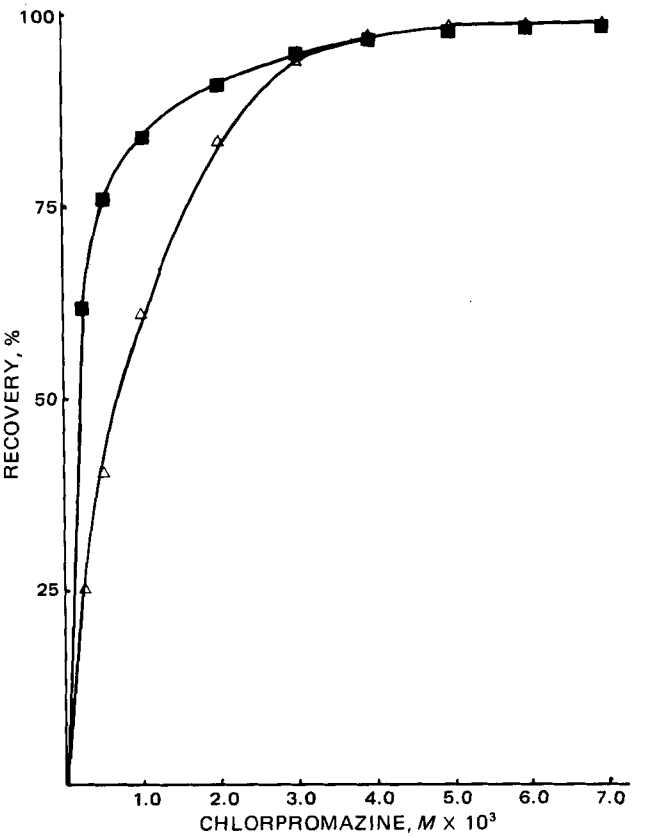

**Figure 1**—*Recovery of the chloroform extract as a function of chlorpromazine with concentrations of* $3 \times 10^{-5}$ M *hematoporphyrin* (△) *and* $3 \times 10^{-5}$ M *protoporphyrin* (●) *in the aqueous layer.*

Table I—Recovery of 200 μg of Hematoporphyrin from 20-ml Solutions

| Buffer | In Presence of 20 μg of Cyanocobalamin | In presence of 25% Liver Extract |
|---|---|---|
| 197.5 | 199.0 | 201.0 |
| 197.0 | 197.3 | 196.5 |
| 198.2 | 200.0 | 197.5 |
| 199.8 | 197.5 | 197.2 |
| 200.0 | 196.5 | 199.2 |
| 199.0 | 197.5 | 198.0 |
| 198.5 ± 1.2[a] | 198.0 ± 1.4[a] | 198.2 ± 1.6[a] |

[a] Mean ± *SD*.

**Analysis of Porphyrins in Presence of Cyanocobalamin and Liver Extract**—A preliminary experiment performed using a chlorpromazine ion-pair method with a 5-ml aliquot of 4 μg/ml of cyanocobalamin or of liver extract showed no formation of colored complex in chloroform. Consequently, on assaying porphyrin (200 μg) in the presence of either of these solutions, no interference occurred and hematoporphyrin or protoporphyrin was easily and quantitatively extracted. Table I lists the replicate recovery results of 200 μg of I from 20-ml buffer solutions alone, in the presence of IV, and with 25% of V. The porphyrins were also completely extracted from urine according to the described ion-pair method with chlorpromazine.

## RESULTS AND DISCUSSION

The red complexes of hematoporphyrin and protoporphyrin assayed by the described method showed adherence to Beer's law. Figure 1 shows that a $5 \times 10^{-3}$ *M* concentration of chlorpromazine was necessary for a total recovery of the porphyrin at a concentration of $3 \times 10^{-5}$ *M*( ratio 3:500). Figure 2 shows the recovery profile of hematoporphyrin using a fixed ratio of 3:500 between porphyrin and chlorpromazine in chloroform from buffer solution as a function of pH. At pH 6.5, hematoporphyrin was completely extracted; protoporphyrin was completely extracted in a wider pH range.

The extracted species are well defined and the reported method can be considered sensitive and accurate. Table I shows that the mean recovery for hematoporphyrin was 99.0–99.2%.

The method can be applied for determining porphyrins in pathological urine.

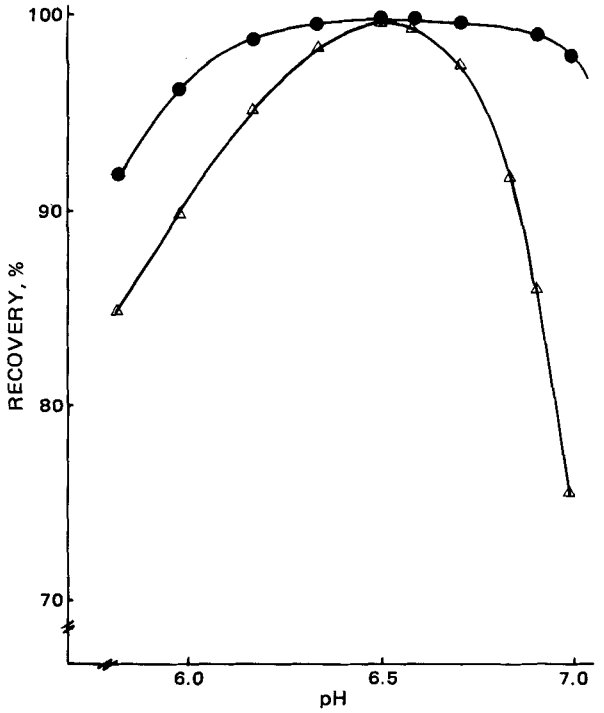

**Figure 2**—*Hematoporphyrin and protoporphyrin recovery–pH profile after 20-ml chloroform extraction of 20 ml of aqueous solution containing* $5 \times 10^{-3}$ M *hematoporphyrin (△) and* $3 \times 10^{-5}$ M *protoporphyrin (■).*

# Area under the Plasma Concentration–Time Curve Resulting from Constant-Rate Drug Input

**Keyphrases** □ Drug infusion—relationship with area under the plasma concentration–time curve □ Equations—relationship between infusion equation and area under the plasma concentration–time curve

*To the Editor:*

Plasma concentration–time data obtained from constant-rate drug input (*i.e.*, intravenous infusion or constant-rate absorption) are frequently analyzed by dividing the resulting curve into two segments: concentrations achieved during and those obtained after stopping the infusion. However, equations are available for analyzing the entire curve, and computer programs are capable of fitting such data to the appropriate equation. Benet (1) encouraged use of the equation describing the entire concentration–time curve. This communication reports on the relationship between the parameters of an infusion equation and the total area under the plasma concentration–time curve ($AUC_0^\infty$).

## THEORY

Assuming, for simplicity, a one-compartment model, the equation describing the entire concentration–time curve is given by:

$$C = \left(\frac{FK_0}{KV}\right)(e^{KT} - 1)\,e^{-Kt} \qquad \text{(Eq. 1)}$$

where $F$ is the fraction of the dose absorbed ($F = 1$ for intravenous infusion), $K_0$ is the constant rate of drug input, $K$ is the elimination rate constant, $V$ is the apparent volume of distribution, $t$ is the time beginning from the start of infusion, and $T$ is the time of infusion (which equals $t$ during infusion). In fitting Eq. 1, it will generally appear in the form:

$$C = (A)(e^{KT} - 1)e^{-Kt} \qquad \text{(Eq. 2)}$$

where $A$ equals $FK_0/KV$. The terms $A$ and $K$ are treated as parameters and $T$ is fixed for intravenous infusion. In the case of constant-rate drug absorption (*e.g.*, sustained-release products), $T$ should also be treated as a parameter rather than holding it constant at some arbitrary value. The solid line shown in Fig. 1 represents plasma concentrations resulting from constant-rate drug input up to time $T$ and exponential decline in concentrations at later times.

The term $A$ in Eq. 2 may be recognized as the steady-state plasma concentration ($C_{ss}$) that would be achieved if infusion were to continue for a sufficiently long period of time. This value is denoted in Fig. 1 as the dashed line. The total area under the solid line in Fig. 1 may be shown to be equal to:

$$AUC_0^\infty = \frac{FK_0T}{KV} \qquad \text{(Eq. 3)}$$

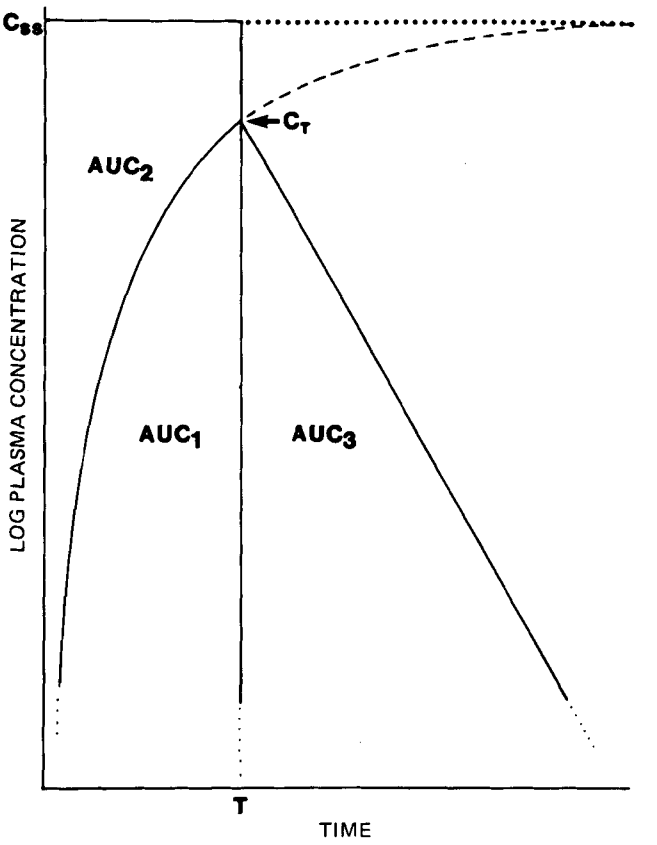

**Figure 1**—*Log-plasma concentration as a function of time during and after constant-rate drug infusion (solid line). Drug is infused for a time* T *and results in a maximum concentration,* $C_T$. *The dashed line represents the approach to a steady-state plasma concentration,* $C_{ss}$, *if infusion were to continue indefinitely. Also,* $AUC_1$ *is the area under the curve during infusion and up to time* T, $AUC_3$ *is the postinfusion area from time* T *to time* ∞, *and* $AUC_2$ *is the difference between,* $C_{ss}T$ *and* $AUC_1$.

where the product $FK_0T$ equals the dose absorbed.

Therefore, the product of the term $A$ (in Eq. 2) and $T$ will equal $AUC_0^\infty$:

$$AUC_0^\infty = \frac{FK_0T}{KV} = C_{ss}T = AT \qquad \text{(Eq. 4)}$$

Equation 4 may also be viewed by considering the geometric areas indicated in Fig. 1. The total area under the curve is equal to:

$$AUC_0^\infty = AUC_1 + AUC_3 \qquad \text{(Eq. 5)}$$

The calculated $AUC_0^\infty$ in Eq. 4, $AT$, is given by:

$$AUC_0^\infty = AUC_1 + AUC_2 = C_{ss}T = AT \qquad \text{(Eq. 6)}$$

Since $AUC_1$ is common to both Eqs. 5 and 6, $AUC_2$ must be equal to $AUC_3$.

$$AUC_2 = C_{ss}T - AUC_1 \qquad \text{(Eq. 7)}$$

$$AUC_2 = \frac{FK_0T}{KV} - \int_0^T \frac{FK_0}{KV}(1 - e^{-kt})\,dt \qquad \text{(Eq. 8)}$$

The integral in Eq. 8 may be shown to be equal to:

*0022-3549/81/1100-1296$01.00/0*
*© 1981, American Pharmaceutical Association*

$$\int_0^T \frac{FK_0}{KV}(1 - e^{-Kt})\,dt = -\frac{FK_0T}{KV} + \frac{FK_0}{KVK}(1 - e^{-KT}) \quad \text{(Eq. 9)}$$

Placing Eq. 9 into Eq. 8 gives:

$$AUC_2 = \frac{FK_0}{KVK}(1 - e^{-KT}) \quad \text{(Eq. 10)}$$

Equation 10 is equal to the plasma concentration at time $T$, divided by $K$:

$$AUC_2 = \frac{C_T}{K} \quad \text{(Eq. 11)}$$

This expression may be recognized as being equal to $AUC_3$ which is conventionally used to calculate the postinfusion area and, therefore, $AUC_2 = AUC_3$.

The relationship indicated in Eq. 4, that area is the product of $C_{ss}$ and $T$, appears not to have been previously reported. Furthermore, assuming linear kinetics, this relationship is model independent. The only difference in calculation for multicompartment models is that $AUC_0^\infty$ is the product of $T$ and the sum of all the appropriate coefficients (*e.g.*, $A + B$, in a two-compartment model).

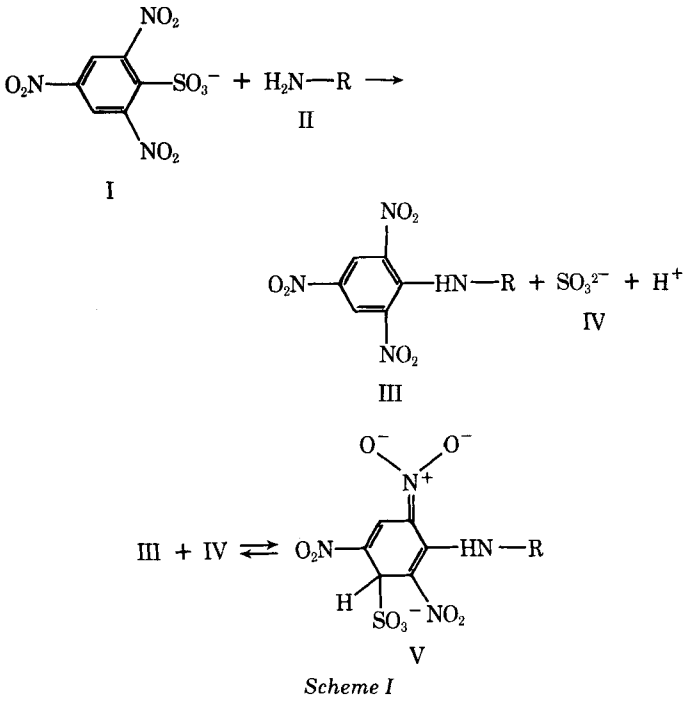
## Kinetic Study on Rapid Reaction of Trinitrobenzenesulfonate with Human Serum Albumin

**Keyphrases** □ Trinitrobenzenesulfonate—kinetics of reaction with human serum albumin □ Kinetics—of reaction of trinitrobenezenesulfonate with human serum albumin □ Albumin, human serum—kinetics of reaction with trinitrobenzenesulfonate

*To the Editor:*

Trinitrobenzenesulfonate (I) has been used as a reagent for the chemical modification of amino groups in amino acids, peptides, and proteins (1–4). The basic mechanism for the reaction of I with amines (II) was proposed previously (5, 6) (Scheme I). The trinitrophenylated II (III) reacts further with sulfite ion (IV) to form the sulfite monoadduct (V). It was reported that III and V have UV absorption maxima at 340 and 420 nm, respectively, giving an isosbestic point at 367 nm during the reaction of III and IV (5, 6).

The distinction between, and identification of, the drug binding sites on human serum albumin were made previously by us on the basis of the inhibition of the reaction of *p*-nitrophenyl acetate with the albumin caused by several drugs (7). When the albumin was modified with I to characterize the drug binding sites, rapid reaction of I with the albumin was found. In this communication, we describe the localization of the reactive site on the albumin



*Scheme I*

for I and the kinetics and mechanism for the reaction.

All reactions in this study were carried out in pH 7.4, 0.067 *M* phosphate buffer ($\mu = 0.2$, adjusted with sodium chloride) at 25°. To localize the reactive site on the albumin for I, the fluorescence spectra of the albumin excited at 300 nm were measured[1]. The intensity of the emission

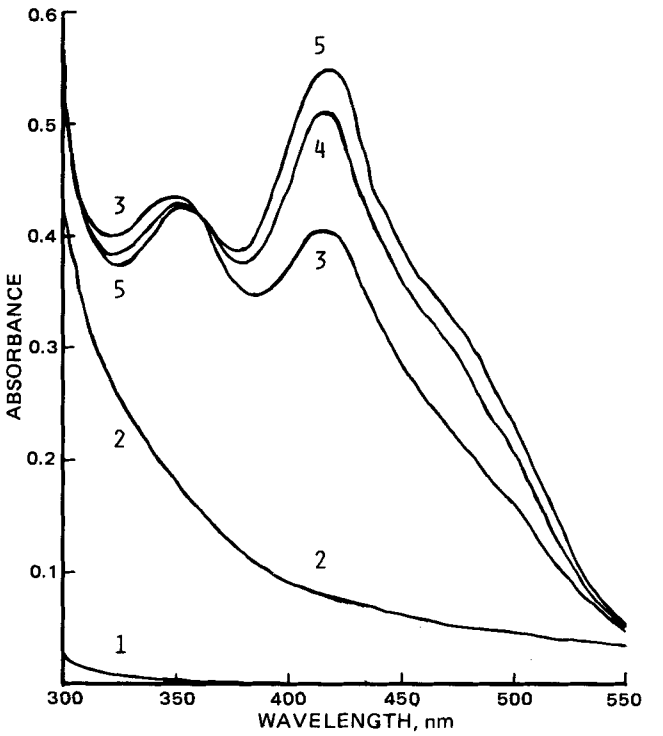


**Figure 1**—*UV absorption spectra. 1, 2.5 × 10⁻⁵ M I; 2, 1.0 × 10⁻⁴ M albumin; 3, 2.5 × 10⁻⁵ M I and 1.0 × 10⁻⁴ M albumin; 4, 2.5 × 10⁻⁵ M I, 1.0 × 10⁻⁴ M albumin, and 5.0 × 10⁻⁵ M NaHSO₃; and 5, 2.5 × 10⁻⁵ M I, 1.0 × 10⁻⁴ M albumin, and 1.0 × 10⁻⁴ M NaHSO₃.*

spectrum for the reaction mixture of I and the albumin was smaller than that for the albumin solution. This reduced emission spectrum indicates that the reactive site for I is located close to tryptophan residue 214, which is the lone tryptophan residue of the albumin (7–9). This important drug binding site on albumin was named Site I by Sudlow *et al.* (10) and U site by us (7).

When the reaction of I ($2.5 \times 10^{-5}$ *M*) with albumin ($1.0 \times 10^{-4}$ *M*) was followed spectrophotometrically at 340 nm, the reaction was completed rapidly. In contrast, when the reaction was monitored at 420 nm, the absorbance gradually increased (half-life ~30 sec) after the initial rapid increase in the absorbance up to ~0.25. Thus, the reaction proceeded *via* two steps. Figure 1 shows the UV absorption spectra of each reactant solution and the reaction mixtures after the spectral changes were complete. The spectra of 3, 4, and 5 show the isosbestic point at ~360 nm. These kinetic and spectroscopic results suggest that the reactions similar to Scheme I (trinitrophenylation and sulfite monoaddition) occur in the reaction of I with the albumin.

The rate of the trinitrophenylation of the albumin was followed at 360 nm (isosbestic point of III and V) with a stopped-flow spectrophotometer[2]. The pseudo-first-order analyses could be applied under the excess molar concentration of the albumin over that of I (2:8 concentration ratio). The pseudo-first-order rate constants ($\sim 2.5 \times 10^{-1}$ $sec^{-1}$) were almost independent of the albumin concentrations. This independence suggests that the trinitrophenylation occurs *via* Michaelis–Menten-type complex formation and that the dissociation constant of the complex is very small. Therefore, the overall reactions of I with the albumin may be represented as in Scheme II, where $k_2$ is the first-order rate constant of the I–albumin complex for the trinitrophenylation. The rate constants for the formation of V and the elimination of IV from V are expressed by $k_3$ and $k_{-3}$, respectively, and $K_S$ and $K_P$ represent the dissociation constants of the complex and V, respectively. Detailed studies on the kinetics and mechanism for the reactions shown in Scheme II are in progress.

$$\text{I} + \text{albumin} \overset{K_S}{\rightleftharpoons} \text{I–albumin} \xrightarrow{k_2} \text{III} + \text{IV} + \text{H}^+$$

$$\text{III} + \text{IV} \underset{k_{-3},\, K_P}{\overset{k_3}{\rightleftharpoons}} \text{V}$$

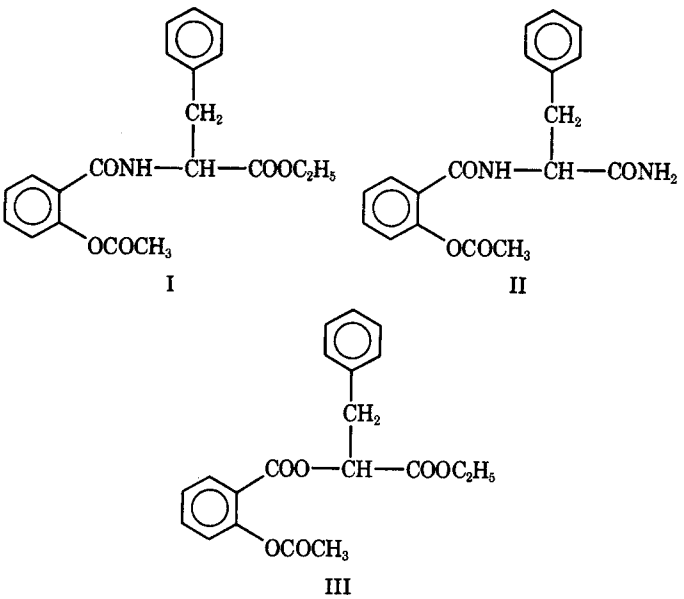
# Physicochemical Property Modification Strategies Based on Enzyme Substrate Specificities I: Rationale, Synthesis, and Pharmaceutical Properties of Aspirin Derivatives

**PRADIP K. BANERJEE * and GORDON L. AMIDON ***

Received November 3, 1980, from the *School of Pharmacy, University of Wisconsin, Madison, WI 53706.* Accepted for publication April 2, 1981. *Present address: Tablet Products Research and Development, Abbott Laboratories, North Chicago, IL 60064.

**Abstract** □ A rationale is developed for drug physicochemical property modification based on making derivatives that are substrates for known enzymes. The approach requires knowledge of the enzyme–substrate specificities to select the appropriate derivative. As a class, the digestive enzymes represent possible reconversion sites. It is shown that by using only known specificities of these enzymes, the physicochemical properties of a drug may be modified in almost any manner desired by appropriate derivative choice, with enzymatic regeneration remaining effective. The strategy is applied to making a stable aspirin derivative that is activated *in vivo*. Of the derivatives made, aspirin phenylalanine ethyl ester was shown to be stable in suspension form for over 4 years. It was also shown that aspirin is regenerated from the derivative in the presence of the enzymes α-chymotrypsin and carboxypeptidase *in vitro*. This biochemical approach to drug physicochemical property modification offers a new and powerful rationale for improving drug product efficacy.

**Keyphrases** □ Aspirin—derivatives, physicochemical property modification strategies based on enzyme specificities, synthesis, and pharmaceutical properties □ Derivatives—aspirin, physicochemical property modification strategies based on enzyme specificities, synthesis, and pharmaceutical properties □ Physicochemistry—aspirin derivatives, property modification strategies based on enzyme specificities, synthesis, and pharmaceutical properties



A number of inherent undesirable properties may preclude the use of a drug molecule in clinical practice, and drug derivatization has been long recognized as an important means of producing more efficacious pharmaceutical products. Central to the prodrug design is *in vivo* reconversion. The drug derivative must rapidly, or at a controlled rate, be reconverted to the active therapeutic agent *in vivo* while at the same time be sufficiently stable *in vitro* such that a stable pharmaceutical product can be developed. It was suggested (1) that hydrolytic enzymes could serve as an important class of reconversion sites. In the rational design of prodrugs, it is necessary to consider: (*a*) what structural modifications of the parent molecule are necessary to reduce or eliminate the particular undesirable effect, and (*b*) what conditions are available *in vivo* (enzymes, pH, *etc.*) to regenerate the parent molecule from the prodrug.

The objective of this report was to develop and test a rationale for prodrug design using current knowledge of the hydrolase enzyme specificities. By combining the current understanding of the enzyme specificities with the need for drugs with more desirable pharmaceutical properties, new and novel drug derivatives can be suggested.

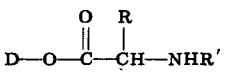
**Table I—Possible Changes in Physical Properties of Drugs with Free OH Groups**



drug amino acid

| Drug | Amino Acid | R′ | Change in Physical Properties |
|---|---|---|---|
| Nonpolar | Polar–acidic–basic | H, $COCH_3$ | More polar–ionic |
| Polar | Nonpolar | $COCH_3$ | Less polar |
| Liquid at room temperature | Polar–nonpolar | H | To a salt |
| Low aqueous solubility | Acidic–basic | $HCOCH_3$ | To acid or base (salt) |

This study attempted to make aspirin derivatives such that a stable suspension formulation could be made. A secondary goal was to reduce the local gastric irritation and bleeding associated with aspirin therapy.

This report describes the synthesis and some pharmaceutical properties of aspirin phenylalanine ethyl ester (I), aspirin phenylalanine amide (II), and aspirin phenyllactic ethyl ester (III).

## THEORY

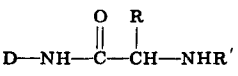
**Prodrug Considerations**—On the basis of the known specificities of the enzymes reviewed (1), a general rationale for modification of a drug's physical properties can be developed. Given that a drug has a free carboxyl, amino, or hydroxyl group, corresponding esters or amides of amino acids can be made so as to alter the physical properties in almost any desired direction from that of the parent drug, with one or more of the hydrolase enzymes serving as the *in vivo* reconversion site(s).

The diverse properties of the various amino acid residues, combined with the fact that they are usually nontoxic, gives this approach wide applicability. Classifying the amino acids as nonpolar, polar, acidic, and basic, a given drug molecule may be made more or less polar or more or less soluble in a given solvent. Its acid/base properties may be altered or completely changed (*i.e.*, converted from acidic to basic drug or vice versa), or it may be converted from a neutral compound to an ionic (acidic or basic) compound or from an ionic to a neutral compound. Thus, great flexibility is afforded the pharmaceutical scientist in modifying physical properties of drugs using this rationale.

Tables I–III briefly summarize some of these possibilities. In general, for compounds in Tables I and II, α-chymotrypsin, trypsin, elastase, or an aminopeptidase could serve as a reconversion site. For compounds in Table III, a carboxypeptidase or an initial cleavage of the ester group by α-chymotrypsin–trypsin–elastase followed by a carboxypeptidase would effect the reconversion.

A recent example of a prodrug approach utilizing lipases as target sites for reconversion is the study by Baugess *et al.* (2). The acetate and dodecanoate esters of acetaminophen were shown to be substrates for lipases. The acetate ester was completely hydrolyzed in 15 min *in vitro*, and its pharmacokinetics in dogs were indistinguishable from those of the parent drug. Since the proteolytic enzymes α-chymotrypsin and carboxypeptidase A are the target reconversion sites, their properties are briefly reviewed, followed by the aspirin derivatives selected.

**Table II—Possible Changes in Physical Properties of Drugs with Free $NH_2$ Groups**



drug amino acid

| Drug | Amino Acid | R′ | Change in Physical Properties |
|---|---|---|---|
| Weak base | Nonpolar | $COCH_3$ | To a neutral compound |
| Weak base | Acidic | $COCH_3$ | To an acidic compound |
| Zwitterionic | Polar–nonpolar | $COCH_3$ | To an ionic (acidic) compound |
| Weak base | Polar–nonpolar | H | Change in pKa |

**α-Chymotrypsin**—α-Chymotrypsin, an endopeptidase involved in protein digestion, has a molecular weight of ~25,000 g/mole. α-Chymotrypsin catalyzes the hydrolysis of a broad spectrum of peptides, amides, and esters. An absolute requirement of the substrate candidate is that the amino acid residue be of L-configuration. Substrates having an aromatic residue (*e.g.*, phenylalanine, tryptophan, and tyrosine) are hydrolyzed at appreciable rates (3), but the hydrolysis of substrates having hydrophobic residues (*e.g.*, leucine and methionine) is also catalyzed (4).

Kinetic studies have revealed a bell-shaped relationship between the overall reaction rate and pH, with maximum activity occurring near pH 8. The kinetic scheme shown in Scheme I seems to apply to an α-chymotrypsin-catalyzed hydrolysis.

$$E + S \overset{K_S}{\rightleftharpoons} E\ S \overset{k_{+2}}{\underset{k_{-2}}{\rightleftharpoons}} E - P_2 \overset{k_{+3}}{\underset{k_{-3}}{\rightleftharpoons}} E + P_2$$
$$+$$
$$P_1$$

*Scheme I*

The three reaction steps represent the formation of the noncovalent (Michaelis) enzyme–substrate complex, the formation of an acyl enzyme with the loss of the leaving group, and the deacylation step. For nonspecific substrates with good leaving groups and for specific ester substrates, the deacylation step is rate limiting; for specific amides, the rate is determined by the acylation step.

**Carboxypeptidase A**—The primary action of carboxypeptidase A is that of a C-terminal exopeptidase. The enzyme is also a good esterase. Having a molecular weight of ~34,600 g/mole, the active enzyme consists of a single chain of 307 amino acid residues and one zinc ion. The amino acid sequence is known completely (5). The zinc ion has been shown to be essential for catalytic activity, even though its removal does not greatly affect the enzyme structure (6). There are two absolute requirements for potential carboxypeptidase A substrates (7, 8); the terminal carboxyl group must be free and the C-terminal residue must be of the L-configuration. The hydrolysis of substrates wherein R is a branched aliphatic or, optimally, an aromatic group is significantly favored.

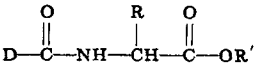
**Aspirin Derivatives**—The chemical instability of aspirin was studied extensively (9–12). For present purposes, the pH of maximum stability is 2.5. The pH is below that usually observed for esters due to the presence of the carboxyl group, which functions as a general base catalyst and increases the reaction rate at pH 2.5–8. Aspirin, being a weak acid, also shows minimum solubility in acid. However, even suspensions of aspirin are not satisfactorily stable (12).

One approach to stabilizing aspirin is to esterify the carboxyl group. While this approach does improve stability, the esters (prodrugs) typically do not revert back to aspirin because the acetyl group is more labile than the ester group, with the resultant formation of salicylic acid esters (13). If the ester group were chemically more labile than the acetyl group, formulation instability would likely be a problem.

The aspirin derivatives in the present study (I–III) were chosen such that rapid biochemical reconversion in the intestinal tract would be affected. In each case, improved chemical stability is expected since the carboxyl group is masked. The esters and amides were chosen such that prodrug solubility would be somewhat less than that of the aspirin-free acid and further increase the stability of aspirin in suspension form. Other amino acid and ester groups could be chosen to obtain somewhat different physical properties if desired.

The biochemical reconversion of I–III is expected to be *via* an initial α-chymotrypsin hydrolysis of the ester or amide group followed by a

**Table III—Possible Changes in Physical Properties of Drugs with Free COOH Groups**



drug amino acid

| Drug | Amino Acid | R′ | Change in Physical Properties |
|---|---|---|---|
| Weak acid | Polar–nonpolar | H | change in pKa |
| Weak acid | Basic | H | Zwitterionic compound |
| Weak acid | Basic | $OC_2H_5$ | To a basic compound |
| Zwitterionic | Polar/nonpolar | $OC_2H_5$ | To a basic compound |

carboxypeptidase cleavage of the amide-releasing aspirin in the intestinal lumen or at the membrane wall (14). To the extent that the gastric irritation associated with oral dosing of aspirin is a local phenomenon (15–17), this approach may also reduce or eliminate the problem since aspirin would not be formed until the prodrug reached the intestine.

## EXPERIMENTAL

**Phenylalanine Ethyl Ester, Hydrochloride**—Thionyl chloride (10 ml) was added to ethanol (40 ml), portionwise, in cold. Phenylalanine (2.3 g) was added to the mixture and refluxed for 2 hr. The reaction mixture was cooled, and the solvent was evaporated under reduced pressure. The flaky solid residue was washed with cold anhydrous ether and was then purified by selective precipitation from the ethanol–ether mixture, mp 154–156°, yield 2.9 g.

**Aspirin Phenylalanine Ethyl Ester (I)**—Aspirin[1] (1.8 g) was dissolved in 35 ml of dry methylene chloride and dicyclohexylcarbodiimide[2] (1 g) was added to it at room temperature. The mixture was stirred for 2 hr, and the precipitated dicyclohexylurea was filtered off.

To the filtrate was added a mixture of phenylalanine ethyl ester hydrochloride (1.15 g, 5 mmoles) and triethylamine (0.5 g, 5 mmoles) dissolved in 10 ml of methylene chloride. The mixture was stirred overnight at room temperature and the solvent was removed under reduced pressure. Dry ethyl acetate (20 ml) was added to the residue. A white precipitate appeared, which was filtered and found to be dicyclohexylurea. The filtrate was washed three times with 10% sodium bicarbonate and three times with water to make it free from alkali and then dried over anhydrous magnesium sulfate. The dried extract was filtered, and the solvent was removed under reduced pressure.

The residue was dissolved in ethanol, and water was added until turbidity appeared. It was then kept in the freezer overnight. The oily precipitate solidified and was filtered and further purified by selective precipitation from ethanol–water mixtures, mp 72–74°, yield 1.6 g. The product gave a single spot on TLC. Structure was confirmed by NMR[3] and mass spectrum ($M^+$ = 356); NMR (90 MHz, $CDCl_3$): δ 1.35 (t, 3H, $CH_3$ of ethyl ester), 2.1 (S, 3H, $OCOCH_3$ of aspirin), 3.27 (d, 2H, aromatic $CH_2$ of phenylalanine), 4.2 (q, 2H, $COOCH_2$ of ethyl ester), 5.05 (m, 1H, CH of phenylalanine group), 7.1–7.65 (m, 7H, aromatic H), and 8.05 (d, 1H, aromatic H proton next to CONH group of aspirin nucleus).

**Phenylalanine Amide**—To a solution of L-phenylalanine (0.83 g) in water–dioxane (1:1, 8 ml) and triethylamine (1.05 ml, 7.5 m*M*) was added 2-*tert*-butoxycarbonyloxyamino-2-phenylacetonitrile[1] (1.36 g) at room temperature. The solution was stirred overnight at room temperature. After 15 ml of water was added to the reaction mixture, it was washed twice with 15-ml portions of ethyl acetate; the ethyl acetate washings were discarded. The aqueous layer was acidified to pH 2.0 by 5% citric acid solution and saturated with sodium chloride. It was then extracted with three 20-ml portions of ethyl acetate, and the combined ethyl acetate extracts were washed three times with saturated sodium chloride solution to make the organic extract acid free. The ethyl acetate extract was dried over anhydrous magnesium sulfate and filtered, and the solvent was removed under reduced pressure to obtain an oily residue of *tert*-butoxycarbonylphenylalanine, yield 1.2 g.

Ethyl chloroformate was added dropwise over 10 min at −10° to a well-stirred solution of *tert*-butoxycarbonylphenylalanine and triethylamine in dry tetrahydrofuran. The mixture was stirred for 30 min at −10° and then saturated with dry ammonia. The reaction mixture was stirred overnight at room temperature, the solvent was evaporated under reduced pressure, and the residue was stirred with 20 ml of ice-cold water, filtered, and dried at 40–60°. It was then treated with 4 *N* hydrochloric acid–dioxane for 30 min at room temperature. The solvent was removed to obtain a solid residue of L-phenylalanine amide hydrochloride.

**Aspirin Phenylalanine Amide (II)**—To a solution of 1.8 g of aspirin in 35 ml of dry methylene chloride was added 1.1 g of dicyclohexylcarbodiimide. The reaction mixture was stirred for 2 hr at room temperature, and a white precipitate of dicyclohexylurea was formed and removed by filtration. To the filtrate was added a mixture of 5 m*M* L-phenylalanine amide (1.1 g) and 5 m*M* triethylamine (0.7 ml) in 15 ml of methylene chloride. The reaction mixture was stirred overnight at room temperature, and the solvent was removed under reduced pressure. The residue was dissolved in chloroform and washed once with water, three times with 15-ml portions of 10% sodium bicarbonate, and three times with 10-ml portions of 2 *N* HCl, followed by a final washing with water to make it acid free.

The organic extract was evaporated to dryness under reduced pressure, and the residue was washed with ether, filtered, and recrystallized from chloroform, mp 176–178°, yield 1.4 g. The structure was identified by NMR and mass spectrum ($M^+$ = 327). The product gave a single spot on TLC; NMR (90 MHz, $CDCl_3$): δ 2.2 (s, 3H, $OCOCH_3$ of aspirin), 3.15 (d, 2H, aromatic $CH_2$ of phenylalanine), 4.92 (m, 1H, CH of phenylalanine group), 7.05–7.65 (m, 7H, aromatic H), and 7.85 (d, 1H, aromatic H proton next to CONH group of aspirin nucleus).

**Aspirin Phenyllactic Ethyl Ester (III)**—A solution of 0.4 g of aspirin chloride dissolved in 10 ml of tetrahydrofuran was chilled to 5°; to it was added a cooled solution of L-phenyllactic acid (0.33 g) in 4 ml of tetrahydrofuran. Aliquots of pyridine totaling 0.5 ml were added to the reaction mixture over 5 min, and the system was stirred at 5° for 1 hr. After an additional hour of stirring at room temperature, the solvent was removed on a rotary evaporator and the clear colorless oil was dissolved in chloroform. The chloroform solution was extracted with water, dried over anhydrous magnesium sulfate, and evaporated under reduced pressure to yield a colorless oil, which was purified by selective precipitation from chloroform by *n*-hexane. The oil did not solidify. Its purity was checked by TLC, and NMR and mass spectrometry were used to confirm its identity as L-phenyllactic acid ester of aspirin.

Aspirin phenyllactic acid (0.23 g) was dissolved in dry methylene chloride, and the solution was chilled to 0°. To it was added magnesium ethoxide-dried ethanol (0.35 ml) followed by dicyclohexylcarbodiimide (0.13 g, 0.7 mmole). After stirring at 0° for 1 hr, it was stirred for an additional 1 hr at room temperature. The solvent was removed under reduced pressure to obtain a clear colorless oil, which was further purified by selective precipitation from ethanol by water. The oil could not be solidified. TLC showed only one spot, the NMR and mass spectrometry ($M^+$ = 355) confirmed it to be III; NMR (90 MHz, $CDCl_3$): δ 1.3 (t, 3H, $CH_3$ of ethyl ester), 2.1 (s, 3H, $OCOCH_3$ of aspirin), 3.27 (d, 2H, aromatic $CH_2$ of phenylalanine), 4.2 (q, 2H, $COOCH_2$ of ethyl ester), 5.45 (m, 1H, CH of phenylalanine group), 7.05–7.65 (m, 7H, aromatic H), and 7.95 (d, 1H, aromatic H proton next to COO group of aspirin nucleus).

**Aspirin Phenylalanine**—Compound I (60 mg) was dissolved in 10 ml of ethanol and added to 100 ml of a pH 7.5 phosphate buffer solution containing α-chymotrypsin (100 mg). It was mixed well, allowed to stand for ~2 min, and then transferred to a 250-ml separator. It was then acidified with 2 *N* HCl to pH 1.0 and extracted with 100 ml of chloroform. A very thick emulsion resulted on shaking, and the layer had to be separated by centrifugation at 2000 rpm for 20 min.

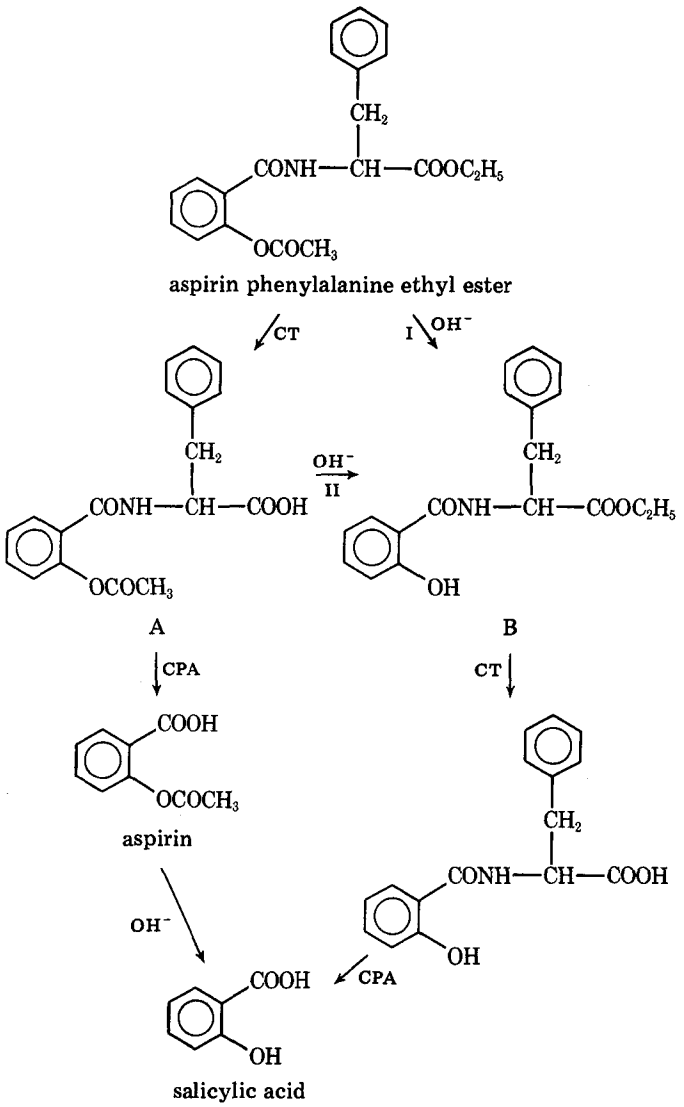
The upper aqueous layer was aspirated out, the lower layer was dried over anhydrous magnesium sulfate, and the solvent was removed in a rotary evaporator to obtain a clear, colorless, oily residue, which was further purified by selective precipitation from ethanol with water. NMR and mass spectrometry ($M^+$ = 328) confirmed it to be aspirin phenylalanine; NMR (90 MHz, $CDCl_3$): δ 2.1 (s, 3H, $OCOCH_3$ of aspirin), 3.27 (d, 2H, aromatic $CH_2$ of phenylalanine), 5.05 (m, 1H, CH of phenylalanine group), 7.0–7.65 (m, 7H, aromatic H), and 7.85 (d, 1H, aromatic H proton next to CONH group of aspirin nucleus).

**TLC Systems**—To follow the hydrolysis of aspirin phenylalanine ethyl ester qualitatively and to identify the products, a TLC system was sought that would separate the reactants and products. Of several solvent systems tried, methanol–acetic acid–ether–benzene (1:18:60:20) was able to resolve aspirin and salicylic acid (which appears as a dense blue spot under short wavelength UV). The support was silica gel with $UV_{254}$ fluorescent background. This solvent system could not differentiate between aspirin and I. However, cyclohexane–chloroform acetic acid (4:5:1) was able to distinguish between aspirin and I but not between aspirin and salicylic acid.

TLC plates were run in both solvents simultaneously to allow identification of all the degradation products of I in simulated intestinal fluid. All chloroform extracts were spotted on silica gel plates, 0.25 mm thick, and developed for 15 cm in both solvents. The spots were detected under a short wavelength UV detector.

**Shelflife Studies of I**—Compound I (5 mg) was dissolved in 1 ml of ethanol and transferred quantitatively to a 100-ml volumetric flask, and the volume was made up with 0.066 *M* phosphate buffer of pH 7.5, 6.6, or 5.6. Aliquots (5 ml) were withdrawn at timed intervals, taken in 15-ml centrifuge tubes, and extracted with 5-ml portions of chloroform. The aqueous layer was removed by aspiration. Two 0.5-ml portions of the chloroform extracts were placed in 10-ml volumetric flasks, and the solvent was evaporated with a gentle nitrogen stream. To Flask A was added 0.5 ml of ethanol and 1 ml of 5 *N* NaOH. The mixture was heated in a

[1] Monsanto Co.
[2] Aldrich Chemical Co.
[3] Melting points were determined in capillaries and are uncorrected. NMR spectra were recorded with a Varian E-390 spectrometer with tetramethylsilane as the internal standard. All structures were confirmed by NMR and mass spectra.



*Scheme II—Possible hydrolytic pathways of aspirin phenylalanine in presence of chymotrypsin (CT) and carboxypeptidase A (CPA) mixture.*

boiling water bath for 45 min and cooled to room temperature, and the volume was made up with distilled water. To Flask B was added 0.5 ml of ethanol, and the volume was made up with distilled water. Fluorescence of both the samples was determined at excitation/emission wavelengths of 328/400 nm.

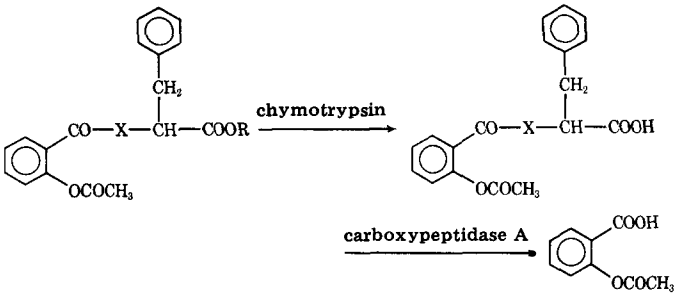
Scheme II shows that of all possible degradation products, only I and salicylic acid phenylalanine ethyl ester (being nonionic) are extractable in chloroform. Salicylic acid phenylalanine ethyl ester has the same excitation and emission maxima as salicylic acid. Therefore, by subtracting the fluorescence of B from A, the fluorescence corresponding to salicylic acid generated by the alkali digestion of I was obtained. A standard solution of I carried through the described procedure served as the standard.

**Table IV—Enzyme Kinetic Parameters for Aspirin Derivatives** [a]

| | α-Chymotrypsin | | Carboxypeptidase | |
|---|---|---|---|---|
| | $K_m$, mole/liter | $K_{cat}$, $sec^{-1}$ | $K_m$, mole/liter | $K_{cat}$, $sec^{-1}$ |
| Aspirin phenylalanine ethyl ester (I) | $1 \times 10^{-6}$ | 2.91 | $1.3 \times 10^{-4}$ [b] | $8.5 \times 10^{-2}$ [b] |
| Aspirin phenyllactic ethyl ester (III) | $2.5 \times 10^{-5}$ | $3.7 \times 10^{-3}$ | $1 \times 10^{-4}$ | 25 |
| Aspirin phenylalanine amide (II) | $5.1 \times 10^{-4}$ | $5 \times 10^{-3}$ | $1.3 \times 10^{-4}$ | $8.5 \times 10^{-2}$ |

[a] References 18 and 19. [b] Done at pH 8.5.

**Table V—Estimated Range of *In Vivo* Reconversion Rates ($S_0 = 10^{-5}$ *M*)**



| Structure | $E_0$, *M* | pH | $t_{1/2}$ Maximal Rate (Zero Order), $v = k_{cat}E_0$ | $t_{1/2}$ Minimal Rate (First Order), $v = (k_{cat}/K_m)E_0S$ |
|---|---|---|---|---|
| X = NH R = $C_2H_5$ | $10^{-4}$ | 8.5 | 5.9 sec | 16.8 sec |
| X = O R = $C_2H_5$ | $10^{-4}$ | 7.5 | 13.5 sec | 61.9 sec |
| X = NH R = $C_2H_5$ | $10^{-6}$ | 8.5 | 10 min | 28 min |
| X = O R = $C_2H_5$ | $10^{-6}$ | 7.5 | 22.5 min | 103 min |

**Solubility Determination**—Compound I (~300 mg) was stirred with 100 ml of distilled water at 25.00 ± 0.02°. Aliquots of the solution were withdrawn until no change in concentration was observed. Equilibrium was reached in 20 hr. After the aliquots were diluted 10 times, 1 ml was placed in a 10-ml volumetric flask; 1 ml of 5 *N* NaOH was added, and the solution was heated in a boiling water bath for 45 min. After cooling, the solution was diluted to volume with distilled water, and fluorescence measurements were taken at excitation/emission wavelengths of 328/400 nm, using a $10^{-6}$ *M* solution of I, taken through all the described steps, as a standard. The solubility was determined to be $4.7 \times 10^{-4}$ *M*.

## RESULTS AND DISCUSSION

**Summary of Enzyme Kinetic Results**—The detailed enzyme kinetic studies were reported previously (15, 16), and only the most significant results are summarized here. Of the aspirin derivatives studied, I was the best substrate for α-chymotrypsin while aspirin phenyllactic acid was the best substrate for carboxypeptidase. The kinetic parameters are given in Table IV. The values for the kinetic parameters are consistent with values for other well-known substrates of these enzymes. Table V shows the aspirin reconversion process for the ethyl esters. Given the kinetic results in Table IV, the α-chymotrypsin hydrolysis step would be rate limiting for III while the carboxypeptidase hydrolysis step would be rate limiting for I. Both steps were slow for the amide derivative.

The very approximate estimates of the *in vitro* reconversion half-lives in Table V are based on the kinetic parameters for the appropriate rate-limiting step. Whether such estimates reflect the *in vivo* situation is not yet known. However, the results indicate that regeneration of aspirin *in vivo* is at least possible. Compound I was selected for further studies. This choice was based in part on the rapid first step of the reconversion. Since all derivatives had relatively low aqueous solubilities by design, the rapid hydrolysis of the ester, to produce an acid, would increase the dissolution rate of the ethyl ester and perhaps give better *in vivo* performance.

**Hydrolytic Pathway of I**—Scheme II shows the possible hydrolytic pathways for I. Figure 1 shows the TLC results on a solution containing the prodrug and α-chymotrypsin and carboxypeptidase. The results

**Table VI—Kinetic Rate Constants and Shelflife of I in Aqueous Solutions**

| pH | $k_{obs} \times 10^3$, $hr^{-1}$ | $t^{90}$, hr |
|---|---|---|
| 7.5 | 9.84 | 10.8 |
| 6.6 | 2.77 | 38.3 |
| 5.6 | 1.92 | 55.2 |

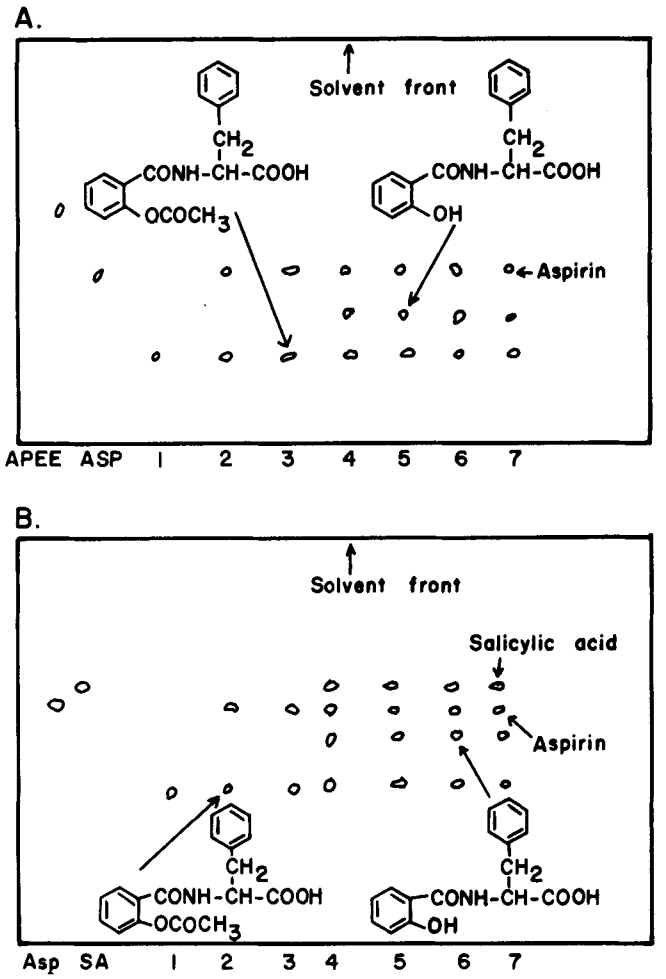


*Figure 1.—Thin-layer chromatogram of the chloroform extract of a mixture of I, α-chymotrypsin (50 mg/100 ml), and carboxypeptidase A (25 mg/100 ml) in pH 7.5 phosphate buffer. The support was silica gel with fluorescent indicator $UV_{254}$. The solvents were cyclohexane–benzene–acetic acid (4:5:1) (A) and methanol–acetic acid–ether–benzene (1:18:60:20) (B). Key: spot 1, 1 min; spot 2, 2 min; spot 3, 5 min; spot 4, 10 min; spot 5, 20 min; spot 6, 45 min; and spot 7, 2 hr. APEE = aspirin phenylalanine ethyl ester; ASP = aspirin; and SA = salicylic acid.*

indicate that the ethyl ester group is lost immediately and that aspirin phenylalanine appears. With time, aspirin appears, followed by salicylic acid and the phenylalanine derivative of salicylic acid. While more detailed kinetic studies are needed, these results demonstrate that aspirin is regenerated in solution in the presence of the enzymes.

**Shelflife Studies of I in Aqueous Solutions**—Logarithms of concentrations of I remaining in the aqueous solutions at various pH values were plotted against time. Reactions were followed up to 10% degradation. From the slopes of these plots, the pseudo-first-order rate constant, $k_{obs}$, was determined. The pseudo-first-order rate constants at several pH values and the corresponding shelflives are given in Table VI.

In case of suspension, the degradation rate is given by:

$$\frac{dc'}{dt} = k_1 s \qquad \text{(Eq. 1)}$$

where $c'$ is the concentration of the drug in solution (mass/volume), $k_1$ is the first-order rate constant, and $s$ is the solubility of the drug expressed in the same unit as $c'$. For $v$ milliliters of suspension:

$$v\frac{dc'}{dt} = \frac{dc}{dt}\,(\text{mass/time}) = -k_1 vs = -k_0 \qquad \text{(Eq. 2)}$$

where $k_0$ is the zero-order rate constant for the drug in suspension.

The solubility of I was $4.7 \times 10^{-4}$ $M$ (*i.e.*, 0.167 mg/ml) compared to that of $1.85 \times 10^{-2}$ $M$ (*i.e.*, 3.33 mg/ml) of aspirin. The calculated shelflife of a 600 mg/5 ml of suspension of I (*i.e.*, an equivalent of 300 mg/5 ml of aspirin) was found to be 4.27 years at pH 5.6 compared to 38 days for 300 mg/5 ml of aspirin suspension at its optimum pH (2.25) for stability.

# Physicochemical Property Modification Strategies Based on Enzyme Substrate Specificities II: α-Chymotrypsin Hydrolysis of Aspirin Derivatives

**PRADIP K. BANERJEE** * **and GORDON L. AMIDON** ˣ

Received November 3, 1980, from the *School of Pharmacy, University of Wisconsin, Madison, WI 53706.* Accepted for publication April 2, 1981. * Present address: Tablet Products Research and Development, Abbott Laboratories, North Chicago, IL 60064.

**Abstract** □ Three aspirin derivatives, aspirin phenylalanine ethyl ester, aspirin phenylalanine amide, and aspirin phenyllactic ethyl ester, were investigated with respect to their hydrolysis by α-chymotrypsin. Of the three compounds, aspirin phenylalanine ethyl ester was the best substrate, with $k_{cat} = 25\ sec^{-1}$ and $K_m = 1.3 \times 10^{-6}\ M$ at pH 8.0. The results for all substrates were in the range of expectation based on kinetic data for other substrates. The apparent latitude in the nature of the acylamide substituent of α-chymotrypsin substrates makes this enzyme a good potential reconversion site for many drug derivatives.

**Keyphrases** □ Aspirin—derivatives, hydrolysis by α-chymotrypsin □ Derivatives—aspirin, synthesis by α-chymotrypsin hydrolysis □ α-chymotrypsin—hydrolysis of aspirin derivatives □ Physicochemistry—modification strategies based on enzyme substrate specificities, α-Chymotrypsin hydrolysis of aspirin derivatives

Previously (1), a rationale for selecting amino acid derivatives of aspirin was described and the syntheses of aspirin phenylalanine ethyl ester (I), aspirin phenylalanine amide (II), and aspirin phenyllactic ethyl ester (III) were reported. These derivatives were so designed that after an initial cleavage of the terminal ethyl ester or amide linkage, carboxypeptidase A regenerates aspirin *in vivo*. This paper reports kinetic studies of these derivatives in the presence of α-chymotrypsin.

## EXPERIMENTAL

**Materials**—α-Chymotrypsin was obtained as a dialyzed, salt-free, lyophilized-powder[1]. The operational normality of α-chymotrypsin solutions was determined by a direct spectrophotometric titration as described previously (2).

**Kinetic Measurements**—The hydrolysis of the prodrugs was followed by automatic titration[2] at a constant pH.

All solvents and chemicals were reagent grade. Triple-distilled water was used in preparing solutions, and the reaction vessel was thermostated at 25.00 ± 0.02°. Dry nitrogen gas was gently blown into the reaction vessel to exclude atmospheric carbon dioxide from the system.

The titrating mechanism was set at the desired pH, and sufficient volume of the prodrug solution containing 0.1 *M* potassium chloride was pipetted into the reaction vessel and allowed to equilibrate for 10 min during magnet stirring. The solution was then brought to the desired pH; when a stable baseline was obtained, 10 μl of a suitable concentration of enzyme was added. The automatic titrating mechanism maintained the set pH during the hydrolytic reaction by adding increments of base as small as 0.1 μl and continuously recording the amount of base consumed *versus* time.

In runs with III, substrate stock solutions were made in acetonitrile. An aliquot of the stock solution was added to the reaction vessel containing a predetermined volume of 0.1 *M* potassium chloride solution, and then the titration was performed in the same manner as described.

The pH-stat results were fit by regression analysis to a polynomial of the form $y = a_0 + a_1 t + a_2 t^2$, where $y$ is the moles of alkali consumed, $t$ is time, and $a_1$ is the initial rate of hydrolysis.

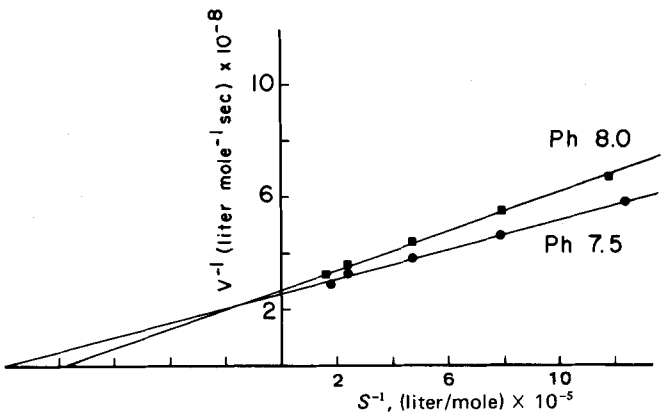

**Figure 1**—*Lineweaver–Burk plot for the hydrolysis of I by 1.79 × 10⁻⁹ M α-chymotrypsin at pH 7.5 and by 2 × 10⁻¹⁰ M α-chymotrypsin at pH 8.0.*

## RESULTS AND DISCUSSION

α-Chymotrypsin-catalyzed hydrolysis follows the general kinetic scheme shown in Scheme I.

$$E + S \underset{}{\overset{K_S}{\rightleftharpoons}} E \cdots S \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} EP_2 \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} E + P_2$$
$$\Big\downarrow +\ P_1$$

*Scheme I*

The initial rate is given by the Michaelis–Menten equation:

$$V_0 = \frac{k_{cat} E_0 S_0}{K_m + S_0} \qquad \text{(Eq. 1a)}$$

where $S_0$ and $E_0$ are the initial amounts of substrate and enzyme ($S_0 \gg E_0$), or by the Lineweaver–Burk equation:

$$\frac{1}{V_0} = \frac{1}{k_{cat} E_0} + \frac{K_m}{k_{cat} E_0} \frac{1}{S_0} \qquad \text{(Eq. 1b)}$$

Plots of $1/V_0$ *versus* $1/S_0$ for I and II at pH 7.5 and 8.0 are shown in Figs. 1 and 2. Straight lines were obtained in all cases, and $k_{cat}$ and $K_m$ were calculated from the slopes and intercepts. These results are summarized in Table I.

It was shown (3) that $k_{cat}/K_m$ is the most meaningful kinetic parameter for comparing different substrates. Good substrates will have a large $k_{cat}$ and low $K_m$ (tight binding) value and, hence, a large $k_{cat}/K_m$ value. At low substrate concentrations ($S \ll K_m$), the enzymatic reaction is first order (with $E_0$ constant), with the rate constant equal to $(k_{cat}/K_m)E_0$. Hence, at a given enzyme level, $E_0$, $k_{cat}/K_m$ determines the reaction rate at low substrate.

Table I shows that for I, $k_{cat}/K_m$ is smaller by a factor of six at pH 7.5 than at pH 8.0 but that $K_m$ does not change significantly. The $k_{cat}$ value was eight times smaller at pH 7.5 than at pH 8.0. For *N*-acetyl phenylalanine ethyl ester, $k_{cat}$ is three times smaller at pH 7 than at pH 7.8 (4). Both $K_m$ and $k_{cat}$ values for I were smaller than those for the *N*-acetyl derivatives. However, the ratio of $k_{cat}/K_m$ was of comparable magnitude to that for the *N*-acetyl derivative. A similar change in $k_{cat}/K_m$ was also noticed for I hydrolysis. The change in structure of the prodrug from ethyl ester to an amide caused a reduction in the hydrolysis rate by a factor of $10^5$. This finding was consistent with the results reported (4) for *N*-acetyl-L-phenylalanine derivatives.

*0022-3549/81/1200-1304$01.00/0*
*© 1981, American Pharmaceutical Association*

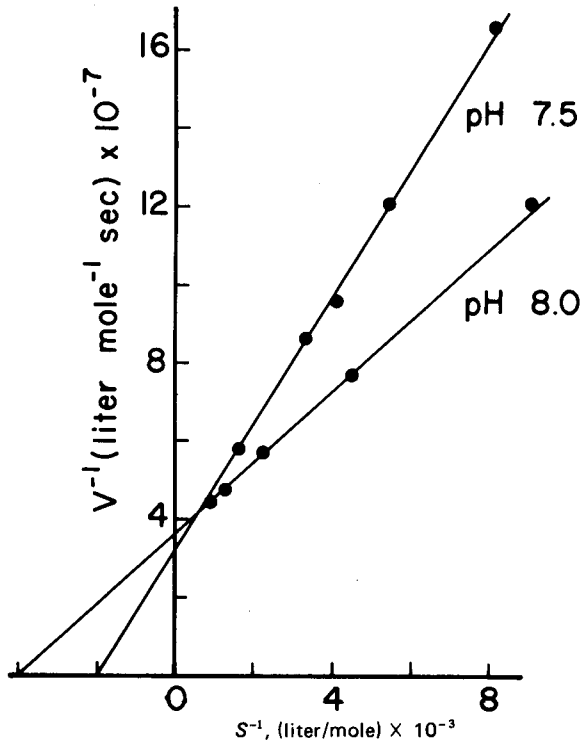

**Figure 2**—*Lineweaver–Burk plot for the hydrolysis of II by 6.26 × 10⁻⁶ M α-chymotrypsin at pH 7.5 and by 4.4 × 10⁻⁶ M α-chymotrypsin at pH 8.0.*

Correlation between hydroxide-ion-catalyzed hydrolysis rate constants and the first-order enzymatic hydrolysis rate constant, $k_{cat}/K_m$, was shown (3). For aspirin phenylalanine derivatives, the change in reactivity may be attributed to the electronic effect of the substituent rather than to any change in binding with the active site. Table I also shows that *N*-acetyl and *N*-aspirin derivatives have $k_{cat}/K_m$ values within an order of magnitude. Therefore, for these substrates, the chymotrypsin-catalyzed hydrolysis is reasonably independent of the drug molecule, a requirement for general application of this approach. The hydrolysis rates obtained were within the expected range.

Experiments with III had to be carried out under conditions of approximately equal substrate and enzyme concentrations. This approach violates one basic assumption of the derivation of the Michaelis–Menten equation ($S_0 \gg E_0$). Dixon (5) described an elegant and simple direct plot for determining $K_m$ when a substantial fraction of the substrate is bound.

**Table I—Kinetic Parameters for α-Chymotrypsin-Catalyzed Hydrolysis**

| Substrate | $K_m$, mole/liter | $k_{cat}$, $sec^{-1}$ | $\frac{k_{cat}}{K_m}$, moles sec/liter | pH |
|---|---|---|---|---|
| Aspirin phenylalanine ethyl ester (I) | $1 \times 10^{-6}$ | 2.91 | $2.91 \times 10^6$ | 7.5 |
| | $1.3 \times 10^{-6}$ | 25 | $1.92 \times 10^7$ | 8.0 |
| *N*-Acetyl phenylalanine[a] ethyl ester | $1.2 \times 10^{-3}$ [a] | 160[a] | $1.33 \times 10^5$ [a] | 7.8 |
| | $0.88 \times 10^{-3}$ [a] | 63[a] | $7.16 \times 10^4$ [a] | 6.99 |
| Aspirin phenyllactic ethyl ester (III) | $2.02 \times 10^{-5}$ | $7.93 \times 10^{-3}$ | $3.96 \times 10^2$ | 8.0 |
| | $2.5 \times 10^{-2}$ | $3.7 \times 10^{-3}$ | $1.48 \times 10^2$ | 7.5 |
| *O*-Acetyl phenyllactic[b] ethyl ester | $2.3 \times 10^{-2}$ | 0.6 | 26.1[b] | 8.0 |
| Aspirin phenylalanine amide (II) | $5.1 \times 10^{-4}$ | $5 \times 10^{-3}$ | 9.8 | 7.5 |
| | $2.4 \times 10^{-4}$ | $6.2 \times 10^{-3}$ | 24.7 | 8.0 |
| *N*-Acetyl phenylalanine[a] amide | $3 \times 10^{-2}$ [a] | $4.6 \times 10^{-2}$ [a] | 1.53[a] | 7.9 |

[a] Taken from Ref. 4. [b] Taken from Ref. 12.

The velocity at any $[S]$ is given by $v = k_{cat}[ES]$. At some given point on the velocity curve, one can write:

$$v = V_{max}\left(\frac{n-1}{n}\right) \quad \text{(Eq. 2)}$$

where $n$ is a whole number. Therefore, at the given point on the velocity curve:

$$k_{cat}[ES] = V_{max}\left(\frac{n-1}{n}\right) \quad \text{(Eq. 3)}$$

$$K_m = \frac{[E][S]}{[ES]} = \frac{([E]_0 - [ES])([S]_0 - [E])}{[ES]} \quad \text{(Eq. 4)}$$

After making appropriate substitutions, one obtains:

$$K_m = \frac{[S]_t}{n-1} - \frac{[E]_t}{n} \quad \text{(Eq. 5)}$$

A series of lines are drawn from the origin through points on the velocity curve where $v = V_{max}[(n-1)/n]$. Since $n$ is a whole number, the points correspond to $1/2V_{max}$, $2/3V_{max}$, $3/4V_{max}$, *etc.* Each line intersects a horizontal line of height $V_{max}$ at different $[S]_n$ values, called $[S]_2$ (for the line through $1/2V_{max}$), $[S]_3$ (for the line through $2/3V_{max}$), $[S]_3$ (for the line through $2/3V_{max}$), and so on. The value of each $[S]_n$ is given by:

$$[S]_n = \left(\frac{n}{n-1}\right)[S]_t \quad \text{(Eq. 6)}$$

where $[S]_t$ is the total substrate concentration required for a given $n$. Consequently:

$$[S]_t = \left(\frac{n-1}{n}\right)[S]_n \quad \text{(Eq. 7)}$$

and from Eq. 5:

$$K_m = \frac{[S]_n}{n} - \frac{[E]_t}{n} \quad \text{(Eq. 8)}$$

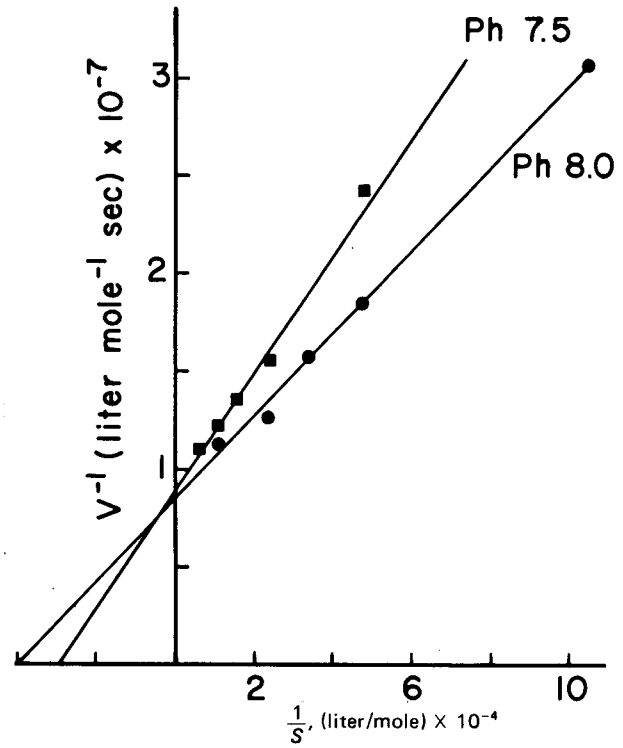

**Figure 3**—*Lineweaver–Burk plot for the hydrolysis of III by 3.02 × 10⁻⁵ M α-chymotrypsin at pH 7.5 and by 1.5 × 10⁻⁵ M α-chymotrypsin at pH 8.0.*

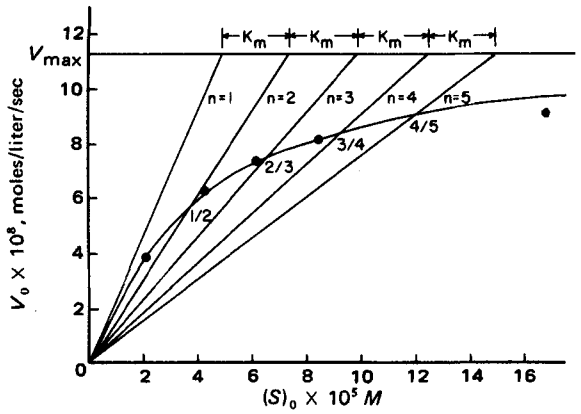

**Figure 4**—*Dixon plot for determining* $K_m$ *for the hydrolysis of III by* $3.02 \times 10^{-5}$ M *α-chymotrypsin at pH 7.5.*

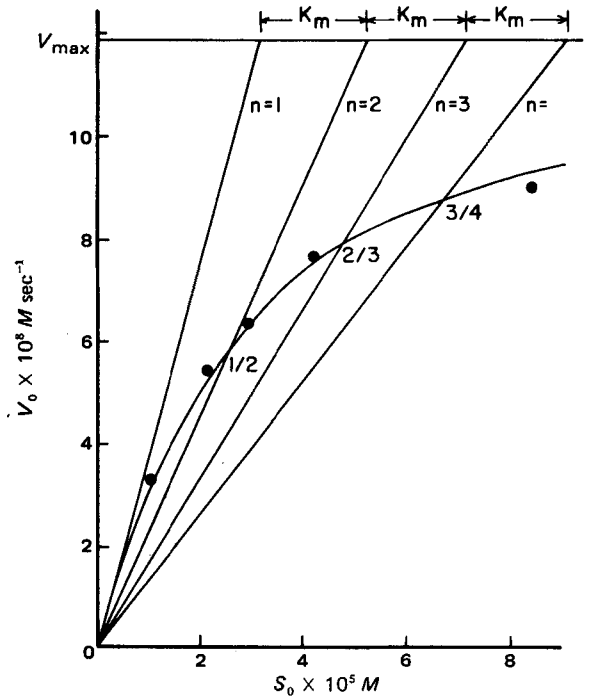

**Figure 5**—*Dixon plot for determining* $K_m$ *for the hydrolysis of III by* $1.5 \times 10^{-5}$ M *α-chymotrypsin at pH 8.0.*

or:

$$[S]_n = nK_m + [E]_t \qquad \text{(Eq. 9)}$$

The intercepts on the $V_{max}$ line occur at increments of $K_m$, *i.e.*:

$$[S]_n - [S]_{n-1} = K_m \qquad \text{(Eq. 10)}$$

This procedure requires a knowledge of $V_{max}$. It was shown (6) that if the $V_{max}$ value chosen is too low, the distances between the intercepts (*i.e.*, $K_m$) decrease toward the right. If the $V_{max}$ value chosen is too high, the intervals increase toward the right. Thus, the method gives a check on the assumed value of $V_{max}$.

The $V_{max}$ values used in the Dixon plots were obtained from the Lineweaver–Burk plots (Fig. 3) of the data. The Dixon plots are shown in Figs. 4 and 5; the intercepts were at constant intervals on the $V_{max}$ axis, indicating the validity of the $V_{max}$ values used. The $K_m$ values obtained by the Dixon method (Table I) were only slightly lower than those found by the Lineweaver–Burk method.

Table I shows that the $k_{cat}/K_m$ ratio was much lower for III than for its phenylalanine analog. This finding may be explained by the specificity of α-chymotrypsin in terms of sites on the enzyme complementary to the four groups oriented tetrahedrally about the α-carbon atom of the substrates (6–8). The substrate groups may fit into the corresponding sites or associate with them with varying effects. The α-acylamido group fits into its site and associates by hydrogen bonding (9, 10). For the phenyllactic acid derivative, the acylamido hydrogen capable of hydrogen bonding is lacking. This condition probably leads to less favorable orientation and a concomitant reduction in the reaction rate ($k_{cat}$).

It was shown (11) that all esters of the same acyl group give the same steady-state hydrolysis rate, indicating that deacylation is the rate-limiting step. For the amides, the rate depends on the amide group involved (*i.e.*, acylation is rate limiting). Therefore, for ester hydrolysis with α-chymotrypsin, $k_{cat} \approx k_3$; for amides, $k_{cat} \approx k_2$. It may be shown from the enzyme kinetic scheme (Scheme I) that $K_m$ and the equilibrium constant $K_s$ are related as follows:

$$K_m = \frac{k_3}{k_2 + k_3} K_s \qquad \text{(Eq. 11)}$$

If $k_2 \gg k_3$:

$$K_m \approx \frac{k_3}{k_2} K_s \qquad \text{(Eq. 12)}$$

If $k_3 \gg k_2$:

$$K_m \approx K_s \qquad \text{(Eq. 13)}$$

Bender and coworkers (4, 11) outlined some consequences of Scheme I for two types of substrates, esters and amides. They showed that the leaving groups (the ester or amide moieties) contribute very little, if anything, to the binding of substrates to α-chymotrypsin. Thus, $K_s$ values for amides and esters of the same acylamino acids should be similar. Because $K_s = K_m$ for the amide substrate, this experimentally determined value may be used as $K_s$ for the ester. In this way, all rate constants for various substrates can be evaluated. At pH 8.0, the values obtained for I are $K_s = 2.4 \times 10^{-4}$ *M*, $k_2 = 9.8 \times 10^3$ sec$^{-1}$, and $k_3 = 25$ sec$^{-1}$. The values for II are $K_s = 2.4 \times 10^{-4}$ *M*, $k_2 = 6.1 \times 10^{-3}$ sec$^{-1}$, and $k_3 = 25$ sec$^{-1}$.

Therefore, of the three synthesized prodrugs of aspirin, I showed the highest hydrolysis rate in the presence of α-chymotrypsin. The kinetic parameters obtained were within the range of expectation based on prior knowledge of the properties of α-chymotrypsin.

# Physicochemical Property Modification Strategies Based on Enzyme Substrate Specificities III: Carboxypeptidase A Hydrolysis of Aspirin Derivatives

**PRADIP K. BANERJEE** * **and GORDON L. AMIDON** ˣ

Received November 3, 1980, from the *School of Pharmacy, University of Wisconsin, Madison, WI 53706.* Accepted for publication April 2, 1981. * Present address: Tablet Products Research and Development, Abbott Laboratories, North Chicago, IL 60064.

**Abstract** □ The aspirin derivatives aspirin phenylalanine and aspirin phenyllactic acid were studied as substrates for carboxypeptidase A. The phenyllactic acid derivative (an ester) was the best substrate but showed considerable product inhibition. The kinetic parameters for both substrates were in the range expected on the basis of other known substrates. The results indicate that the acylamide substituent (drug) has only a small effect on the enzyme kinetic parameters. Consequently, carboxypeptidase A may serve as a reconversion site for many drug derivatives.

**Keyphrases** □ Aspirin—derivatives, hydrolysis by carboxypeptidase A □ Derivatives—aspirin, hydrolysis by carboxypeptidase A □ Carboxypeptidase A—hydrolysis of aspirin derivatives □ Physicochemistry—modification strategies based on enzyme substrate specificities, carboxypeptidase A hydrolysis of aspirin derivatives

A rationale for making amino acid derivatives of aspirin and their synthesis was reported previously (1). The kinetics of hydrolysis of the derivatives were studied in the presence of $\alpha$-chymotrypsin, and aspirin phenylalanine ethyl ester was the most rapidly hydrolyzed substrate (2). The amino acid derivatives of aspirin were so designed that after the initial cleavage of the terminal ester or amide linkage by $\alpha$-chymotrypsin, carboxypeptidase A would hydrolyze the remaining ester or amide linkage to regenerate aspirin *in vivo*. This paper reports the results of the kinetic studies of aspirin phenylalanine (I) and aspirin phenyllactic acid (II) in the presence of carboxypeptidase A.

## EXPERIMENTAL

**Materials**—Compounds I and II were prepared by the methods already described (1). Carboxypeptidase A was obtained as a suspension of crystals in toluene–water[1]. Before use, enzyme crystals were washed twice with distilled water and dissolved in 3.0 *M* sodium chloride solution. The solutions were centrifuged and stored at 4° in concentrations of ~30 mg/ml. Such solutions were reported (3) to have exhibited no change in activity over several months. Working solutions were prepared daily by diluting the stock solutions to the desired concentrations with 1.0 *M* sodium chloride. Enzyme concentrations were measured by absorbance at 278 nm and using a molar absorptivity of $6.49 \times 10^4$ liters/mole cm (4).

For measuring enzyme activity, stock enzyme was diluted to a 10–25 $\mu$g/ml concentration in 10% lithium chloride immediately before use. The substrate solution was freshly prepared and contained 0.001 *M* hippuryl-L-phenylalanine, 0.025 *M* tromethamine, and 0.5 *M* sodium chloride. The spectrophotometer was set at 254 nm. In the control cell were placed 2.9 ml of substrate solution and 0.1 ml of 10% lithium chloride; in the test cell, 0.1 ml of enzyme solution was added at zero time to 2.9 ml of substrate solution. The increase in absorbance was recorded. Enzyme activity was calculated using the following:

$$\text{units/mg of protein} = \frac{\Delta A_{254}/\text{min}}{0.36 \times \dfrac{\text{mg of enzyme}}{\text{ml of reaction mixture}}} \quad \text{(Eq. 1)}$$

where a unit of activity is defined to be equal to 1 $\mu$mole of substrate hydrolyzed/min under the specified conditions and 0.36 is the molar absorbance index of hippuric acid that is formed stoichiometrically.

**Kinetic Measurements**—The hydrolyses of I and II were followed by automatic titration at constant pH.[2] The method was previously described (2).

## RESULTS AND DISCUSSION

**Aspirin Phenylalanine (I)**—The products of carboxypeptidase A-catalyzed hydrolysis of I are aspirin and phenylalanine. The pKa of the $\alpha$-amino group of phenylalanine is 9.24; at pH 7.5, it is present almost completely as $NH_3^+$. Thus, at pH 7.5, the dissociable proton is consumed by the product amino acid, thereby not requiring any external alkali to maintain the pH. However, at pH 8.5, 18.19% of the phenylalanine is present in the nonionized form. Experiments were performed at pH 8.5 rather than at pH 7.5, accounting for this factor.

In these studies, the Michaelis–Menten assumption of $S_0 \gg E_0$ was

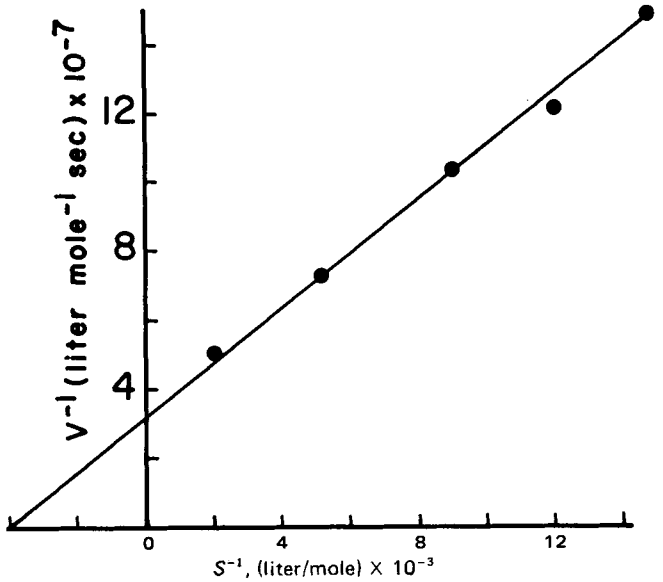

**Figure 1**—*Lineweaver–Burk plot for the hydrolysis of I catalyzed by $1.0 \times 10^{-5}$ M carboxypeptidase A at pH 8.5.*

[a] Taken from Ref. 3. [b] Performed at pH 8.5.

not adhered to. A Lineweaver–Burk plot (Fig. 1) was used to obtain $V_{max}$, which was then used in the Dixon plot (Fig. 2) to obtain $K_m$. The $K_m$ value obtained from the Dixon plot was slightly lower than that obtained from the Lineweaver–Burk plot. The $K_m$ value for I shown in Table I was obtained from the Dixon plot.

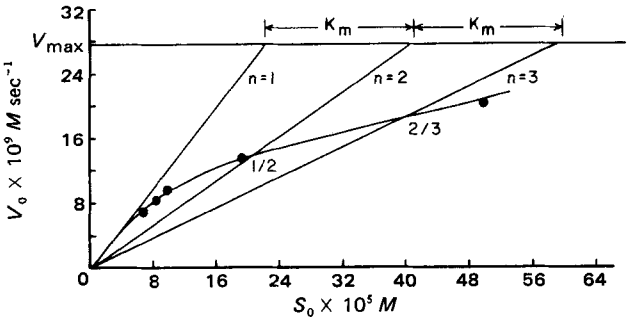

**Figure 2**—*Dixon plot for determining* $K_m$ *for the hydrolysis of I by 1.0* $\times 10^{-5}$ M *carboxypeptidase A at pH 8.5.*

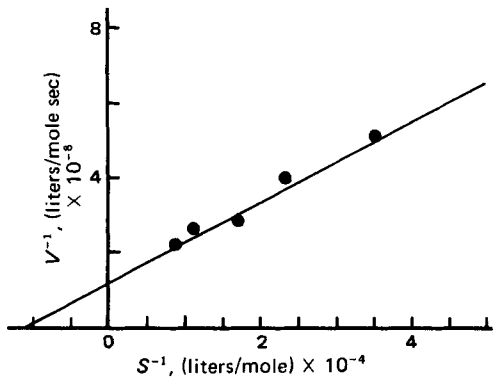

**Figure 6**—*Lineweaver–Burk plot for the hydrolysis of II by 2.45 × $10^{-10}$ M carboxypeptidase A at pH 7.5.*

**Aspirin Phenyllactic Acid (II)**—The results of six runs measuring the hydrolysis rates of II at six different concentrations catalyzed by carboxypeptidase A at pH 7.5 are illustrated in Fig. 3. The points shown were taken from the continuous record of the titrator for calculation purposes. The curves of this plot do not seem to follow a simple kinetic order, and the sharp decrease of hydrolysis rates with time suggests that product inhibition of the enzyme plays an important role. Significant product inhibition of carboxypeptidase A was reported (5, 6).

The scheme that fits the kinetics of the carboxypeptidase A-catalyzed hydrolysis of II is shown in Scheme I ($E$ is carboxypeptidase A, $S$ is II, $P_1$ is aspirin, and $P_2$ is L-phenyllactic acid). The L-phenyllactic acid ($P_2$) produced during hydrolysis acts as a competitive inhibitor.

$$E + S \underset{k_2}{\overset{k_1}{\rightleftarrows}} ES \overset{k_{cat}}{\rightleftarrows} E + P_1 + P_2$$

$$E + P_2 \underset{k_{-i}}{\overset{k_i}{\rightleftarrows}} EP_2$$

*Scheme I*

The corresponding integrated Michaelis–Menten equation is:

$$\frac{[S]_0 - [S]}{t} = \frac{K_m(K_i + [S]_0)}{(K_m - K_i)t} \ln([S]_0/[S]) + \frac{V_{max}}{1 - K_m/K_i} = \frac{a}{t} \ln \frac{[S]_0}{[S]} + \frac{V_{max}}{1 - K_m/K_i} \quad \text{(Eq. 2)}$$

where:

$$K_m = \frac{k_{-1} + k_2}{k_1}$$

$$K_i = \frac{k_{-i}}{k_i}$$

$$a = \frac{K_m(K_i + [S]_0)}{K_m - K_i}$$

**Table II—Kinetic Parameters for Carboxypeptidase A Hydrolysis of II**

| Kinetic Parameter | Calculated by Lineweaver–Burk Method | Calculated by Integrated Michaelis–Menten Equation |
|---|---|---|
| $K_m$, mole/liter | $8.74 \times 10^{-5}$ | $1 \times 10^{-4}$ |
| $K_i$, mole/liter | — | $4 \times 10^{-6}$ |
| $V_{max}$, mole/liter | $8.55 \times 10^{-9}$ | $6 \times 10^{-9}$ |
| $k_{cat}$, $sec^{-1}$ | 35 | 25 |

The integrated Michaelis–Menten equation for competitive product inhibition applies satisfactorily to the kinetic data obtained at pH 7.5 for II. This finding is illustrated by Fig. 4 in which $([S]_0 - [S])/t$ is plotted *versus* $1/t \ln([S]_0/[S])$. The linearity of the plots obtained is consistent with the proposed competitive product inhibition since the lines would curve for other types of product inhibition.

The intercept of the ordinate of Fig. 4 is a function of $V_{max}$, $K_m$, and $K_i$, and the slopes of the straight lines, $a$, are related to $K_m$, $K_i$, and $[S]_0$ by:

$$[S]_0 = a\left(1 - \frac{K_i}{K_m}\right) - K_i \quad \text{(Eq. 3)}$$

Thus, to separate the various kinetic parameters, Fig. 5 plots the values of $[S]_0$ *versus* the respective slopes, $a$, from Fig. 4. The intercept along the $[S]_0$ axis is $-K_i$; hence, $K_m$ and $V_{max}$ can be calculated. The $K_i$ value was considerably smaller than $K_m$, indicating strong competitive inhibition by the product, L-phenyllactic acid.

As a check on the applicability of the integrated Michaelis–Menten equation and the computed kinetic constants, $K_m$ and $V_{max}$ also were determined by the Lineweaver–Burk procedure. Figure 6 shows that the double reciprocal plot of the kinetic results is linear. The agreement between kinetic parameters calculated by the two procedures at pH 7.5 is good (Table II).

An overall summary of the carboxypeptidase A-catalyzed hydrolysis is given in Table I along with some results obtained from the literature for comparison purposes. Compound II was a better substrate than the corresponding phenylalanine derivative. The values of $k_{cat}/K_m$ obtained were comparable to those of the substrates reported previously, indicating that the reconversion rate was in the expected range and that the acylamide drug moiety had only a small effect on enzyme kinetics.

# Pharmacokinetics of Indapamide in Dogs

**PETER E. GREBOW** ˣ **and JO A. TREITMAN**

Received November 10, 1980, from the *Biochemistry and Drug Disposition Department, Revlon Health Care Group, Tuckahoe, NY 10707.* Accepted for publication May 13, 1981.

**Abstract** □ Four beagle dogs received both an oral and intravenous dose (1 mg/kg) of indapamide in a crossover design. The blood levels and urinary excretion of intact indapamide were measured, and the pharmacokinetic parameters of the drug were defined. The results indicate that indapamide is completely bioavailable after an oral dose and does not undergo first-pass metabolism. Excretion of unchanged drug from the kidney accounted for only a small percentage of the drug's clearance. While the dog is very similar to the human in its handling of indapamide, the dog clears indapamide approximately twice as fast as humans.

**Keyphrases** □ Indapamide—pharmacokinetics in dogs □ Pharmacokinetics—indapamide, dogs □ Antihypertensive agents—indapamide, pharmacokinetics in dogs

Indapamide[1], 1-(3-sulfamyl-4-chlorobenzamido)-2-methylindoline, is a new antihypertensive agent which has been shown to be clinically effective at daily doses of 2.5 and 5.0 mg (1–5). A terminal elimination half-life of ~15 hr was observed in human volunteers who received 5.0-mg oral doses of indapamide (6). A study (7) in which humans received radiolabeled indapamide orally showed that the drug was extensively metabolized, with only ~5% of the administered drug excreted unchanged in the urine. Therefore, renal clearance was considered to account for only a small percentage of indapamide's total body clearance.

The present study in dogs was designed to define the pharmacokinetic parameters of indapamide. Dogs were given both oral and intravenous doses to determine the fraction of dose systemically available after the oral dose.

## EXPERIMENTAL

**Animals**—Four male beagle dogs, weighing an average of 12.1 kg, were administered ~1 mg/kg of indapamide as an oral solution or as an intravenous injection in a crossover design. Two dogs initially received the oral dose, while the other two received the intravenous dose. A 2-week wash-out period was used between doses. Prior to dosing, the dogs were fasted overnight. They were maintained in metabolism cages and provided with water *ad libitum* throughout the study. Four hours after dosing, the dogs were given 480 ml (16 oz) of dog food mixed with an equal volume of water.

**Treatment**—The oral solution was prepared by dissolving 100 mg of indapamide[2] in 50 ml of polyethylene glycol 400[3], followed by dilution with water to a final concentration of 0.2 mg/ml. Approximately 60 ml of this solution was administered to each dog *via* a gastric tube, followed by 25 ml of water to rinse the gastric tube. The intravenous solution was prepared by dissolving indapamide in absolute ethanol to a final concentration of 5 mg/ml. After administration of the intravenous dose as a bolus, the dogs received ~75 ml of water *via* a gastric tube.

Blood samples (6 ml) for the first 12 hr after dosing were collected by an indwelling catheter in the jugular vein of the dog. Thereafter, blood samples were collected by venipuncture from the cephalic vein. The samples were collected in plastic syringes and transferred to polypropylene tubes[4] for storage. Sodium oxalate was the anticoagulant. With the intravenous dose, blood samples were collected just prior to and at 0.25, 0.5, 1, 2, 4, 6, 8, 12, 24, 30, 48, and 72 hr after dosing. Blood samples were collected just prior to and at 0.5, 1, 2, 3, 4, 6, 8, 12, 24, 30, 48, and 72 hr after the oral dose.

Urine was collected by catheterization just prior to and at 4, 8, 12, 24, 48, and 72 hr after dosing. This urine was combined with the urine collected in the metabolism cages during the appropriate time intervals, and the total urine volume was measured. All samples were divided into aliquots, and the urine and blood samples were maintained at −20° until assayed.

**Assay of Indapamide in Blood and Urine**—Measurement of blood and urine concentrations of indapamide was performed using a semiautomated fluorescence assay (8). The procedure was shown to be sensitive (25 ng/ml) and specific for the intact drug.

**Data Treatment**—Pharmacokinetic parameters for the intravenous blood data were calculated by standard techniques (9, 10). A two-compartment open model (Scheme I) was used to describe the blood concentrations of indapamide following the intravenous dose. Blood concentrations ($C$) of indapamide for any time $t$ after an intravenous dose are given by the relationship:

$$C = Ae^{-\alpha t} + Be^{-\beta t} \quad \text{(Eq. 1)}$$

where $A$ and $B$ are the zero-time intercepts determined by extrapolation of the linear distribution ($\alpha$) and terminal elimination ($\beta$) phases, respectively. These rate constants were calculated by the methods of residuals using a least-squares best fit to calculate the slopes. The intercompartmental transfer rate constants were then calculated as follows:

$$k_{12} = \alpha + \beta - k_{21} - k_{10} \quad \text{(Eq. 2)}$$

$$k_{21} = \frac{A\beta + B\alpha}{A + B} \quad \text{(Eq. 3)}$$

$$k_{10} = \frac{\alpha\beta}{k_{21}} \quad \text{(Eq. 4)}$$

The volume of distribution of the central compartment ($V_c$) was calculated as follows:

$$V_c = \frac{\text{dose}}{A + B} \quad \text{(Eq. 5)}$$

The apparent volume of distribution, $V_\beta$, for indapamide was calculated using:

$$V_\beta = \frac{\text{dose}}{\beta AUC_{0-\infty}} \quad \text{(Eq. 6)}$$

where $AUC_{0-\infty}$ is as defined later.

The $V_\beta$ of indapamide after an oral dose was calculated using Eq. 6, which is model independent. However, the oral dose was considered to be only that fraction that was available. This fraction, $F$, was calculated as the ratio of the area under the blood *versus* time curve after an oral dose to that following an intravenous dose.

The following additional parameters were calculated for both the oral and intravenous administrations of indapamide: area under the blood concentration *versus* time curve for the first 48 hr ($AUC_{0-48}$), which was calculated by the trapezoidal rule; and total area under the blood concentration *versus* time curve ($AUC_{0-\infty}$), which was calculated using:

$$AUC_{0-\infty} = AUC_{0-48} + \frac{C_{48}}{\beta} \quad \text{(Eq. 7)}$$

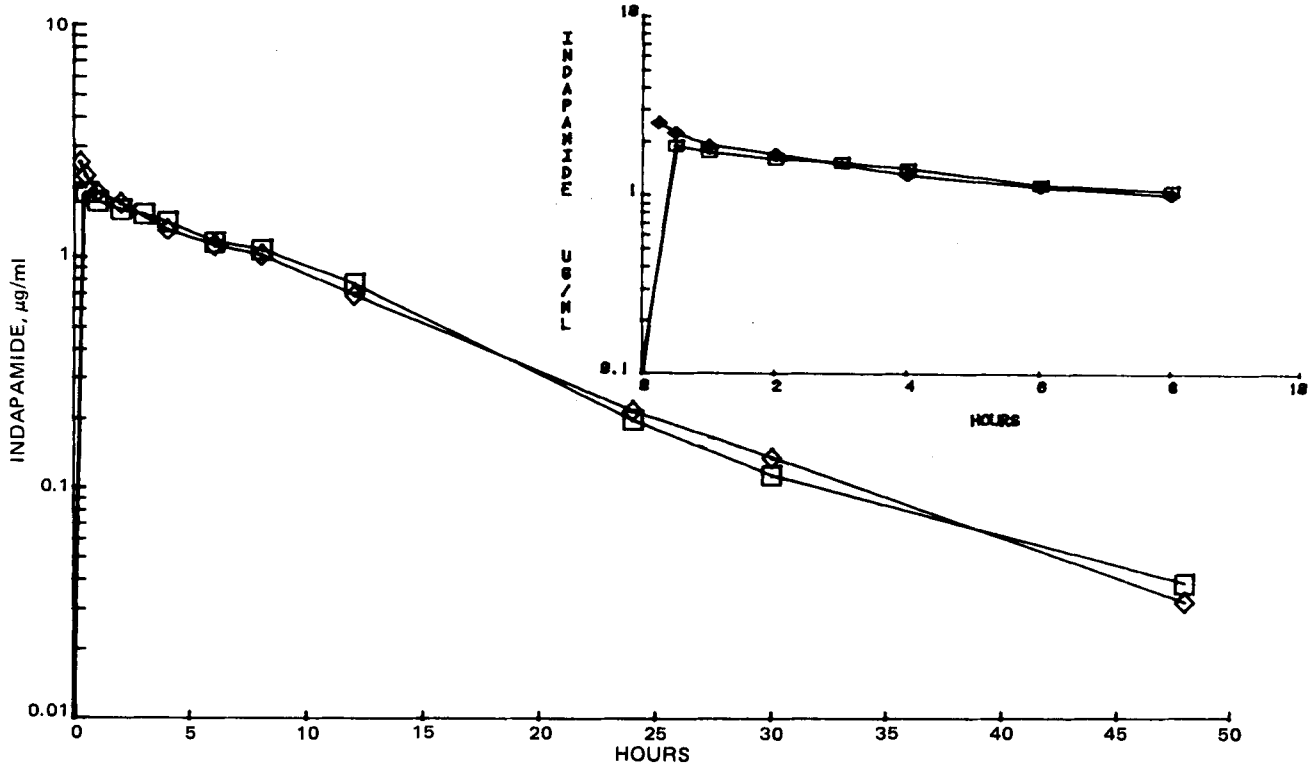

**Figure 1**—*Average indapamide blood concentrations after an oral (□) or intravenous (◇) dose of 1 mg/kg.*

where $\hat{C}_{48}$ was calculated from the slope of the terminal linear segment of the semilogarithmic plot of blood concentration *versus* time. The total body clearance ($Cl_T$) was calculated using:

$$Cl_T = V_\beta \beta \qquad \text{(Eq. 8)}$$

Average renal clearance ($Cl_R$) was determined by plotting the rate of excretion of unchanged indapamide in urine ($\Delta U/\Delta t$) as a function of the blood concentration of indapamide at the midpoint of the collection interval. The slope of this graph was calculated by linear regression and was equal to $Cl_R$. The total renal clearance was also estimated by dividing the total amount of indapamide recovered in the urine by $AUC_{0-\infty}$.

## RESULTS AND DISCUSSION

A two-compartment open model was chosen to describe the blood indapamide concentrations following the intravenous dose to dogs. This selection was made after visual inspection of the data. While these data possibly might be better described by an equation containing three or four exponential terms, the data at the latter time points were not sufficient to allow such analysis. The two-compartment model, however, appeared to be adequate since the fit of the theoretical to the experimental data was acceptable for all dogs, with correlation coefficients of at least 0.98. In addition, the $AUC_{0-48}$ values calculated from the parameters of the best fit were within 5% of the areas calculated by the trapezoidal rule.

Linear regression of the terminal elimination phase after an oral dose did not give evidence for a two-compartment model but for only a one-compartment one. This phenomenon occurs when the absorption rate constant of a drug is sufficiently close to the distribution rate constant that the distributive phase is not observed following absorption (9). The absorption rate of indapamide was not measured in this study since a sufficient number of points during the absorption phase was not obtained. Thus, only the analysis of the intravenous data was used to define the pharmacokinetic parameters of indapamide.

**Blood Concentrations**—Mean blood concentrations of indapamide in four dogs after an oral or intravenous dose of 1 mg/kg are shown in Fig. 1. After the oral dose, the average maximum blood concentration ($C_{max}$) obtained for indapamide was 1.95 μg/ml and the average time of peak blood concentrations ($T_{max}$) was 1.3 hr. Indapamide was rapidly absorbed after dosing with an oral solution.

Blood levels were significantly higher for the intravenous dose than the oral dose for only the 1st hr after dosing. At 4 hr after dosing, the average blood concentration of indapamide was higher after the oral dose than after the intravenous dose. The *AUC* values for the blood concentration *versus* time curves are shown in Table I. The average values for $AUC_{0-\infty}$ were 23.3 and 23.9 μg hr/ml for the oral and intravenous doses, respectively. It can be concluded from these data that the *AUC* values after the oral and intravenous doses were essentially the same and that the fraction of drug available was 1.0. Therefore, these results indicate that indapamide, although extensively metabolized (7), is completely bioavailable after an oral dose and does not undergo first-pass metabolism by the gut or liver.

A similar conclusion could be arrived at by using only the data obtained after the oral dose and calculating $F$ by the following (9):

$$F = \frac{Q}{Q + \dfrac{\text{dose}}{(AUC_{0-\infty})_{po}}} \qquad \text{(Eq. 9)}$$

**Table I—Pharmacokinetic Parameters for Intravenous and Oral Indapamide in Dogs**

| Parameter | Intravenous[a] | Oral |
|---|---|---|
| $AUC_{0-48}$, μg hr/ml | 23.5 ± 3.2 | 23.0 ± 1.4 |

[a] Mean ± *SD*. [b] Amount of indapamide excreted in the urine (0–48 hr)/$AUC_{0-\infty}$.

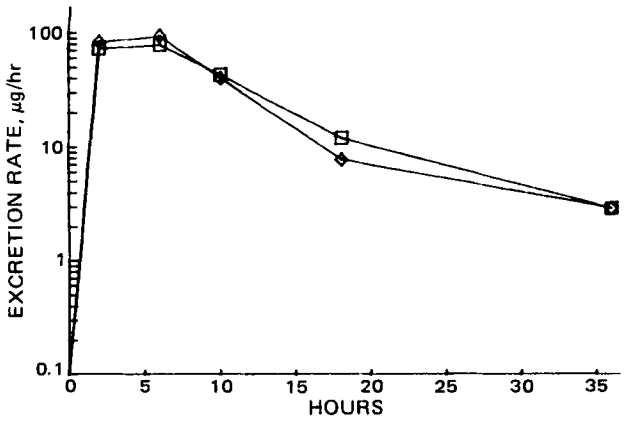

**Figure 2**—*Average indapamide urinary excretion rates after an oral (□) or intravenous (◇) dose of 1 mg/kg.*

where $Q$ is the liver blood flow in dogs [43 ml/min/hr (11)], the dose is 1 mg/kg, and the average $AUC_{0-\infty}$ is 1.95 μg hr/ml kg. A value of 0.98 was calculated for $F$ using these parameters.

The pharmacokinetic parameters were calculated for each dog after the intravenous and oral doses and are shown in Table I. The average terminal half-life for elimination of unchanged indapamide was 8 hr after both the oral and intravenous dose. The average $V_\beta$ was 0.50 for the oral dose and 0.49 liter/kg for the intravenous dose. Thus, there was no apparent difference in the way indapamide was handled after either an oral or intravenous dose. The average $V_c$ after the intravenous dose was calculated to be 0.34 liter/kg.

Plasma indapamide concentrations at 2 and 8 hr after dosing were measured, and the average ratio of whole blood to plasma concentrations for all samples was 5.4 ± 1.4.

**Urinary Excretion and Renal Clearance**—The average urinary excretion rate profiles after the intravenous and oral doses are shown in Fig. 2. Comparison of data after the oral and intravenous dose revealed no significant differences in the amount or rate of urinary excretion of unchanged indapamide. Within 48 hr after oral or intravenous dosing, averages of 8.2 and 8.1% of the dose were eliminated in the urine as unchanged indapamide, respectively. It was estimated that only ~0.2% of the dose was excreted in the urine as unchanged indapamide between 48 and 72 hr.

Renal clearance and average incremental renal clearance data for all dogs are presented in Table II. The renal clearance during the 4–8-hr interval was significantly higher than the values obtained for the other time intervals. This point caused considerable error in the calculation of renal clearance as evidenced by the increase in the correlation value when it was omitted. This temporal dependence of renal clearance was not related to the blood indapamide concentrations but instead may have been related to the administration of food and water to the dogs at 4 hr after dosing. This water intake may have increased the urine flow during the 4–8-hr period and thus decreased indapamide reabsorption.

However, while the renal clearance of indapamide appears to have been dramatically altered during this period, there was little change in total drug clearance because of the small involvement of the kidneys.

Renal clearance was also estimated by dividing the amount of unchanged indapamide excreted in the urine by 48 hr ($U_{0-48}$) after dosing by the $AUC_{0-\infty}$. This value should closely approximate the true value since a negligible amount of unchanged indapamide is excreted in the urine after 48 hr. The average values were 0.72 ml/min after the oral dose and 0.74 ml/min after the intravenous dose (Table I). These values compare favorably with those obtained graphically (0.79 and 0.87 ml/min, respectively).

**Table II—Average Renal Clearance of Indapamide in Four Dogs following Oral or Intravenous Dosing**

| Time Interval, hr | $C_B(\bar{T})$[a], μg/ml | $\Delta U/\Delta t$, μg/hr | $\Delta U/\Delta t/C_B(\bar{T})$, ml/min |
|---|---|---|---|
| | Oral Dosing | | |
| 0–4 | 1.633 | 73.1 | 0.746 |
| 4–8 | 1.168 | 79.8 | 1.139 |
| 8–12 | 0.826 | 43.6 | 0.880 |
| 12–24 | 0.416 | 12.2 | 0.489 |
| 24–48 | 0.088 | 3.0 | 0.568 |
| | $Cl_R$[b] = 0.89 ml/min; $r^2$ = 0.88 | | |
| | $Cl_R$[c] = 0.787 ml/min; $r^2$ = 0.97 | | |
| | Intravenous Dosing | | |
| 0–4 | 1.715 | 84.0 | 0.816 |
| 4–8 | 1.141 | 95.2 | 1.391 |
| 8–12 | 0.817 | 40.6 | 0.828 |
| 12–24 | 0.410 | 7.9 | 0.321 |
| 24–48 | 0.087 | 3.0 | 0.575 |
| | $Cl_R$[b] = 1.005 ml/min; $r^2$ = 0.81 | | |
| | $Cl_R$[c] = 0.873 ml/min; $r^2$ = 0.98 | | |

[a] Blood indapamide concentration at midpoint of time interval. Extrapolated values were used for those times when no blood sample was collected. [b] Renal clearance calculated by the graphical method using all points. [c] Renal clearance calculated by the graphical method excluding the 4–8-hr point.

Values of $C_{max}$ for blood concentrations of indapamide in humans (6) were ~0.3 μg/ml after a total dose of 5 mg (~0.07 mg/kg). These values, when corrected for dose, are approximately double the $C_{max}$ values obtained in the present study. This difference could be explained by the differences in the $V_\beta$ values of the two species. The values for dogs and humans are 0.5 and 0.3 liter/kg, respectively.

For humans, the elimination half-life has been reported as 15 hr (6); in the present study in dogs, a half-life of only 8 hr was observed. This difference may reflect a difference in the hepatic clearance rate in the two species since the renal clearance is ~10% or less of the total clearance for both species. Indeed, in both dogs and humans, indapamide clearance is considerably less than the liver blood flow, which may be a result of the drug's binding to the blood constituents and/or its intrinsic clearance.

# Mass Transport Properties of Co(polyether)polyurethane Membranes II: Permeability and Sorption Characteristics

**WILLIAM A. HUNKE * and LLOYD E. MATHESON, Jr. ˣ**

Received September 4, 1979, from the *College of Pharmacy, University of Iowa, Iowa City, IA 52242.* Accepted for publication April 24, 1981. *Present address: Sterling-Winthrop Research Institute, Rensselaer, NY 12144.

**Abstract** □ A series of co(polyether)polyurethane polymers containing polyethylene glycol 600, 1000, or 1540 was synthesized, purified by reprecipitation, and cast into clear, tough, flexible membranes using the solution method. Hydration and membrane swelling increased with increasing polyethylene glycol molecular weight. Paroxypropione, 5-nitrosalicylic acid, sulfaguanidine, and phenylbutazone were used as penetrants at a 1 m*M* donor concentration. Transport rates through the 1540 and 1000 copolymer membranes were in decreasing order: paroxypropione > 5-nitrosalicylic acid > sulfaguanidine > phenylbutazone; however, through the 600 copolymer membrane the rates were paroxypropione ≫ 5-nitrosalicylic acid ~ sulfaguanidine. Phenylbutazone did not penetrate during the experiment. Good agreement was obtained between apparent diffusion coefficients calculated by both the time lag and nonsteady-state methods. Boundary layer effects were examined by variations in stirring speeds. Evidence that diffusion may occur primarily through the aqueous region of the hydrated membranes is presented.

**Keyphrases** □ Model membrane systems—polyurethane copolymers, permeability and sorption characteristics □ Copolymers, polyurethane—model membrane systems, permeability and sorption characteristics □ Permeability—polyurethane copolymers, model membrane systems, permeability and sorption characteristics

The systematic modification of a polymer structure to alter its diffusional characteristics is a promising approach for the development of new model membranes and drug delivery systems. It was suggested (1) that the hydrophilic–hydrophobic character of a membrane may be controlled by suitable structural modifications. Membranes, while combining the seemingly opposite properties of mechanical strength and the ability to swell in water, have been prepared by copolymerization of hydrophilic and hydrophobic reactants (2–4). The membranes formed from these copolymers allowed the transport of permeants at rates comparable to porous dialysis membranes, but with the apparent selectivity of partitioning-type membranes (5).

Therefore, a series of co(polyether)polyurethane polymers composed of hydrophilic polyethylene glycol 600, 1000, or 1540 blocks and hydrophobic urethan segments was synthesized and characterized as described previously (6). The purpose of this study was to determine the mechanism of diffusion for a group of ionizable permeants with a wide range of physical and chemical properties. Sorption of the permeants, paroxypropione, 5-nitrosalicylic acid, sulfaguanidine, and phenylbutazone, were examined. The system was also analyzed for boundary layer effects.

## EXPERIMENTAL

**Materials**—Paroxypropione[1], 5-nitrosalicylic acid[1], sulfaguanidine[2], and phenylbutazone[2] were used as received.

**Methods**—Beer's law plots were prepared for each permeant at 27, 37, and 47° in 0.05 *M* phosphate buffer. A thermostated UV-cell holder was used to control sample temperatures during spectrophotometric[3] analysis.

Permeability of the polymer membranes was studied at 27, 37, and 47° using the described permeants at constant donor concentrations. A diffusion cell similar to one designed by Flynn and Smith (7) was used (6). The donor side was connected *via* tubing[4] from its sampling ports to a two-channel tubing pump[5] and an open donor solution reservoir. The receiving side of the diffusion cell was similarly connected to a UV micro flowcell[6] and the other channel of the tubing pump. The tubing on the receiving side, between the UV micro flowcell and tubing pump, was cut to facilitate filling the receiving side of the diffusion cell. Pieces of tubing[7] were used in the tubing pump drive, for connections to the sampling ports and UV micro flowcell, and to reconnect the break in the receiving side tubing after filling. Internal stirring speeds were controlled by using a synchronous motor[8] attached through an external gear system.

A diffusion experiment was begun by mounting a hydrated membrane between the halves of the diffusion cell. The assembled diffusion cell was placed into its cell holder which, in turn, was immersed in a specially constructed water bath maintained at the desired temperature ±0.3°. The receiving side of the diffusion cell, tubing, and UV micro flowcell were filled with preheated buffer by turning on the pump. In all cases, the buffer was 0.05 *M* phosphate at pH 7.5. The tubing was connected under the surface of the buffer to exclude air from the system.

The spectrophotometer, with the UV micro flowcell in place, was zeroed against the blank buffer in a 1-cm quartz cell. The connecting tubing on the donor side was then pumped full of preheated 0.001 *M* permeant in buffer from the 200-ml donor reservoir. To initiate diffusion across the membrane, preheated permeant solution was injected into the donor side chamber through a sampling port using a glass syringe. The donor side tubing from the donor reservoir, which had been left unattached so that solution could be injected, was secured to the sampling port, and the absorbance was recorded continuously *versus* time. Sink conditions were maintained in all cases. The two-channel tubing pump was set to deliver ~18 ml/min. The exact flow rate was determined prior to a diffusion experiment by measuring the amount of solution delivered in 3 min.

The use of a donor solution reservoir ensured a constant donor solution concentration and thus eliminated the possibility that a significant portion of permeant would be sorbed by the membrane. Zentner *et al.* (8) discussed the treatment of diffusion data under these conditions.

Membranes were removed from the glass plates after hydration with buffer and were soaked for at least 20 min before use.

Permeability characteristics of the polymers were determined as a function of the drying time of the membranes, which were heated at 50° for up to 4 days. Normally, membranes were cast, dried at 50° overnight, and then stored in a desiccator at room temperature.

Permeability characteristics were also examined as a function of the length of time the membranes were stored in the desiccator after an initial drying time of 8–12 hr at 50°. Membranes cut from the same casting were stored for up to 10 days before hydrating and performing the diffusion experiments.

Distribution coefficients were determined in triplicate using a solution depletion method at 27, 37, and 47° for each permeant. The initial absorbate concentration was the same as the permeant donor solution

concentration in the diffusion experiments. The time required to reach equilibrium for each polymer was estimated by preliminary absorption and diffusion experiments to be ~4 hr for the 1540 copolymer, 12 hr for the 1000 copolymer, and 24 hr for the 600 copolymer.

The permeant solution in each tube was assayed spectrophotometrically, and an experimental distribution coefficient was calculated by:

$$K = \frac{W_S/V_W}{C_S} \qquad \text{(Eq. 1)}$$

where $K$ is the distribution coefficient, $W_S$ is the equilibrium weight of permeant sorbed calculated from the concentration of the solution before and after sorption, $V_W$ is the membrane wet volume, and $C_S$ is the absorbate concentration in micrograms per milliliter remaining in solution after absorption completion.

To use this method, it was necessary to obtain a value for $V_W$. After absorption was complete, the membranes were removed from the solutions and dried overnight between two sheets of filter paper at 50°. Each membrane was then weighed to obtain the membrane dry weight, which was converted to wet volume, $V_w$, by:

$$V_w = \frac{V_R W_D}{\rho_D} \qquad \text{(Eq. 2)}$$

where $W_D$ is the dry weight of the membrane, $\rho_D$ is the dry density, and $V_R$ is the ratio of the wet membrane volume to the dry membrane volume. The $\rho_D$ and $V_R$ values were averages calculated from the wet and dry dimensions of three sample membranes of each type of polymer as described earlier (6).

## RESULTS AND DISCUSSION

Fabrication of the polymers into membranes results in the exposure of a large surface area of polymer to the potentially deleterious effects of light and moisture. No changes were observed in the diffusional characteristics of the membranes with increases in either drying or storage time.

Figure 1 is a representative plot showing the diffusion of all four permeants at 37° through the 1540 copolymer membrane. This plot was normalized for thickness of the membrane by multiplying the moles of permeant diffused by the thickness of the membrane. The rank order of transport was paroxypropione > 5-nitrosalicylic acid > sulfaguanidine > phenylbutazone in both the 1540 and 1000 copolymer membranes. The rank order of transport was paroxypropione ≫ sulfaguanidine ≥ 5-nitrosalicylic acid in the 600 copolymer. Phenylbutazone did not penetrate during the experiment.

Figure 2 is a composite plot representing the permeability of paroxypropione through the three different membranes at 37°. The rank order of permeability was 1540 copolymer > 1000 copolymer ≫ 600 copolymer.

The apparent permeability coefficient, $P'$, for each permeant was calculated from steady state using:

$$P' = \frac{(dm/dt)(h_m)}{(A)(C_d)} \qquad \text{(Eq. 3)}$$

where $dm/dt$ is the steady-state slope (mass per second), $h_m$ is the membrane thickness (centimeters), $A$ is the diffusional area of the membrane (square centimeters), and $C_d$ is the donor solution concentration (moles).

The apparent diffusion coefficient, $D'$, was calculated for each permeant in each polymer, except 5-nitrosalicylic acid and sulfaguanidine in the 600 copolymer, by:

$$D' = \frac{h_m^2}{(6)(t_L - t_c)} \qquad \text{(Eq. 4)}$$

where $t_L$ is the apparent lag time intercept and $t_c$ is the time required for the receiving side chamber contents to reach the UV micro flowcell. The term $t_c$ is given by:

$$t_c = \frac{3.7 \text{ ml}}{\text{pumping rate (ml/sec)}} \qquad \text{(Eq. 5)}$$

where 3.7 ml is the volume of the section of tubing leading from the diffusion cell to the UV micro flowcell. The results of the permeability experiments are shown in Table I for the 1540 copolymer.

Under certain circumstances, it may not be feasible to continue a diffusion experiment until steady-state diffusion is reached (9). An equation was derived to evaluate the diffusional parameters during the nonsteady-state period (10, 11):

$$\log \frac{M}{t^{1.5}} = \log \frac{8C_dK}{\sqrt{\pi h_m^2}} + \frac{3}{2}\log D' - \frac{h_m^2}{9.2D'}\frac{1}{t} \qquad \text{(Eq. 6)}$$

where $M$ is the amount permeated at $t$, the corrected time $(t - t_c)$ in seconds; $C_d$ is the concentration of the donor solution $(M)$; $K$ is the distribution coefficient; and $h_m$ is the thickness of the membrane. Use of the equation is restricted to early nonsteady-state diffusion across a single barrier. From the slope of a plot of $\log M/t^{1.5}$ *versus* $1/t$, the apparent diffusion coefficient of the permeant in the membrane can be calculated.

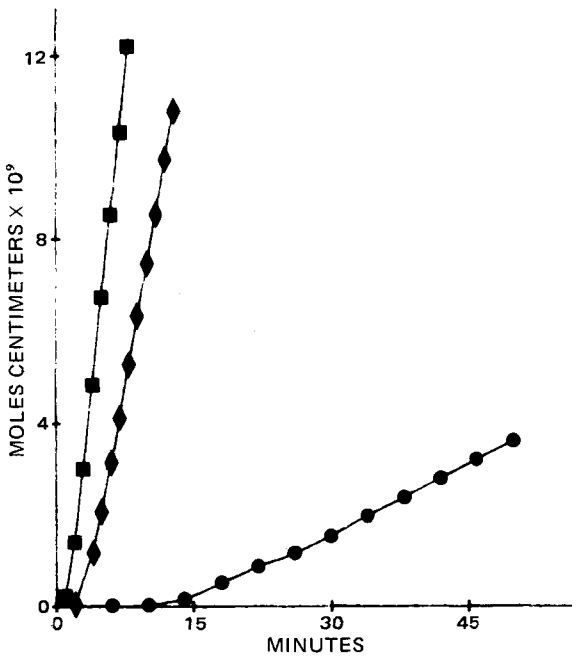

**Figure 2**—*Representative plot of diffusion of paroxypropione at 37° through 600 copolymer (●), 1000 copolymer (◆), and 1540 copolymer (■) membranes at 30, 200, and 200 rpm, respectively, normalized for membrane thickness.*

[a] Each value is the mean of three experiments.

This approach was used for the calculation of $D'$ for the diffusion of 5-nitrosalicylic acid and sulfaguanidine across the 600 copolymer since penetration was relatively slow. Boundary layer effects were negligible in this membrane. Permeability data are given in Table II.

Since paroxypropione penetrates the 600 copolymer rapidly enough to use the lag time steady-state method to calculate $D'$, the applicability of Eq. 6 was tested by calculating $D'$ utilizing both methods. The resulting apparent diffusion coefficient from the lag time was $1.5 \times 10^{-9}$ $cm^2$/sec, while the diffusion coefficient calculated using the nonsteady-state method was $1.2 \times 10^{-9}$ $cm^2$/sec.

Boundary layer effects can be seen in Table I. The apparent permeability coefficient for the permeants in the 1540 copolymer increased with an increasing stirring rate. In Fig. 3, the apparent permeability coefficients from a series of diffusion experiments for 5-nitrosalicylic acid through the 1540 copolymer at 37° are plotted *versus* stirring rates of 10–200 rpm. The apparent permeability coefficient increased with increasing stirring rate due to a reduction in thickness of the boundary layers on either side of the membrane. The boundary layer contribution was observed because of the relatively high diffusion coefficients of 5-nitrosalicylic acid in the 1540 copolymer.

This change is predicted for a series barrier where the boundary layers contribute a significant amount of resistance to the overall barrier resistance (8, 12–14). If diffusional processes are assumed to offer the most resistance to the overall permeation process, then under steady-state diffusion conditions and boundary layers of equal thickness:

$$F = \frac{C_d}{\frac{2h_l}{D_{aq}} + \frac{h_m}{KD}} \qquad \text{(Eq. 7)}$$

where $F$ is the flux, $C_d$ is the penetrant concentration in the bulk donor solution, $h_l$ is the boundary layer thickness, $h_m$ is the membrane thickness, $D_{aq}$ is the diffusion coefficient for the permeant in the aqueous phase, $D$ is the diffusion coefficient for the permeant in the membrane, and $K$ is the distribution coefficient. The terms in the denominator are defined as the aqueous boundary layer resistance and the membrane resistance to diffusion, respectively (15).

**Table II—Results of Diffusion Experiments with the 600 Copolymer at 30 rpm**

| Permeant | Temperature | Apparent[a] Permeability Coefficient × $10^8$, $cm^2$/sec | Apparent Diffusion Coefficient × $10^9$, $cm^2$/sec |
|---|---|---|---|
| Paroxypropione | 27° | 11.0 | 1.6 |
| | 37° | 17.0 | 2.6 |
| | 47° | 27.0 | 4.8 |
| 5-Nitrosalicylic acid | 27° | — | — |
| | 37° | 1.3 | 0.6 |
| | 47° | 2.6 | 1.4 |
| Sulfaguanidine | 27° | 0.5 | 0.5 |
| | 37° | 0.5 | 0.8 |
| | 47° | 0.9 | 1.9 |

[a] Apparent $P$ is the product of $D$ and the distribution coefficient.

Boundary layer effects were not significant in the 600 copolymer since an increase in $P'$ for paroxypropione in the 600 copolymer at 37° was not seen with increased stirring rates. Thus, $P'$ was calculated as $1.7 \times 10^{-7}$ $cm^2$/sec at both 30 and 200 rpm.

The apparent diffusion coefficient, $D'$, was also affected by changes in boundary layer contributions (Table I). This effect on $D'$ is due to the use of $t_L$, which is sensitive to the effects of the boundary layers.

The contribution of boundary layer resistance to the overall resistance of the barrier can be evaluated by plotting $1/P'$ *versus* $1/h_m$, as suggested by Hwang *et al.* (14), using

$$1/P' = \frac{1}{P} + \frac{2h_l}{D_{aq}}\frac{1}{h_m} \qquad \text{(Eq. 8)}$$

where $P$ is the permeability coefficient adjusted for the boundary layer contribution. The slope of such a plot is the resistance due to the boundary layer, $R_{2h_l}$, and the reciprocal of the intercept is $P$. Figure 4 shows such a plot for the diffusion of 5-nitrosalicylic acid at 37° through the 1540 copolymer at four stirring speeds. Table III contains the values of $P$ and $D$ for the four stirring speeds. These $P$ and $D$ values are essentially constant when compared to Fig. 3, which suggests that the boundary layer contribution was largely eliminated.

Figure 5 shows that the relative contribution of the membrane resistance to the overall barrier resistance increases with increasing stirring rate. The resistance of the membrane, $R_m$, is given by:

$$R_m = \frac{h_m}{P} \qquad \text{(Eq. 9)}$$

where $h_m$ is the membrane thickness (taken as $5.08 \times 10^{-3}$ cm) and $P$ is the reciprocal of the intercept of Eq. 8.

The diffusion data adjusted for boundary layer effects for the 1540 copolymer and the 1000 copolymer are given in Tables IV and V. The diffusion data for the 600 copolymer were not adjusted for boundary layer effects since no significant effects were observed. The adjusted $P$ and $D$ values are in the same rank order as the apparent permeability and apparent diffusion coefficients but are preferred since they represent the diffusional properties of the membrane alone and not the contribution of the boundary layers.

For each permeant, as the percent polyethylene glycol (or the percent water absorbed) increased, an increase in the magnitude of the diffusion coefficient was observed (Fig. 6). These results suggest that the extent of hydration of the membrane greatly influenced the diffusivity of a permeant in these membranes.

This dependence of $D$ on the hydration state of the membrane may be explained by the free volume theory (16, 17), which is given by:

$$\ln D = \ln D_{aq}\phi q_2 - V^*/V_{f,1}\left(\frac{1}{H} - 1\right) \qquad \text{(Eq. 10)}$$

where $D$ is the diffusion coefficient for the permeant in the swollen membrane, $D_{aq}$ is the aqueous diffusion coefficient for the permeant, $\phi q_2$ is the probability of finding a hole unobstructed by polymer large enough for the molecule to diffuse through, $V^*$ is a characteristic volume pa-

rameter for the permeant, $V_{f,1}$ is the free volume of water, and $H$ is the hydration of the membrane expressed as (wet volume − dry volume)/wet volume.

The hydration of the membrane calculated as a weight fraction was used here as an approximation for $H$ as discussed earlier (16). For a more rigorous treatment, the volume fraction may be used to calculate $H$.

Plots of the diffusion coefficient *versus* $(1/H - 1)$ for each permeant (except phenylbutazone) at 37° were made according to Eq. 10 and are shown in Fig. 7. The hydration of each polymer, $H$, was determined at room temperature and was used in all plots. While the water content of hydrogels are not necessarily temperature independent (18, 19), Refojo and Yasuda (20) showed changes in water content of only 3–4% for some hydrogels over 10–90°. Thus, changes in membrane hydration with temperature would be expected to be quite small and result in only slight differences in slope between the free volume plots at various temperatures.

Methods to correct the data for temperature-induced changes in swelling (hydration) were developed (18); but due to insufficient data, no correction for this effect was made here. The linearity of the free volume plots implies that the transport of the solutes through these membranes occurs primarily in water-filled pores or channels within the membranes.

The free volume theory of diffusion is most often applied to noninteractive systems in which the distribution coefficients range from 0 to 1. Therefore, further study may be required to confirm the applicability of the free volume theory of diffusion in these more interactive polymer–permeant systems.

Other evidence for the existence of small pores is given by the magnitude of the activation energy of diffusion for the permeants in the membrane (7–20 kcal/mole) compared to the activation energy of diffusion for a permeant in water (~4 kcal/mole) (9). This increase implies that the polymer chains form small pores that can impede the transport of the permeant through the aqueous regions in the membrane; thus, more energy is required for diffusion. It was suggested (17) that the hydrated polymer chains are relatively mobile, so that the size and shape of the water-filled pores or channels changes continuously.

The ability of the polymers to absorb the permeants was studied using a solution depletion method at three temperatures. The results are given in Table VI. The magnitude of the distribution coefficients indicates that a significant amount of permeant was sorbed. The rank order of the distribution coefficients was paroxypropione > phenylbutazone > 5-nitrosalicylic acid > sulfaguanidine. The distribution coefficients are not simply the result of permeant dissolved in water present inside the swollen membrane since, if this were the case, the $K$ values would range between zero and 1. Since the sorption experiments were done in buffer at pH 7.5, 5-nitrosalicylic acid (pKa 2.3) and phenylbutazone (pKa 4.4) were almost completely ionized and paroxypropione (pKa 7.8) was ~50% ionized. At pH 7.5, sulfaguanidine (pKa 2.8) was essentially unionized.

[a] Mean of three determinations.

This finding suggests that these polymers are capable of sorbing both the unionized and ionized forms of the molecules.

It can also be seen that, except for paroxypropione, the distribution coefficients are rather insensitive to polymer composition and the resulting hydration state of the membrane. For penetrants insensitive to polymer composition, it is difficult to deduce whether the hydrophilic or the hydrophobic portion is primarily responsible for sorption. In the case of paroxypropione, the increase in the distribution coefficient with decreasing polyethylene glycol content of the polymer suggests an affinity for a more hydrophobic environment. This finding lends support to other suggestions (3, 21) that the hydrophobic urethan block may provide a site for permeant interaction with these types of polymers.

It appears that the permeant loading of the membranes may be affected by the distribution coefficient of the drug, but the lack of correlation between the distribution coefficient and permeability indicates a lack of support for diffusion through the membrane material itself. Perhaps in polyethylene glycol copolymer membranes prepared with polyethylene glycols with molecular weights of <600, the distribution coefficient would be a better predictor of membrane permeability.

Highly ionic species are readily transported, and the apparent consistency of the data with the free volume theory for diffusion is consistent with the transport of some permeants through aqueous channels. That sorption of the various permeants by these membranes was demonstrated need not eliminate the aqueous channel mechanism of diffusion in favor of a partitioning mechanism. The sorption of permeants by the membrane may be, for example, a reversible binding of the permeant to the polymer chains. This would increase the membrane concentration of permeant but not necessarily require that the permeant dissolve in the polymer and diffuse through the polymer phase of the membrane. The permeant might alternatively desorb back into and subsequently diffuse through the aqueous phase. The path taken by the permeant through the swollen membrane depends on the relative permeability of the permeant in the aqueous and polymer phases (9). The ability of the polymer to absorb the penetrant had no predictive relationship with diffusion through the membranes.

# Convenient Synthesis of 6-Nor-9,10-dihydrolysergic Acid Methyl Ester

**A. MICHAEL CRIDER *x, RICHARD GRUBB *, KENNETH A. BACHMANN *, and ARUN K. RAWAT ‡**

Received January 22, 1981, from the **College of Pharmacy, University of Toledo, Toledo, OH 43606*, and the ‡*Alcohol Research Center, C.S. 10002, Toledo, OH 43699.* Accepted for publication April 8, 1981.

**Abstract** □ 6-Nor-9,10-dihydrolysergic acid methyl ester (IV) was prepared by demethylation of 9,10-dihydrolysergic acid methyl ester (II) with 2,2,2-trichloroethyl chloroformate, followed by reduction of the intermediate carbamate (III) with zinc in acetic acid. The 6-ethyl-V and 6-*n*-propyl-VI derivatives were prepared by alkylation of IV with the appropriate halide. All of the ergoline derivatives were evaluated for stereotyped behavior in rats, with 6-nor-6-ethyl-9,10-dihydrolysergic acid methyl ester (V) being active but much less potent than apomorphine. Compound VI was evaluated for its effect on blood pressure; at a dose of 30 mg/kg ip, it significantly lowered diastolic pressure in normotensive rats.

**Keyphrases** □ Ergolines—demethylation of the *N*-6 methyl group by 2,2,2-trichloroethyl chloroformate □ Derivatives—6-alkyl, of 6-nor-9,10-dihydrolysergic acid methyl ester □ Stereotyped behavior—ergolines, synthesis of 6-alkyl derivatives of 6-nor-9,10-dihydrolysergic acid methyl esters and evaluation in rats

Various compounds containing the ergoline (I) ring system are potent inhibitors of prolactin release (1–8). Ergolines appear to inhibit prolactin release by a dopaminergic mechanism (9). Due to their prolactin inhibitory activity, ergolines such as bromocriptine and lergotrile have demonstrated potential therapeutic value in the control of postpartum lactation and amenorrhea–galactorrhea associated with hyperprolactinemia. Additionally, these ergoline derivatives have potential in the treatment of parkinsonism (10).

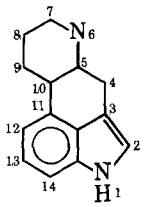
Replacement of the methyl group of I at position 6 by either ethyl or *n*-propyl groups increases prolactin inhibition (4, 6–7, 10). The most commonly employed method for demethylation of the *N*-6 methyl group of the ergoline system is a modification of the von Braun degradation (11), but an extremely poisonous cyanogen bromide is required in the reaction.

This paper reports a convenient synthesis of 6-nor-9,10-dihydrolysergic acid methyl ester (IV) utilizing 2,2,2-trichloroethyl chloroformate as the demethylating agent. The synthesis and pharmacological activity of the 6-ethyl-V and 6-*n*-propyl-VI derivatives of IV are also described.

## RESULTS AND DISCUSSION

**Chemistry**—The synthesis of 6-nor-9,10-dihydrolysergic acid methyl ester (IV) was described previously (11). In this investigation, demethylation at position 6 of 9,10-dihydrolysergic acid methyl ester (II) was accomplished by modification of the von Braun degradation. The intermediate 6-nor-6-cyanoergoline was reduced by hydrogenation in the presence of Raney nickel to yield IV. The 6-nor-6-cyanoergolines have also been reduced to yield 6-nor-ergolines with sodium borohydride (12) and with zinc in acetic acid (13).

Several recent reports described the use of 2,2,2-trichloroethyl chloroformate to demethylate tertiary methylamines (14–16). The corresponding demethylated trichloroethyl carbamate derivatives are easily cleaved by reduction with zinc in acetic acid. In view of our present research program to synthesize 6-nor-6-alkylergolines as potential



I

dopaminergic agonists, the use of 2,2,2-trichloroethyl chloroformate as a demethylating agent was of interest.

Treatment of II with 2,2,2-trichloroethyl chloroformate in refluxing methylene chloride with potassium bicarbonate as the base afforded 6-nor-6-(2,2,2-trichloroethoxycarbonyl)-9,10-dihydrolysergic acid methyl ester (III) in a 90% yield. Reduction of the carbamate (III) with zinc in acetic acid at room temperature readily gave IV.

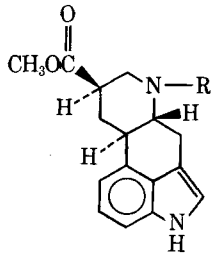
The 6-nor-6-ethyl-V and 6-nor-6-*n*-propyl-VI derivatives were prepared by alkylation of IV with an appropriate alkyl iodide in dimethylformamide with potassium carbonate as the base. Although the preparation of 6-nor-6-ethyl-9,10-(V) (11) and 6-nor-6-*n*-propyl-9,10-dihydrolysergic acid methyl ester (VI) (17) has been described, the biological activity of these compounds has not yet been reported.

The use of 2,2,2-trichloroethyl chloroformate represents a novel method for demethylation of the *N*-6-methyl group. The carbamate III is a potentially useful intermediate for the synthesis of potent dopaminergic ergolines such as pergolide (8).

**Pharmacology**—Of those ergolines examined for inducibility of behavioral stereotypy, only V exhibited any activity in doses up to 30 mg/kg. Not only was V less potent than apomorphine when behavior was ranked according to Costall *et al.* (18) (Fig. 1), but qualitative differences in behavior were also observed. For example, V elicited less gnawing behavior than apomorphine but produced intense salivation. The highest dose of V tested for activity (25 mg/kg) approached the lowest dose for which lethality was observed (30 mg/kg). Death appeared due to respiratory arrest and was sometimes preceded by clonic seizures.

Table I lists the mean activity per rat. The activities for apomorphine and V are depicted in Figs. 1 and 2 and are expressed as a percentage of the maximum activity observed. The ratios of killed per treated rats are given in Table II.

During the tests for behavioral stereotypy, both II and VI were noted to elicit flushing of the tail, ears, and paws. This effect was especially pronounced and reproducible for VI and occasioned the analysis of VI on blood pressure. Compound VI did not significantly alter systolic pressure, but single intraperitoneal doses (30 mg/kg) significantly lowered



II: R = $CH_3$
III: R = $CO_2CH_2CCl_3$
IV: R = H
V: R = $CH_2CH_3$
VI: R = $CH_2CH_2CH_3$

**Table I—Induction of Behavioral Stereotypes [a] in Rats**

| Compound | Dose[b], mg/kg | *n* | Mean Activity/Rat |
|---|---|---|---|
| Controls[c] | 1 | 6 | 0 |
| Apomorphine | 10 | 15 | 12.7 |
| II | 30 | 4 | 0.25 |
| III | 30 | 4 | 0 |
| V | 3 | 4 | 0.25 |
| | 6 | 4 | 1.0 |
| | 9 | 4 | 1.25 |
| | 15 | 4 | 2.25 |
| | 20 | 4 | 3.5 |
| | 25 | 4 | 5.25 |
| VI | 30 | 3 | 0.33 |

[a] Stereotypic behavior was scored according to the scale of Costall *et al.* (18). [b] All compounds were administered intraperitoneally in polyethylene glycol 400 (70%). [c] Controls received polyethylene glycol 400 (1 ml/kg).

diastolic pressure in normotensive rats (Fig. 3). The hypotensive effect of VI occurred at 2 hr and was sustained for 1 hr. The hypotensive effects of VI relative to polyethylene glycol 400 (PEG) may have been obscured by an apparently abrupt (although statistically insignificant) increase in diastolic pressure (Fig. 3).

Hypotensive activity with certain ergolinyl methyl esters was reported previously (19, 20).

## EXPERIMENTAL[1]

**6-Nor-6-(2,2,2 - trichloroethoxycarbonyl)-9,10-dihydrolysergic Acid Methyl Ester (III)**—A mixture of II (21) (0.425 g, 0.0015 mole), potassium bicarbonate (0.729 g, 0.0073 mole), and 2,2,2-trichloroethyl chloroformate (0.619 g, 0.0029 mole) in 60 ml of absolute methylene chloride was refluxed for 24 hr. 2,2,2-Trichloroethyl chloroformate (1.48 g, 0.0070 mole) was added, and refluxing was continued for an additional 24 hr. The reaction mixture was cooled, filtered, and evaporated under reduced pressure to yield a white solid. Recrystallization from absolute methanol gave 0.602 g (90%) of crystalline product, mp 208–210°; IR (KBr): 3485 (N–H, indole) and 1740 (C=O, ester and carbamate) $cm^{-1}$; NMR (dimethyl sulfoxide-$d_6$): $\delta$ 3.70 (s, 3H, $COOCH_3$), 4.90 (s, 2H, $OCH_2CCl_3$), 6.67–7.20 (m, 4H, aromatic), and 7.27 (s, 1H, NH).

*Anal.*—Calc. for $C_{19}H_{19}Cl_3N_2O_4$: C, 51.19; H, 4.30; Cl, 23.86; N, 6.29. Found: C, 51.14; H, 4.20; Cl, 24.21; N, 6.13.

**6-Nor-9,10-dihydrolysergic Acid Methyl Ester (IV)**—A solution of III (0.877 g, 0.0020 mole) in 100 ml of acetic acid was treated in one portion with powdered zinc dust (2.58 g, 0.039 g-atom), and the mixture was stirred for 60 hr at room temperature. Then the reaction mixture was filtered, and the inorganic residue was washed with acetic acid. The reaction mixture was diluted with water (100 ml) and extracted two times

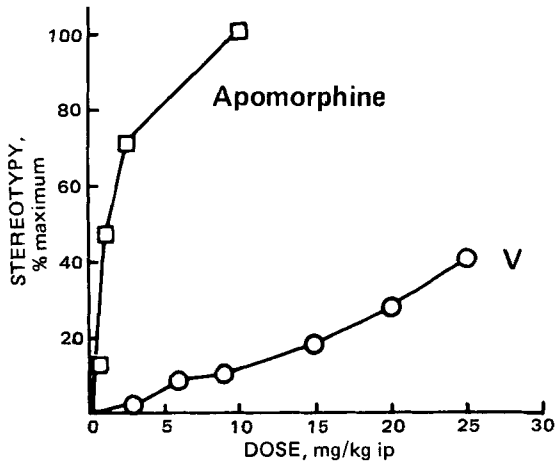

**Figure 1**—*Dose–response curves for stereotypic behavior induced by apomorphine (□) or V (○).*

[1] Melting points were determined on a Fisher-Johns melting-point apparatus and are uncorrected. IR spectra were recorded as potassium bromide pellets with a Perkin-Elmer 137 spectrophotometer. NMR spectra were recorded on a Varian EM 360A spectrometer. Chemical shifts are reported in parts per million ($\delta$) relative to tetramethylsilane (1%) as the internal standard. Analytical data were obtained from Micro-Analysis Inc., Wilmington, Del.

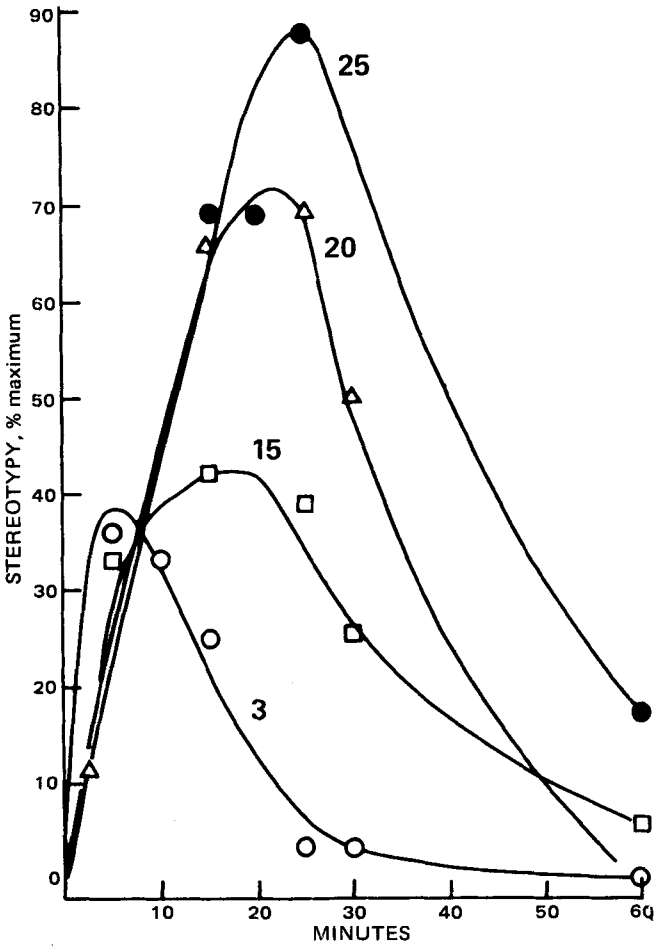

**Figure 2**—*Time course of stereotypic behavior induced by graded doses of V. Numbers denote doses of V (milligrams per kilogram).*

with 50-ml portions of chloroform. The aqueous acetic acid solution was cooled in an ice bath and carefully basified with 8 *N* $NH_4OH$ solution.

The basic solution was extracted three times with 75-ml portions of chloroform. The combined chloroform extracts were dried (sodium sulfate), filtered, and evaporated under reduced pressure to yield 0.384 g (72%) of a light-tan solid. The hydrogen maleate salt was prepared and recrystallized from methanol to yield analytically pure material, mp 211–213° [lit. (11) mp of the free base 172°]; IR (KBr): 3300 (N–H, indole) and 1700 (C=O, ester) $cm^{-1}$; NMR (dimethyl sulfoxide-$d_6$): $\delta$ 3.70 (s, 3H, $COOCH_3$), 7.10 (s, 1H, NH), and 6.50–7.17 (m, 4H, aromatic).

*Anal.*—Calc. for $C_{20}H_{22}N_2O_6$: C, 62.16; H, 5.75; N, 7.25. Found: C, 62.20; H, 5.88; N, 7.04.

**6-Nor-6-*n*-propyl-9,10-dihydrolysergic Acid Methyl Ester (VI)**—A mixture of IV (0.300 g, 0.0011 mole) and potassium carbonate (0.306 g, 0.0022 mole) in 25 ml of dimethylformamide was treated with *n*-propyl iodide (0.377 g, 0.0022 mole). After heating for 24 hr at 50°, the reaction mixture was cooled, filtered, and evaporated under reduced pressure to afford a light-brown oil. The oil was taken up into 200 ml of chloroform and washed with 200 ml of water. The chloroform phase was dried (sodium sulfate), filtered, and concentrated under reduced pressure to give a light-tan solid. Recrystallization from methanol afforded, in two crops, 0.162 g (47%) of analytically pure material, mp 215–216° [lit. (17) 212–214°]; IR (KBr): 3300 (N–H, indole) and 1730 (C=O, ester) $cm^{-1}$; NMR

**Table II—Lethality of V**

| Dose, mg/kg | Dead/Treated |
|---|---|
| 20 | 0/4 |
| 25 | 0/4 |
| 30 | 1/4 |
| 40 | 1/4 |
| 50 | 2/4 |

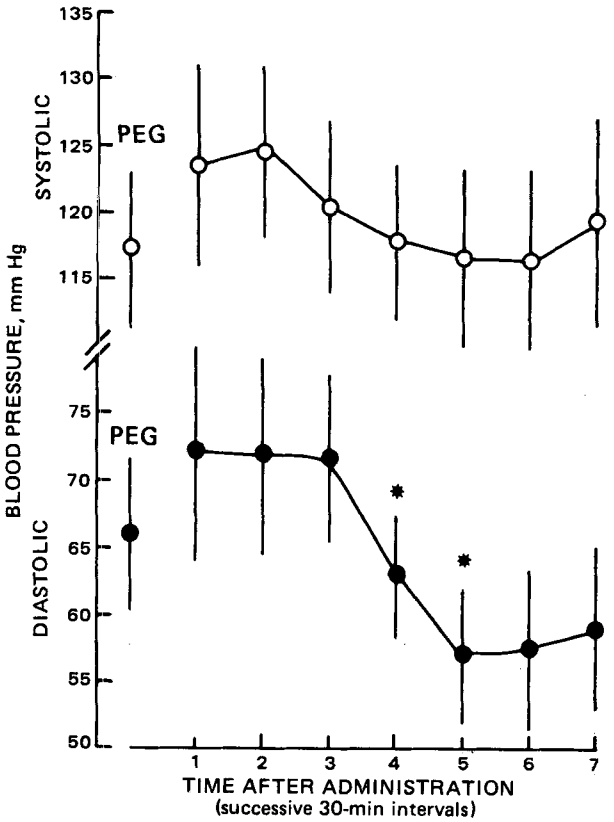

**Figure 3**—*Impact of VI on blood pressure. Vertical bars denote standard error of the mean (n = 4), and asterisk signifies* $p < 0.05$.

($CDCl_3$): δ 0.90 (t, 3H, $CH_2CH_2CH_3$), 1.07–3.53 (m, 13H), 3.70 (s, 3H, $COOCH_3$), 6.87–7.23 (m, 4H, aromatic), and 7.97 (s, 1H, NH).

*Anal.*—Calc. for $C_{19}H_{24}N_2O_2$: C, 73.02; H, 7.76; N, 8.97. Found: C, 73.04; H, 7.59; N, 8.94.

**6-Nor-6-ethyl-9,10-dihydrolysergic Acid Methyl Ester (V)**—This compound was synthesized from IV (0.202 g, 0.0008 mole), potassium carbonate (0.103 g, 0.0008 mole), and ethyl iodide (0.233 g, 0.0015 mole) in 25 ml of dimethylformamide in the same manner as described for VI. Column chromatography of the product with silica gel as the adsorbent and chloroform–methanol (95:5) as the solvent, gave, after evaporation of the solvents, 0.162 g (75%) of a light-brown solid, mp 168–169° [lit. (11) 170–174°]; IR (KBr): 3300 (N–H, indole) and 1730 (C=O, ester) $cm^{-1}$.

**Pharmacological Testing**—Ergolines II, III, V, and VI were evaluated for their ability to induce stereotypic behavior in rats. Stereotyped behavior was scored with the system of Costall *et al.* (18). Male Sprague–Dawley rats[2] were given intraperitoneal injections of test substances dissolved in polyethylene glycol 400 (70%). Dosages are listed in Table I. Apomorphine was used as a reference compound, and control animals received only polyethylene glycol 400 (1 ml/kg). Observations were made for 6 hr while animals were housed individually in clear, polycarbonate cages (25.4 × 46.4 × 20.3 cm).

The time course of V after single intraperitoneal doses was evaluated using a slightly different scoring system. Animals were accorded points graded for intensity as follows: no activity, 0; sniffing, 1, 2, or 3; licking, 4, 5, or 6; and gnawing, 7, 8, or 9. Figure 2 shows the time course for V following doses of 3, 9, 15, 20, and 25 mg/kg. Activity is expressed as a percentage of the maximum observed.

Blood pressure was recorded directly from the carotid artery. Heparinized rats were anesthetized with urethan (1.2 g/kg ip). Polyethylene cannula tubing[3] (0.58-mm i.d., 0.97-mm o.d.) was inserted into the carotid artery and connected *via* a three-way valve to a pressure transducer[4]. Recordings were made with a physiological recorder[5]. The system was calibrated prior to recording blood pressure for each animal. Both systolic and diastolic pressures were recorded continuously.

Each animal served as its own control, receiving polyethylene glycol 400 initially, followed by VI at a dose of 30 mg/kg. All injections were given intraperitoneally. Animals were allowed to stabilize for 60 min after injection of polyethylene glycol 400 and prior to the injection of VI dissolved in polyethylene glycol 400 (*vide supra*). Pressures for each animal for the control (polyethylene glycol 400) interval and for each successive 30-min interval after treatment with VI represent average pressures ($n = 7$) for the interval (Fig. 3). Pressure differences between polyethylene glycol 400 treatment and treatment with VI were evaluated for significance using the paired rank sum test of Wilcoxon (22).

The acute toxicity of V was determined by noting the number of animals surviving 24 hr after administration.

# Preliminary Evaluation of Mesoionic 6-Substituted 1-Methylimidazo[2,1-*b*][1,3]thiazine-5,7-diones as Potential Novel Prodrugs of Methimazole

**ROBERT A. COBURN ˣ, MICHAEL D. TAYLOR, and WALTER L. WRIGHT**

Received February 20, 1981, from the *Department of Medicinal Chemistry, School of Pharmacy, State University of New York at Buffalo, Amherst, NY 14260.* Accepted for publication April 24, 1981.

**Abstract** □ A series of five 6-alkyl- and 6-aryl-mesoionic 1-methylimidazo[2,1-*b*][1,3]thiazine-5,7-diones was synthesized and found to produce 1-methyl-3*H*-imidazole-2-thione (methimazole) upon alkaline hydrolysis or treatment with amine or thiol reagents. The alkaline hydrolysis followed a second-order rate expression, being dependent on both substrate and hydroxide-ion concentrations. The rate constants for the five derivatives fell within 6–15 × $10^{-2}$ liter/mole min at 40°. These compounds were stable in aqueous acidic solutions and in human serum or rat liver homogenate under conditions producing rapid hydrolysis of the methimazole prodrug 1-carbethoxy-3-methylimidazole-2-thione (carbimazole).

**Keyphrases** □ Methimazole—potential new prodrugs, evaluation of mesoionic 6-substituted 1-methylimidazo[2,1-*b*][1,3]thiazine-5,7-diones □ Prodrugs—of methimazole, evaluation of mesoionic 6-substituted 1-methylimidazo[2,1-*b*][1,3]thiazine-5,7-thiones □ Thyroid inhibitors—methimazole evaluation of mesoionic 6-substituted 1-methylimidazo[2,1-*b*][1,3]thiazine-5,7-diones

Considerable interest has been directed toward the development of prodrugs to modify the pharmacodynamic properties of known therapeutic agents, and several labile functionalities have been employed to accomplish this goal (1, 2). During previous investigations (3–8) involving the syntheses and chemistry of bicyclic mesoionic heterocycles related to the purinones, several examples were found in which the novel structures of these heterocycles rendered them susceptible to nucleophilic attack, often leading to ring-opened products (5, 6).

The present study examined the feasibility of exploiting the nucleophilic susceptibility of mesoionic 6-substituted 1-methylimidazo[2,1-*b*][1,3]thiazine-5,7-diones[1] (I) in the development of a methimazole prodrug (II) in which both lipophilicity and lability might be controlled by substituents eliminated from the released drug.

II: R = H
III: R = $CO_2C_2H_5$

## EXPERIMENTAL[2]

UV spectrophotometer[3] was employed for the collection of kinetic data wherein sample temperature was maintained with a circulating constant-temperature bath[4].

**Synthesis**—Five derivatives of I (Table I) were synthesized using a procedure generally useful in the synthesis of various similar mesoionic heterocycles (5, 8). Appropriately substituted malonic acids, obtained commercially or by ethoxycarbonation (9) of arylacetic acid esters, were converted in good yield by the use of phosphorus oxychloride to the corresponding bis-2,4,6-trichlorophenyl esters (10). Heating of a mixture of these esters and II neat at 120–140° produced I*a*–I*e* in moderate yields[5].

**Anhydro-5-hydroxy-1-methyl-7-oxo-6-phenyl-7*H*-imidazo[2,1-*b*][1,3]thiazinium Hydroxide (I*d*)**—The following procedure illustrates the preparation of the compounds in Table I. A mortar-ground mixture of II (3.0 g, 0.027 mole) and bis-2,4,6-trichlorophenyl phenylmalonate (14.4 g, 0.027 mole) was heated *via* an oil bath at 120° for 25 min while a slow nitrogen stream was introduced to carry off subliming trichlorophenol. The resulting melt was cooled and triturated with cold anhydrous ether (50 ml), filtered, and washed repeatedly with cold ether–acetone (2:1). The resulting pale-orange solid was recrystallized from acetone with carbon treatment to give I*d* as fine white needles (3.0 g, 44%, mp 287–289° dec. [lit. (11)mp 271–273° dec.]; IR (KBr): 3170 (w), 3140 (w), 1599 (s), 1581 (s), and 1572 (s) $cm^{-1}$; NMR (dimethyl sulfoxide-$d_6$): δ 8.10 (d, 1H, $J$ = 2 Hz, 3-H), 7.81 (d, 1H, $J$ = 2 Hz, 2-H), 7.50–7.15 (m, 5H, phenyl), and 3.77 (s, 3H, $CH_3$); UV (water): 234 (4.2 log ε), and 299 (3.9) nm.

**Reaction of I*d* with Benzylamine**—Benzylamine (170 mg, 1.6 mmoles) was added to a suspension of 20 mg (0.77 mmole) of I*d* in absolute ethanol (15 ml). The reaction mixture was stirred for 48 hr at room temperature, during which time the starting material dissolved. Reduction of the solution volume to ~5 ml by evaporation at reduced pressure and cooling gave 190 mg (72%) of *N,N'*-dibenzyl-2-phenylpropane-1,3-diamide as white crystals, mp 165–165.5°; IR (KBr): 3290 (m) and 1670 (s) $cm^{-1}$; NMR (dimethyl sulfoxide-$d_6$) δ 8.58 (t, 2H, $J$ = 6 Hz, NH, exchangeable with deuterium oxide), 7.37 (s, 5H, phenyl), 7.25 (s, 10H, phenyl), 4.58 (s, 1H, methine), and 4.35 (d, 4H, $J$ = 6 Hz, $CH_2$).

*Anal.*—Calc. for $C_{23}H_{22}N_2O_2$: C, 77.07; H, 6.19; N, 7.82. Found: C, 77.11; H, 6.22; N, 7.78.

The ethanolic filtrate obtained upon collection of this product was evaporated under reduced pressure, and the resulting solid residue was extracted with 10 ml of warm chloroform. The extract was filtered, and petroleum ether (10 ml) was added to give a precipitate. The precipitate was collected and recrystallized from chloroform–petroleum ether, yielding 70 mg of II (80%). This material was identical with an authentic sample of II as judged by TLC (silica gel, ethyl acetate, $R_f$ 0.38), mixed melting point (144–146°), and IR spectra.

**Reaction of I*d* with Thiobenzyl Alcohol**—A solution of thiobenzyl alcohol (140 mg, 1.2 mmoles) and I*d* (150 mg, 0.58 mmole) in 10 ml of absolute ethanol was refluxed for 1.25 hr. The oily residue, obtained upon evaporation of solvent under reduced pressure, was dissolved in ethyl acetate (2 ml) and placed on a silica gel column (30 g). Elution with ethyl acetate gave 52 mg of II (79%), mp 144–146°.

**1-Methyl-2(3*H*)-imidazolone (IV)**—The procedure employed was a modification of a reported method (12). Aminoacetaldehyde dimethyl acetal (3.65 g, 0.035 mole) was added dropwise over 10 min to a stirred solution of methyl isocyanate (1.85 g, 0.035 mole) in 15 ml of absolute

[1] Alternative nomenclature: 6-substituted anhydro-5-hydroxy-1-methyl-7-oxo-7*H*-imidazo[2,1-*b*][1,3]thiazinium hydroxides.

[2] Melting points were determined with a Fisher–Johns hot-stage apparatus and are uncorrected. Microanalyses were performed by Atlantic Microlab Inc., Atlanta, Ga. $^1$H-NMR spectra were recorded on a Varian T-60A spectrometer with tetramethylsilane as an internal standard. IR specrtra were recorded with a Perkin-Elmer 727B spectrophotometer and a Nicolet 7199 FT-IR interferometer. UV spectra were obtained with a Beckman model 25 spectrophotometer.

[3] Gilford model 2400.

[4] Tamson model TE-3.

[5] While this work was in progress, an alternative synthesis of I*d* was reported (11) using II and (chlorocarbonyl)phenylketene.

**Table II—Rate Constants for Alkaline Hydrolysis of Ia–Ie**

| Compound | $k \pm SD \times 10^2$, liters/mole min[a] | Relative Rate |
|---|---|---|
| Ia | 8.92 ± 0.06 | 1.00 |
| Ib | 6.25 ± 0.27 | 0.70 |
| Ic | 7.32 ± 0.29 | 0.82 |
| Id | 14.7 ± 0.12 | 1.65 |
| Ie | 13.3 ± 0.44 | 1.49 |

[a] Second-order rate constants in aqueous sodium hydroxide (0.05–0.40 *N*) at 40° and constant ionic strength (2.00 *M*).

ethanol maintained at 0–5°. Following the addition, the solution was stirred for 1 hr at room temperature and then refluxed for 4 hr. Concentrated hydrochloric acid (0.03 ml) in water (10 ml) was added, and the solution was stirred overnight. Addition of 5 ml of 5% $NaHCO_3$ solution transformed the color from red to pale yellow. Filtration of the solution and evaporation under reduced pressure gave a viscous oil, which crystallized on standing. Recrystallization from chloroform–petroleum ether gave 1.97 g (57%) of IV as transparent plates, mp 140–142° [lit. (12) mp 139–140.5].

**Product Identification for Alkaline Hydrolysis of Ic**—A suspension of Ic (0.5 g, 1.8 mmoles) in 50 ml of 1 *N* NaOH was stirred for 48 hr, during which time all material dissolved. TLC analysis (silica gel, ethyl acetate) indicated the complete disappearance of starting material ($R_f$ 0.12) and the appearance of two new spots ($R_f$ 0.06 and 0.38) corresponding to those of an alkaline solution of benzylmalonic acid and II. The UV absorption spectrum of the reaction solution was identical to that of a 1 *N* NaOH solution containing 1.8 mmoles each of benzylmalonic acid and II.

The extract obtained by continuous extraction of the reaction solution with ethyl acetate for 24 hr was dried (magnesium sulfate) and evaporated to give II, as evidenced by mixed melting point and comparison of IR spectra. The reaction solution was acidified (pH 1) with concentrated hydrochloric acid and continuously extracted for 6 hr with ethyl acetate. The residue of the evaporated extract was identified as benzylmalonic acid by comparison of its IR spectrum with that of an authentic sample.

**Kinetics of Hydrolysis of Ia–Ie**—Stock solutions were prepared by dissolving Ia–Ie (50 μmoles) in 1 ml of dimethyl sulfoxide. Sodium hydroxide solutions were prepared (0.05, 0.15, 0.30, and 0.40 *N*) by dilution of 2.00 *N* NaOH with 2.00 *M* KCl. To cells containing the alkaline solutions (2 ml), equilibrated at 40.0 ± 0.1°, was added 10 μl of the stock solution. The loss of absorbance at 300 nm was monitered with the $OD_\infty$ value (optical density) observed to be 0 ± 2%. Pseudo-first-order rate constants were obtained from the slopes of the plots of $\ln[(OD_t - OD_\infty)/(OD_0 - OD_\infty)]$ *versus* time. Each compound was examined in triplicate. Second-order rate constants (Table II) were calculated from the linear regression of $k_{obs}$ with the hydroxide-ion concentration.

**Serum Hydrolysis of Ia, Ib, and III**—Substrate Ia (20 mg), Ib (20 mg), or III (30 mg) was dissolved in 5 ml of pH 7.4 phosphate buffer solution (0.05 *M*) at 37°. The substrate solution (1 ml) was added to 3 ml of human serum[6], and the resulting solution was shaken and incubated at 37°. Aliquots (75 μl) were taken at intervals and added to cells containing 3 ml of buffer solution. Absorbance of the resulting solution was recorded at 300 (Ia and Ib) or 290 (III) nm. A blank solution lacking substrate was similarly treated.

**Rat Liver Homogenate Treatment of Ia, Ib, and III**—A modification of a reported procedure (13) for the hydrolysis of acetanilide was employed. A 300-g male Sprague-Dawley rat was sacrificed, and the liver was removed, rinsed in cold 0.2 *M* buffer solution[7] (pH 8.1), blotted, and weighed (11 g). The liver was minced and homogenized in 20 ml of cold buffer in a chilled tissue grinder[8] maintained in an ice bath.

Buffer solutions of Ia, Ib, or III (1 mg/ml) and homogenate were separately equilibrated (37°) immediately prior to use. Substrate solution (3 ml), buffer (1 ml), and homogenate (2 ml) were mixed and incubated at 37° in a shaker bath. At intervals, a 0.5-ml aliquot was removed and added to 2 ml of ice-cold 10% trichloroacetic acid solution, which was then centrifuged (700 rpm, 3 min), and 1 ml of the supernate was added to a cell containing 3 ml of buffer. The absorbance of this solution was recorded at 300 (Ia and Ib) or 290 (III) nm. A blank solution employing buffer instead of substrate solution was similarly treated as well as a substrate solution of III in which buffer was substituted for homogenate.

## RESULTS

The mesoionic imidazothiazinediones (Ia–Ie) were white crystalline solids stable in light and air and showed no spectroscopic evidence of decomposition in 1 *N* HCl solution over 24 hr. In 1 *N* NaOH, Ic showed a gradual dissolution at room temperature as an apparent function of limited aqueous solubility and hydrolysis to benzylmalonate and II. No other products were detected by TLC or spectroscopic analyses. A potential alternative hydrolysis product, 1-methyl-2(3*H*)-imidazolone (IV), possibly resulting from hydroxide-ion attack at the bridgehead carbon position, was synthesized and found to be clearly distinguishable from II by the chromatographic and spectroscopic methods employed. Since the UV spectrum of the hydrolysis products showed no significant absorbance beyond 280 nm, the rate of alkaline hydrolysis was readily monitored by observing the loss of absorbance of the longest wavelength maxima of Ia–Ie at 300 nm.

The alkaline hydrolysis followed second-order kinetics, dependent on both substrate and hydroxide-ion concentration. The observed rate constants (Table II), showed only a twofold range of values for the five derivatives investigated. The second-order rate expression is consistent with either a rate-limiting attack by hydroxide ion or a rate-limiting decomposition of an adduct of I and hydroxide ion. No evidence was obtained concerning which pseudocarbonyl group is initially involved in the reaction.

[6] Grand Island Biological Co., Grand Island, N.Y.
[7] Trimethamine.
[8] Potter-Elvehjem, with Teflon resin pestle.

Compound II was produced in ethanolic solution from Ia or Id by reaction with two equivalents of benzylamine, with complete conversion within 48 hr at room temperature or 30 min at reflux. No other products except for the corresponding malondiamide were detected by chromatographic or spectral analyses. Compound II was also produced from Id by reaction for 75 min with thiobenzyl alcohol in refluxing ethanol.

Alkyl derivatives Ia and Ib were sufficiently water soluble to allow examination of their stability at pH 7.4 in the presence of human serum. Under conditions wherein III underwent rapid hydrolysis (complete conversion within 2 hr), Ia and Ib showed no evidence of decomposition in the presence of human serum for 10 hr at 37°. Similarly, Ia and Ib showed no evidence of decomposition in the presence of rat liver homogenate over 5 hr, while III was completely hydrolyzed within 5 min under the same conditions.

## DISCUSSION

Compound III, a derivative of II, is already in clinical use. Several studies in humans (14–17) have shown III to be absorbed and rapidly converted to II, an agent useful in the control of hyperthyroidism (18). Although III was designed as a potentially longer acting derivative of II (19), its conversion to II in serum is so rapid that there appears to be little therapeutic advantage over the use of II (17).

A number of bicyclic mesoionic pyrimidinedione derivatives have been reported to result from the condensation of bis-trichlorophenyl malonate esters and *sec*-amino azaheterocycles (5, 6, 20–23). These compounds, which may be viewed as 8-aza analogs of I, undergo ring opening in reaction with benzylamine by nucleophilic attack at the 5-position pseudocarbonyl group (5). However, there is some indication that anionic nucleophiles, such as hydroxide ion, attack the bridgehead carbon position of these 8-aza analogs (5). An analogous reaction of I with hydroxide ion could lead to the formation of IV. Alternatively, hydroxide-ion attack at the 5-position of I would produce a thiol ester, which would be susceptible to hydrolytic production of II. The general utility of mesoionic derivatization for prodrug modification would depend on the controllability of the hydrolytic and/or enzymic decomposition rates by use of various 6-position substituents. These substituents may also provide a means of influencing absorption and distribution by modifying the lipophilicity of the agent.

The conversion of I to II by alkaline hydrolysis and by amine and thiol reagents was demonstrated. However, the variety of substituents investigated showed only a limited influence on the rate of alkaline hydrolysis. The substituents employed exhibited a very limited range of electronic effects, being predominately electron-releasing groups. More strongly electron-withdrawing substituents would be expected to increase the electrophilicity of the pseudocarbonyl groups or to increase the concentration of the hydroxide-ion adduct, leading to an increased alkaline hydrolysis rate. Condensation of malonate esters containing *p*-nitrophenyl or acyl substituents with II was unsuccessful, probably because of the increased ease of malonate-carbanion formation. However, by analogy to the chemistry exhibited by the mesoionic pyrimidinediones (5), electrophilic substitution reactions on I should be facile at the 6-position.

In conclusion, although Ia–Ie produce II by alkaline hydrolysis or by reaction with amine or thiol reagents, their stability to human serum or rat liver homogenate indicate that their decomposition rate *in vivo* is likely to be insufficient. Other derivatives of I with electron-withdrawing 6-position substituents may overcome this deficiency.

# Noninvasive Dissolution Measurement Using Perturbed Angular Correlation

**R. M. BEIHN * and G. A. DIGENIS ‡x**

Received June 12, 1980, from the **Veterans Administration Medical Center, Lexington, KY 40506*, and the ‡*Divisions of Medicinal Chemistry and Nuclear Medicine, Colleges of Pharmacy and Medicine, University of Kentucky, Lexington, KY 40506.* Accepted for publication April 6, 1981.

**Abstract** □ A novel noninvasive technique was developed to measure dissolution of the water-soluble component of a solid dosage form using indium 111 and perturbed angular correlation. The method involves time-delayed coincidence counting of two cascading γ-rays that exhibit angular correlation. This angular correlation can be perturbed if the intermediate excited state of the nucleus is reoriented due to an interaction with its environment. When such an interaction occurs, as in a phase change (solid to liquid), the perturbation changes can be shown by anisotropy. A highly perturbed condition in the solid state results in low values (0.02–0.04), while increasing values of anisotropy indicate dissolution. Anisotropy values reach 0.14–0.15 when the total unperturbed physical state (liquid) exists. The worth of this technique was demonstrated by both *in vitro* and *in vivo* determinations of dissolution rates.

**Keyphrases** □ Perturbed angular correlation—noninvasive dissolution measurement *in vivo* and *in vitro* □ Dissolution—noninvasive measurement *in vivo* and *in vitro* using perturbed angular correlation, solid dosage forms □ Noninvasive dissolution measurement—of solid dosage forms using perturbed angular correlation, *in vivo* and *in vitro*

Radionuclides with simple decay schemes have been widely utilized as labels for following drug absorption, metabolism, and excretion. External scintigraphy was used to follow labeled solid dosage forms while their behavior in the human stomach was monitored (1). Some radionuclides, following radioactive decay, emit two or more γ-rays in cascade; those γ-rays emitted following an initial one are released immediately or are delayed for some very predictable time unique to that nucleus.

## BACKGROUND

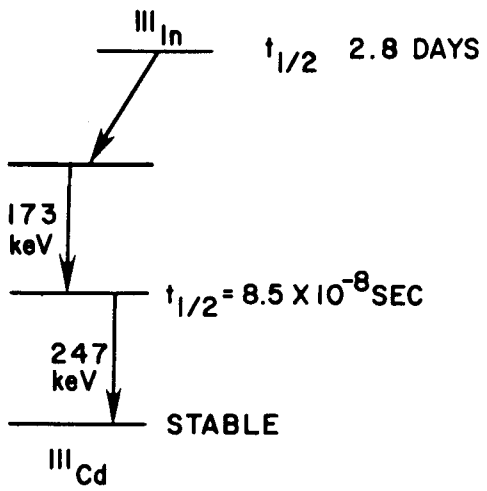
Indium 111 is a radionuclide with a delay during its γ-cascade (Scheme I). Occasionally, for some radionuclides the γ-rays may exhibit an angular correlation since the directional emission of a γ-ray depends on the orientation of the magnetic moment of the nucleus involved. For indium 111, this angular correlation can be perturbed if the intermediate excited state of the nucleus is reoriented due to an interaction with its environment. The major perturbing influence on the emission angular correlation is the interaction of external gradients of the quadrupole moment of the nucleus (2). The theory of perturbed angular correlation was thoroughly reviewed by Steffen and Frauenfelder (3, 4).

Some recent investigations used indium 111 and perturbed angular correlation measurements to monitor the structural and rotational behavior of biological macromolecules (5–7). It also was reported that inhibition of nuclear rotational properties of indium 111 by chemical binding, temperature reduction, and increased viscosity can be observed (8, 9).

The purposes of this work were to measure the conversion of one distinct state of nuclei to another, illustrating a phase change from solid indium chloride to liquid indium chloride, and to illustrate a noninvasive technique for measuring a phase change from solid to liquid in a solid dosage form using indium chloride (indium 111) and perturbed angular correlation.

## EXPERIMENTAL

**Dosage Form Preparation**—Three different formulations of solid dosage forms were prepared with commercially available excipients: Formulation 1, lactose (89%), microcrystalline cellulose (10%), and magnesium stearate (1%), (by weight); Formulation 2, dibasic calcium phosphate (89%), microcrystalline cellulose (10%), and magnesium stearate (1%); and Formulation 3, only sucrose. Each formulation was prepared in bulk for convenient storage. Several grams of each mixture was placed in separate round-bottom flasks, and 95% ethanol was added to allow a satisfactory suspension.



*Scheme I—Indium 111 decay scheme illustrating the γ-ray cascade with the delayed intermediate nuclear state following the first gamma emission.*

Indium 111 in the chloride[1] form was pipetted into each flask to an activity concentration of 20 μCi/200 mg of formulation powder. Indium 111 has a half-life of 2.8 days, and it decays by electron capture and γ-emission with energies of 173 and 247 kev (Scheme I). The ethanol was evaporated in a flask evaporator until dryness was achieved. The powder was removed by scraping, pulverized using a mortar and pestle, and then compressed into 200-mg tablets.

A representative number of tablets were counted for indium 111 activity using a γ-ray scintillation detector for homogeneity testing. Several tablets of each formulation were used for a disintegration time determination[2], and some were used to test for hardness[3].

**Instrumentation**—Three sodium iodide γ-ray detectors were positioned in a flat plane on three sides of a beaker in which the dosage form was tested (Fig. 1). The 12.7 × 7.62-cm detectors were positioned 20 cm from the geometric center of the beaker containing the tablet. For electronic clarity, the detectors were labeled 1, 2, and 3 such that Detector 2 was positioned 90° to Detector 1 and Detector 3 was positioned 180° to Detector 1 (Fig. 1).

The γ-ray spectrometry equipment[4] consisted of a single high voltage power supply for the three detectors, three preamplifiers, three linear amplifiers, and three pulse height analyzers designated 1, 2, and 3 (Fig. 1). There were two time-to-pulse height converters (TPC) for coincidence counting (designated A and B), two additional pulse height analyzers for selecting differential or integrated coincidence delay times, and two count scalers for recording the coincidence counts from Converters A and B (Fig. 1).

Pulse height Analyzer 1 was energy calibrated for counting the 173-kev

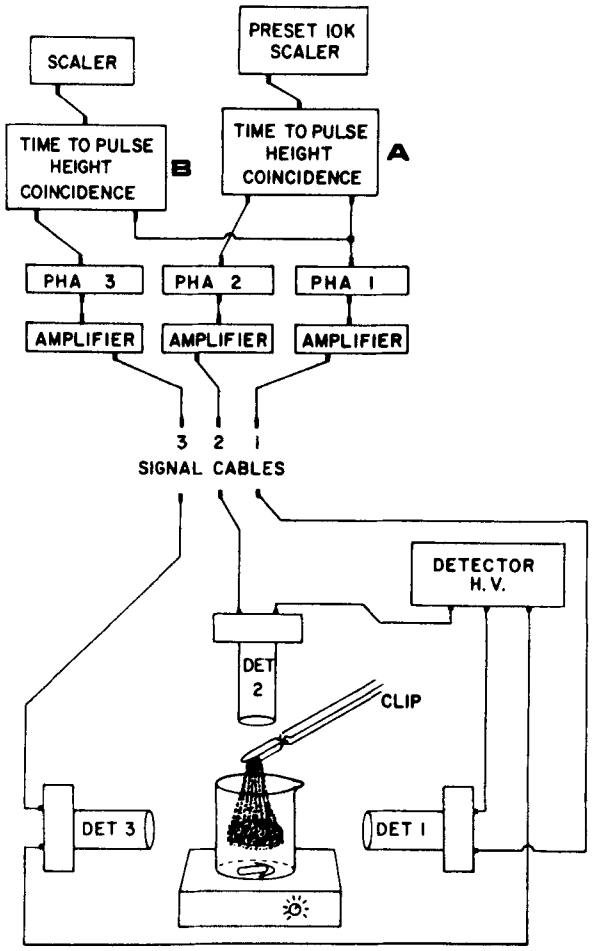

**Figure 1**—*Apparatus assembly illustrating the positioning of the radiation detectors in a flat plane around the tablet for an* in vitro *dissolution experiment using perturbed angular correlation. The schematic of electronic equipment required for coincidence counting between Detectors 1 and 2 (90°) and 1 and 3 (180°) is illustrated. A cotton gauze sheet containing the solid dosage form was suspended 6 cm from the bottom and in the center of a glass beaker containing the dissolution medium (see* Experimental*). Three pulse height analyzers (PHA) were utilized.*

γ-ray while Analyzers 2 and 3 were calibrated for the 247-kev emission. Converters A and B were calibrated to accept coincidence delay times between 70 and 100 nsec.

**Procedure**—The apparatus used for the experimental determination of dissolution consisted of a 10 × 10-cm single-layer cotton gauze sheet with a mesh size sufficiently small to prevent the tablet and larger particles from falling through. The gauze containing the solid dosage form was suspended 6 cm from the bottom and in the center of a 1000-ml glass beaker containing 700 ml of hydrochloric acid–water (Fig. 1). A hemostat clamped to the gauze and a ring stand held the dosage form in place. The aqueous dissolution medium was stirred with a magnetic stirring bar at ~100 rpm and remained at 25–26°.

Immediately after the tablet was immersed and positioned, serial coincident counting on the scalers was begun, which continued until the completion of the experiment. Throughout the experiment, 0.5-ml samples were removed using a 1-ml tuberculine syringe fitted with a 0.22-μm filter to prevent particles from being collected. These samples, removed at appropriate time intervals, were transferred to sample vials and counted in a well γ-counter.

## RESULTS AND DISCUSSION

Assessment of dosage form homogeneity was performed when tablets within a batch of each preparation were counted. Results indicate the tablets were prepared with a homogeneous distribution of indium 111 since they varied by only 2%.

The two γ-rays emitted during the indium 111 to cadmium 111 decay are illustrated in Scheme I. The 247 kev γ-ray is delayed by 85 nsec. The probability that it will be emitted at some time $t$ and at some angle $\theta$ to the direction of the 173-kev γ-ray is given by:

$$\omega(\theta, t) = \frac{1}{\tau} e - \frac{t}{\tau}\left[1 + A_2\left(\frac{3\cos^2\theta - 1}{2}\right)\right] \qquad \text{(Eq. 1)}$$

where $\tau$ is the mean life of the intermediate nuclear state ($1.21 \times 10^{-7}$ sec), $t$ is the interval of time between the two γ-rays, and $A_2$ is a coefficient −0.18. This numerical value of $A_2$ may vary with the solid angle subtended by the γ-ray detectors used. If $\tau$ is long enough and the magnitude of the electric field gradients at the nucleus from the environment are great enough, then the angular correlation of the two cascading γ-rays can be perturbed. When a perturbation factor $G_2(t)$ is inserted into the second term of Eq. 1, its approximate behavior can be shown by anisotropy to be:

$$A \simeq -\frac{3}{2} A_2 G_2(t) \qquad \text{(Eq. 2a)}$$

and:

$$A = 1 - \frac{\omega\,(180°, t)}{\omega\,(90°, t)} \qquad \text{(Eq. 2b)}$$

where $\omega(180°, t)$ and $\omega(90°, t)$ are coincident count rates in each of the two selected angles, 180 and 90°.

The coincidence counts from either the 180 or 90° detector are those counts of the 247-kev γ-ray that are detected within 70–100 nsec following the Detector 1 observation of the 173-kev γ-ray. The 173-kev γ-ray initiates a constant-rise time pulse in each A and B time-to-pulse height converter. When the 180 and 90° detectors count a 247-kev γ-ray, the rising pulse is stopped in Converter A or B, and its magnitude is analyzed with a differential window corresponding to 70–100-nsec delays. These coincidence counts were recorded on each of two scalers.

Since the perturbation factor $G_2(t)$ behavior can be shown by anisotropy ($A$), the coincidence counts $\omega\,(180°, t)$ from the 180° detector and those counts $[\omega\,(90°, t)]$ from the 90° detector were substituted into the relation $A = 1 - \omega\,(180°, t)/\omega\,(90°, t)$ for computation. For anisotropy ($A$) calibration, a maximum perturbed dry solid dosage form was counted. Then a sample of liquid [$^{111}$In]chloride was counted. The calculation of anisotropy ($A$) resulted in values of 0.02–0.04 for the perturbed state (dry) and of 0.14–0.15 for the unperturbed state (liquid), a mean increase of 4.8-fold.

To illustrate the changing of anisotropy values during a dissolution experiment, a sucrose tablet was prepared with [$^{111}$In]chloride as previously described. After it was placed in the apparatus, coincidence data were collected and calculated. The results from a typical experiment are shown in Fig. 2. The experiment ran for 26 min, with nine data points collected for the calculation of anisotropy. Initially, the anisotropy value was 0.02, representing the dry perturbed state; then, after ~24 min, the values of 0.14 for anisotropy were calculated, illustrating the unperturbed liquid state. Those intermediate anisotropy values represent varying numbers of indium 111 atoms in transition from the dry to the liquid state. By simply observing the graph in Fig. 2, the percent dissolution of the radionuclide from the solid form for any desired time can be found. After ~13 min, 50% of the indium 111 was in solution, which was verified by liquid sample removal and counting the indium 111 in a well scintil-

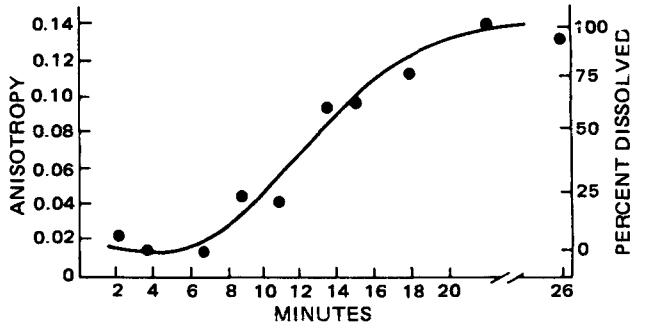

**Figure 2**—*Anisotropy* versus *time for a [$^{111}$In]chloride-labeled sucrose tablet measured* in vitro *using perturbed angular correlation, illustrating the progressive change of anisotropy corresponding to that quantity of the [$^{111}$In]chloride dissolved.*

**Table I—Summary of Perturbed Angular Correlation Dissolution Times [a] and Concomitant Sampling Verification *In Vitro* along with Physical Parameters of Each Dosage Form Tested**

| Tablet | Perturbed Angular Correlation Method Time[a], min[b] | Sampling Method Time[a], min[b] | Revolutions per Minute | Hardness | USP Disintegration Time, min[b] |
|---|---|---|---|---|---|
| Sucrose[c] | 10.8 ± 3.3 | 11.3 ± 3.4 | 100 | NA | NA |
| Lactose[d] | 5.8 ± 2.4 | 6.6 ± 2.6 | 100 | 9 | 6 |
| Dical[e] (Run 1) | 76 ± 9.0 | 80 ± 8.9 | 100 | 11 | 13 |
| Dical[e] (Run 2) | 60 ± 7.0 | 58 ± 7.6 | 400 | 11 | 13 |

[a] Time to achieve 50% dissolution. [b] Average of three determinations. [c] Sucrose (100%) and [$^{111}$In]chloride. [d] Lactose (89%), microcrystalline cellulose (10%), magnesium stearate (1%), and [$^{111}$In]chloride. [e] Dicalcium phosphate (89%), microcrystalline cellulose (10%), magnesium stearate (1%), and [$^{111}$In]chloride.

lation counter. All other experiments had samples removed for corroborative measurements.

Results for this and similar experiments indicate a time delay prior to the onset of tablet dissolution. The delay in the sucrose formulation was ~6 min (Fig. 2). Presumably, this observed delay was due to continued nuclear perturbation in the viscous stagnate layer from the highly structured aqueous conditions existing therein. As the [$^{111}$In]chloride escaped into the unstructured water of the media, the exhibition of free nuclear motion was evident in the notable change of the anisotropy values.

Two additional formulations were prepared, one (called "dical tablet") containing dibasic calcium phosphate (89%), microcrystalline cellulose (10%), and magnesium stearate (1%), and the other (called "lactose tablet") containing lactose (89%), microcrystalline cellulose (10%), and magnesium stearate (1%). Each formulation contained [$^{111}$In]chloride. Hardness and USP disintegration tests were conducted on these formulations. Perturbed angular correlation and sampling measurements were performed from the beginning of the dissolution experiment through completion (Table I). Table I shows that in all experiments there was good agreement between perturbed angular correlation measurements and the indium 111 sampling method for the determination of percent dissolution *in vitro* as a function of time.

Included in Table I are the results of perturbed angular correlation and sampling measurements for the dical tablet at two different stirring rates. Run 1 was stirred at 100 rpm, and Run 2 was stirred vigorously at ~400 rpm. When the stirring rate increased, the dissolution rate increased, indicated by both perturbed angular correlation and sampling measurements (Table I). The reduction in time was from 76 to 60 min using the perturbed angular correlation technique and from 80 to 58 min using the sampling method.

After the *in vitro* dissolution measurements using perturbed angular correlation were shown to be successful, an *in vivo* measurement on the lactose formulation was attempted on one subject to illustrate its *in vivo* applicability. Three detectors were positioned to view the anterior, posterior, and left lateral sides of the volunteer. It was estimated that they were equidistant from the stomach where the tablet would be located.

The calculated anisotropy values were not expected to be the same as those in the *in vitro* experiments, but their changing values would nevertheless reflect the physical state of the solid dosage form. The *in vivo* dissolution data are illustrated in Fig. 3. The anisotropy behavior is quite similar to that in the *in vitro* experiments, differing only in actual anisotropy values, including the delays of onset of dissolution.

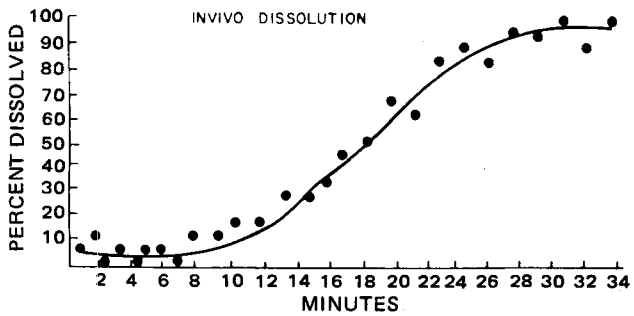

**Figure 3**—*Dissolution* versus *time for a lactose tablet measured in a human subject indium 111 and perturbed angular correlation. Graph shows an 8-min delay for onset of dissolution of the radionuclide, which was complete by 28 min.*

Figure 3 shows that 50% dissolution of [$^{111}$In]chloride from a lactose tablet was achieved in the stomach of the human subject in ~17 min, while the *in vitro* data on the identical dosage form (Table I) showed a dissolution in 5.8 min (perturbed angular correlation) and 6.6 min (sampling method). With a hardness value of 9, the USP disintegration test demonstrated a 6-min disintegration time for the lactose formulation. When the same volunteer with an identical lactose tablet was studied by a previously developed external scintigraphy technique (1), the tablet exhibited a disintegration time of 21 min. These results indicate that there is no good correlation between *in vitro* and *in vivo* measurements for the lactose formulation since they differ so widely in the times of disintegration and dissolution.

The dibasic calcium phosphate formulation was also tested with the same human volunteer. Table I shows that the dical formulation with a hardness of 11 disintegrated[2] in 13 min and that the times for 50% dissolution measured using perturbed angular correlation and sampling were 76 and 80 min, respectively. When the *in vivo* measurement using perturbed angular correlation was performed on this dibasic calcium phosphate formulation, there was evidence that ~40% dissolution had occurred over 30 min. No further dissolution was observed as illustrated by unchanging anisotropy values.

An identical dosage form was then examined *in vivo* by external scintigraphy (1) to gain insight into the dissolution of this dosage form by monitoring its disintegration behavior. The *in vivo* disintegration results showed the dosage form remained motionless in the lower stomach near the duodenal bulb for ~11 min and then began to disintegrate partially until 25 min. During this time, the loss of radioactivity from the original tablet was ~31%. The remaining core of the tablet was then expelled through the pyloric valve and proceeded to move through the small bowel, changing locations repeatedly. This main core of the tablet remained intact throughout the additional period of observation of 52 min.

The data obtained with the perturbed angular correlation method show that this technique, when coupled with external scintigraphy (1), may permit the *in vitro* and *in vivo* study of the disintegration behavior of a solid dosage form. This technique follows the dissolution pattern of the radionuclide and does not provide information on the dissolution of any particular component of the solid dosage form. The technique might prove useful in comparative studies in which various solid dosage formulations could be compared for their disintegration properties.

One further experiment was performed to assess the effects of the physical geometry of the source when acquiring perturbed angular correlation data. A drop of liquid [$^{111}$In]chloride was placed as a source in the bottom of a 150-ml glass beaker, yielding an anisotropy value of 0.13. When the bottom of the beaker was covered with a dilute solution of hydrochloric acid, the resulting anisotropy was 0.15. When the beaker was filled 25%, the anisotropy value was 0.17; when it was 50% filled, the anisotropy value was 0.15; and when it was 75% filled, the anisotropy value was 0.15. These results indicate no significant problem in detecting an unperturbed liquid state of indium 111 with varying geometric configurations.

## CONCLUSION

In the present study, a chemical phase change was observed in solid dosage forms using indium 111 and a perturbed angular correlation measurement. When this novel technique is performed in conjunction with a previously described external scintigraphy method (1), the study of the *in vivo* dissolution and disintegration behavior of a solid dosage form can be accomplished in a qualitative and quantitative manner. The technique monitors the extent of dissolution of the dosage form as a function of solubilization of the radionuclide from the solid dosage form.

The method does not measure dissolution of a pharmacologically active ingredient or any other ingredient in the solid dosage form.

With minor detector modifications, this method should contribute significantly in the evaluation of viscosity gradients and sedimentation rates in heterogeneous dosage forms.

# Interaction of Tablet Disintegrants and Magnesium Stearate during Mixing I: Effect on Tablet Disintegration

**G. K. BOLHUIS, A. J. SMALLENBROEK, and C. F. LERK ×**

Received September 11, 1980, from the *Laboratory for Pharmaceutical Technology, State University Groningen, Antonius Deusinglaan 2, 9713 AW Groningen, The Netherlands.* Accepted for publication May 13, 1981.

**Abstract** □ The effect of magnesium stearate on the disintegration of tablets was studied. Three different preblends, containing a slightly or a strongly swelling disintegrant, were mixed before compression with magnesium stearate for different time periods. The results show that a strongly swelling disintegrant, such as sodium starch glycolate in contrast to potato starch, can reduce the deteriorating effect of hydrophobic lubricants on tablet disintegration. However, the interaction between magnesium stearate and potato starch or sodium starch glycolate and the resulting differences in disintegration characteristics can be masked by the use of disks in the USP disintegration apparatus.

**Keyphrases** □ Tablets—disintegration, effect of magnesium stearate during mixing □ Magnesium stearate—effect on tablet disintegration during mixing □ Disintegration—tablets, effect of magnesium stearate during mixing

Previous work (1, 2) showed that magnesium stearate can have a strong negative effect on binding properties of tablet excipients. The phenomenon of decreasing crushing strength with increasing mixing time is caused by the formation of a lubricant film interfering with particle binding. The lubricant film is a result of adhesion to the substrate of magnesium stearate molecules, which are sheared off mechanically from the magnesium crystals during mixing (1–4). The formation of such a hydrophobic film can dramatically decrease the wettability of a powder mix, as was shown for sodium chloride–magnesium stearate blends (4). Thus, the deteriorating effect of hydrophobic lubricants on tablet disintegration is not only dependent on the nature and concentration of the lubricant used (5–11) but also on the mixing intensity of the tablet ingredients with the lubricants (12, 13).

The present study concerned the effect of magnesium stearate on tablet disintegration. Three different preblends, containing a slightly or a strongly swelling disintegrant, were mixed before compression with magnesium stearate for different time periods. Particular attention was focused on the effect of disks in the USP disintegration apparatus.

## EXPERIMENTAL

**Materials**—The disintegrants used were dried potato starch[1] (moisture content ~8%) and sodium starch glycolate[2] NF XV. The other excipients were unmilled dibasic calcium phosphate dihydrate[3], extra-fine crystalline lactose[4], aspirin[5] (crystalline acetylsalicylic acid), and magnesium stearate[6].

**Methods**—*Mixing*—Preblends of filler and disintegrants were prepared by mixing[7] the excipients for 15 min, using glass vessels with a loading of ~20%. If not stated otherwise, the rotation speed was 90 rpm. After addition of 0.5% magnesium stearate, mixing was continued for a specified period.

*Tablet Compression*—Tablets were prepared by introducing manually 520.8 mg of the blend containing sodium starch glycolate or 625 mg of the blend containing potato starch into a prelubricated 13-mm die of a compression device mounted between the plattens of an instrumented hydraulic press[8]. The samples were compressed at a compression force of 20 kN with a loading rate of 2 kN/sec.

*Crushing Strength*—The crushing strength of the tablets was determined immediately after compression using a motorized instrument[9]. The data given are the means of at least five tablets.

*Disintegration time*—The disintegration time of the tablets was determined using the USP XIX apparatus. If not stated otherwise, the test was performed without disks. The data given are the means of the dis-

## RESULTS AND DISCUSSION

Table I gives the effect of mixing time for mixing filler–disintegrant preblends with 0.5% magnesium stearate on both disintegration time and crushing strength of tablets compressed from aspirin with 20% potato starch or 4% sodium starch glycolate. The effect of mixing with magnesium stearate on the crushing strength of tablets without disintegrant is given in Fig. 1. Since the aspirin tablets showed only a slight decrease in crushing strength (from 4.5 to 3.2 kg) during 30 min of mixing with magnesium stearate (Fig. 1), the dramatic decrease (down to 0.1 kg with 2 min of mixing) in crushing strength of the tablets containing 20% potato starch must be attributed to a strong interaction between potato starch and magnesium stearate. This finding is consistent with previous results (3) showing that lubricants can exercise a strong negative effect on the binding properties of starch and starch derivatives.

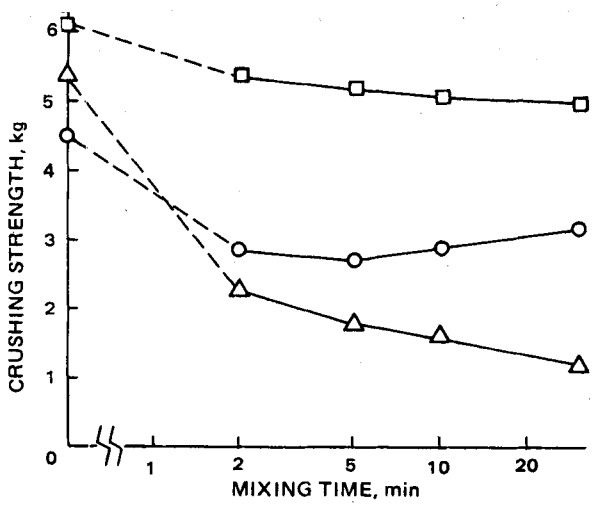

**Figure 1**—*Crushing strength* versus *mixing time (log scale) for tablets of fillers without disintegrants with 0.5% magnesium stearate. Key:* ○, *aspirin;* □, *dibasic calcium phosphate dihydrate; and* △, *lactose.*

In contrast to the decrease in crushing strength, the tablets showed a 10-fold increase in disintegration time after 5 min of mixing of the preblends with magnesium stearate. Since sodium starch glycolate is generally used in lower concentrations, the crushing strength of the aspirin tablets containing only 4% of this disintegrant exhibited a smaller decrease than the tablets containing 20% potato starch (Table I). The tablets initially showed a slight decrease in disintegration time with increasing mixing time with magnesium stearate, followed by a slight increase to values that are relatively low (especially when crushing strength is considered) compared with those of the tablets containing potato starch.

Table II shows the effect of mixing 0.5% magnesium stearate on tablets from dibasic calcium phosphate dihydrate with either 20% potato starch or 4% sodium starch glycolate. Since magnesium stearate hardly affected the binding properties of materials such as dibasic calcium phosphate dihydrate (Fig. 1), which undergo complete fragmentation under compression (3), the decrease in crushing strength of the tablets containing disintegrant must be caused by an interaction of the lubricant with the disintegrant.

Like the aspirin tablets, the dibasic calcium phosphate dihydrate tablets showed an increase in disintegration time with increasing mixing time with magnesium stearate. The most pronounced increase in disintegration time was exhibited by tablets containing 20% potato starch (Table II).

The lactose tablets showed an extremely strong decrease in crushing strength with an increase in mixing time of the blend with magnesium stearate (Table III). This result may be due to the effect of lubricant on the binding properties of both lactose (Fig. 1) and the disintegrants. A strong increase in disintegration time, which is consistent with the other results, was found for tablets with 20% potato starch; tablets with 4% sodium starch glycolate maintained fast disintegration, even when the

| 10 | >1800 | 65 | 20 | 11 |
| 30 | >1800 | 90 | 56 | 13 |

[a] A 0-min mixing time means no lubricant was added.

tablet blend had been mixed for 30 min with magnesium stearate.

These results indicate that all increases in tablet disintegration time must be caused by the formation of a lubricant film on substrate particles of magnesium stearate molecules during mixing. As expected from previous work (2), the deleterious effect of magnesium stearate on disintegration time was dependent on mixing intensity. Table IV shows that the disintegration time of the dibasic calcium phosphate dihydrate tablets with 20% potato starch after 5 min of mixing with lubricant decreased from 825 to 21 sec when the velocity of the mixer decreased from 90 to 65 rpm. Tablets with 4% sodium starch glycolate acquired a still shorter disintegration time when mixing intensity decreased.

The remarkable difference in effect of mixing the preblends containing potato starch or sodium starch glycolate with magnesium stearate on tablet disintegration must be attributed to the difference in disintegration behavior of these materials. The hydrophobic magnesium stearate film formed during mixing will have a negative effect on the wettability of the tablet ingredient particles and, therefore, retard water penetration into the tablets. Since a complete coating of lubricant is not formed during mixing (12), the lubricant film will not be perfect and water will enter the disintegrant particles. Since sodium starch glycolate particles, in contrast to potato starch particles, swell extensively when brought in contact with water (14), it may be assumed that a small amount of water can already destroy the hydrophobic lubricant film. Microscopic examination of lubricated sodium starch glycolate particles confirmed that the particles bulge when brought into water. However, the swelling of potato starch may be insufficient to collapse the lubricant film on the disintegrant particles.

The disintegration times given in Tables I–IV refer to the method described in USP XIX but without disks. Table V gives the effect of the disks on the disintegration times obtained. The results show that the deleterious effect of magnesium stearate on the disintegration time of dibasic calcium phosphate dihydrate tablets can largely be masked by the disks.

The differences in disintegration time obtained with and without disks are likely due to the mechanical damage of the lubricant film during the disintegration test by the disks used, so that water can penetrate even the lubricant-coated, slightly swelling, potato starch particles.

These results prove that the use of disks in the USP disintegration apparatus can mask differences in tablet formulation (15, 16) as well as differences in preparation conditions such as mixing intensity.

# General Model for Dissolution Rates of $n$-Component, Nondisintegrating Spheres

**G. R. CARMICHAEL *, S. A. SHAH ‡§, and E. L. PARROTT ‡x**

Received January 9, 1981, from the *Chemical and Materials Engineering Program and the ‡Division of Pharmaceutics, College of Pharmacy, University of Iowa, Iowa City, IA 52242. Accepted for publication April 7, 1981. §Present address: Zenith Laboratories, Northvale, NJ 07646.

**Abstract** □ The dissolution rates of compressed spheres consisting of two and three components were measured. A general model for dissolution rates of $n$-component, nondisintegrating spheres is discussed. Experimental cases are presented to support the model for two- and three-component spheres, two-component interacting spheres, and three-component spheres containing two components that complex.

**Keyphrases** □ Dissolution—general model for $n$-component, nondisintegrating spheres ■ Spheres—$n$-component, nondisintegrating, general model for dissolution rates □ Models, dissolution—for $n$-component, nondisintegrating spheres

Few studies on dissolution rates have involved multicomponent solids. One early study (1) involving the dissolution of a two-component system examined the dissolution rates of several poorly soluble weak acids and tribasic sodium phosphate in various mole fractions. The dissolution rates of salicylic acid and povidone from compressed disks also were reported (2). Diffusion models also were suggested (3) for the dissolution of nondisintegrating multicomponent mixtures containing noninteracting components and complexing components. Shah and Parrott (4) applied the model to the dissolution of four two-component solids.

This study presents a general model for the dissolution rates of a nondisintegrating sphere containing any number of components. The model was developed from the viewpoint of mass transfer, and experimental cases are presented demonstrating its application to two- and three-component solids, two-component interacting solids, and three-component solids with two components interacting.

## THEORY

A model for the dissolution rate of a spherical solid particle may be described assuming that (*a*) the dissolution rate is diffusion controlled, (*b*) the diffusion layer thickness is always the same for all particles of the same size, (*c*) the concentration change of the dissolved solid in the dissolution medium is negligible, (*d*) the effective particle shape approximates a sphere, and (*e*) the initial solid composed of $n$ components is homogeneous.

From the viewpoint of mass transfer, if multicomponent diffusion effects are ignored, the change in mass with time, $dW_i/dt$, of a noninteracting component in the solid can be expressed as:

$$\frac{dW_i}{dt} = -k_i S_i (C_i^* - C_i) \qquad \text{(Eq. 1)}$$

where $k_i$ is the liquid phase mass transfer coefficient, $S_i$ is the surface area available for mass transfer, and $C_i^*$ and $C_i$ are the interfacial and bulk mass concentrations of species in the liquid phase, respectively, for components $i = 1$ to $n$. Since the surface area of a sphere is $4\pi r^2$, Eq. 1 may be written as:

$$\frac{dW_i}{dt} = -k_i 4\pi r_i^2 (C_i^* - C_i) \qquad \text{(Eq. 2)}$$

The mass of a given component in the solid is related to the volume of the particle, the mass fraction, $X_i$, and the bulk density, $\rho$. Since:

$$W_i = \frac{4}{3}\pi r_i^3 X_i \rho \qquad \text{(Eq. 3)}$$

and if $X_i$ is not a function of time, Eq. 2 may be written as:

$$-\frac{dr_i}{dt} = \frac{D_i (C_i^* - C_i)}{h X_i \rho} \qquad \text{(Eq. 4)}$$

where, for diffusion-controlled dissolution in which there is no chemical reaction, the liquid phase mass transfer coefficients are expressed in terms of diffusion coefficients, $D_i$, and the film thickness, $h$.

As dissolution proceeds, the more soluble components dissolve faster and are depleted near the solid–liquid interface, resulting in a surface layer composed of the least soluble component. At any time, the solid is conceptualized as consisting of a homogeneous core with the initial composition, an outer shell of the least soluble component, and, between them, $n - 2$ concentric layers comprised of components of intermediate solubilities. If the $n$th component is the least soluble component, Eq. 4 may be written as:

$$-\frac{dr_n}{dt} = \frac{D_n}{X_n h \rho}(C_n^* - C_n) \qquad \text{(Eq. 5)}$$

and:

$$-\frac{dr_i}{dt} = \frac{D_i (C_i^* - C_i)}{(h + r_n - r_i) X_i \rho} \qquad \text{(Eq. 6)}$$

where $h$ is the film thickness and $(h + r_n - r_i)$ includes an internal diffusion thickness (or resistance) of $r_n - r_i$.

Equations 2, 5, and 6 may be used to calculate the dissolution rates of $n$-component solids. The fluxes, $J_i$, may be found from the equations:

$$J_i = \frac{1}{S_n}\frac{dW_i}{dt} = -k_i \frac{S_i}{S_n}(C_i^* - C) \qquad \text{(Eq. 7)}$$

and:

$$J_n = \frac{1}{S_n}\frac{dW_n}{dt} = -k_n (C_n^* - C_n) \qquad \text{(Eq. 8)}$$

where the fluxes are normalized in terms of the external surface area, $S_n$, of the solid.

The weight of the solid at any time can be calculated from:

$$W = \sum_{i=1}^{n} W_i \qquad \text{(Eq. 9)}$$

These equations will be used to model the dissolution of two- and three-component solids. In addition, these equations can be modified to include cases with interaction between the components.

## EXPERIMENTAL

**Preparation of Compressed Spheres and Measurement of Densities**—Material that passed through an 80-mesh sieve but was retained on a 100-mesh sieve was compacted at 4540 kg of force, by means of a hydraulic press[1], into compressed spheres having a diameter of 1.270 ± 0.005 cm. The bulk density of the compressed spheres was determined by displacement (4). The true density of the material was determined by means of a pycnometer using $n$-heptane.

**Dissolution Rate**—The dissolution rate was determined in distilled water at 25 ± 0.1°, as described previously (5, 6), under conditions where the concentration of the solutes did not exceed 5% of solubility. The dissolution apparatus and procedure were described previously (4, 6), and the dissolution rates are given in Tables I and II.

**Analytical Procedures**—The simultaneous analysis of two-compo-

nent spheres of aspirin (ASA) and salicylic acid (SAL), and of aspirin and phenacetin (PH), and of three-component spheres of aspirin, caffeine (CAF), and phenacetin using simultaneous equations was discussed previously (4, 7).

## RESULTS AND DISCUSSIONS

**Two-Component, Noninteracting Solids**—Two systems (aspirin–salicylic acid and aspirin–phenacetin) were studied. The experimental dissolution rates for various compositions of both systems are given in Table I. The solubilities and diffusion coefficients used in the calculations are compiled in Table III. The weight of the spheres and the fluxes (dissolution rates) were calculated from Eqs. 1 and 5–9. These equations were solved simultaneously using a fourth-order Runge–Kutta procedure (8).

For example, at 2 hr, the theoretical predicted weights are compared to the experimentally determined weights for aspirin–salicylic acid spheres in Fig. 1 and for aspirin–phenacetin spheres in Fig. 2. The predicted weights are within 6% of the determined weights, and the calculated values indicate that the maximum loss of weight occurs at an intermediate value of $X_{ASA}$.

**Table III—Physical Parameters of Species in Water at 25°**

| Material | $D_i$, cm²/sec | $C_i^*$ g/ml |
|---|---|---|
| Aspirin | $8.01 \times 10^{-6}$ [a] | $4.44 \times 10^{-3}$ [a] |
| Salicylic acid | $10.12 \times 10^{-6}$ [b] | $2.24 \times 10^{-3}$ [c] |
| Caffeine | $6.79 \times 10^{-6}$ [d] | $23.2 \times 10^{-3}$ [e] |

The general model predicts that maximum dissolution rates occur for composite solids in which there is no internal diffusion resistance (all the $r_i$ values are equal). This critical composition can be found by equating the right-hand sides of Eq. 6 with $r_n = r_i$ and $C_i = 0$; thus:

$$\frac{D_1 C_1^*}{hX_1\rho} = \frac{D_2 C_2^*}{hX_2\rho} \qquad \text{(Eq. 10)}$$

which can be rearranged to:

$$\frac{X_2}{X_1} = \frac{D_2 C_2^*}{D_1 C_1^*} \qquad \text{(Eq. 11)}$$

where $X_1 + X_2 = 1$.

In general, the $r_i$ values of the dissolving components are not equal and may vary with time. For example, in Fig. 3 the radius is plotted *versus* time for different initial compositions of aspirin and phenacetin. Where $X_{ASA} = 0.1$ and phenacetin comprises the outer shell, the external radius of the solid varies linearly with time while the radius of the homogeneous core varies nonlinearly. In Fig. 3, the internal diffusion thickness for aspirin is dependent on time. For the critical composition of the solid, the internal resistance is zero and $r_{ASA} = r_{PH}$.

Since the internal diffusion thickness is dependent on time, the fluxes are also time variant (Eqs. 7 and 8). Examples of this situation are shown in Fig. 4 for an aspirin–salicylic acid sphere with $X_{ASA} = 0.2$ and for aspirin–phenacetin spheres with $X_{ASA} = 0.2$ and 0.7. Since there is no internal resistance at $t = 0$, the fluxes have their maximum value; subsequently, the flux of the more soluble component decreases as the internal resistance is increased. The average flux, $\bar{J}$, may be calculated by:

$$\bar{J} = \frac{\int_0^t J(t)\,dt}{\int_0^t dt} \qquad \text{(Eq. 12)}$$

At 2 hr, the theoretical average fluxes of aspirin and salicylic acid were calculated and plotted in Fig. 5 for the aspirin–salicylic acid spheres of various composition. The symbols represent the experimental values. Similarly, the average fluxes of aspirin and of phenacetin are plotted *versus* composition in Fig. 6 for comparison to theoretical values.

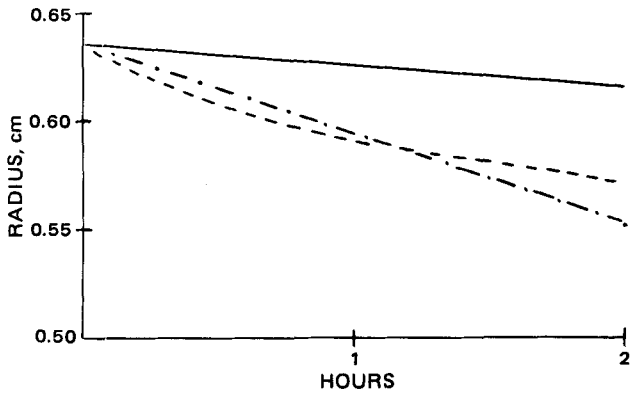

**Figure 3**—*Radius of layers of the components of a dissolving aspirin–phenacetin sphere with a bulk density of 1.42 g/cm³ as a function of time at the critical composition and at $X_{ASA}$ = 0.1. Key: —, $r_{PH}$ at $X_{ASA}$ = 0.1; ---, $r_{ASA}$ at $X_{ASA}$ = 0.1; and —·—, $r_{PH}$ = $r_{ASA}$ at $X_{ASA}$ = 0.8.*

**Three-Component, Noninteracting Solids**—For three-component, noninteracting solids, the critical composition is found from:

$$\frac{D_1C_1^*}{hX_1\rho} = \frac{D_2C_2^*}{hX_2\rho} = \frac{D_3C_3^*}{hX_3\rho} \qquad \text{(Eq. 13)}$$

or:

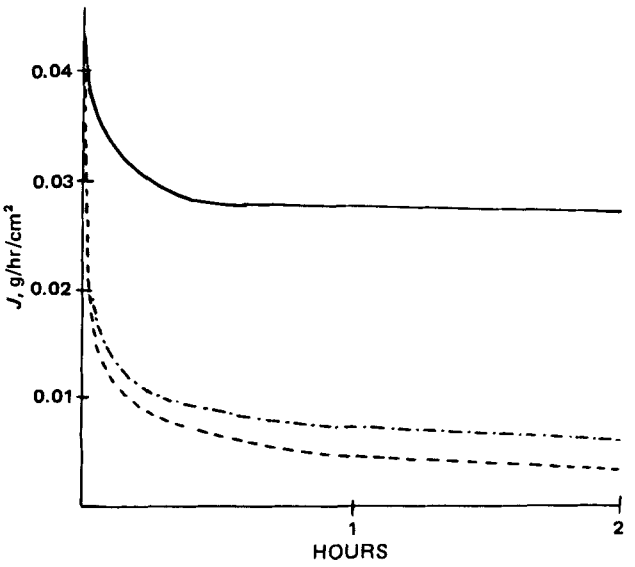

**Figure 4**—*Instantaneous flux from two-component spheres as a function of time. Key: —, $J_{PH}$ at $X_{ASA}$ = 0.7 and $X_{PH}$ = 0.3 with a bulk density of 1.42 g/cm³; ---, $J_{ASA}$ at $X_{ASA}$ = 0.2 and $X_{PH}$ = 0.8 with a bulk density of 1.42 g/cm³; and —·—, $J_{ASA}$ at $X_{ASA}$ = 0.2 and $X_{SAL}$ = 0.8 with a bulk density of 1.46 g/cm³.*

$$\frac{X_2}{X_1} = \frac{D_2C_2^*}{D_1C_1^*} \qquad \text{(Eq. 14)}$$

$$\frac{X_2}{X_3} = \frac{D_2C_2^*}{D_3C_3^*} \qquad \text{(Eq. 15)}$$

where $X_1 + X_2 + X_3 = 1$.

For the argument of model comparison, no interaction is assumed to occur in the dissolution of an aspirin–caffeine–phenacetin solid. With this assumption, the average fluxes for the components were calculated and plotted in Fig. 7 at $X_{PH}$ = 0.5. For $X_{PH}$ values greater than ~0.1, the phenacetin is the outer shell, and the flux of phenacetin is constant for all $X_{ASA}$ values. For $X_{PH}$ of < 0.1, either the caffeine or the aspirin can be the outer shell, depending on the composition. As shown in Fig. 8 at $X_{PH}$ = 0.05, if $X_{ASA} \geq 0.2$, aspirin is the outer shell, and if $X_{ASA} \leq 0.2$, phenacetin is the outer layer.

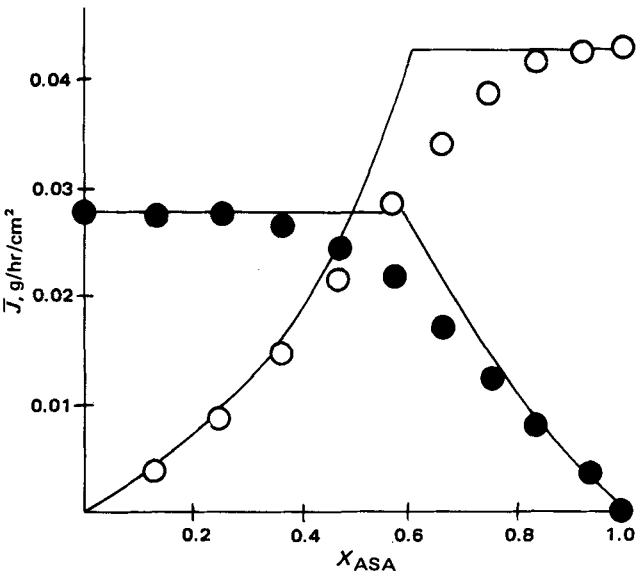

**Figure 5**—*Comparison of experimental fluxes of the components of aspirin–salicylic acid spheres with a bulk density of 1.4 g/cm³ of various compositions. Smooth curves are theoretical average fluxes. Key: ○, aspirin; and ●, salicylic acid.*

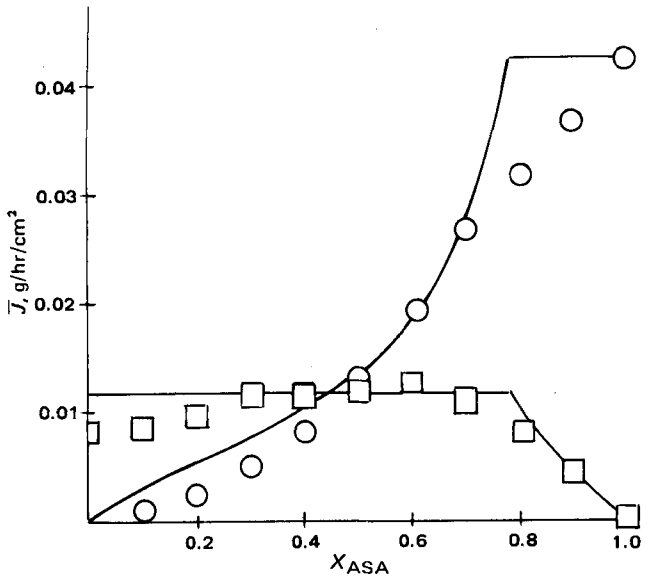

**Figure 6**—*Comparison of experimental fluxes of the components of aspirin–phenacetin spheres with a density of 1.4 g/cm³ of various compositions. Smooth curves are theoretical average fluxes. Key: ○, aspirin; and □, phenacetin.*

**Two-Component, Interacting Solids**—The general modeling discussed may be extended to include interacting solids. Consider the case in which components $A$ and $B$ react according to the reaction $A + B \rightleftarrows AB$ and the equilibrium constant, $K$, is expressed as:

$$K = \frac{\tilde{C}_{AB}}{\tilde{C}_A \tilde{C}_B} \qquad \text{(Eq. 16)}$$

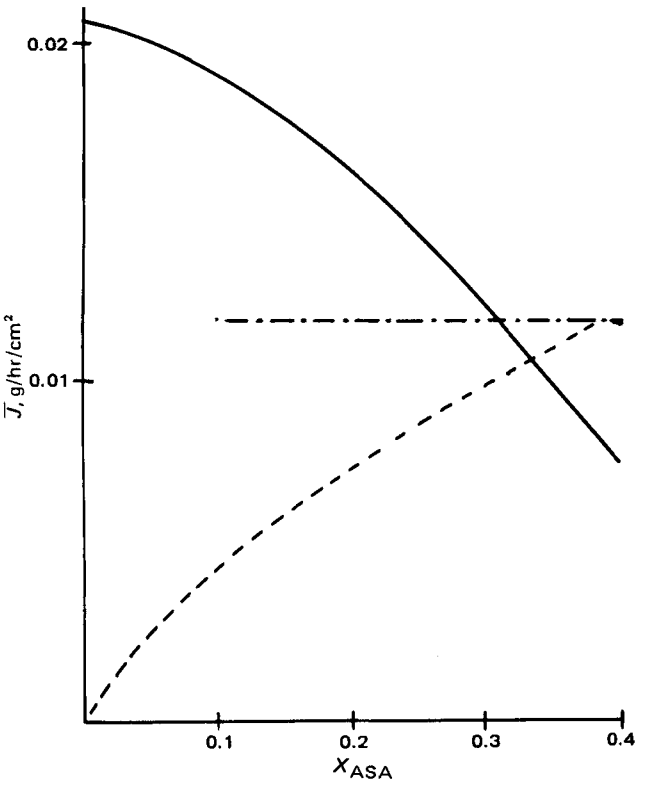

**Figure 7**—*Average fluxes of components of aspirin–caffeine–phenacetin spheres with a density of 1.5 g/cm³, $X_{PH}$ = 0.5, and various compositions of aspirin and caffeine. Key: ---, aspirin; —, caffeine; and -·-·-, phenacetin.*

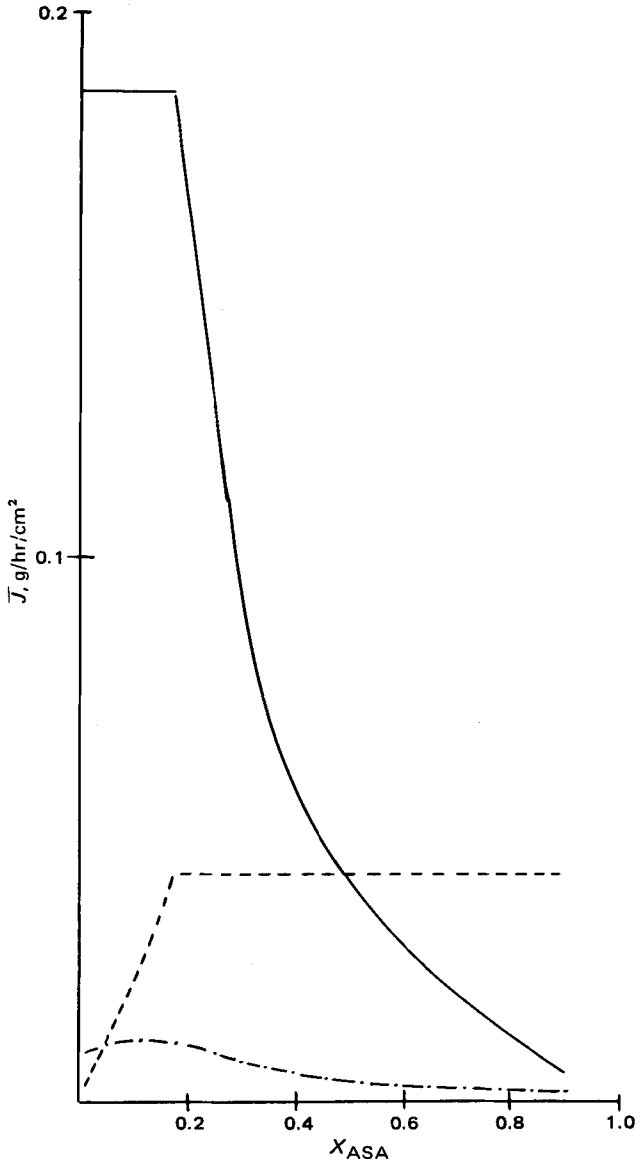

**Figure 8**—*Average fluxes of components of aspirin–caffeine–phenacetin spheres with a density of 1.5 g/cm³, $X_{PH}$ = 0.05, and various compositions of aspirin and caffeine. Key: ---, aspirin; —, caffeine; and -·-·-, phenacetin.*

with the concentrations being expressed in molar concentrations as indicated by tildes.

The mass transfer may be expressed for the two-component, interacting system by:

$$-\frac{dW_A}{dt} = k_A S_A C_A^* + k_{AB} S_B M_A \tilde{C}_{AB}^* \qquad \text{(Eq. 17)}$$

$$-\frac{dW_B}{dt} = k_B S_B C_B^* + k_{AB} S_A M_B \tilde{C}_{AB}^* \qquad \text{(Eq. 18)}$$

where $M_A$ and $M_B$ are the molecular weights of $A$ and $B$, respectively. Expressions for $r_A$ and $r_B$ may be found as discussed.

For the critical composition:

$$\frac{X_A}{X_B} = \frac{D_A C_A^* + M_A D_{AB} \tilde{C}_{AB}^*}{D_B C_B^* + M_B D_{AB} \tilde{C}_{AB}^*} \qquad \text{(Eq. 19)}$$

where $X_A + X_B = 1$.

Theoretically calculated values are drawn as solid lines in Fig. 9 in which the mass of a dissolving aspirin–caffeine sphere at 1 and 2 hr is plotted *versus* composition. The symbols represent experimental values. The model and experimental values are in good qualitative and quantitative agreement over the entire range of $X_{ASA}$.

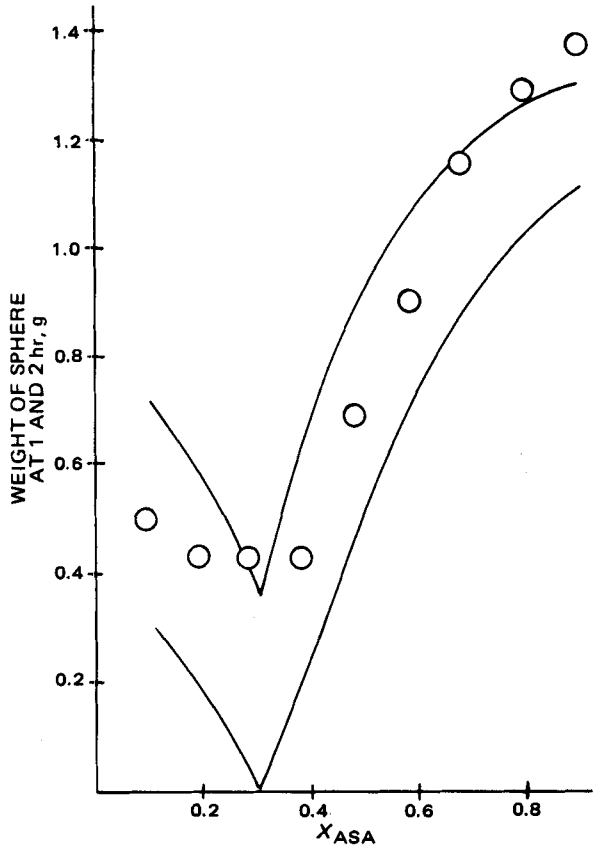

**Figure 9**—*Relation of composition to weight of a dissolving aspirin–caffeine sphere with a bulk density of 1.5 g/cm³. Smooth curves are theoretical, and points are experimental values. Key: upper curve, t = 1 hr; lower curve, t = 2 hr; and ○, experimental values at t = 1 hr.*

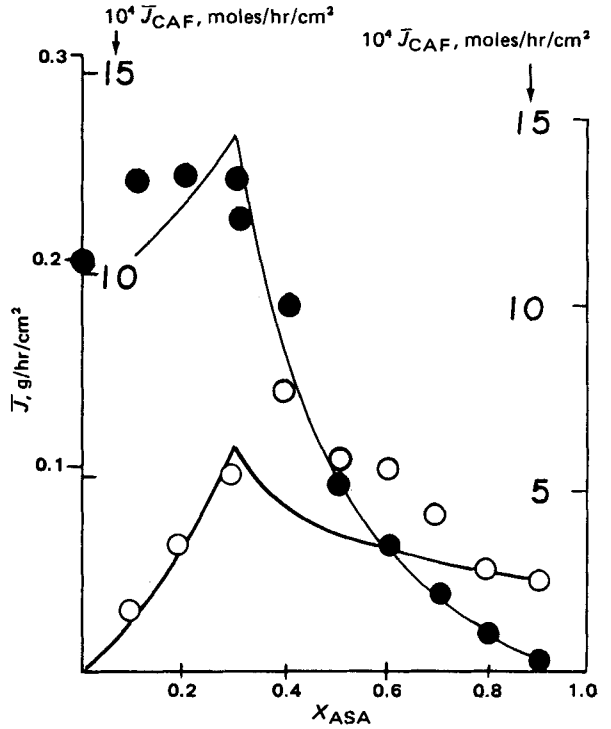

**Figure 10**—*Comparison of theoretical and experimental fluxes of the two components for an interacting two-component sphere with a bulk density of 1.5 g/cm³. Smooth curves are theoretical fluxes. Key: ○, aspirin; and ●, caffeine.*

The fluxes predicted by the model are compared to the experimentally determined fluxes in Fig. 10. The differences between interacting and noninteracting systems can be seen by comparing Fig. 10 with Figs. 5 and 6. There are no regions in a two-component, interacting system in which either flux is independent of the mass fraction. In addition, in a noninteracting system, the flux of aspirin can not exceed 0.043 g/hr/cm²; in interacting systems, the flux of aspirin can greatly exceed the noninteracting limit over a broad range of $X_{ASA}$ values.

**Three-Component Systems with Two Components Interacting**—If a third component, $I$, is added to the two-component, interacting system, then in addition to Eqs. 17 and 18, an equation for mass transfer of $I$ must be considered, *i.e.*:

$$-\frac{dW_I}{dt} = k_I S_I C_I^* \qquad \text{(Eq. 20)}$$

The expressions for the critical composition for this system are:

$$\frac{X_A}{X_B} = \frac{D_A C_a^* + M_A D_{AB} \tilde{C}_{AB}^*}{D_B C_B^* + M_B D_{AB} \tilde{C}_{AB}^*} \qquad \text{(Eq. 21)}$$

and:

$$\frac{X_I}{X_B} = \frac{D_I C_I^*}{D_B C_B^* + M_B D_{AB} \tilde{C}_{AB}^*} \qquad \text{(Eq. 22)}$$

where $X_I + X_A + X_B = 1$.

The equilibrium constant for the 1:1 aspirin–caffeine complex was reported to be 17.4 liters/mole (9). The hypothetical fluxes for each component of an aspirin–caffeine–phenacetin solid are shown in the remaining plots (see *Appendix*). The model for three components with two components interacting is plotted in Figs. 11 and 12, and it may be compared to Figs. 7 and 8 in which no interaction was hypothetically assumed between aspirin and caffeine. For $X_{PH} \geq 0.1$, the general shapes of the flux curves are similar (Fig. 11); however, for $X_{PH} \leq 0.1$, the effects of complexation are apparent (Fig. 12).

Due to caffeine–aspirin complexation, the flux of aspirin may be greater than in the hypothetical noninteracting case. In addition, for the inter-

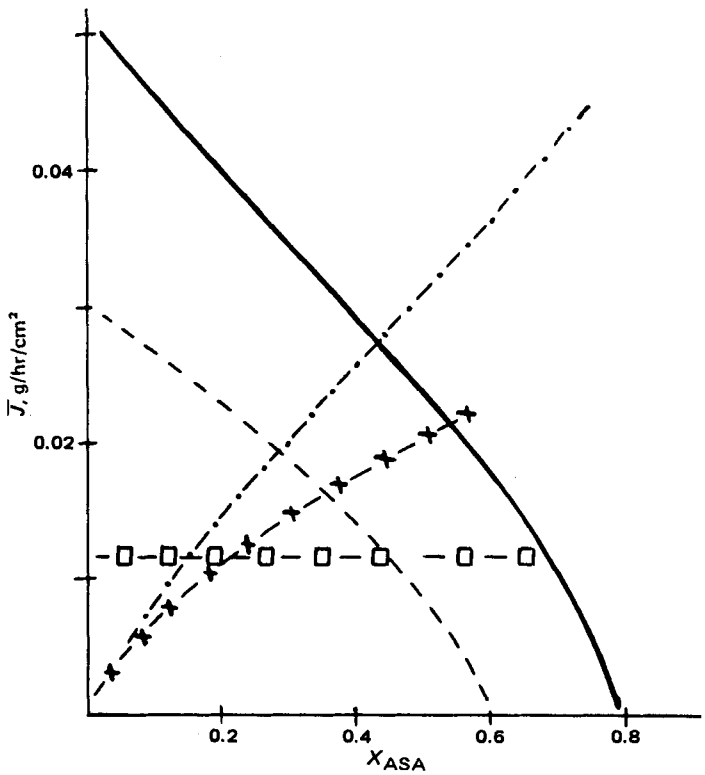

**Figure 11**—*Theoretical average fluxes of components of aspirin–caffeine–phenacetin spheres with a bulk density of 1.5 g/cm³, $X_{PH} \geq 0.1$, and various compositions of aspirin and caffeine. The hypothetical noninteracting case for this system is given in Fig. 7. Key: —, caffeine at $X_{PH} = 0.2$; - - -, caffeine at $X_{PH} = 0.4$; —·—, aspirin at $X_{PH} = 0.2$; ×–×–, aspirin at $X_{PH} = 0.4$; and □–□–, phenacetin at $X_{PH} = 0.2$ and $X_{PH} = 0.4$.*

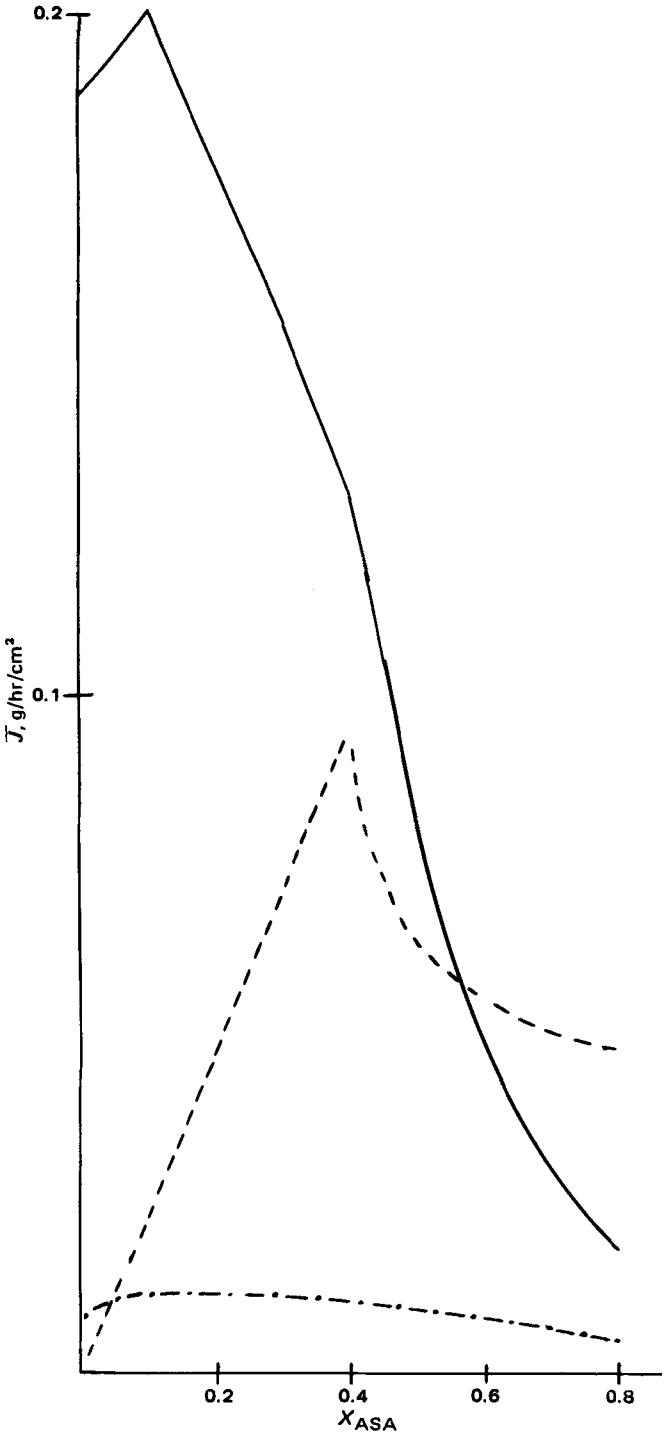

**Figure 12**—*Theoretical average fluxes of components of aspirin–caffeine–phenacetin spheres with a bulk density of 1.5 g/cm³, $X_{PH}$ = 0.05, and various compositions of aspirin and caffeine with complexation. Key: ---, aspirin; —, caffeine; and -·-·-, phenacetin.*

acting case, three distinct regions occur as shown in Fig. 12. For $X_{ASA} \geqq 0.4$, aspirin forms the outer shell, and the fluxes of all three components decrease with increases in $X_{ASA}$. For $0.1 \leqq X_{ASA} \leqq 0.4$, phenacetin comprises the outer shell, and the flux of phenacetin remains constant while the flux of aspirin increases and the flux of caffeine decreases as $X_{ASA}$ is greater. Caffeine forms the outer shell for $X_{ASA} \leqq 0.1$, and the fluxes of all three components increase as $X_{ASA}$ is greater.

The experimental data for the three-component, interacting system (Table II) are comparable with reasonable qualitative agreement to the theoretical values in the remaining figures. In Fig. 13 with equal mole fractions of aspirin and phenacetin, the flux of caffeine is shown to be an

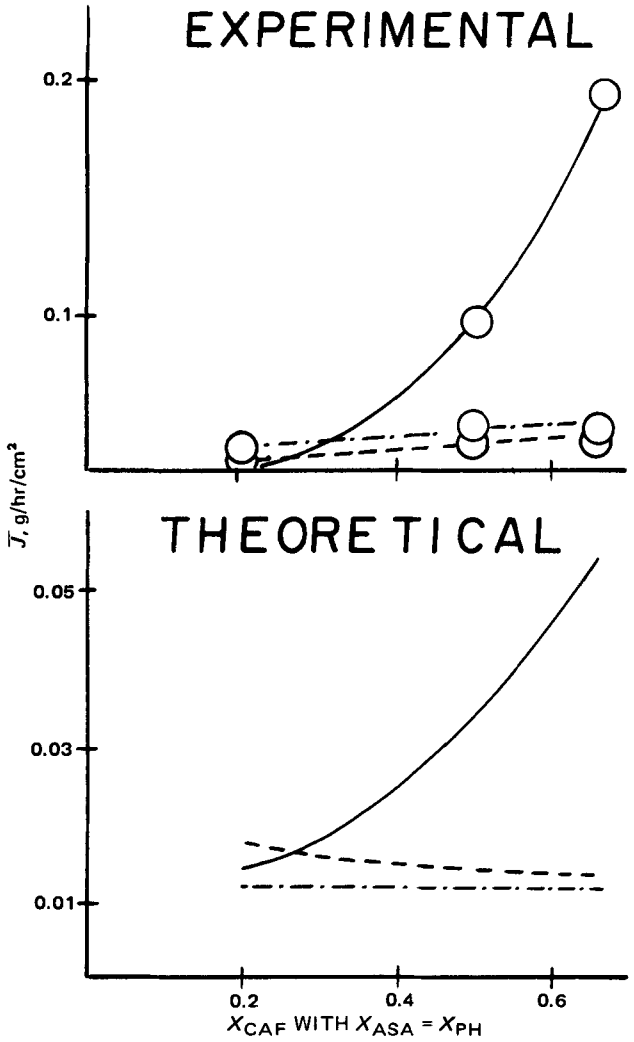

**Figure 13**—*Theoretical average and experimental fluxes of each component in a three-component, interacting system with equal mole fractions of aspirin and phenacetin. Densities are given in Table II. Key: ---, aspirin; —, caffeine; and -·-·-, phenacetin.*

increasing function of the mole fraction of caffeine; however, the fluxes of aspirin and phenacetin are relatively insensitive to the mole fraction of caffeine.

In Fig. 14 with equal mole fractions of aspirin and caffeine, the fluxes of aspirin and caffeine decrease exponentially as the mole fraction of phenacetin is increased, while the flux of phenacetin is less sensitive to change in the fraction of phenacetin. As shown in Fig. 15 with equal mole fractions of caffeine and phenacetin, the flux of aspirin increases as the mole fraction of aspirin increases, but the flux of caffeine decreases as the mole fraction of aspirin increases.

## APPENDIX

The mathematics of the calculation of the fluxes is illustrated for a three-component solid with two interacting components.

The equations for the flux of the dissolution of aspirin (ASA)–caffeine (CAF)–phenacetin (PH) solids with an interaction between the aspirin and caffeine are obtained from Eqs. 7 and 8 using Eqs. 17, 18, and 20 (see text for definitions):

$$J_{ASA}(t) = k_{ASA}\frac{S_{ASA}}{S_{PH}}C^{\cdot}_{ASA} + k_{ASA\text{-}CAF}\frac{S_{ASA}}{S_{PH}}M_{ASA}\bar{C}^{\cdot}_{ASA\text{-}CAF} \quad \text{(Eq. A1)}$$

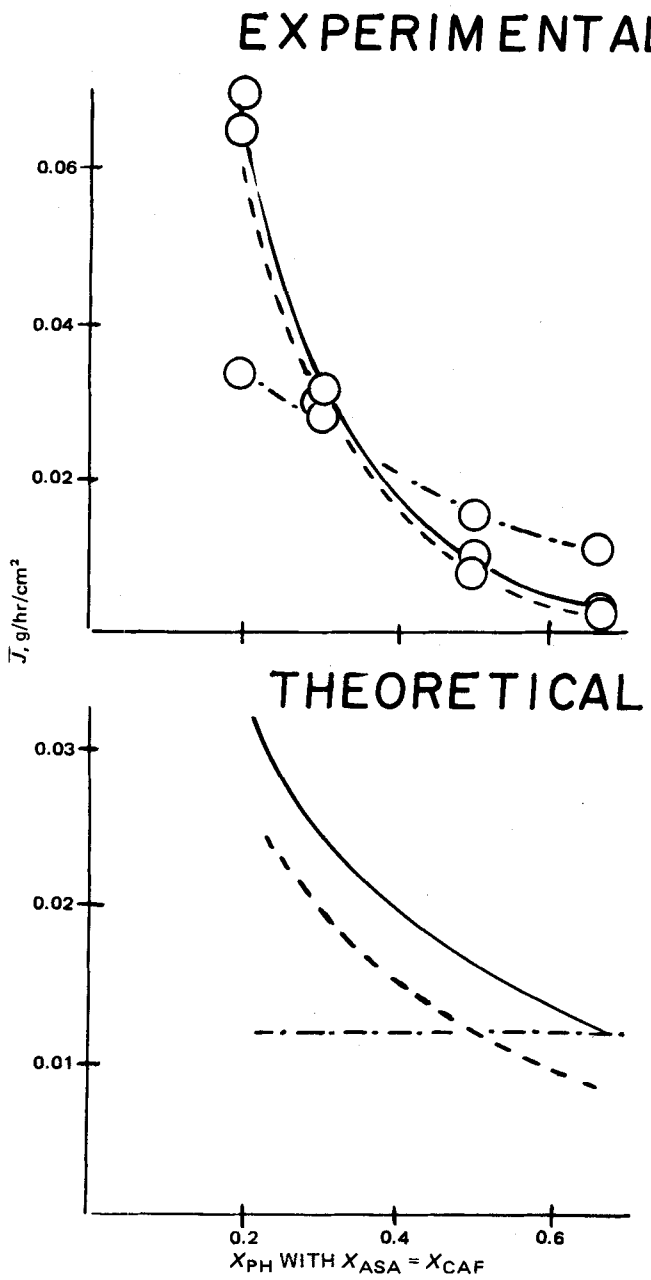

**Figure 14**—*Theoretical average and experimental fluxes of each component in a three-component, interacting system with equal mole fractions of aspirin and caffeine. Densities are given in Table II. Key: ---, aspirin; —, caffeine; and —·—, phenacetin.*

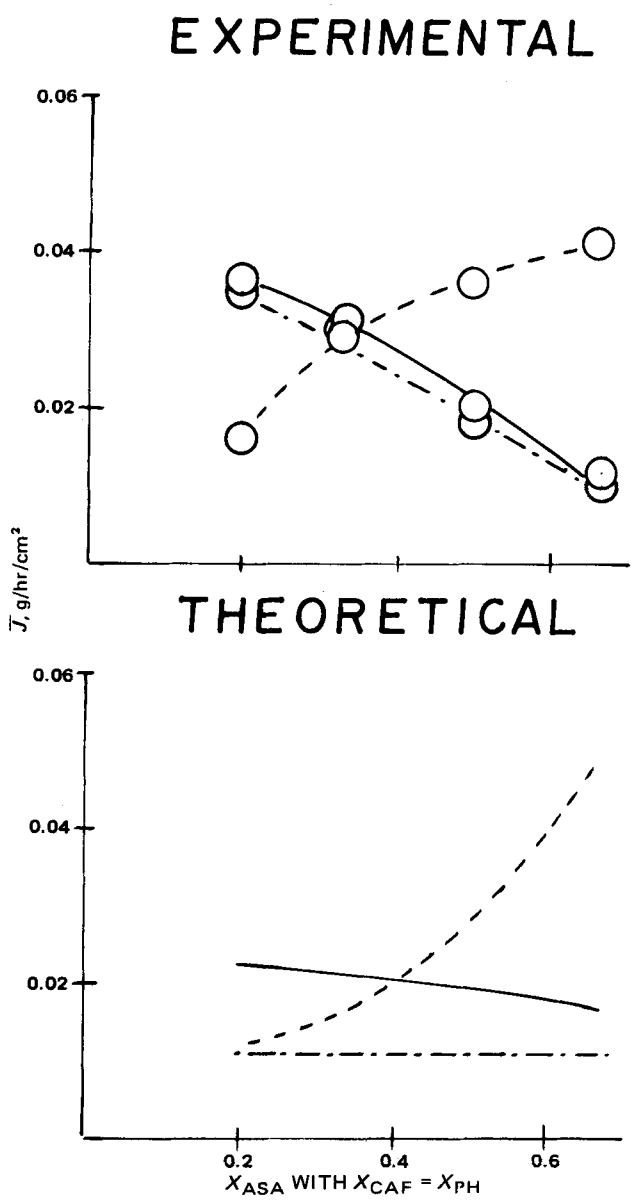

**Figure 15**—*Theoretical average and experimental fluxes of each component in a three-component, interacting system with equal mole fractions of caffeine and phenacetin. Densities are given in Table II. Key: ---, aspirin; —, caffeine; and —·—, phenacetin.*

$$J_{CAF}(t) = k_{CAF}\frac{S_{CAF}}{S_{PH}}C^{*}_{CAF} + k_{ASA\text{-}CAF}\frac{S_{CAF}}{S_{PH}}M_{CAF}\tilde{C}^{*}_{ASA\text{-}CAF} \quad \text{(Eq. A2)}$$

$$J_{PH}(t) = k_{PH}C^{*}_{PH} \quad \text{(Eq. A3)}$$

When phenacetin is the outer layer:

$$k_{ASA} = \frac{D_{ASA}}{h + r_{PH} - r_{ASA}} \quad \text{(Eq. A4)}$$

$$k_{CAF} = \frac{D_{CAF}}{h + r_{PH} - r_{CAF}} \quad \text{(Eq. A5)}$$

$$k_{PH} = \frac{D_{PH}}{h} \quad \text{(Eq. A6)}$$

and:

$$S_{ASA} = 4\pi r^2_{ASA} \quad \text{(Eq. A7)}$$

$$S_{CAF} = 4\pi r^2_{CAF} \quad \text{(Eq. A8)}$$

$$S_{PH} = 4\pi r^2_{PH} \quad \text{(Eq. A9)}$$

For the experimental conditions at 25°, the diffusivities and solubilities are given in Table III. The film thickness, $h$, was determined experimentally to be $30 \times 10^{-4}$ cm, and the equilibrium constant for a 1:1 aspirin–caffeine complex was taken as 17.4 liters/mole. With the use of these physical parameters and Eqs. A4–A9, Eqs. A1–A3 can be written as:

$$J_{ASA}(t) = \left(\frac{9.76 \times 10^{-8}}{30 \times 10^{-4} + r_{PH} - r_{ASA}}\right)\left(\frac{r_{ASA}}{r_{PH}}\right)^2 \text{g/cm}^2\text{/sec} \quad \text{(Eq. A10)}$$

$$J_{CAF}(t) = \left(\frac{2.22 \times 10^{-7}}{30 \times 10^{-4} + r_{PH} - r_{CAF}}\right)\left(\frac{r_{CAF}}{r_{PH}}\right)^2 \text{g/cm}^2\text{/sec} \quad \text{(Eq. A11)}$$

$$J_{PH}(t) = 3.3 \times 10^{-6}\ \text{g/cm}^2\text{/sec} \quad \text{(Eq. A12)}$$

As shown by these equations, the fluxes are dependent on the indi-

vidual radii. The equations describing the radii are obtained from Eq. 6:

$$-\frac{dr_{ASA}}{dt} = \frac{D_{ASA}C^*_{ASA} + D_{ASA\text{-}CAF}M_{ASA}\tilde{C}^*_{ASA\text{-}CAF}}{(h + r_{PH} - r_{ASA})X_{ASA}\rho} \quad \text{(Eq. A13)}$$

$$-\frac{dr_{CAF}}{dt} = \frac{D_{CAF}C^*_{CAF} + D_{ASA\text{-}CAF}M_{CAF}\tilde{C}^*_{ASA\text{-}CAF}}{(h + r_{PH} - r_{CAF})X_{CAF}\rho} \quad \text{(Eq. A14)}$$

$$-\frac{dr_{PH}}{dt} = \frac{D_{PH}C^*_{PH}}{hX_{PH}\rho} \quad \text{(Eq. A15)}$$

where:

$$X_{PH} + X_{ASA} + X_{CAF} = 1 \quad \text{(Eq. A16)}$$

At 25°, the equations can be written as:

$$-\frac{dr_{ASA}}{dt} = \frac{9.76 \times 10^{-8}}{(30 \times 10^{-4} + r_{PH} - r_{ASA})X_{ASA}\rho} \text{ cm/sec} \quad \text{(Eq. A17)}$$

$$-\frac{dr_{CAF}}{dt} = \frac{2.22 \times 10^{-7}}{(30 \times 10^{-4} + r_{PH} - r_{CAF})X_{CAF}\rho} \text{ cm/sec} \quad \text{(Eq. A18)}$$

$$-\frac{dr_{PH}}{dt} = \frac{3.33 \times 10^{-6}}{X_{PH}\rho} \text{ cm/sec} \quad \text{(Eq. A19)}$$

These equations are coupled ($r_{ASA}$ is a function of $r_{PH}$, *etc.*). For given values of $X_i$ and $\rho$, these equations can be solved simultaneously to yield $r_{ASA}$, $r_{CAF}$, and $r_{PH}$ as a function of time. A fourth-order Runge–Kutta procedure (8) was used in this study to solve these equations. When the radii are evaluated, the instantaneous fluxes may be calculated from Eqs. A10–A12. The average fluxes may be calculated using Eq. 12.

The equations describing the cases in which either aspirin or caffeine is the outer layer can be obtained similarly. The equations describing the hypothetical case in which aspirin and caffeine do not interact are obtained by setting $\tilde{C}^*_{ASA\text{-}CAF}$ to zero in these equations.

# Reversed-Phase High-Pressure Liquid Chromatographic Analysis of Sulconazole in Plasma

**M. FASS ˣ, B. ZARO, M. CHAPLIN, and S. MATIN**

Received June 2, 1980, from *Syntex Research, Palo Alto, CA 94304.* Accepted for publication May 12, 1981.

**Abstract** □ A sensitive and specific analytical method for the measurement of sulconazole in plasma is described. The compound was extracted from plasma at pH 10 with hexane–methylene chloride. Samples were subjected to high-pressure liquid chromatography (HPLC) using an acetonitrile–phosphate buffer mixture as the mobile phase. The components of interest were measured using a variable-wavelength detector at 229 nm. Sulconazole concentrations of ≥0.5 μg/ml can be measured with confidence using this method. Linear calibration curves were constructed over the concentration range of 0.5–5 μg/ml for sulconazole from dog plasma. A dog was administered a single oral 1000-mg dose of tritiated sulconazole nitrate; total plasma radioactivity and sulconazole plasma levels determined by HPLC are reported.

**Keyphrases** □ Sulconazole—reversed-phase high-pressure liquid chromatographic analysis in plasma □ High-pressure liquid chromatography—analysis of sulconazole in plasma □ Antifungal agents—sulconazole, reversed-phase high-pressure liquid chromatographic analysis.

Sulconazole nitrate, 1-[β-(4″-chlorobenzylthio)-2′, 4′-dichlorophenethyl]imidazole mononitrate (I), is a potential new antimycotic agent[1] developed for human use. Since it is necessary to conduct animal toxicity studies supported by plasma level data for new drugs, a sensitive and specific analytical method was developed.

A high-pressure liquid chromatographic (HPLC) method for the determination of econazole, a structural analog of sulconazole, was described previously (1). Direct application of this extraction–injection method to sulconazole analysis provided unsatisfactory chromatography. Interfering peaks at the retention time of the compounds of interest were observed, and laborious distillation of ether prior to extraction to remove peroxides did not prevent random oxidative degradation of sulconazole.

This paper describes a reversed-phase HPLC method for the measurement of sulconazole in plasma using a structurally related analog as the internal standard. The method was applied to the measurement of sulconazole in the plasma of a dog given a single oral dose of 1000 mg of tritiated sulconazole nitrate.

## EXPERIMENTAL

**Reagents and Materials**—All solvents[2] were distilled-in-glass and liquid chromatography grade. All chemicals[1], available in-house, were analytical grade and were used without further purification. Inorganic reagents were prepared in purified water[3]. Standard solutions of sulconazole were prepared in methanol at the following concentrations: 40 μg/ml (stock solution) and 20, 16, and 4 μg/ml (spiking solutions). The internal standard solution was prepared in methanol at a concentration of 100 μg/ml. Solutions were stored at 4°. Standard solutions were prepared every 2 weeks.

vidual radii. The equations describing the radii are obtained from Eq. 6:

$$-\frac{dr_{ASA}}{dt} = \frac{D_{ASA}C^*_{ASA} + D_{ASA\text{-}CAF}M_{ASA}\tilde{C}^*_{ASA\text{-}CAF}}{(h + r_{PH} - r_{ASA})X_{ASA}\rho} \quad \text{(Eq. A13)}$$

$$-\frac{dr_{CAF}}{dt} = \frac{D_{CAF}C^*_{CAF} + D_{ASA\text{-}CAF}M_{CAF}\tilde{C}^*_{ASA\text{-}CAF}}{(h + r_{PH} - r_{CAF})X_{CAF}\rho} \quad \text{(Eq. A14)}$$

$$-\frac{dr_{PH}}{dt} = \frac{D_{PH}C^*_{PH}}{hX_{PH}\rho} \quad \text{(Eq. A15)}$$

where:

$$X_{PH} + X_{ASA} + X_{CAF} = 1 \quad \text{(Eq. A16)}$$

At 25°, the equations can be written as:

$$-\frac{dr_{ASA}}{dt} = \frac{9.76 \times 10^{-8}}{(30 \times 10^{-4} + r_{PH} - r_{ASA})X_{ASA}\rho} \text{ cm/sec} \quad \text{(Eq. A17)}$$

$$-\frac{dr_{CAF}}{dt} = \frac{2.22 \times 10^{-7}}{(30 \times 10^{-4} + r_{PH} - r_{CAF})X_{CAF}\rho} \text{ cm/sec} \quad \text{(Eq. A18)}$$

$$-\frac{dr_{PH}}{dt} = \frac{3.33 \times 10^{-6}}{X_{PH}\rho} \text{ cm/sec} \quad \text{(Eq. A19)}$$

These equations are coupled ($r_{ASA}$ is a function of $r_{PH}$, *etc.*). For given values of $X_i$ and $\rho$, these equations can be solved simultaneously to yield $r_{ASA}$, $r_{CAF}$, and $r_{PH}$ as a function of time. A fourth-order Runge–Kutta procedure (8) was used in this study to solve these equations. When the radii are evaluated, the instantaneous fluxes may be calculated from Eqs. A10–A12. The average fluxes may be calculated using Eq. 12.

The equations describing the cases in which either aspirin or caffeine is the outer layer can be obtained similarly. The equations describing the hypothetical case in which aspirin and caffeine do not interact are obtained by setting $\tilde{C}^*_{ASA\text{-}CAF}$ to zero in these equations.

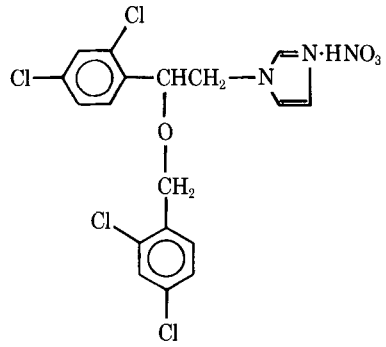
I



II

**Extraction**—Plasma (400 μl) was added to 400 μl of purified water in a 15-ml test tube. Samples were then fortified with the internal standard at the 12.5-μg/ml level (50 μl of 100 μg/ml of spiking solution) and made alkaline by the addition of 100 μl of 1 *N* potassium hydroxide. This mixture was extracted with 6 ml of hexane–methylene chloride (1:1). Tubes were shaken on a tilter for 3 min, and samples were then centrifuged[4] at 4000 rpm for 6 min. The upper organic layer was transferred to a 15-ml conical test tube and was blown to dryness under nitrogen. Samples were reconstituted in 100 μl of methanol, and 25 μl was injected onto the chromatograph.

**Preparation of Standard Curve**—Samples of control plasma were spiked with sulconazole at concentrations of 0.5, 1.0, 2.5, 4.0, and 5.0 μg/ml and with the internal standard at a fixed concentration of 12.5 μg/ml. Concentrations of sulconazole were calculated from calibration curves constructed by plotting the ratio of the peak height of sulconazole to the peak height of the internal standard *versus* the concentration of sulconazole spiked.

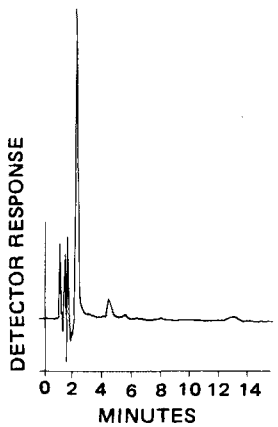


**Figure 1**—*Chromatogram of unfortified plasma. Conditions were a μBondapak $C_{18}$ column, acetonitrile–0.01 M $NaH_2PO_4$ buffer (pH 8.0) as the mobile phase, and a 2-ml/min flow rate.*

[4] Model HNS. IEC, Needham, Mass.

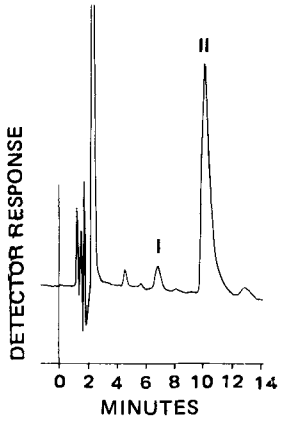

**Figure 2**—*Chromatogram of plasma fortified at the 0.5-μg/ml level with I and at the 12.5-μg/ml level with II.*

**HPLC and Chromatography Conditions**—A high-pressure liquid chromatograph[5] was equipped with a solvent programmer, an injector, and a spectrophotometric variable-wavelength detector[6] set at 229 nm. Samples were analyzed on a 4-mm × 30-cm reversed-phase column[7] fitted with a 4-mm × 8-cm precolumn[8]. The mobile phase was a solvent system of acetonitrile–0.01 *M* $NaH_2PO_4$ buffer (pH 8.0, 66:34), and the flow rate was 2 ml/min.

Each day, prior to sample injection, the column was equilibrated with mobile phase for ~20 min or until a level baseline was achieved. To check column suitability, a 25-μl aliquot of standard solution of sulconazole (20 μg/ml) and the internal standard (50 μg/ml) in methanol was injected onto the chromatograph under the described conditions. The suitability of the column was established by following three chromatographic parameters:

1. Resolution (R). The column was considered acceptable if the resolution of sulconazole and the internal standard was equal to or better than baseline separation or an *R* value of 1.5 as determined by the resolution equation (2).
2. Peak height ratio. A maximum variation of 5% for peak height ratio for injection on the same day was acceptable before major changes in the solvent system or column were implemented.
3. Retention time. The retention times for sulconazole and the internal standard were ~7 and 10 min, respectively. Retention times for replicate injections on a single day were not expected to vary by more than 5%.

| 96.0 | 3.331 | BDL |
| 168.0 | 2.379 | BDL |

[a] Below detectable level.

**Dog Experiment**—A female beagle received 1000 mg (four capsules) of tritiated sulconazole nitrate after an overnight fast. A 20-ml water wash immediately followed the dose, and feeding was resumed 4 hr after dosing. Blood samples were drawn at 0.5, 1, 2, 4, 6, 8, 24, 48, 72, 96, and 168 hr following drug administration. Plasma levels of sulconazole nitrate radioequivalents and unchanged sulconazole were determined in these samples.

**Total Sulconazole Radioequivalent Determination**—Total sulconazole radioequivalents in dog plasma were determined by liquid scintillation spectrometry. Plasma samples of 0.1–0.2 ml were mixed with 10 ml of scintillation fluid[9]. Corrections were made for quenching and machine[10] efficiency by the automatic external standard method.

## RESULTS AND DISCUSSION

A sensitive and specific HPLC method was developed that utilized the natural 229-nm UV-absorbing property of sulconazole, measuring levels of ≥0.5 μg/ml.

A structurally similar compound miconazole nitrate 1-[2-(2,4-dichlorophenyl)-2-(2,4-dichlorobenzyloxy)ethyl]imidazole mononitrate (II), was used as the chromatographic internal standard. This compound possesses UV, extraction, and chemical properties similar to sulconazole and was chromatographically resolved under the described conditions.

Good chromatography was achieved by employing a relatively nonpolar extracting solvent containing no oxidants and a solvent system at a slightly basic pH. Reproducibility of this method was shown by construction of calibration curves over the concentration range of 0.5–5.0 μg/ml. The coefficients of variation obtained for the calibration curve points were 3.92, 2.05, 1.20, 2.5, and 1.09%, respectively (n = 5). A chromatogram of an unfortified plasma sample is shown in Fig. 1. Chromatograms of plasma samples fortified with 0.5 and 5 μg/ml of sulconazole are shown in Figs. 2 and 3, respectively. A chromatogram of a plasma sample taken from a dog 6 hr after oral dosing with a 1000-mg capsule of sulconazole nitrate is shown in Fig. 4.

A plasma sample from a dog dosed with sulconazole was extracted with methanol and subjected to TLC. An authentic sulconazole standard was run alongside on the same plate. The plate was developed with an ammonium hydroxide–chloroform–methanol system (1:99:1). After drying, 1-cm sections of the plate were scraped into liquid scintillation vials and counted for radioactivity. Based on $R_f$ values, it was determined that the percentage of radioactivity at the sulconazole $R_f$ value represented the same fraction of the total radioactivity as the level of sulconazole obtained by HPLC. These TLC data support the identity of the HPLC peak at the retention time of sulconazole.

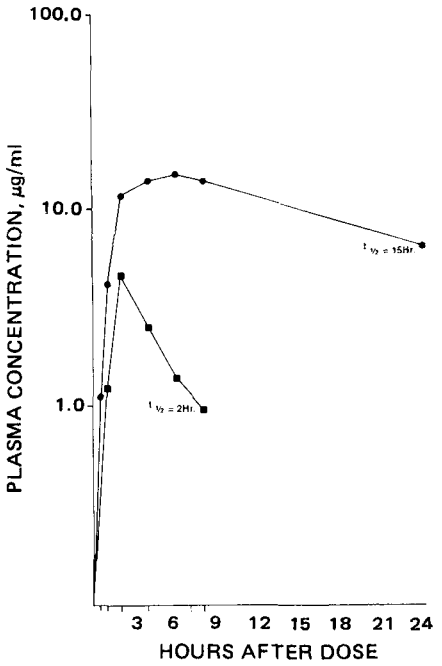

**Figure 5**—*Plasma levels of total sulconazole nitrate radioequivalents (●) and concentration of unchanged drug (■) in a dog given 1000 mg of tritium-labeled sulconazole nitrate.*

The overall recovery of sulconazole through the method was established by spiking plasma with tritiated sulconazole and processing the samples through the procedure. Radioactivity in the sample prior to injection onto the chromatograph was determined, and the recovery of sulconazole was 85%.

The developed method was applied to the analysis of plasma samples from a dog dosed with 1000 mg of tritiated sulconazole nitrate. Concentrations of total sulconazole radioequivalents and unchanged sulconazole in plasma are shown in Table 1 and Fig. 5. The peak unchanged sulconazole plasma level occurred at 2 hr following dose administration, and the peak total sulconazole radioequivalent level occurred at 6 hr after dosing. The half-life of unchanged sulconazole in this dog was 2 hr. The half-life observed for the total sulconazole radioequivalents was 15 hr. The data demonstrate that in the one animal studied, orally administered sulconazole is rapidly and extensively metabolized.

# Relative Bioavailability of Aspirin Gum

**D. W. WOODFORD** * **and L. J. LESKO** ‡x

Received July 28, 1980, from the *College of Pharmacy, Rutgers University, New Brunswick, NJ 08854, and the ‡Drug Concentration Laboratory, University of Massachusetts Medical Center, Worcester, MA 01605. Accepted for publication April 8, 1981.

**Abstract** □ The bioavailability of aspirin gum relative to unbuffered aspirin tablets was determined in six normal volunteers. Twenty-four hours following the administration of two aspirin tablets, 91.2 ± 1.7 % (*SE*) of the 648-mg dose was recovered in the urine. The relative bioavailability of aspirin gum was 69.5 ± 3.4 % (*SE*), based on cumulative 24-hr urinary excretion of total salicylate after the chewing of three gum tablets for 15 min. The chewed gum was analyzed for total salicylate and contained an average of 37.8% of the administered dose. When added to the cumulative amount of total salicylate excreted in the urine at 24 hr after dosing, the salicylate contained in the chewed gum accounted for essentially 100% of the dose administered. Chewing aspirin gum for up to 30 min did not significantly ($p > 0.05$) reduce the amount of salicylate entrapped in the gum base when compared to chewing times of 5, 10, and 15 min. Based on the results of this study, four pieces of aspirin gum would be needed to provide the same amount of salicylate to the general circulation as two 324-mg aspirin tablets.

**Keyphrases** □ Aspirin gum—relative bioavailability compared to unbuffered aspirin tablets in six normal volunteers □ Bioavailability—aspirin gum compared to unbuffered aspirin tablets in six normal volunteers □ Dosage forms—comparison of salicylate availability from aspirin gum and unbuffered aspirin tablets

Aspirin is the most frequently used nonprescription analgesic, and selection of an aspirin product should be based on formulation preference and proven efficacy (1). Bioavailability studies have been conducted on many dosage forms of aspirin including aqueous solutions (2, 3), compressed tablets (4, 5), effervescent tablets (6, 7), controlled-release tablets (8), enteric-coated tablets (9–11), and rectal suppositories (12). These studies have shown that the bioavailability differences between products apparently are related to formulation factors. Recognizing the potential for therapeutic inequivalence, the American Pharmaceutical Association published a bioavailability monograph for aspirin (13).

One aspirin product omitted from this bioavailability monograph was aspirin chewing gum[1]. There have been no reported investigations in humans of the relative bioavailability of aspirin from gum formulations. Aspirin gum was introduced commercially in 1924; in 1976, the total sale of aspirin gum was nearly 80 million gum pieces[2]. The label claims for aspirin gum include "for the temporary relief of minor sore throat pain, headache, aches and pains of colds and flu and muscular aches and pains." The efficacy of aspirin gum as a systemic analgesic is dependent on the rate and extent of aspirin bioavailability.

This investigation evaluated the relative bioavailability of aspirin gum by comparing the urinary excretion of total salicylate after dosing with aspirin gum and regular aspirin tablets.

## EXPERIMENTAL

**Subjects**—Six male volunteers, 18–31 years of age (27.3 ± 1.5 years, mean ± *SE*) were selected. The study was approved by the institutional human studies review committee and valid, written, informed consent was obtained from each volunteer prior to his entering the study. The mean (±*SE*) body weight of the volunteers was 72.9 (±5.6) kg, and each volunteer was within 10% of his ideal body weight for his height and build (14). Each volunteer was determined to be in good physical health with no history of aspirin allergy, GI tract ulcers, or cardiac, hepatic, or renal disease.

The volunteers were instructed to refrain from taking any medication for at least 7 days prior to the study and to abstain from alcoholic beverages for 24 hr prior to dosing. All volunteers fasted, with the exception of water, for 12 hr prior to dosing, and fasting was continued for 4 hr after dosing. On the evening before each study day, the volunteers were instructed to empty their bladders and to drink 180 ml of water. Upon arising, the volunteers again emptied their bladders and drank 180 ml of water at 1 and 0.5 hr prior to dosing.

**Drug Administration**—On the 1st study day, the volunteers were assigned at random either the aspirin gum[3] or the aspirin tablets[4]; on the 2nd study day, the volunteers received the alternate formulation. The 2 study days were separated by a washout period of 7 days. At 8 am on each study day, the volunteers assigned the gum chewed three pieces (226.8 mg of aspirin/gum piece; total aspirin dose of 680.4 mg) for 15 min, swallowing saliva and any fragments of coating loosened by the chewing process. After chewing was completed, the gum was expectorated into a plastic vial and frozen at −20° for later salicylate analysis, and the volunteers were instructed to drink 120 ml of water. The volunteers assigned the aspirin tablets swallowed two tablets (324 mg of aspirin/tablet; total aspirin dose of 648 mg) with 120 ml of water. Previous replicate analysis for potency showed the gum and tablet to contain 98 and 105% of the label claim, respectively. To promote adequate urine flow, all volunteers were instructed to drink 180 ml of water 2 hr following the administration of each dosage form.

**Urine Collection**—Immediately before dosing, the volunteers emptied their bladders completely and an aliquot of the blank urine was collected and frozen at −20°. After dosing, urine was collected by complete voiding at 1, 2, 3, 4, 6, 8, 10, 12, and 24 hr. The volume and pH of voided urine were measured at each collection time, and an aliquot was frozen at −20° for salicylate analysis.

**Effect of Chewing Time**—Four of the six volunteers included in the bioavailability study were instructed to chew three aspirin gum pieces for 5, 10, 15, or 30 min, respectively, on 4 separate days. After chewing, the gum was expectorated into a plastic vial and the amount of salicylate remaining in the chewed gum was measured to determine if chewing time influenced salicylate release from the gum.

**Assay of Total Salicylate in Urine**—The total amount of salicylate in the urine samples was measured using the procedure of Chiou and Onyemelukwe (15). Briefly, 3.0 ml of urine and 2.0 ml of concentrated hydrochloric acid were added to a 50-ml culture tube, which was then incubated at 100° for 17 hr. After cooling to room temperature, 6.0 ml of chloroform was added to the tube and the mixture was shaken mechanically for 10 min. Following centrifugation, 3.0 ml of the chloroform was added to 6.0 ml of Trinders reagent (without mercuric chloride). After vortex mixing, the absorbance of the upper, aqueous phase was measured at 540 nm[5].

The concentration of salicylate in the urine sample was determined from a standard curve prepared by measuring the absorbance of sodium salicylate solutions of known concentrations after subjecting them to the described procedure. Each urine sample was analyzed in duplicate, and the average value was used to calculate the amount of total salicylate excreted during each collection interval. Urine blanks, urine standards spiked with known amounts of sodium salicylate, and aqueous sodium salicylate standard solutions were assayed with each batch of the vol-

| 12 | 385.3 ± 25.8 | 462.9 ± 28.0 |
| 24 | 433.6 ± 19.8 | 592.6 ± 11.1 |

unteer's urine samples as a quality control check. The total salicylate measured in the urine samples was converted to milligrams of aspirin by multiplying by 1.125.

**Assay of Total Salicylate in Chewed Gum**—The amount of salicylate contained in chewed gum was determined as follows. The chewed gum was placed in a flask containing 50 ml of 1 *N* HCl, heated to 100°, and stirred for 1 hr. After cooling to room temperature, the mixture was centrifuged and the hydrochloric acid was removed and diluted to 100 ml with 1 *N* HCl. This solution was diluted 1:100, and the absorbance of this diluted solution was measured spectrophotometrically at 240 nm. The concentration of salicylate in the solution was determined from a standard curve constructed by subjecting sodium salicylate solutions of known concentration to the same procedure previously described.

The absorbance spectrum of the salicylate solution obtained from the gum analysis was compared to the absorbance spectrum of a standard solution of sodium salicylate. There were no differences between the spectra in the general shape of the curves or the wavelengths where maxima and minima occurred, indicating that the observed absorbance was due to salicylate. The amount of salicylate recovered from the gum was converted to milligrams of aspirin by multiplying by 1.125.

**Bioavailability Calculations**—The relative bioavailability of aspirin gum ($F_{rel}$) was calculated as the percentage of aspirin equivalent eliminated in the urine in the 24 hr ($U_\infty$) following the administration of each dosage form after correcting for the dose ($D$) of aspirin administered:

$$F_{rel}(\%) = \left[\frac{U_\infty \text{ (gum)}}{U_\infty \text{ (tablet)}}\right]\left[\frac{D \text{ (tablet)}}{D \text{ (gum)}}\right] \times 100 \qquad \text{(Eq. 1)}$$

**Statistical Analysis**—A paired $t$ test was used to determine the significance of differences in the mean total aspirin bioavailability between the gum and the tablet, respectively. A one-way analysis of variance was used to determine the significance of the effect of chewing time on the amount of aspirin recovered from chewed gum.

## RESULTS AND DISCUSSION

Table I lists the mean ± *SE* amounts of total salicylate (in terms of equivalent aspirin) excreted in the urine at various intervals up to 24 hr following dosing. After tablet administration, a mean ± *SE* of 91.2 ± 1.7% of the aspirin dose was recovered in the urine. This percentage of dose recovered is consistent with the values reported by other investigators (16, 17) who recovered virtually 100% of the aspirin dose as metabolites in the urine. The analytical method used in this study to measure total salicylate in urine accounts for aspirin, salicylic acid, and all other metabolities. Collection of total urine for 24 hr also provides enough time for recovery of essentially all of the dose based on a plasma elimination half-life of salicylate of 3 hr after a single dose of ~650 mg (18). When aspirin gum was chewed, only 63.5 ± 2.9% (mean ± *SE*) of the dose was recovered.

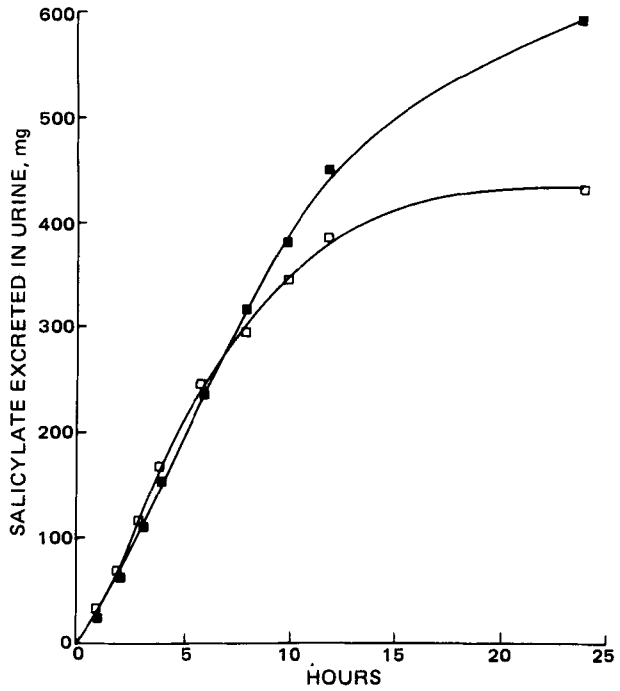

**Figure 1**—*Mean cumulative urinary salicylate (expressed as milligrams of aspirin) excretion curves for six subjects following administration of three aspirin gum pieces (680.4 mg) (□) or two aspirin tablets (648 mg) (■).*

Figure 1 shows the mean cumulative urinary excretion curves for six subjects following administration of gum and tablet dosage forms. Differences in the rate and extent of bioavailability are reflected in the shape of the curves. For up to 6 hr following dosing, the curves are practically superimposable, so it may be concluded that the dosage forms are bioequivalent in terms of bioavailability rate. However, beyond 6 hr, both curves begin to diverge and approach different asymptotic values. The total amounts (mean ± *SE*) of aspirin equivalent excreted in the urine 24 hr following the administration of the tablets and the gum were 592.6 ± 11.2 and 433.6 ±19.8 mg, respectively. The difference between dosage forms in the total amount of salicylate excreted shows that the extent of aspirin gum bioavailability was less than that of aspirin tablets.

The individual cumulative amount of total salicylate recovered in the urine at 24 hr following dosing and the relative bioavailability of aspirin gum are shown in Table II. The differences in total salicylate recovered in the urine were significant ($p < 0.05$), and the bioavailability of aspirin gum ranged from 61.0 to 81.0% (mean ± *SE* of 69.5 ± 3.4%). Since the renal clearance of free salicylate is pH dependent, urine pH possibly may influence the excretion pattern of aspirin metabolites and affect the evaluation of aspirin bioavailability. The pH of each urine sample col-

| 15 | 213.6 | 261.9 | 276.5 | 202.2 | 238.6 ± 18.2 |
| 30 | 170.4 | 209.5 | 217.0 | 242.1 | 209.8 ± 14.9 |

lected during the study was recorded, and average pH values of all urine samples collected following administration of the tablet and gum were 6.1 and 6.3, respectively. The differences in urine pH between the two sets of urine samples were not significant ($p > 0.05$) using a paired $t$ test, and it was concluded that urine pH did not influence the determination of relative bioavailability.

The amounts of salicylate remaining in the gum for each individual volunteer after chewing for 15 min are listed in Table III. The average amount of salicylate remaining in the gum represents 37.8% of the dose administered. When added to the 24-hr urinary recovery of salicylate, the amount of total salicylate in the chewed gum mass accounted for 101.6 ± 2.0% (mean ± *SE*) of the administered dose. Therefore, it may be concluded that the difference in the extent of bioavailability between aspirin gum and tablets is due to salicylate becoming entrapped or bound to the gum base during chewing.

Table IV shows the effect of chewing time on the amount of salicylate retained in the gum base. After 5 min, the average amount of salicylate in the chewed gum was equivalent to 42.7% of the administered dose. For chewing times of 10, 15, and 30 min, the average percentages of dose remaining in the gum between 5 min and the other chewing times were not significant ($p > 0.05$); therefore, the use of a 15-min chewing time in the bioavailability study did not influence the determination of relative bioavailability.

In aspirin bioavailability studies where single doses in excess of ~500 mg are used, consideration must be given to the possible effects of dose-dependent kinetics on the determination of relative bioavailability. This is particularly crucial in bioavailability studies based on the measurement of serum salicylate concentrations where dose-dependent kinetics may influence the shape of the serum concentration–time curve and possibly bias bioavailability calculations. In this study, total aspirin bioavailability for the gum and tablet was determined in terms of salicylate by analysis of total salicylate recovery in the urine for up to 24 hr. This type of bioavailability study design for aspirin eliminates any bias due to dose-dependent kinetics. In addition, measurement of total salicylate in the urine provides the most accurate estimation of total bioavailability because it masks intra- and interpatient variability in rates of salicylate absorption and metabolism which may affect the size and shape of a serum salicylate–time curve (19).

Since few studies have correlated relative bioavailability with relative therapeutic efficacy, the clinical significance of the inferior bioavailability of aspirin gum is unclear. However, many studies have shown aspirin to be superior to placebo in the treatment of pain, and it is generally thought that the onset and magnitude of pain relief are a function of the rate and extent of aspirin bioavailability from its dosage form. No published studies document the effectiveness of aspirin gum as a systemic analgesic, and, based on the data presented in this report, it may be concluded that two 324-mg aspirin tablets will provide as much salicylate to the general circulation as four 227-mg aspirin gums. Furthermore, the usual recommended adult dose of aspirin gum which is two pieces, is less than the minimum therapeutic dose of 324 mg.

# Influence of Administration Route on Drug Delivery to a Target Organ

**SVEIN ØIE** ˣ **and JIN-DING HUANG**

Received November 3, 1980, from the *Department of Pharmacy, School of Pharmacy, University of California, San Francisco, CA 94143.* Accepted for publication April 16, 1981.

**Abstract** □ Mathematical relationships describing the delivery of drug to a target organ after intra-arterial, intravenous, and oral administration are presented. This discussion clearly demonstrates that administration into a blood vessel leading to the target organ often is superior to intravenous administration. However, this superiority is not clear from traditional plasma concentration monitoring data.

**Keyphrases** □ Drug delivery—to a target organ, influence of administration route, mathematical relationships □ Administration routes—influence on drug delivery to a target organ, mathematical relationships □ Mathematical models—influence of administration route on drug delivery to a target organ

When the rate and extent of drug absorption is of concern, the first choice for drug delivery is usually the intravenous route. Intravenous administration delivers drug directly into the bloodstream and virtually assures almost immediate delivery to the target organ(s). Because there is no drug loss at the administration site, a drug delivered intravenously is considered to be completely available to the body. However, if a drug were to precipitate during an intravenous injection due to poor solubility in plasma, distribution of the drug would be delayed. The precipitated drug would eventually redissolve and be distributed to the remainder of the body. Thus, the site of precipitation can be viewed as a site of retention rather than a site of loss.

Although no drug is lost at the administration site, there exists the possibility for drug loss in the body prior to its reaching the site of measurement or the target organ. For example, if a drug is administered intravenously, the drug must first traverse the lungs before it can be further distributed in the body. Thus, any drug eliminated in the lungs reduces the amount of drug available to the other organs (1). Furthermore, only a fraction of the drug not metabolized by the lungs leaves the left ventricle for the target organ. The remaining drug leaving the left ventricle circulates to other tissues and organs where elimination can occur before recirculation to the target organ is possible.

One way to circumvent the potential for drug loss is to administer the drug intra-arterially, *i.e.*, directly into an artery leading to the target organ (2, 3). Although intra-arterial injections are more difficult than venipuncture to perform, as well as being more uncomfortable for the patient, it is sometimes the preferred route (3–7). Intra-arterial drug administration ensures that the entire dose administered will reach the target organ.

Because little information exists in this area, no clearcut parameters have been established to determine the superiority of one administration route over another. Utilization of pharmacokinetic principles may prove to be useful.

The following report discusses mathematical relationships describing: (*a*) the amount of drug delivered to the target organ by both intra-arterial and intravenous administration routes, and (*b*) the amount of drug reaching the liver after an oral dose if the liver is the target organ. This latter situation parallels that of an intra-arterial injection into an artery leading to a target organ except that the drug must traverse the GI tract where loss can occur prior to its reaching the liver.

## KINETIC MODEL

A flow model for drug disposition, described in Scheme I, is used in this discussion. Compartment 1 is the lungs, receiving blood from the right ventricle; compartments 2 through $n$ represent the remainder of the body, compartmentalized and receiving blood from the left ventricle. Compartments 2 through $m$ are all capable of eliminating the drug and comprise the liver (Compartment 3), the mesenteric vascular bed (Compartment 2), the kidneys, *etc.*; compartment $m + 1$ to $n$ represents the organs and tissues incapable of eliminating the drug and are, therefore, considered to be storage compartments.

The blood clearance of any compartment ($Cl_i$) reflects the elimination rate with respect to the whole blood concentration entering the compartment ($C_{in}$) and not the concentration in the compartment itself (which would represent the intrinsic clearance of the compartments). From steady-state values, this is expressed as:

$$Cl_i = \left(\frac{dA_i/dt}{C_{in}}\right)_{ss} \qquad \text{(Eq. 1)}$$

where $dA_i/dt$ is the rate of elimination in compartment $i$, and $ss$ denotes steady-state conditions. More important, however, is the fact that clearance can be determined from the total amount eliminated from time zero to time infinity by the organ $[\int_0^\infty (dA_i/dt)\,dt]$ and the total area under the blood concentration *versus* time-curve from time zero to time infinity ($\int_0^\infty C_i\,dt$) entering the organ; *i.e.*:

$$Cl_i = \frac{\int_0^\infty (dA_i/dt)\,dt}{\int_0^\infty C_{in}\,dt} \qquad \text{(Eq. 2)}$$

Therefore, the arterial concentration (or left ventricle concentration) is used as a reference blood concentration for most organs. This procedure is identical to using the venous blood concentration from a storage compartment as the reference concentration. However, pulmonary clearance is defined with respect to the right ventricle concentration, although it is relatively easy to convert pulmonary clearance from its present definition ($Cl'_1$) to one with respect to left ventricle concentration ($Cl_1$) by using the following relationship:

$$Cl_1 = Cl'_1 \Big/ \left(1 - \frac{Cl'_1}{Q_1}\right) \qquad \text{(Eq. 3)}$$

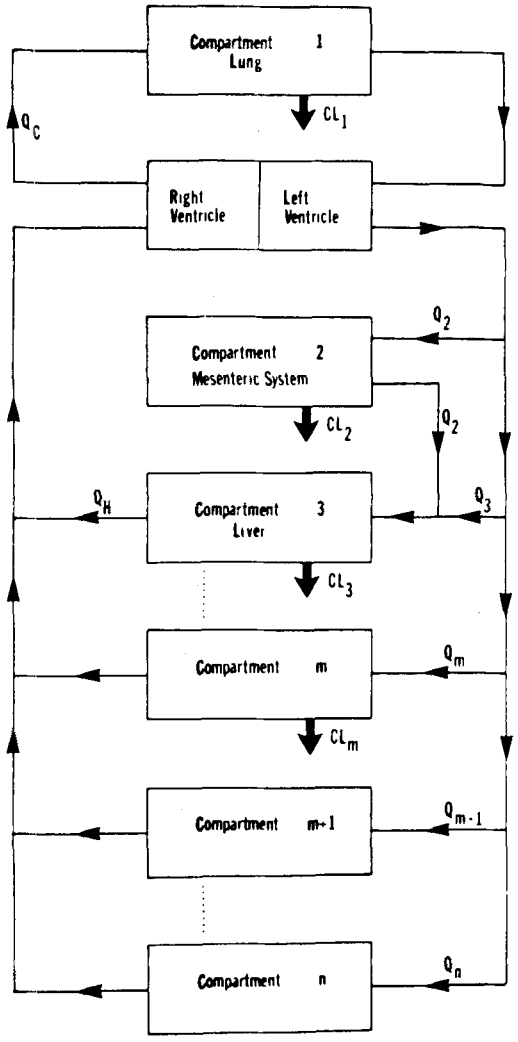
where $Q_1$ is the pulmonary blood flow that is equal to the total cardiac output ($Q_C$). If the pulmonary clearance is low, the two clearances are essentially the same. Only if the pulmonary clearance is large is it necessary to make the conversion.

**Intra-Arterial Injection into Artery Leading to Target Organ**—If the target organ is $m$, the amount delivered to this organ ($A_{E,m}$) from time zero to time infinity is equal to:

$$A_{E,m} = D + \int_0^\infty C_L Q_m\,dt \qquad \text{(Eq. 4)}$$

where $D$ is the dose administered, $C_L$ is the left ventricle blood concentration, and $Q_m$ is the blood flow to the target organ. Blood flow is assumed to be time and concentration independent. The term $\int_0^\infty C_L\,dt$ can be obtained by the following development:

*0022-3549/81/1200-1344$01.00/0*
*© 1981, American Pharmaceutical Association*



*Scheme I—Pharmacokinetic model of drug disposition.*

The fraction ($F_{L,i}$) of the drug delivered to an eliminating organ that leaves the same compartment is:

$$F_{L,i} = 1 - \text{fraction lost} = 1 - \frac{A_{\text{lost},i}}{A_{E,i}} = 1 - \frac{\int_0^\infty (dA_i/dt)\,dt}{\int_0^\infty Q_i C_{\text{in}}\,dt} \qquad \text{(Eq. 5)}$$

From Eqs. 2 and 5:

$$F_{L,i} = 1 - \frac{Cl_i}{Q_i} \qquad \text{(Eq. 6)}$$

The amount leaving the left ventricle ($A_{L,L}$) from time 0 to time infinity is equal to:

$$A_{L,L} = \sum_{i=2}^{m} \int_0^\infty C_L Q_i\,dt = Q_C \int_0^\infty C_L\,dt \qquad \text{(Eq. 7)}$$

where $Q_C$ is the cardiac output.

The total amount entering the left ventricle ($A_{E,L}$) is expressed by:

$$A_{E,L} = \int_0^\infty C_R Q_C \left(1 - \frac{Cl_1'}{Q_C}\right) dt = (Q_C - Cl_1') \int_0^\infty C_R\,dt \qquad \text{(Eq. 8)}$$

where $C_R$ is the blood concentration in the right ventricle. The amount leaving the right ventricle ($A_{L,R}$) can be expressed by:

$$A_{L,R} = \int_0^\infty C_R Q_C\,dt = Q_c \int_0^\infty C_R\,dt \qquad \text{(Eq. 9)}$$

By using the fraction lost in each eliminating compartment as expressed in Eq. 6, the total amount entering the right ventricle ($A_{E,R}$) can readily be obtained:

$$A_{E,R} = \int_0^\infty C_L \left[Q_2\left(1 - \frac{Cl_2}{Q_2}\right) + Q_3\right]\left(1 - \frac{Cl_3}{Q_2 + Q_3}\right) dt + \left[\sum_{i=4}^{m} C_L Q_i \left(1 - \frac{Cl_i}{Q_i}\right) dt\right] + \left(\sum_{i=m+1}^{n} \int_0^\infty C_L Q_i\,dt\right) + D\left(1 - \frac{Cl_m}{Q_m}\right) \qquad \text{(Eq. 10)}$$

The first part of the right-hand side of Eq. 10 takes into account that part of the hepatic blood flow which must pass through the GI tract *via* the mesenteric system before reaching the liver *via* the portal vein.

With the assumption that no elimination occurs in the ventricles, the amount leaving each ventricle from time zero to time infinity is equal to the amount entering. By combining Eqs 7–10 and defining $Q_2 + Q_3$ as the hepatic blood flow ($Q_H$), the following is obtained:

$$\int_0^\infty Cl\,dt = \frac{D\left(1 - \frac{Cl_m}{Q_m}\right)}{\frac{Cl_1' Q_C}{Q_C - Cl_1'} + \left(\sum_{i=2}^{m} Cl_i\right) - \frac{Cl_2 Cl_3}{Q_H}} \qquad \text{(Eq. 11)}$$

By combining Eqs. 4 and 11, the total amount entering the target organ after an intra-arterial injection into an artery leading to this organ is:

$$A_{E,m} = D\left(1 + \frac{Q_m - Cl_m}{\frac{Cl_1' Q_C}{Q_c - Cl_1'} + \left(\sum_{i=2}^{m} Cl_i\right) - \frac{Cl_2 Cl_3}{Q_H}}\right) \qquad \text{(Eq. 12)}$$

Furthermore, by combining Eqs. 3 and 12 to express all clearances with respect to the left ventricle concentration, the following is obtained:

$$A_{E,m} = D\left(1 + \frac{Q_m - Cl_m}{\left(\sum_{i=1}^{m} Cl_i\right) - \frac{Cl_2 Cl_3}{Q_H}}\right) \qquad \text{(Eq. 13)}$$

As can be seen from Eq. 13, the total amount reaching the target organ after an intra-arterial injection depends not only on the dose but also on the blood flow to this organ, its clearance, portal blood flow, and cardiac output, as well as the various clearances in the different parts of the body (see *Discussion*).

**Intra-Arterial Injection into Artery Not Leading to Target Organ**—In this case, the amount administered is assumed to be injected into Compartment $m - 1$ instead of the target organ, Compartment $m$. Thus, the amount delivered to Compartment $m$ is:

$$A_{E,m} = \int_0^\infty C_1 Q_m\,dt \qquad \text{(Eq. 14)}$$

Similarly to Eq. 13, $A_{E,m}$ can be expressed as:

$$A_{E,m} = D\frac{Q_m\left(1 - \frac{Cl_{m-1}}{Q_{m-1}}\right)}{\left(\sum_{i=1}^{m} Cl_i\right) - \frac{Cl_2 Cl_3}{Q_H}} \qquad \text{(Eq. 15)}$$

**Intravenous Bolus Dose Administration**—This situation is equivalent to delivering the drug directly into the right ventricle. In this case, by using similar development as in the two previous sections, the amount delivered to the target organ can be shown to be equal to:

$$A_{E,m} = \frac{DQ_m}{\left(\sum_{i=1}^{m} Cl_i\right) - \frac{Cl_2 Cl_3}{Q_H}} \qquad \text{(Eq. 16)}$$

**Oral Dose When Target Organ Is Liver**—The amount of an oral dose delivered to the liver ($A_{E,3}$) is equal to the amount leaving the GI tract [$D(1 - G)$] and escaping elimination in the GI wall. It is assumed that this amount is equal to the fraction that usually escapes elimination in the mesenteric system, $1 - (Cl_2/Q_2)$, plus the amount delivered *via* the vascular system through recirculation:

$$A_{E,3} = \int_0^\infty C_L \left[Q_2\left(1 - \frac{Cl_2}{Q_2}\right) + Q_3\right] + (1 - G)\left(1 - \frac{Cl_2}{Q_2}\right) \qquad \text{(Eq. 17)}$$

Using a similar development as for Eq. 10 and defining $(1 - G)$ [$1 - (Cl_2/Q_2)$] as $(1 - E)$, one obtains:

$$A_{E,3} = D\,(1-E)\left[1+\frac{(Q_H - Cl_2)\left(1-\frac{Cl_3}{Q_H}\right)}{\left(\sum_{i=1}^{m} Cl_i\right)-\frac{Cl_2Cl_3}{Q_H}}\right] \qquad \text{(Eq. 18)}$$

**Intravenous Dose When Target Organ is Liver**—The amount of drug delivered to the liver in this situation is equal to:

$$A_{E,3} = \int_0^\infty C_L\left[Q_2\left(1-\frac{Cl_2}{Q_2}\right)+Q_3\right] \qquad \text{(Eq. 19)}$$

By using a similar development as before, it can be demonstrated that:

$$A_{E,3} = \frac{D(Q_H - Cl_2)}{\left(\sum_{i=1}^{m} Cl_i\right)-\frac{Cl_2 - Cl_3}{Q_H}} \qquad \text{(Eq. 20)}$$

## DISCUSSION

**Intra-Arterial Injection Leading to Target Organ *versus* Intravenous Injection**—The ratio of the amount of drug entering the target organ from the intra-arterial to the intravenous injection ($Y_T$) can be obtained from Eqs. 13 and 16:

$$Y_T = 1+\frac{\left(\sum_{i=1}^{m-1} Cl_i\right)-\frac{Cl_2Cl_3}{Q_H}}{Q_m} \qquad \text{(Eq. 21)}$$

Because $Q_H$ always is larger than $Cl_2$ or $Cl_3$, this relationship is always greater than one as long as $\Sigma_{i=1}^{m-1} Cl_i$ is not zero. Therefore, Eq. 21 demonstrates that an intra-arterial injection of a drug into an artery leading to the target organ always delivers more drug to the target organ than an intravenous bolus dose. The single exception is when only the target organ eliminates the drug since then the two modes of administration are identical.

The advantage of intra-arterial administration increases under the following circumstances:

1. Lung clearance is high. In this case, the intravenously administered drug has to pass through the lungs and be partially metabolized before it can reach the target organ.
2. Elimination by other organs is high in comparison to target organ blood flow. In this case, a large amount of drug leaving the left ventricle per heart beat circulates to various organs where possibilities for elimination exist. Therefore, only a fraction of the drug is returned to the general circulation for recirculation to the target organ. This conclusion, however, is not readily determined from regular concentration monitoring data or from evaluation of bioavailability.

Bioavailability is practically determined as the amount delivered to the site of measurement from a test dose to that of a control dose. By considering the intra-arterial dose as the test dose, the intravenous dose as the control, and, for simplistic reasons, the sampling site as the venous side of storage compartment $n$, the bioavailability ($F$) can be expressed as:

$$F_T = \frac{\left(\int_0^\infty ClQ_n\,dt\right)\text{ intra-arterially}}{\left(\int_0^\infty ClQ_n\,dt\right)\text{ intravenously}} \qquad \text{(Eq. 22)}$$

Derivation yields:

$$F_T = 1-\frac{Cl_m}{Q_m} \qquad \text{(Eq. 23)}$$

This result indicates that an intravenous dose always delivers more drug to the sampling site than an intra-arterial injection. Therefore, use of this site to evaluate various drug administration routes may be inadequate and misleading.

A similar conclusion can be drawn from the theoretical evaluation of intra-arterial *versus* intravenous administration of chemotherapeutics by Chen and Gross (8). They evaluated a slightly different kinetic flow model, and their clearances were defined in terms of the intrinsic clearance values of the various organs at steady state. Again, however, an advantage of intra-arterial injections with respect to delivery to the target organ was observed ($Y_T$), in conjunction with a decreased systemic availability ($F_T$).

**Intra-Arterial Injection Not Leading to Target Organ *versus* Intravenous Injection**—In this case, the ratio of the amount delivered to the target organ from the various administration routes ($Y_N$) can be obtained from Eqs 14 and 15:

$$Y_N = 1-\frac{Cl_{m-1}}{Q_{m-1}} \qquad \text{(Eq. 24)}$$

and bioavailability is expressed by:

$$F_N = 1-\frac{Cl_{m-1}}{Q_{m-1}} \qquad \text{(Eq. 25)}$$

In this situation, it is clear that an intravenous dose delivers more drug to the target organ than an intra-arterial dose. The intra-arterial dose has to pass to a nontarget organ ($m-1$) where it can be partially eliminated before it reaches the venous circulation. However, the intravenous dose reaches the venous circulation directly; *i.e.*, if the decision is made to administer a drug intra-arterially, it is imperative to identify the target organ to ensure that the drug is administered into an artery leading to that target organ.

The use of venous drug concentration monitoring or traditional bioavailability determination accurately reflects the relative amounts reaching the target organ by these two administration routes only when intra-arterial administration is into an artery not leading to the target organ.

**Oral Dosing *versus* Intravenous Injection When Target Organ Is Liver**—From Eq. 18, it can be seen that the ratio of drug delivered to the liver by these two routes ($Y_0$) is equal to:

$$Y_0 = (1-E)\left[1+\frac{\left(\sum_{i=1}^{m} Cl_i\right)-Cl_3}{Q_H - Cl_2}\right] \qquad \text{(Eq. 26)}$$

Thus, it is possible to predict when oral administration is advantageous over intravenous injection if the target organ is the liver. However, extensive knowledge of the various clearances for a drug is required. In principle, the larger the fraction of the dose that reaches the liver in its first pass [$(1-E) \rightarrow 1$] and the larger the extrahepatic clearance is in comparison with hepatic blood flow, the greater is the likelihood for an oral dose to be superior to an intravenous injection.

Bioavailability ($F_0$) is equal to:

$$F_0 = (1-E)\left(1-\frac{Cl_3}{Q_H}\right) \qquad \text{(Eq. 27)}$$

This relationship always predicts that the intravenous route is superior to the oral route provided $E$ and $Cl_3$ are not zero.

Using traditional bioavailability determinations to decide on an optimal drug delivery route may sometimes be misleading. Based on this discussion, it appears that when blood (or plasma) concentration in a peripheral vein is used for determining the best administration route, the choice will invariably be the intravenous route. However, alternative routes are sometimes able to delivery more drug to the target organ than an intravenous dose. Therefore, care should be taken in drug plasma monitoring or the use of steady-state plasma concentrations or bioavailability data when different administration routes are considered for optimization of drug therapy.

On the other hand, if two dosage formulations given *via* the same route are compared, such reservation is not necessary. In this case, the drug traverses the same path before it reaches the measurement site or the target organ. Therefore, the ratio of the amount delivered to the measurement site accurately reflects the ratio reaching the target organ.

This discussion should not be considered as being limited to the two special examples provided. The same conclusions can be reached in other situations, such as intramuscular injection when the muscle is the target organ, inhalation when the lung is the target organ, and intrathecal injection when the spinal nerves are the target.

# Determination of Flurbiprofen and Ibuprofen in Dog Serum with Automated Sample Preparation

**B. G. SNIDER ˣ, L. J. BEAUBIEN, D. J. SEARS, and P. D. RAHN**

Received December 1, 1980, from the *Control Research Laboratories, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication April 23, 1981.

**Abstract** □ Methods for the determination of flurbiprofen and ibuprofen in dog serum were developed using high-performance liquid chromatography and automated serum extraction. Sample extraction was automated by use of cartridges packed with a styrene–divinylbenzene macroreticular resin in a microprocessor-controlled centrifugal system. The average recoveries were 98.9% for flurbiprofen and 94.5% for ibuprofen. The limits of detection were ~0.04 μg/ml for flurbiprofen at 254 nm and 0.5 μg/ml for ibuprofen at 230 nm. The relative standard deviations for the determination of a laboratory standard between days was 2.4% (20 μg/ml) for flurbiprofen and 1.7% (13 μg/ml) for ibuprofen. Peak height ratios were linear with concentrations of 0.04–100 μg/ml for flurbiprofen and 1.0–50 μg/ml for ibuprofen. These methods are simple, rapid, sensitive, and specific. The use of an automated sample preparation procedure improved the between-day precision by a factor of two when compared to a manual extraction procedure. These methods were applied to bioavailability studies in dogs.

**Keyphrases** □ Flurbiprofen—determination in dog serum with automated sample preparation □ Ibuprofen—determination in dog serum with automated sample preparation □ Bioavailability—determination of flurbiprofen and ibuprofen in dog serum with automated sample preparation

Flurbiprofen [*dl*-2-(2-fluoro-4-biphenylyl)propionic acid] and ibuprofen [*dl*-2-(*p*-isobutylphenyl)propionic acid] are nonsteroidal anti-inflammatory drugs. Several gas chromatographic (GC) procedures were previously developed for flurbiprofen (1) and ibuprofen (2–4). Methods using high-performance liquid chromatography (HPLC) were previously developed for ibuprofen (5, 6) and similar compounds: indoprofen (7), ketoprofen (8), and naproxen (8). To reduce the amount of labor and time involved in performing assays for flurbiprofen or ibuprofen in serum, an HPLC procedure using an automated sample processor[1] was developed. The previously developed GC procedures use manual liquid–liquid sample preparations and derivatization prior to analysis. Sample extraction with the automated sample processor uses a liquid–solid extraction with a cartridge packed with a styrene–divinylbenzene macroreticular resin in a microprocessor-controlled centrifugal system, resulting in reduced analysis effort and improved assay precision.

## EXPERIMENTAL

**Reagents and Materials**—Reagents were of at least analytical reagent grade quality, and acetonitrile[2] was distilled-in-glass grade. Stock solutions of flurbiprofen[3] and ibuprofen[3] were prepared in pH 7.2 phosphate buffer (0.05 *M*).

**Instrumentation**—A variable-wavelength detector[4], a solvent pump[5], and an autoinjector[6] were used for the chromatographic analysis. Preparation of samples was performed with an automated sample processor.

**Chromatographic Conditions**—Chromatography took place on a 0.46-cm i.d. × 25-cm long column packed with octadecylsilane bonded to microparticulate silica[7] (10 μm). The precolumn, 4.2 cm × 0.3-cm i.d., was packed with octadecylsilane bonded to microparticulate silica[8] (30 μm). The mobile phase was acetonitrile–0.05 *M* acetic acid (40:60).

The flow rate was 2.0 ml/min, the column temperature was ambient, and the column back-pressure was ~1500 psi. The approximate retention times of flurbiprofen and ibuprofen were 14 and 19 min, respectively. Preliminary work was performed with the acetonitrile–water ratio at 50:50 and the flow rate at 1.2 ml/min. The mobile phase was filtered and deaerated by vacuum sonication prior to use.

**Automated Extraction**—The automated sample processor is designed to perform automatic extractions simultaneously of up to 12 liquid samples in 30 min or less. Centrifugal force is used to move solvents through an extraction resin bed. The system is composed of an inner rotor, which holds extraction columns, and a larger outer rotor, which holds the corresponding effluent and recovery cups. The extraction column is comprised of a sample reservoir and a resin bed. The rotor first spins clockwise to force the sample through the resin bed. A predetermined amount of wash solvent is forced through the resin bed and into an effluent cup. In this manner, unwanted components are removed from the column. The rotor direction is then reversed so that the extraction column is positioned over the recovery cup.

An aliquot of a second solvent elutes the component of interest and is collected in the recovery cup. If desired, the extract is then heated and blown to dryness. The dried extract is manually reconstituted and transferred to another instrument. Fifteen programs are currently available which vary timing, compartment temperature, and the option of sample evaporation.

**Assay Procedure**—Blank serum spiked with 100 μl of flurbiprofen or ibuprofen solutions in 0.05 *M* phosphate buffer (pH 7.2) was used to prepare standards to obtain a calibration curve for each chromatographic run. One milliliter of blank or sample serum was pipetted into the car-

**Table I—Effect of Mobile Phase pH and Percent Acetonitrile on the Retention Times of Flurbiprofen and Ibuprofen (1.0 ml/min)**

| Acetonitrile, % | pH | Retention Time of Flurbiprofen, min | Retention Time of Ibuprofen, min |
|---|---|---|---|
| 60 | 3 | 6.3 | 7.8 |
| 55 | 3 | 6.9 | 8.7 |
| 50 | 3 | 9.6 | 12.6 |
| | 4 | 7.8 | 11.1 |
| | 5 | 5.4 | 8.7 |
| 40[a] | 3 | 17.0 | 22.0 |

[a] At 2.0 ml/min.

tridges. Standard cartridges were spiked with the appropriate stock solution and were rotated to promote mixing. A 0.2-ml aliquot of 0.5 *M* $H_2SO_4$ was added to each cartridge, which then was rotated to promote mixing. The cartridges were loaded into the automated sample processor. Water and methanol were added to the appropriate reservoirs in amounts sufficient to wash each cartridge with 1.0 ml of water and elute each cartridge with 2.0 ml of methanol. The addition of the washing and eluting solvents and the evaporation of the methanol by blowing air at 50° over the aluminum recovery cups were performed by the automated sample processor. The dried contents of the recovery cups were dissolved in the mobile phase. To determine ibuprofen at 10 μg/ml, the cups were reconstituted with 1 ml of mobile phase containing 6.0 μg of flurbiprofen/ml as the internal standard, and 0.2-ml aliquots of the reconstituted samples were chromatographed. In the determination of flurbiprofen, mobile phase containing ibuprofen was used to reconstitute the samples.

Peak heights were measured for flurbiprofen and ibuprofen, and the peak heights for the analyte were divided by that of the internal standard. Linear least-squares fit of the peak height ratios was used to calculate the serum drug concentration.

**Drug Administration**—Male beagle dogs were fasted for 16 hr prior to dosing and for 4 hr after administration. Flurbiprofen and ibuprofen were dosed as solutions of sodium salts (pH 7) in a hard gelatin capsule. For ibuprofen, 4 ml of a 20 mg/ml solution was administered to each dog; for flurbiprofen, 4 ml of a 12.5 mg/ml solution was administered. Blood was collected in 10-ml evacuation tubes and allowed to clot. Separated serum was stored at −18° prior to analysis.

## RESULTS AND DISCUSSION

**HPLC**—For the determination of flurbiprofen in the 0.04–2-μg/ml range, a mobile phase of acetonitrile–0.1 *M* acetic acid (50:50) was used with UV detection at 254 nm. The effect of the mobile phase pH and percent acetonitrile on the retention times of flurbiprofen and ibuprofen are shown in Table I. By using a low pH for the mobile phase, ion-pairing is not necessary for adequate retention of the two compounds. The relative retention times of some metabolites of flurbiprofen are shown in Table II, and all are well resolved from flurbiprofen as well as ibuprofen. The major metabolite in dogs is 4′-hydroxyflurbiprofen (9). At 254 nm, the molar absorbtivity of ibuprofen was only 1.2% that of flurbiprofen.

To determine flurbiprofen above 10 μg/ml, the ibuprofen concentration needed to provide equivalent responses became quite large, and problems occurred with low ibuprofen recovery with the manual extraction procedure. Therefore, UV absorbance was monitored at 230 nm to optimize ibuprofen sensitivity and still have adequate sensitivity for flurbiprofen. However, a peak that eluted at approximately the same retention time as ibuprofen was observed, and the mobile phase was changed to acetonitrile–0.05 *M* acetic acid in water (40:60) at 2.0 ml/min to separate this interfering peak from ibuprofen. A typical chromatogram of extracted blank serum and serum spiked with flurbiprofen and ibuprofen is shown in Fig. 1.

**Isolation of Flurbiprofen and Ibuprofen from Serum**—Various

**Table II—Relative Retention Times of Flurbiprofen, Ibuprofen, and Flurbiprofen Metabolites**

| Compound | Relative Retention Time, min |
|---|---|
| Flurbiprofen | 1.0 |
| Ibuprofen | 1.3 |
| 2′-Hydroxyflurbiprofen | 0.56 |
| 4′-Hydroxyflurbiprofen | 0.50 |
| 3′-Hydroxyflurbiprofen | 0.53 |

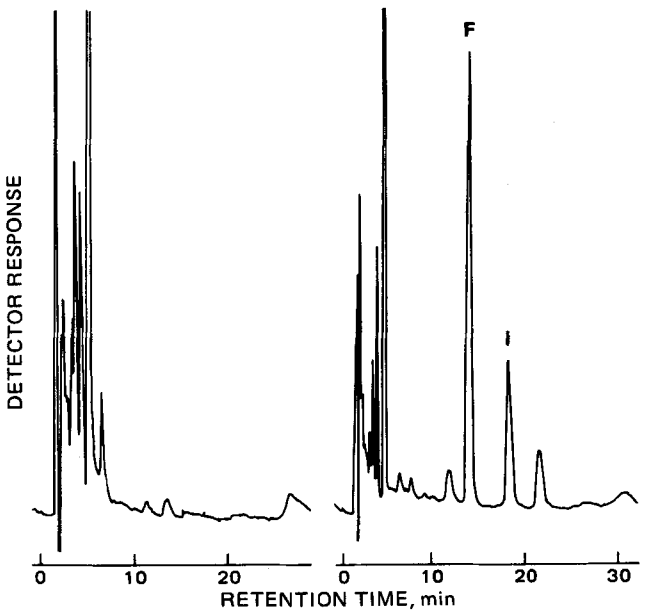

**Figure 1**—*HPLC chromatograms of drug serum extracts. Key: left, serum sample without administration of drug; and right, serum sample containing flurbiprofen (F) (6.0 μg/ml) and ibuprofen (I) (10 μg/ml).*

methods for the isolation of flurbiprofen and ibuprofen from serum were investigated. Precipitation of serum proteins with acetonitrile followed by analysis of the supernate was suggested as an alternative method for serum sample preparation (7). However, for flurbiprofen and ibuprofen, very low recoveries were obtained when this method was used, and the supernate contained a large amount of dissolved solids. Acidifying the serum before addition of acetonitrile improved recovery, but this approach was discontinued because of problems with injecting large amounts of acid. An extraction procedure developed previously (1) was used, except that toluene was substituted for benzene in the extraction, and the sample cleanup steps involving TLC were omitted. An automated sample extraction procedure was also developed and compared to the manual extraction procedure.

To optimize the automated extraction procedure, several different eluting solvents were investigated and the amounts of wash solvent, and eluting solvent, and the acid added were varied. These experiments attempted to reduce the amount of insoluble material acquired in extraction, to obtain quantitative recovery, and to minimize the number of extraneous peaks produced in the chromatogram. The more polar eluting solvents tended to yield cleaner reconstituted samples. The extent to which the serum was acidified influenced both flurbiprofen recovery and the number of extraneous peaks displayed in the chromatogram. Unacidified serum yielded 37% recovery. One late-eluting peak was eliminated by reducing the amount of acid used from 250 to 200 μl. For each extraction column, the use of 1.0 ml of water (wash solvent), 2.0 ml of methanol (eluting solvent), and 200 μl of 0.5 *M* $H_2SO_4$ produced the cleanest samples with the greatest recovery.

**Assay Linearity, Precision, and Accuracy**—Linearity of peak height ratios with the concentration of flurbiprofen and ibuprofen was investigated. Calibration curves prepared from serum spiked with the appropriate amounts of flurbiprofen or ibuprofen showed no significant deviation from linearity in the 0.04–100-μg/ml range for flurbiprofen and in the 1–200-μg/ml range for ibuprofen. Correlation coefficients for the fit of the experimental points to a line were between 0.998 and 1.000. The intercepts were not significantly different from zero in all cases, and no interferences from constituents in blank serum were found.

The extraction efficiency was determined over the same ranges as those for the linearity, and the average recoveries were 98.9 ± 3.3% and 94.5 ± 1.2% for flurbiprofen and ibuprofen, respectively.

To investigate the precision of the extraction process, six runs with six samples each of a pooled serum sample containing 20 μg of flurbiprofen/ml were prepared. The mean relative standard deviation of the extraction within the six samples was ~1.8%. The relative standard deviation for different runs of the automated sample processor was ~1.3%. Therefore, the extraction process was reproducible both within run and between run. This precision was obtained without adding the internal

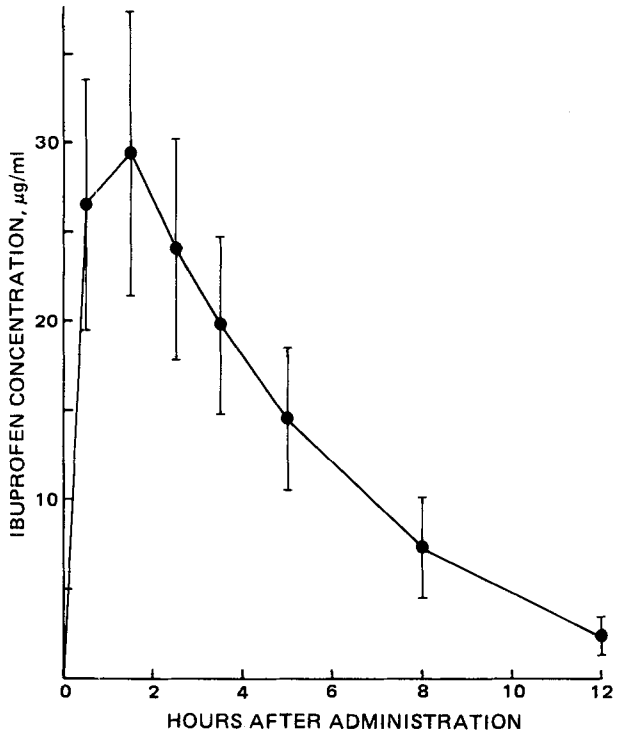

**Figure 2**—*Average (±SD) serum ibuprofen concentrations in male beagle dogs (n = 8, average weight 14.9 ± 2.2 kg) after single oral administration of 80 mg of ibuprofen as a solution of the sodium salt.*

standard prior to extraction, thus reducing the number of steps required for the assay.

The reproducibility of the entire assay was later demonstrated when a set of 300 samples was assayed in eight chromatographic runs of 16 hr each. The average of the laboratory standard (a pooled sample of serum) over the 8 days was 26.3 μg/ml, and the relative standard deviation was 2.4%. The relative standard deviation of standards in the 5–100 μg/ml concentration range was 3.2–0.8%. The relative standard deviation of the slope was 4%. The reproducibility of the extraction from day to day was a considerable improvement over the manual extraction procedure, which typically had a 6.0% *RSD* for the laboratory standard.

**Assay Sensitivity**—With a UV detector at 0.05 aufs, assay sensitivities based on a signal 2% of full scale were 1 and 2 μg/ml for flurbiprofen and ibuprofen, respectively, for a 0.06-ml injection from a reconstituted volume of 2 ml. When the dried extract was reconstituted in 1 ml and 0.2 ml was injected, the sensitivity was improved to 0.5 μg/ml for ibuprofen and to 0.2 μg/ml for flurbiprofen. Flurbiprofen can be determined at levels as low as 0.04 μg/ml if a 254-nm detector is used because absorbance is at a maximum at 248 nm and a single-wavelength detector at 254 nm has a higher signal to noise ratio than a variable-wavelength detector.

**Assay Problems**—Only a few problems occurred using the automated sample processor. Occasionally, the flow of samples through the cartridge was too slow, and water was left at the top of the cartridge at the end of analysis. This can result from insoluble material in the sample plugging the cartridge and from the cartridge drying out and flow becoming too slow. The first problem can be solved by filtering the sample, and placing an expiration date on the cartridge minimizes the second problem. The incidence of these problems was infrequent (~1%). The cartridges can be prescreened for suitability by placing 1.0 ml of water in them and checking to see if all of the water flowed through the cartridge in <1 min under the conditions typically used to force the serum–buffer mixture through the cartridge.

Another problem observed with ibuprofen was a change in recovery from 95 to 60% for one batch of cartridges when elution with 1 ml of methanol was used. The recovery between cartridges was still reproducible, with the assay variation being approximately the same for this lot as for other lots when 95% recovery was obtained. This finding is not surprising because of the reproducible manner in which the automated sample processor performs the extraction. For example, the relative standard deviation for the addition of eluting solvent to the cartridge was 1.5%. This situation is analogous to the use of a segmented flow system in which transfer of the sample through the various steps may not yield 100% recovery, but the recovery is reproducible from sample to sample. The reason for the dependence of recovery on the lot used involves the different elution properties of various lots of resin. If the standards are extracted with the same lot of cartridges as the samples, the change in recovery will not affect the quantitation unless the recovery becomes quite low. In this case, the detection limit and precision of the assay will be affected. The amount of methanol used for elution was changed to 2 ml/cartridge to minimize this problem, and recovery then increased from 60 to 86%.

**Serum Levels in Dogs**—The average serum concentration curve for the oral administration of 80 mg of ibuprofen is shown in Fig. 2. For ibuprofen, the average peak concentration was 29.4 μg/ml, the average time of individual peak occurrence was 1.5 hr, and the half-life calculated from the terminal slope was 2.8 hr. For flurbiprofen, the average peak concentration was 31.0 μg/ml, the average time of individual peak occurrence was 2.2 hr, and the half-life calculated from the terminal slope was 35 hr.

These methods are suitable for determining the pharmacokinetics of these two drugs and for evaluating drug availability from various dosage forms in dogs.

# Characterization of Albumin Microspheres by Sedimentation Field-Flow Fractionation

KARIN D. CALDWELL, GEORGE KARAISKAKIS *, MARCUS N. MYERS, and J. CALVIN GIDDINGS ×

Received January 19, 1981, from the *Department of Chemistry, University of Utah, Salt Lake City, UT 84112.* Accepted for publication May 12, 1981. *Present address: Department of Chemistry, University of Patras, Patras, Greece.

**Abstract** □ Sedimentation field-flow fractionation (FFF) is a new technique that separates and characterizes submicron particles. In the present work, two independent sedimentation FFF methods are presented to characterize bovine serum albumin microspheres in terms of particle size, polydispersity, and diffusion coefficient. Particle diameters and polydispersities determined by the two sedimentation FFF methods were in excellent agreement with each other and in good agreement with values calculated from transmission electron microscopy (TEM) measurements. The diameters calculated from the two FFF methods and TEM were 0.349, 0.346, and 0.354 μm, respectively.

**Keyphrases** □ Field-flow fractionation—characterization of albumin microspheres □ Microspheres—albumin, characterization by field-flow fractionation □ Particle characterization—by field-flow fractionation

Field-flow fractionation (FFF) is a high-resolution method capable of separating and characterizing a wide variety of macromolecules and particles of submicron and larger size (1, 2). Examples of materials previously studied include lattices (3), viruses (4), proteins (5), emulsions, liposomes, and blood cells.

In FFF, separation occurs in a thin-flow channel. A carrier solution transports components through the channel at different rates and then carries them to a collection device and/or a detector. The rate of migration is controlled by an external field (which retards migration) applied across the channel perpendicular to the flow. Different external fields lead to different "subtechniques" of FFF. Sedimentation FFF is a subtechnique utilizing a gravitational or centrifugal field.

The degree of retention (retardation relative to the carrier solution) in sedimentation FFF is determined by the particle mass and density, field strength, and carrier solution density. Field strength, flow rate, and carrier solution density can be varied to meet the requirements for resolution, analysis time, and maximum particle concentration. A recent review (2) presents details of the apparatus, applications, and a theory of retention.

## THEORY

In sedimentation FFF, particles migrate to one wall of the channel under the influence of centrifugal forces. This motion is counteracted by diffusion. After an appropriate relaxation time, these processes arrive at a steady-state balance, and particles of a given size form a diffuse layer of mean thickness $l$. The magnitude of $l$ is smallest for the largest particles, which interact most strongly with the field. When flow is started in the thin channel, a parabolic flow profile develops, with zero velocity at the walls. Because the speed of elution of a given particle type depends on the mean distance, small particles with large $l$ values elute ahead of large particles.

The degree of retention in FFF is measured by the retention ratio $R$:

$$R = V^0/V_r \qquad \text{(Eq. 1)}$$

where $V^0$ is the void volume of the channel and $V_r$ is the retention volume of the particle zone. For well-retained zones, $R$ is simply related to the dimensionless layer thickness retention parameter, $\lambda = l/w$:

$$R = 6\lambda \qquad \text{(Eq. 2)}$$

The value of $\lambda$ is determined by field strength, particle characteristics, and various experimental parameters. For spherical particles of diameter $d$:

$$\lambda = l/w = 6kT/\pi d^3 w \Delta\rho G \qquad \text{(Eq. 3)}$$

where $w$ is the channel thickness, $k$ is Boltzmann's constant, $T$ is the absolute temperature, $\Delta\rho$ is the difference between particle and carrier solution density, and $G$ is the field strength in units of acceleration. The combination of Eqs. 1–3 yields:

$$d = \left(\frac{36kT}{\pi w\, \Delta\rho G V^0}\right)^{1/3} V_r^{1/3} \qquad \text{(Eq. 4)}$$

From this equation, $d$ can be calculated directly from $V_r$ if the particle density is known.

In addition, the polydispersity and diffusion coefficient of a particulate sample can be calculated from the peak width of the eluted sample as measured by the plate height. The theory of plate height ($H$) in sedimentation FFF specifies that $H$ can be closely approximated by:

$$H = \chi w^2 \langle v \rangle / D + 9L(\sigma_d/d)^2 \qquad \text{(Eq. 5)}$$

where $D$ is the diffusion coefficient of the particles, $\langle v \rangle$ is the mean flow velocity of the carrier solution, $L$ is the channel length, and $\chi$ is the nonequilibrium coefficient, which, under normal conditions of high retention ($\lambda \to 0$), takes the form:

$$\chi = 24\lambda^3 \qquad \text{(Eq. 6)}$$

The $\chi$-containing term in Eq. 5 is for plate height due to nonequilibrium effects. The second term on the right of Eq. 5 represents the polydispersity contribution to $H$, expressed as a function of $\sigma_d$, the standard deviation of the particle diameter within the sample.

Diffusion coefficient $D$ can be expressed in terms of $d$ using the Stokes–Einstein equation:

$$D = kT/3\pi\eta d \qquad \text{(Eq. 7)}$$

where $\eta$ is the viscosity of the carrier solution.

There are two independent methods whereby polydispersity $\sigma_d$ can be calculated from the plate height. In Method A, the value of $d$ is obtained from retention measurements *via* Eq. 4; $D$ can then be calculated in terms of $d$ using Eq. 7. The only remaining unknown, $\sigma_d$, is calculated from Eq. 5 once experimental $H$ values are obtained (*Experimental*). In Method B, the flow rate is varied and a plot of $H$ *versus* $\langle v \rangle$ is prepared. From the slope, $24\lambda^3 w^2/D$, the value of $D$ is obtained. From the intercept, $9L(\sigma_d/d)^2$, the value of $\sigma_d$ can be calculated.

## EXPERIMENTAL

**Apparatus**—The apparatus described previously (2) for sedimentation FFF was used with one modification: the seal employed a polytef O-ring instead of the rubber ones used conventionally. This modification allowed 95% ethanol to be used as a carrier solution. The channel dimensions were length 47.5 × thickness 0.0254 × width 1.00 cm. The void volume of the column was measured as 0.90 ml by injection of a nonretained sample. A controller was used to set the motor speed of the centrifuge. The rotation rate was measured by a pulse counter connected to a slotted disk on the centrifuge shaft. Ancillary equipment included a metering pump, a UV monitor for detection at 254 nm, and a chart recorder.

Plate height $H$ was determined graphically from the elution diagrams displayed on the chart recorder in the following manner (6):

$$H = \frac{L}{5.54}\left(\frac{w_{1/2}}{s}\right)^2 \qquad \text{(Eq. 8)}$$

where $w_{1/2}$ equals the peak width on the chart measured at half the peak height and $s$ is the distance on the chart from the start of flow to the position of the peak maximum.

**Sample**—The bovine serum albumin microspheres were prepared using a procedure developed earlier (7) for preparation of human serum albumin for labeling with technetium 99m to visualize the reticuloendothelial system. Because the microspheres were not intended for medical use, the UV irradiation and autoclaving steps were omitted; instead, the microspheres were washed three times with ethanol and then suspended in ethanol. This preparation was injected into the sedimentation FFF column and fractionated by the conventional procedure (2).

The microspheres from this preparation were examined by transmission electron microscopy to compare the sedimentation FFF results to those obtained by an established procedure. The TEM results were calculated by measuring diameters of 300 particles from photomicrographs.

## RESULTS AND DISCUSSION

The first set of experiments consisted of sedimentation FFF runs at various field strengths (rotation rates). A typical fractogram is shown in Fig. 1. The purposes of these experiments were to verify that the theory provides self-consistent results under different experimental conditions and to provide redundant data for characterization of the albumin microspheres by Method A. The results of these experiments are given in Table I. The consistency in $d$ shows the application of theory to be valid

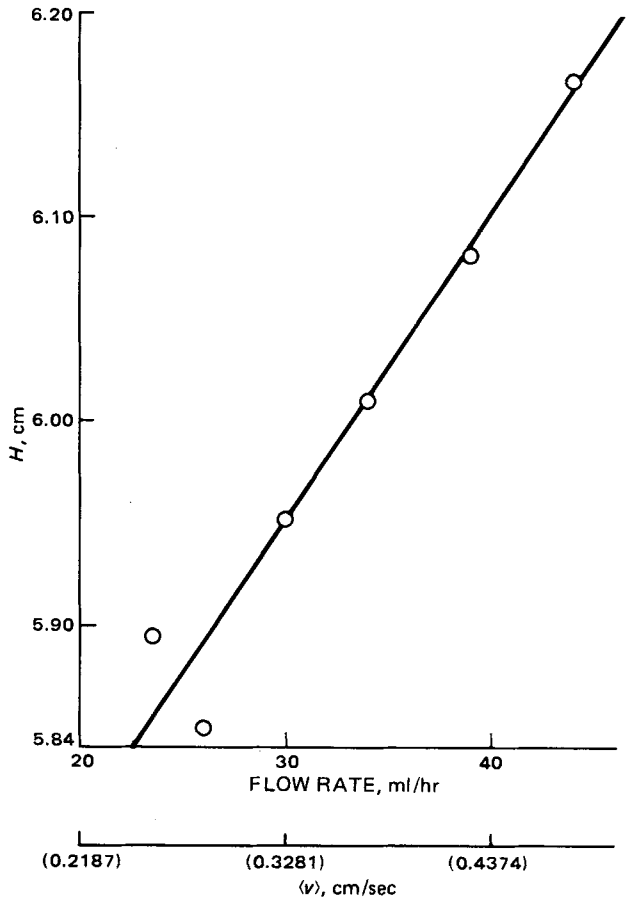

**Figure 2**—*Plot of plate height* versus *flow rate for albumin microspheres at a field strength of 13,510 cm/sec$^{-2}$.*

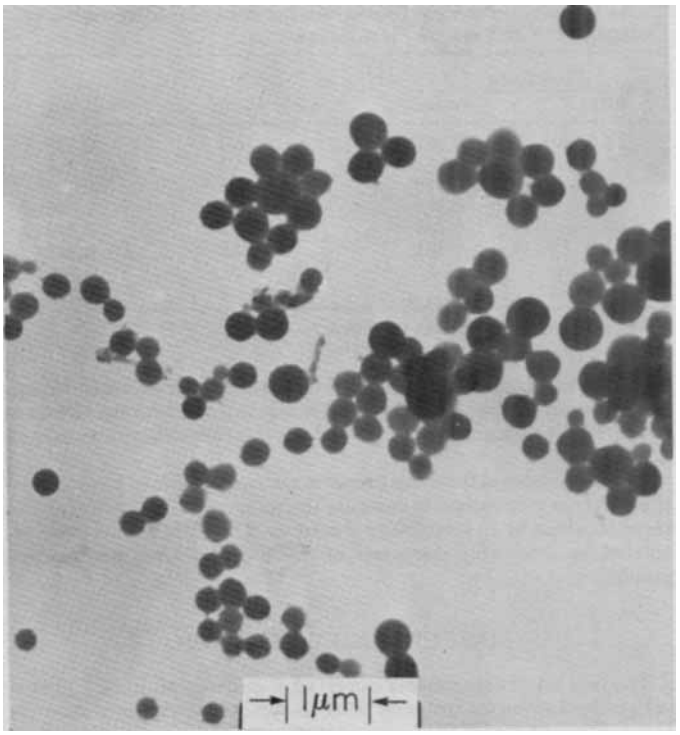

**Figure 3**—*TEM photomicrograph of albumin microspheres.*

over the range of rotation rates investigated (250–500 rpm). The density of the particles was assumed to be 1.36 g/ml based on literature values (8).

A second set of experiments was run at six different flow rates, maintaining a spin rate of 400 rpm. The results (Table II) demonstrate the consistency of mean particle diameter measured under different flow conditions. These results complement those of Table I in showing the FFF results to be independent of experimental conditions. The flow-dependent runs were also used to obtain the plate height data necessary for Method B. The plot of $H$ *versus* $\langle v \rangle$, necessary for Method B, is shown in Fig. 2.

Table III summarizes and compares the particle-size and polydispersity results obtained from the two FFF methods and the TEM observations. The first row of the table shows the results of Method A [called FFF(A)]. These results were obtained from the run (Fig. 1) at 400 rpm at a flow rate of 30 ml/hr. The ability to calculate valid data from just one run is based on unpublished results of separate experiments studying many monodisperse polystyrene latex samples on two different apparatus, which showed that plate height and thus polydispersity measurements were independent of field strength and the apparatus used. Because the instrument run time was only 1.5 hr, FFF(A) was the most rapid method of characterization.

**Table III—Characterization of Albumin Microspheres by Three Methods**

| Method | $d$, μm | $\sigma_d$, μm | $D$, cm²/sec |
|---|---|---|---|
| FFF(A) | 0.349 | 0.040 | $1.15 \times 10^{-8}$ |
| FFF(B) | 0.346 | 0.039 | $1.13 \times 10^{-8}$ |
| TEM | 0.354 | 0.062 | — |

The results of Method B [FFF(B)], requiring the calculation of $\sigma_d$ from the intercept of the $H$ *versus* $\langle v \rangle$ plot of Fig. 2, are also shown in Table III. This measurement of $\sigma_d$ requires more time than needed for FFF(A) because several separate runs are required to construct the plot of Fig. 2.

The third characterization was by the more conventional electron microscopy method. Table III lists the results of this characterization as well. Figure 3 is a typical photomicrograph from which measurements were made.

Table III shows that the two independent FFF methods yield results in excellent agreement. These results are further confirmed by reasonable agreement with those of electron microscopy. However, the FFF results, particularly from Method A, are much more conveniently obtained than those from TEM. FFF thus appears to be a rapid and accurate method for characterizing albumin microspheres and other submicron particles.

# Dissolution, Stability, and Absorption Characteristics of Dicumarol in Polyethylene Glycol 4000 Solid Dispersions

**WILLIAM R. RAVIS** ˣ **and CHIEN-YU CHEN**

Received January 21, 1981, from the *Department of Pharmacal Sciences, School of Pharmacy, Auburn University, Auburn, AL 36849.* Accepted for publication April 10, 1981.

**Abstract** □ The dissolution characteristics of dicumarol were markedly enhanced by preparing dispersions of drug in polyethylene glycol 4000. Solid dispersions of varying weight fractions were formed by a melt method without measurable drug degradation or evaporation. There were no significant differences in dissolution rates among weight fractions, with dynamic solubilities being ~2.5 times greater than dicumarol's equilibrium solubility. No indications of drug polymer complexation were noted from equilibrium or *in situ* absorption experiments. Incorporation of solid dispersions into direct compression tablets provided dosage forms with fast-release properties relative to test tablets of physical mixtures and a commercially available product. Percentages dissolved in 30 min were 370% greater for 1:3 and 1:5 (w/w) solid dispersion tablets compared to a commercial tablet at 37° with a pH 7.5 dissolution buffer. X-ray diffraction of test powder revealed that the crystalline nature of the drug had altered during fusion preparation. Dissolution traits and drug stability for solid dispersions were maintained over 1 year of storage.

**Keyphrases** □ Dicumarol—dissolution, stability, and absorption characteristics in polyethylene glycol 4000 solid dispersions □ Dissolution—dicumarol in polyethylene glycol 4000 solid dispersions □ Polyethylene glycol 4000—effect on dicumarol dissolution, stability, and absorption

The preparation of drug–polymer disperions by fusion and solvent techniques has successfully increased dissolution properties (1–8) and bioavailability (5, 6, 9–12) of poorly water-soluble drugs. Properties of water-soluble polymers such as large molecular size, high viscosity, and supercooling can provide a dispersed drug in a metastable or fast-release form (1, 2). Povidone has been a popular choice as an inert carrier for dispersions prepared by solvent or coprecipitation methods. Among several examples, griseofulvin (3), sulfathiazole (4), and reserpine (5, 6) demonstrate faster dissolution rates when they are dispersed in povidone by a solvent method. For the fusion or melt method, polyethylene glycols have been employed extensively. The dissolution of prednisolone, methyltestosterone, hydrocortisone, and digitoxin has been enhanced by polyethylene glycol fusion dispersions (7). Similarly, enhanced dissolution rates of griseofulvin (2, 8), nitrofurantoin, ethotoin, and coumarin (13) in polymer melt systems were reported.

The oral anticoagulant dicumarol, 3,3′-methylene-bis[4-hydroxycoumarin], is practically insoluble in water (14). It is reported to be poorly and erratically absorbed from both powder and tablet dosage forms (15–17). The bioavailability of dicumarol in tablets is influenced by the type and amount of excipients (18). This drug's classification as dissolution rate limited was supported in studies in dogs (19) where a strong relationship between dissolution data and bioavailability and prothrombin time was noted.

Reports of poor and erratic bioavailability serve as a stimulus for examining new dicumarol formulations that may provide more complete and consistent absorption. The present investigation reports the preparation of dicumarol and polyethylene glycol 4000 solid dispersions by a fusion method and discusses possible mechanisms for their fast-release properties.

## EXPERIMENTAL

**Preparation of Test Powders**—Solid dispersions of polyethylene 4000[1] and dicumarol[2] were prepared from physical mixtures by the fusion or melt method. Physical mixtures representing drug to polyethylene glycol 4000 ratios of 1:1, 1:3, and 1:5 (w/w) were heated over a thermostatic plate with constant stirring until a clear homogeneous melt was obtained. Melts were quickly poured on air-cooled aluminum pans or were glass-suspended in a vented hood. After 1 hr, solidified dispersions were stored in a desiccator for 2 days prior to pulverization.

Other physical mixtures containing heated drug and polymer were obtained by separately heating each component to 280° and then cooling and storing as described for dispersions. Particle-size reductions of physical mixtures were performed by a ball mill while reductions for solid dispersions and heated physical mixtures were accomplished by light tituration in a cooled mortar. Test powders were modified by sieving to provide particle sizes of 100–60 mesh for dispersions and physical mixtures and of <140 mesh for dicumarol.

**Stability Testing of Physical Mixtures and Solid Dispersions**—Assessments of dicumarol stability were conducted by UV spectroscopy, paper chromatography, and TLC. Alkaline solutions (0.1 *N* NaOH) prepared from powders and tablets were utilized in a paper separation with acetic acid–benzene–water (2:2:1) as a solvent (20) as well as for two thin-layer separations on silica gel plates[3] with fluorescent indicator[3]. Thin-layer solvent systems included 3 *M* ammonium hydroxide–ethyl acetate (1:1) and ether–chloroform–acetone (60:30:1). Additional separations were performed with solutions prepared by redissolving dicumarol precipitates obtained from acidified samples.

In chromatographic experiments in which [$^{14}$C]dicumarol[4] was incorporated into solid dispersions, silica gel plates were scraped in sections following development. The radioactivity of each scraping was determined by suspending each in cocktail[4] and counting with the aid of a liquid scintillation counter[5]. All samples were corrected for quenching by quench curves.

**Nonequilibrium Solubility Studies**—Powder dissolution testing was conducted with a 1000-ml, three-necked, round-bottom flask containing 700 ml of 0.05 *M* phosphate buffer (pH 7.5). The apparatus was maintained at 37.0 ± 0.5° by a water bath. To mix the medium, a sleeve stirrer positioned 4 cm from the flask bottom was connected to a constant-speed motor adjusted to 60 rpm. Test powders containing 100-mg equivalents of dicumarol were added to the medium at time zero followed by 4-ml sampling with replacement. Samples were immediately filtered with 0.05- or 0.22-$\mu$m filters[6], and absorbance values were obtained at 314 nm[7] for each sample before and following pH adjustment to 12 with 4 *N* NaOH. Amounts dissolved were calculated from standard curves in pH 7.5 and 12.0 media and corrected for sample dilution (21).

**Preparation of Test Tablets**—After storage of test powders for periods not exceeding 2 weeks, portions of physical mixtures and solid

dispersions were combined and blended with anhydrous lactose[1]. The diluent was added to provide tablets of equal weight, 325 mg. To most formulations, 1% magnesium stearate[1] was added to minimize capping. Formulations were prepared as direct compression tablets with the aid of a single-punch tablet press[8]. Compression force was adjusted to give tablets of comparable hardness (4.4 ± 0.6 kg). Tablet lots were tested for hardness[9], content uniformity, thickness, dissolution, stability, and weight variation.

**Tablet Dissolution Studies**—The tablet dissolution apparatus, comprised of a beaker and basket arrangement, was maintained at 37.0 ± 0.5° by a water bath. The dissolution medium consisted of 1000 ml of deaerated, 0.05 *M* phosphate buffer (pH 7.5). Studies were conducted with test tablets and a selected commercial product. At frequent time intervals after immersion of the baskets, which were rotated at 50 rpm, 4.0-ml samples were withdrawn. Samples were filtered and treated as described for powder nonequilibrium studies.

**Absorption from *In Situ* Intestinal Loops**—Male Sprague-Dawley rats[10], 260–300 g, were fasted 24 hr prior to the procedure. After anesthetization with 40 mg of pentobarbital sodium[2]/kg ip, a midline incision was made. A 15-cm segment representing the upper jejunum was carefully cannulated and gently rinsed with warm saline to remove lumenal matter. Tubing was attached to each cannula and was then passed through a perfusion pump[11] leading to a reservoir. Perfusion was carried out in a recycling fashion with the 60 ml of drug containing buffer maintained at 37.0 ± 0.5° in the reservoir. The perfusion buffer was passed through the intestine in a proximal to distal direction at a calibrated rate of 4.8 ml/min. This rate provided rapid perfusion without overly distending the intestinal segment. Samples were taken from the reservoir, and amounts absorbed were corrected for fluid flux based on reservoir volume.

Dicumarol levels in perfusion samples were determined by a previously described method (17) as revised by Nagashima *et al.* (22).

**Data Analysis**—The amounts dissolved in powder and tablet dissolution studies were compared between preparations and sample times by one- or two-way analysis of variance and Tukey testing (23).

**X-Ray Diffraction Studies**—Test powders were firmly packed on a slide with glass windows. Diffraction spectra[12] were prepared by scanning at a rate of 2°/min in terms of a $2\theta$ angle.

## RESULTS AND DISCUSSION

**Preparation and Stability Studies**—The temperature required for obtaining melts of dicumarol with polyethylene glycol 4000 was below that of the pure drug, 290°, and measurably decreased as the weight fraction of polymer was increased. Lowering in melting points as a function of weight fraction for binary systems is not an unexpected or unique phenomenon (1, 24). For dicumarol–polyethylene glycol 4000 dispersions of 1:1, 1:3, and 1:5, melt temperatures necessary to obtain a visually clear, homogeneous liquid were 275, 263, and 255°, respectively. Dispersions of drug to polymer weight fractions of >1:1 (such as 2:1) could not be prepared at a temperature less than the drug's melting point. Smaller weight fractions were not considered appropriate based on results of powder dissolution studies.

Powdered and milled physical mixtures of 280° heated and unheated drug and polymer appeared white and crystalline, while melted dispersions were orange brown. Polarized light microscope examination indicated the presence of crystalline materials in dispersions and physical mixtures. The crystalline appearance of all physical mixtures, composed of heated and unheated components, resembled that of powdered dicumarol and polyethylene glycol while that of the melt dispersions was distinctly different. Fusion products contained smaller crystals of orange-like reflection dispersed in a clear polymer matrix.

The concern for possible drug degradation was emphasized by the coloration of fusion products and by other studies (7) demonstrating drug degradation in polyethylene glycol melts. Three chromatographic separations of $^{14}C$-labeled dicumarol dispersions failed to show any degradation materials. Similar chromatographic studies performed with solutions of dispersion powders and direct compression tablets that had been stored for 1 year revealed lack of degradation or drug loss.

It was concluded from the stability tests that, at the temperature required for drug–polymer melts, drug decomposition did not occur and, thus, was not responsible for the coloration of the fusion dispersions. The heating temperature necessary to discolor polymer or drug separately exceeded the melt temperatures for fusion. The orange-brown coloration apparently is unique to the solid dispersion. Differences in color between dispersions obtained by melting without measurable drug degradation and their physical mixtures were reported (2).

**Nonequilibrium Solubility Studies**—Solubility experiments for comparing powder dissolution rates demonstrated a dramatic enhancement in initial dicumarol solubility for the three dispersions (Fig. 1). Physical mixtures of heated materials gave similar release profiles to those of other physical mixtures and powdered drug. As summarized in Table I, the maximum observed solubility for dispersions over the 23-hr studies was approximately twofold greater than that of the physical mixtures, with maximum levels for dispersions noted at 60 min compared to >660 min for physical mixtures and pure drug.

Among the three weight fractions, significant differences in the amounts of dicumarol dissolved were not found at any sampling interval. Large variability in the initial amounts released by the dispersion appeared to mask any small differences that might exist between the prepared weight fractions. At the end of 23 hr, final dicumarol concentrations for all dispersions were 30% greater than dicumarol powder or dicumarol powder incorporated into physical mixtures. Comparisons of the percentage dissolved by time showed the drug levels to be constant for all dispersions for 8–23 hr. Whether dicumarol's solubility in the media of solid dispersion preparation approaches that of pure drug after 23 hr was not examined.

The supersaturated state of the media created by the solid dispersions represented a dissolution of <40% of the drug initially added to the system, thereby maintaining solid drug in excess throughout the experiments. Amounts dissolved in 10 min were eightfold greater for dispersions compared to powdered pure drug. Drug levels fell rapidly after 60 min for all dispersions, providing profiles that might be expected for a high energetic drug form (5, 25–28). The ratio of dynamic to equilibrium solubility for dicumarol dispersions was ~1.4 for all weight fractions, while the ratio of the dynamic solubility for dispersions relative to the equilibrium solubility for dicumarol powder was 2.5. Upon standing, drug crystallization and loss in UV absorbance were noted in withdrawn dissolution samples. To obtain solubility values accurately, it was necessary to filter and obtain absorbance measurements immediately.

UV spectra and calculations of amounts dissolved for alkalinized and nonalkalinized filtered samples from respective standard curves seemed to confirm the existence of a supersaturated state in the early time periods. Filtration of samples through 0.45–0.05-$\mu$m filters did not alter measured drug concentrations. A similar dissolution characteristic was described (28) for polymorphs of cortisone acetate. Another mechanism for describing the overshoot of equilibrium concentration during initial dissolution periods was proposed earlier (29). By this explanation, drug release from a polymer mixture continues after saturation as a result of further dissolution of drug in complex with polymer, which acts as a drug carrier.

The similarity of drug release for pure drug compared to physical mixtures demonstrates the relative noninteractive nature of drug and polymer such that wetting and complexation features of polyethylene glycol may be negligible in this dispersion system. Wetting effects may explain the slightly faster initial dissolution rates of physical mixtures compared to drug powder. Observations of higher equilibrium solubilities for the dispersion and the possible participation of the polymer as a

| 1:5, 1-year storage[b] | 3.0 | 39.6 (2.6) | 72.0 (2.6) | 79.6 (2.4) | 78.1 (2.8) |
| 1:1, 1-year storage[b] | 6.7 | 16.5 (1.6) | 47.6 (2.2) | 58.3 (1.5) | 75.2 (2.5) |

[a] Mean ± *SD*; $n = 6$. [b] Significantly ($p < 0.05$) greater amounts dissolved at all sampling periods compared to physical mixture or commercial product.

dissolution carrier presented a need to evaluate better any contributions that polymer and dicumarol complexation may have on the dispersion's performance. In addition, dicumarol was reported (30) to interact with povidone to form highly soluble complexes. With conditions identical to previous studies, polyethylene glycol was predissolved in the media at three concentrations corresponding to those expected for complete polymer dissolution in the dispersions. As summarized in Table I and Fig. 2, equilibrium solubilities after 6 hr were independent of polymer concentrations. Amounts released prior to 6 hr decreased slightly as the levels of polyethylene glycol increased, which may be the result of viscosity influences on release rate.

Neither milling, melting, nor separate heating of dicumarol or polyethylene glycol 4000 to a temperature exceeding that required for melts influences dissolution (Table I). Marked enhancement in dicumarol dissolution in prepared fusion dispersions apparently is unique to the fusion product and not secondary to the polymer effects or the results of applied temperature.

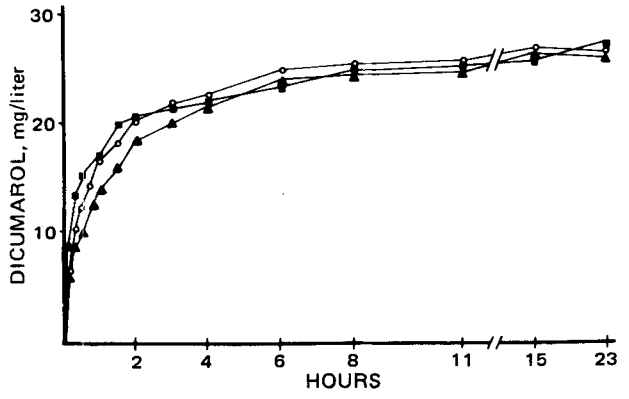

**Figure 2**—*Dissolution of dicumarol powder and physical mixture at 37°. Key: ○, dicumarol powder; ■, 1:5 (w/w) dicumarol–polyethylene glycol 4000 physical mixture; and ▲, dicumarol powder in 0.071% polyethylene glycol 4000 dissolution media.*

Since higher solubility of dicumarol in solid dispersions did not seem to be a consequence of polymer–drug complexation, the elevated drug levels during the latter portion of the equilibrium experiments may be the result of an inhibitory effect of the polymer on the drug's conversion to a stable, less soluble crystalline species. Prevention of nucleation and recrystallization to a stable crystalline form by solutions of high molecular weight polymers such as povidone was previously discussed (4, 5). In evaluating the influence of the drug–polymer dispersion ratio with respect to polymer medium concentration, retardation of stable crystal formation was independent of the polymer ratio. Therefore, the minimum inhibitory polymer levels appear to be <0.014% with 37° dissolution media.

**Tablet Dissolution Studies**—Solid dispersions and physical mixtures were incorporated into direct compression tablets to evaluate the effects of tableting on dicumarol release from solid dispersions and to provide a solid dosage form for future comparative bioavailability studies. Tablets were designed to be of equal weight by the addition of lactose and were nondisintegrating.

Results of tablet dissolution experiments expressed as percentage released are presented in Table II and Fig. 3. Calculation of dissolution rate constants through application of tablet dissolution models was considered inappropriate since previous nonequilibrium profiles revealed that observed release kinetics would be complex and reflective of both rapid release and crystallization. Comparisons of percentage dissolved at 5–90 min gave the rank order for the dissolution of test tablets containing 1% magnesium stearate as a lubricant: 1:5 = 1:3 >1:1 solid dispersions >1:5 physical mixture = commercial product.

Tablets containing the dispersions of 1:3 and 1:5 weight fractions showed marked increases in percentage released at 10, 30, 60, and 90 min compared to commercial and physical mixture forms with approximate increases of 290, 366, 290, and 245%, respectively. Dissolution profiles for tablets representing the three weight fractions stored for 1 year were identical to those for freshly prepared tablets. The markedly slower dissolution noted for the nondisintegrating tablet compared to previously examined powders indicates that this drug's dissolution may be further maximized by incorporating powdered dispersion into disintegrating tablets or capsules.

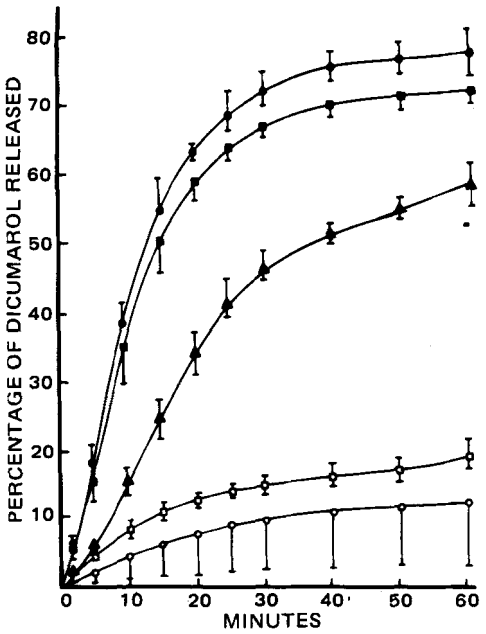

**Figure 3**—*Dissolution profiles of test tablets and a commercial product. Key: ●, 1:5 (w/w) dicumarol–polyethylene glycol 4000 dispersion; ■, 1:3 (w/w) dicumarol–polyethylene glycol 4000 dispersion; ▲, 1:1 (w/w) dicumarol–polyethylene glycol 4000 dispersion; ○, 1:5 (w/w) dicumarol–polyethylene glycol physical mixture; and □, commercial product.*

The inclusion of a lubricant, magnesium stearate, prevented tablet capping during direct compression. It was noted (18) that the incorporation of several magnesium compounds such as magnesium hydroxide and magnesium oxide into dicumarol formulations increased drug absorption. In that same study, magnesium stearate had no significant influence on the completeness of drug absorption, which is consistent with dissolution results in the present study showing equal or lower release rates for lubricant-containing tablets relative to those with no lubricant.

The apparent slower dissolution of dicumarol from the 1:1 dispersions compared to dispersions of higher percentages of polyethylene glycol 4000 could result from the greater portion of a slower dissolving diluent, lactose, in this formulation and/or to more extensive nucleation and conversion of a metastable to a less soluble stable form during the initial dissolution period. The latter explanation appears plausible considering the possible inhibitory effects of dissolved polymer on crystallization and recognizing that the low polymer to drug ratio tablet would supply the least polyethylene glycol concentration on dissolution. Substantial crystallization may occur initially if the levels of polymer in the bulk are below those necessary to inhibit renucleation. However, this explanation is probably inadequate since the 90-min percentages dissolved were not significantly different among the three ratios. In addition, predissolving the polymer did not alter the profiles for the 1:1 dispersion tablets. In experiments where the nondisintegrating tablets were removed from baskets after 20 min, 1:1 dispersion tablets appeared to dissolve slower. Thus, lactose dissolution may be rate limiting.

**X-Ray Diffraction Studies**—Spectra of unmilled dicumarol and milled polyethylene glycol 4000 appear in Fig. 4; spectra for the milled 1:1 dispersion and its physical mixture appear in Fig. 5. The major dicumarol diffraction peaks of 24.9, 26.9, and 11.8° could be identified in the solid dispersion sample as weak intensity peaks with ~18% of the intensity of drug alone in the physical mixture. All visible peaks for the physical mixture could be identified as those of polyethylene glycol 4000 or dicumarol. The intensities of major drug peaks were substantially greater in the physical mixture compared to the dispersion, which may indicate a loss in the drug's initial crystalline form during the fusion process. Peaks for the solid dispersions, appearing at ~23.4 and 20.8°, did not correspond to any of the major peaks noted for the polymer or drug. Other dicumarol peaks, such as measured at 10.4°, displayed increased intensity in the dispersion.

Observations of unidentifiable peaks accompanied by the disappearance of component peaks may be in accordance with spectral changes

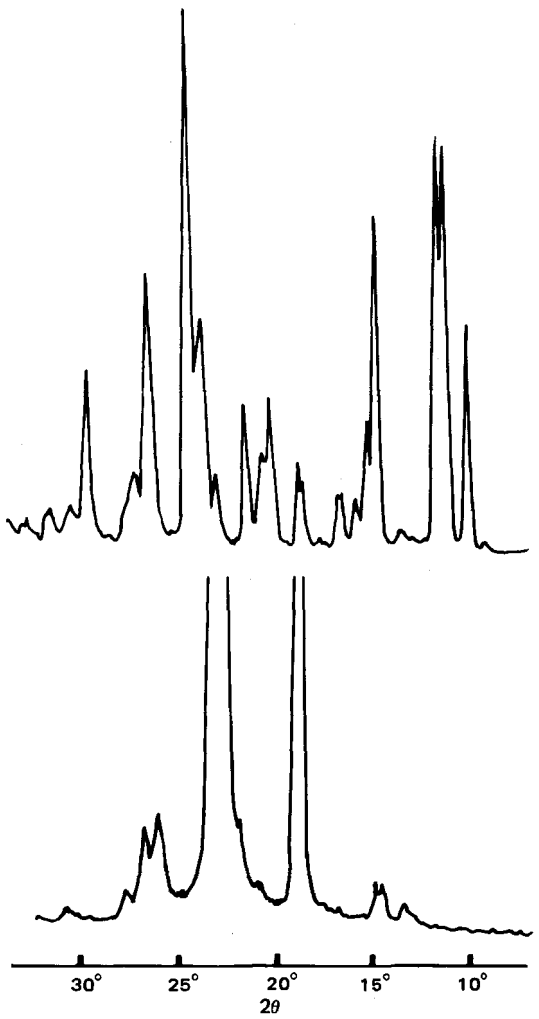

**Figure 4**—*X-ray diffraction spectra of dicumarol (top) and milled polyethylene glycol 4000 (bottom).*

expected for partial polymorphic conversion or solid solution. However, the presence of component peaks in the melts does not allow partial eutectic formation and particle-size reduction to be completely ruled out. The identification of well-defined peaks and the absence of a raising baseline seems to exclude amorphous drug formation as a major factor in the dispersion.

**Dicumarol *In Situ* Absorption**—*In situ* rat intestinal loops were utilized to examine dicumarol absorption from solutions prepared from drug alone, physical mixtures, and fusion dispersions. Solutions of high molecular weight polymer in the GI lumen may alter absorption by viscosity effects (31), solvent effects (32), and drug complexation (33). Table III shows the percentage of initial drug concentration remaining at 30 and 90 min for the recycling perfusion of jejunal segments. Dicumarol

**Table III—Absorption of Dicumarol by Infused [a] *In Situ* Intestinal Loops**

| | Percentage Remaining to be Absorbed [b] | | | |
|---|---|---|---|---|
| Minute | Dicumarol Powder | 1:5 Dicumarol–Polyethylene Glycol Physical Mixture | 1:5 Dicumarol–Polyethylene Glycol Dispersion | Statistical Analysis [c] |
| 0 | 100 | 100 | 100 | |
| 30 | 29.9 (4.9) [d] | 36.1 (9.0) | 34.7 (6.6) | NS [e] |
| 90 | 22.4 (3.4) | 22.7 (6.2) | 29.9 (3.4) | NS [e] |

[a] Recirculating infusion of a 15-cm segment at a rate of 4.8 ml/min. [b] Infusion buffer consisted of 60 ml of Krebs–Henseliet buffer with a dicumarol concentration of 10 μg/ml. [c] Analysis of variance with $p < 0.05$. [d] Mean ± *SD*; $n = 4$. [e] Not significant.

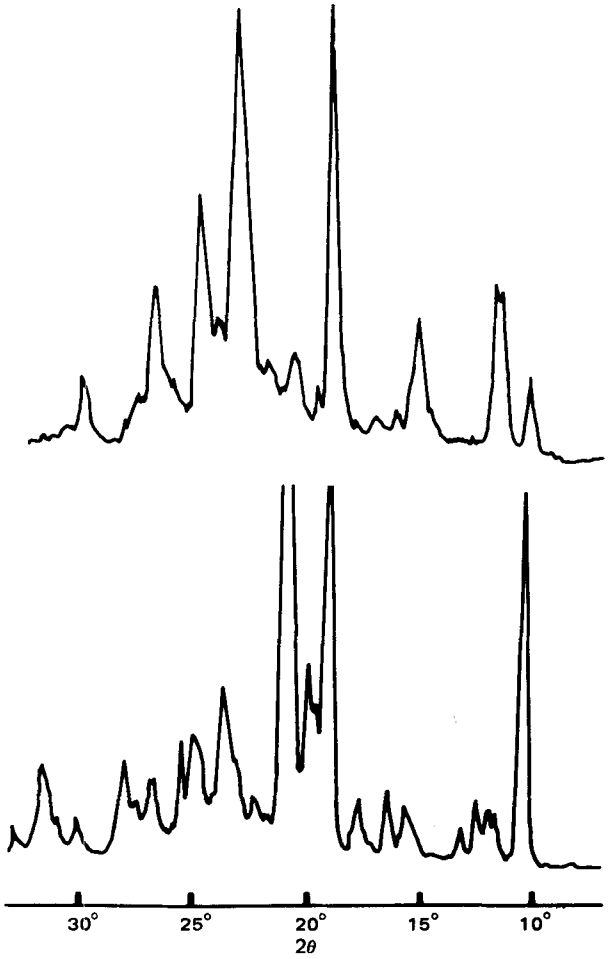

**Figure 5**—*X-ray diffraction spectra of 1:1 (w/w) dicumarol–polyethylene glycol 4000 physical mixture (top) and solid dispersion (bottom).*

rapidly disappeared from all perfusion buffers such that 68% was absorbed in the first 30 min. This initial rapid phase was possibly a result of tissue equilibrium since the absorption rates were substantially less during the 30–90-min interval. While initial *in situ* absorption was probably, in part, perfusion limited since the intestinal clearance rate of 2.3 ml/min was 48% of the perfusion rate, no significant effects of polyethylene glycol on this drug's absorption can be reported. These observations would confirm the absence of strong complexation as previously discussed as well as demonstrate that the polymer does not alter the membrane absorption of this drug *in situ*.

## CONCLUSIONS

Observations of rapid drug disappearance from *in situ* loops and low equilibrium solubility would support previous statements (16, 19) of dicumarol's dissolution rate-limited character and, thereby, formulation sensitivity. The present study showed that the dissolution characteristics of dicumarol can be enhanced through the preparation of melt fusion products with polyethylene glycol 4000 without detectable degradation. Unlike other polyethylene glycol–drug (8) dispersion systems, complexation between drug and polymer cannot be considered as a factor contributing to higher dissolution rates for powders and tablets. Preliminary studies of X-ray diffraction patterns demonstrated that fusion products contained crystalline materials that could not be identified as either pure drug or polymer.

Further investigations employing differential thermal analysis and X-ray diffraction need to be performed to characterize the apparent high energy form of dicumarol in fusion dispersions. Based on X-ray microscopy and dissolution results, partial polymorphic conversion or solid solution formation seems to be an attractive explanation. After 1 year of storage for powders and direct compressed tablets, stability was unaltered and enhanced dissolution traits appeared unaffected. Investigations are currently being conducted with the aid of the described tablet dosage form to evaluate dicumarol's dissolution–bioavailability relationship.

# Dissolution Kinetics of Phenylbutazone

K. G. MOONEY * §, M. RODRIGUEZ-GAXIOLA ‡, M. MINTUN ‡, K. J. HIMMELSTEIN ‡, and V. J. STELLA * ×

Received August 8, 1980, from the *Department of Pharmaceutical Chemistry and the ‡Department of Chemical Engineering, University of Kansas, Lawrence, KS 66045. Accepted for publication April 17, 1981. §Present address: Boehringer Ingelheim, Ridgefield, CT 06877.

**Abstract** □ This study investigated the possible effects of simultaneous, noninstantaneous, reversible chemical ionization of carbon acids on the dissolution of a typical pharmaceutical carbon acid, phenylbutazone, and its deutero analog. The dissolution rate *versus* pH profile for phenylbutazone was consistent with phenylbutazone acting as if it were an acid where the ionization can be considered instantaneous. In view of the dissolution behavior of phenylbutazone under various conditions, it is unlikely that the noninstantaneous ionization kinetics demonstrated for this compound play a major role in determining the dissolution rate, either *in vitro* or *in vivo*, since the average residence time in a typical aqueous diffusion layer for phenylbutazone dissolution is longer than the reaction time for its ionization. Slowing the reaction time with a primary isotope effect by deuterium substitution for the ionizable proton caused significant deviation from classical behavior for *d*-phenylbutazone.

**Keyphrases** □ Phenylbutazone—dissolution kinetics □ Kinetics—dissolution phenylbutazone □ Dissolution—kinetics of phenylbutazone □ Anti-inflammatory agents—phenylbutazone, dissolution kinetics

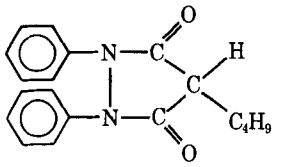
In modeling the dissolution of carboxylic acids into aqueous, alkaline media (1, 2), all reversible ionization reactions occurring in the diffusion layer are considered instantaneous[1]. Carbon acids, where the dissociating proton is bound to a carbon atom rather than to a heteroatom, have been shown to undergo noninstantaneous rates of ionization (3–5); *i.e.*, proton abstraction rate constants are considerably slower than $10^{10}$ $M^{-1}$/sec. The present study investigated the possible effects of simultaneous, noninstantaneous, reversible chemical ionization of carbon acids on the dissolution of phenylbutazone (I).

An anti-inflammatory agent, phenylbutazone was chosen because it has been demonstrated to have dissolution rate-limited absorption (6–9) and noninstantaneous ionization kinetics (3). Furthermore, studies on the mass transport of phenylbutazone have described behavior that seemed not entirely explicable by models with the assumption that this drug undergoes instantaneous ionization (10–12).

The pH-stat, rotating-disk system described previously (1) was particularly useful for the study of the phenylbutazone dissolution mechanism in aqueous media of variable bulk solution pH since buffers have been demonstrated to catalyze markedly the rate processes involved in its ionization (3). The inclusion of buffers in the dissolution medium complicates the theoretical considerations of any model and prevents any possible effects of noninstantaneous ionization on phenylbutazone dissolution rates from being observed.

## THEORETICAL

The ionization kinetics of phenylbutazone can be described by Schemes I and II and are adapted from the work of Stella and Pipkin (3). In these



I

schemes, $K$ is the diketo form of phenylbutazone, $E^-$ is the enolate anion, and $OH^-$ and $H^+$ represent hydroxide and hydrogen ions, respectively. It was demonstrated (3) that in an aqueous solution of ionic strength ($\mu$) 0.1 and at 25°, an enol form comprises a minor portion of the total undissociated phenylbutazone (~2%). Therefore, it was assumed that solid phenylbutazone exists predominantly as the diketo form, and any ionization during dissolution due to reaction with water and hydroxide ion was regarded as occurring solely from this species.

It was assumed that a previously described (1) diffusion layer model generally applied; the only difference between the previous model and the present one was that chemical reactions involving the diketo or enolate forms of phenylbutazone were assumed to be noninstantaneous with respect to the diffusion process. Phenylbutazone species were not presumed to be in equilibrium with one another at any point within the diffusion layer.

When the bulk solution pH ($pH_{bulk}$) was maintained only by controlled addition of hydroxide ion from a pH-stat system (1), the various reactions occurring within the diffusion layer were given by Schemes I and II.

$$K \underset{k_2}{\overset{k_1}{\rightleftharpoons}} H^+ + E^-$$

*Scheme I*

$$K + OH^- \underset{k_4}{\overset{k_3}{\rightleftharpoons}} H_2O + E^-$$

*Scheme II*

Also occurring in the diffusion layer was the spontaneous ionization of water (Scheme III).

$$H^+ + OH^- \rightleftharpoons H_2O$$

*Scheme III*

At steady state during the dissolution of phenylbutazone, a mass balance for each diffusing species may be written accounting for both chemical ionization reactions and Fickian diffusion within the diffusion layer:

$$\frac{\partial[K]}{\partial t} = D_K \frac{\partial^2[K]}{\partial X^2} - \Big[[K](k_3[OH^-] + k_1) - [E^-](k_2[H^+] + k_4)\Big] = 0 \quad \text{(Eq. 1)}$$

$$\frac{\partial[E^-]}{\partial t} = D_E \frac{\partial^2[E^-]}{\partial X^2} - \Big[[E^-](k_2[H^+] + k_4) - [K](k_3[OH^-] + k_1)\Big] = 0 \quad \text{(Eq. 2)}$$

$$\frac{\partial[OH^-]}{\partial t} = D_{OH} \frac{\partial^2[OH^-]}{\partial X^2} - \Big[k_3[K][OH^-] - k_4[E^-]\Big] = 0 \quad \text{(Eq. 3)}$$

$$\frac{\partial[H^+]}{\partial t} = D_H \frac{\partial^2[H^+]}{\partial X^2} - \Big[k_2[E^-][H^+] - k_1[K]\Big] = 0 \quad \text{(Eq. 4)}$$

where $[K]$, $[E^-]$, $[OH^-]$, and $[H^+]$ represent the concentrations of the various species; $D_K$, $D_E$, $D_{OH}$, and $D_H$ are their diffusivities; $t$ is time; $k_{1-4}$ are the rate constants described in Schemes I and II; and where $x$ is the distance of any point from the solid-liquid interface.

The relationship between $[H^+]$ and $[OH^-]$ is defined in the diffusion layer by:

[1] Instantaneous is regarded here in the chemical kinetic sense, in which a reaction rate constant is at or approaches the diffusion-controlled limit of ~$2 \times 10^{10}$ $M^{-1}$/sec.

0022-3549/81/1200-1358$01.00/0
© 1981, American Pharmaceutical Association

$$K_w = [H^+][OH^-] \quad \text{(Eq. 5)}$$

but the relationships between $[K]$ and $[E^-]$ and $[H^+]$ and $[OH^-]$ cannot be given by a series of simple equilibria because of the noninstantaneous nature of the ionization reactions involved. Since the rates of interconversion between $K$ and $E^-$ at any point in the film depended on their respective concentrations and $[H^+]$ and $[OH^-]$ at that position, there was no simple analytical solution of Eqs. 1–4. Therefore, to predict whether the noninstantaneous nature of phenylbutazone ionization was likely to affect the dissolution rate of the acid, numerical integration methods were used with Eqs. 1–4 to provide approximate film concentration profiles for $[K]$ and interfacial pH values, $pH_0$, under various $pH_{bulk}$ conditions.

## EXPERIMENTAL

**Materials**—Phenylbutazone[2] and 2-naphthoic acid[3] were obtained in pure crystalline forms. Deuterium oxide[3] (99.9 mole % purity), deuterium chloride[3] solution (10 *M*), and sodium deuteroxide[3] (40% solution) were all used without further purification. Reagent grade hydrochloric acid[4] and sodium hydroxide[4] were obtained as prepared (1 *M*) solutions. All other chemicals were reagent grade.

**Preparation of Deuterated Phenylbutazone and 2-Naphthoic Acid**—Deuterated phenylbutazone was prepared by dissolving ~5 g of nondeuterated phenylbutazone in 50 ml of deuterium oxide and 1.0 ml of 40% sodium deuteroxide with vigorous agitation. Upon addition of 1–2 ml of 10 *M* deuterium chloride, a gel-like precipitate was formed; it was filtered and dried at 50–60° under vacuum for 1–2 hr. After recrystallization in 99.9% deuterated ethanol[3] (*d*-ethanol), TLC, using a solvent system of 7% (v/v) acetone in toluene, showed only one spot that corresponded to phenylbutazone.

The melting point of the pure phenylbutazone standard (starting material) was 105–106°, and that of the precipitate prior to recrystallization was 95–106° (transition observed in that range). The polymorphism of phenylbutazone has been well documented(13, 14), and it appeared that the highest melting and, therefore, most thermodynamically stable crystalline form of phenylbutazone, has a melting point of 105–106°. After recrystallization in *d*-ethanol and drying at 50–60° *in vacuo* for 2 hr, deuterated phenylbutazone (*d*-phenylbutazone) gave a sharp melting point of 105–106°. Therefore, it was assumed that the crystalline form of *d*-phenylbutazone was very similar to that of the pure nondeuterated material.

2-Naphthoic acid was deuterated in a similar manner, using approximately the same amounts of solid and reagents. On measuring the melting points of the starting protonated material and the deuterated precipitate, they were 184–185° (lit. mp 185–187°) and 179–181°, respectively. After recrystallization of the precipitated deuterated compound in *d*-ethanol, the melting point of the pure solid was only 180–181°, ~4° lower than the starting material.

IR and NMR spectra were obtained to confirm the deuteration sites in both compounds. Phenylbutazone was deuterated only at the 2-position, with the percentage deuteration being estimated at >90%. Naphthoic acid was similarly deuterated only on the exchangeable carboxy function, the percentage deuteration again being estimated at >90%. Both deuterated compounds were stored in a desiccator until required.

**Solubility and pKa Measurement of Phenylbutazone**—The aqueous solubility of phenylbutazone at $\mu = 0.5$ (potassium chloride) and 25° was determined as described earlier (1). Additionally, a spectrophotometric method was used to obtain the pKa of phenylbutazone independently. Phenylbutazone showed a strong bathochromic shift at 240–300 nm on addition of base to an aqueous solution of the compound. Thus, aliquots of an approximate $1.3 \times 10^{-5}$ *M* aqueous solution of phenylbutazone at $\mu = 0.5$ with potassium chloride were taken and, using 0.1–1.0 *M* NaOH or HCl, were adjusted to pH values of 2.0–10.0. The absorbance of each solution was measured at 262 nm with a UV–visible spectrometer[5].

The pKa and intrinsic solubility of 2-naphthoic acid were measured by the solubility method as described previously (1) at 25° and $\mu = 0.5$ (potassium chloride).

**Initial Dissolution Rate Measurement as Function of Rotation Speed and pH**—Phenylbutazone and 2-naphthoic acid in both their deuterated and protonated forms were compressed into solid disks of 1.3-cm diameter as described previously (1).

The adherence of the dissolution rate from a rotating disk of constant surface area at a given $pH_{bulk}$ to a diffusion layer-controlled model described by the Levich–Nernst relationship (1) was tested for in all four compounds. Phenylbutazone, 2-naphthoic acid, and deuterated 2-naphthoic acid (*d*-2-naphthoic acid) were tested in a medium of $pH_{bulk}$ 2.00 (0.49 *M* KCl–0.01 *M* HCl), $\mu = 0.5$, and 25°. Dissolution rates of phenylbutazone and *d*-phenylbutazone were also measured at $pH_{bulk}$ 6.50 as a function of disk rotation speed, using a pH-stat system to maintain the bulk solution pH constant. To compare phenylbutazone dissolution rates under acidic conditions, the dissolution rates of *d*-phenylbutazone were also measured at 600 rpm under acidic conditions. The method and apparatus used were exactly as described previously (1).

To measure dissolution rate as a function of $pH_{bulk}$, the solid acid disks were rotated at a constant speed in media of different pH values. For phenylbutazone and *d*-phenylbutazone, the disk rotation speed was 600 rpm; for *d*-2-naphthoic acid and 2-naphthoic acid, it was 450 rpm. The difference was due to the compound's relative solubilities and the period of time required to measure each dissolution rate.

**Dissolution Rate Simulations**—Where phenylbutazone and/or deuterated phenylbutazone dissolution was simulated, the boundary conditions were defined as follows:

1. At the rotating-disk surface, *i.e.*, $X = 0$, $[K]$ is given by the intrinsic solubility of phenylbutazone, $[HA]_0$.

2. To estimate the boundary condition for $[E^-]$ at the wall, the experimentally observed flux ($J_{obs}$) was used since it was equal to the sum of $K$ flux, $J_K$, and $E^-$ flux, $J_E$, and $[E^-]$ was changed successively until the value for $J_{obs}$ simulated was equal to $J_{obs}$ experimentally observed.

3. To set the boundary condition for $[OH^-]$, it was assumed that at any given point, the $[E^-]$ flux out of the diffusion layer should be equal to the influx of $[OH^-]$ plus the flux of $[H^+]$ out (1) since any change in the flux of $[OH^-]$ must also be reflected by corresponding changes in $[E^-]$ and $[H^+]$. This statement was expressed as:

$$\text{flux of } [E^-] \text{ out} = \text{flux of } [OH^-] \text{ in} + \text{flux of } [H^+] \text{ out} \quad \text{(Eq. 6)}$$

4. The value of $J_{OH}$, as well as of $J_E$ and $J_H$, can be calculated at any given point in the diffusion layer by using Fick's first law of diffusion (15). Then, when $[OH^-]$ flux calculated by this means was found to be equal to the value obtained using Eq. 6, the boundary condition for $[OH^-]$ was defined. Thus:

$$D_{OH}\frac{d[OH^-]}{dX} = \text{flux of } [E^-] - \text{flux of } [H^+] \quad \text{(Eq. 7)}$$

5. The boundary condition for $[H^+]$ at the wall was given by the equilibrium relationship between $[OH^-]$ and $[H^+]$ (Eq. 5).

6. Since the bulk concentrations for $E^-$ and $K$ were very low, they were considered to be zero (initial rates were assumed). The boundary conditions at $X = h$ for $[OH^-]$ and $[H^+]$ were given by the bulk pH. Thus, all boundary conditions required for the simulation of phenylbutazone dissolution were set. These conditions are summarized here.

At $X = 0$:

$$[K]_0 = \text{solubility of HA}$$

$$[E^-]_0;\ J_{obs} = J_K + J_E$$

$$[OH^-]_0;\ D_{OH}\frac{d[OH^-]}{dX} = J_E - J_h$$

$$[H^+]_0 = \frac{K_w}{[OH^-]_0}$$

At $X = h$:

$$[K]_h = 0$$

$$[E^-]_h = 0$$

$$[OH^-]_h = \text{from bulk pH}$$

$$[H^+]_h = \text{from bulk pH}$$

To solve the two-point value problem, conditions on each side of the boundary must be specified. This was not the case in these simulations. One alternative was to guess the initial slopes at one boundary and to solve the problem as an initial value problem "shooting" repeatedly at the other boundary until the known boundary conditions were satisfied (16, 17). Since this approach was costly and time consuming, a second

[2] Ciba-Geigy Pharmaceuticals, Summit, N.J.

[4] Fisher Scientific Co., Fair Lawn, N.J.
[5] Model 219, Cary Instruments, Calif.

approach was taken where the dissolution of phenylbutazone was simulated assuming steady-state conditions. The nonsteady-state solution continued until steady state was achieved. It was necessary to establish four initial conditions besides the eight boundary conditions already described to solve the system as a nonsteady-state problem.

Thus, the initial conditions for phenylbutazone and all of the diffusing species were given by, at $t = 0$:

$$[K]_0 = \text{solubility of } [HA]_0$$

$$[OH^-]_0 = \text{from bulk pH}$$

$$[H^+]_0 = \text{from bulk pH}$$

$$[E^-]_0 = 0$$

The mathematical model representative of phenylbutazone dissolution was represented by a set of four nonlinear partial differential equations (Eqs. 1–4), which could be written in finite difference forms.

Let the diffusion layer be divided into $M$ grid points denoted by $X_i$, $i = 1,2,\ldots M$. The time index was given by the subscript $n$, where $n + 1$ is the new time and $n$ is the old time.

The left side of Eqs. 1–4 written in finite-difference approximation by:

$$\frac{\partial[N]}{\partial t} = \frac{[N]_{i,n+1} - [N]_{i,n}}{\Delta t} \qquad \text{(Eq. 8)}$$

where $N$ represents any of the species, $K$, $E^-$, $OH^-$, or $H^+$. The right side of Eqs. 1–4 can be written in terms of the Crank–Nicolson (15, 18) implicit finite-difference formulation, around the node $i$, as follows:

$$\frac{\partial^2[N]}{\partial X^2} = \frac{D_N}{2}\delta_X^2[N]_{i,n+1} + \frac{D_N}{2}\delta_X^2[N]_{i,n} - (\text{kinetic term})_{i,n+1} \qquad \text{(Eq. 9)}$$

where:

$$\delta_X^2[N]_{i,n+1} = \frac{[N]_{i-1,n+1} - 2[N]_{i,n+1} + [N]_{i+1,n+1}}{(\Delta X)^2} \qquad \text{(Eq. 10)}$$

$$\delta_X^2[N]_{i,n} = \frac{[N]_{i-1,n} - 2[N]_{i,n} + [N]_{i+1,n}}{(\Delta X)^2} \qquad \text{(Eq. 11)}$$

where $D_N$ is the diffusivity of the particular $N$ species being considered.

As shown by the preceding equations, the kinetic terms impose nonlinear characteristics to the system. If it is assumed that these kinetic terms are considered at time $n$ instead of time $n + 1$, the solution of these equations becomes available by using a Crank–Nicolson technique. This assumption causes no great deviation compared to the results obtained using the shooting method.

When Eqs. 1–4, expressed by finite-difference approximations, were applied to the various grid points in the diffusion layer, a set of $M - 1$ linear equations resulted at each time step. The coefficients formed a tridiagonal matrix, which could be solved by a Gaussian elimination technique (19) with a maximum of three variables per equation.

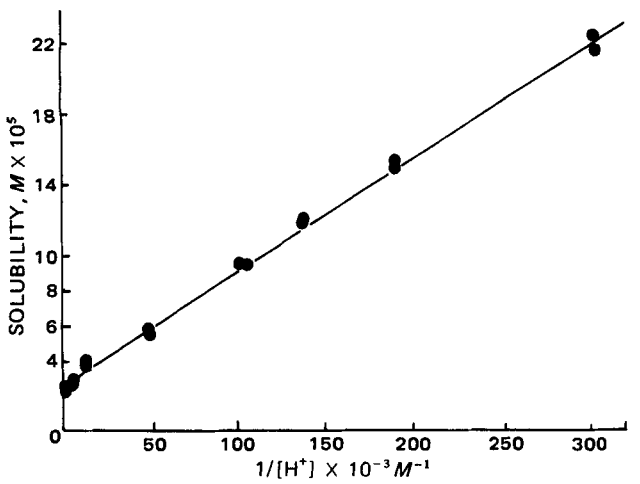

**Figure 1**—*Plot of the aqueous solubility of phenylbutazone* versus *1/[H⁺] (25° at μ = 0.5 with potassium chloride).*

After solving the system for $[N]_{i,n+1}$ at the next iteration, the process was tested for convergence at every grid node:

$$\frac{\text{abs}[\Delta[N]_{i,n+1} - \Delta[N]_{i,n}]}{\text{abs}\,\Delta[N]_{i,n+1}} < \text{convergence}$$

where $\Delta[N]_i$ was the difference of $[N]$ between two grid points, and the value of tolerance was specified.

The Crank–Nicolson method was stable for all values of the ratio $\lambda = \Delta t/(\Delta X)^2$ for linear equations. However, this system was not linear. When a small $\Delta t$ was used, the amount of computation was large. For the case of $\lambda < 4000$, the system was stable but convergence was reached over a longer period. When $\lambda > 20{,}000$, the system became unstable. Finally, when $\lambda = 4000$, the system converged rapidly, saving computation time.

## RESULTS AND DISCUSSION

The solubility of phenylbutazone was measured as a function of the reciprocal of the hydrogen-ion concentration ($1/[H^+]$) in 0.1 $M$ acetate buffers ($\mu = 0.5$ with potassium chloride). The results are plotted in Fig. 1. The intrinsic solubility of undissociated phenylbutazone species, $[HA]_0$, and the macroscopic dissociation constant, $K_a$, are related to the total solubility ($S$) of phenylbutazone by:

$$S = [HA]_0 + \frac{K_a[HA]_0}{[H^+]} \qquad \text{(Eq. 12)}$$

By plotting $S$ *versus* $1/[H^+]$, a straight-line relationship gives $[HA]_0$ as the intercept and $([HA]_0K_a)$ as the slope. Dividing the slope by the intercept gives $K_a$, which is the macroscopic dissociation constant for phenylbutazone (3).

The pKa of phenylbutazone determined by spectrophotometry may be given by:

$$\text{pKa} = \text{pH} + \log\frac{A_{\text{base}} - A_{\text{obs}}}{A_{\text{obs}} - A_{\text{acid}}} \qquad \text{(Eq. 13)}$$

where pKa is the macroscopic value measured at $\mu = 0.5$ with potassium chloride, $A_{\text{base}}$ is the absorbance of a given solution of phenylbutazone under basic conditions where the phenylbutazone is virtually 100% in its anion form, $A_{\text{acid}}$ is the absorbance of the same solution under acidic conditions where phenylbutazone exists essentially as 100% in the protonated form, and $A_{\text{obs}}$ is the absorbance of the same solution at a pH between the two extremes (denoted as pH in Eq.13). The pKa values of phenylbutazone under these experimental conditions were 4.61 (solubility technique) and 4.54 (spectrophotometric technique), and the intrinsic solubility was $2.61 \times 10^{-5}$ $M$.

**Deuteration of Phenylbutazone and 2-Naphthoic Acid**—IR and NMR studies of the deuterated and nondeuterated forms of phenylbutazone and 2-naphthoic acid showed conclusively that the acidic proton of the nondeuterated forms was exchanged for deuterium and that no other protons in the molecules were affected. NMR spectra of both pairs of compounds showed the disappearance of the acidic proton signal ($\delta$ 12.5 ppm for 2-naphthoic acid[6] and 3.2 ppm for phenylbutazone[7] with reference to a tetramethylsilane standard). On deuteration, no other differences in the NMR spectra were observed.

IR spectra of both forms of phenylbutazone were very similar except for a sharpening of a peak at 2860 $cm^{-1}$ and the presence of additional peaks at 2060 $cm^{-1}$ and 1100–1200-$cm^{-1}$ for the deuterated form. The IR spectra for both forms of 2-naphthoic acid showed a more noticeable difference between the compounds. The broad band, typically associated with intermolecular hydrogen bonding (2200–2100 $cm^{-1}$), was present in the spectrum of the protonated form but virtually absent in that of the deuterated form. This finding suggested that the lower melting point of the deuterated 2-naphthoic acid (180–181°) compared to that of the protonated form (184–185°) was due to a significantly lower degree of hydrogen (or deuterium) bonding in the deuterated 2-naphthoic acid.

**Initial Dissolution Rates as a Function of Disk Rotation Speed**—Table I shows the initial dissolution rates of phenylbutazone as a function of disk rotation speed in solutions of $pH_{bulk}$ 2.0 and 6.50 and of *d*-phenylbutazone as a function of the same disk rotation speeds at $pH_{bulk}$ 6.50. These data are plotted *versus* $\omega^{1/2}$ (a function of rotation speed) in Fig. 2. Table II shows the initial dissolution rates of 2-naphthoic acid and *d*-2-naphthoic acid in a solution of $pH_{bulk}$ 2.0 at varying disk

[6] Solvent used was deuterated chloroform–dimethyl sulfoxide-$d_6$, ~1:2.

[7] Solvent used was carbon tetrachloride with tetramethylsilane standard in deuterated chloroform.

**Table I—Initial Dissolution Rates ($J_{obs}$) of Phenylbutazone and *d*-Phenylbutazone at Varying Disk Rotation Speeds in Media of $\mu$ = 0.5 with Potassium Chloride and Varying $pH_{bulk}$ at 25°**

| Disk Rotation Speed, rpm | Phenylbutazone $\omega^{1/2}$[a] | Phenylbutazone $J_{obs}$ ($\pm SD$)[b] (at $pH_{bulk}$ 2.00[c]) × $10^5$ | Phenylbutazone $J_{obs}$[b] (at $pH_{bulk}$ 6.5[d]) × $10^5$ | *d*-Phenylbutazone, $J_{obs}$[b] (at $pH_{bulk}$ 6.5[d]) × $10^5$ |
|---|---|---|---|---|
| 100 | 3.24 | 1.23 (±0.26) | 3.68 | 3.04 |
| 200 | 4.58 | 1.66 (±0.04) | 4.74 | 3.66 |
| 300 | 5.61 | 1.80 (±0.17) | 5.88 | 4.32 |
| 450 | 6.87 | 2.04 (±0.12) | 6.64 | 4.94 |
| 600 | 7.93 | 2.58 (±0.34)[e] | 7.24 | 5.66 |
| 900 | 9.71 | — | 8.67 | 6.50 |

[a] The angular velocity of the disk in radians per second. [b] The standard deviation is from at least four measurements; where standard deviation values are not given, the mean was obtained from two or three similar values. (The $J$ units are mg $cm^{-2}$/sec and not moles $cm^{-2}$/sec). [c] In 0.01 *M* HCl/0.49 *M* KCl solution. [d] In 0.5 *M* KCl solution, pH-statted. [e] *d*-Phenylbutazone under these conditions gave an initial dissolution rate of $2.98 \times 10^{-5}$ ($\pm 0.23 \times 10^{-5}$) mg $cm^{-2}$/sec.

**Table II—Initial Dissolution Rates ($J_{obs}$) of 2-Naphthoic and *d*-2-Naphthoic Acids at Varying Disk Rotation Speeds in Media of $\mu$ = 0.5 with Potassium Chloride and $pH_{bulk}$ 2.00[a] at 25°**

| Rotation Speed, rpm | $\omega^{1/2}$[c] | $J_{obs}$ ($\pm SD$)[b] (at $pH_{bulk}$ 2.00 × $10^5$) 2-Naphthoic Acid | $J_{obs}$ ($\pm SD$)[b] (at $pH_{bulk}$ 2.00 × $10^5$) *d*-2-Naphthoic Acid |
|---|---|---|---|
| 100 | 3.24 | 3.63 (±0.09)[d] | 3.71 (±0.13) |
| 200 | 4.58 | 4.88 (±0.06) | 4.87 (±0.13) |
| 300 | 5.61 | 5.78 (±0.05) | 5.74 (±0.17) |
| 450 | 6.87 | 7.37 (±0.47) | 7.32 (±0.48) |
| 600 | 7.93 | 8.52 (±0.52) | 8.40 (±0.18) |
| 900 | 9.71 | 10.09 (±0.57) | 10.01 (±0.36) |

[a] Medium was 0.01 *M* HCl/0.49 *M* KCl with no pH-stat used during dissolution runs. [b] The standard deviation from three repeated runs. [c] The angular velocity of the disk in radians per second. [d] All units are in mg/$cm^2$/sec.

rotation speeds. These data were not plotted because they are essentially identical to those given previously (1). All the dissolution rate data as a function of rotation speed are summarized in Table III.

The Levich–Nernst model states that $J$, the dissolution rate from a rotating disk of solid material, is directly proprotional to $\omega^{1/2}$, a function of the disk's rotation speed, as seen by:

$$J = 0.62\, D^{2/3}\nu^{-1/6}C_S\omega^{1/2} \qquad \text{(Eq. 14)}$$

where $D$ is the diffusivity of the dissolving solute, $\nu$ is the kinematic viscosity of the dissolution medium, $C_S$ is the saturated solubility of the dissolving solute in the medium, and $\omega$ is the angular velocity of the rotating disk in radians per unit time. From Fig. 2, phenylbutazone under acidic conditions appeared to show a reasonable degree of linearity when $J$ was plotted against $\omega^{1/2}$. Therefore, phenylbutazone dissolves by a diffusion layer-controlled mechanism under acidic conditions since the correlation coefficient for this plot was reasonable and the calculated diffusivity from these data ($4.90 \times 10^{-6}$ $cm^2$/sec) was very close to that obtained from the square root relationship previously discussed (1) using the diffusivity of benzoic acid under identical conditions as a standard.

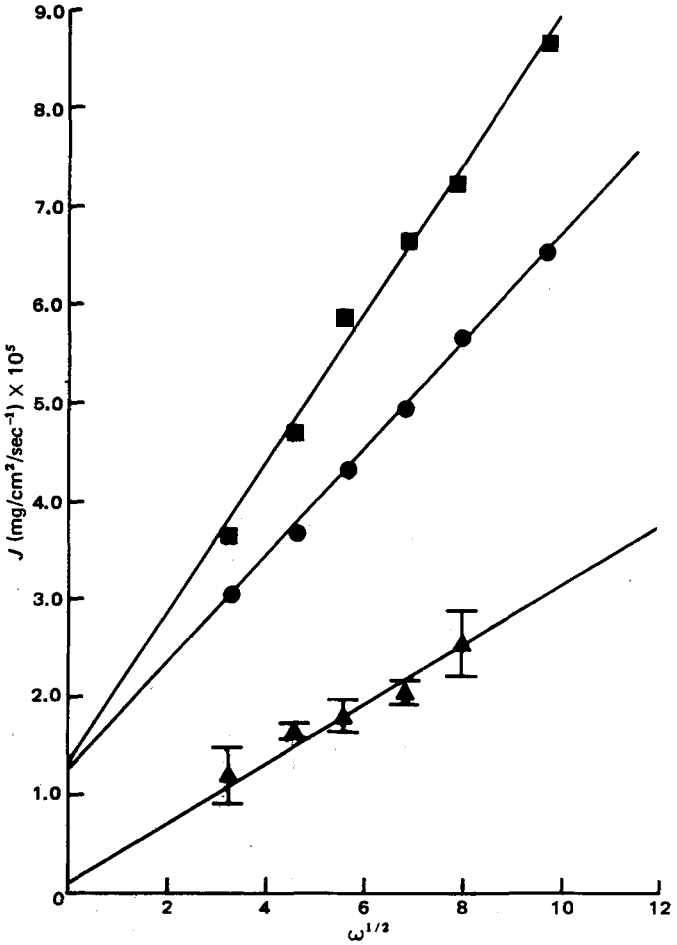

**Figure 2**—*Levich plot of the dissolution rate (J) as a function of the square root of the angular velocity ($\omega^{1/2}$) of a rotating disk of phenylbutazone (■) and d-phenylbutazone (●) at pH 6.5 (maintained by a pH-stat) and of phenylbutazone (▲) at pH 2.0 (25° at $\mu$ = 0.5 with potassium chloride).*

Initial dissolution rates of phenylbutazone and *d*-phenylbutazone with varying rotation speed at $pH_{bulk}$ 6.50 did not strictly obey the Levich model but showed the type of behavior that indomethacin displayed in earlier work under similar conditions (1). An additional mechanism appeared to be contributing to the dissolution rate of $pH_{bulk}$ 6.50, which was independent of the disk rotation speed as shown by a nonzero intercept.

It was assumed that a modified form of the Levich–Nernst relationship applies:

$$J = (0.62\, D^{2/3}\nu^{-1/6}C_S)\omega^{1/2} + \text{constant} \qquad \text{(Eq. 15)}$$

where the constant represents the nonzero intercept at zero rotation speed. The cause of this nonzero intercept is unknown but is being studied.

**Table III—Summary of Data Obtained for Protonated and Deuterated Forms of 2-Naphthoic Acid and Phenylbutazone from the $J_{obs}$ *versus* $\omega^{1/2}$ Regression Analysis (Data in Tables I and II) Performed at Varying $pH_{bulk}$ and 25°**

| Compound | $pH_{bulk}$ | Slope of $J_{obs}$ *versus* $\omega^{1/2}$ × $10^6$ | Intercept of $J_{obs}$ *versus* $\omega^{1/2}$ × $10^5$ | Correlation Coefficient for $r$ | Diffusivity from Slope, ($cm^2$/sec) × $10^6$ |
|---|---|---|---|---|---|
| 2-Naphthoic acid | 2.00 | 10.44 | 0.01 | 0.9991 | 6.52[a] |

| 10.20 | 6.16 | 297.75 | — | 295.60 |

[a] $J^H_{theor}$ is the calculated flux, assuming phenylbutazone acts as a classical acid; $J^H_{obs}$ is the observed flux of phenylbutazone; and $J^D_{obs}$ is the observed flux of *d*-phenylbutazone. All values of $J$ are in units of moles $cm^{-2}/sec \times 10^{11}$.

The two forms of phenylbutazone did not dissolve at the same rate at a given disk rotation speed at $pH_{bulk}$ 6.5, with *d*-phenylbutazone dissolving more slowly than phenylbutazone. Although *d*-phenylbutazone dissolution rates were not extensively measured under acidic conditions, a value was determined at 600 rpm at $pH_{bulk}$ 2.00, and it did not differ significantly from that obtained for phenylbutazone under the same conditions. Hence, the difference in dissolution rates of these compounds at $pH_{bulk}$ 6.50 may be due to a difference in the ionization rates of the two species within the diffusion layer.

The dissolution rates of 2-naphthoic acid and *d*-2-naphthoic acids under acidic conditions as a function of disk rotation speed showed that there was no significant difference between the two compounds when ionization was suppressed during the dissolution process. Thus, it was assumed that the deuteration of 2-naphthoic acid did not affect the intrinsic solubility of the acid, despite differences in crystal lattice energies (assumed from the melting point data) being observed between the dissolving solids. In view of the lability of deuterium bonded to a carboxylic acid oxygen atom, the similarity between results obtained for the dissolution rates of the two forms of 2-naphthoic acid was probably due to rapid exchange of deuterium with hydrogen in water immediately at the solid–liquid interface during dissolution. Thus, the diffusion rate of the nondeuterated form away from the solid–liquid interface was observed in both cases.

**Initial Dissolution Rates as Function of $pH_{bulk}$**—Tables IV and V contain initial dissolution rate data for both deuterated and protonated forms of phenylbutazone and 2-naphthoic acid as a function of $pH_{bulk}$ (maintained by pH-stat) and at a constant rotation speed. Also included are the theoretical values expected if 2-naphthoic acid and phenylbutazone acted as classical acids, ionizing instantaneously as they diffused through the diffusion layer (1).

Adherence of the dissolution rates of 2-naphthoic acid to the model described earlier (1), assuming instantaneous chemical-ionization reactions within the diffusion layer, was already established. Since the values for 2-naphthoic acid and the *d*-2-naphthoic acid ($J^D_{obs}$) closely agreed at every $pH_{bulk}$ value tested and since these values approximated those predicted by theory ($J_{theor}$), it may be reasoned that the deuterated and nondeuterated forms of 2-naphthoic acid diffuse and simultaneously react with base in the same way and to the same extent. This reasoning also confirmed that the two compounds dissolved and instantaneously achieved equilibrium with the reacting base in the diffusion layer and, therefore, acted in a classical manner. This behavior was consistent with the more rapid exchange of deuterium for hydrogen relative to the time taken for the molecules to traverse the diffusion layer. If exchange occurred instantaneously for the *d*-2-naphthoic acid at the solid–liquid interface, then it should dissolve identically to 2-naphthoic acid.

The data for deuterated and nondeuterated phenylbutazone (Table IV and Fig. 3) may be compared in the same way as for 2-naphthoic acid. Comparison between the $J_{obs}$ values for the two phenylbutazone forms to the $J_{theor}$ values for the same $pH_{bulk}$ showed that the fluxes of *d*-phenylbutazone were significantly slower than those of phenylbutazone by ~10–45% over the neutral $pH_{bulk}$ range. Furthermore, phenylbutazone gave experimental dissolution rates very close in value to those predicted by the theory (1) that assumed instantaneous equilibrium. Therefore, at 25° and $\mu = 0.5$ with potassium chloride and over a wide range of bulk solution pH, phenylbutazone was an example of a compound dissolving into a reactive medium showing simultaneous noninstantaneous chemical reaction that could be treated as if its ionization was instantaneous; *i.e.*,

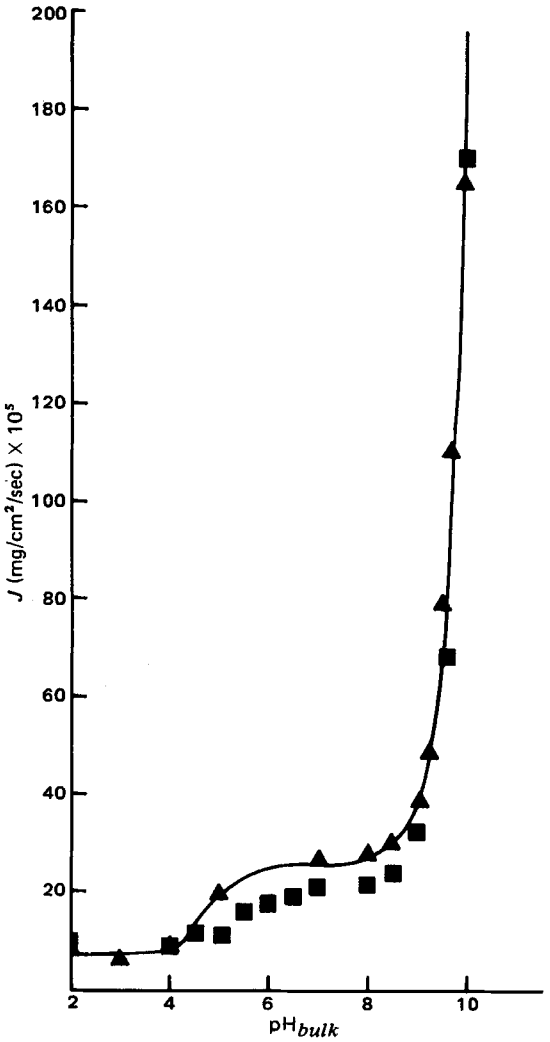

**Figure 3**—*Dissolution rate (J) versus $pH_{bulk}$ profile for phenylbutazone (▲) and d-phenylbutazone (■) from a rotating disk (600 rpm) dissolving in an aqueous medium (25° at $\mu = 0.5$ with potassium chloride). The $pH_{bulk}$ was maintained with a pH-stat. The continuous line represents the profile generated treating phenylbutazone as a carboxylic acid.*

**Table V—Absolute Dissolution Rates from Rotating Disks of 2-Naphthoic Acid (450 rpm) as a Function of Bulk pH [a]**

| $pH_{bulk}$ | $pH_0$ ($X = 0$ from theory) | $J^H_{theor}$, (moles $cm^{-2}/sec$) $\times 10^{10}$ | $J^H_{obs}$, (moles $cm^{-2}/sec$) $\times 10^{10}$ | $J^D_{obs}$, (moles $cm^{-2}/sec$) $\times 10^{10}$ |
|---|---|---|---|---|
| 2.00 | 2.00 | 3.950 | 4.280 | 4.249 |
| 6.00 | 4.28 | 11.130 | 13.300 | 13.547 |
| 7.00 | 4.29 | 11.200 | 13.820 | 13.853 |

[a] $J^H_{theor}$ is the calculated mass transport rate, $J^H_{obs}$ is the observed flux of the protonated acid, and $J^D_{obs}$ is the observed flux of the deuterated acid.

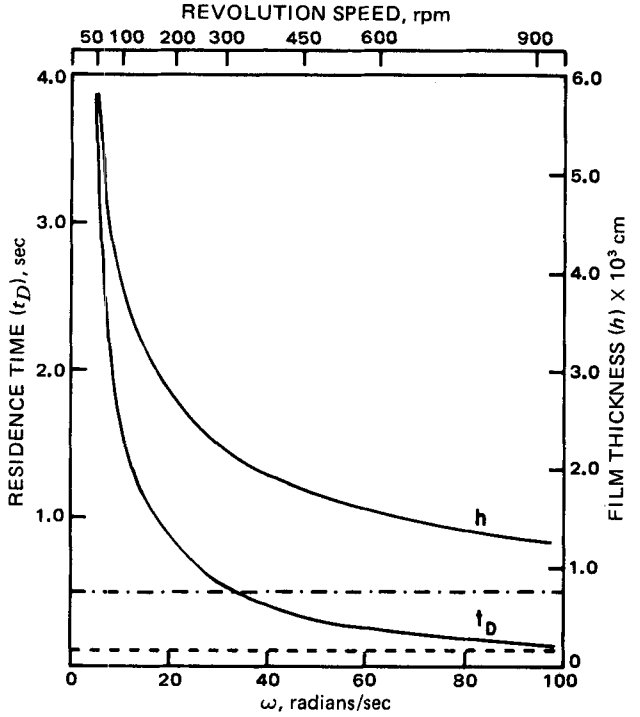

**Figure 4**—*Plot of residence time* ($t_D$) *and apparent diffusion layer thickness* (h) *for phenylbutazone as defined by Eqs. 18 and 19* versus *ω (angular velocity) for dissolution from a rotating disk. Times are shown for three half-lives for the deprotonation reaction (at* $pH_{bulk}$ *6.5). Key: ---, phenylbutazone, and -·-, d-phenylbutazone.*

the experimental results suggested that the ionization was still rapid enough that, relative to the diffusional processes, phenylbutazone still acted classically.

Contrary to the results shown for deuterated and nondeuterated 2-naphthoic acids, *d*-phenylbutazone dissolution between $pH_{bulk}$ 5.00 and 9.00 was markedly slower than that of phenylbutazone. It was thought that by studying *d*-phenylbutazone, where deuterium was exchanged for hydrogen at the ionizing center of the phenylbutazone molecule, any effects on its dissolution rate in reactive media due to the noninstantaneous ionization kinetics of phenylbutazone would be amplified. The rationale for this approach was explained earlier (12) and was based on the comparative strengths of a C–D and a C–H bond, a greater free energy of activation ($\Delta G^{\ddagger}$) being required to break the C–D bond for ionization than that required in the breaking of the C–H bond. Hence, the values of $k_1$ and $k_3$ in Schemes I and II should be smaller for *d*-phenylbutazone, whereas $k_2$ and $k_4$ should remain the same as in phenylbutazone if it is assumed that the reverse reaction, once the deuterium is removed, involves only protons.

**Residence Time and Ionization Reaction Time in Diffusion Layer**—When phenylbutazone diffuses across the aqueous diffusion layer during dissolution in an unreactive medium (*i.e.*, under acidic conditions) under steady-state conditions, the concentration profile for the acid will be linear as given by the Nernst model (1). Higuchi *et al.* (20) demonstrated that, under these conditions, the residence time ($t_D$), which was the average lifetime of a diffusing molecule in the diffusion layer of thickness $h$, was inversely proportional to the diffusivity of the molecule. The relationship between $t_D$, the diffusivity, and diffusion layer thickness is given by:

$$t_D = \frac{h^2}{2D_K} \qquad \text{(Eq. 16)}$$

where $D_K$ is as previously described. Since an expression for $h$ is given by the Levich rotating disk model shown by:

$$h = 1.612\, D_K^{1/3}\, \nu^{1/6}\, \omega^{-1/2} \qquad \text{(Eq. 17)}$$

substitution for $h$ may be performed in Eq. 16 to give:

$$t_D = \frac{1.3\, \nu^{1/3}}{D_k^{1/3}\, \omega} \qquad \text{(Eq. 18)}$$

Thus, for the specific case of steady-state initial dissolution conditions from a rotating disk, Eq. 18 states that $t_D$ is inversely proportional to $\omega$, the angular velocity of the disk in radians per unit time.

Figure 4 shows a plot of residence time and diffusion layer thickness *versus* $\omega$ for phenylbutazone, assuming that no chemical reaction occurs during the dissolution process (calculated from parameter values previously determined). For convenient representation of the relationship between $t_D$, $h$, and rotation speed, the abscissa is also marked in revolutions per minute (directly proportaional to $\omega$).

When phenylbutazone was dissolving into a medium of pH greater than its pKa, it would tend to dissociate according to the pH of the diffusion layer. With classical acids, this dissociation process was instantaneous, as described for 2-naphthoic acid. For a carbon acid such as phenylbutazone, however, the observed rate constant for the rate of approach to this equilibrium can be slow (3).

Astarita (21) defined a reaction time ($t_r$) that is similar to the half-life in a first-order or pseudo-first-order reaction and is given by:

$$t_r = \frac{1}{k} \qquad \text{(Eq. 19)}$$

where $k$ is a simple first-order or pseudo-first-order rate constant defining the reaction processs. Therefore, the $t_r$ value represents the time taken to complete 63% of the given reaction by a first-order mechanism.

If the given average reaction time was much longer than the average residence time of phenylbutazone in the diffusion layer under defined hydrodynamic conditions, the reaction would only effectively take place in the bulk solution. As the reaction time ($t_r$) decreased to where it became closer in value to $t_D$, the dissociation reaction would influence the flux as defined by Eqs. 1–4. Once $t_r$ becomes much smaller than $t_D$, phenylbutazone should behave classically, *i.e.*, as in the case of 2-naphthoic acid.

Phenylbutazone ionization kinetics cannot normally be represented by a simple overall first-order process (3). Stella and Pipkin (3) described an equation for calculating the observed buffer-independent rate constant for approach to the ionization equilibrium (Eq. 20) for phenylbutazone and specified conditions under which it may be simplified.

$$k_{obs} = k_1 + k_3[OH^-] + \frac{k_2[H^+]K_{a,enol}}{K_{a,enol} + [H^+]} + \frac{k_4 K_{a,enol}}{K_{a,enol} + [H^+]} \qquad \text{(Eq. 20)}$$

where $k_{obs}$ is the rate constant for the approach to equilibrium, $k_{1-4}$ are

**Table VI—Calculated $k_{obs}$ and ($t_r$) across the Diffusion Layer of Phenylbutazone Dissolving in $pH_{bulk}$ 6.50 Using a pH-stat at $\mu$ = 0.5 and 25°**

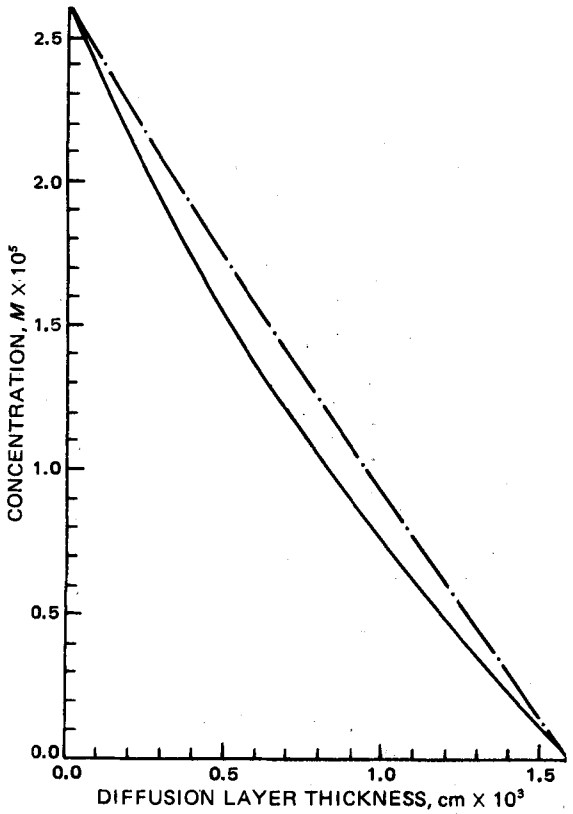

**Figure 5**—*Concentration profiles across an aqueous diffusion layer for phenylbutazone (– –) and* d*-phenylbutazone (–·–) at* $pH_{bulk}$ *5.*

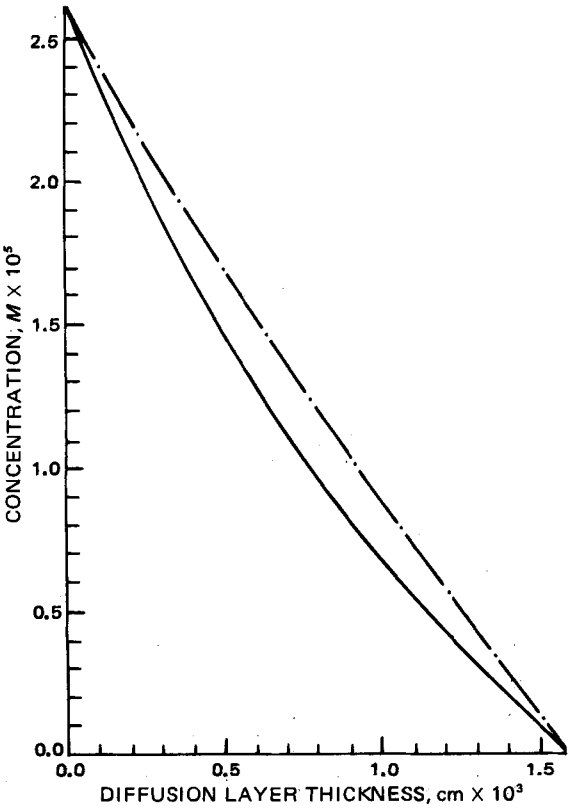

**Figure 6**—*Concentration profiles across an aqueous diffusion layer for phenylbutazone (– –) and* d*-phenylbutazone (–·–) at* $pH_{bulk}$ *7.*

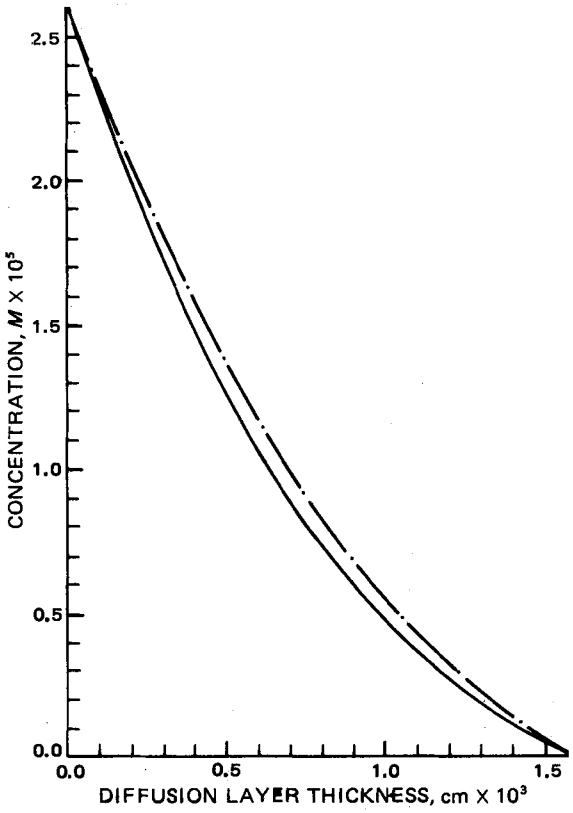

**Figure 7**—*Concentration profiles across an aqueous diffusion layer for phenylbutazone (– –) and* d*-phenylbutazone (–·–) at* $pH_{bulk}$ *9.*

as given previously, $[H^+]$ is the hydrogen-ion concentration, $[OH^-]$ is the hydroxide-ion concentration at which $k_{obs}$ is determined, and $K_{a,enol}$ is the dissociation constant of the enolic form of phenylbutazone (3). Although all of the data for these parameters were measured at $\mu = 0.1$ and 25° (3), it will be assumed that the values would remain reasonably unchanged in a medium of ionic strength 0.5.

From the phenylbutazone dissolution data measured in $pH_{bulk}$ 6.50 using varying rotation speeds and Eq. 20, it was possible to gain some insight into the approximate values of $k_{obs}$ within the diffusion layer during dissolution. Since the nondeuterated phenylbutazone dissolved in a classical manner in reactive media, the model used for instantaneous reaction (1) may be applied to phenylbutazone to estimate $[H^+]$ and $[OH^-]$ across the diffusion layer for any given bulk solution conditions.

Accordingly, $pH_{bulk}$ 6.50 at 600 rpm was chosen and the values of $[OH^-]$, $[H^+]$, and pH in the diffusion layer was calculated using the instantaneous reaction model (1). From these values, it was possible to use a simplified version of Eq. 20 to calculate the corresponding values for $k_{obs}$ at each point in the diffusion layer. The simplified form of Eq. 20 is given by:

$$k_{obs} = k_1 + \frac{k_2[H^+]K_{a,enol}}{K_{a,enol} + [H^+]} \qquad \text{(Eq. 21)}$$

which assumes from Eq. 20 that $k_3[OH^-]$ and $k_4$ are negligible relative to the other terms in the equation. Table VI shows the variation of $k_{obs}$ across the film if the equilibrium values of $[OH^-]_X$ and $[H^+]_X$ actually exist at a given position $X$ in the diffusion layer. Under these same conditions, $t_D$ is 0.27 sec at 600 rpm.

The $t_r$ values across the film do not differ by much and they approach the limiting value $t_r = 1/k_{obs} \simeq 0.1$ sec. This value is displayed in the plot given in Fig. 4; assuming that the deviation from Levich–Nernst behavior seen at $pH_{bulk}$ 6.50 in Fig. 2 is not significant, $t_D$ only approaches the limiting $t_r$ value when very rapid revolution speeds are used. Therefore, any effects that may be due to noninstantaneus ionization of phenylbutazone in the diffusion layer would only be significant when $t_D$ approaches the value of $t_r$. Note that the limiting pH at $X = 0$ was ~5. At this pH, the dissociation of phenylbutazone favors formation of its enolate anion. If $t_r$ for establishing this equilibrium was longer or about the same as $t_D$

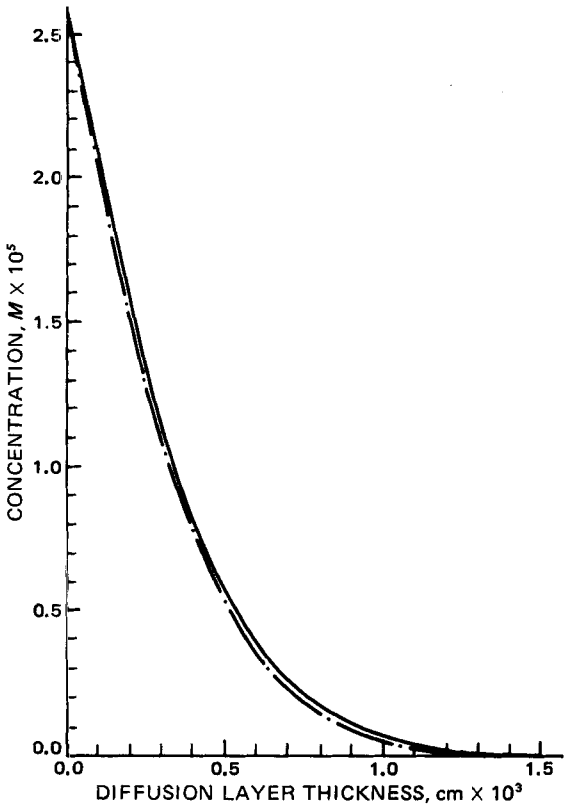

**Figure 8**—*Concentration profiles across an aqueous diffusion layer for phenylbutazone (– –) and* d*-phenylbutazone (-·-) at* $pH_{bulk}$ *10.*

in the diffusion layer, then deviation from classical behavior should have been observed under the described conditions.

To support these statements, the behavior of *d*-phenylbutazone under identical conditions was studied. Deuterated phenylbutazone should show a slower rate of approach to equilibrium in its ionization due to a primary isotope effect; *i.e.*, $k_1$ and $k_3$ for the initial dissociation of *d*-phenylbutazone will have a greater initial $t_r$ value than phenylbutazone under the same conditions. Therefore, the rotation speed at which $t_D$ becomes numerically similar to the limiting $t_r$ value was expected to be lower for *d*-phenylbutazone than for phenylbutazone, assuming again that the Levich–Nernst model applied and there were no differences in $D_{HA}$ and $[HA]_0$ between the two compounds.

The limiting $t_r$ value of *d*-phenylbutazone may be approximated by assuming a value for the primary isotope effect for the deprotonation of phenylbutazone. If a primary isotope effect of five was assumed (22) in $k_1$ (ignoring $k_3$), a limiting $t_r$ value of ~0.5 sec was calculated. This value was also displayed in Fig. 4 and indicated how $t_D$ approaches the limiting value of $t_r$ at much slower disk rotation speeds than in the case of phenylbutazone. Hence, any noninstantaneous reaction with base in the diffusion layer will affect the dissolution rates of *d*-phenylbutazone more than those of phenylbutazone under the same conditions. This finding was confirmed in Fig. 2 where the dissolution rates of *d*-phenylbutazone at $pH_{bulk}$ 6.50 were significantly slower than those of phenylbutazone under identical conditions.

The qualitative arguments expressed here were useful in interpreting the differences in dissolution rates between phenylbutazone and *d*-phenylbutazone. Figures 5–8, obtained by integrating numerically Eqs. 1–4, show the concentration gradients existing across the diffusion layer during dissolution of phenylbutazone and its deutero analog for pH 5, 7, 9, and 10. It was assumed in these simulations that *d*-phenylbutazone was dedeuterated by hydroxide ion and water five times slower than deprotonation of phenylbutazone. Calculated fluxes and pH at the interface are shown in Table VII.

The simulations appear to represent the flux data adequately. The observed dissolution rates for *d*-phenylbutazone were higher (pH 7 and 9) than the predicted theoretical values because deuterium was only abstracted once in practice but the model assumed that the rate of dissociation was that for deuterium for all abstractions. It can be seen from the figures that at pH 5 and 7, the concentration gradient between phenylbutazone and its deutero analog was more marked than when these two compounds dissolved under more basic conditions. At pH 9, the gradient difference was smaller; at pH 10, it was negligible. These results were consistent with the earlier argument that as the $pH_{bulk}$ is raised, the diffusion layer reaction time becomes faster and both phenylbutazone and *d*-phenylbutazone approach classical behavior ($t_r < t_D$). Thus, under neutral to slightly acidic conditions, deuterated phenylbutazone deviates from classical behavior. However, when basic conditions prevail, the dissolution of that compound was faster since the high concentration of hydroxide ion increased the rate of *d*-phenylbutazone ionization.

**Table VII—Simulated ($J_{theor}$) and Observed ($J_{obs}$) Initial Dissolution Rates for Phenylbutazone and *d*-Phenylbutazone at Various $pH_{bulk}$ Values** [a]

| $pH_{bulk}$ | $pH_0^{calc}$ [b] | Phenylbutazone | | *d*-Phenylbutazone | |
|---|---|---|---|---|---|
| | | $J_{theor}$ | $J_{obs}$ | $J_{theor}$ | $J_{obs}$ |
| 5 | 4.77 | 19.95 | 19.95 | 11.24 | 11.25 |
| 7 | 4.95 | 27.18 | 27.18 | 16.23 | 20.27 |
| 9 | 5.17 | 38.34 | 38.39 | 27.59 | 32.95 |
| 10 | 5.85 | 189.54 | 187.01 | 187.01 | 169.97 |

[a] All values of $J$ are in units of moles $cm^{-2}$/sec. [b] Calculated from the simulations.

In view of the dissolution behavior of phenylbutazone under various conditions, it is unlikely that noninstantaneous ionization kinetics, demonstrated so clearly for this compound (3), play a major role in determining the dissolution rate, either *in vitro* or *in vivo*. This is due to the fact that the average diffusion layer residency time for a typical aqueous diffusion layer is longer than the average reaction time for the ionization of this carbon acid.

# High-Pressure Liquid Chromatography of Amiodarone in Biological Fluids

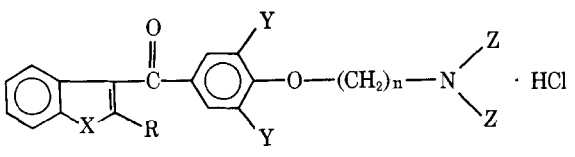
L. J. LESKO *x, A. MARION *, A. T. CANADA *, and C. HAFFAJEE ‡

Received January 5, 1981, from the * *Drug Concentration Laboratory, Department of Pharmacy and Clinical Pharmacy, and the* ‡ *Department of Medicine, University of Massachusetts Medical Center, Worcester, MA 01605.* Accepted for publication March 24, 1981.

**Abstract** □ A rapid, sensitive, and specific method of analysis for amiodarone in serum, urine, and tissue by high-pressure liquid chromatography is described. Sample preparation includes acidification with two volumes of 0.2 *M* acetate buffer followed by extraction into five volumes of hexane. The organic solvent is dried, and the residue is reconstituted in mobile phase and injected into the chromatograph. Separation is obtained using a silica column and a chloroform–methanol–ammonia mobile phase. Detection at 254 and 280 nm showed the assay to be specific in the presence of other commonly administered drugs. Levels of 0.05 μg/ml can be measured with a precision of ±15%; but with appropriate modification of the procedure, levels as low as 0.025 μg/ml can be measured with suitable precision. The inter- and intraday coefficient of variation for replicate analysis of spiked serum samples is <5%. This method is useful for single- and multiple-dose pharmacokinetic studies of amiodarone in animals and humans.

**Keyphrases** □ Amiodarone—high-pressure liquid chromatography in biological fluids □ High-pressure liquid chromatography—amiodarone in biological fluids □ Vasodilator—amiodarone, high-pressure liquid chromatography in biological fluids

Amiodarone[1] (I), a benzofuran derivative, is structurally similar to thyroxine. It is an effective antiarrhythmic agent for the treatment of supraventricular and ventricular tachyarrhythmias (1, 2). The pharmacokinetics of amiodarone have been studied in animals and humans following the administration of radiolabeled amiodarone and the measurement of total radioactivity in serum and urine (3). However, because of the nonspecificity of total radioactivity measurements, a sensitive and specific method of analysis for unlabeled amiodarone is needed. Flanagan *et al.* (4) described a high-pressure liquid chromatographic (HPLC) method for the measurement of amiodarone in plasma or serum with a sensitivity of 0.05 μg/ml, but they did not indicate if the assay was sensitive enough for single-dose pharmacokinetic studies. One disadvantage of their method is the use of a mobile phase containing 15 parts of ether. Its volatility may cause chromatographic variations.



I: X = O, R = $C_4H_9$, Y = I, n = 2, Z = $C_2H_5$
II: X = S, R = $C_2H_5$, Y = Br, n = 3, Z = $C_3H_7$

[1] Cordarone, Labaz Laboratories, Ambares, France.

The present report describes a rapid, sensitive, and specific HPLC technique for amiodarone in serum, urine, or tissues. Because of a concentrating step during sample preparation, a sensitivity of 0.025 μg/ml with acceptable precision was obtained. This method was used to measure amiodarone in biological fluids of dogs and humans in single- and multidose pharmacokinetic studies and is acceptable for postmortem tissue analysis.

## EXPERIMENTAL

**Reagents and Chemicals**—Amiodarone hydrochloride[2] and the internal standard[2] (II), a benzothiophene derivative of amiodarone, were used as received. Chloroform[3], methanol[3], and hexane were HPLC grade. All other reagents and solvents were analytical grade quality and were used as received.

**Amiodarone Standard**—A stock solution of amiodarone (1.0 mg/ml) was prepared by dissolving 10.6 mg of amiodarone hydrochloride in 10.0 ml of methanol. Serum standards were prepared by spiking blank control serum with appropriate microliter volumes of the stock solution to obtain five serum standards with the following concentrations of amiodarone: 0.125, 0.25, 0.50, 1.0, and 2.0 μg/ml.

**Internal Standard**—A stock solution of the internal standard (1.0 mg/ml) was made by dissolving 10.0 mg in 10.0 ml of methanol. An internal standard working solution was prepared by dilution of an aliquot of the stock solution with acetate buffer to contain 0.5 μg/ml.

**Acetate Buffer**—A 0.2 *M* acetate buffer was prepared by mixing 10.9 parts of Solution A (27.2 g of hydrous sodium acetate/liter) with 89.1 parts of Solution B (11.5 ml of acetic acid/liter). The pH of the buffer was adjusted to 3.8 by dropwise addition of either acetic acid or 1 *N* NaOH.

**Instruments and Chromatographic Conditions**—A microparticulate, stainless steel, normal-phase column[4], 4.0 mm × 30 cm, at ambient temperature was used for separation. The column was used with a septumless injector[5], a solvent delivery system consisting of a dual-piston pump[6], and a dual fixed-wavelength UV absorbance detector[7] equipped with 254- and 280-nm filters. The eluting solvent was chloroform–methanol–ammonium hydroxide (98.95:1.0:0.05) at a flow rate of 0.8 ml/min. A dual-pen recorder[8] with a range of 0–10 mv was used with a chart speed of 0.5 cm/min. Peak heights were measured to the nearest half-millimeter with a metric ruler.

Prior to analysis, the chromatographic system was stabilized for 10–20 min and 20 μl of a standard test mixture of amiodarone (1 μg/ml) and the internal standard (1 μg/ml) in the mobile phase was injected into the chromatograph. A response factor was calculated from the resulting peak heights to confirm accurate operation.

**Sample Preparation**—To a disposable screw-capped glass culture tube (16 × 125 mm) were added 0.5 ml of serum or urine and 1.0 ml of the internal standard working solution. The sample was extracted with 5.0 ml of hexane by gentle shaking on a horizontal shaker[9] for 10 min. For tissue analysis, 1.0 ml of tissue homogenate, prepared by homogenizing 1.0 g of blotted tissue in 10.0 ml of distilled water, was mixed with 2.0 ml

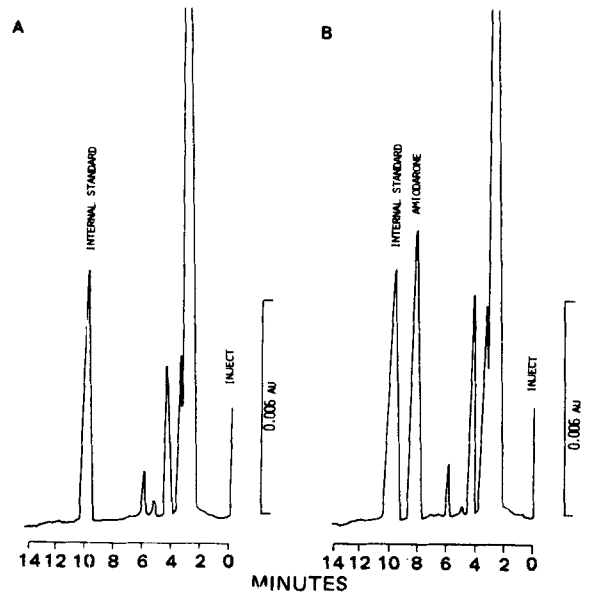

**Figure 1**—*Representative high-pressure liquid chromatogram of blank human serum (A) and human serum containing amiodarone, 1 μg/ml (B).*

of internal standard working solution and extracted with 10.0 ml of hexane. The organic phase (upper) was separated by centrifugation at 1600 × *g* for 5 min and transferred to a clean, disposable, glass test tube. The hexane was evaporated at 60° under a gentle nitrogen stream. The residue was reconstituted in 50 μl of mobile phase by vortex mixing[10], and 20 μl was injected into the liquid chromatograph. The concentration of amiodarone in the serum was determined from a calibration curve of peak height ratio (amiodarone to internal standard) *versus* amiodarone concentration in serum standards carried through this procedure.

## RESULTS AND DISCUSSION

Chromatograms obtained from blank human serum and serum spiked with amiodarone are shown in Fig. 1. The peaks representing amiodarone and the internal standard are symmetrical and well removed from the solvent front and extraneous serum peaks. The retention times of amiodarone and the internal standard are 8.2 and 10.0 min, respectively. Some control of retention times is possible by varying the proportion of ammonium hydroxide in the mobile phase. Increasing amounts of ammonium hydroxide decrease the retention times of both compounds. Reducing the amount of ammonium hydroxide increases retention times and results in notable peak tailing. Although the ratio of methanol in the mobile phase does not significantly alter retention times, a small quantity of methanol is useful in modifying the silica stationary phase and facilitating reproducible separation and peak symmetry.

Calibration curves of peak height ratio *versus* concentration were obtained by analyzing serum standards containing amiodarone in concentrations ranging from 0.05 to 2.0 μg/ml. Calibration curves were prepared using two different wavelengths for detection, 254 and 280 nm. (Detection at two wavelengths is a simple way to validate that there is only one solute under the peak of interest eluting from the column.) The calibration curves at both wavelengths were linear over the concentration range studied. The least-squares linear regression line representing the best fit of the amiodarone data at 254 nm had a slope of 1.69 and a *y* intercept (where *y* = peak height ratio) of −0.04 ($r$ = 0.999). The corresponding line at 280 nm had a slope of 1.01 and a *y* intercept of −0.03 ($r$ = 0.999). Although assay sensitivity is better at 254 nm, the assay is operated routinely at 280 nm. At this wavelength, detector noise is considerably less and solvent transparency to the detector is better, resulting in a more stable baseline and shorter equilibration time.

Assay precision was determined by repeated analysis of spiked serum samples containing low (0.25 μg/ml) and high (1.0 μg/ml) concentrations of amiodarone. The mean concentration, standard deviation, and coefficient of variation for intra- and interday analysis are shown in Table I. The within-day and day-to-day variation at each concentration was <5%.

[10]Vortex-genie, Scientific Industries, Springfield, Mass.

**Table I—Precision Data for the Determination of Amiodarone in Serum**

| Concentration, μg/ml | Intraday | | | Interday | | |
|---|---|---|---|---|---|---|
| | *n* | Mean ± *SD*, μg/ml | *CV*, % | *n* | Mean ± *SD*, μg/ml | *CV*, % |
| 1.0 | 5 | 0.993 ± 0.026 | 2.62 | 10 | 0.951 ± 0.040 | 4.21 |
| 0.25 | 5 | 0.230 ± 0.006 | 2.61 | 10 | 0.225 ± 0.011 | 4.89 |

The analytical recovery of amiodarone from serum was determined by comparing peak heights of amiodarone obtained by analyzing extracted, spiked serum specimens to the peak heights obtained by direct injection of methanolic solutions of amiodarone containing an amount of amiodarone equivalent to the amount in the spiked serum specimens. The mean ± *SD* recovery of amiodarone was 81.9 ± 5.0% ($n$ = 10) at a concentration of 1.0 μg/ml and 79.7 ± 2.5 ($n$ = 3) at a concentration of 0.25 μg/ml.

The sensitivity of this method is 0.05 μg/ml using 0.2 ml of serum samples and 0.01 aufs. The intraday coefficient of variation for spiked serum samples containing 0.05 μg/ml was ±13.0% ($n$ = 5). Lower concentrations of amiodarone may be detected with an analytical error of <±15% by increasing serum volume, detector attenuation, or injection volume. Detection at 254 nm would also increase sensitivity if necessary. Amiodarone concentrations of 0.025 μg/ml in serum were easily measurable by including such modifications in the procedure.

The described method for amiodarone analysis in serum has been used in single-dose pharmacokinetic studies and for monitoring serum amiodarone concentrations in patients receiving long-term amiodarone therapy. A typical serum amiodarone concentration–time profile obtained in two patients after administration of a single 800-mg oral loading dose is shown in Fig. 2. Amiodarone appears to be absorbed relatively slowly and disappears rapidly from the serum, at least following the first dose. Detailed studies of amiodarone pharmacokinetics in dogs and humans are being conducted.

The present assay uses a silica column and a nonaqueous mobile phase. Although bonded, reversed-phase systems using aqueous mobile phases are preferred by many chromatographers for the analysis of drugs in serum, a normal-phase, liquid–solid chromatographic system is useful for such drugs as amiodarone, cimetidine, trimethoprim, and tricyclic antidepressants. The mobile phase requirements are usually similar: a pure, organic solvent such as chloroform or methylene chloride of intermediate polarity similar to the solute; a small proportion of a miscible, more polar solvent, such as methanol or isopropanol, to modify the adsorbent activity of the stationary silica phase; and a small amount of base to adjust the ionization state of the solute and to minimize peak tailing. The amiodarone assay has been used for over 3 years and has proven to be simple, reliable, and accurate. Column life is often as long as 1 year or over 500 injections. The base in the mobile phase has not caused any apparent deterioration in column efficiency.

A single-step solvent extraction procedure is used to separate amiodarone from serum and to concentrate it. An acidic pH is optimal for the extraction. Organic solvents useful for extraction of amiodarone from serum include ether, methylene chloride, chloroform, and hexane. Hexane provides the cleanest extract and no back-extraction is required. Pretreatment of the serum before injection is rapid, and as many as 20–30 serum samples/day can be analyzed by one technician.

No endogenous substances or drugs have been found to interfere with

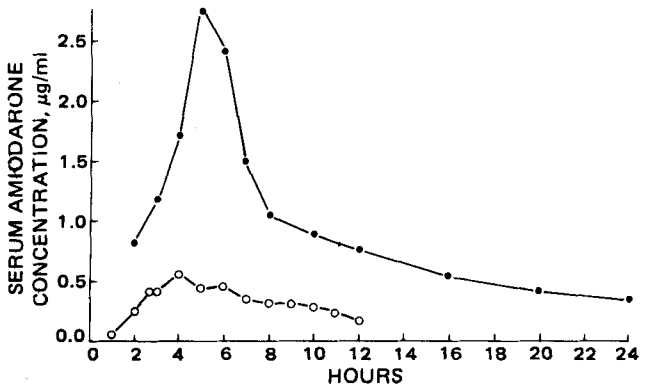

**Figure 2**—*Serum amiodarone concentrations in two patients after an 800-mg oral loading dose. Key:* ○, *Patient 1; and* ●, *Patient 2.*

amiodarone analysis using this procedure. The assay has been used for patients receiving amiodarone in combination with drugs such as procainamide, quinidine, lidocaine, disopyramide, digoxin, prednisone, furosemide, and other thiazide diuretics.

# Influence of the Method of Application on Pharmacokinetics of Nitroglycerin from Ointment in Humans

**S. SVED *x, W. M. McLEAN ‡, and I. J. McGILVERAY ***

Received April 6, 1981, from the **Bureau of Drug Research, Health Protection Branch, Health and Welfare Canada, Ottawa, Ontario, Canada K1A 0L2*, and the ‡*Drug Consultation Services, Ottawa General Hospital, and Department of Pharmacology, University of Ottawa, Ottawa, Ontario, Canada K1H 8L6.* Accepted for publication June 2, 1981.

**Abstract** □ A study was designed to test the influence of surface area on the percutaneous absorption of nitroglycerin from a commercial ointment formulation, using a simple crossover design. On separate occasions, three volunteers were given 16 mg of nitroglycerin (2%) over a 25- and 100-cm$^2$ area. Plasma nitroglycerin concentration was measured at 30, 45, 60, and 90 min using a sensitive capillary GLC–electron-capture detection method capable of quantitating to 150 pg/ml. Plasma concentrations at all times increased at least twofold with the increased surface area; highest observed concentrations were 0.17 and 0.41 ng/ml, respectively. A fourth volunteer received 16 and 32 mg of nitroglycerin over 100 cm$^2$. Doubling the dose increased the 0–90-min *AUC* by only 76% but caused a 3.5-fold increase in the 90-min plasma concentration. These results suggest that the surface area of application significantly influences the pharmacokinetics of nitroglycerin ointment.

**Keyphrases** □ Nitroglycerin—ointments, effect of method of application on pharmacokinetics, humans □ Ointments—nitroglycerin, effect of method of application on pharmacokinetics, humans □ Pharmacokinetics—effect of method of application on nitroglycerin ointments, humans □ Vasodilators—nitroglycerin ointments, effect of method of application on pharmacokinetics, humans

Nitroglycerin (glyceryl trinitrate), a vasodilator, is used extensively in the treatment of angina, cardiac infarction, and other circulatory conditions (1). However, because of its rapid elimination (2, 3), sustained-release or percutaneous dosage forms were developed. It was recently shown (4) that the ointment dosage form is more bioavailable than a sustained-action oral capsule formulation, and evidence was presented (5) that blood concentrations obtained after ointment application were dose dependent. However, neither study examined the influence of surface area on percutaneous absorption. It was also demonstrated (6) that the amount of nitroglycerin absorbed through the skin of a rhesus monkey was dependent on the surface area (but not the anatomical area) of application; however, the importance of this finding may not be generally recognized in the everyday use of this dosage form.

The present study investigated the influence of the surface area of application of the ointment on nitroglycerin bioavailability.

## EXPERIMENTAL

Three healthy adult male volunteers were each given 650 mg of acetaminophen orally (to control possible side effects), followed by 16 mg of nitroglycerin as a 2% ointment[1]. In the first part of the experiment ("small area"), the ointment was spread on paper[2] cut to 25 cm$^2$, and the paper was applied over the chest near the sternum and covered with an adhesive bandage. In the second part ("large area"), performed 2 months later on the same volunteers, an identical amount of nitroglycerin ointment was spread over 100 cm$^2$ in the same region of the chest, outlined on the skin with the help of a template. The ointment was applied as uniformly as possible with a stainless steel spatula and immediately occluded with a sheet of aluminum foil attached with adhesive tape. A fourth volunteer received 16 and 32 mg of nitroglycerin ointment (2%) spread over 100 cm$^2$ as described for the large area experiment.

Blood (10 ml) was collected by venipuncture, using an all-glass syringe, at the times indicated in Tables I and II, and dispensed at once into a chilled glass tube containing 0.3 ml of heparin sodium (300 U/per tube) and 50 μl of 0.002 *M* $AgNO_3$ (7). The contents were mixed by inversion, centrifuged immediately in the cold (5 min, 2000 rpm, 4°), and the plasma was separated for the nitroglycerin assay.

The assay method[3] consisted of mixing 1 or 2 ml of plasma with 100 μl of 1 *M* $AgNO_3$ (8), extracting with 10 ml of redistilled pentane containing 3 ng of *o*-dinitrobenzene[4], and evaporating the solvent in an ice bath with a gentle nitrogen stream. The residue was redissolved in 25 μl of redistilled hexane, and 4 μl of this solution was chromatographed on a capillary GLC system[5] equipped with an electron-capture detector[6], using a 25-m methyl silicone gum-coated open tubular column[7]. The chromatographic conditions were carrier gas, helium (6-ml/min septum purge, 2-ml/min column flow); makeup gas, argon–methane (95:5, 30 ml/min); injection, splitless, at 200°, 30-sec delay; oven, programmed temperature from 80 to 130° at 30°/min; detector, 150°; and retention

times, 3.8 min for nitroglycerin and 5.5 min for *o*-dinitrobenzene. Quantitation was by the peak height ratio method.

A two-compartment open model without lag time [$C_t = Ae^{-\alpha t} + Be^{-\beta t} - (A + B)e^{-k_a t}$] was used with an iterative computer program to fit a weighted ($1/y$) least-squares nonlinear regression curve to the experimental points. Goodness of fit was estimated as $r^2 = 1 - (\Sigma \text{ deviation}^2/\Sigma \text{ observation}^2)$.

## RESULTS AND DISCUSSION

The described method was specific for the unchanged drug and quantitative to ~0.15 ng/ml, and a detection limit of ~0.05 ng/ml. A standard curve, consisting of 20 determinations from 0.2 to 5.0 ng/ml, gave a mean relative standard deviation of 7.8% (range 2.5–12.3%) and a coefficient of determination ($r^2$) of 0.987. The regression of peak height ratio on concentration gave a slope of 0.483 ml/ng and an intercept of −0.004.

Table I shows the results obtained in three volunteers. After the application of 16 mg of nitroglycerin over 25 $cm^2$, the highest blood concentrations were observed at 30 min, with values of 0.15–0.18 ng/ml, close to the quantitation limit of the method, followed by a rapid decline to below the detection limits at 90 min. Because of these low concentrations, no meaningful area under the curve (*AUC*) values could be calculated. When the same amount of ointment was applied to the same volunteers but over a 100-$cm^2$ area, peak plasma concentrations occurred at 45 min and the decline was much slower. All concentrations were at least double the corresponding concentrations in the small area experiment.

For certain drugs, percutaneous absorption is known to be influenced by occluding the skin. However, this does not appear to be the case with nitroglycerin (9). In addition, it seems unlikely that the differences in the vapor barrier characteristics of the wax-impregnated paper used in the small area experiment and the aluminum foil used in all subsequent experiments would account for the differences obtained.

Table II shows the effect of dose on plasma nitroglycerin levels in one volunteer with the area held constant. The 16-mg dose over the 100-$cm^2$ area gave results very similar to those obtained for the three previous volunteers, although the relative absorption rate appeared to be marginally slower. With double the dose over the same surface area, absorption continued for a substantially longer time, as shown by the 3.5-fold increase in the 90-min blood concentration. However, the *AUC* (0–90 min) increased by only 76%, suggesting a nonlinear transfer process.

Preliminary pharmacokinetic studies for one experiment (Table II, 16 mg) prolonged for 6.5 hr (Fig. 1) suggest a two-compartment open model, with a distribution phase ($\alpha$) lasting for ~2 hr and a terminal

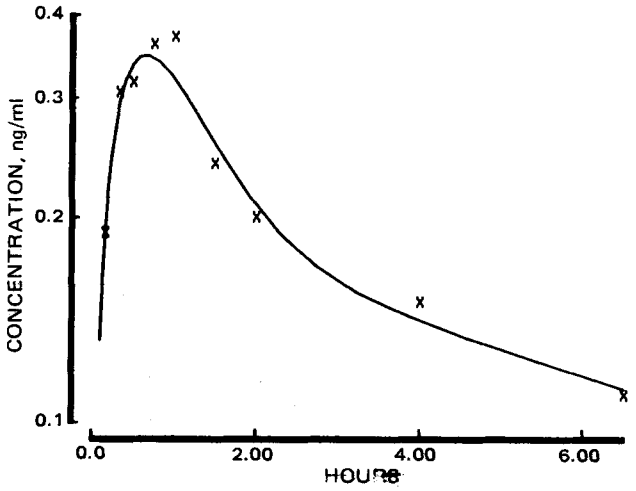

**Figure 1**—*Plasma profile of nitroglycerin following ointment application with a 16-mg dose in 2% ointment spread over 100 $cm^2$. The solid line indicates least-squares nonlinear regression to a two-compartment open model without lag time ($C_t = 28.1e^{-1.94t} + 0.197e^{-0.086t} - 28.3e^{-1.98t}$). Goodness of fit ($r^2$) = 0.994.*

decay ($\beta$) with a half-life of 3.5 hr. Nitroglycerin elimination from the blood is known to be rapid, with a half-life of 4–8 min after sublingual administration (4). Therefore, the apparent long terminal half-life in the present experiment must be due to other processes, *e.g.*, prolonged absorption.

These results agree well with those of Maier-Lenz *et al.* (4) who reported venous plasma concentrations between 0.4 and 0.7 ng/ml 60 min after the application of 30.6 mg of nitroglycerin in a 2% ointment, but they differ from those reported by Armstrong *et al.* (5), who obtained ~3 ng/ml after 0.27 mg of nitroglycerin/kg over 58 $cm^2$. The differences may be attributed largely to experimental design since the latter workers measured the concentration in arterial rather than venous blood and also examined percutaneus absorption in patients pretreated with intravenous nitroglycerin.

While the results reported here are only preliminary, they illustrate the cardinal importance of the application method, especially surface area, in the pharmacokinetics and, possibly, clinical efficacy of nitroglycerin ointments. These results indicate that the ointment should be carefully and consistently applied.

# Effect of Pirprofen on Protein Binding of Warfarin and Tolbutamide in Human Plasma

**RICHARD C. LUDERS** ˣ **and DOLLY CHAO**

Received January 21, 1981, from the *Research Department, Pharmaceuticals Division, Ciba-Geigy Corporation, Ardsley, NY 10502.* Accepted for publication May 14, 1981.

**Abstract** □ The extent of warfarin and tolbutamide binding to plasma proteins was determined with and without pirprofen by an ultrafiltration procedure employing $^{14}C$-labeled drugs. Results from *in vitro* studies at 37° showed that the degree of binding amounted to 97.8% for warfarin and 95.6% for tolbutamide. The binding characteristics of these drugs were not altered when plasma containing either warfarin or tolbutamide at concentrations equivalent to those expected normally after therapeutic dosing were concomitantly spiked with therapeutic amounts of pirprofen. Consequently, potentiation resulting from drug displacement would not be anticipated in humans when pirprofen is administered along with warfarin or tolbutamide.

**Keyphrases** □ Pirprofen—effect on protein binding of warfarin and tolbutamide □ Tolbutamide—protein binding in presence of pirprofen □ Warfarin—protein binding in presence of pirprofen □ Binding, protein—tolbutamide and warfarin

Pirprofen, 3-chloro-4-(2,5-dihydro-1*H*-pyrol-1-yl)-α-methyl benzeneacetic acid, is a new nonsteroidal anti-inflammatory agent which is well tolerated and highly effective in the treatment of rheumatoid arthritis (1–3). Investigations in these laboratories showed that pirprofen is bound to plasma proteins to an extent greater than 99.8%[1]. Concurrent salicylate administration causes a reduction of plasma pirprofen concentrations of ~31% in rats (4) and ~38% in humans[1].

## BACKGROUND

It has been well established that concomitant administration of two highly protein-bound drugs can lead to a displacement of one drug by the other when the two drugs compete for the same binding sites (5, 6). Drug displacement results in the availability of more free or unbound drug, which, in turn, might lead to a change in the distribution and elimination of the affected drug (7, 8). Certain nonsteroidal anti-inflammatory drugs, such as phenylbutazone, when administered concomitantly with warfarin cause total plasma warfarin concentrations to decrease by 50% while free drug increases to 65% (9). A study in rats showed that ibuprofen increased total clearance and the anticoagulant effect of warfarin (10); however, human serum containing ibuprofen showed only a 10% increase in free warfarin (11). Naproxen caused a partial displacement (14–17%) of warfarin (12).

Since arthritics undergoing chronic pirprofen therapy also might receive other drugs concomitantly, it was important to study the relationship between pirprofen concentrations and protein binding of drugs likely to be administered with pirprofen. The results of *in vitro* binding studies with warfarin and tolbutamide are discussed in this paper.

## EXPERIMENTAL

Pooled heparinized human plasma was obtained from healthy volunteers and spiked with either [$^{14}C$]warfarin[2] (1 or 10 μg/ml) or [$^{14}C$]tolbutamide[3] (20, 40, 100, or 200 μg/ml) in the presence of pirprofen[4] (0, 25, 50, 100, or 200 μg/ml).

The spiked samples were allowed to equilibrate at room temperature for at least 1 hr. Plasma aliquots, 1 or 2 ml, of each sample were pipetted into membrane cones[5], which had been soaked previously in distilled water for a minimum of 1 hr. These membranes were contained in conical supports[6], which were placed inside centrifugation tubes[7]. To ensure a uniform filtration, the seam of the membrane cone was faced toward the rotating direction. A prerun centrifugation[8] of 12 minutes (~1000×*g*) was necessary to eliminate the water content of the membrane. The ultrafiltrate (~300 μl) was collected after a second centrifugation (7 min) at the same speed. Another group of samples was carried through the same procedure (equilibration and treatment of filter cones) at 37 ± 2°. The centrifugation at elevated temperature was accomplished by placing the centrifuge inside a large oven maintained at 37 ± 2°.

Aliquots of 10–150 μl of the spiked plasma samples and of the ultrafiltrate were mixed with 15 ml of scintillation cocktail[9] and assayed for carbon 14 by liquid scintillation spectrometry[10]. Unbound warfarin and tolbutamide were expressed in percent and were obtained from the ratio of radioactivity measurements in the ultrafiltrate (unbound drug) to those in whole plasma (total drug). Means and standard deviations were obtained from four analyses.

Recoveries of warfarin and tolbutamide from the filtration cones were determined prior to the binding studies. Two milliliters of a pH 7.4 buffer solution containing 199.8 ng of tolbutamide/ml or 10.5 ng of warfarin/ml was added to the filtration cones and carried through the described procedure. Aliquots of 400 μl of the filtrate were then taken for radioactivity measurements. The data obtained from four replicate analyses (Table I) gave average recoveries of 99 ± 0.4% for tolbutamide and 92 ± 0.5% for warfarin.

**Table I—Percent Recovery of [$^{14}C$]Tolbutamide and [$^{14}C$]-Warfarin from Filtration Cones**

| Drug | Concentration, ng/ml | Determinations[a] 1 | 2 | 3 | 4 | Average ±*SD* |
|---|---|---|---|---|---|---|
| Warfarin | 10.5[b] | 92 | 92 | 91 | 92 | 92 ± 0.5 |

[a] Room temperature (22 ± 2°). [b] Equivalent to the amount of free drug in a plasma sample containing 1 μg of warfarin/ml. [c] Equivalent to the amount of free drug in a plasma sample containing 4 μg of tolbutamide/ml.

## RESULTS AND DISCUSSION

**Warfarin**—The results of binding studies at 37° (Fig. 1) indicate that the amount of free or unbound warfarin was 2.2 ± 0.15% (mean ± *SD*) for drug levels of 1–10 μg/ml. Conversely, 97.8% of the drug was bound to plasma protein. The data obtained at room temperature indicate about one-half as much unbound warfarin (1.1%). Yacobi and Levy (12) reported that 99.1% of the drug was bound to serum proteins for serum drug concentrations of 1.25 μg/ml.

When the warfarin samples (37°) were spiked with 50 μg/ml of pirprofen, a mean of 2.4 ± 0.24% (*SD*) was found; at 100 μg/ml, free warfarin averaged 2.3 ± 0.06% (*SD*). For these concentrations, pirprofen did not significantly ($p = 0.05$) alter warfarin binding. Since peak plasma concentrations of 23–44 μg/ml occur after chronic dosing with pirprofen (13) and since warfarin concentrations at steady state range from 1.6 to 4.1 μg/ml (9, 14), one would not expect warfarin to be displaced when therapeutic amounts of pirprofen are administered concomitantly with the anticoagulant. However, at pirprofen concentrations of 200 μg/ml or approximately four times the maximum levels found clinically, free

warfarin increased by 27 (room temperature) and 20% (37°).

**Tolbutamide**—The extent of binding to plasma proteins was 95.6 ± 0.15% (mean ± *SD*) at 37° for plasma tolbutamide levels between 40 and 100 µg/ml (Fig. 2). Similar results were obtained at room temperature for tolbutamide concentrations between 20 and 100 µg/ml. These values are comparable to those of Miller *et al.* (15), who reported 96.8 and 96.0% binding in young and old subjects, respectively, for plasma drug concentrations of 100 µg/ml, and to those of Zilly *et al.* (16), who found 95% binding following a 20-min intravenous infusion of 1600 mg of tolbutamide.

At 37°, no change in tolbutamide binding (95.6 ± 0.17%; $p = 0.05$) was observed when plasma samples containing 40–100 µg of tolbutamide/ml were spiked with pirprofen at levels up to 50 µg/ml. An increase in free tolbutamide was noted, however, for higher tolbutamide concentrations. As observed in Fig. 2, free tolbutamide increased to 8.0 (room temperature) and 9.9% (37°) for tolbutamide levels of 200 µg/ml. Although levels of this magnitude are not normally maintained after dosing with tolbutamide (17–19), the *in vitro* binding data suggest that binding sites were nearing saturation, resulting in greater availability of unbound drug. At these high concentrations, there is a suggestion that pirprofen can partially displace tolbutamide. The results (room temperature and 37°) show that the addition of 50 µg of pirprofen/ml increased free tolbutamide to ~11% of the total drug fraction.

In conclusion, pirprofen did not alter the binding characteristics of tolbutamide or warfarin when these compounds were added to plasma (*in vitro*) at levels expected normally after therapeutic dosing. Consequently, a change in pharmacological response from warfarin or tolbutamide resulting from drug displacement would not be anticipated in humans when either of these compounds is administered concomitantly with pirprofen.

# Importance of Radiochemical Purity of Radiolabeled Drugs Used for Determining Plasma Protein Binding of Drugs

**Keyphrases** □ Binding, plasma protein—effect of radiochemical impurity of radiolabeled drugs □ Drugs, radiolabeled—effect of radiochemical impurity on determination of plasma protein binding of drugs □ Impurity, radiochemical—of radiolabeled drugs, effect on determination of plasma protein binding of drugs

*To the Editor:*

Plasma protein binding of drugs has been the subject of intensive study for many years. It is an important pharmacological parameter, since it frequently affects drug distribution and elimination (1–3) and duration and intensity of pharmacological effects of drugs (4–6). A number of factors are known to affect the determination of drug protein binding, including the use of vacuum container[1] blood collection tubes (7, 8), some polyvinyl intravenous tubing (7, 9), and the administration of heparin (used therapeutically or as heparin lock) (9, 10). All of these factors result in diminished drug binding. An additional factor that has not received sufficient attention, although it has been stressed (11), is the importance of radiochemical purity of the radiolabeled drugs used in the determination of drug protein binding.

Equilibrium dialysis has become the most commonly used method for determining drug protein binding in clinical pharmacokinetic studies. Tracer amounts of radiolabeled drugs are added on either side of the dialysis membrane, usually on the buffer side. After dialysis has reached equilibrium, the unbound or free fraction of the drug ($f_f$) is usually calculated as the ratio of the radioactivity determined in the buffer phase to that determined in the plasma phase, correcting for volume differences, if any, between the two phases subjected to liquid scintillation counting, as follows:

$$f_f = \frac{R_B \times V_P}{R_P \times V_B} \qquad \text{(Eq. 1)}$$

where $R_B$ and $R_P$ represent the radioactivities determined in the buffer and plasma phases, respectively, and $V_P$ and $V_B$ represent the volumes of the plasma and buffer phases counted, respectively.

These calculations assume that the radiolabeled drug used is absolutely void of any radiochemical impurities. However, this is usually not the case unless the radiolabel is purified before use, since most commercially available radiolabeled drugs contain unknown, although small, amounts of radiochemical impurities. These radiochemical impurities containing the radioactive isotope (usually carbon 14 or tritium) may be a starting material or intermediary compounds in the chemical synthesis of the radiolabeled drug, or breakdown products of the drug.

[1] Vacutainer.

To evaluate the effects of varying degrees of radiochemical impurities present in the dialysis on the determination of plasma protein binding of drugs, Eq. 1 has to be modified. The observed free fraction ($f_f'$) can be calculated for varying combinations of the true or actual free fraction ($f_f$) and the fraction of impurities in the radiolabel used ($f_i$) assuming that $V_P$ equals $V_B$, using the expression:

$$f_f' = \frac{[R_T - (R_T \times f_i)]\, f_f + \left(\frac{R_T \times f_i}{2}\right)}{[R_T - (R_T \times f_i)] + \left(\frac{R_T \times f_i}{2}\right)} \qquad \text{(Eq. 2)}$$

where the numerator represents $R_B$ and the denominator represents $R_P$ in Eq. 1 and $R_T$ represents the total radioactivity added (consisting of both the drug of interest and the impurities); it is assumed that the radiochemical impurities are not bound to plasma proteins and distribute evenly in the plasma and buffer phases. The former terms in the numerator and denominator in Eq. 2 represent the actual free fraction, while the sum of the latter terms in the numerator and denominator represents the radioactivity due to radiochemical impurities.

Simulations were carried out using Eq. 2 to illustrate the effects of varying degrees of radiochemical impurities in the radiolabel used on the determination of plasma protein binding of drugs. Figure 1 shows simulations of the observed free fraction *versus* the actual free fraction, when the impurities in the radiolabel vary from 2.5–10% of the total radioactivity added. It can be seen that increasing the percentage of impurities in the radiolabel results in an

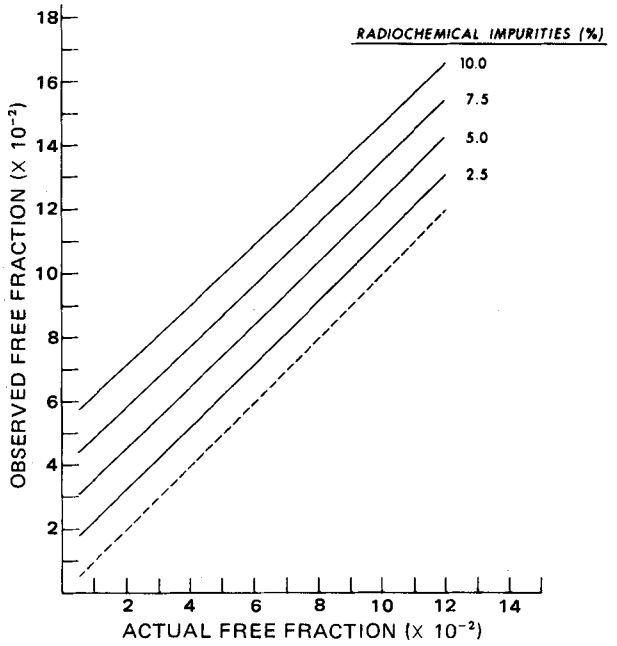

**Figure 1**—*Effects of varying degrees of radiochemical impurities present in dialysis on the determination of plasma protein binding of drugs.*

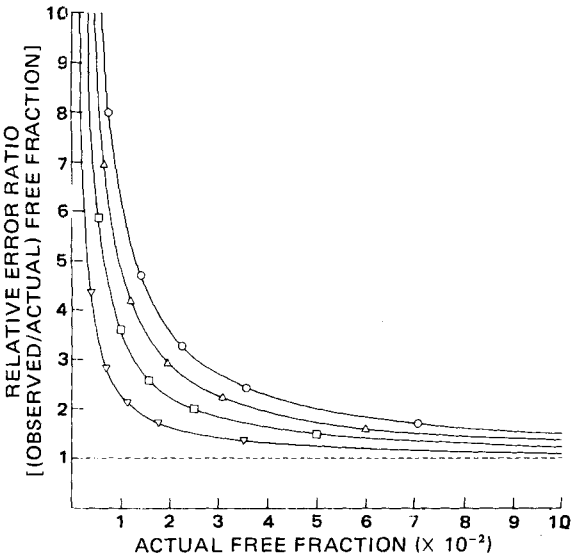

**Figure 2**—*Effects of varying degrees of radiochemical impurities present in dialysis on the relative error involved in the determination of plasma protein binding of drugs. Key:* ○, *10.0;* △, *7.5;* □, *5.0; and* ▽, *2.5% radiochemical impurities.*

upward shift of the linear relationship between the observed *versus* the actual free fraction.

However, the relative error on the determination of drug protein binding caused by the radiochemical impurities varies markedly depending on the actual free fraction; the lower the actual free fraction the greater the relative error and vice versa. This relative error can be expressed as the ratio of the observed to actual free fraction, which indicates how many times higher the observed free fraction is than the actual free fraction.

Figure 2 shows a plot of this relative error ratio *versus* the actual free fraction. It has an expected hyperbolic form for any given degree of radiochemical impurities present because the independent variable is in the denominator of the dependent variable. It can be seen from Fig. 2 that the observed free fraction will be ~2.3–6.3 times higher than an actual free fraction of 0.01 when radiochemical impurities vary from 2.5–10%, while the observed free fraction is only ~1.1–1.5 times higher than an actual free fraction of 0.1 with the same range of radiochemical impurities present.

The use of a radiolabel containing radiochemical impurities in dialysis for the determination of protein binding in clinical pharmacokinetic studies will not only result in a wrong value, but it will make all comparisons of binding data difficult. Such comparisons are frequently of interest, *e.g.*, when evaluating the effects of other drugs or disease states on the protein binding of drugs or when comparing drug binding in different groups of age or sex. This effect can be illustrated by two groups of drug binding data with average actual free fractions of 0.01 and 0.02. When a radiolabel with 5% radiochemical impurities is used, this 100% difference in the actual free fractions will reduce to a 28% difference in the free fractions, *i.e.*, the observed free fractions will be 0.035 and 0.045. It is likely that a true statistically significant difference among various groups of binding data may therefore become obscured. Because of the significance of drug protein binding in clinical pharmacology, it is suggested that radiolabels used for the determinations of plasma protein binding of drugs be purified prior to dialysis, *e.g.*, by high-pressure liquid chromatography, and that the stability of the radiolabel be verified postdialysis in both buffer and plasma phases.

## Determination of Renal Clearances Using Arterial and Venous Plasma: Procainamide in Rabbits

**Keyphrases** □ Procainamide—renal clearance, determination using timed-interval method, rabbits □ Renal clearance—determination of procainamide using arterial and venous plasma, rabbits □ Pharmacokinetics—determination of renal clearance of procainamide using arterial and venous plasma, rabbits

*To the Editor:*

The timed-interval method is commonly employed in pharmacokinetic studies to determine the renal clearance ($Cl_r$) of a drug compound:

$$Cl_r = \frac{X_{t_1-t_2}}{AUC_{t_1-t_2}} \qquad \text{(Eq. 1)}$$

where $X_{t_1-t_2}$ and $AUC_{t_1-t_2}$ are the amount of the intact drug excreted and the area under the plasma concentration curve between times $t_1$ and $t_2$, respectively. To date, the potential effect of the source of plasma data, either arterial or venous, on the estimation of clearance using Eq. 1 has rarely been evaluated. The arterial and venous differences of six compounds were recently reported (1). The present

## Determination of Renal Clearances Using Arterial and Venous Plasma: Procainamide in Rabbits

**Keyphrases** □ Procainamide—renal clearance, determination using timed-interval method, rabbits □ Renal clearance—determination of procainamide using arterial and venous plasma, rabbits □ Pharmacokinetics—determination of renal clearance of procainamide using arterial and venous plasma, rabbits

*To the Editor:*

The timed-interval method is commonly employed in pharmacokinetic studies to determine the renal clearance ($Cl_r$) of a drug compound:

$$Cl_r = \frac{X_{t_1-t_2}}{AUC_{t_1-t_2}} \qquad \text{(Eq. 1)}$$

where $X_{t_1-t_2}$ and $AUC_{t_1-t_2}$ are the amount of the intact drug excreted and the area under the plasma concentration curve between times $t_1$ and $t_2$, respectively. To date, the potential effect of the source of plasma data, either arterial or venous, on the estimation of clearance using Eq. 1 has rarely been evaluated. The arterial and venous differences of six compounds were recently reported (1). The present

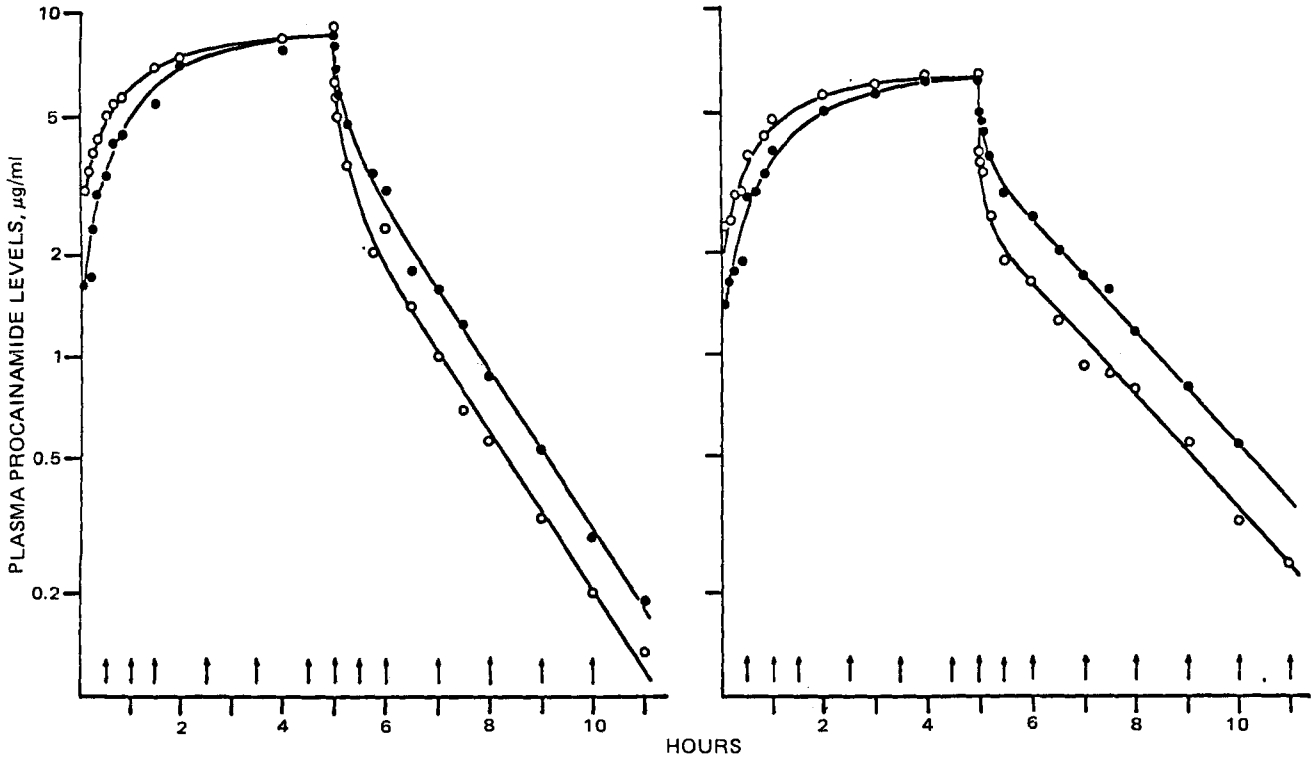

**Figure 1**—*Arterial (○) and venous (●) plasma procainamide concentration following constant intravenous infusion of procainamide hydrochloride, 52.4 and 92.4 mg/hr for 5 hr into rabbit 1 (left) and rabbit 2 (right), respectively. The arrows indicate the end of each renal clearance determination period.*

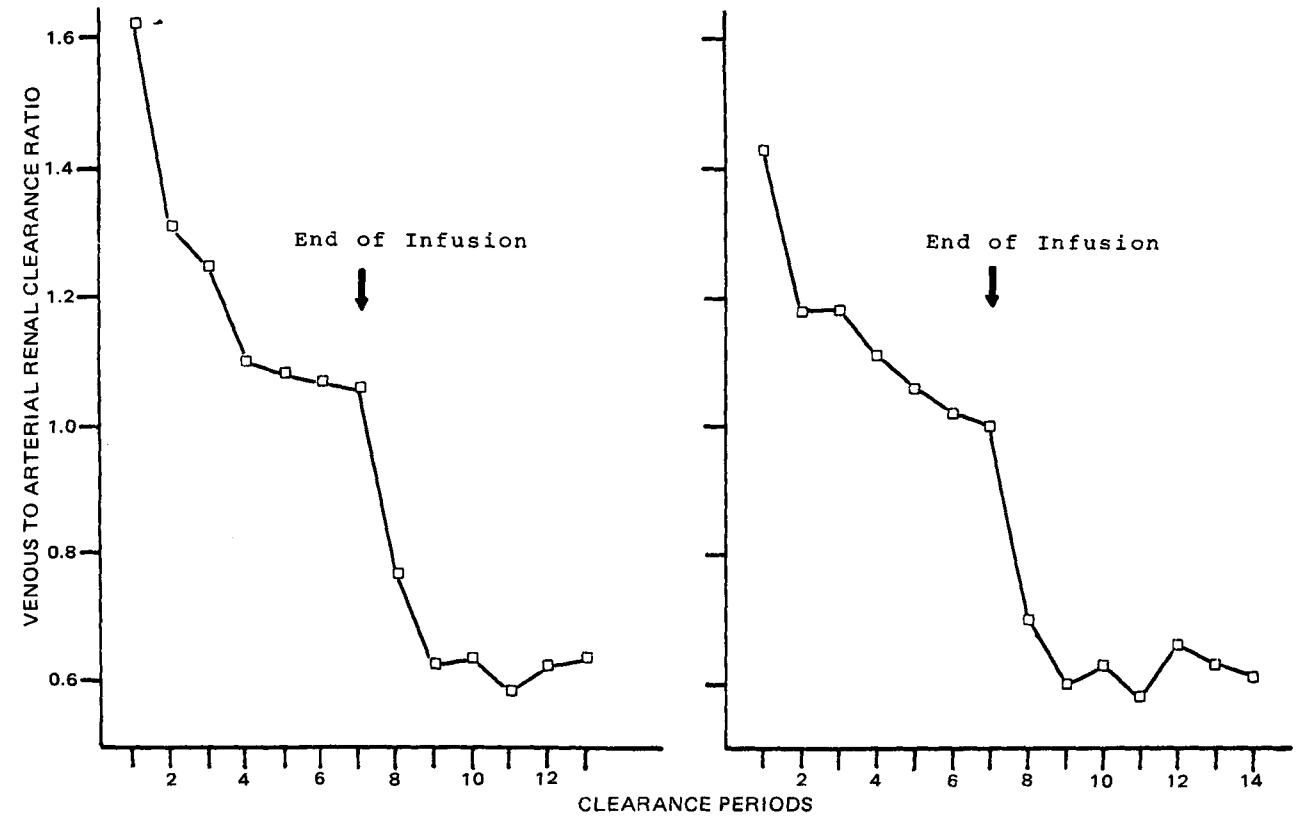

**Figure 2**—*Venous to arterial renal clearance ratios during and after constant intravenous infusion of procainamide hydrochloride in rabbit 1 (left) and rabbit 2 (right). The abscissa represents the number of renal clearance determination periods.*

communication reports the preliminary results of the influence of arterial–venous (A–V) differences on the determination of renal clearance of procainamide in rabbits using the described method during and after intravenous infusion.

The right carotid artery and the jugular vein of two pigmented male rabbits were catheterized with polyethylene tubings after anesthetization with 1.0 g of urethan/kg[1]. A third catheter was placed into the sacral part of the vena cava *via* the right femoral vein. The tip of the cannula was positioned at the junction of the femoral branch and was confirmed after termination of the experiment. The animals were allowed to recover overnight. Infusion solutions were prepared by dissolving varied amounts of procainamide hydrochloride[2] in normal saline before the study and were administered to the rabbits by a constant-infusion syringe pump[3] into the jugular vein for 5 hr. Arterial and venous blood were collected simultaneously from the carotid artery and femoral vein together with urine samples at predetermined times during and after infusion. A pediatric Forley catheter was introduced into the urinary bladder for collection of urine. Distilled water (3 × 20 ml) was flushed into the bladder shortly before each collection time. An aliquot from the pooled urine and washings was collected. Plasma and urine procainamide concentrations were determined by a modified HPLC assay (2).

The plasma profiles of the two rabbits are shown in Fig. 1. During the infusion arterial plasma levels rose rapidly and appeared to reach steady state at 5 hr. Venous plasma levels, however, were lower than the arterial levels at all times but approached them asymptotically toward the end of the infusion. Both curves began to drop with the venous curve being higher than the arterial curve shortly after the infusion. During the terminal phase, both curves decayed virtually parallel to each other with mean venous to arterial (V/A) ratios of ~1.6 for both rabbits.

Renal clearances were determined by Eq. 1 and the resultant V/A clearance ratios are shown in Fig. 2. Renal clearance measurements using venous data resulted in persistently higher values during infusion and lower values postinfusion than arterial data.

By definition, renal clearance is defined as the virtual volume of arterial plasma flowing into the kidney completely cleared of drug per unit of time. The drug concentrations in the systemic arterial plasma can be considered practically identical at any time. Therefore, it seems only appropriate that Eq. 1 is used with arterial plasma data, unless there is no significant A–V difference. Our results suggest that venous data gave rise to overestimation of renal clearance during infusion and underestimation postinfusion. At steady state, both arterial and venous plasma levels appeared to be identical (Fig. 1); hence, no difference in renal clearance estimate is to be expected from using either data.

The problem of venous sampling in clearance measurements was pointed out earlier (3) and was the subject of a recent review (4). Since relatively little effort has been directed toward the differentiation of arterial and venous blood data in pharmacokinetic analysis, our data provided evidence of the existence of significant A–V differences (Fig. 1) and its consequences (Fig. 2) in renal clearance estimations. It is our opinion that sampling arterial plasma is preferred in renal clearance studies in animals using the described timed-interval method. Nevertheless, venous sampling could be useful when employing steady-state infusion or multiple dosing (area during a dosing interval at steady state) methods. The latter methods should be of special value in human studies where the risk of arterial sampling can be avoided.
