the preliminary search for a suitable mobile solvent, a solvent programmer was used with the HPLC instrument[10].

The best separation of the four steroids, prednisone, cortisone, prednisolone, and hydrocortisone, was obtained using the ternary solvent of 25% tetrahydrofuran–12.5% methanol in water (Solvent A). The resolution with this ternary system was optimized (39) by combining the two binary mixtures, 30% tetrahydrofuran–water and 50% methanol–water. Although baseline separation was not achieved, each steroid could be analyzed successfully in the presence of up to 10% of the other three steroids. An experiment was performed utilizing hydrocortisone standard (20 μg/ml) with 2 μg/ml each of the other three steroids added and dexamethasone (internal standard, 30 μg/ml). The hydrocortisone in this mixture was determined to be 99.9% (area ratio) and 98.6% (peak height ratio).

The best separation of the steroid acetates, cortisone acetate, prednisolone acetate, and hydrocortisone acetate, was obtained using 30% tetrahydrofuran in water. However, the retention times were too long (~30 min) for routine analytical work. The best separation within an acceptable time was obtained with 45% acetonitrile in water (Solvent B).

Table II gives the retention data, and Figs. 1 and 2 provide typical chromatograms obtained using the octylsilane microparticle (5 μm) silica column with Solvents A and B.

**Replication Study**—A mixture of hydrocortisone, dexamethasone, and cortisone acetate reference standards in 0.5% acetic acid in methanol was used. Ten 10-μl injections were made onto the octylsilane-bonded column with the automatic injector (Table III).

In general, the coefficient of variation was more acceptable for peak height values. Therefore, peak heights were used for all sample determinations.

**Linearity Study**—Standard mixtures containing hydrocortisone, dexamethasone, and cortisone acetate in 0.5% acetic acid in methanol were injected onto the octylsilane-bonded column. A straight line was fit to the peak height and area data by linear least squares, and the coefficient of determination ($r^2$) was calculated (Table IV).

These corticosteroids give linear responses in the given concentration ranges. Peak height data appeared to be more acceptable for quantitation of these corticosteroids.

**Extraction Recovery Studies**—A known amount of reference standard (~0.5 mg) was added to a 5.0-ml aliquot of the first dilution of the sample preparation and 5 ml of methanol in a 125-ml separator. The extraction was followed beginning with "Then 2 ml of aqueous saturated sodium chloride solution. . . ."

The recovery of standard added to the sample was determined by the proposed HPLC, blue tetrazolium (31), and isoniazid (34) methods (Table V). The results show that extraction is suitable.

**Precision of HPLC Analysis of Samples**—Six replicate determinations of two commercial samples were performed by the proposed direct dilution and extraction procedures (Table VI).

**Analysis**—The results of the analysis of commercial samples (Table VII) are given in Table VIII. The HPLC results for most samples by both procedures were comparable, indicating that either is suitable. However, since continuous injections of methanolic extracts of cream, lotion, or ointment samples could plug or otherwise shorten the life of the HPLC column, the proposed extraction procedure is the sample preparation method of choice.

A 0.5% solution of acetic acid in methanol was recommended as the diluting solvent for corticosteroid acetate esters so that ester hydrolysis

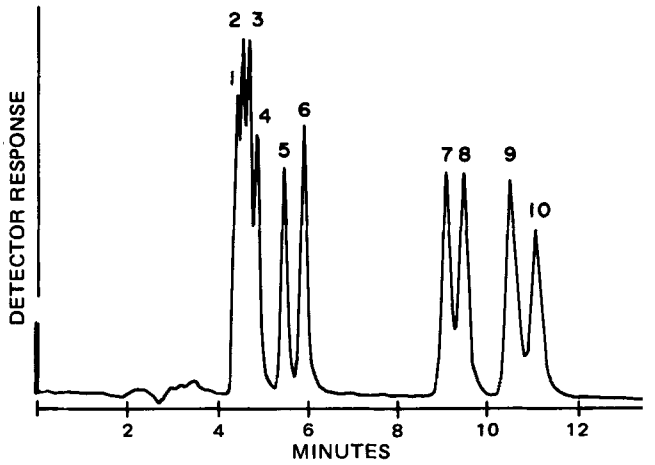

**Figure 2**—*Chromatogram of standard mixture. The column was octylsilane bonded to microsilica (5μm). Solvent B was 45% acetonitrile in water. The flow rate was 1 ml/min, the pressure was 800 psi, the temperature was ambient, and the detector was at 254 nm (0.05 aufs). Key: 1, prednisolone; 2, hydrocortisone; 3, prednisone; 4, cortisone; 5, methylparaben; 6, dexamethasone; 7, prednisolone acetate; 8, hydrocortisone acetate; 9, propylparaben; and 10, cortisone acetate.*

[10] Model 201 liquid chromatograph with two model 6000 pumps and a model 660 solvent programmer, Waters Associates, Milford, Mass.

will not occur in the sample preparation. Without acetic acid, Samples 23 and 24 had almost completely hydrolyzed within 1–2 hr. The 10% sulfacetamide sodium in these samples probably caused the rapid hydrolysis, but other corticosteroid acetate ester samples and standards also had small amounts of free corticosteroid alcohol present (<2%) after being in methanol solution overnight.

Samples 2, 7–9, 11, and 14, which were official USP hydrocortisone preparations, illustrate the need for a more specific assay such as HPLC. The official blue tetrazolium results for these samples were 5–30% higher than those from the proposed HPLC method. Chromatograms for Samples 2, 7–9 (hydrocortisone), and 21 (prednisolone) had one or more small peaks (<5% of the main peak) in addition to the main steroid peak. The retention volume for one of these small peaks in each chromatogram corresponded to that of the C-17 ketone degradation standard (Table II, Compounds I and III). Samples 2, 4, 8, and 9 also had an early eluting peak with a retention volume close to that of the C-17 carboxylic acid degradation product of hydrocortisone, which was reduced or completely removed by extraction (Table II, Compound VI).

Other active ingredients in the samples did not interfere with the proposed HPLC determination. Most of these compounds either were not detected by the 254-nm absorbance detector or were probably retained completely by the column (iodohydroxyquin and related compounds). Sulfacetamide and salicylic acid eluted mainly in the column dead volume, 2–3 ml. Chloramphenicol ($V$ = 22 ml) was detected but was well separated from prednisolone ($V$ = 9.5 ml). Samples 12 and 13 were analyzed with and without benzoyl peroxide (which was packaged in a separate vial to be added to the lotion before dispensing), because decomposition appeared to begin soon after addition of benzoyl peroxide.

The parabens were well separated from the steroids studied, except cortisone acetate. With Solvent B, the recommended solvent for acetate esters, propylparaben and cortisone acetate eluted too close for accurate quantitation of cortisone acetate. Therefore, cortisone acetate cannot be used as an internal standard for other acetate esters; another mobile solvent must be used for cortisone acetate analysis in the presence of propylparaben.

The proposed HPLC procedure is recommended to replace or at least to supplement the blue tetrazolium, phenylhydrazine, isoniazid, and UV spectrophotometric methods in the analysis of corticosteroids in topical pharmaceuticals based on the data presented in this and other (1–30) papers.

# Disintegration–Dissolution Analysis of Percent Dissolved–Time Data

**ADNAN EL-YAZIGI**

Received June 2, 1980, from the *Department of Pharmaceutics, College of Pharmacy, University of Riyadh, Riyadh, Saudi Arabia.* Accepted for publication October 28, 1980.

**Abstract** □ A simple, graphical method is described for the disintegration–dissolution analysis of cumulative percent dissolved–time data. The technique is based on a biexponential equation with the assumption of first-order disintegration and dissolution according to a simple dissolution model. The dissolution data obtained for six commercial tablets and capsules adequately fit the developed equation. The described method is simple and can handle initial data points that are usually ignored by other techniques.

**Keyphrases** □ Disintegration–dissolution—analysis of percent dissolved–time data □ Dissolution model—method for analysis of percent dissolved–time data □ Pharmacokinetics—method for analysis of percent dissolved–time data

Most techniques used to interpret the percent dissolved–time data of tablets and capsules are based on semilogarithmic plots in which the early data points that precede the dissolution lag time are not considered (1–4). Kitazawa *et al.* (5, 6) utilized the initial data points and calculated the dissolution rate constants of uncoated tablets from the two straight lines obtained by plotting the dissolution data semilogarithmically against time. It was assumed that when the two lines intersect, the surface area greatly increases, causing a sudden increase in the dissolution rate. This assumption, however, is questionable since the change in the surface area is likely to be continuous. Furthermore, the early data points that most frequently form a curve above the terminal line (1) may be a function of both dissolution and disintegration. Drug release from conventional tablets or capsules usually involves two sequential time-dependent processes, disintegration (or content deaggregation for capsules) and dissolution, which occur simultaneously until disintegration is completed.

Drug release from a tablet having a rather idealized formulation was analyzed previously according to a disintegration–dissolution model; however, the mathematics involved are complicated and require computer programs, which may not be available or suitable for routine analysis of dissolution data (7, 8). This paper describes a simple graphical method for disintegration–dissolution analysis of percent dissolved–time data for commercial tablets or capsules in which all data points obtained were utilized and the dissolution and disintegration rate constants were estimated.

## THEORETICAL

When a tablet or capsule dissolves, it first disintegrates (capsule disintegration implies shell dissolution and content deaggregation) into small particles which, in turn, due to their large surface area, release the drug into the dissolution liquid. A more detailed scheme comprising an additional step in which the drug dissolves directly from the tablet surface also was reported (9); however, the amount released through this step is very small and need not be considered.

If one assumes that disintegration and dissolution are first-order processes and that $A$, $A_p$, and $A_s$ represent the amounts of drug in the dosage form, small particles, and solution, respectively, at any given time, $A \xrightarrow{k_d} A_p \xrightarrow{k_s} A_s$, the following differential equations can be written:

$$\frac{dA}{dt} = -k_d A \qquad \text{(Eq. 1)}$$

$$\frac{dA_p}{dt} = k_d A - k_s A_p \qquad \text{(Eq. 2)}$$

$$\frac{dA_s}{dt} = k_s A_p \qquad \text{(Eq. 3)}$$

where $k_d$ and $k_s$ are apparent first-order rate constants for disintegration and dissolution, respectively.

The Laplace transforms of Eqs. 1–3 are:

$$s\bar{A} - A_0 = -k_d\bar{A} \qquad \text{(Eq. 4)}$$

$$s\bar{A}_p = k_d\bar{A} - k_s\bar{A}_p \qquad \text{(Eq. 5)}$$

$$s\bar{A}_s = k_s\bar{A}_p \qquad \text{(Eq. 6)}$$

where the bar above the function and the $s$ represent the Laplace transform for the function and $A_0$ is the amount of drug in the dosage form at time zero. Rearrangement of Eq. 4, substitution for $\bar{A}$ in Eq. 5, and rearrangement yield:

$$\bar{A}_p = \frac{k_d A_0}{(s + k_d)(s + k_s)} \qquad \text{(Eq. 7)}$$

Substituting for $\bar{A}_p$ in Eq. 6 and rearranging produce:

$$\bar{A}_s = \frac{k_s k_d A_0}{s(s + k_d)(s + k_s)} \qquad \text{(Eq. 8)}$$

which, when solved using Laplace transform table (8) and rearranged, gives:

$$A_0 - A_s = \frac{k_d A_0}{k_d - k_s} e^{-k_s t} - \frac{k_s A_0}{k_d - k_s} e^{-k_d t} \qquad \text{(Eq. 9)}$$

Multiplying both sides of Eq. 9 by $100/A_0$ yields:

$$100 - f_s = \frac{100 k_d}{k_d - k_s} e^{-k_s t} - \frac{100 k_s}{k_d - k_s} e^{-k_d t} \qquad \text{(Eq. 10)}$$

where $f_s = (A_s/A_0) \times 100$ is the cumulative percent dissolved at time $t$.

If disintegration is more rapid than dissolution (*i.e.*, $k_d > k_s$), which is generally the case (7), a semilogarithmic plot of $(100 - f_s)$ *versus* time results in a biexponential curve with a terminal linear segment whose slope is equal to $-(k_s/2.303)$. The apparent first-order disintegration rate constant ($k_d$) can be estimated from the plot using the method of residuals (10).

## EXPERIMENTAL

**Materials**—Anhydrous theophylline[1], isoniazid[2], tetracycline hydrochloride[1], and ampicillin[3] were used for the preparation of standard curves as obtained. All tablet and capsule formulations tested (A[4], B[5], C[6], D[7], E[8], and F[9]) were purchased commercially.

**Dissolution Studies**—Dissolution tests were performed using a two-blade stirrer apparatus at 25 or 50 rpm. This apparatus was similar to the USP XIX apparatus, except that the basket assembly was replaced

| D | 11.4 (1.09) | 11.4 | 1.0 |
| E | 9.92 (5.6) | 10.1 | 0.98 |
| F | 24.6 (2.09) | 20.5 | 1.2 |

[a] Mean. [b] Standard deviation.

by a 30-cm long glass shaft with one end attached to the motor and the other end equipped with a 7.6-cm glass blade connected in the center to the shaft. The dissolution medium, 900 ml of distilled water, was maintained at 37 ± 0.1°. The tablet or capsule was dropped directly into the vessel, and stirring and timing were initiated. At the indicated intervals (Fig. 1), 1-ml samples were withdrawn through a filtration unit[10] and analyzed spectrophotometrically at the maximum for each drug after suitable dilution.

**Disintegration Test**—Disintegration times were determined in the same apparatus used for the dissolution studies with a minor modification. This modification consisted of a slightly concave, round, 10-mesh stainless steel screen placed in the vessel horizontally and anchored on the wall so that the distance between the screen center and the vessel bottom was 1 cm. The disintegration test was carried out under the same conditions as in the dissolution studies. The distance between the blade and the screen center (2 cm) was identical to that used in the dissolution test. The disintegration time was defined as the time when the disintegrated particles passed through the screen or suspended in the dissolution fluid. The described method permits the determination of disintegration time under the same conditions as in dissolution tests, as well as observation of the disintegration process.

**Estimation of Disintegration Time from Dissolution Data**—Theoretically, as Eq. 10 indicates, the disintegration time is equal to infinity. However, since the percent remaining for disintegration after six disintegration half-lives is equal to 1.56%, which is negligible, it may be assumed that the disintegration time $DT_{calc} = 6t_{1/2d}$ or:

$$DT_{calc} = 6\left(\frac{0.693}{k_d}\right) = \frac{4.158}{k_d} \qquad \text{(Eq. 11)}$$

The values of $DT_{calc}$ calculated from Eq. 11 coincided well with those estimated from the semilogarithmic plots, where $DT_{calc}$ was taken as the time when the straight-line segment of the curve commences.

## RESULTS AND DISCUSSION

Figure 1 demonstrates the dissolution profiles obtained for the tablet and capsule formulations tested. The selection of these commercial products for evaluation of the described method was arbitrary.

The apparent first-order dissolution and disintegration rate constants ($k_s$ and $k_d$, respectively) were estimated by plotting log $(100 - f_s)$ *versus* time and the slope of the terminal linear segment is equal to $-(k_s/2.303)$. The apparent first-order disintegration rate constant was determined

[10] Millipore.

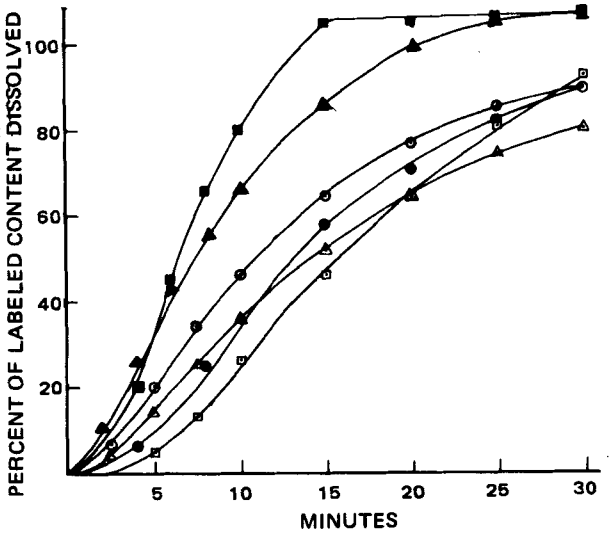

**Figure 1**—*Dissolution profiles for the formulations tested (mean of six determinations). Key: ●, A; ■, B; ▲, C; ○, D; △, E; □, F; solid symbols, tablets; and open symbols, capsules.*

by plotting the residual $(100 - f_s)$ against time semilogarithmically and the slope of the resulting straight line equal to $-(k_d/2.303)$. The values of $k_s$ and $k_d$ obtained are provided in Table I.

As demonstrated in Figs. 2 and 3, the fit was adequate; however, better fit may have been obtained if the analysis was carried out using nonlinear regression analysis. For Formulation B, dissolution was rapid and fewer data points were used.

The estimation of $k_d$ and $k_s$ also can be achieved by plotting log $(dA_s/dt)$ (rate of dissolution) *versus* time using the method of residuals given by:

$$\frac{dA_s}{dt} = \frac{k_s k_d A_0}{k_d - k_s}\left(e^{-k_s t} - e^{-k_d t}\right) \qquad \text{(Eq. 12)}$$

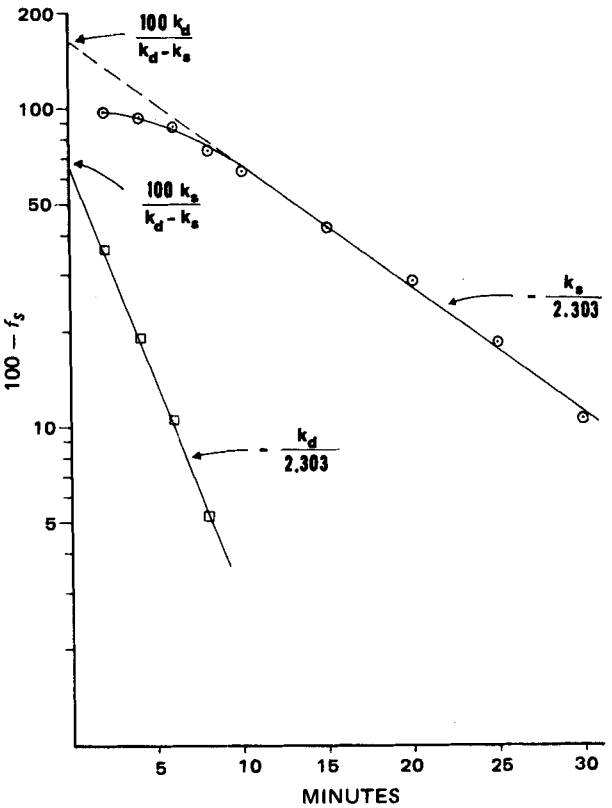

**Figure 2**—*Semilogarithmic plot of 100 minus cumulative percent dissolved (100 − $f_s$) against time for Tablet A. Key: ○, actual values; and □, residual values.*

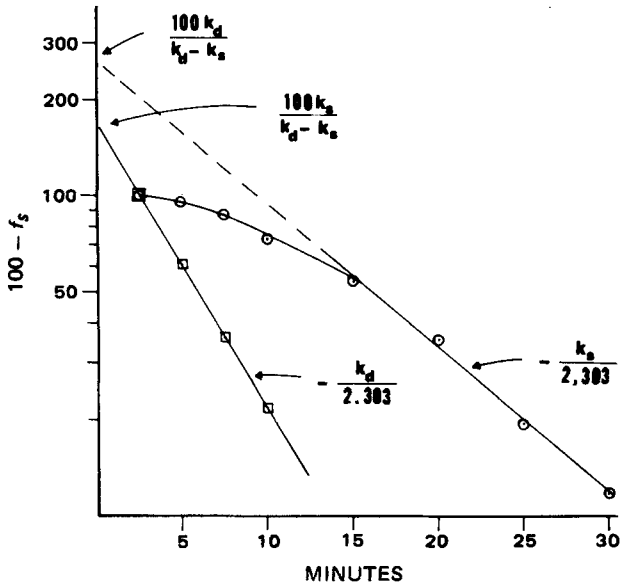

**Figure 3**—*Semilogarithmic plot of 100 minus cumulative percent dissolved (100 − $f_s$) versus time for Capsule F. Key:* ○, *actual values; and* □, *residual values.*

which can be derived by solving Eq. 7 to yield:

$$A_p = \frac{k_d A_0}{k_d - k_s}(e^{-k_s t} - e^{-k_d t}) \qquad \text{(Eq. 13)}$$

and substituting for $A_p$ in Eq. 3. To estimate $k_d$ accurately using Eq. 12, dissolution tests should be carried out automatically so that a sufficient number of early ($dA_s/dt$) points can be used in the plotting.

The values of $DT_{exp}$ were in good agreement with those of $DT_{calc}$ (Table II). These data confirm that the method proposed, in addition to its simplicity, is capable of reliably characterizing both dissolution and disintegration. In fact, if the percent dissolved–time data are well described by Eq. 10, the amount of drug in small particles at any given time ($A_p$) can be determined by employing Eq. 12, which permits the prediction of the disintegration time course. Such an approach is being investigated.

Previous models (5, 6) are in sharp disagreement with the present method, which assumes that dissolution occurs at a single rate constant throughout the dissolution test. In fact, the early data points that constitute the first dissolution phase according to previous models (5, 6) may not only represent dissolution but disintegration as well. By separating the disintegration component of these points from that of dissolution, a good estimate of the disintegration rate constant ($k_d$) may be obtained.

The described method provides a comprehensive, practical, and simple tool for the disintegration–dissolution analysis of dissolution rate data where familiar mathematics is employed. The good fit of the data obtained to the developed equation does not imply that drug dissolution and disintegration are first order in nature; it indicates that dissolution data for conventional tablets and capsules may be described by Eq. 10, in which case $k_s$ and $k_d$ can be estimated graphically.

# Synthesis of Alkylaminoalkylamides of Substituted 2-Aminopyrroles as Potential Local Anesthetic and Antiarrhythmic Agents II: β-Amines

**J. WALTER SOWELL, Sr. *x, ALAN J. BLOCK ‡, MARY ELIZABETH DERRICK *§, JOHN J. FREEMAN *, JOSEPH W. KOSH *, PHILIP F. MUBARAK *§, and PAUL A. TENTHOREY ‡¶**

Received September 9, 1980, from the **College of Pharmacy, University of South Carolina, Columbia, SC 29208*, and ‡*Astra Research Laboratory, Framingham, MA 01701.* Accepted for publication October 23, 1980. §Present address: Medical University of South Carolina, Charleston, SC 29403. ¶Present address: Bristol-Myers International Division, New York, NY 10022.

**Abstract** □ The synthesis, local anesthetic and antiarrhythmic properties, and CNS toxicity of 14 2-(3-alkylaminoalkylamido)-pyrroles are described. Most of the compounds exhibited local anesthetic activity by the guinea pig wheal test, with seven showing comparable or greater activity than lidocaine. Most compounds also exhibited antiarrhythmic activity; three compounds had more potent activity than lidocaine. All compounds exhibiting antiarrhythmic activity also were toxic to the CNS. However, two of the three compounds having greater activity than lidocaine possessed more desirable therapeutic indexes.

**Keyphrases** □ 2-(3-Alkylaminoalkylamido)pyrroles—synthesis, evaluated for local anesthetic activity in guinea pigs and for antiarrhythmic activity and CNS toxicity in mice □ Anesthetic activity, potential—2-(3-alkylaminoalkylamido)pyrroles synthesized and evaluated for activity in guinea pigs, structure–activity relationships □ Antiarrhythmic activity, potential—2-(3-alkylaminoalkylamido)pyrroles synthesized and evaluated for activity in mice, structure–activity relationships □ Structure–activity relationships—2-(3-alkylaminoalkylamido)pyrroles synthesized and evaluated for anesthetic activity and antiarrhythmic activity and CNS toxicity in guinea pigs and mice

Previous publications reported the synthesis and pharmacological evaluation of several series of 2-(2-alkylaminoalkylamido)pyrroles (I*a*) as potential local anesthetic and antiarrhythmic agents (1–3). Many of these compounds possessed significant activity (1–3), but most compounds with the desired activity were also toxic to the central nervous system (CNS).

Several series of antiarrhythmic agents derived from substituted anilines were reported recently (4–6). The β-amino analog (II*b*) of tocainide (II*a*) was more potent

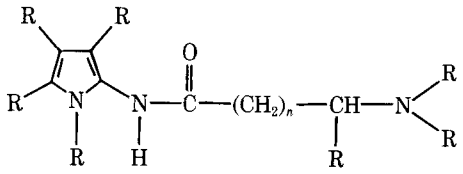
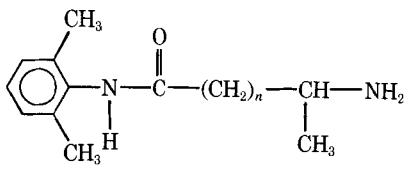
[a] Ethyl acetate.

and had a more favorable therapeutic ratio for CNS side-effects in animals than tocainide (6). Therefore, elongation of the intermediate chain between amide and amine functions might improve the pharmacological properties of aminoanilides related to lidocaine. The transfer of this method to a series of pyrrole analogs of lidocaine was considered a reasonable approach to enhance antiarrhythmic activity and to decrease CNS toxicity in this new class of antiarrhythmic agents.

As an extension of the 2-(2-alkylaminoalkylamido)-pyrrole (Ia) research, the synthesis and pharmacological evaluation of 14 2-(3-alkylaminoalkylamido)pyrroles (Ib) are presented. Compounds with a more acceptable therapeutic index than those previously reported are being sought.



Ia: $n = 0$
Ib: $n = 1$



IIa: $n = 0$
IIb: $n = 1$

## RESULTS AND DISCUSSION

**Chemistry**—Acylation of various substituted 2-amino-3-cyanopyrroles (7–10) with 3-bromobutyryl chloride (11), *trans*-2-butenoyl chloride, or 3-chloropropionyl chloride in acetone, utilizing pyridine as a base, gave the requisite amide (IIIa–IIIh) precursors to the 2-(3-alkylaminoalkylamido)pyrroles (Ib) (Table I). The purity of these amides was determined by elemental analyses and TLC. IR and NMR spectra were consistent with the assigned structures.

The various substituted 2-(3-alkylaminoalkylamido)-3-cyanopyrroles (IVa–IVl) (Table II) were obtained either by Michael addition of a primary or secondary amine to the 2-butenamide (IIIa) or by nucleophilic displacement of the halogen of the β-haloamides (IIIb–IIIh) by the appropriate primary or secondary amine. For both methods, the products were obtained after refluxing (6–12 hr) the requisite amide (IIIa–IIIh) in ethanol or 2-propanol with a four- to fivefold excess of amine.

The crude products were isolated by removal of the alcohol and excess unreacted amines *in vacuo*. The residues were dissolved in 5–10% HCl and filtered, and the aqueous filtrates were made alkaline (pH 9–10) with 10% NaOH. The solid products (IVe, IVf, IVi, IVj, and IVl) were collected and purified further by recrystallization from methanol–water (4:1). The amines that oiled or gummed upon addition of alkali were extracted into chloroform, and the chloroform was removed *in vacuo* after drying. The residues were dissolved in an appropriate boiling solvent, treated with charcoal, and collected as oils or gums upon cooling.

The 2-(3-alkylaminoalkylamido)-3-carbamylpyrroles (IVm and IVn) were obtained by hydrolysis of the nitrile in IVi and IVj, respectively, in 85% phosphoric acid at 125–130° for 5 min. The free amines were precipitated by alkalinization of the cold dilute phosphoric acid solutions with 20% NaOH.

Percent yields, melting points, and purification data for the 2-(3-alkylaminoalkylamido)pyrroles (IVa–IVn) are given in Table II. These amines were characterized as their corresponding hydrochloride salts.

The 2-(3-alkylaminoalkylamido)pyrrole hydrochlorides (Va–Vf and Vh–Vn) were prepared by treating an acetone solution or suspension of the corresponding free bases with a slight excess of concentrated hydrochloric acid. In the case of IVg, the hydrochloride salt (Vg) precipi-

[a] The oils and gums were dissolved in boiling recrystallization solvent(s), treated with activated charcoal, filtered, and collected as oils or gums after cooling. [b] Where yields were not reported for free amine, the yield for salt was based on the haloamide or crotonamide precursor. [c] Acetone. [d] Hydrochloride salt obtained was analytically pure. [e] Ethyl acetate. [f] Hydrochloride was formed during workup procedure; therefore, free base was not isolated.

tated upon addition of 5% HCl to the crude residue remaining after removal of the reaction solvent and excess *n*-butylamine *in vacuo*.

Data for the hydrochloride salts (V*a*–V*n*) are given in Table II. These compounds were characterized on the basis of elemental analyses, TLC, and IR and NMR spectral data.

The β-haloamides and final products possessing an asymmetric center were obtained as racemic mixtures in this work.

**Pharmacology**—*Local Anesthetic Activity*—Activity was observed for all compounds evaluated at a solution concentration of 0.50%. Noticeable differentiation in local anesthetic activity was observed at 0.25%. At that concentration, V*a*–V*d* were more potent than lidocaine, V*k*, V*l*, and V*n* were comparable in potency, and all remaining compounds were less potent.

Further evaluation of V*a*–V*d* at a 0.125% solution concentration demonstrated their superiority over lidocaine under these test conditions. The durations of local anesthetic activity were 1.67, 1.42, 2.67, and 1.75 times longer than that of lidocaine (Table III).

Local anesthetic data previously reported (3) and the present results strongly support the introduction of a methyl group on the pyrrole nitrogen to augment local anesthetic activity. This finding applies for the 2-(2-alkylaminoalkylamido)pyrroles (I*a*) and the 2-(3-alkylaminoalkylamido)pyrroles (I*b*). The present work shows that the I*b* compounds are substantially more potent local anesthetics than their corresponding α-amine homologs (I*a*).

*Antiarrhythmic Activity and CNS Toxicity*—Antiarrhythmic activity, measured as protection against chloroform-induced ventricular tachycardia, and acute CNS toxicity, measured as drug-induced ataxia, were determined in mice as previously described (3). The results are listed as $ED_{50}$ values, together with 95% Fieller limits and therapeutic indexes, in Table IV. All compounds tested, except V*g*, had antiarrhythmic activity; V*a*, V*c*, and V*d* were more potent than lidocaine, V*b* was equipotent, and the rest were less potent. Paralleling the findings on local anesthetic activity, the derivatives with a methyl substituent on the pyrrole nitrogen were more potent than those with a hydrogen substituent. More importantly, therapeutic indexes were also increased by the introduction of an *N*-methyl substituent. A comparison with previously published α-alkylaminoalkylamidopyrroles showed the β-derivatives to have higher potencies (except V*e*) and higher therapeutic indexes (except in hydrogen-substituted pyrroles). The extension of the intermediate chain, leading from α-amines to β-amines, again improved the therapeutic properties of a class of antiarrhythmic agents.

## EXPERIMENTAL[1]

**2-(2-Butenamido)-3-cyano-1,4,5-trimethylpyrrole (III*a*)**—A solution of 2-amino-3-cyano-1,4,5-trimethylpyrrole (22.3 g, 0.15 mole) (10) in 150 ml of acetone with pyridine (13.1 g, 0.16 mole) was prepared in a 500-ml round-bottom flask equipped with a drying tube. This solution was stirred in an ice bath for 10 min, followed by the dropwise addition of *trans*-2-butenoyl chloride (18.8 g, 0.18 mole). The solution was stirred in the ice bath for 10 min and then for another 15 min after the ice bath was removed. The reaction mixture was brought to reflux and allowed to cool to room temperature, and then the dark solution was poured over crushed ice (500 g).

After the ice had melted, the crude product was collected by filtration, suspended in distilled water, filtered, and dried. The gray product (13.8 g, 42.3%) was recrystallized twice from absolute methanol to yield light-tan crystals (homogeneous on TLC; in ethyl acetate, $R_f$ 0.46), mp 174.5–175.5° dec.; IR (KBr): 3420, 3050, 2980, 2920, 2220, 1675, 1645, 1540, 1195, 960, 935, 830, and 680 $cm^{-1}$; NMR (dimethyl sulfoxide-$d_6$): δ 1.9 (d, 3H, $CH_3$ of CO–C=C–$CH_3$), 2.00 (s, 3H, $CH_3$ at C-4), 2.09 (s, 3H, $CH_3$ at C-5), 3.33 (s, 3H, $CH_3$ at N-1), 5.8–6.3 (complex m, 1H, CH of CO–CH=C–C), 6.5–7.1 (complex m, 1H, CH of CO–C=CH–C), and 9.7–10.1 (broad s, 1H, NH of amide) ppm. Table I gives the results of the elemental analyses.

**2-(3-Bromobutyramido)-3-cyano-4,5-dimethylpyrrole (III*c*)**—The procedure for III*c* is given as a general method of synthesis of III*b*–III*h*. A solution of 2-amino-3-cyano-4,5-dimethylpyrrole (40.5 g, 0.30 mole) (7) in pyridine (26.1 g, 0.33 mole) and 300 ml of acetone was stirred in an ice bath while 3-bromobutyryl chloride (61.2 g, 0.33 mole) (11) was added dropwise. After the addition was complete, the dark-brown solution was stirred at room temperature for an additional 20 min; it then was poured over 400 g of ice. The resulting suspension was stirred until the ice had melted, and the crude product was collected by filtration.

The product was resuspended in 300 ml of distilled water, collected by filtration, and air dried. One gram of the crude amide (75.5 g, 88.6%) was recrystallized from 25 ml of methanol–water (4:1) to yield a white powder (homogeneous on TLC; in ethyl acetate, $R_f$ 0.66), mp 141.5–142.5°; IR (KBr): 3420, 3160, 3100, 3020, 2900, 2205, 1650, 1610, 1500, 1480, 1450, 1320, 1230, 1210, 1000, and 670 $cm^{-1}$; NMR (dimethyl sulfoxide-$d_6$): δ 1.70 (d, 3H, CHBrC$H_3$), 1.90 (s, 3H, $CH_3$ at C-4), 2.02 (s, 3H, $CH_3$ at C-5), 2.92 (d, 2H, $COCH_2$), 4.50 (q, 1H, C*H*BrCH$_3$), 10.52 (s, 1H, NH), and 11.17 (s, 1H, NH). Table I gives the results of the elemental analyses.

**Method A: 2-(3-Pyrrolidinobutyramido)-3-cyano-1,4,5-trimethylpyrrole Hydrochloride (V*a*)**—The procedure for the synthesis of V*a* was also used for V*d*. A suspension of III*a* (8.7 g, 0.04 mole) in 80 ml of absolute 2-propanol with pyrrolidine (11.4 g, 0.16 mole) was refluxed, with continuous stirring, for 12 hr to give a clear brown solution. The solvent and excess pyrrolidine were removed *in vacuo*, and the gummy residue was dissolved in 50 ml of warm 10% HCl. The acidic solution was filtered, 200 g of ice was added, and the product was suspended in the solution by the addition of 10% aqueous potassium hydroxide. The alkaline aqueous suspension (pH 9–10) was extracted with two 150-ml

**Table III—Local Anesthetic Activity of 2-(3-Alkylaminoalkylamido)pyrrole Hydrochlorides as Determined by the Guinea Pig Wheal Test [a]**

| Compound | Solution Concentration 0.50% | 0.25% | 0.125% |

[a] Protection against chloroform-induced tachycardia. [b] Observed prior to exposure to chloroform. [c] Subcutaneous administration. [d] Approximate 95% Fieller limits. [e] Lack of water solubility prevented determination. [f] Tremor, $ED_{50}$ <20 mg/kg.

[1] All IR spectral data were determined on a Beckman Acculab-4 spectrophotometer using the potassium bromide technique. NMR spectra were determined on a Hitachi Perkin-Elmer R24 high-resolution spectrophotometer with tetramethylsilane as the internal reference. The reported melting points were obtained using a Thomas-Hoover capillary apparatus and are uncorrected. The reported analyses of carbon, hydrogen, chlorine, and nitrogen were obtained from Atlantic Microlab, Atlanta, Ga. TLC was performed using Eastman Chromatogram sheets (type 6060, silica gel); the sheets were developed in an iodine chamber.

portions of chloroform, and the organic solution then was extracted with 300 ml of saturated sodium chloride solution. The chloroform was removed *in vacuo*, and the residue was dissolved in 200 ml of boiling cyclohexane, treated with activated charcoal, and immediately filtered while hot.

After cooling to room temperature, a gummy residue was collected from the bottom of the flask by decantation. This residue was dissolved in 100 ml of acetone, 4 ml of concentrated hydrochloric acid was added, and the mixture was placed in the freezer. After 24 hr, fine gray crystals (6.5 g, 50%) were collected (homogeneous on TLC; in acetone, $R_f$ 0.28), mp 222–223° dec.; IR (KBr): 3130, 3020, 2575, 2485, 2210, 1690, 1550, 1530, 1440, 1175, 1150, 975, and 710 $cm^{-1}$; NMR (dimethyl sulfoxide-$d_6$): $\delta$ 1.39 [d, 3H, $CH_3$ of $-CO-C-C(CH_3)-N^+$], 1.6–2.0 (complex m, 4H, $\beta$-methylenes of pyrrolidino), 1.99 (s, 3H, $CH_3$ at C-4), 2.05 (s, 3H, $CH_3$ at C-5), 2.7–3.1 [complex m, CH, $\alpha$-methylenes of pyrrolidino and methylene of $CO-CH_2-C(C)-N^+$], 3.26 (s, 3H, $CH_3$ at N-1), 3.6–4.0 [complex m, 1H, methine of $-CO-C-CH(C)-N^+$], 10.5 (s, 1H, NH of amide or $^+NH$), and 11.1–11.6 (broad s, 1H, $^+NH$ or NH of amide) ppm. Table II gives the results of the elemental analysis.

**Method B: 2-(3-Pyrrolidinobutyramido)-3-cyano-4,5-dimethylpyrrole (IV*e*)**—The procedure for IV*e* is given as a general method of synthesis of IV*b*, IV*c*, and IV*e*–IV*l*. A solution of 2-(3-bromobutyramido)-3-cyano-4,5-dimethylpyrrole (III*c*) (20.0 g, 0.07 mole) in 150 ml of *n*-propanol was stirred while pyrrolidine (29.9 ml, 0.42 mole) was added. The solution was refluxed with stirring for 8 hr, and then the solvent and excess amine were removed *in vacuo*. The residue was dissolved in 300 ml of 5% HCl, and the solution was filtered. The acidic filtrate was poured over 200 g of ice and made alkaline with 10% NaOH (pH 10), and the tan precipitate was collected by filtration. The crude product was recrystallized from 280 ml of methanol–water (4:1), yielding white crystals (16.0 g, 83.3%) which were collected and dried. The crystals were suitable for hydrochloride salt formation (homogeneous on TLC; in ethyl acetate, $R_f$ 0.47), mp 168–169°. The data for the analogs are given in Table II.

**2-(3-Pyrrolidinobutyramido)-3-cyano-4,5-dimethylpyrrole Hydrochloride (V*e*)**—The procedure for V*e* is given as a general method of synthesis of V*b*, V*c*, and V*e*–V*n*. A solution of the free amine (IV*e*) (8.0 g, 0.03 mole) in 100 ml of acetone was filtered, and the filtrate was treated with 3.0 ml of concentrated hydrochloric acid. The sealed flask was placed in the freezer for 1 hr, yielding white crystals; these crystals were collected by filtration, washed with acetone, and dried. The crystals (8.3 g, 89.2%) were analytically pure (homogeneous on TLC; in ethyl acetate, $R_f$ 0.24), mp 94–95.5° dec.; IR (KBr): 3510, 3400, 3225, 3030, 2980, 2640, 2600, 2210, 1670, 1620, 1460, 1330, 1230, 1180, 1080, and 760 $cm^{-1}$; NMR (dimethyl sulfoxide-$d_6$): $\delta$ 1.40 (d, 3H, $CHCH_3$), 1.95 (s, 3H, $CH_3$ at C-4), 2.05 (s, 3H, $CH_3$ at C-5), 2.00 (broad m, 4H, $\beta$-carbons on pyrrolidine), 2.95 (d, 2H, $COCH_2$), 3.50 (m, 1H, $COCH_2CH$), 2.80–3.80 (broad m, 4H, $\alpha$-carbons on pyrrolidine), 10.80 (s, 1H, NH), and 11.35 (s, 2H, NH). Table II lists the results of the elemental analyses.

**Method C: 2-(3-Diethylaminopropionamido)-3-carbamyl-4,5-dimethylpyrrole (IV*m*)**—The procedure for IV*m* was also used for IV*n*. A solution of 2-(3-diethylaminopropionamido)-3-cyano-4,5-dimethylpyrrole (IV*i*) (13.12 g, 0.05 mole) in 85% $H_3PO_4$ (30 ml) was heated with stirring at 127–129° for 5 min. The contents of the vessel were cooled, crushed ice (200 g) was added, and the pH was adjusted to 10 by the addition of a saturated sodium hydroxide solution. The product was collected, resuspended in distilled water (300 ml), collected by filtration, and dried. The crude amine (10.0 g, 71.3%) was recrystallized from methanol–water (1:2) to yield off-white crystals (9.0 g, 90%), which were suitable for hydrochloride salt formation. [See Table II for analog and *Method B* for hydrochloride salt (V*m*) formation.]

**Pharmacology**—*Local Anesthetic Activity*—The guinea pig wheal method of Bulbring and Wajda (12) was employed in determining activity. The methodology was described previously (1–3).

*Antiarrhythmic Activity and CNS Toxicity*—A modification of the method of Lawson (13) was employed in assessing the antiarrhythmic activity and acute CNS toxicity. The methodology was described previously (3). Briefly, the mice were exposed to chloroform following subcutaneous injection of the target compounds. After respiratory arrest was evoked, a thoracotomy was performed; multilead ECGs were recorded for ~45 sec. If the ventricular rate was <520 beats per minute during this period, it was presumed that ventricular tachycardia had been prevented and the mouse was considered "protected." Symptoms of ataxia were monitored during the 20-min period between injection of the target compound and exposure to chloroform.

# Human Metabolism of 7-Substituted Theophyllines: $N^3$-Demethylation and Lack of Oxidation of Proxyphylline

E. TARRUS, I. GARCIA, and J. SEGURA ˣ

Received July 24, 1980, from the *Division of Biochemistry and Biopharmaceutics, Institute of Research, Laboratories Almirall, Cardoner, 68-74, Barcelona-24, Spain.* Accepted for publication October 17, 1980.

**Abstract** □ Proxyphylline metabolism after oral administration to humans was studied. The only metabolic process detected was $N^3$-demethylation, and 1-methyl-7-(2-hydroxypropyl)xanthine was isolated and identified. Proxyphylline was excreted in urine both as unchanged compound (12.7% of dose) and as its metabolic product (30.2% of dose). The latter substance was not found (detection limit = 1 μg/ml) in the systemic circulation. Thus, it probably does not participate in the pharmacological activity of proxyphylline *in vivo*, although it was as active as the parent drug in relaxing the guinea pig tracheal chain. Lack of metabolism to uric acid derivatives is explained by the low affinity of both substances toward the enzymes that oxidize xanthine (xanthine oxidase) and methylxanthine derivatives. The presence of the metabolite in urine interferes with some analytical methods developed for estimation of unchanged proxyphylline. Published data on the urinary excretion of this drug need reevaluation.

**Keyphrases** □ Proxyphylline—metabolism after oral administration, $N^3$-demethylation □ Pharmacokinetics—proxyphylline, diuretics, $N^3$-demethylation □ Xanthine derivatives—metabolism of proxyphylline in humans □ Diuretics—proxyphylline, metabolism after oral administration, $N^3$-demethylation

Substitution of the hydrogen atom at position 7 of the theophylline nucleus has received increased attention in the search for better tolerated and pharmacologically more selective theophylline-like compounds (1–9). The biodegradation of 7-substituted theophyllines follows three main metabolic pathways in humans: $N$-dealkylation of one or two of the alkyl groups at positions 1, 3, and 7; $C^8$-oxidation of the unchanged drug and/or its $N$-dealkylated metabolites to uric acid derivatives; and conjugative or oxidative metabolism of the $N^7$-side chain.

The chemical structure of the $N^7$-substitution dictates the relative importance of these metabolic pathways for each individual compound. The metabolism of theophyllines with small alkyl side chains such as caffeine (10–13) or with large ones such as pimefylline (14), xanthinol (15), or fenethylline (16) has been described. Little is known, however, about the biodegradation of theophyllines substituted by medium-sized hydroxy alkyl groups (17, 18), although some of them, such as etofylline, dyphylline, and proxyphylline, are widely used in treatment of respiratory tract diseases.

A study of proxyphylline [7-(2-hydroxypropyl)theophylline] metabolism was undertaken because serious discrepancies exist in the literature about the amount of unchanged proxyphylline excreted in the urine of volunteers given the drug orally (19, 20). The variability of the results seems to be unrelated to the specificity of the analytical method used and suggests the existence of metabolic products structurally similar to the parent drug. Other methylxanthines are oxidized to uric acid derivatives either by xanthine oxidase, *i.e.*, 1-methylxanthine (21–23), or by other enzymatic systems (24). In a preliminary step, the possible interaction between proxyphylline and xanthine oxidase was investigated. Nevertheless, relevant information was obtained after oral administration of the drug to volunteers. The results of these studies confirm the existence of a metabolite and indicate that the main, if not the only, metabolic process of the drug in humans is $N^3$-demethylation.

## EXPERIMENTAL

**Incubations with Xanthine Oxidase**—The determination of enzymatic activity was carried out by the method of Domingo (25), which measures the absorbance at 600 nm of the oxidized form of 2,6-dichloroindophenol. The enzymatic system contained 0.027 mg of xanthine oxidase[1]/ml, $3.5 \times 10^{-5}$ $M$ 2,6-dichloroindophenol[2], and several concentrations of xanthine[2], proxyphylline[3], and isolated proxyphylline metabolite. The incubation medium and the solutions used were prepared in a 0.05 $M$ phosphate buffer (pH 7.4) (26). Solutions of xanthine, theophylline[3], and metabolite were prepared by dissolving the drugs in a small volume of concentrated sodium hydroxide, followed by addition of the phosphate buffer and final adjustment of the pH to 7.4 with dilute hydrochloric acid. The temperature was maintained at 25 ± 1°, and the absorbance was determined with a spectrophotometer[4].

**Drug Administration to Humans**—In a preliminary qualitative assay, an oral dose of 300 mg of proxyphylline was administered to two healthy men. Proxyphylline was dissolved in water containing sucrose. No food was allowed from 9 hr before until 2 hr after drug administration. Urine was collected prior to the experiment and for the 0–8 and 8–24-hr periods. Excreted volumes were measured, and 25-ml samples were stored at −20° until analysis by TLC.

In a second quantitative assay, 300 mg of proxyphylline was administered to five healthy men (73–98 kg, mean 81.8 kg; 23–38 years, mean 30.8 years). The administration conditions and urine collection procedures were the same as in the preliminary assay. Blood samples were obtained from the cubital veins of the forearm with heparinized syringes immediately before administration and at 0.5, 1, 2, 4, 6, 8, and 12 hr. The plasma was separated after centrifugation and stored under the same conditions as urine until analysis.

To isolate enough of the proxyphylline metabolite to study its structure and properties, three gelatin capsules, each containing 750 mg of proxyphylline, were administered to six healthy men, one capsule every 12 hr. All urine excreted for 9 hr after the third dose was collected and stored at −20° until analysis.

**Isolation and Purification of Proxyphylline Metabolite**—Urine excreted by the six volunteers (2.85 liters) was chromatographed through a glass column (30 × 3.5 cm) filled with resin[5]. Excess water in the column then was removed by vacuum applied to the lower end, and the column was eluted with 900 ml of methanol. Air bubbles were removed by gentle agitation of the resin with a glass rod. The methanol eluate was evaporated to dryness *in vacuo*. The residue was washed three times with 50 ml of methanol, once with 35 ml of chloroform, and twice with 14 ml of ethanol and was dried *in vacuo* over phosphoric anhydride for 2 days. A white powder (364 mg) was obtained.

This compound was shown by TLC[6] in Solvent Systems 1 (chloroform–methanol–25% ammonia solution, 10:4:1) and 2 (chloroform–methanol–ethyl acetate–99.5% acetic acid, 78:10:10:2) to be mainly the expected proxyphylline metabolite ($R_f$ 0.42 in Solvent 1 and $R_f$ 0.23 in Solvent 2). Its purity was 84–88% as determined by comparison of its molar absorptivity with that of proxyphylline and xanthine at 270 nm (pH 7.4). The identification of its structure was carried out by spectro-

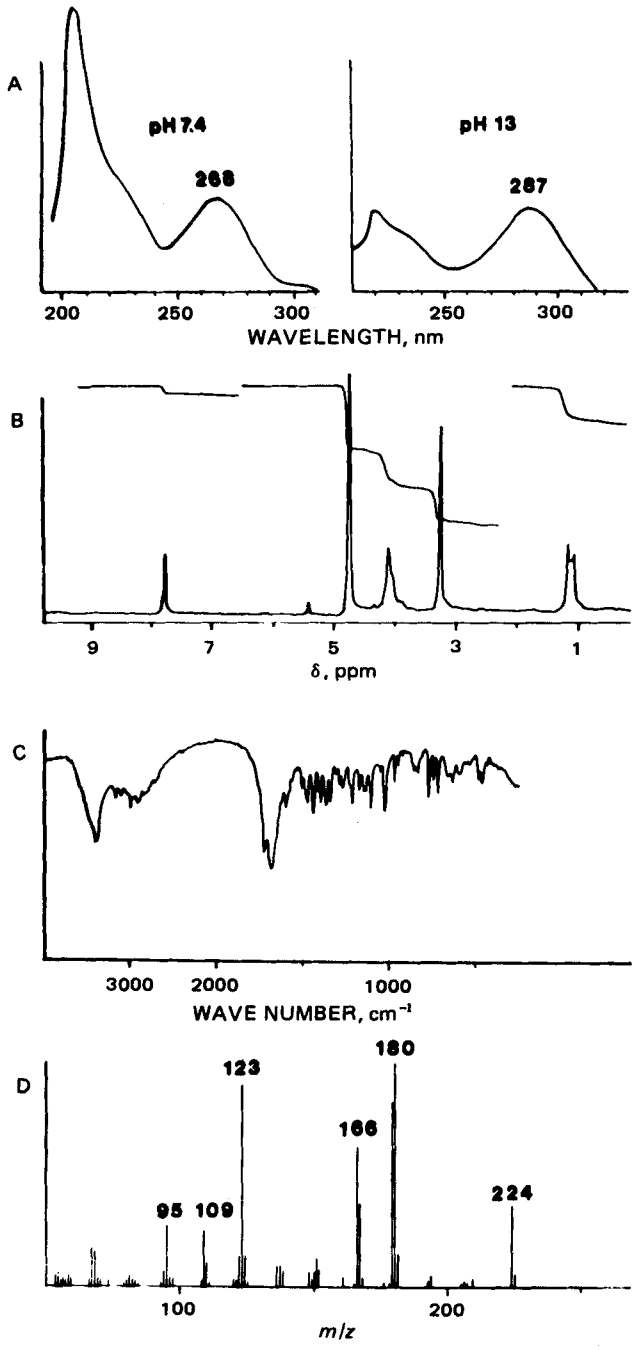

**Figure 1**—*UV (A), NMR (B), IR (C), and mass (D) spectra of the metabolic product of proxyphylline, 1-methyl-7-(2-hydroxypropyl)-xanthine, isolated from human urine.*

metric methods. Measurements of UV absorption spectra[4] were performed in methanol or aqueous solutions. The spectra in aqueous solutions were obtained at pH 13 (0.5 *N* NaOH) or pH 7.4. [The compounds were dissolved in a minimal amount of concentrated sodium hydroxide, 0.1 *M* phosphate buffer (pH 7.4) was added, and the pH was adjusted to 7.4 with dilute hydrochloric acid]. IR spectra[7] were obtained using potassium bromide pellets. NMR spectra[8] were obtained in a 0.5 *N* NaOD solution in deuterium oxide. Tetramethylsilane was used as the internal standard. Mass spectra[9] were obtained at 70 ev, and samples were introduced by direct-probe insertion.

**Pharmacological Activity of Proxyphylline and Its Purified Metabolite on Isolated Guinea Pig Tracheal Chain**—A guinea pig tracheal chain was prepared according to the method of Castillo and De Beer (27). It was immersed in a bath containing an oxygenated Kreb's solution and was subjected to an initial tension of 0.5 g. The addition of isoproterenol[10], theophylline, proxyphylline, and the purified proxyphylline metabolite to the bath allowed comparison of their relative myorelaxant effects[11]. Isoproterenol, theophylline, and proxyphylline were dissolved directly in saline (0.9% NaCl). However, to obtain a saline solution of proxyphylline metabolite, it was necessary to boil and reflux the suspension for ~15 min. The metabolite was stable under these conditions. The concentrations studied for each compound are indicated in Fig. 2.

**Quantitative Analysis of Proxyphylline and Its Metabolite in Human Plasma and Urine**—*Proxyphylline in Plasma*—Plasma samples (1 ml) were made alkaline with 0.5 *N* NaOH (0.2 ml) and were extracted for 1 hr with chloroform (6 ml). The organic phase was separated by centrifugation and evaporated under a nitrogen stream. The residue was dissolved in chloroform, applied to precoated thin-layer plates[6], and developed further with Solvent System 2. Quantification was carried out by photodensitometry[12] by measuring the diminution of background fluorescence at 525 nm (excitation at 254 nm) induced by the proxyphylline spot ($R_f$ 0.36). The calibration curves were obtained after addition of known amounts of proxyphylline to plasma samples subsequently subjected to extraction.

*Proxyphylline Metabolite in Plasma*—Plasma samples (1 ml) were added to resin[5] (0.3 g) and shaken for 5 min. The aqueous phase was separated, and the resin was eluted three times with 1 ml of methanol with vigorous shaking for 5 min. The extracts were combined and evaporated to dryness under a nitrogen stream, and the residue was dissolved in a small amount of methanol. Quantitation was carried out by TLC and photodensitometry[12] as previously described, using Solvent System 2. The addition of known amounts of purified metabolite to plasma samples showed that the extraction yield was nearly 100%. The detection limit was 1 μg/ml.

*Proxyphylline and Its Metabolite in Urine*—Samples of urine (40 μl) were applied directly onto precoated thin-layer plates, which were developed with Solvent System 1. Analysis was performed by photodensitometry[12] as previously described. The responses were compared with those obtained from known amounts of proxyphylline and its purified metabolite added to control urines. The $R_f$ value of proxyphylline in this system was 0.79.

## RESULTS AND DISCUSSION

The oral administration of caffeine (1,3,7-trimethylxanthine) to rats and humans gives rise to the excretion of the following substances: 1,3,7-trimethylxanthine (10), 1,3,7-trimethyluric acid (11), 1,3-dimethylxanthine (theophylline) (12), 1,3-dimethyluric acid (10), 1,7-dimethylxanthine (paraxanthine) (10), 1,7-dimethyluric acid (13), 1-methylxanthine (10), 1-methyluric acid (10, 13), 7-methylxanthine (10), 7-methyluric acid (13), and 3-methyluric acid (11). Thus, there are two main metabolic pathways for caffeine, *N*-demethylation and $C^8$-oxidation of the various methylxanthines to uric acid derivatives. The metabolism of theophylline and theobromine, when given orally to humans, is similar (10, 28).

The $C^8$-oxidative metabolism can be partially studied by following the reaction of each substrate with the enzyme, xanthine oxidase. It is known that caffeine (29) and other methylxanthines are not oxidized by this enzyme, whereas 1-methylxanthine is oxidized to its uric acid derivative by bovine milk (21) or by rat hepatic (22) xanthine oxidases. Recently, it was demonstrated by giving theophylline and allopurinol to humans (23) that 1-methyluric acid seems to be the only metabolite arising from direct oxidation of its substrate (1-methylxanthine) by hepatic xanthine oxidase. Therefore, the oxidative metabolism of proxyphylline and its isolated metabolite by xanthine oxidase was studied.

Bovine milk xanthine oxidase was used since this enzyme and human hepatic xanthine oxidase have a similar specificity for purine derivatives (21). Proxyphylline was incubated at concentrations of $1 \times 10^{-4}$ and $1 \times 10^{-3}$ *M*, and its metabolite was incubated at $1 \times 10^{-4}$ and $5 \times 10^{-4}$ *M*. These concentrations were equal to and were five and 10 times higher than the concentration of xanthine that saturates the system (21). Under these conditions, no reaction was observed, which may have been due to either a lack of affinity for the enzyme or a lack of intrinsic activity of the enzyme when the substrates are at the active site. The ability of proxyphylline and its metabolite to inhibit competitively the xanthine–xan-

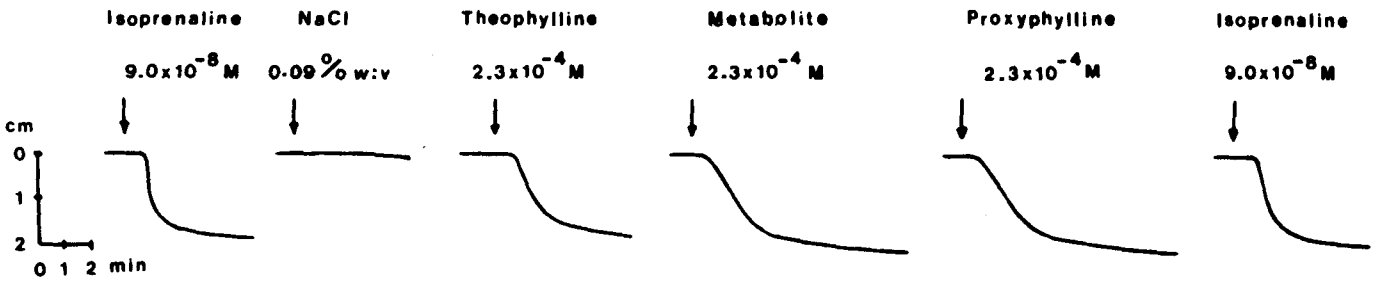

**Figure 2**—*Effects induced by isoproterenol (isoprenaline), theophylline, proxyphylline, and its metabolite on the myorelaxation of the isolated guinea pig tracheal chain. The substances were dissolved in 0.9% NaCl and were added (4 ml) to the bath (40 ml) to reach the final concentrations indicated in the figure.*

thine oxidase system was studied to distinguish between these possibilities. The xanthine concentrations in the incubation media were $2.5 \times 10^{-6}$, $5 \times 10^{-6}$, $1 \times 10^{-5}$, and $1 \times 10^{-4}$ *M*. The concentrations of proxyphylline and the metabolite were the same as previously indicated. Neither substance altered the oxidation rate of xanthine, which suggests that they have a low affinity for the enzyme, as is the case for caffeine, theophylline, and theobromine (30). Apparently the di- and trisubstitution of the xanthine nucleus prevents the interaction with xanthine oxidase (21, 30).

When 300 mg of proxyphylline was given orally to two volunteers, visual evaluation (254 nm) of thin-layer plates of urine extracts showed only two new spots compared with control urine. One spot was identified as unchanged proxyphylline. Only 28.4 mg was excreted during the first 8 hr, and 24.8 mg was excreted during the following 16 hr. The second compound had lower $R_f$ values and was excreted in higher concentrations. This metabolite was isolated from the combined urine of six volunteers given high doses of proxyphylline. Its structure was investigated by spectral methods, and it was identified as 1-methyl-7-(2-hydroxypropyl)xanthine based on the following evidence:

1. The UV absorption spectrum of the metabolite in methanol and aqueous neutral solutions (Fig. 1A) was virtually identical to that of proxyphylline and xanthine. Under these conditions, the absorbance maximum of uric acid was at 290 nm. The absorption maximum of the metabolite shifted to 287 nm in alkaline solutions (Fig. 1A), as occurs with xanthine but not with proxyphylline. The tautomerism of $N^3$-H is involved in the bathochromic shift of the xanthine spectrum (31). No tautomerism exists for $N^1$-H (31).

2. Apart from the disappearance of the singlet corresponding to a 1-methyl group, the NMR spectrum of the metabolite (Fig. 1B) was similar to that of proxyphylline: $\delta$ 1.28 (d, C–$CH_3$), 3.27 (s, N–$CH_3$), 3.46 (s, N–$CH_3$), 4.10 (m, $CH_2$–CHOH), and 8.08 (s, ≡CH) ppm. It was shown (32, 33) that the $N^1$-methyl group always appears upfield with respect to the $N^3$-methyl group. Thus, the methyl group ($\delta$ 3.25 ppm) in the spectrum of the metabolite is located at position 1.

3. The IR spectrum of the metabolite (Fig. 1C) confirmed the lack of $C^8$-oxidation since no variation was observed in the CO stretching bands when compared to proxyphylline (1650 and 1690 $cm^{-1}$).

4. The mass spectrum (Fig. 1D) confirmed the postulated structure. The molecular ion ($M^+$ at *m/z* 224) is in accordance with the formula $C_9H_{12}N_4O_3$. The $N^7$-side chain is unaltered as indicated by the fragmentation of the $\alpha$ and $\beta$ bonds (*m/z* 166, 167, 179, and 180) when compared to proxyphylline (34). All ions bearing the purine ring appeared 14 amu lower than the corresponding ions in the proxyphylline spectrum (34), thus confirming the absence of the $N^3$-methyl group.

5. The solubility of the metabolite in aqueous neutral solutions (pH 7.4) was comparable to that of xanthine but much lower than that of proxyphylline. The solubility of the metabolite increased in strong alkaline media due to the ionization of the tautomeric enolic form involving $C^2$ and $N^3$.

$N^3$-Demethylation of proxyphylline is in accord with the metabolic stability of the caffeine methyl groups (1 > 7 > 3) in humans (10). No $N^7$- or $N^1$-metabolic dealkylation of proxyphylline metabolite is subsequently produced, in accordance with the results of Cornish and Christman (10), who found that didealkylation did not occur when theophylline and theobromine were given to humans. They did not observe urinary excretion of xanthine or uric acid above the normal levels. Other $N^7$-substituted theophyllines with larger side chains are $N^7$-dealkylated to produce theophylline, *e.g.*, pimefylline {7-[2-[(3-pyridylmethyl)amino]ethyl]theophylline} (14) and fenethylline {7-[2-[($\alpha$-methylphenethyl)amino]ethyl]theophylline} (16), whereas xanthinol {7-[2-hydroxy-3-[(2-hydroxyethyl)methylamino]propyl]theophylline} and dyphylline [7-(2,3-dihydroxypropyl)theophylline] behave as proxyphylline and its metabolite since no $N^7$-dealkylation is observed (15, 17, 18). The latter four compounds carry an hydroxyl group on the $\beta$-position of the side chain that may prevent the carbinolamine formation postulated (35, 36) to be the first step of *N*-dealkylation. The complexity of the $N^7$-side chain also seems to play an important role in the $C^8$-metabolic oxidation of this class of substances. Proxyphylline and its metabolite, like other theophyllines substituted in position 7 by large groups, are not oxidized, whereas the 7-methylxanthines are excreted partially as uric acid derivatives (10, 11, 13). The enzymatic system involved, however, was not determined. Xanthine oxidase does not seem to be involved (21, 24, 30).

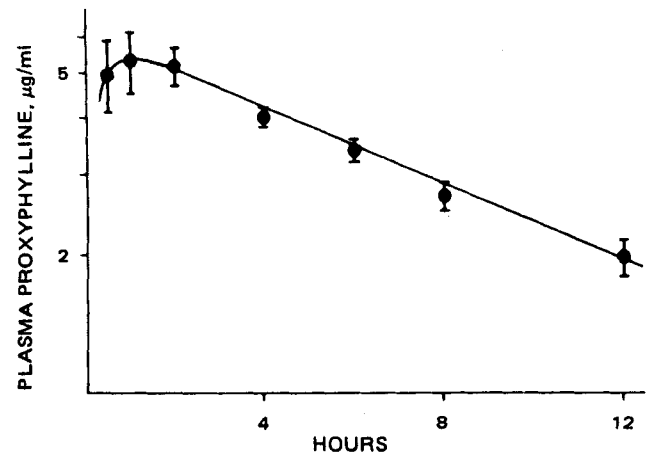

**Figure 3**—*Mean plasma concentrations of unchanged proxyphylline in five human volunteers given 300 mg of the drug by the oral route. Vertical bars are units of the standard error of the mean.*

Equimolar amounts of proxyphylline and its metabolite gave an equivalent relaxation of the isolated guinea pig tracheal chain, although these compounds were less active than theophylline and isoproterenol (Fig. 2). The metabolite was not detected (detection limit = 1 µg/ml) in the plasma samples of six volunteers given 300 mg of proxyphylline orally. The levels of the parent drug in the same samples (Fig. 3) were similar to those previously described for an equivalent dose (19, 20, 37–40). These results indicated that in spite of its $\beta$-adrenergic activity, 1-methyl-7-(2-hydroxypropyl)xanthine probably does not participate in the clinical actions of proxyphylline. Despite the lack of detection of the metabolite in the systemic circulation, it was verified as the major pathway for the renal excretion of proxyphylline in humans (Table I). The mean values of metabolite excreted in the urine were 16.9% of the dose in the 0–8-hr period and 13.3% of the dose during the following 16 hr. These values were twice those found for proxyphylline (8.5 and 4.1%, respectively).

**Table I—Cumulative Urinary Excretion of Proxyphylline and Its Metabolite** [a]

| Hours | Proxyphylline | Metabolite |
|---|---|---|
| 8 | 8.5 ± 3.0 [b] | 16.9 ± 2.9 |
| 24 | 12.6 ± 2.9 | 30.2 ± 3.6 |

[a] Oral administration of 300 mg of proxyphylline to five humans. [b] Percentage of dose (mean ± *SEM*).

The high amounts of 1-methyl-7-(2-hydroxypropyl)xanthine appearing in the urine of humans given proxyphylline and the close similarity between the chemical structure of both compounds indicate the need for specific methods to estimate the unchanged drug concentrations in those samples. Some results obtained by nonspecific spectrophotometric methods (19, 41, 42) will need reevaluation. It has been verified that the method of Driever (43), modified by Ritschel and Banarer (41) to estimate unchanged proxyphylline in urine, does estimate the unchanged drug plus its metabolite, 1-methyl-7-(2-hydroxypropyl)xanthine.

# Biodehalogenation and Metabolism of [$^{125}$I]-4-Iodobiphenyl

**J. E. SINSHEIMER** [x] **and Y. Y. SHUM** *

Received January 31, 1980, from the *College of Pharmacy, University of Michigan, Ann Arbor, MI 48109.* Accepted for publication October 14, 1980. *Present address: Warner-Lambert/Parke-Davis Pharmaceutical Resarch Division, Ann Arbor, MI 48106.

**Abstract** □ [$^{125}$I]-4-Iodobiphenyl has been used as a model compound to investigate the *in vivo* metabolism of iodinated aromatic compounds in the rat. Material balance studies showed that 57.6% of the injected dose was excreted *via* feces and 41.2% *via* urine. Distribution studies indicated uptake of inorganic iodide in the thyroid. In the feces, 2.2% of the dose was unmetabolized iodobiphenyl, 2.6% was 2-hydroxy-4′-iodobiphenyl, 21.9% was 4-hydroxy-4′-iodobiphenyl, and 20.9% was a polar fraction of which only 10.3% could be silylated. In urine, 1.6% of the dose was 2-hydroxy-4′-iodobiphenyl, 4.9% was 4-hydroxy-4′-iodobiphenyl, 1.9% was 2-hydroxy-4′-iodobiphenyl, 17.7% was 4-hydroxy-4′-iodobiphenyl glucuronide and sulfate conjugates, and 8.2% was inorganic iodide. About 3.0% of the dose in the urine polar fraction could be methylated.

**Keyphrases** □ 4-Iodobiphenyl—metabolism in rats, distribution studies □ Metabolism—4-iodobiphenyl and metabolites, distribution studies in rats □ Distribution—4-iodobiphenyl and metabolites, metabolism and distribution studies in rats

The increasing medicinal use of iodinated organic compounds as positive X-ray contrast media (1) as well as diagnostic, scanning, and radiopharmaceutical agents (2) prompted this study of the biodehalogenation and metabolism of iodocompounds. *In vitro* mechanisms for the biodehalogenation of some model compounds were reported previously (3). This paper describes the *in vivo* biodehalogenation and metabolism of 4-iodobiphenyl (I) as a model compound used in rats.

## EXPERIMENTAL[1]

**Chromatographic Solvent Systems**—Benzene–methanol–formic acid (90:9:1) (Solvent System 1) and benzene–methanol (85:15) (Solvent System 2) were used for TLC[2], *n*-butyl alcohol–0.5 *M* $NH_4OH$–ethanol–water (20:20:2:1) (Solvent System 3) was used for paper chromatography, and *n*-butyl alcohol–acetone–concentrated ammonium hydroxide–water (65:20:10:5) (Solvent System 4) was used for resin paper chromatography.

**[$^{125}$I]-4-Iodobiphenyl**—This compound (specific activity, 9.0 μCi/mg; radiochemical purity by reverse isotopic dilution, 99.7%) was synthesized by an exchange reaction described previously (3).

**4-Hydroxy-4′-iodobiphenyl (II)**—Compound II was prepared from 4-hydroxybiphenyl and benzoyl chloride according to a literature method (4). The product was recrystallized in chloroform, mp 202° [lit. (4) mp 199°]; IR (KBr): 3300 (OH), 1580, 1520 (aromatic H), 1470–1420 (CH), 1380, 1250 (aromatic OH), 1120, 1000, 810, and 720 (aromatic H) $cm^{-1}$; NMR (acetone-$d_6$): δ 8.57 (broad s, 1H, aromatic OH), 7.92 (d of d, 2H, $J_{ab}$ = 9.0 Hz, $J_{ac}$ = 2.6 Hz, aromatic H), and 7.07 (d of d, 2H, $J_{ab}$ = 9.0 Hz, $J_{ac}$ = 2.0 Hz, aromatic H); mass spectrum (75 ev): *m/z* (relative intensity) 298 (1.0%) $[M + 2]^+$, 297 (14.1) $[M + 1]^+$, 296 (100) $[M]^+$, 267 (1.3), 169 (7.5) $[M - I]^+$, 168 (10.6) $[M - HI]^+$, 152 (3.8) $[M - HOI]^+$, 141 (19.7), 139 (8.0), 118 (metastable), 115 (14.3), and 96.5 (metastable).

**2-Hydroxy-4′-iodobiphenyl (III)**—Compound III was synthesized from 2-hydroxybiphenyl and benzoyl chloride using the same procedure as used for the preparation of II. The product was recrystallized in pentane, mp 75° [lit. (5) mp 74°]; IR (KBr): 3470–3020 (aromatic OH), 1470, 1390 (aromatic H), 1268 (aromatic OH), 1188, 1130, 1120, 1042, 1010, 834, 814, 756, 700, 612, and 540 (aromatic H) $cm^{-1}$; NMR ($CDCl_3$): δ 5.40 (s, 1H, aromatic OH), 6.90 (d of t, 1H, $J_{ab}$ = 9.0 Hz, $J_{ac}$ = 2.0 Hz, aromatic H), 7.20 (d of d, 2H, $J_{ab}$ = 9.0 Hz, $J_{ac}$ = 2.0 Hz, aromatic H), 7.40 (t, 1H, $J_{ab}$ = 2.0 Hz, aromatic H), 7.68 (d of d, 2H, $J_{ab}$ = 9.0 Hz, $J_{ac}$ = 2.0 Hz, aromatic H), and 7.94 (d, 2H, $J_{ab}$ = 9.0 Hz, aromatic H); mass spectrum (75 ev): *m/z* (relative intensity) 297 (14%) $[M + 1]^+$, 296 (100) $[M]^+$, 170 (20) $[M - I]^+$, 169 (10), 168 (2.0), 141 (9.0), and 115 (4.0).

**Reverse Isotopic Dilution**—In a manner analogous to previously reported analyses (6), ~1 g of II or III, accurately weighed, was transferred to a 300-ml round-bottom flask and dissolved completely in a small volume of acetone. Fecal extracts or urine samples were pipetted (1.0 ml) into the flask, and sufficient methanol was added to give a homogeneous solution. Solvents were removed *in vacuo*, and the residue was recrystallized from chloroform. Three samples of ~10 mg from each recrystallization were weighed accurately and counted for radioactivity in a γ-counting system. Recrystallization was repeated until constant specific activity was obtained.

***In Vivo* Studies**—Sprague–Dawley rats, 200–250 g, were housed in separate stainless steel metabolism cages and quarantined for at least 1 day prior to use. Rat food[3] and water were supplied *ad libitum*.

[$^{125}$I]-4-Iodobiphenyl was diluted with carrier 4-iodobiphenyl (I) and dissolved in sterilized peanut oil to give a final concentration of 110 μCi/100 mg/ml for intraperitoneal injection.

Tissue distribution studies were conducted after a single intraperitoneal injection of 0.5 ml of the peanut oil solution was given to 18 female rats. Sets of three rats were killed in an ether chamber at 3, 6, 24, 48, 72, and 96 hr after injection, and major tissues were excised and weighed. Representative samples of these tissues were weighed, and their radioactivities were determined (Table I).

Pretreatment with Lugol's solution was done with two rats, which were administered orally 0.3 ml of Lugol's solution (50 mg of elemental iodine and 100 mg of potassium iodide in 100 ml of water) once per day for 2 days. Control rats were dosed with distilled water under the same schedule. On the 3rd day, 3.9 μCi of [$^{125}$I]-4-iodobiphenyl in 0.5 ml of ethanol was administered to each rat by intraperitoneal injection. Rats were kept in separate metabolic cages for 24 hr before they were killed. Thyroid glands from each rat were excised, trimmed, weighed, and counted for activity in a γ-counting system.

Balance studies were conducted on three male rats, each receiving a single intraperitoneal injection of 1.0 ml of the dosage solution. Urine and fecal samples were collected for 18 days to observe excretion patterns of the metabolites.

Three rats received a single intraperitoneal injection of 1.0 ml of the dosage solution every 4 days for a total of 3.0 ml of solution to accumulate higher quantities of metabolites. Control rats were treated in a manner corresponding to each group but were injected only with sterilized peanut oil.

Rat urine and feces were collected separately after [$^{125}$I]-4-iodobiphenyl injections. Urine samples were quantitated for radioactivity, quick frozen in an acetone–dry ice bath to prevent mold growth, and stored at −25° until analyzed for metabolites. Feces were air dried and powdered, and samples (5–10 mg) were measured daily for radioactivity by γ-counting. They also were stored at −25° until investigated further.

For identification of fecal metabolites, the total combined daily powdered feces were extracted with methanol for 48 hr in a soxhlet apparatus. The methanol extract was reduced to 50.0 ml *in vacuo*. Aliquots (100 μl) of this solution were assayed by γ-counting to estimate the percentage of extractable activity.

Volumes (0.5 ml) of the concentrated fecal methanol extract were subjected to TLC analysis in Solvent Systems 1 and 2. Unmetabolized [$^{125}$I]-4-iodobiphenyl and its hydroxylated metabolites were identified by cochromatography with nonradioactive reference compounds in these solvent systems. The main body of the fecal methanol extract was applied to preparative chromatographic plates and developed in System 1. Bands of [$^{125}$I]-4-iodobiphenyl and its hydroxylated metabolites were extracted from the plates with appropriate solvents, concentrated, and subjected

[1] Spectra were obtained on Perkin-Elmer 337 IR, Varian A-60-A NMR, and DuPont 21-490 mass spectrometers. γ-Counting was either by liquid scintillation counting on Beckman LS-200 and 150 instruments with a phosphorus 32 window at 5% accuracy or 5-min intervals or with a Searle 1185 γ-system.

[2] Brinkmann 5 × 20 × 0.025-cm silica gel 60 F-254 on glass or Eastman silica chromatogram sheet 6060 for analytical measurements and Brinkmann 20 × 20 × 0.2-cm silica gel 60 F-254 on glass for preparative separations.

to GLC–mass spectrometric analysis. Part of the GLC output was collected *via* a three-way collector into scintillation vials and quantitated by liquid scintillation counting. Only the radioactive GLC peaks were analyzed by mass spectrometry.

Assay of [$^{125}$I]-4-iodobiphenyl and its hydroxylated metabolites was accomplished by estimation of their percentage contributions in TLC patterns developed in Solvent System 1. The results were subsequently confirmed by reverse isotopic dilution in the fecal methanol extracts with corresponding reference compounds.

Acid or base hydrolysis of the fecal polar fraction was done by extracting origin band materials with methanol and reducing the extract to 1.0 ml with nitrogen. An equal volume of 8 *N* HCl or 5% NaOH was added. The mixture was refluxed for 5 hr, and the solution was extracted with ether. Both aqueous and ether solutions were examined with TLC in Solvent System 1 for products.

Enzyme hydrolysis of the fecal polar fraction was performed by taking the methanol extract of the origin band to dryness under a nitrogen stream. The residue was dissolved in 2.5 ml of pH 7.4 phosphate buffer to which 0.1 ml (10,000 Fishman units) of β-glucuronidase–arylsulfatase of snail origin[4] (*Helix pomatia*) was added before it was incubated at 37° for 72 hr. After incubation, the content was centrifuged at 1720×*g* for 30 min, and the supernate was chromatographed in Solvent System 1 for detection of hydrolyzed products.

Silylation of the fecal polar fraction was carried out by reducing the methanol extract of the origin band to complete dryness. The dried residue was reacted with 1.0 ml of *N,O*-bis(trimethylsilyl)acetamide, and the mixture was refluxed in a tightly capped vial for 30 min in a sand bath until a clear solution was observed. This solution was cooled and spotted on TLC plates to be developed in Solvent System 2. The distribution of activity on the chromatogram was reconstructed by liquid scintillation counting of silica gel fractions scraped from consecutive 0.5-cm strips. Radioactivity was extracted from the detected bands, purified, and subjected to GLC–mass spectrometric analysis.

Urine samples (50–100 μl) were assayed daily for radioactivity by γ-counting. Radioactivity distributions of unmetabolized [$^{125}$I]-4-iodobiphenyl, their hydroxylated metabolites, and the conjugates were estimated after TLC in Solvent System 1. Values for II and III and their glucuronide and sulfate conjugates were confirmed after hydrolysis by reverse isotopic dilution.

Enzymatic hydrolysis was done on 2.0-ml samples of urine, which had been dried under a gentle nitrogen stream. To the residue were added 1.0 ml of pH 7.4 phosphate buffer and 0.1 ml of β-glucuronidase–arylsulfatase[4] (*Helix pomatia*) or β-glucuronidase[4] (bovine liver). The mixture was incubated in a constant-temperature water bath at 37° for 48–72 hr with constant shaking. The hydrolysis was stopped by heating in a steam bath for 5 min, and the protein was removed by centrifugation. The supernate was spotted on TLC plates and developed in Solvent System 1.

The urinary polar fractions, which failed to be hydrolyzed by enzymes, were methylated by dimethylformamide dimethylacetal (7) and quantitated by TLC in Solvent System 2 after derivatization.

The radioactivity of inorganic iodide in the urine was estimated by paper (8) and resin paper (9) chromatography in Solvent Systems 3 and 4, respectively. These values were confirmed by lead iodide reverse isotopic dilution and methyl iodide exchange experiments (9).

## RESULTS

**Tissue Distribution**—Typical tissue radioactivities of iodine 125 for the organ examined are listed in Table I. At all times, the thyroid gland had the highest activity. After 24 hr, there was minor but consistent uptake of radioactivity by fatty tissue as compared to blood levels. Pretreatment of rats with Lugol's iodide solution daily for 2 days prior to administration of [$^{125}$I]-4-iodobiphenyl suppressed thyroid uptake by 90%. This competitive thyroid uptake experiment indicated that the thyroid activity was due to metabolically liberated inorganic iodide.

**Balance Studies**—The excretion of radioactivity in feces and urine for three rats was followed for 18 days, with an average total fecal excretion of 57.6% of the administered dose and an average total urinary excretion of 41.2%. In both cases, most radioactivity was eliminated in the first 6 days.

**Fecal Metabolites**—Methanol extraction of powdered dry feces indicated that 96.7% of feces activity could be extracted by this method. Chromatographic analysis of the concentrated feces methanol extract on TLC plates in Solvent System 1 gave rise to four radioactive bands with $R_f$ values at 0.00, 0.21, 0.38 and 0.64. They were labeled $F_A$, $F_B$, $F_C$, and $F_D$ and found to possess 20.9, 26.4, 8.4, and 2.4% of the radioactivity of the original dose, respectively. Each radioactive band was scraped off the plate, extracted, and subjected to further analysis.

A radioactive band from the condensed hexane extract of $F_D$ cochromatographed with 4-iodobiphenyl (I) at $R_f$ 0.64 (System 1) and 0.62 (System 2) and corresponded to I by GLC–mass spectrometry after separation on a 5% OV-1 column. Reverse isotopic dilution with I indicated 3.8% of the fecal methanol extract (2.2% of the injected dose) was due to unmetabolized [$^{125}$I]-4-iodobiphenyl, a value in agreement with the 2.4% found for band $F_D$.

Radioactive band $F_C$ was extracted with chloroform. When this extract was cochromatographed with 2-hydroxy-4′-iodobiphenyl (III), a radioactive spot corresponding to a UV-quenching spot was obtained at $R_f$ 0.38 in System 1 and at $R_f$ 0.50 in System 2. GLC–mass spectrometric analysis of the $F_C$ chloroform extract, similar to that described for $F_D$, resulted in a mass spectral fragmentation pattern consistent with III: *m/z* (relative intensity) 297 (16%), 296 (100), 170 (6.0), 169 (13), 168 (13), 141 (52), and 115 (42).

When reverse isotopic dilution experiments of the fecal methanol extract were done with III, only 2.6% of the injected dose activity could be identified as III. Based on the similarity of the mass spectrum of band $F_C$ to the spectra of both references II and III, band $F_C$ probably contained other hydroxylated metabolites in addition to III. The reverse isotopic dilution results compared to the TLC results indicate that the 2-hydroxy isomer (III) is about a third of band $F_C$ (Table II).

Cochromatography of an extract of radioactive band $F_B$ with 4-hydroxy-4′-iodobiphenyl (II) gave radioactive spots with $R_f$ values of 0.21 in System 1 and 0.28 in System 2, which corresponded to the reference material. GLC–mass spectrometric analysis of band $F_B$ was also consistent with that of II: *m/z* (relative intensity) 297 (15.4), 296 (100), 267 (2.3), 169 (10.8), 168 (10), 152 (3.8), 151 (3.8), 148 (5.4), 141 (20.8), 139 (18.5), and 115 (18.5). Reverse isotopic dilution experiments with II on the fecal methanol extract indicated that 21.9% of the dose activity was converted to II in the feces.

On the basis of TLC Systems 1 and 2, band $F_A$, which consistently remained at the origin, contains highly polar metabolites such as sulfates, glucuronides, and mercapturic acid derivatives.

Repeated attempts to hydrolyze band $F_A$ materials with acid, base, and β-glucuronidase–arylsulfatase enzymes failed to create new radioactive TLC bands of higher $R_f$ values in either System 1 or 2. Derivatization of $F_A$ materials finally led to the formation of a product with *N,O*-bis(trimethylsilyl)acetamide. Upon chromatography of this product, a radioactive band at $R_f$ 0.81 in System 2 was obtained, and it was estimated that about half of the original $F_A$ materials had reacted (9.8% of the injected dose). Efforts to elucidate the structure of this $F_A$ derivative by GLC–mass spectrometry were not successful.

**Urinary Metabolites**—Analysis of the urinary metabolites started with cochromatography of the urine with fecal methanol extracts in Solvent System 1. This chromatogram indicated that most of the urinary metabolite activity (~32.0% of the injected dose) lay under the origin

**Table I—Tissue Distribution of Radioactivity after Intraperitoneal Administration of [$^{125}$I]-4-Iodobiphenyl (55 μCi/0.5 ml of Injection) to Rats**

| Tissue | Radioactivity, cpm/mg | | | | | |
|---|---|---|---|---|---|---|
| | 3 hr | 6 hr | 24 hr | 48 hr | 72 hr | 96 hr |
| Thyroid | 79 | 63 | 2426[a] | 5377 | 7255 | 3025 |
| Fat | 4 | 17 | 96 | 78 | 59 | 53 |

[a] In separate experiments, in which rats were pretreated with Lugol's solution prior to administration of 3.9 μCi of [$^{125}$I]-4-iodobiphenyl, 24-hr thyroid activities were 9.7 and 21.6 cpm/mg. These values were compared to 137.4, 199.2, and 258.9 cpm/mg for nonpretreated rats at the same dose of I.

**Table II—4-Iodobiphenyl and Metabolites Expressed as Percent of Dose**

| Compound | Feces | | Urine | |
|---|---|---|---|---|
| | TLC[a] | RID[b] | TLC | RID |
| 4-Iodobiphenyl (I) | 2.4[c] (1.8–2.8)[e] | 2.2 (2.11–2.26) | None detected | —[d] |
| 4-Hydroxy-4′-iodobiphenyl (II) | 26.4 (24.0–27.2) | 21.9 (21.3–22.5) | 4.9 (4.0–5.4) | — |
| Total other monohydroxy iodobiphenyls | 8.4 (7.0–9.2) | — | 1.6 (1.2–1.8) | — |
| 2-Hydroxy-4′-iodobiphenyl (III) | — | 2.6 (2.53–2.63) | — | — |
| II β-glucuronide or sulfate | None detected | — | 18.2 (16.1–19.8) | 17.7 (17.2–18.3) |
| Total other monohydroxy iodobiphenyl β-glucuronide or sulfate | None detected | — | 6.4 (5.9–7.5) | — |
| III β-glucuronide or sulfate | None detected | — | — | 1.9 (1.82–1.93) |
| Methylated urinary polar metabolites | — | — | 3.0 (1.6–4.0) | — |
| Silylated fecal polar metabolites | 10.3 (8.0–13.7) | — | — | — |
| Inorganic iodide | — | — | 7.3[f] (6.91–7.87) | 8.2[g] (8.10–8.26) |

[a] TLC values are averages of data from three rats. [b] Reverse isotopic dilution values. [c] Numerical values are expressed as percentage of administered dose. [d] Not determined. [e] Numbers in parentheses express the range of values. [f] Determined by resin paper chromatography (Ref. 9). [g] Determined by lead iodide reverse isotopic dilution method (Ref. 9).

band, representing highly polar materials. Only 4.9% of the dose activity could be accounted for in the urine as free phenolic II, and an additional 1.6% was III. No unmetabolized I could be detected in urine.

To determine if any glucuronide or sulfate conjugates were present in the urinary polar fraction, the polar fraction at the origin was extracted with methanol, dried, and hydrolyzed in buffer solution with β-glucuronidase–arylsulfatase enzyme (*Helix pomatia*). TLC of the hydrolyzed products in System 1 showed that 18.2 and 6.4% of the injected dose in the urinary polar fraction corresponded in $R_f$ to II and III, respectively. Thus, in the urine, a total of 23.1% of the dose activity could be accounted for as II and its glucuronide or sulfate conjugates. Similarly, 8.0% of the dose activity was transformed into metabolites corresponding in $R_f$ to III and its conjugates.

Confirmation of the TLC-derived quantitation of the two free phenolic metabolites was sought by two separate reverse isotopic dilution experiments using the urinary polar radioactive fraction that had been hydrolyzed enzymatically. Compounds II and III were used as the reference compounds. Based on these results, it was calculated that II accounted for 17.7% (18.2% by TLC) and III accounted for 1.9% (TLC indicated 6.4%) of the original dose. The remaining 4.5% was speculated to be due to other monohydroxy iodobiphenyls in a manner similar to the corresponding fecal metabolite band.

Differentiation between glucuronide and sulfate conjugates of the phenolic metabolites was made by independent enzyme hydrolysis of the urinary polar fraction methanolic extracts by β-glucuronidase–arylsulfatase from *Helix pomatia versus* bovine β-glucuronidase. Comparisons by TLC indicated that of the 18.2% of II released by enzyme hydrolysis, 16.1% was from sulfate conjugates while only 2.2% was due to glucuronide conjugates. Similarly, of the 6.4% released as material cochromatographing with III, 5.1% was from sulfate and only 1.3% was from glucuronide conjugates.

Treatment of the polar band left at the origin after enzyme hydrolysis with dimethylformamide dimethylacetal revealed that about half (3.1% of dose) of the activity could react. The product, when chromatographed in System 1, showed a radioactive band at $R_f$ 0.70. When chromatographed in System 2, this band appeared at $R_f$ 0.60. Due to the minute quantity that could be isolated from this radioactive band, attempted GLC–mass spectrometric analyses to characterize its structure were not successful.

The various metabolites of I found in the rat feces and urine are summarized in Table II, together with their relative percentages of the administered dose.

## DISCUSSION

While biotransformations of 4-iodobiphenyl (I) have not been reported previously, those of 4-chlorobiphenyls have been studied extensively (10–14). Results of the present study agree with the literature in that hydroxylation at the *para*-position and subsequent partial conjugation are the major metabolic pathways.

No hydroxylation at position 2′ was found for a number of animal species administered 4-chlorobiphenyl (10–14). However, the present finding of hydroxylation at this position for iodobiphenyl agrees with such transformation of biphenyl *per se* (15–18).

The presence of metabolites hydroxylated at positions 2′ and 4′ of I is consistent with the formation of 2′,3′- and of 3′,4′-arene oxide intermediates of I in the initial biotransformation of this compound. The reaction product of the urinary polar fraction after enzyme hydrolysis and subsequent reaction with dimethylformamide dimethylacetal was speculated to be a methyl derivative of a mercapturic acid metabolite of I. A mercapturic acid metabolite would be a logical arene oxide derivative, and the electron-withdrawing effect of the attached iodophenyl moiety would stabilize the arene oxide which, in turn, would allow more time for glutathione conjugation (19). The findings of West *et al.* (20), who reported isolation of *N*-acetyl-*S*-biphenyl-L-cysteine from rat urine after dosing with biphenyl, support such conjugation. Also supporting this conjugation is the work of Wood and his associates (21, 22) who were able to isolate [$^{131}$I]-4-iodophenylmercapturic acid after oral administration of [$^{131}$I]iodobenzene to rats.

The fecal polar fraction resisted hydrolysis, indicating the absence of glucuronide or sulfate metabolites, but it reacted with *N,O*-bis(trimethylsilyl)acetamide. This fraction also could contain mercapturic acid conjugates or their precursors.

Even though no deiodination was detected in metabolic studies of 4,4′-diiodobiphenyl in rabbits (23), results from the present studies indicated that a substantial amount of inorganic iodide could be found from the metabolism of I in rats. The absence of dehalogenation by rabbits also was pointed out by Block and Cornish (10) in their studies of 4-chlorobiphenyl. Thus, a species difference in dehalogenation of biphenyl compounds may be indicated.

**Abstract** □ The interaction of two homologous series of biliary contrast agents with native human and bovine serum albumin and with modified human serum albumin was investigated using circular dichroism and equilibrium dialysis. For most derivatives, extrinsic Cotton effects were observed for the interaction with both albumins. In some cases, these effects were strongly affected by only small changes in the chemical structure of the drugs. These large differences in extrinsic Cotton effects can be explained by definite effects of the chemical structures on the binding site selectivity of some drugs. For example, iopodate preferentially binds to the warfarin binding site of human serum albumin, while an ethyl group into the propionic acid side chain reduces the affinity for the warfarin site but strongly increases the affinity for the diazepam binding site of human serum albumin.

**Keyphrases** □ Biliary contrast agents—interaction with native and modified human serum albumin, optical studies on warfarin and diazepam binding sites of albumin □ Albumin, human serum—interaction of biliary contrast agents with native and modified albumin, optical studies of warfarin and diazepam binding sites □ Binding sites—warfarin and diazepam binding sites on human serum albumin molecule, interaction of biliary contrast agents with albumin □ Structure–activity relationships—interaction of biliary contrast agents with native and modified human serum albumin, optical studies of warfarin and diazepam binding sites

Contrast agents for the intravenous or oral visualization of the biliary tract are, in general, highly bound to albumin in the blood of humans and laboratory animals (1). Because of their strong binding to albumin, their low lipophilicity, and their low volumes of distribution, plasma protein binding of biliary contrast agents seems to be an important determinant of the pharmacokinetics of these drugs (2, 3). Furthermore, since the toxicity of the biliary contrast agents increases with increasing plasma protein binding, binding mechanisms leading to high albumin binding and high toxicity may have similarities (1, 4).

Therefore, detailed knowledge of the degree of albumin binding of the biliary contrast agents and of the binding mechanisms is of great interest. Thus, it must be determined which moieties of the contrast medium molecules are important for high binding and to which sites of the human serum albumin molecule the substances are bound. While some quantitative data on affinity constants and numbers of binding sites for two groups of homologous biliary contrast agents were published previously (5), this study describes qualitatively their interaction with human serum albumin, using optical methods and modified albumin derivatives.

## EXPERIMENTAL

**Materials**[1]—The human serum albumin[2] had an electrophoretic purity of 100%. All other chemicals were obtained from commercial suppliers.

**Preparation of Albumin Derivatives**—The modification of human serum albumin with 2-hydroxy-5-nitrobenzyl bromide (XII·Br) was reported in detail elsewhere (6). Human serum albumin was dissolved in 10 *M* urea adjusted to pH 4.4 by acetic acid, and a 1100-fold molar excess of XII·Br was added (XII–albumin). Another albumin sample was treated similarly but without the reagent and was called urea–albumin (control). Albumin modified with *o*-nitrophenylsulfenyl chloride (XIII·Cl) was prepared with a 22-fold molar excess of the reagent in 20% acetic acid (7) to yield XIII–albumin. With both reagents, the lone tryptophan residue of human serum albumin was modified completely (7).

For the preparation of tetranitromethane- (XIV) modified human serum albumin derivatives (XIV–albumin), a 4-, 15-, or 64-fold molar excess of tetranitromethane was added to human serum albumin dissolved in 0.05 *M* tromethamine buffer and adjusted to pH 8.0, resulting in the modification of 2.2, 5.1, or 7.8 tyrosine residues per albumin molecule, respectively. The modification was described in detail elsewhere (7).

The degree of tryptophan and tyrosine residue modification of the albumin derivatives was determined spectrophotometrically and by amino acid analysis (6, 7).

**Circular Dichroism Measurements**—Circular dichroism measurements were performed with a spectropolarimeter[3] calibrated with *d*-camphorsulfonic acid. All solutions were prepared in 67 m*M* phosphate buffer (pH 7.4). Results are expressed as molar ellipticities $[\theta]$ (degree square centimeter per decimole), calculated with reference to the albumin concentration, using a molecular weight of 69,000. The optical path length was 10 mm, and the albumin concentration was 30 or 13.1 $\mu M$. Difference spectra were obtained by subtracting the effect of the corresponding albumin derivative as the blank.

**Equilibrium Dialysis Experiments**—The binding of the $^{125}$I-labeled

# Optical Studies on Interaction of Biliary Contrast Agents with Native and Modified Human Serum Albumin

**K. J. FEHSKE and W. E. MÜLLER ˣ**

Received July 24, 1980, from the *Pharmakologisches Institut der Universität Mainz, D-6500 Mainz, West Germany.* Accepted for publication October 24, 1980.

**Abstract** □ The interaction of two homologous series of biliary contrast agents with native human and bovine serum albumin and with modified human serum albumin was investigated using circular dichroism and equilibrium dialysis. For most derivatives, extrinsic Cotton effects were observed for the interaction with both albumins. In some cases, these effects were strongly affected by only small changes in the chemical structure of the drugs. These large differences in extrinsic Cotton effects can be explained by definite effects of the chemical structures on the binding site selectivity of some drugs. For example, iopodate preferentially binds to the warfarin binding site of human serum albumin, while an ethyl group into the propionic acid side chain reduces the affinity for the warfarin site but strongly increases the affinity for the diazepam binding site of human serum albumin.

**Keyphrases** □ Biliary contrast agents—interaction with native and modified human serum albumin, optical studies on warfarin and diazepam binding sites of albumin □ Albumin, human serum—interaction of biliary contrast agents with native and modified albumin, optical studies of warfarin and diazepam binding sites □ Binding sites—warfarin and diazepam binding sites on human serum albumin molecule, interaction of biliary contrast agents with albumin □ Structure–activity relationships—interaction of biliary contrast agents with native and modified human serum albumin, optical studies of warfarin and diazepam binding sites

Contrast agents for the intravenous or oral visualization of the biliary tract are, in general, highly bound to albumin in the blood of humans and laboratory animals (1). Because of their strong binding to albumin, their low lipophilicity, and their low volumes of distribution, plasma protein binding of biliary contrast agents seems to be an important determinant of the pharmacokinetics of these drugs (2, 3). Furthermore, since the toxicity of the biliary contrast agents increases with increasing plasma protein binding, binding mechanisms leading to high albumin binding and high toxicity may have similarities (1, 4).

Therefore, detailed knowledge of the degree of albumin binding of the biliary contrast agents and of the binding mechanisms is of great interest. Thus, it must be determined which moieties of the contrast medium molecules are important for high binding and to which sites of the human serum albumin molecule the substances are bound. While some quantitative data on affinity constants and numbers of binding sites for two groups of homologous biliary contrast agents were published previously (5), this study describes qualitatively their interaction with human serum albumin, using optical methods and modified albumin derivatives.

## EXPERIMENTAL

**Materials**[1]—The human serum albumin[2] had an electrophoretic purity of 100%. All other chemicals were obtained from commercial suppliers.

**Preparation of Albumin Derivatives**—The modification of human serum albumin with 2-hydroxy-5-nitrobenzyl bromide (XII·Br) was reported in detail elsewhere (6). Human serum albumin was dissolved in 10 *M* urea adjusted to pH 4.4 by acetic acid, and a 1100-fold molar excess of XII·Br was added (XII–albumin). Another albumin sample was treated similarly but without the reagent and was called urea–albumin (control). Albumin modified with *o*-nitrophenylsulfenyl chloride (XIII·Cl) was prepared with a 22-fold molar excess of the reagent in 20% acetic acid (7) to yield XIII–albumin. With both reagents, the lone tryptophan residue of human serum albumin was modified completely (7).

For the preparation of tetranitromethane- (XIV) modified human serum albumin derivatives (XIV–albumin), a 4-, 15-, or 64-fold molar excess of tetranitromethane was added to human serum albumin dissolved in 0.05 *M* tromethamine buffer and adjusted to pH 8.0, resulting in the modification of 2.2, 5.1, or 7.8 tyrosine residues per albumin molecule, respectively. [a] Extrinsic Cotton effects are given as molar ellipticities ($[\theta]$), calculated with reference to the concentration of drug bound at the wavelength of the induced circular dichroism maximum ($\lambda_{max}$). All data are difference values, using the Cotton effects of human or bovine serum albumin at the same wavelength as the blank. Albumin concentrations of 30 $\mu M$ and drug concentrations of 60 $\mu M$ were used. [b] $\bar{x} \pm s_{\bar{x}}$ = mean ± *SEM*; $n = 6$.

biliary contrast agents, [$^{14}$C]warfarin, and [$^{14}$C]diazepam to the albumin derivatives was determined by equilibrium dialysis using an albumin concentration of 36 $\mu M$ and varying concentrations of the contrast agents. All solutions were prepared with 67 m$M$ phosphate buffer (pH 7.4). The albumin solution (0.9 ml) was dialyzed for 16 hr at 25° in the dark against the buffer (0.9 ml) containing the labeled drugs. Dialysis cells (1 ml) and cellophane dialysis membranes[4] were used. The radioactivity on both sides of the membrane was determined by liquid scintillation spectrometry.

## RESULTS

**Interaction with Native Human and Bovine Serum Albumin**—The binding of most of the intravenous and oral biliary contrast agents to native human and bovine serum albumin significantly changed the circular dichroism spectra of the proteins between 250 and 350 nm (Fig. 1). Maxima and shoulders of the induced circular dichroism spectra correlated sufficiently with maxima and shoulders of the UV absorbance spectra of the ligands. Thus, the induced Cotton effects undoubtedly were extrinsic in origin and originated by binding-induced optical perturbations of electronic transitions of the contrast agent molecules.

The extrinsic Cotton effects of iodipamide (an example of the intravenous contrast agents) consisted of at least three Gaussian components (8), with a small positive band at ~310 nm, a larger negative one at 270 nm, and a shoulder at ~285 nm (Fig. 1). Increasing the length of the aliphatic bridge between both triiodobenzoic acid nuclei of the intravenous contrast agents significantly altered the induced Cotton effects (Table I). The weak band at 310 nm disappeared completely, while the strong band at ~270 nm was present in all intravenous contrast agents investigated, although great differences in the intensity and sign of this band were observed (Table I).

The intensity of the extrinsic Cotton effects depended on the concentration of the ligands, as shown for I (iodipamide) in Fig. 2, where the three extrinsic circular dichroism bands of I increased differently with increasing concentrations. The positive band at 310 nm seemed to be associated mainly with binding to the single high-affinity binding site (5) since this band increased only to about one molecule bound per molecule of human serum albumin (Fig. 2). The band at 270 nm also was generated at secondary binding sites. The induced Cotton effects at 285 nm seemed to be higher at the secondary sites than at the high-affinity binding site, as might be concluded from the shape of the curve in Fig. 2.

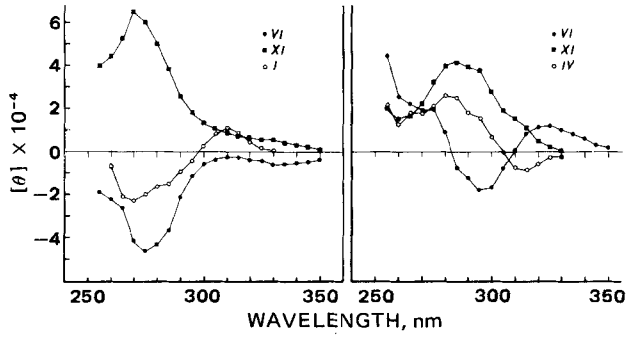

**Figure 1**—*Extrinsic Cotton effects of some biliary contrast agents (60 μM) in the presence of human (left) or bovine (right) serum albumin. The albumin concentration was 30 μM. The data are difference values, using the Cotton effects of the albumins at each wavelength as a blank. Each point represents the mean of three determinations.*

While I and II are bound to human serum albumin more strongly than III–V, I and II are bound less strongly to bovine serum albumin than the other three derivatives (5). Accordingly, only for the interaction of III–V with bovine serum albumin were induced Cotton effects found (Fig. 1 and Table I). The positions of the circular dichroism band were in agreement with those found in the interaction with human serum albumin (Table I).

As with the intravenous agents, the binding of the oral biliary contrast agents to human serum albumin induced extrinsic Cotton effects with a strong band at ~270 nm and a weak band above 300 nm (Fig. 1 and Table II). The band intensity at 270 nm differed little for the six compounds, but the sign of this band was highly dependent on the substitu-

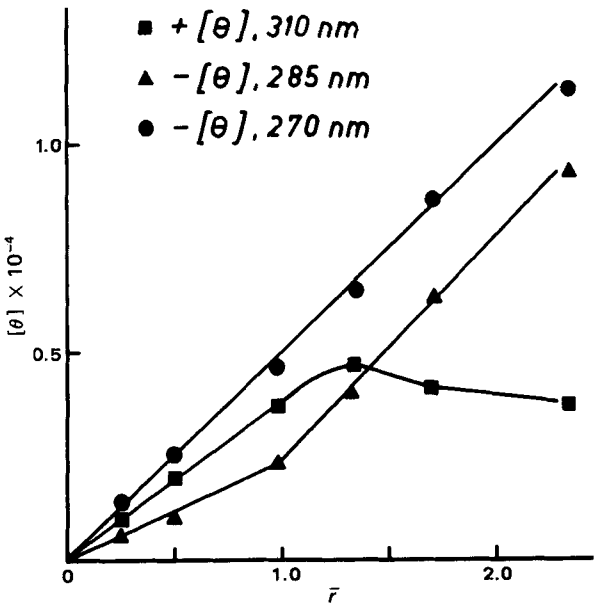

**Figure 2**—*Correlation between the concentration of I bound to human serum albumin (30 μM) and the intensity of the induced Cotton effects at three different maxima (given as molar ellipticity, [θ], calculated with reference to the albumin concentration). The concentration bound is given as r̄ (moles of I bound per mole of albumin). Each point represents the mean of six determinations.*

[a] Extrinsic Cotton effects are given as molar ellipticities ($[\theta]$), calculated with reference to the concentration of drug bound at the wavelength of the induced circular dichroism maximum ($\lambda_{max}$) or shoulder (*). All data are difference values, using the Cotton effects of human or bovine serum albumin at the same wavelength as the blank. Albumin concentrations of 30 $\mu M$ and drug concentrations of 60 $\mu M$ were used. [b] $\bar{x} \pm s_{\bar{x}}$; $n = 6$.

ents of the triiodobenzene moiety (Table II). While this band was positive for VII and XI, the introduction of an ethyl group in the propionic acid side chain of XI made this band negative (VI in Table II). This dramatic effect was not found for the binding to bovine serum albumin since the band at 270 nm, if present, was positive for all compounds.

As found for the intravenous contrast agent I, the intensity of the extrinsic Cotton effects of the oral contrast agents depended on the ligand concentration. The induced optical activity of XI (iopodate) bound to human serum albumin increased only until the first molecule of XI was bound per albumin molecule but decreased at higher concentrations (Fig. 3). Again, the introduction of an ethyl group in XI was followed by a binding change to optically active binding sites, as shown by the increase of both bands of VI with increasing numbers of molecules bound per molecule of human serum albumin (Fig. 3).

**Optical Studies with Tryptophan- and Tyrosine-Modified Human Serum Albumin**—Previous studies labeled the specific warfarin binding site of human serum albumin by modification of the lone tryptophan residue with XII-Br or XIII-Cl (8). The highly reactive tyrosine residue is part of the indole and benzodiazepine binding site, which can be modified selectively with XIV (7). Accordingly, XII–albumin and XIV–albumin were used to investigate the significance of the warfarin and the diazepam binding sites for the interaction of the biliary contrast agents with human serum albumin. Since the tryptophan modification by XII-Br includes an unfolding of the protein in acidic urea solution, urea–albumin was used to measure the effect of the acidic unfolding on the binding of the compounds to human serum albumin.

The unfolding procedure only slightly changed the extrinsic Cotton effects of I, VI, and XI and those of iophenoxic acid and iopanoic acid, two oral biliary contrast agents that are structurally related to VI and XI (Table III). However, the tryptophan modification reduced the extrinsic Cotton effects of I and iophenoxic acid at both concentrations investigated by ~40–50%. The most striking observation was made for VI where the large negative band at 270 nm disappeared after the tryptophan modification and a small positive band appeared at ~260 nm (Fig. 4 and Table III). On the other hand, the extrinsic Cotton effects of XI and of iopanoic acid were not reduced by the tryptophan modification.

The modification of about two out of the 18 tyrosine residues of human serum albumin (XIV–albumin) had no influence on the extrinsic Cotton effects of I at 310 nm, while those at 270 nm were reduced to ~50% (Table IV). Furthermore, the extrinsic Cotton effects of iophenoxic acid were influenced only slightly by the modification of two tyrosine residues, but

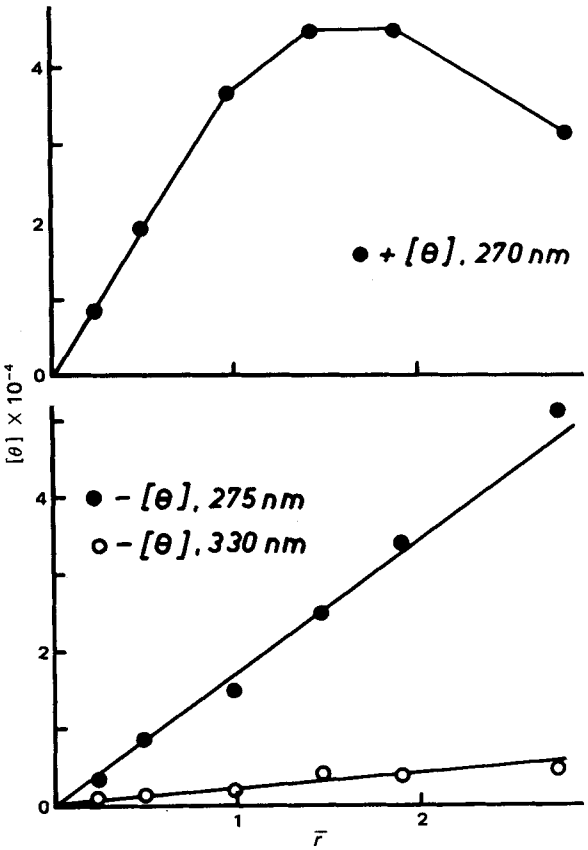

**Figure 3**—*Correlation between the concentration of XI (upper) and VI (lower) bound to human serum albumin (30 μM) and the intensity of the induced Cotton effects at different maxima (given as molar ellipticity, [θ], calculated with reference to the albumin concentration). The concentration bound is given as r̄ (moles of drug bound per mole of albumin). Each point represents the mean of six determinations.*

[a] The binding of the two contrast agents to the human serum albumin derivatives (36 μM) was investigated by equilibrium dialysis. Curved Scatchard plots were resolved to obtain $n$ (number of binding sites) and $K$ (association constant) by a graphical method according to Pennock (9). For each individual Scatchard plot, 30–40 experiments at eight to 10 different concentrations of the drugs were performed.

those of iopanoic acid were strongly reduced at both ligand concentrations. However, the modification of only two tyrosine residues (XIV-albumin) had an interesting effect on the extrinsic Cotton effects of the structurally related compounds, VI and XI. While the negative Cotton effects of VI were increased by nearly 100% at both ligand concentrations (Fig. 4 and Table III), the positive band of XI disappeared at a molar drug to albumin ratio of one and became negative at higher drug to albumin ratios (Fig. 5 and Table III). Increasing the degree of tyrosine modification to 5.1 was followed by a reduction of the Cotton effects of VI and XI, and the Cotton effects of both contrast agents became positive again when 7.8 tyrosine residues were modified per molecule of albumin (Figs. 4 and 5).

**Equilibrium Dialysis Studies on Binding of I and XI to Native and Modified Human Serum Albumin**—As calculated from the curved Scatchard plot (Fig. 6) by the method of Pennock (9), I binds to native human serum albumin *via* one high-affinity and two low-affinity binding sites (Table IV). While the unfolding in acidic urea (urea-albumin) was nearly without effect on the binding of I, the modification of the lone tryptophan residue with XII-Cl as well as with XIII-Br strongly reduced the association constant of the high-affinity binding site for I (Fig. 6 and Table IV). The secondary binding sites remained nearly unaffected by the tryptophan modifications. The modification of about two tyrosine residues with XIV, on the other hand, had a significantly smaller effect on the high-affinity binding site of I than did the modification of the tryptophan residue. In all three modified albumin derivatives, the number of high-affinity binding sites was reduced from ~1.0 to ~0.7–0.82, possibly not an effect of the modification of a specific amino acid residue.

In contrast to I, neither tryptophan modification affected the high-affinity binding site of XI. The slightly reduced affinity found for XII-albumin also was found for urea-albumin and, therefore, may be an effect of unfolding during modification. Also in contrast to I, the tyrosine modification reduced the affinity of the high-affinity binding site up to ~25% of the value found for native albumin. Neither tryptophan nor the tyrosine modifications significantly changed the number of high-affinity

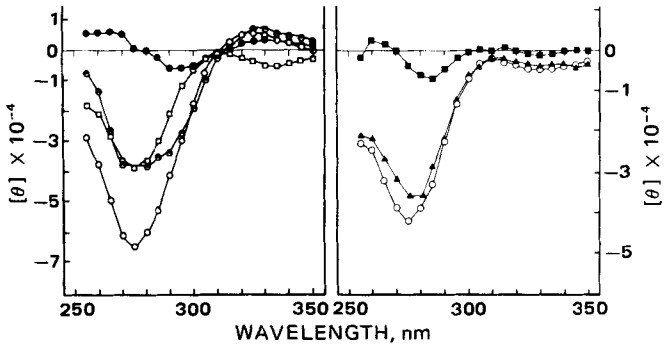

**Figure 4**—*Induced circular dichroism spectra of VI bound to human serum albumin and modified albumin derivatives (all were 13.1 μM). Intensity is given as molar ellipticity, [θ], calculated with respect to the albumin concentration. Compound VI was used at a molar drug to albumin ratio of 3. Data are difference values, using the Cotton effects of the albumin alone as a blank. Each point is the mean of three determinations. Key (left): □, native human serum albumin; ○, XIV-albumin (degree of modification 2.2); ◒, XIV-albumin (5.1); and ●, XIV-albumin (7.8). Key (right): ○, albumin; ▲, urea-albumin; and ■, XII-albumin.*

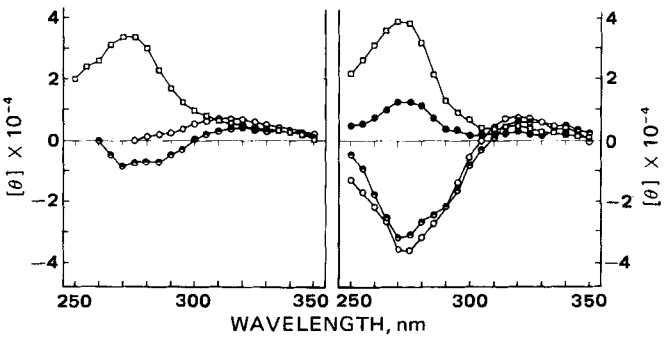

**Figure 5**—*Induced circular dichroism spectra of XI bound to human serum albumin and modified albumin derivatives (all were 13.1 μM). Intensity is given as molar ellipticity, [θ], calculated with respect to the albumin concentration. Compound XI was used at molar drug to albumin ratios of 1 (left) and 3 (right). Data are difference values, using the Cotton effects of the albumins alone as a blank. Each point is the mean of three determinations. Key: □, native human serum albumin; ○, XIV-albumin (degree of modification 2.2); ◒, XIV-albumin (5.1); and ●, XIV-albumin (7.8).*

Table V—Inhibition (Percent Displacement, $\bar{x} \pm s_{\bar{x}}$, $n = 3$) of Diazepam and Warfarin Binding to Human Serum Albumin by Biliary Contrast Agents [a]

| Displacer | Diazepam | | Warfarin | |
|---|---|---|---|---|
| | D/P 1.5 | D/P 4.5 | D/P 1.5 | D/P 4.5 |
| Iopanoic acid | 32.2 ± 1.0 | 38.2 ± 0.7 | 10.3 ± 0.6 | 46.6 ± 1.6 |
| Iophenoxic acid | 6.1 ± 0.9 | 26.9 ± 1.0 | 37.8 ± 0.6 | 78.7 ± 1.1 |
| I (iodipamide) | 1.8 ± 0.9 | 3.4 ± 1.0 | 23.1 ± 0.8 | 43.4 ± 1.5 |
| VI | 16.0 ± 1.0 | 36.2 ± 1.1 | 8.0 ± 1.4 | 29.0 ± 1.7 |
| XI (iopodate) | 7.1 ± 0.4 | 14.0 ± 0.2 | 7.0 ± 1.4 | 23.2 ± 1.0 |

[a] The inhibition of the binding of diazepam (40 $\mu M$) and of warfarin (72 $\mu M$) to human serum albumin was investigated by equilibrium dialysis, using the displacing drugs at two different molar drug to albumin concentration ratios (D/P). The data are given as percent displacement of the fraction bound under control conditions (diazepam = 84.9%; warfarin = 79.7%).

binding sites nor the properties of the secondary binding sites of XI (Table IV).

**Effect of Biliary Contrast Agents on Binding of Diazepam and Warfarin to Native Human Serum Albumin**—Only a few specific binding sites exist on the human serum albumin molecule, which mediate the high-affinity binding of most strongly albumin-bound drugs (10). Two of the most important are the warfarin and diazepam binding sites (10). To determine to which site the contrast agents are bound, displacement of the two specific ligands, warfarin and diazepam, was studied by equilibrium dialysis (Table V).

At low concentrations (drug to protein ratio of ~1), iopanoic acid preferentially bound to the diazepam site and iophenoxic acid bound to the warfarin site. At higher concentrations, both drugs seemed to bind to both binding sites.

By contrast, even at higher concentrations, I did not interfere with the diazepam binding site, as was demonstrated by its failure to displace diazepam. The high potency in displacing warfarin, however, suggests that the high-affinity binding site of I might be identical with the warfarin binding site.

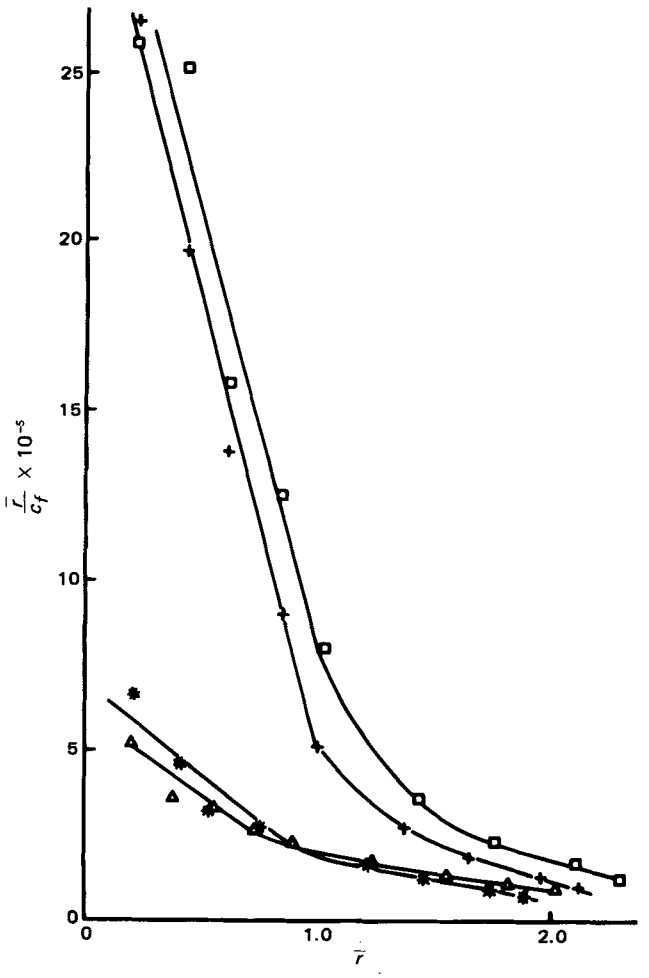

**Figure 6**—*Scatchard plot of the binding of I to human serum albumin and modified albumin derivatives. The albumin concentration was 36 μM. Each point is the mean of three or four determinations. Key: □, albumin; △, XIII-albumin; +, urea-albumin; and *, XII-albumin.*

Compounds VI and XI, which differ largely regarding their extrinsic Cotton effects in the presence of the modified albumin derivatives, seemed to bind to both sites. However, VI preferentially interacted with the diazepam site while XI had a higher affinity for the warfarin site, as suggested by their potencies in inhibiting the binding of diazepam and warfarin, respectively (Table V).

## DISCUSSION

The binding of optically inactive small organic molecules to optically active macromolecules can induce optical activity into the ligand molecule so that, within the range of the UV or visible absorption spectra of the ligands, induced Cotton effects can be observed (11, 12). Such induced circular dichroism spectra have proved to be extremely useful in gaining insight into the molecular mechanism of the interactions of drugs with serum albumins (7, 8, 11–13).

The induced circular dichroism spectra of the investigated intravenous biliary contrast agents, as far as induced optical activity was observed, had one component in common: an induced band around 270 nm whose sign and intensity varied for the compounds. This band might be due to optical perturbations of electronic transitions in the triiodobenzoic acid moieties of the compounds, the only common structure of the investigated intravenous biliary contrast agents. However, the structural parameters leading to high induced optical activity of the intravenous contrast agents are not obvious since neither the degree of albumin binding (5) nor the length or lipophilicity of the aliphatic bridge between both triiodobenzoic acid moieties seemed to be the major determinant for high induced optical activity.

In general, considering their extremely high binding to human serum albumin, the intravenous biliary contrast agents gave only weak extrinsic Cotton effects when bound to human serum albumin. This result and the failure to find any clear correlation between intensity of the extrinsic Cotton effects and their chemical structure may indicate that the complex between these compounds and human serum albumin lacks the structural specificity found for other drugs when bound to albumin (14–17).

As was found for the intravenous biliary contrast agents, all oral biliary contrast agents had a common induced circular dichroism band around 270 nm when bound to human or bovine serum albumin, possibly due to the triiodobenzene moiety of the drugs. With human serum albumin, the band intensity varied little for the oral compounds, suggesting a similar spatial relationship of their complexes with human serum albumin. For the binding of VI and XI to human serum albumin, their Cotton effects at 270 nm had opposite signs, even though the only difference in their chemical structure was the introduction of an ethyl group in position 2 of the propionic side chain (VI). This observation supports earlier findings on iophenoxic acid, indicating that the optical properties of the complexes of the oral biliary contrast agents are extremely sensitive to even small changes of the ligand chemical structure (18).

As already mentioned, the positive Cotton effects of XI seemed to be associated mainly with its high-affinity binding site, while the negative Cotton effects were induced at all binding sites of XI. Accordingly, only negative Cotton effects were observed after tyrosine modification, presumably induced at the secondary binding sites.

Previously it was shown that the lone tryptophan residue of human serum albumin is part of the warfarin binding site and can be selectively modified by XII-Br and XIII-Cl (8), while a highly reactive tyrosine residue, which can be nitrated selectively by low concentrations of XIV, is part of the indole and benzodiazepine binding site (7). Thus, the interaction of drugs with both specific binding sites of human serum albumin can be studied indirectly by displacement of the marker ligands, diazepam and warfarin, and directly by the binding of the drugs to the

modified albumin derivatives.

The results obtained with I give some evidence that the single high-affinity binding site of the intravenous biliary contrast agents (5) might be identical with the warfarin binding site of human serum albumin. This conclusion can be made from the strong displacement of bound warfarin, the large reduction of the extrinsic Cotton effects of I bound to XII–albumin at 310 nm that are associated only with binding to the high-affinity binding site, and the large reduction of the association constant of the high-affinity binding site for XII–albumin or XIII–albumin. By contrast, binding of I to the diazepam binding site may be negligible, as shown by the lack of any displacement of human serum albumin-bound diazepam and by the small effects of the tyrosine modification on the binding parameters of I.

With the oral biliary contrast agents, the specificity for one of the two sites of human serum albumin is not so pronounced. However, as revealed by their displacing potencies for diazepam and warfarin and their binding behavior for tyrosine- and tryptophan-modified albumin, VI is bound preferentially to the warfarin binding site but XI is bound to the diazepam binding site. This observation is interesting considering the small difference in the chemical structures of these contrast agents. A similar observation was made for the structurally related oral biliary contrast agents, iopanoic and iophenoxic acids, which differ only by the substitution of a phenolic hydroxyl group in iophenoxic acid and by an amino group in iopanoic acid (18). The data support earlier observations that the high-affinity binding sites of both drugs are different (18, 19); it seems that iophenoxic acid is bound preferentially to the warfarin site while iopanoic acid is bound preferentially to the diazepam binding site.

The latter results indicate that it will be difficult to find common characteristics for drugs bound specifically to the warfarin binding site and for drugs bound specifically to the indole and benzodiazepine binding site since only small changes in the chemical structure of the ligands can have pronounced effects on the binding site selectivity of the drugs.

In summary, the data clearly showed that the serum albumin binding of biliary contrast agents is quite unusual in respect to the structural parameters leading to strong binding to human and bovine serum albumin. Furthermore, small variations of the chemical structure of the contrast agents can effect large changes in the binding site selectivity. The diazepam and the warfarin binding sites of human serum albumin (two important drug binding sites of the protein) are involved in the binding of the biliary contrast agents. Since many other drugs also are bound to these sites, the biliary contrast agents must be considered as potent displacers of many drugs *in vivo*, especially with regard to their high plasma concentration *in vivo* (20, 21). However, the short plasma half-life of the intravenous biliary contrast agents or the short use of the oral biliary contrast agents makes it unlikely that such displacements are clinically important. However, evidence is accumulating that the plasma protein binding of the biliary contrast agents is extremely important for their distribution, hepatic uptake, and biliary and renal elimination (20–23). Therefore, exact knowledge about the mechanisms involved in the plasma protein binding of these drugs could be helpful for understanding the pharmacokinetics of the biliary contrast agents.

# Interaction of Xanthan Gum with Suspended Solids

**JOSEPH S. TEMPIO * and JOEL L. ZATZ ˣ**

Received August 18, 1980, from the *College of Pharmacy, Rutgers—the State University of New Jersey, Piscataway, NJ 08854.* Accepted for publication October 24, 1980.

*Present address: Smith Kline and French Laboratories, Philadelphia, PA 19101.

**Abstract** □ Xanthan gum was adsorbed significantly by magnesium carbonate, aluminum hydroxide, zinc oxide, and calcium carbonate, giving Langmuir-type isotherms. Saturation adsorption was higher from 0.9% NaCl than from water due to reduced mutual repulsion of polymer segments in the presence of the salt. Adsorption resulted from electrostatic attraction between positively charged particles and the negatively charged polymer. $\zeta$-Potential measurements correlated with the adsorption data but were not predictive of the flocculation state. The results indicate that flocculation of magnesium carbonate and aluminum hydroxide by xanthan gum is consistent with a bridging mechanism.

**Keyphrases** □ Xanthan gum—interaction with magnesium carbonate, aluminum hydroxide, zinc oxide, and calcium carbonate □ Adsorption—xanthan gum by suspended solids □ Flocculation—bridging mechanism, magnesium carbonate and aluminum hydroxide with xanthan gum

Xanthan gum produces flocculation of pharmaceutical suspensions (1, 2). Studies utilizing sedimentation volume, microscopy, and particle-size measurement showed that changes in interparticulate structure could be induced by the polymer (2). Flocculation was attributed to the joining of several particles by adsorbed polymer molecules, which

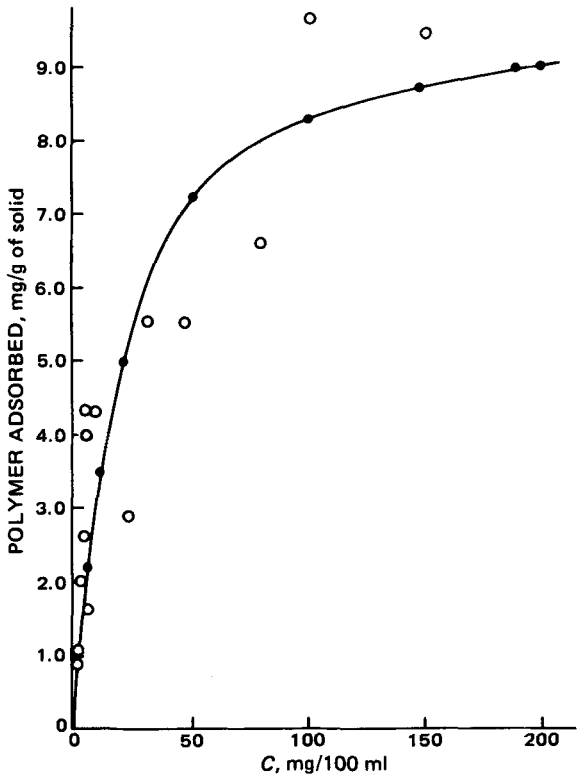

**Figure 2**—*Adsorption isotherm of xanthan gum from 0.9% NaCl onto magnesium carbonate. Key: ●, theoretical values calculated with Eq. 2; and ○, experimental values.*

are incorporated into the network of aggregated particles (1). Polymer adsorption is an essential feature of this flocculation mechanism. Microelectrophoretic measurements demonstrated that polymeric flocculants were adsorbed by suspended colloidal particles (3). In the presence of excess flocculant, the $\zeta$-potential of several materials was controlled by the surface properties of the flocculant and was independent of the nature of the material. Electrostatic attraction often is involved in adsorption (4), but both adsorption and flocculation can occur if the polymer and particle surface carry the same charge, provided that the $\zeta$-potential of the particle is not too high (5). In some systems, a given polymer functions as both flocculant and deflocculant, depending on its concentration at the particle surface (6).

This study investigated the adsorption of xanthan gum by the solids whose suspension properties were reported previously (2). Adsorption is a prerequisite for flocculation by bridging, and these data are required to decide whether bridging is the mechanism of flocculation by xanthan gum, as was suggested (1).

## EXPERIMENTAL

**Materials**—Xanthan gum, dried aluminum hydroxide gel, magnesium carbonate, calcium carbonate, and zinc oxide were the same materials used in a previous study (2). Silica[1] was 80–100 mesh. Water was distilled. All other materials were USP or reagent grade.

**Preparation of Suspensions**—The procedure used was described previously (2).

**Polymer Analysis**—Polymer samples were analyzed for the concentration of xanthan gum by the Seliwanoff reaction. This method is valid for systems where xanthan gum is the only carbohydrate present.

A 1-ml sample of polymer solution (containing 5–250 ppm of xanthan gum) was pipetted into a 10-ml screw-capped culture tube. Then 1 ml of a 4% resorcinol solution in distilled water (prepared fresh daily) was added, followed by 6 ml of concentrated sulfuric acid. The acid was added rapidly, and the tube was mixed with a vortex mixer. Heat and gas were evolved in most cases. The tubes then were placed in an ice water bath for ~5 min until cooled to near room temperature and then were allowed to stand at room temperature for 10–25 min. The concentrations were determined spectrophotometrically at 494 nm within ~1 hr of preparation (7, 8). The absorbance of the samples was read in 1-cm silica cells on a spectrophotometer[2].

Reagent and polymer blanks were run with each analysis. The Beer's law plot in water and 0.9% NaCl was linear throughout the concentration range of interest ($y = 50.8x - 0.10$ and $y = 45.9x + 0.0085$, respectively, for concentrations of 0.005–0.03%).

**Adsorption Determinations**—The amount of polymer adsorbed was determined indirectly from the difference between the initial polymer concentration and the amount found at equilibrium upon analysis of the supernate after drug addition. Kinetic studies indicated that 3–7 days was required for equilibrium.

Flasks containing the suspensions were placed in a shaker bath[3] at 25 ± 1°. Agitation was at a level sufficient to maintain the bulk of the powders in suspension in all samples. After 7 days, the samples were removed from the shakers, and 1-ml aliquots were withdrawn and diluted, if necessary, for analysis.

When the supernate was not clear, it was decanted from the settled fraction and centrifuged[4] at 2000 rpm for 20 min.

**$\zeta$-Potential**—The $\zeta$-potential of the suspensions was measured by electrophoresis[5]. All samples were diluted with distilled water prior to the measurement of the electrophoretic mobility. $\zeta$-Potentials were calculated by the Helmholtz–Smoluchowski formula (9):

$$\zeta = \frac{\nu_e 4\pi\eta}{\epsilon} \qquad \text{(Eq. 1)}$$

where $\nu_e$ is the electrophoretic mobility of the particle, $\eta$ is the viscosity, and $\epsilon$ is the dielectric constant of the suspending medium.

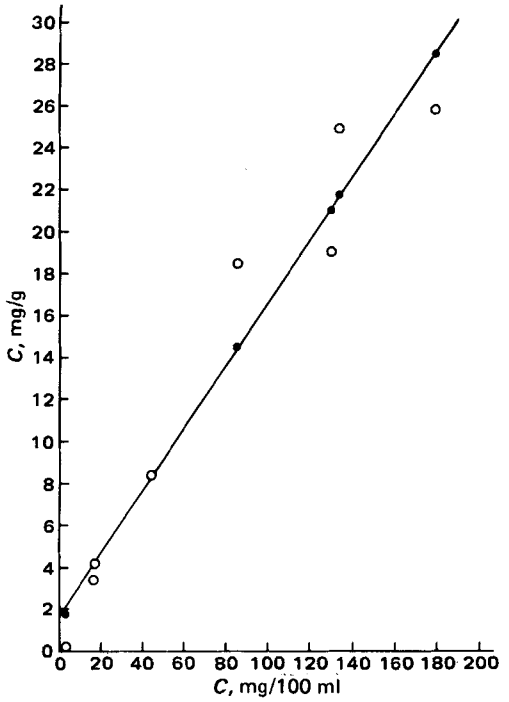

**Figure 3**—*Linearized Langmuir plot of xanthan gum from water onto magnesium carbonate. Key:* ●, *theoretical values calculated with Eq. 3; and* ○, *experimental values.*

**Surface Tension**—Surface tensions of the xanthan solutions were determined using the Wilhelmy plate method. A roughened platinum plate was employed, and double-distilled water was used as a standard.

## RESULTS AND DISCUSSION

**Surface Tensions**—At concentrations up to 0.3%, xanthan gum lowered the surface tension of water or 0.9% NaCl by no more than 3 dynes/cm. Thus, this polymer exhibited little surface activity in aqueous solution.

**Adsorption Isotherms**—Isotherms for xanthan gum adsorption by magnesium carbonate from solution in water and 0.9% NaCl are plotted in Figs. 1 and 2, respectively. The isotherms appear to be the Langmuir type, represented by:

$$Y = Y_m bC/(1 + bC) \qquad \text{(Eq. 2)}$$

where $Y$ is amount adsorbed (in milligrams per gram), $Y_m$ is the amount adsorbed at saturation of the solid surface, $C$ is the equilibrium polymer concentration, and $b$ is a constant. Taking the reciprocal and multiplying through by $C$ yield:

$$C/Y = 1/Y_m b + C/Y_m \qquad \text{(Eq. 3)}$$

This equation is recognizable as the equation of a line with a slope of $1/Y_m$ and intercept $1/Y_m b$.

The adsorption data are plotted according to Eq. 3 in Figs. 3 and 4. The curves are linear; correlation coefficients were significant at the 95% confidence level.

Figures 1–4 were typical of all isotherms. Equation 3 was used to determine the parameters of the isotherms (Tables I and II). For each solid, the saturation adsorption, $Y_m$, from the salt solution (Table II) was greater than that from water (Table I). The amount of polymer that can be accommodated at a saturated surface depends on the available surface area and the area required for each polymer unit. When polymer segments are charged, as xanthan gum is, mutual repulsion prevents close approach of the segments to each other. Polymer–polymer repulsion is reduced in the presence of 0.9% NaCl, permitting closer packing of the polymer segments at the solid–liquid interface, thereby reducing the average area occupied by each polymer unit and raising the $Y_m$ value.

Adsorption alone is insufficient to define a flocculation mechanism. The essential question is whether adsorption is extensive enough in the suspensions to make bridging possible. The adsorption isotherms represent a plot of adsorption *versus* the equilibrium polymer concentrations. The total amount of polymer in the system is the sum of the amount adsorbed and the amount remaining in solution:

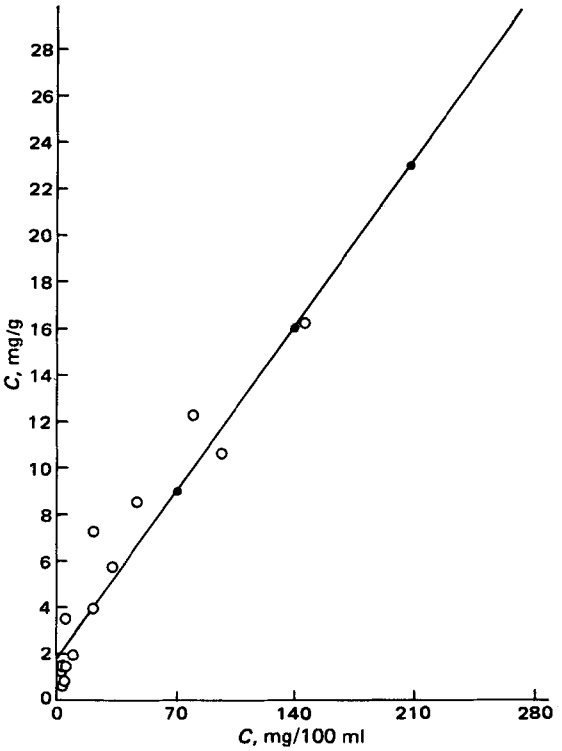

**Figure 4**—*Linearized Langmuir plot of xanthan gum from 0.9% NaCl onto magnesium carbonate. Key:* ●, *theoretical values calculated with Eq. 3; and* ○, *experimental values.*

$$\text{total polymer} = YA + VC \qquad \text{(Eq. 4)}$$

where $A$ is the amount of adsorbent present (in grams) and $V$ is the volume of liquid in contact with the adsorbent. Half-coverage at the solid–liquid interface (*i.e.*, $Y = \frac{1}{2}Y_m$) is taken to represent sufficiently extensive adsorption for bridging (10).

Previous studies on suspensions containing the same solid drugs contained 5 g of solid (except for the calcium carbonate suspension, which used 10 g of solid) and 30–200 mg of xanthan gum in 100 ml of suspension medium (2). The adsorption isotherms and Eq. 4 were used to calculate the amount of xanthan gum at half-coverage in those systems (Table III). The amount required was 23–81 mg, and these values fell within the range of xanthan gum amounts that were actually utilized. Thus, it may be concluded that adsorption is extensive enough to allow flocculation by polymer bridging.

**Table I—Adsorption of Xanthan Gum from Water at 25°**

| Substance | $Y_m$, mg/g | Intercept of Linearized Plot, g/100 ml[a] | $r$ |
|---|---|---|---|
| Magnesium carbonate | 6.67 | 1.6 | 0.972 |
| Aluminum hydroxide | 16.6 | 1.1 | 0.944 |
| Calcium carbonate | 3.59 | 4.8 | 0.961 |
| Zinc oxide | 4.55 | 2.7 | 0.964 |

[a] According to Eq. 3.

**Table II—Adsorption of Xanthan Gum from 0.9% NaCl Solution at 25°**

| Substance | $Y_m$, mg/g | Intercept of Linearized Plot, g/100 ml[a] | $r$ |
|---|---|---|---|
| Magnesium carbonate | 9.83 | 1.8 | 0.949 |
| Aluminum hydroxide | 22.6 | 1.1 | 0.972 |
| Calcium carbonate | 11.1 | 2.3 | 0.947 |
| Zinc oxide | 7.30 | 2.9 | 0.949 |

[a] According to Eq. 3.

**Table III—Total Amount of Xanthan Gum in Pharmaceutical Suspension at Half-Coverage**

| Substance | Total Xanthan Gum, mg | |
|---|---|---|
| | Water | 0.9% NaCl |
| Magnesium carbonate[a] | 27 | 43 |
| Aluminum hydroxide[a] | 60 | 81 |
| Calcium carbonate[b] | 35 | 81 |
| Zinc oxide[a] | 23 | 39 |

[a] Using 5 g + 100 ml of suspension medium. [b] Using 10 g + 100 ml of suspension medium.

**Desorption**—Several samples that had reached adsorption equilibrium were centrifuged to separate solid material from the liquid phase. Fifty milliliters of the liquid medium was replaced with medium containing no xanthan gum and then agitated for 7 days in the shaker bath. When the samples were reanalyzed, the xanthan gum concentration in solution did not exceed half its value prior to dilution. This finding indicated that the adsorbed polymer molecules were not desorbed upon dilution.

**ζ-Potential and Surface Charge**—The zero point of charge is the condition when the charge at a solid interface is zero. For solids dispersed in water, pH values may be used as an indication of the surface charge, provided that hydrogen or hydroxyl ions are potential-determining ions. This appears to be the case for oxides, hydroxides, and carbonates in aqueous systems (11–14).

A slightly soluble hydroxide like aluminum hydroxide has a positive surface charge below the pH of the zero point of charge due to the dissociation of amphoteric surface hydroxide groups and the adsorption from solution of metal–hydroxo complexes (11). The surface potential of calcium carbonate is due to the hydrolysis or adsorption of surface ions or complexes. The hydroxide ion is dominant (13). At pH below the point of zero charge, the surface potential of zinc oxide is expected to be dominated by the $Zn^{2+}$ ion and adsorption of $H^+$ and metal–hydroxo complexes (14).

The pH values for a suspension supernate were compared with reported values of the zero point of charge for the various solids (Table IV). The ζ-potential values are believed to be a more reliable indication of the surface condition. The zero point of charge for a particular sample of substance depends markedly on the history of the sample, and literature zero point of charge values for different samples of the same material vary widely (17).

Classical theory dictates that high absolute values of ζ-potential are associated with deflocculated systems. The potential energy–distance curves for such systems show a primary minimum at short distances, due to van der Waals attractive forces, and a relatively steep threshold, due to charge–charge repulsion. However, only one system studied, calcium carbonate, was deflocculated in water. Parodoxically, calcium carbonate had the lowest ζ-potential.

The measurement of ζ-potential of concentrated suspensions containing polymers by electrophoresis is complicated because dilution is required. Dilution of systems containing adsorbed materials can result in desorption, with consequent alterations in the measured potential. Since xanthan gum did not undergo desorption upon dilution, this measurement was feasible.

The addition of xanthan gum to the suspended solids caused a reduction in ζ-potential and a reversal in sign to negative values (Fig. 5). The curves resemble the adsorption isotherms in that the potentials approach limiting values. The ζ-potential curves confirm polymer adsorption and indicate that the potential is determined largely by the layer of adsorbed polymer, which is negatively charged.

In the presence of xanthan gum, aluminum hydroxide and magnesium carbonate are flocculated (2). The fact that the ζ-potential is not negligible for these systems again illustrates its limited utility in predicting flocculation behavior. ζ-Potential measurements are of value, but they must be combined with other techniques to obtain a complete view of a disperse system.

**Table IV—pH of Supernate of Suspended Solids**

| Substance | Supernatant pH | Zero Point of Charge | Reference |
|---|---|---|---|
| Magnesium carbonate | 9.2 | 8.5 | 11 |
| Aluminum hydroxide | 6.3 | 8.5 | 12 |
| Calcium carbonate | 11.1 | 10.8 | 15 |
| Zinc oxide | 7.2 | 9.0 | 16 |

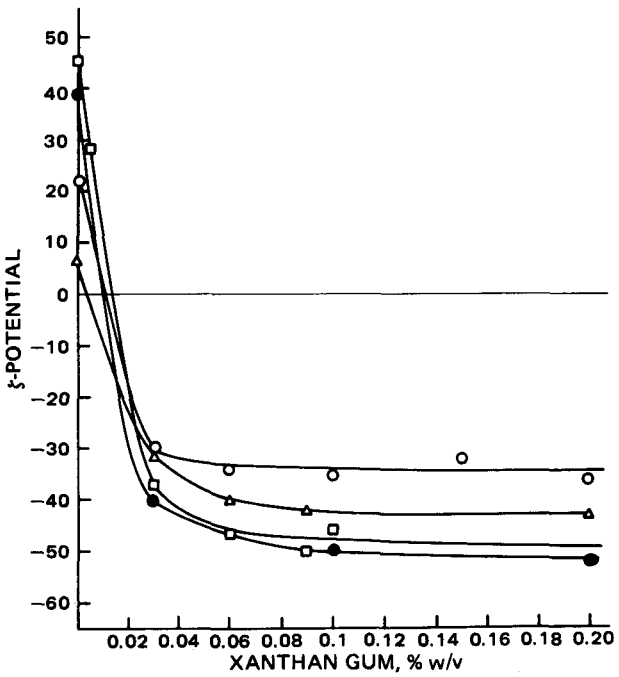

**Figure 5**—*ζ-Potential of solid drugs as a function of xanthan gum concentration. Key:* □, *aluminum hydroxide;* ●, *zinc oxide;* ○, *magnesium carbonate; and* △, *calcium carbonate.*

The adsorption mechanism of xanthan gum by the solids investigated is most likely electrostatic. The positively charged surfaces are expected to attract strongly the oppositely charged polymer molecules. Since xanthan gum has little surface activity, an adsorption mechanism based on hydrophobic interaction with the surface is not likely.

Experiments with silica provide an interesting comparison. The ζ-potential of silica in water was 55 mv. Suspensions containing 5 g of silica in 100 ml of water were deflocculated, with a sedimentation volume of 0.05. There was no change in sedimentation volume upon addition of xanthan gum. Adsorption studies revealed that xanthan gum was not adsorbed to any significant extent. In this case, the negative potential on the particles prevented polymer adsorption and precluded flocculation by bridging.

**Conclusion**—The results provide evidence for bridging as a flocculation mechanism of xanthan gum. Significant adsorption occurred on solids that underwent a change in flocculation state because of the gum. ζ-Potential measurements confirmed polymer adsorption. Previously, it was shown that salt effects on the flocculation of aluminum hydroxide, magnesium carbonate, zinc oxide, and calcium carbonate were minimal and that double-layer repulsion alteration by the electrolyte was not important in the flocculation–deflocculation behavior of these suspensions (2). The lack of correlation between the ζ-potential and the flocculation state is another indication that double-layer effects do not play a major role in controlling flocculation of these materials by xanthan gum.

# Synthesis and Structure–Activity Relationships of Selected Tricyclic Oxime *O*-Ethers as Potential Anticholinergic Agents

**VILAS A. PRABHU *, ROBERT G. BROWN, and JAIME N. DELGADO ˣ**

Received September 29, 1980, from the *College of Pharmacy, University of Texas at Austin, Austin, TX 78712.* Accepted for publication November 3, 1980. *Present address: College of Pharmacy, Southwestern Oklahoma State University, Weatherford, OK 73096.

**Abstract** □ Selected isomeric and nonisomeric oxime *O*-ether derivatives of thioxanthone oxime were synthesized and evaluated for anticholinergic activity. The oxime *O*-ethers were prepared *via O*-alkylation of the oximate anion with appropriate aminoaklyl halides. Separation and isolation of the structural isomers were accomplished through dry-column chromatography. The racemic α-methyl isomer was resolved *via* formation of tartrate diastereomers, which were subsequently isolated. All synthesized compounds exhibited significant antimuscarinic activity. A comparison of the antimuscarinic activities of these compounds revealed that the racemic α-methyl isomer was the most potent and that the racemic β-methyl isomer was the least potent. Structure–activity relationships among the oxime *O*-ether derivatives synthesized are discussed.

**Keyphrases** □ Anticholinergics, potential—selected tricyclic oxime *O*-ethers, synthesis, structure–activity relationships □ Structure–activity relationships—selected tricyclic oxime *O*-ethers as potential anticholinergics, synthesis □ Antimuscarinic activity—comparison of synthesized tricyclic oxime *O*-ethers □ Oxime derivatives—synthesis, comparison as potential anticholinergics

Various structurally and stereochemically different esters exhibiting anticholinergic activity were studied previously (1–4) to obtain information concerning stereospecificity of the parasympathetic postganglionic acetylcholine receptor. One report (3), dealing with α- and β-methylcholine esters of 2-cyclohexyl-2-hydroxy-2-phenylacetic acid, concluded that α-methyl substitution significantly increased antimuscarinic activity and that such an increase was independent of the configuration of the α-substituted carbon atom. Based on these findings, the report indicated that the stereochemistry of the aminoalcohol moiety was not significant in determining antimuscarinic activity.

Previous work (5, 6) demonstrated that oxime derivatives are useful model compounds for the study of structure–activity relationships. More recent studies related geometric (7, 8) and enantiomeric (8) isomerism in oxime *O*-ethers to their anticholinergic activity. These findings (8), however, were not in complete agreement with earlier reports (1–3) concerning the stereochemical significance of the aminoalcohol moiety in determining antimuscarinic potency.

The present study was a further investigation of the possible relationships between structural and stereochemical properties and antimuscarinic activity among oxime *O*-ethers. Selected isomeric and nonisomeric oxime *O*-ethers of thioxanthone oxime (Table I) were synthesized, and a preliminary pharmacological evaluation was conducted to determined their antimuscarinic activity.

## DISCUSSION

Preparation of the oxime directly from thioxanthone was attempted *via* methods described by Gomer *et al.* (6), for the synthesis of xanthoxime, and Wylie *et al.* (9), for the preparation of benzophenone oxime, but was unsuccessful. This failure can be explained by the fact that, in thioxanthone, the carbonyl carbon is considerably less electrophilic and, therefore, less susceptible to nucleophilic attack by the hydroxylamine nitrogen. Subsequently, thioxanthone oxime was prepared by a modified method of Nagrajan *et al.* (10). Accordingly, thioxanthone was converted first to the thione by refluxing it with excess phosphorus pentasulfide in xylene. The thione then was refluxed with hydroxylamine hydrochloride and potassium *t*-butoxide in anhydrous ethanol to yield the oxime in fair yields. Based on the reported mechanism (8, 11) involved in the synthesis of oximes from highly aromatic ketones, a general base-catalyzed mechanism was proposed for the synthesis of thioxanthone oxime. The oxime was quite unstable when exposed to direct sunlight, decomposing to the ketone. The major steps involved in the synthesis of the oxime and the oxime *O*-ethers are depicted in Scheme I.

The oxime *O*-ethers included in this study (Table I) were prepared *via O*-alkylation of the oximate anion with the appropriate aminoalkyl halides. The mechanism of *O*-alkylation involves a nucleophilic attack by the base-generated anionic oximate species on the aminoalkyl halide, resulting in the displacement of the halide ion (12).

The procedure of Huerta *et al.* (8) was used to prepare the α- and β-methylcholine *O*-ethers of the oxime. Accordingly, 2-chloro-*N*,*N*-

dimethylpropylamine was used as the alkylating agent, resulting in the synthesis of both structural isomers (IV and V) in the same reaction mixture. The proposed mechanism (13) implicates the generation of a cyclic aziridinium-ion intermediate, followed by a nucleophilic attack by the oximate anion on the two possible nucleophilic sites of the cyclic aziridinium ion. An attack on the secondary carbon results in the formation of the α-methyl isomer (IV), and a corresponding attack on the tertiary carbon results in the β-methyl isomer (V). It was apparent from the α–β isomeric ratio that a nucleophilic attack on the secondary carbon of the aziridinium ion was favored.

An attempt to separate the structural isomers by high-vacuum distillation failed because of the high thermal decomposition of the oily mixture. Dry-column chromatography was effective for large-scale separation. This technique allowed direct application of the optimal conditions, previously determined by using TLC, to a column adsorbent of the same composition. The separation and purification of the structural isomers were monitored by TLC, and they were identified conclusively based on their NMR and IR spectra.

The NMR spectral data were particularly conclusive. In the α-methyl isomer, the α-methyl group is influenced only by the methine proton adjacent to the amino nitrogen; thus, it was represented by a doublet peak at δ 1.10. The corresponding doublet for the β-methyl group in the β-methyl isomer appeared slightly downfield at δ 1.40, indicating that the methine group influencing the β-methyl group must be adjacent to the ether oxygen. Other differences in the NMR spectra also were useful in assigning the correct structures (Table I).

Resolution of the racemic α-methyl structural isomer into its respective enantiomers was accomplished by preparing diastereomeric salts with tartaric acid, followed by repeated recrystallizations until each diastereomer exhibited a constant melting point and specific rotation. The enantiomeric free bases were liberated from the diastereomers separately by treatment with triethylamine and derivatized to their respective methyl bromide salts. These methyl bromide salts, after several recrystallizations, exhibited essentially equal but opposite specific rotations. All of the established criteria (14) for confirming the relative optical purity of enantiomers were met during resolution. Elemental analyses and optical rotation data of the diastereomers and enantiomers are summarized in Table II.

The β-methyl isomer was not resolved because preliminary pharmacological screening indicated that the α-methyl isomer was several times more potent as an antimuscarinic agent. The chemical purity and structural characterizations of the oxime *O*-ether methyl halide derivatives prepared were confirmed by elemental analyses (Table III).

## EXPERIMENTAL[1]

**Oxime**—*Thioxanthone Oxime*—A previous method (10) was adopted with modifications. Thioxanthone (212 g, 1 mole) was combined with distilled phosphorus pentasulfide (444 g, 2 moles) and refluxed in xylene (2000 ml) for 24 hr. The reaction was monitored with TLC using benzene as the developing solvent. The reaction mixture was filtered while hot, and the filtrate was washed quickly with five 100-ml portions of 2 *N* NaOH followed by five 100-ml portions of distilled water. The filtrate was evaporated under reduced pressure, and the resulting residue was recrystallized from hot absolute ethanol. The crystalline material, thioxanthione (160 g, 70%), melted at 167–168° [lit. (10) mp 168°].

Potassium *t*-butoxide (224 g, 2 moles) was added in small portions to a stirred solution of thioxanthione (160 g, 0.7 mole) in absolute ethanol (1000 ml). Hydroxylamine hydrochloride (140 g, 2 moles) was added to this stirred mixture, which then was refluxed for 8 hr. The reaction mixture was filtered while hot, and the filtrate was evaporated under reduced pressure. The resulting residue was washed several times with xylene and then recrystallized from hot benzene. The analytically pure oxime (63 g, 40%) melted at 193–194° [lit. (10) mp 192–193°]; IR (KBr

[1] Melting points were determined on a Thomas–Hoover Uni-Melt apparatus and are uncorrected. A Beckman IR-8 spectrophotometer was used to obtain IR spectra. Proton NMR spectra were obtained on JEOL C-60HL and Perkin-Elmer R-12A spectrometers with tetramethylsilane and dimethyl sulfoxide as internal standards. Optical rotation data were obtained on a Perkin-Elmer 141 polarimeter. Elemental analyses were performed by Schwarzkopf Microanalytical Laboratories, Woodside, N.Y. Pharmacological determinations were made on a Marco physiograph desk model DMP-4A.

disk): 1620 (C=N) and 980 (N–O) $cm^{-1}$; NMR (dimethylsulfoxide-$d_6$): δ 7.13–8.50 (m, 8H, aromatic H) and 13.07 (s, 1H, NOH).

*Oxime O-Ethers*—Elemental analyses data and appropriate physical constants for all final compounds are summarized in Tables I–III.

**Thioxanthone Oxime *O*-(*N*-Dimethylaminoethyl) Ether (I) and Methyl Halides**—The oxime (7.95 g, 0.035 mole) was dissolved in warm absolute ethanol (100 ml) and placed in a three-necked round-bottom flask. Sodium hydride (3.28 g of a 51.6% mineral oil dispersion, 0.07 mole) was added in small portions to the stirred solution. 2-Chloro-*N*,*N*-dimethylethylamine hydrochloride (1.89 g, 0.035 mole) was dissolved in hot absolute ethanol (100 ml) and added dropwise to the reaction mixture over 30 min. The stirred mixture was refluxed for 72 hr and filtered while hot. The filtrate was evaporated under reduced pressure, and the resulting oily residue was dissolved in petroleum ether. The solution was filtered, and the solvent was evaporated under reduced pressure.

The oily product (6.27 g, 60%) was purified further *via* dry-column chromatography after proper conditions (with respect to solvent and column material) were established with silica gel TLC. A 50.8-cm strip of nylon column was packed with silica gel powder (300 g, 60–200 mesh), and the crude oily product was eluted with ethyl acetate–methanol (10:1). The elution was stopped when the solvent front reached the bottom of the column, which then was sliced into 2.54-cm sections. The contents of each section were extruded into separate beakers and extracted with absolute ethanol (25 ml). The extract in each beaker was analyzed by TLC, and the extracts containing the pure oxime *O*-ether were combined. The combined extracts were filtered, and the filtrate was evaporated under reduced pressure. The oily residue was dissolved in petroleum ether, and the mixture was filtered. Then the solvent was evaporated under reduced pressure to yield the pure oxime *O*-ether (4.37 g, 40%).

The methy bromide derivative (I · $CH_3Br$) was prepared by treating a solution of the free base in absolute ethanol with excess methyl bromide. The mixture was placed in a freezer for 24 hr, and the resulting precipitate was collected on a filter. Recrystallization from absolute ethanol yielded an analytically pure sample, mp 233–234.5°. The methyl iodide derivative was prepared similarly by treating a solution of the free base in absolute ethanol with excess methyl iodide, mp 223–225°.

**Thioxanthone Oxime *O*-[4-(1-Methylpiperidinyl)] Ether (II) and Methyl Bromide Derivative**—Sodium hydride (1.6 g of a 51.6% mineral oil dispersion, 0.034 mole) was added in small portions to a stirred solution of the oxime (3.85 g, 0.017 mole) in dimethyl sulfoxide (100 ml). 4-Chloro-1-methylpiperidine hydrochloride (2.08 g, 0.017 mole) was added to the stirred mixture in small portions. Then the mixture was refluxed for 4 hr, treated with distilled water (200 ml), and extracted with five 100-ml portions of chloroform. The combined chloroform extracts were washed twice with distilled water (100 ml) and dried over anhydrous calcium carbonate. The mixture was filtered, and the solvent was evaporated under reduced pressure. The crude oily material, on purification *via* dry-column chromatography using ethyl acetate–petroleum ether–ethanol (1:1:0.1), yielded the pure oxime *O*-ether (2.2 g, 40%). The methyl bromide derivative was prepared and recrystallized from absolute ethanol, mp 277–278°.

**Thioxanthone Oxime *O*-(*N*-Dimethylaminopropyl) Ether (III) and Methyl Bromide Derivative**—The procedure described for the synthesis of II was adopted for the synthesis of III. Sodium hydride (1.9 g of a 51.6% mineral oil dispersion, 0.04 mole) and 3-chloro-*N*,*N*-dimethylpropylamine hydrochloride (3.2 g, 0.02 mole) were added to a stirred solution of the oxime (4.54 g, 0.02 mole) in dimethyl sulfoxide, and the mixture was refluxed for 4 hr. The reaction mixture was combined with distilled water (200 ml) and extracted with five 100-ml portions of chloroform. The combined chloroform extracts were washed twice with distilled water (100 ml) and dried over anhydrous calcium carbonate. The mixture was filtered, and the solvent was evaporated under reduced pressure. The resulting crude product, on purification *via* dry-column chromatography using ethyl acetate–petroleum ether–ethanol (1:1:0.1), yielded the pure oxime *O*-ether (4.4 g, 70%). The methyl bromide derivative was prepared and recrystallized from absolute ethanol, mp 211–212.5°.

**Thioxanthone Oxime *O*-(α- and β-Methylcholinyl) Ethers (IV and V) and Methyl Halide Derivatives**—A reported method (8) was adopted. Sodium hydride (9.3 g of a 51.6% mineral oil dispersion, 0.2 mole) was added in small portions to a stirred solution of the oxime (20.30 g, 0.1 mole) in absolute ethanol. A solution of 2-chloro-*N*,*N*-dimethylpropylamine hydrochloride (15.8 g, 0.1 mole) in absolute ethanol was added dropwise to the stirred, refluxing, reaction mixture over 1 hr. The mixture was refluxed further for 12 hr, during which the reaction was monitored with TLC using ethyl acetate–petroleum ether–ethanol (1:1:0.1). The hot reaction mixture was filtered, and the filtrate was evaporated under reduced pressure. The resulting oily residue was extracted with isopropyl ether, and the combined extracts were filtered. Evaporation of the solvent under reduced pressure yielded a crude oily mixture of the α- and β-methyl structural isomers (21.88 g, 70%).

**Separation and Isolation of Structural Isomers**—The initial separation of the structural isomers was accomplished on a small scale, with silica gel TLC using ethyl acetate–petroleum ether–ethanol (1:1:0.1). One isomer had an $R_f$ value of 0.14, and the other isomer exhibited an $R_f$ value of 0.28. These TLC results were applied directly to silica gel dry-column chromatography for the large-scale separation. A 91.4-cm nylon column was packed with silica gel (1200 g, 60–200 mesh) powder, previously activated at 115° for 1 hr. The isomeric mixture (20 g) was adsorbed on a separate portion of adsorbent and added to the top of the column. The column then was eluted with a solvent mixture identical to the one used during TLC separation. Development of the column was stopped when the solvent front reached the bottom of the column. The column then was cut into 2.54-cm sections, and the adsorbent in each section was extracted with absolute ethanol into separate beakers.

The contents of each beaker were analyzed by TLC, and extracts containing a single compound with identical $R_f$ values were combined and filtered. Evaporation of the filtrates under reduced pressure yielded the pure α-methyl (9.5 g) and β-methyl (4.5 g) isomers. Based on their IR and NMR spectral data, the isomer with an $R_f$ value of 0.14 was identified as the α-methyl isomer; the isomer with an $R_f$ value of 0.28 was identified as the β-methyl isomer. The IR spectrum of the α-isomer exhibited a charcteristic C=O stretching band at 1040 $cm^{-1}$, while the β-isomer had a corresponding band at 1065 $cm^{-1}$. The NMR spectrum of the α-isomer exhibited a characteristic doublet at δ 1.10 for the α-methyl protons, while the corresponding doublet for the β-methyl protons appeared further downfield at δ 1.40 due to the greater influence of the oxygen atom. Other characteristic differences also were observed in the NMR spectra (Table I) of these structural isomers.

Methyl bromide and methyl iodide derivatives were prepared. The analytically pure methyl bromide derivative of the racemic α-methyl isomer melted at 218–219°, and the methyl iodide derivative melted at 177–179°. The analytically pure methyl bromide derivative of the racemic β-methyl isomer melted at 209–211°, and the methyl iodide derivative melted at 176–178°.

**Resolution**—The racemic α-methyl isomer (6.72 g, 0.018 mole) was dissolved in absolute ethanol (50 ml), and the solution was combined with an equimolar solution of tartaric acid (5.02 g, 0.018 mole) in absolute ethanol (50 ml). The mixture was stirred for 4 hr and allowed to stand for 24 hr. Since no precipitate formed, anhydrous ether was added to the solution, and the mixture was allowed to stand for an additional 12 hr. The resulting crystalline precipitate was collected on a filter and washed several times with anhydrous ether. The crystalline material (9.6 g, mp 110–127°) was redissolved in hot absolute ethanol (30 ml), and the solution was allowed to stand for 8 hr.

The resulting precipitate was recrystallized five times from hot absolute

ethanol to yield a crystalline product {2.0 g, mp 128–130°, $[\alpha]_D^{25}$ +18.60° (*c*, 1.5%, absolute methanol)}. The combined filtrate remaining after isolation of the pure diastereomer (mp 128–130°) was evaporated under reduced pressure. The residue (6.6 g) was dissolved in hot isopropyl alcohol (30 ml) and allowed to stand at room temperature for 12 hr. The precipitate (0.6 g, mp 128–130°) was filtered off, and anhydrous isopropyl ether was added to the filtrate. The precipitate formed; after the solution was allowed to stand for 12 hr, it was collected and recrystallized three times from isopropyl alcohol–isopropyl ether {2.5 g, mp 118–120°, $[\alpha]_D^{25}$ +8.13° (*c*, 2.5%, absolute methanol)}.

The methyl bromide derivative of (+)-IV was prepared from the lower melting diastereomer after regeneration of the free base. The diastereomer (2.5 g) was dissolved in distilled water (20 ml), and the solution was treated with excess triethylamine. The mixture was stirred for 1 hr, and anhydrous isopropyl ether (20 ml) was added. The mixture then was stirred for 30 min. The isopropyl ether layer was isolated, and the aqueous layer was extracted twice with isopropyl ether (10 ml). The isopropyl ether extracts were combined, dried over calcium carbonate, and filtered, and the solvent was evaporated under reduced pressure. The resulting oily residue was redissolved in anhydrous isopropyl ether (20 ml), and the solution was treated with excess methyl bromide. The mixture was placed in a freezer for 24 hr, and the resulting precipitate (1.2 g, mp 217–220°) was recrystallized four times from isopropyl alcohol–isopropyl ether {0.4 g, mp 219–220°, $[\alpha]_D^{25}$ +16.33° (*c*, 5%, absolute methanol)}.

The methyl bromide derivative of (−)-IV was prepared from the higher melting diastereomer after regeneration of the free base. Excess triethylamine was added to the diastereomer (2.6 g) in distilled water (20 ml). The mixture then was stirred for 1 hr, isopropyl ether was added, and the mixture was stirred for an additional 30 min. The isopropyl ether layer was isolated, and the aqueous layer was extracted twice with isopropyl ether (10 ml). The combined extracts were dried over anhydrous calcium carbonate and filtered, and the solvent was evaporated under reduced pressure. The oily residue was dissolved in anhydrous isopropyl ether, and the solution was treated with excess methyl bromide. The mixture was placed in a freezer for 24 hr, and the resulting precipitate (1.6 g, mp 206–212°) was collected and recrystallized three times from isopropyl alcohol {0.5 g, mp 216–218°, $[\alpha]_D^{25}$ −16.43° (*c*, 5%, absolute methanol)}.

Melting points, optical rotation data, and elemental analyses of the diastereomers (tartrates) and enantiomers (methyl bromide) of the α-methyl isomer (IV) are presented in Table II.

## PHARMACOLOGY

Methyl bromide derivatives of the synthesized isomeric and nonisomeric oxime *O*-ethers were evaluated for antimuscarinic (spasmolytic) activity. Various test compound concentrations were used to obtain recordable dose–response curves. The spasmogen (urecholine) concentration was $2.55 \times 10^{-4}$ mmole/90 ml for each dose increment. The atropine sulfate concentration used in all determinations was $2.00 \times 10^{-7}$ mmole/90 ml. All test solutions were freshly prepared aqueous solutions.

**Method**—The method involved measurement of the inhibition (by a spasmolytic agent) of a spasmogen-induced contraction in a smooth muscle tissue (rat ileum) (15). The apparatus consisted of a glass cylinder (100-ml capacity) with an inlet for introducing the Tyrode bathing solution (90 ml) and an outlet for drainage. The bath solution was aerated continuously. The smooth muscle tissues were uniform strips of ileum taken from an unanesthetized, recently sacrificed, albino rat. The normal contractions of the ileum (0% response) were recorded on a physiograph through a myograph transducer. The spasmogen-induced contractions were produced by successive additions of the spasmogen dose increments at regular intervals until maximum response (100%) was achieved. There were no washes between the cumulative additions of the spasmogen.

Determination of antimuscarinic activity of the test compounds was initiated with a standard spasmogen curve, as already described, followed by washings of the muscle tissue. After the muscle strip had resumed its natural, spontaneous contractions, an appropriate dose of the test compound or atropine sulfate was introduced into the bath solution. After a brief interval (1.5 min), spasmogen dose increments were added to the bath until maximum response was achieved. The muscle strip then was washed and the whole process was repeated after 5–10 min for the next determination.

The data (percent response) were plotted on a probability scale (ordinate) *versus* the log of the spasmogen dose, in micromoles per 90 ml (abscissa). The spasmogen dose necessary to elicit a 50% response ($ED_{50}$) after pretreatment with the respective test compound or atropine sulfate was determined graphically. The relative potencies of the test compounds were calculated by comparing their respective $ED_{50}$ values with those of atropine sulfate. The pharmacological data are summarized in Table IV.

**Table IV—Summary of Pharmacological Data** [a]

| Compound | Dose[b], m*M*/90 ml | $ED_{50}$[c], m*M* | Relative[d] Potency | Isomeric[e] Potency Ratio |
|---|---|---|---|---|
| I · $CH_3Br$ | $5.00 \times 10^{-6}$ | $3.23 \times 10^{-3}$ | 0.074 | — |
| II · $CH_3Br$ | $5.00 \times 10^{-6}$ | $2.26 \times 10^{-3}$ | 0.052 | — |
| III · $CH_3Br$ | $5.00 \times 10^{-6}$ | $1.46 \times 10^{-3}$ | 0.033 | — |
| (±)-IV · $CH_3Br$ | $1.00 \times 10^{-6}$ | $2.44 \times 10^{-3}$ | 0.279 | — |
| (±)-V · $CH_3Br$ | $5.00 \times 10^{-6}$ | $1.25 \times 10^{-3}$ | 0.029 | 9.62 |
| (+)-IV · $CH_3Br$ | $1.00 \times 10^{-6}$ | $2.33 \times 10^{-3}$ | — | 1.09 |
| (−)-IV · $CH_3Br$ | $1.00 \times 10^{-6}$ | $2.12 \times 10^{-3}$ | — | — |

[a] Four consecutive determinations using the same muscle strip were made for each compound. [b] Dose of spasmolytic agent. [c] Spasmogen dose necessary to elicit a 50% response after pretreatment with the spasmolytic agent. [d] Spasmolytic activity of the test compound when compared with the spasmolytic activity of atropine sulfate. [e] Comparison of spasmolytic activities of the isomers based on their respective $ED_{50}$.

**Results**—All test compounds exhibited significant antimuscarinic activity (Table IV). Among the compounds tested, (±)-IV was the most potent (1/3 as potent as atropine sulfate) and (±)-V was the least potent (1/35 as potent as atropine sulfate).

The fact that (±)-IV was at least five times more potent than the corresponding *O*-(α-methylcholinyl) ether derivative of benzophenone oxime, which was reported (16) to be 1/22 as potent as atropine sulfate, indicated that the introduction of a sulfur atom in the umbrella-like portion of the oxime *O*-ether increased its antimuscarinic activity. This observation may indicate that the flat, nonpolar area of the muscarinic receptor, with which the umbrella-like moiety is believed to interact, is fairly extensive.

Compounds I, II, and III were 1/14, 1/19, and 1/30 as potent as atropine sulfate, respectively. The data indicate that antimuscarinic activity is optimal when a two-atom *O*-alkyl chain separates the ether oxygen from the amino nitrogen.

The fact that the racemic α-methyl isomer, (±)-IV, was considerably more potent than the racemic β-methyl isomer, (±)-V, was in agreement with previous reports (2, 3, 8). Furthermore, (±)-IV was more potent than the unsubstituted *O*-cholinyl ether derivative, I. These observations, coupled with the fact (17) that, at the receptor site involved, the activity of an antagonist is determined by its ability to bind with the receptor, may explain the α-methyl group's overall positive effect on the binding of (±)-IV with the muscarinic receptor. Such a contribution could be due to the production of a preferred conformation or to binding at an additional site on the receptor. The fact that the β-methyl isomer was less active than I would lead to an opposite conclusion: that the β-methyl group makes a negative overall contribution to the binding of (±)-V with the receptor.

It may be that the relatively large potency difference between the structural isomers cannot be due merely to binding or failure to bind of the methyl group but rather to the effect of the methyl group on binding of the rest of the molecule with the receptor. Such a conclusion would be entirely consistent with earlier reports (17–19) which observed that apparently minor structural changes in a compound can produce unusually large differences in affinities for the muscarinic receptor; such differences cannot be attributed to binding or failure to bind of any one group but rather are due to marked changes in the binding ability of the rest of the molecule.

Finally, no significant enantiomeric potency ratio was observed between (+)-IV and (−)-IV, which is consistent with earlier reports (3, 8). It may be concluded that the α-methyl group contributed positively to the binding of the rest of the molecule; however, configurational changes in the α-carbon atom did not alter significantly the binding of the rest of the molecule with the muscarinic receptor. Hence, no significant potency ratio was observed between the enantiomers.

# Transport of Prostaglandins through Silicone Rubber

**T. J. ROSEMAN ˣ, L. J. LARION, and S. S. BUTLER**

Received August 14, 1980, from *Pharmacy Research, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication November 6, 1980.

**Abstract** □ The *in vitro* release profiles of the F-series of prostaglandins were determined from a silicone rubber matrix of constant surface area. Silicone rubber was selective toward prostaglandin transport and offers potential as a controlled-release delivery system. Drug release patterns were dependent on the lipophilicity of the prostaglandin molecule. For dinoprost (prostaglandin $F_{2\alpha}$), the following sequence was observed: methyl ester > free acid > tromethamine salt. The biologically potent carboprost methyl [(15*S*)-15-methylprostaglandin $F_{2\alpha}$ methyl ester] was released considerably faster than the methyl ester of the parent dinoprost molecule, while release of the tromethamine salts of the two prostaglandins was similar. Permeability rates of the salts were depressed substantially when compared to their respective C-1 methyl esters. Results from independent membrane transport studies supported the observed dependence of steady-state flux on the chemical structure of the prostaglandin molecule. Plots of the amount released per unit area *versus* the square root of time were linear except for the initial drug release phase, and the total amount of prostaglandin released increased as the initial loading dose was raised. The data were analyzed according to a physical model describing drug release from inert matrix systems. The observed concentration dependence was consistent with the predictions of the model.

**Keyphrases** □ Prostaglandins—transport through silicone rubber, effect of lipophilicity, *in vitro* release profiles □ Dinoprost—transport through silicone rubber □ Carboprost—transport through silicone rubber □ Controlled-release delivery—transport of prostaglandins through silicone rubber □ Dosage forms—transport of prostaglandins through silicone rubber

Prostaglandins are a class of $C_{20}$ lipid-like substances that produce a wide spectrum of biological responses (1). Their clinical application in fertility control is well recognized since they possess luteolytic and abortifacient properties, alter ovum transport, and induce menses (2). Naturally occurring dinoprost[1] (prostaglandin $F_{2\alpha}$) and dinoprostone[2] (prostaglandin $E_2$) have been tested clinically by numerous routes of administration in solution, tablet, and suppository dosage forms. The (15*S*)-15-methyl analogs also are being explored as fertility-regulating agents and are considerably more potent (3, 4).

Intrauterine administration reduces undesirable side effects associated with the systemic intravenous route since drug is delivered closer to the uterus. The vaginal route, however, allows for self-administration, and it has been used successfully to terminate pregnancy with dinoprostone suppositories given by a multiple-dosing regimen (5) and with a single carboprost methyl[3] [(15*S*)-15-methylprostaglandin $F_{2\alpha}$ methyl ester] vaginal suppository (6).

## BACKGROUND

Studies in these laboratories have been directed toward the development of a prostaglandin delivery module that can be self-administered, is reversible, and provides continuous drug release for the treatment period following a single administration. Structural modifications of polymeric materials have been made to attain satisfactory prostaglandin release rates.

Nuwayser and Williams (7) showed that the permeability rate of dinoprost in deacetylated cellulose acetate was much greater than in other cellulose derivatives; in the rabbit, Akkapeddi *et al.* (8) demonstrated the abortifacient effectiveness of dinoprost and dinoprostone when incorporated into a series of hydrophilic polymeric materials. Polyacrylamide and polyvinylpyrrolidone gels containing dinoprostone or dinoprost also were effective in fertility control in several animal systems (9–12). Silicone rubber, however, was impervious to dinoprost transport and was discounted as a possible delivery system (9). Yet Spilman and Roseman (13) showed that silicone vaginal rings impregnated with carboprost methyl were effective in producing increased uterine muscle activity, luteolysis, and abortion in the Rhesus monkey.

The delivery system design, therefore, not only depends on the delivery module but also on the chemical form of the drug molecule. The present article provides a physicochemical analysis of the transport mechanism of prostaglandins through silicone rubber. The influence of lipophilicity on release is a dominant factor in assessing the utility of silicone rubber as a delivery system. In this regard, these findings parallel an earlier study with steroids (14).

# Transport of Prostaglandins through Silicone Rubber

**T. J. ROSEMAN ˣ, L. J. LARION, and S. S. BUTLER**

Received August 14, 1980, from *Pharmacy Research, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication November 6, 1980.

**Abstract** □ The *in vitro* release profiles of the F-series of prostaglandins were determined from a silicone rubber matrix of constant surface area. Silicone rubber was selective toward prostaglandin transport and offers potential as a controlled-release delivery system. Drug release patterns were dependent on the lipophilicity of the prostaglandin molecule. For dinoprost (prostaglandin $F_{2\alpha}$), the following sequence was observed: methyl ester > free acid > tromethamine salt. The biologically potent carboprost methyl [(15*S*)-15-methylprostaglandin $F_{2\alpha}$ methyl ester] was released considerably faster than the methyl ester of the parent dinoprost molecule, while release of the tromethamine salts of the two prostaglandins was similar. Permeability rates of the salts were depressed substantially when compared to their respective C-1 methyl esters. Results from independent membrane transport studies supported the observed dependence of steady-state flux on the chemical structure of the prostaglandin molecule. Plots of the amount released per unit area *versus* the square root of time were linear except for the initial drug release phase, and the total amount of prostaglandin released increased as the initial loading dose was raised. The data were analyzed according to a physical model describing drug release from inert matrix systems. The observed concentration dependence was consistent with the predictions of the model.

**Keyphrases** □ Prostaglandins—transport through silicone rubber, effect of lipophilicity, *in vitro* release profiles □ Dinoprost—transport through silicone rubber □ Carboprost—transport through silicone rubber □ Controlled-release delivery—transport of prostaglandins through silicone rubber □ Dosage forms—transport of prostaglandins through silicone rubber

Prostaglandins are a class of $C_{20}$ lipid-like substances that produce a wide spectrum of biological responses (1). Their clinical application in fertility control is well recognized since they possess luteolytic and abortifacient properties, alter ovum transport, and induce menses (2). Naturally occurring dinoprost[1] (prostaglandin $F_{2\alpha}$) and dinoprostone[2] (prostaglandin $E_2$) have been tested clinically by numerous routes of administration in solution, tablet, and suppository dosage forms. The (15*S*)-15-methyl analogs also are being explored as fertility-regulating agents and are considerably more potent (3, 4).

Intrauterine administration reduces undesirable side effects associated with the systemic intravenous route since drug is delivered closer to the uterus. The vaginal route, however, allows for self-administration, and it has been used successfully to terminate pregnancy with dinoprostone suppositories given by a multiple-dosing regimen (5) and with a single carboprost methyl[3] [(15*S*)-15-methylprostaglandin $F_{2\alpha}$ methyl ester] vaginal suppository (6).

## BACKGROUND

Studies in these laboratories have been directed toward the development of a prostaglandin delivery module that can be self-administered, is reversible, and provides continuous drug release for the treatment period following a single administration. Structural modifications of polymeric materials have been made to attain satisfactory prostaglandin release rates.

Nuwayser and Williams (7) showed that the permeability rate of dinoprost in deacetylated cellulose acetate was much greater than in other cellulose derivatives; in the rabbit, Akkapeddi *et al.* (8) demonstrated the abortifacient effectiveness of dinoprost and dinoprostone when incorporated into a series of hydrophilic polymeric materials. Polyacrylamide and polyvinylpyrrolidone gels containing dinoprostone or dinoprost also were effective in fertility control in several animal systems (9–12). Silicone rubber, however, was impervious to dinoprost transport and was discounted as a possible delivery system (9). Yet Spilman and Roseman (13) showed that silicone vaginal rings impregnated with carboprost methyl were effective in producing increased uterine muscle activity, luteolysis, and abortion in the Rhesus monkey.

The delivery system design, therefore, not only depends on the delivery module but also on the chemical form of the drug molecule. The present article provides a physicochemical analysis of the transport mechanism of prostaglandins through silicone rubber. The influence of lipophilicity on release is a dominant factor in assessing the utility of silicone rubber as a delivery system. In this regard, these findings parallel an earlier study with steroids (14).

methyl ester, carboprost methyl, and carboprost tromethamine, were at least 99% pure by GLC and showed a single major zone by TLC. Compression-distilled water and analytical reagent grade chemicals were used. Distilled-in-glass chloroform was used for prostaglandin extraction.

**Release Method**—The preparation of the prostaglandin matrixes and the experimental design of the release rate studies were similar to those reported previously (15). The methyl esters of dinoprost and carboprost first were triturated in a mortar to reduce their particle size. After the prostaglandins were suspended in the silicone monomer[5] and catalyzed with stannous octoate, the mix was placed into a stainless steel circular mold having an exposed surface area of 10 $cm^2$ (Fig. 1). During the curing step, an acrylic resin plate was placed over the elastomer to provide a smooth surface for the subsequent release experiments. The matrix was cured overnight at room temperature, the acrylic resin plate was removed, and the excess flashings were trimmed before release determinations were made.

Release measurements were performed in 100 ml of 0.1 *M* tromethamine buffer (pH 7.0) at 37°. Agitation of the solution was provided by a 300-rpm synchronous motor which rotated a magnetic stirrer. Samples (15–25 ml) were withdrawn through the acrylic resin cover with a syringe and needle, extracted with chloroform, and assayed. The withdrawn solution was replaced with an equal volume of buffer preequilibrated at 37°. For dinoprost tromethamine and dinoprost (free acid), the procedures were identical except that the tromethamine salt was micronized and the waxy free acid was levigated directly into the silicone phase.

The dissolution medium pH was selected to maintain sink conditions for dinoprost when used as the tromethamine salt and free acid. Since concentrations were <0.01 mg/ml and the aqueous solubility at this pH is >200 mg/ml (16), the sink condition was met. This same pH was used for the esters to maintain uniformity of dissolution and to retard any drug decomposition during the experiment. For the methyl esters, the concentrations during dissolution were <10% of their equilibrium solubility values. Stability studies with the methyl ester prostaglandins indicated that no decomposition occurred during sample preparation for dissolution. However, after about 1 week, some degradation of carboprost methyl was noted in the elution medium. When necessary, the concentrations were corrected to reflect accurately the total prostaglandin released. To avoid the potential effect of surface diffusion of drug on the release profiles, dissolution studies were performed within 1 week after device preparation.

The methyl ester samples (15–25 ml) were extracted directly with three equal volumes of chloroform and dried under vacuum with mild heat[6]. For the tromethamine salt and free acid runs, the pH of the withdrawn samples was lowered to 3 with 0.2 *M* citrate buffer (pH 3) and extracted with chloroform as outlined for the esters.

**Membrane Transport**—Fillerless silicone membranes were prepared by polymerizing the silicone monomer[7] with stannous octoate and placing the mix between metal plates separated by the appropriately sized spacers. After curing, the sheet was removed and circular membranes of the desired diameter were punched out. The membrane was soaked overnight in water and then mounted into a diffusion cell originally designed by Flynn and Smith (17), without the screen and with a 60-rpm motor. Throughout the experiment, temperature was maintained at 37°.

At time zero, a preequilibrated saturated solution containing excess prostaglandin in pH 7.0 tromethamine buffer was placed in the donor compartment, while the receptor side contained the buffer with no drug. Samples were taken as a function of time by flushing the receptor compartment with three volumes of fresh buffer. The entire sample then was extracted with chloroform (3 × 25 ml).

The diffusion coefficient of tritium-labeled carboprost methyl [(15*S*)-15-methylprostaglandin $F_{2\alpha}$-11$\beta$-[$^3$H]methyl ester] was determined using the described diffusion cell. Samples (1 ml) were withdrawn, diluted with 10 ml of scintillation fluid[8], and then counted on a liquid scintillation counter[9].

**Analytical Procedures**—GLC was employed to determine prostaglandin concentrations. The dried prostaglandin extracts were treated with 3–4 drops of dry pyridine and 0.5 ml of silylating reagent containing 1 or 3 mg of cholesteryl acetate (internal standard)/ml. For the 15-methylprostaglandin $F_{2\alpha}$ compounds, the silylating reagent was bis(trimethylsilyl)trifluoroacetamide plus 1% trimethylchlorosilane[10], and the solution was allowed to react overnight at room temperature. With the dinoprost compounds, a silylation mixture of *N,O*-bis(trimethylsilyl)-acetamide–trimethylchlorosilane[11] (4:1) was utilized; the reaction was completed in 30 min. Reference standards were prepared by direct treatment of 1 mg of prostaglandin with the appropriate silylating reagent.

After the reaction was complete, 1 μl was injected onto the glass (0.63-cm i.d. × 1.2-m length) column[12] packed with 3% UCW-98 on 80–100-mesh Gas Chrom Q[13]. The flash heater was off, and the column and detector temperatures were 260 and 270°, respectively. The helium gas flow was 60 ml/min, and air and hydrogen rates were adjusted to maximize response; the attenuation was 10 × 32. Unknown prostaglandin concentrations were determined by peak area ratios with standards injected with the samples.

Extraction of solution from a placebo run showed no interfering peaks. The efficiency of the analytical procedures was checked by analyzing samples of known concentrations. Complete prostaglandin recovery resulted from the extractions from aqueous media.

## RESULTS AND DISCUSSION

**Release Profiles of Dinoprost (Prostaglandin $F_{2\alpha}$)**—Studies on prostaglandin release from silicone rubber were initiated using the naturally occurring dinoprost as the model compound. Figure 2 illustrates the release pattern of dinoprost as a function of its chemical form at the C-1 position. Silicone rubber was almost impervious to the transport of dinoprost as the tromethamine salt, while the methyl ester was released continuously as a function of time. The release profile of dinoprost (free acid) fell in between the methyl ester and tromethamine salt. Qualitatively, the release data correlated directly with the expected degree of lipophilicity of the prostaglandin molecule in the silicone matrix phase, *i.e.*, methyl ester > free acid > tromethamine salt.

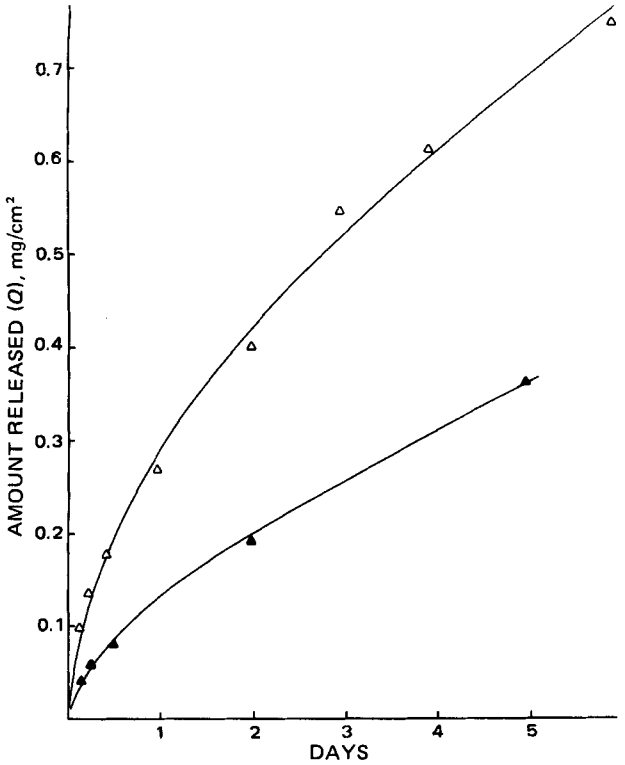

**Figure 3**—*Release profile of dinoprost methyl (prostaglandin $F_{2\alpha}$ methyl ester) from silicone rubber. Key: ▲, 2%; and △, 5%.*

Earlier work on the release of neutral steroidal compounds from silicone rubber suggested that drug transport is due mainly to diffusion through the matrix phase (18). The extremely slow release of dinoprost tromethamine supports this mechanism. At pH 7.0, dinoprost has a solubility in excess of 200 mg/ml. If transport through aqueous channels or pores is an important route for drug release, then the large aqueous solubility of the salt would provide a highly favorable driving force (concentration gradient) for the rapid diffusion of prostaglandin. The lower release rate of the salt form was probably due to a rather limited solubility in the silicone rubber phase. In contrast to the methyl ester of dinoprost, the free acid form was released for only about 2 days. The polymerization reaction for dinoprost (free acid) required a two- to threefold increase in the catalyst concentration, and it appears that the drug participated in the polymerization. If this is the case, the effective drug concentration in the matrix would be reduced and limit the availability of the prostaglandin molecule, as evidenced by the plateau region in Fig. 2. The dependence of release on the initial prostaglandin loading dose is shown in Fig. 3 for dinoprost methyl ester.

**Comparison of Permeability Rates of Dinoprost Methyl (Prostaglandin $F_{2\alpha}$ Methyl Ester) and Carboprost Methyl [(15*S*)-15-Methylprostaglandin $F_{2\alpha}$ Methyl Ester]**—The synthesis and biological activity of carboprost methyl was reported by Bundy *et al.* (19). This compound, along with other 15-methyl analogs of the A and E series of prostaglandins, was not a substrate for the enzyme, 15-hydroxyprostaglandin dehydrogenase, which rapidly inactivates the naturally occurring prostaglandins. The 15-methyl analog is 10 times more potent than dinoprost in promoting uterine activity and has been used successfully to terminate pregnancy by several administration routes (20). Silicone rings and devices containing carboprost methyl exhibit antifertility activity in the Rhesus monkey. A single intravaginal insertion of this device resulted in prolonged uterine activity, luteolysis, and termination of pregnancy (13, 15).

The *in vitro* release of this compound is presented in Fig. 4 for the 0.5–10% concentration range. Continuous drug release was observed for as long as 36 days, with the amount released at a given time increasing as the concentration was raised. This dependence is similar to the release of dinoprost methyl ester as seen in Fig. 3. However, the release rate of the 15-methyl analog was 1.4 times faster than the parent ester of dinoprost. At equal matrix concentrations, this factor reflects the ratio of the square root of the permeability constants ($P$), *i.e.*, the product of the drug solubility in the polymer ($C_s$) times the drug diffusivity in the polymer ($D_s$) (see *Theoretical Analysis*). Steady-state fluxes across a silicone

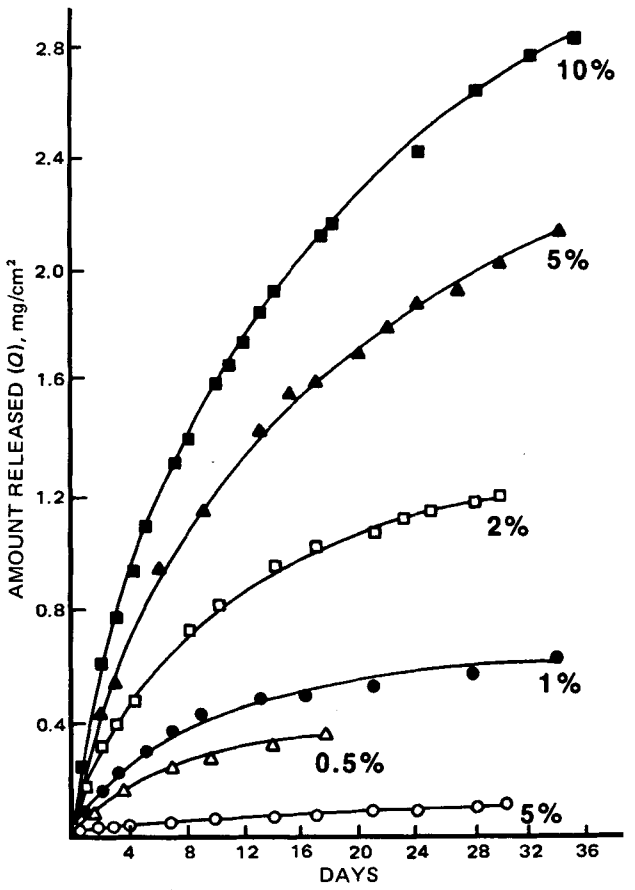

**Figure 4**—In vitro *release profiles of carboprost methyl [(15S)-15-methylprostaglandin $F_{2\alpha}$ methyl ester] from silicone rubber as a function of prostaglandin concentration in the matrix. Key:* ○, *5% tromethamine salt; and all other curves, methyl ester.*

membrane confirm the observed dependence on prostaglandin structure (Fig. 5). When the donor compartment in the diffusion cell is maintained at saturation, the following expression from Fick's law (21) is applicable:

$$\text{rate} = \left(\frac{dQ}{dt}\right)_{ss} = \frac{C_s D_s}{l} \qquad \text{(Eq. 1)}$$

where $l$ is the membrane thickness. Steady-state diffusion rates are related linearly to $C_s D_s$ and, as expected, the flux of the two prostaglandins is different at equal membrane thicknesses. Increasing the thickness decreases the transport in accord with Eq. 1. In contrast to the observed

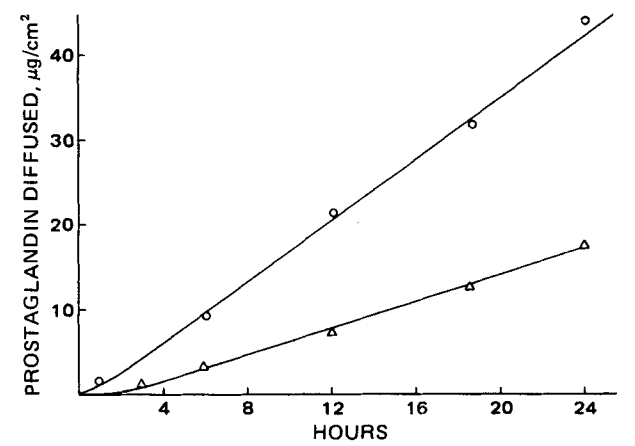

**Figure 5**—*Amount of prostaglandin diffused across a 0.047-cm thick silicone rubber membrane as a function of time. Key:* ○, *carboprost methyl [(15S)-15-methylprostaglandin $F_{2\alpha}$ methyl ester]; and* △, *dinoprost methyl (prostaglandin $F_{2\alpha}$ methyl ester).*

**Table I—Comparisons of Prostaglandin Permeability Constants [a] ($C_sD_s$) from Matrix Release and Membrane Transport Experiments**

| | Matrix Release | Membrane Transport |
|---|---|---|
| Dinoprost methyl (prostaglandin $F_{2\alpha}$ methyl ester) | $0.84^b \times 10^{-8}$ | $0.98 \times 10^{-8c}$ |
| Carboprost methyl [(15*S*)-15-methylprostaglandin $F_{2\alpha}$ methyl ester] | $1.6^b \times 10^{-8}$ | $2.1^c \times 10^{-8}$, $2.6^d \times 10^{-8}$ |

[a] Units are milligrams per centimeter per second. [b] Calculated average from the least-squares slope of $(Q/t^{1/2})$ *versus* $A^{1/2}$. [c] Calculated using a 0.097-cm thick membrane. [d] Calculated using a 0.0470-cm thick membrane.

transport of the esters, the tromethamine salts diffused at negligible rates.

**Theoretical Analysis**—The general equation for drug release from a planar silicone rubber surface is:

$$Q = \frac{-D_s h_a K A \epsilon}{D_a \tau} + \left[\left(\frac{D_s h_a K A \epsilon}{D_a \tau}\right)^2 + \frac{2AD_sC_s\epsilon t}{\tau}\right]^{1/2} \quad \text{(Eq. 2)}$$

where:

$Q$ = amount released per unit area
$t$ = time
$A$ = total concentration of drug in matrix
$D_a$ = diffusion coefficient in the dissolution medium
$D_s$ = diffusion coefficient in the matrix phase
$K$ = partition coefficient ($C_s/C_a$)
$C_a$ = solubility in the dissolution medium
$C_s$ = solubility in the matrix phase
$h_a$ = boundary diffusion layer thickness
$\epsilon$ = volume fraction
$\tau$ = tortuosity

Equation 2 was derived from a physical model which considers both diffusion through the matrix and transport away from its surface across a boundary diffusion layer[14]. For drugs that exhibit high permeability rates, the boundary diffusion layer can offer a major resistance to drug release. However, when the matrix is rate controlling, Eq. 2 reduces to:

$$Q = \left(\frac{2AD_sC_s\epsilon t}{\tau}\right)^{1/2} \quad \text{(Eq. 3)}$$

which was originally derived (22) for drug release from inert matrix systems. Plots of $Q$ *versus* $t^{1/2}$ for the prostaglandin methyl esters are shown in Figs. 6 and 7. Except for an early nonlinear period, Eq. 3 is obeyed. The curvature at early times follows predictions from Eq. 2 when the resistance of the diffusion layer plays a significant role in the total diffusion. As noted in Fig. 7, where a wide range of concentrations are presented, the curvature becomes less as the concentration in the silicone rubber phase decreases. This finding supports the applicability of Eq. 2 at early times because the depleted region in the matrix recedes less at high

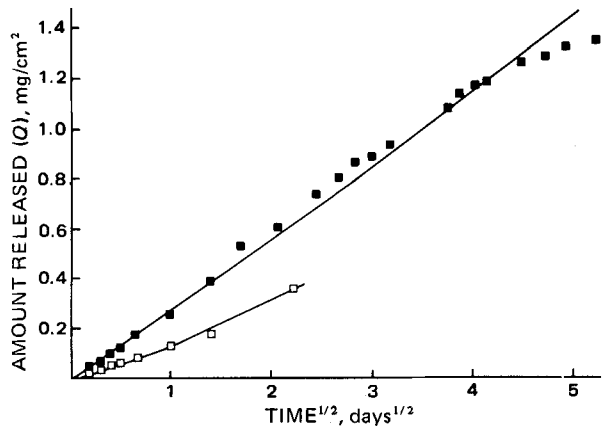

**Figure 6**—*Dependence of* Q *on* $t^{1/2}$ *for the release of dinoprost methyl (prostaglandin $F_{2\alpha}$ methyl ester) from silicone rubber at different loading doses. Key: □, 2%; and ■, 5%.*

[14] The assumptions in the derivation can be found in Ref. 18.

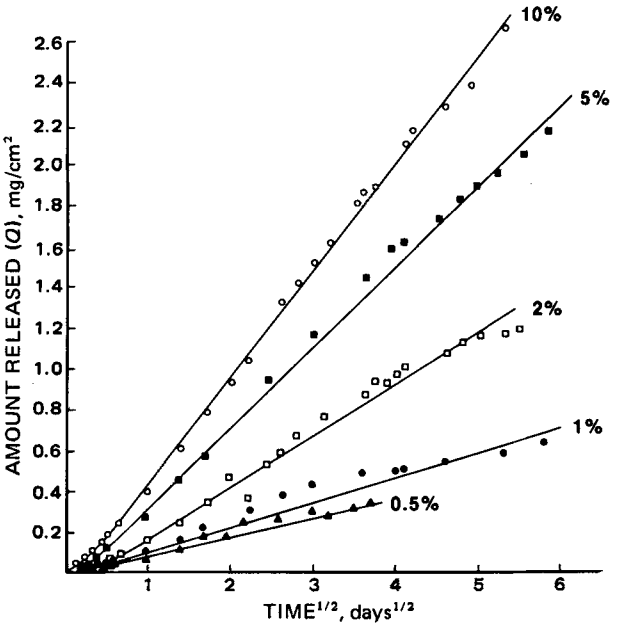

**Figure 7**—*Dependence of* Q *on* $t^{1/2}$ *for the release of carboprost methyl [(15S)-15-methylprostaglandin $F_{2\alpha}$ methyl ester] from silicone rubber at different loading doses.*

loading doses. At low matrix concentrations, drug diffusion occurs across a depleted zone of greater depth and Eq. 3 becomes operative sooner. This is evident in the 0.5% curve where $Q$ *versus* $t^{1/2}$ plots are linear even during the early release stage.

Calculated values for the permeability constants, $C_sD_s$, are given in Table I. Considering the complexities of the studies, favorable agreement between the matrix release and membrane transport data is noted. The slightly higher numbers associated with the membrane transport experiments may be a consequence of faster drug diffusion through a fillerless polymer[15]. Fillerless material was used to obtain additional information on the diffusivity of the prostaglandins since silicone rubber reinforced with diatomaceous earth or silica was reported (23, 24) to increase the lag times ($L$) and yield anomalous diffusivity values calculated from the lag time expression (25):

$$D_s = \frac{l^2}{6L} \quad \text{(Eq. 4)}$$

where $l$ is the membrane thickness and $L$ is the lag time[16]. In the present study, extrapolation of the steady-state portions of the curve in Fig. 5 yielded lag times with high standard errors of the mean, and accurate values could not be determined. However, by utilizing radiolabeled carboprost methyl, the diffusion coefficient of the prostaglandin was determined to be $0.485 \times 10^{-7}$ ($\pm 0.020 \times 10^{-7}$) $cm^2$/sec. The C-15 methyl group is not expected to alter the diffusivity of this series, and the same value can be reasonably assumed for dinoprost methyl ester. The estimated values of $C_s$ for carboprost methyl and dinoprost methyl ester are 0.48 and 0.20 $mg/cm^3$, respectively. Methylation at the C-15 position of dinoprost methyl ester, therefore, appears to make the prostaglandin ester more lipophilic, resulting in increased transport rates.

Previous studies (26) demonstrated that substitution of a less polar carbonyl group for the hydroxyl moiety at C-9 (*i.e.*, dinoprost → dinoprostone) and the addition of lipophilic ester groups at C-1 significantly increase the transport rates of prostaglandins across silicone rubber. The agreement between the permeability constants in Table I for matrix release and membrane transport suggests that membrane transport studies can be used to predict *a priori* release profiles of prostaglandins from monolithic devices according to:

$$Q = \left[2Al\left(\frac{dQ}{dt}\right)_{ss}\right]^{1/2} t^{1/2} \quad \text{(Eq. 5)}$$

[15] Filler, such as silica, is incorporated in the polymer to increase its mechanical properties.

[16] This expression applies when the major resistance to diffusion resides in the membrane. It is valid for these prostaglandins since the resistance in the membrane is at least 100 times greater than in the diffusion layer.

and:

$$\text{rate} = \left[\frac{Al}{2}\left(\frac{dQ}{dt}\right)_{ss}\right]^{1/2} t^{-1/2} \qquad \text{(Eq. 6)}$$

where $(dQ/dt)_{ss}$ is the slope of the steady-state portion of the curve from a diffusion cell experiment (Fig. 5) and the other terms are as were defined. This approach is valuable in screening compounds to assess whether release rates are consistent with their biological dosing patterns.

# NOTES

# Synthesis and Antibacterial and Antifungal Activities of Alkyl and Polyhalophenyl Esters of Benzo[*b*]thiophene-3-carbamic Acid

**A. SHAFIEE ˣ, M. VOSSOGHI, J. WOSSOOGHI, and S. YAZDANI**

Received June 29, 1979, from the *Department of Chemistry, College of Pharmacy, Tehran University, Tehran, Iran.* Accepted for publication December 20, 1979.

**Abstract** □ Several alkyl and polyhalophenyl esters of benzo[*b*]thiophene-3-carbamic acid were prepared and tested for antibacterial and antifungal activities. Two compounds exhibited the highest activity of growth inhibition against some bacteria and fungi.

**Keyphrases** □ Antibacterial activity—alkyl and polyhalophenyl esters of benzo[*b*]thiophene-3-carbamic acid □ Antifungal activity—alkyl and polyhalophenyl esters of benzo[*b*]thiophene-3-carbamic acid □ Benzo[*b*]thiophene-3-carbamic acid—alkyl and polyhalophenyl esters, synthesis, antibacterial and antifungal activities

Dialkylaminoalkyl esters of benzo[*b*]thiophene-2-carboxylic acid[1] reportedly are useful as hypotensive, antiviral, and antifungal agents (1). Derivatives of benzo[*b*]-thiophene-2-carboxamide were reported to have local anesthetic and analgesic activities (2). Some carbamic acids having the benzo[*b*]thiophene moiety showed pesticidal, fungicidal, and insecticidal activities (3).

In continuing studies on the chemistry and antibacterial and fungicidal activities of carbamic acid esters (4–7), alkyl and polyhalophenyl esters of benzo[*b*]thiophene-3-carbamic acid were synthesized and their efficacy was determined.

## DISCUSSION

**Chemistry**—The desired compounds were prepared according to Scheme I.

The reaction of *N*-bromosuccinimide with readily available 3-chloromethylbenzo[*b*]thiophene (I) (8) afforded II. Hydrolysis of II gave benzo[*b*]thiophene-3-carboxylic acid (III) (9). Compound III was converted to benzo[*b*]thiophene-3-carboxyhydrazide (V) by a literature method (10). The hydrazide (V) then was transformed to the carboxazide (VI) by reaction with sodium nitrite in acetic acid. Curtius rearrangement of the azide was achieved readily through heating with alcohols or with polyhalophenols in refluxing benzene. The physical data of the compounds prepared are summarized in Table I.

**Antifungal and Antibacterial Activities**—All compounds listed in Table I were tested against *Candida albicans* (28012), *Penicillium not-*

[1] Benzo[*b*]thiophene also is known as thianaphthene.

# NOTES

# Synthesis and Antibacterial and Antifungal Activities of Alkyl and Polyhalophenyl Esters of Benzo[*b*]thiophene-3-carbamic Acid

**A. SHAFIEE ˣ, M. VOSSOGHI, J. WOSSOOGHI, and S. YAZDANI**

Received June 29, 1979, from the *Department of Chemistry, College of Pharmacy, Tehran University, Tehran, Iran.* Accepted for publication December 20, 1979.

**Abstract** □ Several alkyl and polyhalophenyl esters of benzo[*b*]thiophene-3-carbamic acid were prepared and tested for antibacterial and antifungal activities. Two compounds exhibited the highest activity of growth inhibition against some bacteria and fungi.

**Keyphrases** □ Antibacterial activity—alkyl and polyhalophenyl esters of benzo[*b*]thiophene-3-carbamic acid □ Antifungal activity—alkyl and polyhalophenyl esters of benzo[*b*]thiophene-3-carbamic acid □ Benzo[*b*]thiophene-3-carbamic acid—alkyl and polyhalophenyl esters, synthesis, antibacterial and antifungal activities

Dialkylaminoalkyl esters of benzo[*b*]thiophene-2-carboxylic acid[1] reportedly are useful as hypotensive, antiviral, and antifungal agents (1). Derivatives of benzo[*b*]-thiophene-2-carboxamide were reported to have local anesthetic and analgesic activities (2). Some carbamic acids having the benzo[*b*]thiophene moiety showed pesticidal, fungicidal, and insecticidal activities (3).

In continuing studies on the chemistry and antibacterial and fungicidal activities of carbamic acid esters (4–7), alkyl and polyhalophenyl esters of benzo[*b*]thiophene-3-carbamic acid were synthesized and their efficacy was determined.

## DISCUSSION

**Chemistry**—The desired compounds were prepared according to Scheme I.

The reaction of *N*-bromosuccinimide with readily available 3-chloromethylbenzo[*b*]thiophene (I) (8) afforded II. Hydrolysis of II gave benzo[*b*]thiophene-3-carboxylic acid (III) (9). Compound III was converted to benzo[*b*]thiophene-3-carboxyhydrazide (V) by a literature method (10). The hydrazide (V) then was transformed to the carboxazide (VI) by reaction with sodium nitrite in acetic acid. Curtius rearrangement of the azide was achieved readily through heating with alcohols or with polyhalophenols in refluxing benzene. The physical data of the compounds prepared are summarized in Table I.

**Antifungal and Antibacterial Activities**—All compounds listed in Table I were tested against *Candida albicans* (28012), *Penicillium not-*

[1] Benzo[*b*]thiophene also is known as thianaphthene.

[a] All compounds were crystallized from ether–petroleum ether.

*atum* (S-13), and *Aspergillus niger* (23171) *in vitro* using Sabouraud dextrose agar medium[2].

Each compound was dissolved in acetone to a concentration of 1 mg/ml. These solutions were diluted with hot culture medium to the desired concentrations and autoclaved at 120° for 2 hr. Five replicates of each concentration were prepared. The antifungal activity of all compounds tested, except VIIo and VIIr, was insignificant at a concentration of 10 μg/ml against *A. niger* and *C. albicans*, while most compounds were effective at this concentration against *P. notatum*. Griseofulvin was used as a control (Table II).

All compounds also were tested against *Bacillus subtilis* (NCTC 3610), *Staphylococcus aureus* (ATCC 6538), and *Escherichia coli* (ATCC 10536). Nitrofurantoin was used as a control. The compounds were dissolved in dimethylformamide and diluted to a 0.5% concentration. Standard paper disks with a 6-mm diameter were immersed in the solution and were placed on the inoculated assay medium surface[3].

All of the compounds tested, except VIIo and VIIr, had insignificant antibacterial activity against *S. aureus*. Compounds VII*m* and VIIo–VIIr exhibited moderate activity against *B. subtilis*. The activity of VIIo, VII*q*, and VIIr against *E. coli* was significant (Table III).

## EXPERIMENTAL[4]

**Benzo[*b*]thiophene-3-carboxylic Acid (III)**—A mixture of I (18.25 g, 0.1 mole) and *N*-bromosuccinimide (35.6 g, 0.2 mole) in 250 ml of carbon tetrachloride was irradiated with a 500-w lamp[5] while heating and stirring at reflux temperature for 4 hr. Then the reaction mixture was cooled and filtered, and the solvent was evaporated. The residue was made alkaline with 300 ml of 10% sodium carbonate solution and was heated with stirring on a steam bath for 2 hr. The mixture was cooled and extracted with 200 ml of benzene. Acidification of the aqueous sodium carbonate portion with 6 *N* HCl gave a precipitate. This precipitate was filtered and crystallized from benzene to give 4.4 g (55% yield) of III, mp 175–176° [lit. (9) mp 175–176°].

[2] These microorganisms were obtained from the Department of Parasitology, Public Health Institute, Tehran, Iran.

[3] BP (1968) antibiotic assay medium.

[4] Melting points were taken on a Kofler hot-stage microscope and are uncorrected. IR spectra were recorded using a Perkin-Elmer 267 spectrometer. NMR spectra were determined with a Varian T-60A instrument. Mass spectra were recorded on a Varian Mat III instrument.

[5] General Electric photospot lamp.

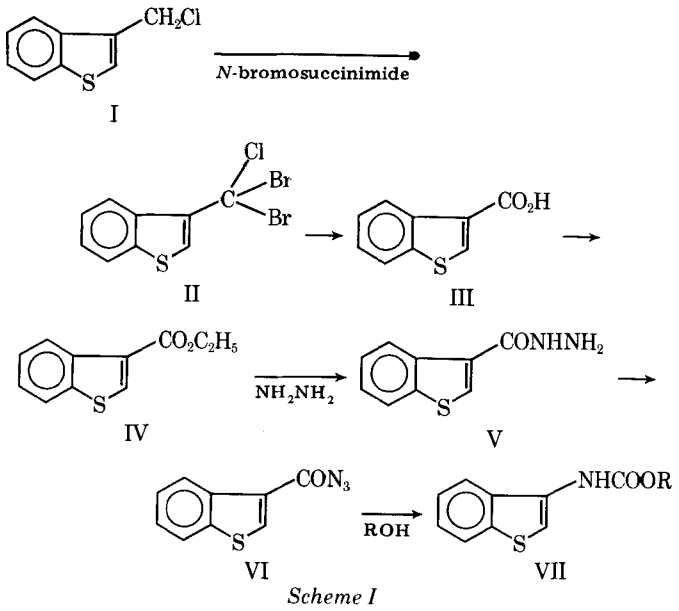

*Scheme I*

**Benzo[*b*]thiophene-3-carboxazide (VI)**—To a stirring solution of V (19.2 g, 0.1 mole) (10) in 200 ml of 50% acetic acid at 0° was added dropwise a solution of sodium nitrite (6.9 g, 0.1 mole) in 100 ml of water. The reaction mixture was stirred for an additional 30 min. The precipitate was filtered, washed with water, dried at room temperature under reduced pressure, and crystallized from ether–petroleum ether to give 4 g (76% yield) of VI, mp 103–105°; IR (KBr): 2170 (azide) $cm^{-1}$.

*Anal.*—Calc. for $C_9H_5N_3OS$: C, 53.20; H, 2.46; N, 20.69. Found: C, 53.45; H, 2.64; N, 20.85.

**Methyl Benzo[*b*]thiophene-3-carbamate (VII*a*)**—A solution of VI (2.03 g, 0.01 mole) in 20 ml of methanol was refluxed for 6 hr. The solvent was evaporated, and the residue was crystallized from ether–petroleum ether to give 1.70 g (82% yield) of VII*a*, mp 63–65°; IR (KBr): 3340 (NH) and 1700 (ester) $cm^{-1}$; NMR ($CDCl_3$): δ 8.10–7.33 (m, 5H, aromatic), 7.05 (broad s, 1H, NH), and 3.85 (s, 3H, $OCH_3$) ppm; mass spectrum: *m/z* (relative intensity) 207 ($M^+$, 100), 175 (57), 148 (39), and 121 (39).

*Anal.*—Calc. for $C_{10}H_9NO_2S$: C, 57.97; H, 4.35; N, 6.76. Found: C, 57.73; H, 4.51; N, 6.95.

Compounds VII*b*–VII*f* were prepared similarly (Table I).

**Phenyl Benzo[*b*]thiophene-3-carbamate (VII*g*)**—A solution of VI (2.03 g, 0.01 mole) and phenol (0.94 g, 0.01 mole) in 30 ml of dry benzene was refluxed for 5 hr, and the mixture then was filtered. The solvent was evaporated, and the residue was crystallized from ether–petroleum ether to give 1.61 g (60% yield) of VII*g*, mp 103–105°; IR (KBr): 3280 (NH) and 1710 (CO) $cm^{-1}$.

*Anal.*—Calc. for $C_{15}H_{11}NO_2S$: C, 66.91; H, 4.09; N, 5.20. Found: C, 66.72; H, 4.28; N, 5.38.

Compounds VII*h*–VII*r* were prepared similarly (Table I).

# Simultaneous Determination of Tetracaine and Its Degradation Product, *p*-*n*-Butylaminobenzoic Acid, by High-Performance Liquid Chromatography

**G. N. MENON and B. J. NORRIS** ˣ

Received January 18, 1980, from the *Department of Analytical Research, Abbott Laboratories, North Chicago, IL 60064.* Accepted for publication October 14, 1980.

**Abstract** □ A high-performance liquid chromatographic method was developed for the simultaneous determination of tetracaine hydrochloride and its hydrolytic degradation product, *p*-*n*-butylaminobenzoic acid. Separation was achieved using a μBondapak $C_{18}$ column and the eluent, water–acetonitrile–methanol (60:20:20), containing 0.06% (v/v) sulfuric acid, 0.5% (w/v) sodium sulfate, and 0.02% (w/v) sodium heptanesulfonate, at a flow rate of 2 ml/min. Salicylic acid and propiophenone were used as internal standards. The UV detector response at 305 nm was linear for tetracaine hydrochloride in the 0.4–2.0-mg/ml range and for *p*-*n*-butylaminobenzoic acid in the 0.003–0.02-mg/ml range. The method is simple and precise.

**Keyphrases** □ Tetracaine—determination by high-performance liquid chromatography □ *p*-*n*-Butylaminobenzoic acid—determination by high-performance liquid chromatography □ High-performance liquid chromatography—determination of tetracaine, *p*-*n*-butylaminobenzoic acid

Tetracaine, a widely used local anesthetic, is formulated either as a 1% solution in water or in combination with other *p*-aminobenzoic esters such as procaine and benzocaine. Hydrolytic degradation of tetracaine occurs in solution, resulting in the formation of *p*-*n*-butylaminobenzoic acid and diethylaminoethanol. *p*-*n*-Butylaminobenzoic acid is only sparingly soluble in water and potentially can cause crystal deposition in tetracaine hydrochloride injection.

## BACKGROUND

To study the ideal pH range for maximum stability of tetracaine hydrochloride in water, it was necessary to determine accurately the intact drug and the extent of *p*-*n*-butylaminobenzoic acid formation at various pH values. The USP method for the tetracaine hydrochloride assay involves extraction of the drug as its free base and back-extraction into dilute acid followed by spectrophotometry (1). Although theoretically *p*-*n*-butylaminobenzoic acid can be determined in the aqueous phase after basic extraction of tetracaine, the values are likely to be high due to the greater susceptibility of tetracaine to alkaline hydrolysis during analytical manipulations.

Therefore, it was necessary to develop a simple analytical scheme to determine both the intact drug and its degradation product, preferably by a single approach. The other available methods are measurement of refractive index, GLC, and partition chromatography (2–5), none of which is ideally suited for a simultaneous assay scheme.

This paper describes a high-performance liquid chromatographic (HPLC) method for the determination of both tetracaine and *p*-*n*-butylaminobenzoic acid in tetracaine hydrochloride injection. The same chromatographic conditions also are applicable to the analyses of several other local anesthetics.

## EXPERIMENTAL

The chromatographic system was equipped with a dual-piston reciprocating pump[1], universal injector[2], and a variable-wavelength UV detector[3]. The separation was performed on a 30-cm × 4-mm i.d. column containing microparticulate (10 μm) bonded octadecylsilane material[4]. The chromatographic peaks were electronically integrated and recorded[5].

**Eluent**—The eluent was water–acetonitrile[6]–methanol[6] (60:20:20) containing 0.06% (v/v) sulfuric acid, 0.5% (w/v) sodium sulfate, and 0.02% (w/v) sodium heptanesulfonate[7] (pH 2.6).

**Internal Standard Solutions**—A 10-mg/ml salicylic acid[8] solution in methanol–water (1:1) was used as the internal standard for tetracaine, and a 10-mg/ml solution of propiophenone[8] in methanol–water (1:1) was used as the internal standard for *p*-*n*-butylaminobenzoic acid.

**Standard Preparation**—The standard solution was prepared by weighing 50 mg of tetracaine hydrochloride USP reference standard into a 50-ml volumetric flask. Five milliliters of a 0.05-mg/ml *p*-*n*-butylaminobenzoic acid reference standard[9] in methanol–water (1:1), 20.0 ml of

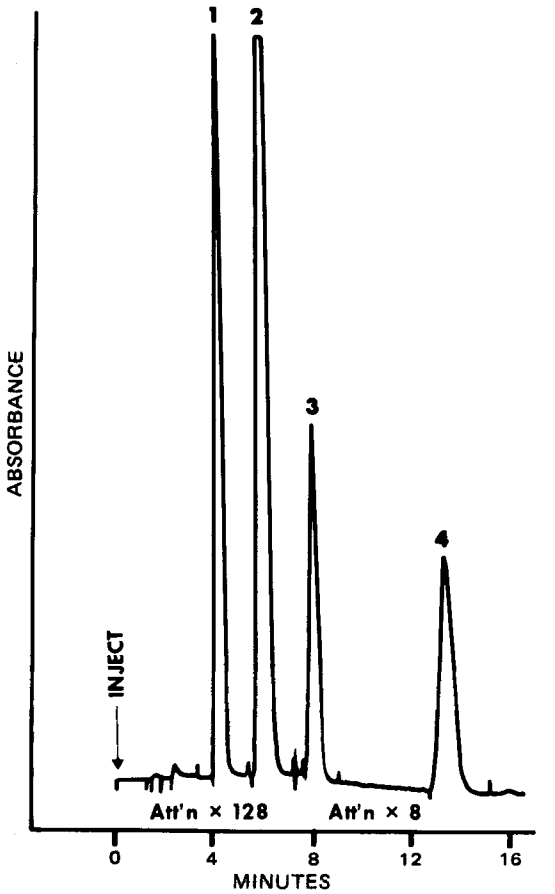

**Figure 1**—*HPLC analysis of tetracaine hydrochloride injection. Key: 1, salicylic acid; 2, tetracaine; 3, propiophenone; and 4,* p-n-*butylaminobenzoic acid.*

the salicylic acid internal standard solution, and 5.0 ml of the propiophenone internal standard solution were pipetted into the flask. The solution was diluted to volume with methanol–water (1:1).

**Sample Preparation**—The sample formulation contained 1% tetracaine in a solution of sodium chloride and acetone sodium bisulfite in water. Five milliliters of the formulation, 20 ml of the salicylic acid internal standard solution, and 5 ml of the propiophenone internal standard solution were pipetted into a 50-ml volumetric flask and diluted to volume with methanol–water (1:1). For analysis of formulations with suspected crystal deposition, it is necessary to homogenize the sample prior to analysis.

**Analysis**—The following chromatographic conditions were used for the analysis: flow rate, 2 ml/min; detector wavelength, 305 nm; and injection volumes for tetracaine hydrochloride and *p-n*-butylaminobenzoic acid, 5 and 50 μl, respectively. Quantitative analysis was accomplished by comparing the peak area ratios of the standard preparations to those of the sample preparations.

## RESULTS AND DISCUSSION

At the pH of the chromatographic eluent, both tetracaine and *p-n*-butylaminobenzoic acid were ionized and formed ion-pairs with heptanesulfonate. Figure 1 shows a typical chromatogram resulting from a 50-μl injection of the sample preparation. The linearity of the detector response was established for 5-μl injections of tetracaine hydrochloride in the 0.4–2.0-mg/ml range (*y*-intercept, 0.017; correlation coefficient, 0.9997) and for 50-μl injections of *p-n*-butylaminobenzoic acid in the 0.003–0.02-mg/ml range (*y*-intercept, 0.01; correlation coefficient, 0.9999). Since the peak area ratio for tetracaine analysis obtained from a 50-μl injection fell beyond the linear working range, the assay was performed using a 5-μl injection.

The accuracy and reproducibility of the method were demonstrated by replicate analyses of a simulated formulation that contained 10.0 mg of tetracaine hydrochloride/ml and was spiked with 0.050 mg of *p-n*-butylaminobenzoic acid/ml. The data generated from these analyses show that the method is accurate and precise.

For eight replicate analyses of a 10-mg/ml tetracaine hydrochloride injection spiked with 0.050 mg of *p-n*-butylaminobenzoic acid/ml, the results were: for tetracaine hydrochloride, 10.0 ± 0.12 mg/ml (*SD*), *RSD* = ±1.2%; and for *p-n*-butylaminobenzoic acid, 0.050 ± 0.0005 mg/ml (*SD*), *RSD* = ±1.0%.

Standard addition experiments also were performed to demonstrate method accuracy. Four formulations were prepared, containing tetracaine hydrochloride at levels ranging from 4 to 20 mg/ml and *p-n*-butylaminobenzoic acid at levels ranging from 0.03 to 0.2 mg/ml. These four formulations were diluted and analyzed according to the experimental conditions; recoveries of tetracaine hydrochloride varied from 98.3 to 101.4% with an average recovery of 99.5 ± 1.4%. Recoveries of *p-n*-butylaminobenzoic acid varied from 100.6 to 104.0% with an average recovery of 102.2 ± 1.7% for the four formulations; the tetracaine hydrochloride bulk drug used to prepare the formulations for the standard addition experiments contained <0.1% of *p-n*-butylaminobenzoic acid, which resulted in slightly higher recoveries of the added degradation product.

*p-n*-Butylaminobenzoic acid has low solubility in aqueous solution, which may result in crystal deposition of the degradation product in tetracaine hydrochloride injection subjected to long-term storage. No crystallization has been observed in actual formulations. However, when simulated formulations were subjected to hydrolytic degradation at high temperature (85°), crystal deposition occurred at concentrations of >0.6 mg of *p-n*-butylaminobenzoic acid/ml in the pH 3.15–5.15 range.

Figure 2 shows a chromatogram obtained from a mixture of six common local anesthetics analyzed with the same HPLC conditions. In the absence of either sulfuric acid or sodium sulfate in the eluent, butamben and pramoxine eluted together and the peaks had certain asymmetry. Slight increases in the capacity factors for the different solutes could be obtained by decreasing the salt concentration; this finding was in agreement with published data on salt effects (6).

Ion-pair reversed-phase chromatography permits simultaneous analysis of tetracaine hydrochloride and its hydrolytic degradation product. The described system has utility in analyzing several other local anesthetics with which it may be coformulated.

# Mass Transport Properties of Co(polyether)polyurethane Membranes I: Preparation and Characterization

**LLOYD E. MATHESON, Jr.** [x], **and WILLIAM A. HUNKE** *

Received September 4, 1979, from the *College of Pharmacy, University of Iowa, Iowa City, IA 52242.* Accepted for publication October 15, 1980. *Present address: Sterling-Winthrop Research Institute, Rensselaer, NY 12144.

**Abstract** □ A series of polyurethane copolymers containing polyethylene glycol 600, 1000, or 1540 was synthesized, purified by reprecipitation, and cast into clear, tough, flexible membranes using the solution method. The weight average molecular weight of each polymer was estimated by gel permeation chromatography. The ability of the various polymers to absorb water was measured and increased with the increasing molecular weight of the polyethylene glycol. The ability of the copolymer membranes to hold a pH gradient decreased with increasing polyethylene glycol molecular weight.

**Keyphrases** □ Model membrane systems—polyurethane copolymers, synthesis and analysis, mass transport properties □ Copolymers, polyurethane—model membrane systems, synthesis and analysis, mass transport properties □ Permeability—polyurethane copolymers, model membrane system, synthesis and analysis

Much attention has been focused on the use of polymeric materials as drug delivery (1, 2) and model membrane (3–5) systems. Most early work utilized polydimethylsiloxane which, while highly permeable to lipophilic drugs (6, 7), is only weakly permeable to hydrophilic, charged species (8). More recently, polymers known as hydrogels have been shown to control release of hydrophobic and hydrophilic agents. Variation in release rates can be controlled by changes in both monomer composition and the amount of cross-linking agent present (9–13).

## BACKGROUND

A promising approach for the development of new model membranes is to modify systematically the polymer structure to alter its diffusion characteristics. It was suggested (14) that the hydrophilic–hydrophobic character of a membrane may be controlled by the choice of suitable structural modifications. Membranes that combine the seemingly opposite properties of mechanical strength and the ability to swell in water have been prepared by simultaneous polymerization (copolymerization) of hydrophilic and hydrophobic reactants (15–17). The membranes formed from these copolymers permitted the transport of permeants at rates comparable to porous dialysis membranes but with the apparent selectivity of partitioning-type membranes (18).

Therefore, a series of copolymers composed of hydrophilic polyethylene glycol blocks and hydrophobic urethane segments was chosen for study. Since these polymers were not readily available commercially, it was necessary to synthesize them and to characterize some of their properties prior to diffusion work. These properties included the abilities of the membranes to hydrate and to maintain a pH gradient. A molecular weight distribution and weight average molecular weight of each polymer system also were determined.

## EXPERIMENTAL

**Materials**—Polystyrene standards[1] were used as received. Isopropylacetone[2] was purified by collecting the fraction boiling at 114–115° at atmospheric pressure, and methylenebis(4-phenyl isocyanate)[3] was distilled at 0.1–0.17 mm Hg. The colorless, clear fraction boiling at 147–151° was collected and stored in a freezer. 1,5-Pentanediol[2] was purified by distillation at 0.2–0.45 mm Hg, and the fraction boiling at 96–99° was collected. All distillates were stored in glass under dry nitrogen. Polyethylene glycols[4] 1540, 1000, and 600 were dried by the application of vacuum and heat for 4 hr. The flask then was flushed with dry nitrogen.

**Methods**—The average molecular weights of the polyethylene glycols were determined by end-group titration (19).

The synthetic procedures used to prepare the co(polyether)polyurethane polymers were similar to those outlined previously (16). Polyethylene glycol (0.012 mole) was dried in a 200-ml, three-necked, round-bottom flask equipped with a sealed polytef stirrer[5], a gas inlet valve, and a 200-mm West condenser fitted with a drying tube. The flask was heated to 110 ± 3°, and a suspension of 0.024 mole of methylenebis(4-phenyl isocyanate) in 25 ml of methyl sulfoxide and 25 ml of isopropylacetone was added to the polyethylene glycol with stirring. The flask was maintained at 110° for 1 hr while stirring continuously.

To the resulting clear, yellowish solution, 0.024 mole of 1,5-pentanediol and 0.016 mole of methylenebis(4-phenyl isocyanate) were added. An additional 2 hr of heating produced a viscous, yellowish solution. The polymer was isolated by pouring the solution into ~500 ml of distilled water, which produced a tough, rubbery, white precipitate. After washing with several volumes of distilled water, the polymer was dried in a heated vacuum desiccator[6] at 50°.

Individual polymer batches were blended and purified by precipitation in distilled water from a 5% (w/v) polymer solution in *N,N*-dimethylformamide. The reprecipitated polymer was washed with five 2000-ml portions of distilled water and placed in a vacuum oven for 48 hr. This procedure was carried out twice for each polymer synthesized.

The membranes were solution cast on plate glass sheets from a filtered 15% (w/v) polymer solution in *N,N*-dimethylformamide. The solution was filtered through a 0.5-μm filter[5] in a pressure filtration apparatus[7] using a 25–50-psi pressure head of dry nitrogen. The solution was spread on the glass plates with the aid of an adjustable doctor knife. The plates then were transferred quickly to an oven and dried at 50° overnight. The membrane was left on the glass plates, stored in a desiccator, and protected from light until used.

To test the effects of reprecipitating the polymer, pieces of membrane prepared from the polyethylene glycol 600 copolymer, either as originally obtained or reprecipitated (once or twice), were soaked in 30 ml of distilled water for 8 hr at 37°. An aliquot of each solution was filtered and then scanned from 240 to 350 nm.

Membranes were removed from the glass plates after hydration with 0.05 *M* phosphate buffer and were soaked for at least 20 min before use in buffer.

The thickness and diameter of both wet and dry membranes were measured by a method similar to that of Garrett and Chemburkar (20) at seven equally spaced points. The percent of water sorbed was determined by weight, and the percent swelling in thickness and diameter was determined by the difference between wet and dry measurements.

The weight average molecular weight of each synthesized polymer was estimated by gel permeation chromatography (21) using a series of gel permeation columns[8] ($10^5$, $10^4$, $10^3$, and 500 Å) with UV grade, nitrogen-blanketed tetrahydrofuran as the mobile phase.

Solutions of polystyrene (0.1–0.5%) calibration standards and polymer (0.5%) samples were prepared and chromatographed using a flow rate of 2.0 ml/min, a chart speed of 2.5 cm/min, and detector sensitivity at 0.5–1.0 aufs.

The intrinsic viscosity of the polystyrene standards in tetrahydrofuran at 25° was estimated using an empirical relationship (22), while the intrinsic viscosity of the polymer samples was measured using a capillary viscometer (23). Intrinsic viscosity was calculated as described previously (24, 25).

Table I—Effect of Polyethylene Glycol Content on Various Physical Parameters of the Co(polyether)polyurethane Membranes [a]

| Polymer Membrane | Polyethylene Glycol Content, % | Water Content in Hydrated Membrane, % | Swelling in Hydrated Membrane (Diameter), % | Swelling in Hydrated Membrane (Thickness), % | Apparent Wet Density, g/cm$^3$ | Apparent Dry Density, g/cm$^3$ |
|---|---|---|---|---|---|---|
| 600 | 37 | 9 | 3 | 1 | 1.26 | 1.24 |
| 1000 | 49 | 26 | 8 | 11 | 1.22 | 1.25 |
| 1540 | 56 | 49 | 14 | 28 | 1.12 | 1.24 |

[a] Average of three membranes.

The surface and cross section of each type of dried polymer membrane were examined using a scanning electron microscope[9]. The conditions used to visualize the sample were varied to optimize the resolution, while the magnification ranged from 100 to 40,000×.

A diffusion cell similar to that described by Flynn and Smith (26) was utilized.

To determine the ability of hydrogen ion to cross the membrane, the donor side of the diffusion cell was connected by tubing[8] from its sampling ports to a two-channel tubing pump[10] and an open donor solution reservoir. The receiving side of the diffusion cell was connected similarly in a closed loop to a glass-jacketed constant-temperature reservoir. A three-hole stopper sealed the reservoir and accommodated the receiving side tubing, a nitrogen inlet, and a pH electrode.

The pH-holding experiment was initiated by thoroughly flushing the receiving side reservoir with dry nitrogen. Exactly 50 ml of preheated 0.001 *M* NaCl was introduced into the nitrogen-blanketed receiving reservoir. The pH of this solution was taken as the zero-time pH reading. The experiment was begun by injecting ~15 ml of preheated 0.001 *M* HCl into the donor side connected to a 100-ml reservoir maintained at 37°. At the specified times, the tubing pump was stopped, and the solution in the receiving side reservoir was allowed to equilibrate for 1 min before the pH reading was taken. The two-channel tubing pump was set to deliver ~18 ml/min. The exact flow rate was determined prior to an experiment by measuring the amount of solution delivered in 3 min.

## RESULTS AND DISCUSSION

Batches of a co(polyether)polyurethane after blending, but prior to casting, were purified by reprecipitation. The efficiency of the procedure in the removal of UV-absorbing impurities from the polymeric material was demonstrated easily by the drop in absorbance at 240 nm from 0.65 prior to reprecipitation to zero after the second reprecipitation. No attempt was made to identify the impurities.

The molecular weight distribution for each polymer demonstrated a large, sharp spike of high molecular weight material followed by the lower molecular weight materials. The weight average molecular weights were 71,000, 28,000, and 34,000 for the 1540, 1000, and 600 copolymers, respectively. The actual values of the average molecular weight calculated for a given polymer are probably less important than the fact that large differences in molecular weight and molecular weight distribution among the polymers were not observed.

Physical measurements were made on the membranes in both the hydrated and dry state. The water content of the swollen membranes was directly proportional to the amount of glycol in the polymer (Table I). This finding is in agreement with the idea that the polyethylene glycol molecules serve as hydrophilic blocks that allow the membrane to swell in aqueous solution (18). The hydrophobic urethane linkages have been considered to act as cross-links between the polymer chains and to anchor the hydrated glycol segments (27).

Examinations of the surfaces and cross sections of each polymer membrane by scanning electron microscopy (resolution limit ~0.05 μm) showed uniform homogeneous structures with no unusual morphology and no apparent pore structure. From these results, it can be concluded that a porous structure, if it exists, would probably be <500 Å in diameter.

The ability of the membranes to maintain a pH gradient was studied since it may be an indication of the permeability of the membranes to ions (Fig. 1). The 600 copolymer membrane successfully maintained the pH gradient throughout the experiment (~1 hr), while the apparent diffusion coefficient for the 1000 and 1540 copolymer membranes were $6.9 \times 10^{-9}$ and $7.0 \times 10^{-8}$ cm$^2$/sec, respectively. The amount of glycol in the polymer molecules and, consequently, the amount of water sorbed do influence the capacity of the membrane to hold a pH gradient.

# Mass Fragmentographic Determination of Timolol in Human Plasma and Urine

**J. B. FOURTILLAN *x, M. A. LEFEBVRE, J. GIRAULT, and Ph. COURTOIS**

Received May 5, 1980, from the *Department of Chromatography and Mass Spectrometry Applied to Clinical Pharmacy, Faculté of Pharmacy, University of Poitiers, Poitiers, France.* Accepted for publication October 28, 1980. *Present address: Laboratoire de Pharmacie Chimique, U.E.R. de Médecine et de Pharmacie, 34, rue du Jardin des Plantes, 86034 Poitiers Cedex, France.

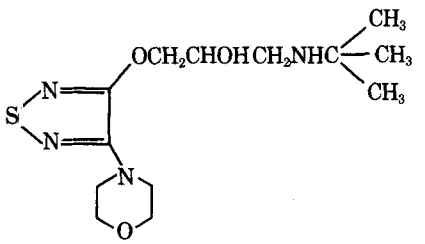
**Abstract** □ A mass fragmentographic procedure was developed for measuring quantities of <1.0 ng of timolol/ml of plasma or urine. The lower limit of sensitivity was 0.5 ng of timolol maleate/ml of plasma. The unchanged drug was extracted into heptane–4% isopentyl alcohol from alkalinized plasma or urine, together with propranolol hydrochloride as the internal standard. The compounds were subsequently back-extracted into 0.1 *N* HCl and then into chloroform following adjustment of the acidic phase to an alkaline pH. The chloroform layer was evaporated to dryness, and the compounds were derivatized with *N*-methyl-*N*-trimethylsilyltrifluoroacetamide–acetonitrile to form the trimethylsilyl derivatives; these derivatives were quantitated by mass fragmentography. Recovery of timolol added to normal plasma and urine was quantitative and reproducible, and no interfering substances were observed in normal biological samples. After a 20-mg oral dose of timolol maleate, plasma levels of ~3.0 ng/ml were observed at 12 hr.

**Keyphrases** □ Timolol—extraction, derivatization, mass fragmentographic determination, plasma and urine □ β-Adrenergic blocking agents—timolol, extraction, derivatization, mass fragmentographic determination, plasma and urine □ Mass fragmentography—determination, timolol, plasma and urine

Timolol maleate, (−)-1-(*tert*-butylamino)-3-[(4-morpholino-1,2,5-thiadiazol-3-yl)oxy]-2-propanol maleate, is a β-adrenergic receptor blocking agent with a high β-adrenergic inhibitor capacity. Due to the intensity of its effect, it is administered orally in small doses, varying between 10 and 20 mg, depending on the treatment needs. In addition, its high extravascular diffusion rate gives it an average apparent volume of distribution of 3.64 liters/kg. A low administered dose and a high apparent volume of distribution contribute to low plasma concentrations. For a proper pharmacokinetic study, assay techniques must be capable of measuring plasma levels as low as 0.5 ng of timolol/ml.

An electron-capture GLC determination of timolol in human plasma and urine was described by Tocco *et al.* (1). The lower limit of sensitivity was 2.0 ng/ml.

This report describes a mass fragmentographic procedure whose sensitivity threshold of 0.5 ng of timolol/ml of plasma enables plasma concentrations to be monitored for over 12 hr after oral administration of a 20-mg single dose of timolol maleate in a healthy adult.



I

## EXPERIMENTAL

**Reagents**—Timolol (I) was used as the maleate salt[1], and propranolol (II) hydrochloride[2] served as the internal standard. All concentrations were expressed in terms of the base salt. Pesticide quality *n*-heptane[3], isopentyl alcohol[3], methylene chloride[4], ethyl acetate[5], and acetonitrile[6] nanograde reagent were used without further purification. Hydrochloric acid, sodium hydroxide, and double-distilled water were used in the preparation of 0.1 *N* HCl and 1.0 and 2.0 *N* NaOH. *N*-Methyl-*N*-trimethylsilyltrifluoroacetamide[7] served as the reagent for preparing the trimethylsilyl derivatives of timolol and propranolol.

## EXPERIMENTAL

**Reagents**—Timolol (I) was used as the maleate salt[1], and propranolol (II) hydrochloride[2] served as the internal standard. All concentrations were expressed in terms of the base salt. Pesticide quality *n*-heptane[3], isopentyl alcohol[3], methylene chloride[4], ethyl acetate[5], and acetonitrile[6] nanograde reagent were used without further purification. Hydrochloric acid, sodium hydroxide, and double-distilled water were used in the preparation of 0.1 *N* HCl and 1.0 and 2.0 *N* NaOH. *N*-Methyl-*N*-trimethylsilyltrifluoroacetamide[7] served as the reagent for preparing the trimethylsilyl derivatives of timolol and propranolol.

**Apparatus**—The samples were analyzed on a GLC–mass spectrometer equipped for mass fragmentography[8] (M.I.D.). The gas chromatograph[9] was equipped with a 20-m × 0.03-cm glass capillary column with 2% OV1[10]. The gas chromatograph was operated isothermally with oven and injection temperatures maintained at 230 and 250°, respectively. The helium carrier gas flow rate was 10 ml/min. Other operating conditions were: source temperature, 260°; separator temperature, 240°; electron-impact energy, 35 ev; and trap current, 100 μamp. The M.I.D. program[11] was used with a computer[12].

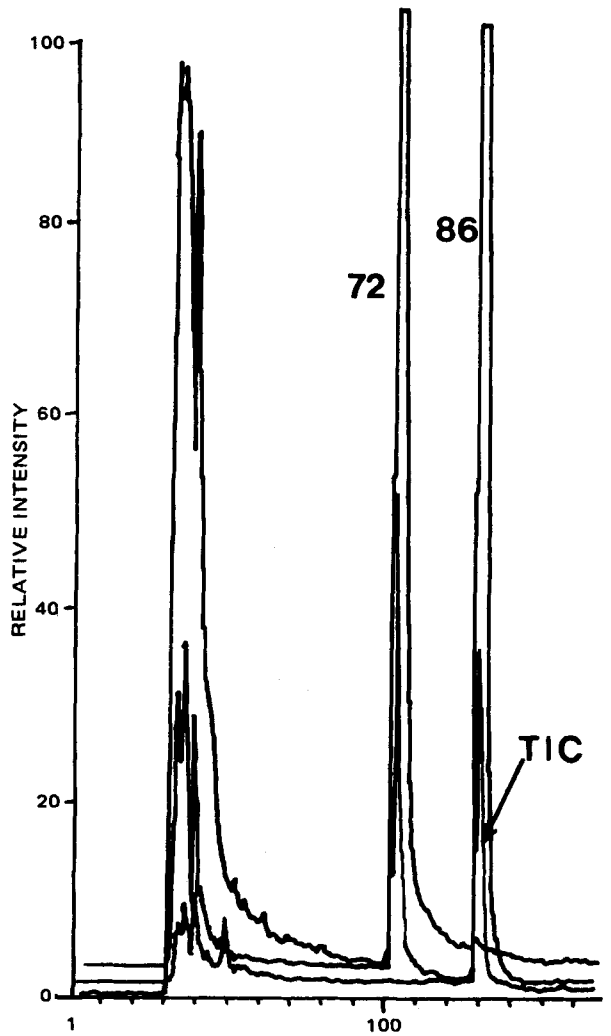

**Figure 1**—*Total ion current of a sample spiked with propranolol and timolol showing the traces of M − 72 and M − 86 fragments corresponding to the most abundant ions of trimethylsilyl derivations of propranolol and timolol.*

**Assay**—The extraction was similar to that described by Tocco *et al.* (1). In a 10-ml glass-stoppered centrifuge tube were placed 1.0 ml of plasma or 0.1 ml of urine, 50 μl of propranolol internal standard (stock solution, 1000 ng/ml of water), 0.1 ml of 1.0 *N* NaOH, and 7 ml of heptane–4% isopentyl alcohol. The mixture was shaken mechanically for 10 min and centrifuged. In a 10-ml glass-stoppered centrifuge tube were placed 1.0 ml of 0.1 *N* HCl and 6 ml of the organic phase.

After the tubes were shaken and centrifuged, the organic phase was discarded by aspiration. To the aqueous phase were added 0.2 ml of 2.0 *N* NaOH and 7.0 ml of methylene chloride. The samples were shaken for 10 min and centrifuged.The organic phase was removed carefully, and 6.0 ml was added to a 10-ml silanized glass-stoppered tube. The contents were evaporated to dryness in a 60° heating block under a nitrogen stream.

The residue was dissolved in 0.1 ml of *N*-methyl-*N*-trimethylsilyltrifluoroacetamide–acetonitrile reagent (10% in acetonitrile), and the stoppered tube was heated at 50° for 45 min. The tubes were cooled to room temperature, and then the contents were evaporated to dryness at 60° using a nitrogen stream. The residue was dissolved in 0.050 ml of ethyl acetate, and 2 μl was chromatographed.

The retention times of derivatized timolol and derivatized propranolol (internal standard) were 410 and 340 sec, respectively. GLC–mass spectrometric analysis showed that the products of silylation were the monotrimethylsilyl derivatives formed with the alcohol function of the lateral chain.

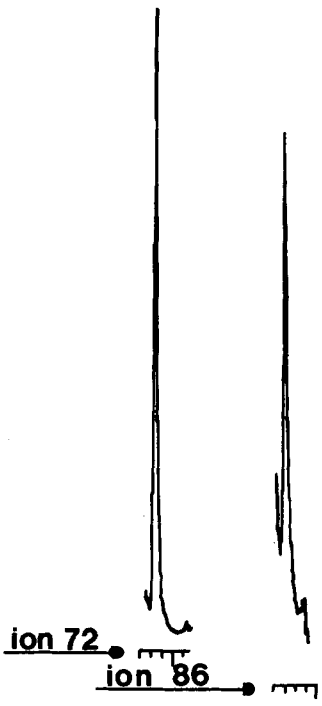

**Figure 2**—*Peaks obtained by mass fragmentography with plasma containing 50.0 ng of propranolol hydrochloride (amplification 20.0, m/z 72) and 1.0 ng of timolol maleate (amplification 150.0, m/z 86)/ml.*

| 12.00 | 0.8 | 7.2 | 1.4 | 3.8 | 2.7 | 3.2 ± 2.5 |

[a] $SEM = RSD/\sqrt{5}$.

The M − 72 and M − 86 fragments, which constituted the most intense fragments in the mass spectra of the trimethylsilyl derivatives of propranolol and timolol, respectively, were used for the mass fragmentographic determination of propranolol and timolol.

Two standard curves (0–10 and 10.0–100.0 ng/ml of plasma) were constructed by analysis of samples of control plasma containing known quantities of timolol and propranolol. The ratios obtained by dividing the intensities of ion 86 by ion 72 were expressed and plotted against the concentrations of timolol maleate, in nanograms per milliliter of plasma or urine. The regression line of the data corresponding to the experimental points was drawn through the origin. Concentrations of timolol maleate were determined by interpolation from the standard curves.

**Timolol in Human Plasma**—Five healthy human subjects (two women and three men) were given a single 20-mg oral dose of timolol maleate (two tablets[13] of 10 mg). Blood was collected in heparinized containers at intervals over 12 hr following the single dose. Plasma was separated by centrifugation and frozen until assayed.

## RESULTS AND DISCUSSION

Figure 1 shows a chromatogram obtained with plasma containing 50 ng of the internal standard and 50 ng of timolol (timolol maleate)/ml using total ion current detection. These peaks correspond to ions *m/z* 72 and 86 that were chosen for mass fragmentographic determination.

Blank plasma or urine samples gave no interfering peaks on the chromatogram. Metabolites of timolol with an unaltered lateral chain could interfere with the timolol peak, but their retention times are different. Two calibration curves prepared from two ranges of plasma levels (0–10.0 and 0–100 ng/ml of a same pool of plasma) indicated that intensity ratios of ions *m/z* 86 and 72 were linear when plotted against the concentrations of timolol maleate.

The lower limit of sensitivity was <0.5 ng of timolol maleate/ml of plasma or urine. Figure 2 shows the run obtained with a human plasma sample when 1.0 ng of timolol maleate was added to 1.0 ml of plasma. This concentration of timolol gave, for *m/z* 86, a peak height of ~100 mm with an amplification value equal to 150. The upper limit of linearity was at least 100 ng/ml. The coefficients of correlation were 0.9804 and 0.9948 for the low and high calibration curves, respectively.

[13] Timacor, Laboratoires Merck Sharp & Dohme, Chibret, Paris, France.

Repeatability assays were performed throughout the experiment on two pools of human plasma samples containing 1 and 50 ng/ml (Tables I and II). Timolol maleate concentrations were determined by interpolation from the corresponding standard curves. The mean concentrations (±*RSD*) were 0.96 ± 0.15 and 50.4 ± 2.1 ng of timolol maleate/ml of plasma with the low and high concentration plasma samples, respectively.

The lower limit of sensitivity for plasma levels expressed as the timolol salt is approximately five times lower than that obtained by Tocco *et al.* (1) using electron-capture GLC.

The accuracy of the technique is good since the relative standard deviation scarcely exceeded 16.0 and 4.2% of the averages obtained in the repeatability tests performed on plasma samples containing 1 (Table I) and 50 ng of timolol maleate/ml of plasma (Table II). These figures reflect an accuracy greater than that obtained with GLC analysis (1, 2).

This mass fragmentographic method is presumed to be specific for determining the intact compound in plasma and urine. The same procedure was applied to numefous urine samples in pharmacokinetic studies.

Plasma timolol levels were determined in five healthy human subjects over 12 hr following a single 20-mg oral dose of timolol maleate (Table III). Mean plasma timolol levels were near 3.2 ng/ml (Table III). The sensitivity level enables good approximate measurement of the plasma concentrations throughout pharmacokinetic studies. The terminal half-life of timolol was 2.62 ± 0.38 hr, and peak plasma levels of 82.5 ng/ml occurred at 1.55 hr after drug administration.

# Synthesis of [4-$^{14}$C]Theophylline

**MICHAEL G. WILLIAMS * and ALBERT M. MATTOCKS ˣ**

Received September 19, 1980, from the *School of Pharmacy, University of North Carolina, Chapel Hill, NC 27514.* Accepted for publication November 4, 1980. *Present address: College of Pharmacy, Medical University of South Carolina, Charleston, SC 29403.

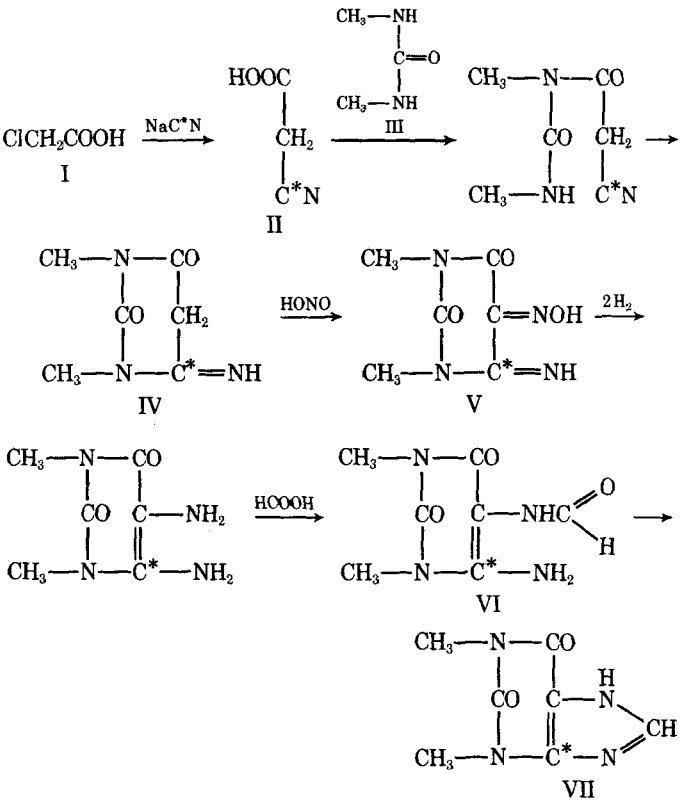
**Abstract** □ The synthesis of [4-$^{14}$C]theophylline is presented with the radiolabel introduced in the first step of the procedure. The label is carried stoichiometrically to theophylline, and yields are satisfactory. The position of the label at position 4 of the purine ring is attractive for discerning metabolic pathways of the drug.

**Keyphrases** □ Theophylline, radiolabeled—synthesis □ Radiolabeled compounds—[4-$^{14}$C]theophylline, synthesis □ Antiasthmatics—synthesis of [4-$^{14}$C]theophylline

Theophylline (3,7-dihydro-1,3-dimethyl-1*H*-purine-2,6-dione), used to alleviate symptoms of bronchial asthma, has been a popular drug for metabolic and pharmacokinetic studies (1–7). Problems inherent in determining its metabolic profile are compounded by the fact that other commonly ingested methylxanthines form metabolites in common with theophylline. In addition, some metabolites are similar to endogenous compounds.

The best method of distinguishing the metabolites of theophylline from those of its analogs or from other compounds is to insert a radiolabel in the purine ring. Theophylline synthesis has been accomplished (8–10), and a general method (8) was used (6) in [8-$^{14}$C]theophylline synthesis. This procedure calls for the insertion of the radiolabel during the last step of synthesis by adding [$^{14}$C]formic acid in excess to 1,3-dimethyl-4,5-diaminouracil. The reaction is stoichiometric with respect to the latter compound and results in yields of ~7.5% with respect to the label.

A high-yield synthetic procedure (Scheme I) was developed to introduce the carbon 14 label stoichiometrically to maintain a desired specific activity during synthesis and to avoid loss of the expensive $^{14}$C-labeled intermediate.



*Scheme I—Synthesis of [4-$^{14}$C]theophylline.*

## EXPERIMENTAL

**Materials**—The following reagent grade materials were used as supplied: chloroacetic acid, sodium carbonate, sodium cyanide, hydrochloric acid, ethanol, 1,3-dimethylurea, acetic anhydride, acetic acid, sodium nitrite, zinc dust, 90% formic acid, and sodium hydroxide. Sodium [$^{14}$C]cyanide[1] (54 mCi/mmole) was diluted with sodium cyanide to give a starting material with a specific activity of 0.72 mCi/mmole.

**[$^{14}$C]Cyanoacetic Acid (II) (11)**—A solution of 0.370 g of chloroacetic acid (I) in 0.6 ml of water at 50° was slowly made alkaline with 0.222 g of sodium carbonate. To the stirred solution at 0° was added dropwise 0.204 g of sodium [$^{14}$C]cyanide in 0.7 ml of ice water, keeping the temperature low. The clear solution was brought to room temperature for 30 min, heated to boiling for 5 min, cooled in an ice bath for 30 min, and slowly acidified with 0.47 ml of concentrated hydrochloric acid.

The clear solution was placed in a desiccator under vacuum until dry, and then the crystalline residue was taken up in 95% ethanol. The sodium chloride byproduct was removed by centrifugation and washed with several portions of alcohol. The combined alcoholic solutions were evaporated at 45° under reduced pressure, leaving a clear viscous concentrate of cyanoacetic acid (II) in alcohol. This material was stored in a desiccator until the last of the alcohol had evaporated and the product had crystallized.

**[4-$^{14}$C]-1,3-Dimethyl-4-amino-2,6-pyrimidinedione (IV) (12)**—To the cyanoacetic acid (II) were added 0.352 g of 1,3-dimethylurea (III), 0.82 ml of acetic anhydride, and 1 ml of acetic acid, and the mixture was heated at 60° for 3 hr. The clear solution became slightly orange. The acetic acid and excess anhydride then were removed as well as possible under reduced pressure without raising the temperature, leaving a burnt-orange viscous residue. This residue was dissolved in 8 ml of water and made alkaline by the slow addition of sodium carbonate and boiling for 2 hr. On cooling, a pale-yellow crystalline precipitate was formed. The yield was 0.375 g or 58% based on sodium cyanide.

**[4-$^{14}$C]-1,3-Dimethyl-4-amino-5-nitroso-2,6-pyrimidinedione (V) (9, 10, 13)**—The dried compound (IV) was dissolved in 8 ml of hot water, and 0.2 g of sodium nitrite was added with stirring. A mixture of 0.85 ml of acetic acid, 0.86 ml of water, and 2.6 g of ice was added in small portions with stirring. The solution turned deep red, and tiny dark-red crystals appeared. The solution was left in the refrigerator overnight to allow the complete precipitation of crystalline product. The product then was filtered out and dried in a desiccator. The yield was 0.420 g or 55% with respect to sodium cyanide.

**[4-$^{14}$C]-1,3-Dimethyl-4-amino-5-formamido-2,6-pyrimidinedione (VI) (10, 14)**—The nitrosated compound (V) was mixed with 0.36 g of zinc dust and placed in a 100-ml round-bottom flask equipped with a reflux condenser. Five milliliters of 90% formic acid was added to the mixture, and the apparatus was swirled continuously as the mixture heated spontaneously. The solution changed from oxblood to yellow over several minutes. The solution then was heated at 60° for 1.5 hr while 2 ml of acetic anhydride was added slowly. Finally, the mixture was cooled, the zinc formate was removed by filtration, and the clear yellow filtrate was dried under reduced pressure at 60°, leaving a solid residue with a yellow-white color. The residue was stored in a desiccator until completely dry.

**[4-$^{14}$C]Theophylline (VII) (10)**—Compound VI was dissolved in 4.5 ml of boiling water, and 0.36 ml of 40% NaOH was added dropwise with

[1] Sodium [$^{14}$C]cyanide, International Chemical and Nuclear Corp.

*0022-3549/81/0500-0576$01.00/0*
*© 1981, American Pharmaceutical Association*

vigorous stirring. The solution was heated for 10 min, at which time another 0.36 ml of 40% NaOH was added. Finally, 50% acetic acid was added in sufficient quantity to give a weak acid reaction. Pale-yellow crystals of theophylline precipitated on cooling. The yield was 0.370 g or 49% with respect to sodium cyanide. The crude theophylline was dissolved in a 10-fold quantity of boiling water, charcoal was added, and the hot solution was filtered. On cooling, white crystals of theophylline were formed.

## RESULTS AND DISCUSSION

A solution of [4-$^{14}$C]theophylline was prepared by dissolving 15.45 mg in sufficient deuterated dimethyl sulfoxide to make 1 ml, and an NMR[2] spectrum was taken with tetramethylsilane as an internal standard. It was identical to the spectrum of a commercial theophylline powder[3]. Furthermore, a methanolic solution of the synthesized compound was spotted on a silica gel plate and developed in chloroform–methanol (9:1) (15) along with a sample of commercial theophylline powder on the same plate. UV spectrodensitometry[4] at 274 nm showed the synthesized and commercial products to have identical $R_f$ values of 0.47; no other UV-absorbing compounds were detected. Scanning the plate with a radiochromatogram scanner[5] showed no measurable radioactivity except that associated with the theophylline peak. Two 0.02-ml samples of the radiolabeled product solution in deuterated dimethyl sulfoxide were counted by scintillation spectrometry[6], and the specific activity was calculated to be 0.69 mCi/mmole.

The introduction of a radiolabel within the purine ring of theophylline is desirable and advantageous in metabolism studies. The described synthesis gives a high yield based on the isotope and is stoichiometric as shown by the calculated and resultant specific activities of the product.

# Kinetics of Pharmacological Effects on Constant-Rate Intravenous Infusion

**Keyphrases** □ Pharmacokinetics—mathematical method for analysis of pharmacological effects on constant-rate intravenous drug infusion □ Mathematics—method for analysis of pharmacological effects on constant-rate intravenous drug infusion □ Kinetics—mathematical method for analysis of pharmacological effects on constant-rate intravenous drug infusion

*To the Editor:*

Over the last 10 years, great interest has developed in monitoring drug and metabolite concentrations in biological fluids to aid in optimizing individual patient drug therapy (1–6). Of course, such drug concentrations are only an indirect index of the ideal monitoring parameter, *i.e.*, pharmacological response. The theoretical bases for quantifying pharmacological response for reversible pharmacodynamic processes were examined thoroughly (7–10). These mathematical relationships were used to elucidate the kinetics of the pharmacological effect of tubocurarine (11–14), succinylcholine (15–17), lysergide (18–20), mercaptomerin (21), ethanol (22), warfarin (23, 24), theophylline (25), and cocaine (26). Each of these drugs elicits a pharmacological effect that can be accurately and reproducibly quantified. This report describes a method for elucidating pharmacokinetic properties following constant-rate intravenous infusion of drugs eliciting quantifiable, reversible pharmacological responses that are immediate, not delayed, effects.

The linear portion of the classic log concentration–response relationship can be described by (7):

$$E = m \log C + e \qquad \text{(Eq. 1)}$$

where $C$ is the concentration, $E$ is the response, $m$ is the slope of the linear portion of $E$ *versus* log $C$, and $e$ is the unit concentration intercept of $E$ *versus* log $C$. With the assumption of instantaneous drug distribution and first-order drug elimination, plasma drug concentration during constant-rate intravenous infusion can be described by the following function of time:

$$C = \frac{k_0}{Cl}(1 - e^{-Kt}) \qquad \text{(Eq. 2)}$$

where $k_0$ is the zero-order infusion rate, $Cl$ is the total body clearance, $K$ is the first-order elimination rate constant, and $t$ is time.

Substitution of Eq. 2 into Eq. 1 provides the relationship describing the pharmacological effect as a function of time during ongoing intravenous infusion:

$$E = m \log \frac{k_0}{Cl}(1 - e^{-Kt}) + e \qquad \text{(Eq. 3a)}$$

or:

$$E = m \log k_0 - m \log Cl + m \log (1 - e^{-Kt}) + e \qquad \text{(Eq. 3b)}$$

As infusion continues toward steady state, the term $e^{-Kt}$ approaches zero. Therefore, at steady state, Eq. 3*b* becomes:

$$E_{ss} = m \log k_0 - m \log Cl + e \qquad \text{(Eq. 4a)}$$

where $E_{ss}$ is the pharmacological effect at steady state. This relationship is most useful following conversion to the form:

$$E_{ss} = m \log k_0 - b \qquad \text{(Eq. 4b)}$$

where $b = m \log Cl - e$; $b$ is the $y$ intercept of $E_{ss}$ *versus* log $k_0$.

For a drug satisfying the prior assumptions, Eq. 4*b* indicates that a plot of the steady-state pharmacological effect *versus* the logarithm of the intravenous zero-order infusion rate is linear with a slope equal to $m$, the slope of the linear portion of the log concentration–response relationship.

Consider the time course of declining pharmacological effect. Rearrangement of Eq. 1 yields:

$$\log C = \frac{E - e}{m} \qquad \text{(Eq. 5)}$$

Postinfusion, monoexponential decline of the plasma drug concentration from the steady-state concentration ($C_{ss}$) achieved *via* constant-rate intravenous infusion is described by:

$$\log C = \log C_{ss} - \frac{Kt}{2.303} \qquad \text{(Eq. 6)}$$

Substituting for log $C$ and log $C_{ss}$ in Eq. 6 from Eq. 5 yields:

$$\frac{E - e}{m} = \frac{E_{ss} - e}{m} - \frac{Kt}{2.303} \qquad \text{(Eq. 7a)}$$

or:

$$E = E_{ss} - \frac{mK}{2.303}t \qquad \text{(Eq. 7b)}$$

Equation 7*b* indicates that a plot of postinfusion pharmacological effect *versus* time declines linearly from steady state, with the slope providing an estimate of the product of $K$ and $m$. Construction of plots of $E_{ss}$ *versus* log $k_0$ (Eq. 4*b*) and $E$ *versus* time, for effect declining from steady state (Eq. 7*b*), provides estimates of $m$ and $mK$, respectively, and thereby enables estimation of $K$. But knowing $K$, the biological half-life ($t_{1/2}$) is readily calculated from:

$$t_{1/2} = \frac{\ln 2}{K} \qquad \text{(Eq. 8)}$$

In addition to the assumptions stated in the original papers on this type of pharmacological effect model, inference of the pharmacokinetic behavior of a drug based on pharmacological effect data requires that no metabolites have measurable interfering pharmacological activity (27). If the decline of pharmacological effect is rate limited by the drug diffusion rate from the site of action, the reformation rate of an essential enzyme, or homeostatic control mechanisms, the apparent elimination rate constant calculated from the equations discussed in this paper will be representative of the rate-limiting process (11, 28).

This method was applied to data obtained from a previous study (29). In that study, 54 patients in a state of hypertensive emergency received sodium nitroprusside infusions in a dose-titration manner to achieve the desired hypotensive effect. Individual data were presented for four

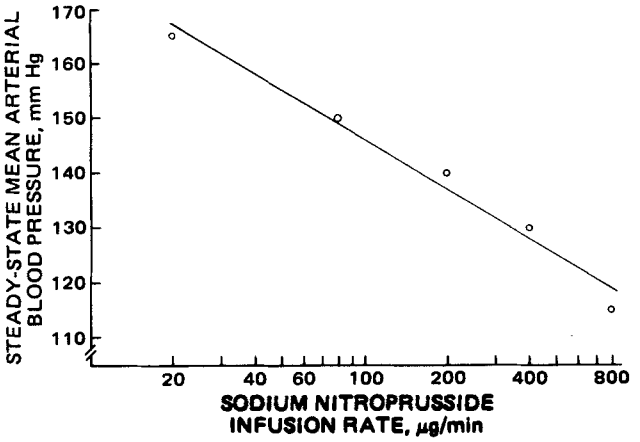

**Figure 1**—*Relationship between steady-state mean arterial blood pressure and sodium nitroprusside infusion rate in one patient with malignant hypertension. The linear regression line is shown (r = −0.99).*

representative patients. Data on one patient, a 45-year-old male with malignant hypertension, renal failure, and congestive heart failure, were presented in sufficient detail to permit the proposed analysis. In accordance with Eq. 4*b*, a linear relationship was obtained between steady-state mean arterial blood pressure and the logarithm of sodium nitroprusside infusion rate over a 40-fold range of zero-order infusion rates (Fig. 1). As shown in Fig. 2, plotting the time course of the hypotensive effect declining from steady state following discontinuation of sodium nitroprusside infusion illustrates adherence to Eq. 7*b*.

Calculation of the slopes in Figs. 1 and 2 provides direct estimates of $m$ and $mK$ of −30.1 mm Hg and 1.40 mm Hg/min, respectively. Therefore, $K$ can be estimated as 0.0465 $min^{-1}$ with a corresponding biological half-life of 14.9 min. This estimate of biological half-life is consistent with the rapidly achieved steady-state hypotensive response observed clinically. This relatively short half-life supports the prior interpretation of the mean arterial blood pressures in Fig. 1 as being reasonable approximations of steady-state values.

This analysis for sodium nitroprusside is exemplary of the potential utility of studying the pharmacokinetic properties of intravenously administered drugs eliciting a quantifiable response. Constant-rate intravenous infusion of a drug having a relatively short biological half-life will enable rapid achievement of steady state at each of the several infusion rates. Although this technique may not be applicable to all drugs, it may provide a basis for practical, exploratory analysis of pharmacological effect data for drugs such as nitroprusside, diazoxide, nitroglycerin, and trimethaphan.

## Plasma Theobromine after Oral Administration of Caffeine to Dogs

**Keyphrases** □ Theobromine—caffeine metabolite, plasma levels following oral administration of caffeine to dogs □ Caffeine—metabolism in dogs, plasma theobromine levels following oral administration of caffeine to dogs □ Metabolism—of caffeine, plasma levels of metabolite theobromine following oral administration of caffeine to dogs

*To the Editor:*

Caffeine (1,3,7-trimethylxanthine), a compound in coffee, tea, and many other beverages, has been used successfully for the treatment of apnea in premature infants

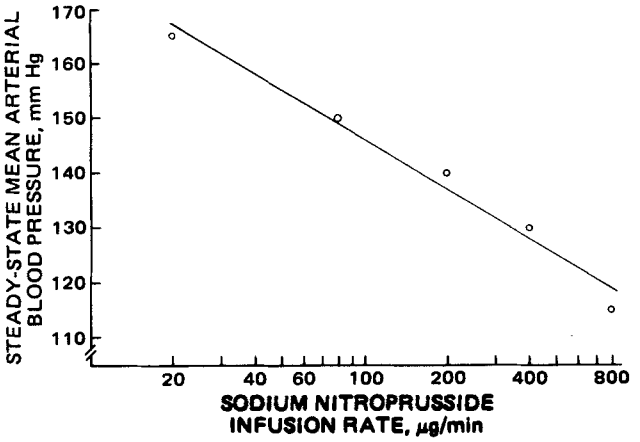

**Figure 1**—*Relationship between steady-state mean arterial blood pressure and sodium nitroprusside infusion rate in one patient with malignant hypertension. The linear regression line is shown (r = −0.99).*

representative patients. Data on one patient, a 45-year-old male with malignant hypertension, renal failure, and congestive heart failure, were presented in sufficient detail to permit the proposed analysis. In accordance with Eq. 4*b*, a linear relationship was obtained between steady-state mean arterial blood pressure and the logarithm of sodium nitroprusside infusion rate over a 40-fold range of zero-order infusion rates (Fig. 1). As shown in Fig. 2, plotting the time course of the hypotensive effect declining from steady state following discontinuation of sodium nitroprusside infusion illustrates adherence to Eq. 7*b*.

Calculation of the slopes in Figs. 1 and 2 provides direct estimates of $m$ and $mK$ of −30.1 mm Hg and 1.40 mm Hg/min, respectively. Therefore, $K$ can be estimated as 0.0465 $min^{-1}$ with a corresponding biological half-life of 14.9 min. This estimate of biological half-life is consistent with the rapidly achieved steady-state hypotensive response observed clinically. This relatively short half-life supports the prior interpretation of the mean arterial blood pressures in Fig. 1 as being reasonable approximations of steady-state values.

This analysis for sodium nitroprusside is exemplary of the potential utility of studying the pharmacokinetic properties of intravenously administered drugs eliciting a quantifiable response. Constant-rate intravenous infusion of a drug having a relatively short biological half-life will enable rapid achievement of steady state at each of the several infusion rates. Although this technique may not be applicable to all drugs, it may provide a basis for practical, exploratory analysis of pharmacological effect data for drugs such as nitroprusside, diazoxide, nitroglycerin, and trimethaphan.

## Plasma Theobromine after Oral Administration of Caffeine to Dogs

**Keyphrases** □ Theobromine—caffeine metabolite, plasma levels following oral administration of caffeine to dogs □ Caffeine—metabolism in dogs, plasma theobromine levels following oral administration of caffeine to dogs □ Metabolism—of caffeine, plasma levels of metabolite theobromine following oral administration of caffeine to dogs

*To the Editor:*

Caffeine (1,3,7-trimethylxanthine), a compound in coffee, tea, and many other beverages, has been used successfully for the treatment of apnea in premature infants

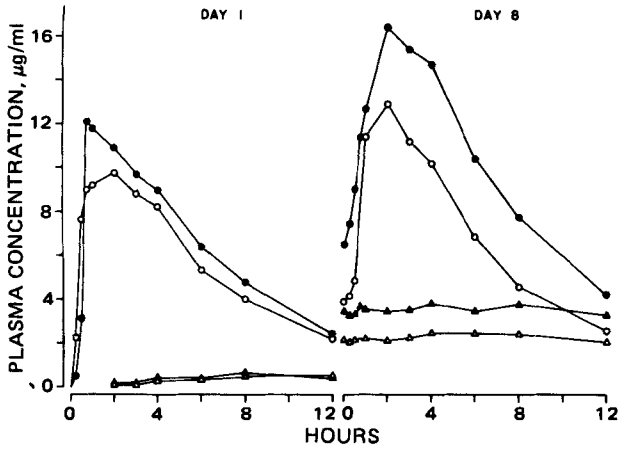

**Figure 1**—*Plasma concentrations of caffeine (●, Dog A; and ○, Dog B) and theobromine (▲, Dog A; and △, Dog B) after the morning doses on Days 1 and 8 during a 100-mg caffeine twice daily regimen.*

(1). Caffeine is absorbed efficiently following oral doses in humans and is eliminated almost entirely by biotransformation (2).

A first step in caffeine metabolism in humans is *N*-demethylation, which may occur at the 1-, 3-, or 7-position. It was suggested that the removals of the 3- and 7-methyl groups to form 1,7-dimethylxanthine and theophylline, respectively, are the major pathways, while the removal of the 1-methyl group to form theobromine is of minor importance (3). Nevertheless, 5% of an administered dose of caffeine was excreted as theobromine in rats (4). Another investigation found the same pathway in beagle dogs after single intravenous caffeine doses of 20 mg/kg (5).

In a recent study in this laboratory (6), the pharmacokinetics of caffeine were examined after single and repeated oral doses to beagle dogs. Theobromine was detected as a metabolite in plasma. Significant accumulation of this metabolite was observed after multiple caffeine doses, as described here.

Two beagle dogs (1-year-old male, Dog A, 11.4 kg, and 2-year-old female, Dog B, 11.7 kg) each received one 100-mg caffeine tablet[1] twice daily at 9:00 am and 9:00 pm for 8 days. The dogs were fasted overnight before the morning doses on Days 1 and 8, after which serial venous blood samples were collected. Plasma caffeine and theobromine were measured by high-performance liquid chromatography as previously described (6). Complete peak resolution was obtained for caffeine, theobromine, and β-hydroxyethyltheophylline (the internal standard), with retention times of 9.6, 4.0, and 6.5 min, respectively. Other xanthines did not interfere.

[1] NoDoz, Bristol-Myers, New York, N.Y.

Individual plasma caffeine and theobromine concentrations in the two dogs are summarized in Fig. 1. Caffeine was absorbed efficiently from a single oral dose, reaching the peak plasma level at 1–2 hr. The average elimination half-life calculated by nonlinear regression analysis (7) of individual data was 4.5 hr. Detectable theobromine levels appeared in the plasma at 2 hr following caffeine administration, rising slowly to 0.5–0.6 μg/ml at 8 hr. The peak time and normalized peak concentration showed excellent agreement with an earlier report (5). After repeated doses of caffeine, the drug showed some accumulation as predicted from the single-dose data. The average caffeine half-life was 3.9 hr, slightly shorter than the single-dose case. Of primary interest here, however, was the accumulation of the metabolite, theobromine. The Day 8 plasma levels, apparently at steady state, indicated a five- to six-fold increase from the single-dose data.

Results of the present study provided quantitative information on *N*-demethylation of caffeine in the dog to form theobromine. While plasma theobromine levels after a single caffeine dose were low, significant accumulation of this metabolite occurred after repeated caffeine administration. This phenomenon needs to be verified in humans. Since theobromine shares some of the common pharmacological activities of caffeine and theophylline (8), it may be necessary to recognize circulating levels of this metabolite when monitoring patients on caffeine therapy.

## REVIEWS

**Goodman and Gilman's The Pharmacological Basis of Therapeutics: 6th Ed.** Edited by ALFRED GOODMAN GILMAN, LOUIS S. GOODMAN, and ALFRED GILMAN. Macmillan, 866 Third Ave., New York, NY 10022. 1980. 1843 pp. 18 × 26 cm. Price $45.00.

This latest edition of L. S. Goodman and A. Gilman continues a time-honored tradition of serving as an accurate source of past and present knowledge upon which therapeutics is based. It differs from its predecessors, however, in the recognition that diseases are dynamic and that standard therapy is inadequate to meet the needs of a patient who, for example, has a myocardial infarction accompanied by diabetes mellitus. Much emphasis is placed on individualization of therapy, the need for compliance, and the results of noncompliance.

Principles of pharmacokinetics and biotransformation patterns appear in the early chapters and reappear in Appendix II under the heading Design and Optimization of Dosage Regimens along with pharmacokinetic data pertaining to oral availability, urinary excretion, plasma binding, and clearance of 100 widely used agents to expedite drug selection by the physician. The intervening chapters reflect those areas that have advanced rapidly in recent years—autonomic and antihypertensive agents, anti-inflammatories, autacoids, antineoplastics, and antimicrobials—and those that haven't—local anesthetics, cathartics, antianemics, salts and ions, vitamins, and oxytocics.

Looking back 4 decades at the first edition, when pharmacology was discarding the mantle of *materia medica* and computer technology was at the abacus stage, the reviewer is impressed with the amount of basic material then available, with the skill of the two authors who organized the information so logically and clearly, and with the realization that practitioners without an understanding of prodrugs, receptor configurations, pharmacokinetics, food and drug interactions, and the phenomena of tolerance and addiction could practice medicine reasonably well. In this edition, 55 contributors, some of whom are specialists in areas unheard of a few decades ago, have produced a noteworthy successor to earlier editions that will enable those who utilize therapeutic skills directly or indirectly in patient management to achieve a refinement in combating disease hitherto unequaled.

**Biochemical Applications of Mass Spectrometry: First Supplementary Volume.** Edited by GEORGE R. WALLER and OTIS C. DERMER. Wiley, 605 Third Ave., New York, NY 10016. 1980. 1279 pp. 21 × 28 cm. Price $150.00.

The editors of *Biochemical Applications of Mass Spectrometry: First Supplementary Volume* are to be congratulated on a job well done. Between the covers of this book (which are separated by 4.6 cm of pages), the novice and the experienced mass spectrometrist alike can find valuable information relating to a host of mass spectrometry-related topics. A section on instrumentation (spectrometers and data systems) is followed by one on the interpretation of mass spectra. Emphasis is on the data systems found in 10 of the leading mass spectrometry laboratories around the world and on computer-based identification of unknowns. Inclusion of a general chapter discussing the interpretation of spectra might have been desirable at this point.

These two sections are followed by the major section—applications—containing approximately 30 chapters covering nearly all of the topics in which biochemists and scientists in related fields would have an interest. Although many of these chapters discuss chemical-ionization and field-desorption-based analyses, this reviewer finds it unfortunate that no chapters are dedicated specifically to these two important techniques. Chapters discussing $^{252}Cf$ plasma desorption mass spectrometry and negative-ion mass spectrometry are included. The emphasis of most of the applications chapters is on structure elucidation, but quantitation is by no means ignored and Chapter 37 covers this topic exclusively. (I must disagree with the authors of this chapter on one point: isotope effects are not always "negligible," and a labeled compound need not behave "isographically" with the analogous unlabeled compound in all chromatographic systems.)

Some of the applications chapters are descriptive, and several are highly detailed and crammed with fragmentation pathways complete with mechanisms. Chapter 25 (flavor components) should be of special value to students and teachers involved in learning about basic mass spectrometry since it contains numerous fundamental fragmentation pathways plus simple but highly illustrative spectra. This chapter also answered a question some of us home gardeners have asked for years—what is the source of the characteristic aroma produced by tomato plant leaves. The answer—2-isobutylthiazole. Chapter 34 (Volatiles Emitted by Humans) reports on some "way-out" applications of mass spectrometry, but it is short on hard data.

Classic chapters include those on fatty acids, amino acids and amino acid sequencing, steroids, hormones, flavonoids, vitamins, and carbohydrates. Newer fields covered equally well are pheromones, drug metabolism, pollutants, and clinical medicine. The value of derivatization and GLC–mass spectrometry is made abundantly clear by many of the authors, and some speak with hope about liquid chromatography–mass spectrometry. All chapters contain useful lists of recent references.

This book should be a welcome addition to the libraries of natural products, synthetic organic and drug metabolism chemists, many persons involved in biological studies where structure elucidation and quantitation are necessary for advances, and researchers working on environmental problems.

*Reviewed by* William J. A. VandenHeuvel
*Merck Sharp & Dohme Research Laboratories*
*Rahway, NJ 07065*

The first supplementary volume continues the standard of excellence established in the original compendium of biochemical mass spectrometry [*cf.*, Book Reviews, *J. Pharm. Sci.*, **62**, 516 (1973)]. Largely written by the original authors, as the subtitle indicates, the discussions and the reference, figure, and table numbering continue from the earlier review. The editors have maintained consistent styles among the 35 chapters contributed by nearly 80 authors. Section I, Instrumentation, begins with a useful discussion of newer ionization and sample handling techniques (Chapter 2). Of less interest to the nonspecialist is the discussion on Data Acquisition and Processing in the following chapter.

Section II, Interpretation of Mass Spectra, describes the latest advances and utility of metastable ions as an aid to interpretation (Chapter 5). Compound Identification by Computer Matching (Chapter 6) might be helpful to those contemplating purchasing access to the MSDC/EPA/NIH MSSS system. On the other hand, the computer programs, the basis for the discussion on automated scientific inferences (Chapter 7), may not be readily accessible.

Section III, Applications, comprising 30 chapters and over 1000 pages, more than amply fulfills the editors' objective to promote mass spectrometric research capabilities and interests in a diverse group of investigators. Building on the discussions of the original volume, the experts chosen to write the individual chapters clearly develop guidelines for the interpretation of the various classes of compounds encountered in biochemistry and organic chemistry. Both the expert and novice would benefit from these reviews in the elucidation of unknown structures. The chapters in this section are filled with structures, fragmentation patterns, and mass spectra. Each review appears to have referenced the literature through 1977, with a significant number of them containing several references from 1978 and a few references from 1979. It should be relatively easy to locate the most recent articles working from the combined reference list of both volumes and Science Citation Index.

The negative-ion review is very timely. Notable omissions from the supplementary volume is the review of positive-ion chemical-ionization and field-ionization/desorption. More recent reviews should be consulted, rather than the original volume, for a background in these areas. The original volume, still in print, should be consulted for the more fundamental interpretation of the various classes of compounds. In summary, the complementary volumes should be in every book collection in institutions where mass spectrometry is being used.

# Derivation and Significance of Valence Molecular Connectivity

LEMONT B. KIER *x and LOWELL H. HALL ‡

Received September 8, 1980, from the *Department of Pharmaceutical Chemistry, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA 23298, and the ‡Department of Chemistry, Eastern Nazarene College, Quincy, MA 02170. Accepted for publication January 7, 1981.

**Abstract** □ The physical basis for valence molecular connectivity was studied. The $\delta^v$ and $\delta$ values are cardinal numbers describing the electronic structure of atoms in their valence states. The value $\delta^v + \delta$ describes the volume of a bonding atom while the value $\delta^v - \delta$ describes the electronegativity. By using the principle of electronegativity equalization, bond electronegativity is defined as $(\delta_i^v \delta_j^v)^{-1/2}$, and the valence molecular connectivity index ($^1\chi^v$) is derived as a sum of these bond descriptions. The valence chi index is interpreted in terms of the information encoded, describing both the volume and electronic characteristics of bonds in molecules. Examples of close relationships with molecular volume and electronic properties are shown. A new way of estimating valence state electronegativity is proposed from a count of exterjacent electrons divided by the quantum number squared for at least the first three quantum levels.

**Keyphrases** □ Molecular connectivity indexes—relationship between molecular volume and electronic composition, mathematical estimation of valence state electronegativity □ Structure–activity relationships—usefulness of molecular connectivity indexes, mathematical estimation, relationship between molecular volume and electronic composition □ Electronegativity—mathematical estimation, usefulness of molecular connectivity indexes, relationship between molecular volume and electronic composition

Molecular connectivity is a method for the quantitation of molecular structure that encodes information about size, branching, cyclization, unsaturation, and heteroatom content (1). It was developed in several stages, beginning with an alkane branching index proposed by Randic (2), a treatment of unsaturation (1, 3), a development of extended bond quantitation (4), and, finally, the most useful addition for the medicinal chemist, a rational way of quantifying heteroatom content (5). The treatment of heteroatoms, introduced by Kier and Hall (1) and called valence molecular connectivity, brought molecular connectivity into the role of a structure quantitation method useful in structure–activity analyses of drug molecules. Several investigators have employed valence molecular connectivity in structure–activity relationship analyses of drugs (Table I).

The growing use of molecular connectivity has resulted in an interest in the significance of the elements of the method and the meaning of the calculated indexes. Several misconceptions have arisen as a result of incomplete understanding of molecular connectivity or of previous bias grounded in physicochemical relationships to drug action. This study explores the fundamental basis of molecular connectivity.

## DISCUSSION

**Method**—The simple molecular connectivity index arises from the assignment of numerical adjacency values to each atom other than hydrogen (the molecular skeleton) in a molecule. These values, called $\delta$ values, are cardinal numbers enumerating the presence of nonhydrogenic-bonded neighbors, irrespective of what the element is or what multiplicity of bonding is present. The assignment of $\delta$ values for acetic acid is shown in Fig. 1*a*. The molecule is dissected into bonds, each described by two $\delta$ values.

A term for each bond ($C_{ij}$) is calculated according to $C_k = (\delta_i \delta_j)_k^{-1/2}$. These terms are summed over the entire molecule to give the simple molecular connectivity index of the first order ($^1\chi$):

$$^1\chi = \Sigma(\delta_i \delta_j)_k^{-1/2} = \Sigma C_k \qquad \text{(Eq. 1)}$$

Applied to acetic acid in Fig. 1*a*, the calculated value for $^1\chi = 3(1 \times 3)^{-1/2} = 1.732$.

An inspection of the acetone molecule in Fig. 1*b* shows an assignment of $\delta$ values. This set of $\delta$ values is the same as for acetic acid. It is possible that the $^1\chi$ value of 1.732 for both of these molecules is sufficiently descriptive so that certain general properties, *e.g.*, size and shape, may be predicted from a relating equation. However, it is more than likely that the obvious difference in the structures must be encoded to relate the molecules to many properties.

To accomplish the encoding of structural differences, Kier and Hall went beyond the structural fact of adjacency and considered the count of the valence electrons participating in sigma, pi, and lone-pair orbitals on each atom, exclusive of bonds to hydrogen. This count, again a cardinal number, is the valence delta ($\delta^v$) used to calculate a valence molecular connectivity index ($^1\chi^v$). The assignment of the $\delta^v$ value to an atom is based on the number of valence electrons ($Z^v$) not involved in bonds to hydrogen. Thus, $\delta_i^v = Z_i^v - h_i$, where $h_i$ is the number of bonded hydrogens on atom $i$. The significance of suppressing hydrogen in this count

| Reductase inhibitors | Benzohydroxamic acids | 38 |

will be discussed later. The calculation of $^1\chi^v$ proceeds exactly as described for the simple molecular connectivity index.

Figures 1*c* and 1*d* show the assignments of $\delta^v$ values to acetic acid and acetone, respectively. The calculated $^1\chi^v$ values are clearly different, 0.928 for acetic acid and 1.204 for acetone. Structural information is encoded in these two different values and also in the common value for the simple $^1\chi$ index. Studies have employed $^1\chi$ and $^1\chi^v$ indexes singly and in concert as structural descriptors in structure–activity relationship analyses. Since molecular information encoded in these $\chi$ values is derived from the $\delta$ values of the atoms, insight into the significance of molecular connectivity begins with analysis of the $\delta$ values.

**Significance of Delta**—Within the context of molecular connectivity, as developed by Kier and Hall, an atom in its valence state can be described by two cardinal numbers: $\delta$, the number of bonded neighbors (excluding hydrogen), and $\delta^v$, the number of valence electrons (excluding those bonding hydrogen). This dual description of atoms is revealed in the matrix shown in Fig. 2 for second quantum level atoms in their valence states. Superimposed on this same matrix are the hydrides of these atoms.

It is apparent that $\delta_i$ is a count of the nonhydrogen sigma-bond electrons contributed by atom $i$. It follows that $\delta_i^v$ is a more inclusive count of all valence electrons (not bonding to hydrogen), including those sigma electrons ($\sigma_i$) enumerated by $\delta_i$. Thus, the relationship is:

$$\delta_i^v = \delta_i + p_i + n_i = \sigma_i + p_i + n_i - h_i \qquad \text{(Eq. 2)}$$

where $p_i$ is the number of $p$ orbital electrons and $n_i$ is the number of lone-pair electrons on atom $i$. The values of $\delta^v$ and $\delta$ depend on the element represented, its valence (hybrid) state, and the number of bonded hydrogen atoms. Thus, from Fig. 2, $\delta = 2$; $\delta^v = 4$, 5, and 6 describes an $sp$ carbon, an $sp^2$ nitrogen, and an $sp^3$ oxygen, respectively. In contrast, $\delta^v$

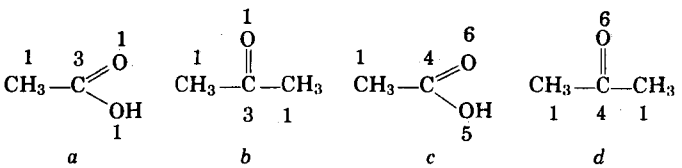

**Figure 1**—*Assignment of $\delta$ and $\delta^v$ values to heteroatom molecules. Key:* a, *acetic acid with simple $\delta$ values;* b, *acetone with simple $\delta$ values;* c, *acetic acid with valence $\delta^v$ values; and* d, *acetone with valence $\delta^v$ values.*

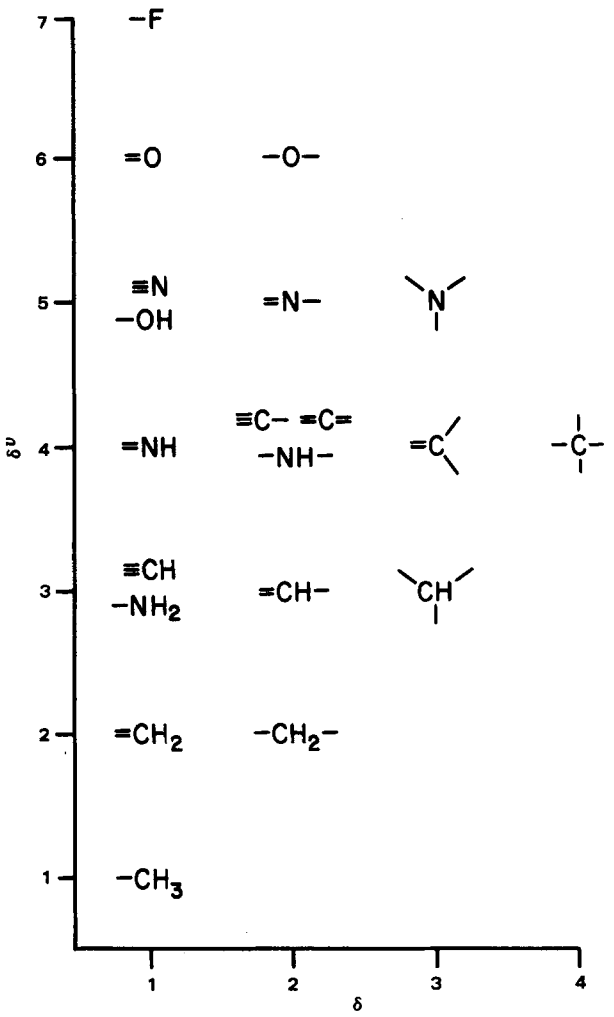

**Figure 2**—*Atoms (and hydrides) defined by $\delta$ and $\delta^v$ values.*

= 4; $\delta$ = 2, 3, and 4 describes an $sp$ carbon, an $sp^2$ carbon, and an $sp^3$ carbon, respectively.

Both $\delta^v$ and $\delta$ contribute to a description of the hybrid state of an element or hydride. With these two cardinal numbers, 20 second quantum level atom valence states and hydrides are described in the matrix in Fig. 2.

It might be anticipated that the information available from $\delta_i^v$ and $\delta_i$, when formulated into bond descriptions and ultimately summed to a molecular value, would be of considerable utility in ranking molecules according to physical property values and biological activities. A wealth of published experience confirms this expectation.

Two basically different kinds of information are encoded in the $\delta^v$ and $\delta$ values of atoms and groups shown in Fig. 2. First, since $\delta^v$ and $\delta$ count sigma, pi, and lone-pair orbitals, it is expected that the space occupied by these orbitals might be described. This orbital space defines the expanse of the atom in its valence state due to the number and kind of orbital domains of the atom. The measured or calculated volume of an atom (hence molecule) is a consequence of the number and kind of orbitals. The physicochemical manifestations of the volume (and closely related surface area) of a molecule are well known and are expected to be related to the volumes of the constituent atoms.

The second type of information expected from the $\delta^v$ and $\delta$ values of a covalently bound atom is of an electronic character. The numbers of sigma, pi, and lone-pair electrons must govern certain electronic properties that may be closely related to $\delta^v$ and $\delta$ of the atoms. When translated into bonds and molecules, this electronic information may bear a significant relationship to certain molecular properties.

**Volume Information from $\delta$ and $\delta^v$**—A number of investigators have dissected molecules into constituent fragment volumes to estimate the molecular volume. A notable contribution in this regard is the work of Bondi (6). Superimposing the Bondi atom volumes onto the $\delta^v$, $\delta$ matrix produces a pattern for direct comparison in Fig. 3.

Figure 3 reveals that the volume of the atom or hydride diminishes with

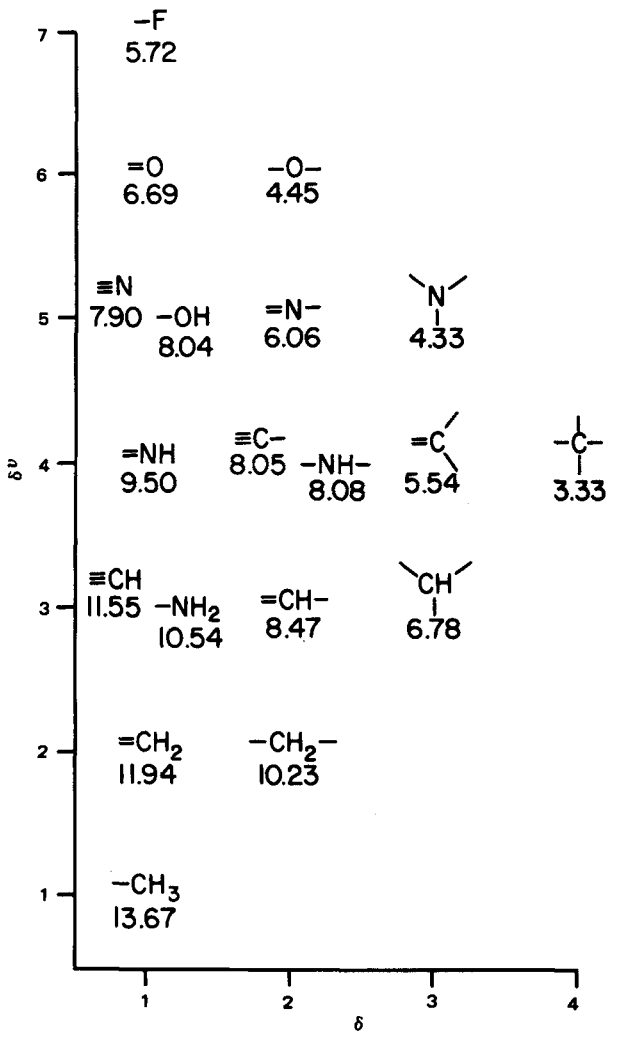

**Figure 3**—*Bondi atom and hydride volumes and $\delta^v$, $\delta$. The value for -O- is averaged from alkyl aryl ethers.*

an increasing $\delta^v$ value when holding $\delta$ constant. The volume also diminishes when $\delta$ increases for a constant $\delta^v$ value. These observations are not unexpected among cases where the number of hydrogens in the group diminishes. In cases where the fragment is a single atom in its valence state, the volume increases with an increase in the number of pi orbitals. This phenomenon occurs even though the number of valence electrons may be less. It is also apparent that the volume diminishes when the number of sigma electrons increases for a constant $\delta^v$ value.

From these observations, it is concluded that the structural features encoded by $\delta^v$ and $\delta$ act cooperatively to diminish the volume as numerical values increase. Such a relationship is revealed using regression analysis:

$$V_{\text{Bondi}} = 17.03 - 1.59(\delta^v + \delta) \qquad \text{(Eq. 3)}$$

$$r = 0.990 \quad s = 0.52 \quad n = 20 \quad F = 859$$

The calculated values are compared with the Bondi volumes in Table II. With Eq. 3, additional fragments and small molecules are predicted. The ability to predict fragment values where experimental data are lacking is an important consequence of this relationship.

So far, only second quantum level elements ($N = 2$) have been considered. A more general equation is possible, accounting for the greater distance of the valence electron orbitals from the nuclei in third quantum level atoms:

$$V_{\text{Bondi}} = 17.03 - 6.36\frac{(\delta^v + \delta)}{N^2} \qquad \text{(Eq. 4)}$$

where $N$ is the principal quantum number. For third-level atoms ($N = 3$), the equation predicts the volumes for -S- and -Cl of 11.38 cm$^3$/mole each, compared to 10.8 and 11.62 cm$^3$/mole from Bondi (6).

Bondi used the fragment values in a roughly additive way to estimate molecular volume. Empirically based correction factors were introduced to account for branching, cyclization, and other structural effects. The formalism of molecular connectivity achieves a similar result without tabulated correction factors. The $\delta$ values are used to describe bonds that are summed to give a molecular index. The molecular index ($^1\chi^v$) can correlate closely with experimental or computed volumes derived from various methods or procedures. For example, amino acid side-chain molar volumes in Table III correlate with a single-valence connectivity index, $^1\chi^v$ (7):

$$V(A)^3 = 29.46\,{}^1\chi^v + 36.30 \qquad \text{(Eq. 5)}$$

$$r = 0.989 \quad s = 3.93 \quad n = 18 \quad F = 696$$

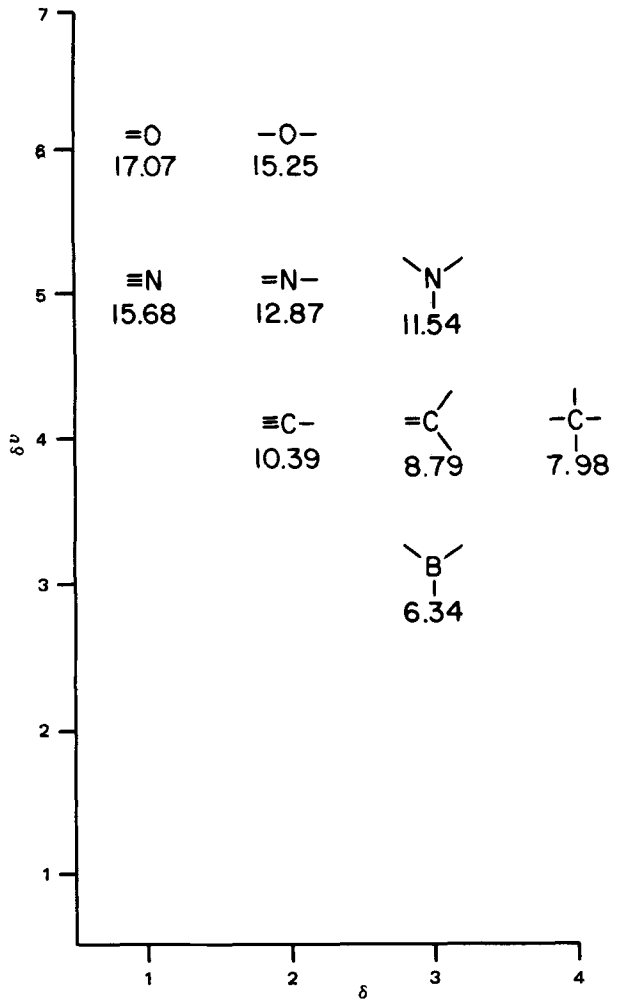

**Figure 4**—*Mulliken electronegativities and* $\delta^v$, $\delta$.

counts of electrons in sigma, pi, or lone-pair orbitals. The number and distribution of electrons certainly influence the electronic characteristics associated with atoms in the valence state. An obvious electronic property of a bonded atom in a molecule is electronegativity. Pauling (8) proposed this concept and defined it as a measure of the power of a chemically bonded atom to attract electrons to itself. Several measures of this characteristic were suggested, the most satisfactory being that of Mulliken (9). He computed electronegativity ($X_M$) as the average value of the ionization potential and the electron affinity. Expressed in electron volts, this value was computed for atoms in their bonding valence states (10). The electronegativity scale of Pauling (8) is more familiar to chemists but does not distinguish among hybrid states of the same atom, although they certainly have different electronegativities (10).

Figure 4 shows the Mulliken electronegativity values on the $\delta$, $\delta^v$ matrix for some second-row atoms. Inspection reveals some obvious trends. For constant $\delta^v = 4$, $\delta = 2$, 3, and 4 describes $sp$, $sp^2$, and $sp^3$ carbon atoms. Electronegativity diminishes in the same order. This electronic effect manifests itself in the decreasing acidity of the bonds:

$$\equiv C\text{–}H > =\overset{|}{C}\text{–}H > -\overset{|}{\underset{|}{C}}\text{–}H$$

As $\delta^v$ decreases for constant $\delta$, electronegativity decreases. The trends suggest that electronegativity is some function of $\delta^v - \delta$. For the nine second-row atom valence states in Fig. 4, the following relationship obtains:

$$X_M = 2.05(\delta^v - \delta) + 6.99 \qquad \text{(Eq. 6)}$$

$$r = 0.989 \quad s = 0.60 \quad n = 9 \quad F = 305$$

This correlation is excellent, with the standard deviation being less than the estimate of Hinze and Jaffe (10) due to uncertainties in the electron affinities. The intercept is close to the electronegativity of hydrogen (7.17 ev), which would have a $\delta^v - \delta$ value of zero.

The interpretation of Eq. 6 is clear. It states that the electronegativity of an atom in its valence state is closely related to the number of electrons in pi and lone-pair orbitals. This is apparent from the relationships:

$$\delta^v = \sigma + p + n - h \qquad \text{(Eq. 7}a\text{)}$$

$$\delta = \sigma - h \qquad \text{(Eq. 7}b\text{)}$$

$$\delta^v - \delta = p + n \qquad \text{(Eq. 7}c\text{)}$$

where $\sigma$ is the number of sigma bonding electrons other than to hydrogen. The observation that the electronegativity of a bound atom is due to the presence of pi and lone-pair orbitals leads to the conclusion that these electrons are inferior to sigma electrons on an atom in screening the core charge. This follows from the usual model that electronegativity manifests itself through sigma bonds; thus, electrons outside of these orbitals leave the core charge ($+Z^v$) less screened than when all valence electrons are sigma bonding ($Csp^3$).

The relationship can be made more general to include atoms of other rows by realizing that the nuclear attraction for valence electrons (hence, the electronegativity) must be related to their distance from the nucleus and the screening effect of intervening electrons. This distance effect may be approximated by the square of the principal quantum number, $N$ (11). The general expression relating the Mulliken electronegativities to the $\delta$ values for 19 atom valence states of the first, second, and third rows, which are prominent in forming covalent bonds, takes the form of:

$$X_m = 7.99\frac{\delta^v - \delta}{N^2} + 7.07 \qquad \text{(Eq. 8)}$$

$$r = 0.988 \quad s = 0.48 \quad n = 19 \quad F = 660$$

The $\delta^v$ value in Eq. 8 for third-row atoms is defined as $\delta^v = Z^v - h$. The usual expression $\delta^v = (Z^v - h)/(Z - Z^v)$ is not used since the use of $N^2$ corrects for the distance of the valence electrons from the nucleus and is more useful in relating the electronegativity directly to the count of exterjacent electrons, $\delta^v - \delta$. The two expressions are numerically very close.

The experimental and calculated results are shown in Table IV. The fifth column in Table IV, $(\delta^v - \delta)/N^2$, is the molecular connectivity valence state electronegativity. This value can be compared to the Pauling estimate of electronegativity by adding 2.5 to the value, although the Pauling value is for an atom irrespective of the valence state.

To conclude this section, it is stated that the number derived from $\delta_i^v - \delta_i$ for atom $i$ describes a property of a valence state atom closely approximated by the electronegativity. Also, the number derived from $\delta_i^v + \delta_i$ for atom $i$ describes a property of a valence state atom closely approximated by the van der Waals volume contribution to the molecule. Mathematically, $\delta_i^v - \delta_i$ and $\delta_i^v + \delta_i$ are orthogonal; that is, they are independent of each other. This orthogonality corresponds to the observation that the Bondi volume and the Mulliken electronegativities from Figs. 3 and 4 autocorrelate only to the extent of $r^2 = 0.21$. Orthogonal descriptors $\delta^v - \delta$ and $\delta^v + \delta$, simply derived from an inspection of atomic valence state structure and relating to electronegativity and van der Waals volume, should be of great practical use.

**Bond Formation**—The $\delta^v$ and $\delta$ values for atoms in their valence states encode information about the electronegativity of atoms. The electronegativity of atoms in bonds influences several properties including ionicity, bond dipole, partial atomic charge, and bond strength, all resulting from electronegativity equalization (12). The calculation of molecular connectivity indexes as a sum of bond indexes thus incorporates some information about electronic structure, encoded in the $\delta$ values.

The $\delta^v$ and $\delta$ values contain information about electron domains or orbitals associated with atoms. Thus, a volume characteristic is encoded in the $\delta$ values. As a result, molecular connectivity indexes contain volume information. With the structural and physical significance of $\delta^v$ and $\delta$ revealed, it is possible to derive the bond index encoding information about structure and properties. A series of concise statements develops this index.

1. The $\delta^v$ value is the number of nonhydrogenic valence electrons on an atom. The $\delta$ value is the number of $\delta^v$ electrons participating in nonhydrogenic $\sigma$ bonds from an atom.

2. The properties of electronegativity and volume encoded in $\delta_A^v$ for an atom ($A$) are considered to be contributed equally from all valence electrons or their orbitals. Thus, one electron from atom $A$ forming one $\sigma$ bond will possess the fraction $1/\delta_A^v$ of the properties encoded in $\delta_A^v$.

3. Atom $A$ brings to the bond $A$–$B$ the fraction $1/\delta_A^v$ of the properties encoded by $\delta_A^v$. Atom $B$ brings to the same bond the fraction $1/\delta_B^v$ of the properties encoded by $\delta_B^v$.

[a] From Ref. 9. [b] From Eq. 8.

4. If the property under consideration is the electronegativity, then orbitals from $A$ and $B$ contributing the fractions $1/\delta_A^v$ and $1/\delta_B^v$, respectively, will become adjusted toward an equal intermediate electronegativity, which may be ascribed to the bond. This principle of electronegativity equalization was set forth by Sanderson (12, 13), who proposed that the geometric mean of the atom electronegativities leads to the best description of the bond electronegativity.

5. From Sanderson (12, 13), $[(1/\delta_A^v)(1/\delta_B^v)]^{1/2}$ is the algorithm appropriate for two bonded atoms. This algorithm is identical to the molecular connectivity description of a bond (1) as shown in Eq. 1.

6. The volume contributed by atom $A$ to a bond $A$–$B$ is the fraction $1/\delta_A^v$ of the total. The fraction $1/\delta_B^v$ is the volume contributed from atom $B$. The bond has a "volume" due to orbital overlap that can be approximated by 2 $[(1/\delta_A^v)(1/\delta_B^v)]^{1/2}$. With a constant of 2, $[(1/\delta_A^v)(1/\delta_B^v)]^{1/2}$ reflects the relative volume of the bond $A$–$B$. This is the same expression describing the electronegativity of the $A$–$B$ bond from statement 5.

7. The orthogonal expressions $\delta_A^v - \delta_A$ and $\delta_A^v + \delta_A$ reflect the electronegativity and volume of atom $A$, respectively. What is the role of $\delta_A$ in the calculation of $^1\chi^v$? Each $\delta_A^v$ appears $\delta_A$ times in the summation of $[(1/\delta_A^v)(1/\delta_B^v)]^{1/2}$ to give $^1\chi^v$. Thus, $^1\chi^v$ can be expected to correlate with some properties related to molecular volume and electronic character.

**Hydrogen Suppression**—It has been stated that hydrogen atoms are "suppressed" in the count of valence electrons and bonding neighbors to an atom (1). Thus:

$$\delta^v = Z^v - h \qquad \text{(Eq. 9}a\text{)}$$

$$\delta = \sigma - h \qquad \text{(Eq. 9}b\text{)}$$

where $Z^v$ is the number of valence electrons, $h$ is the number of hydrogens, and $\sigma$ is the number of bonding sigma electrons. The hydrogen influence in reality is subsummed into modified $\delta^v$ and $\delta$ values reflecting the number of hydrogen atoms on the atom in question. The $\delta^v$ value in combination with the $\delta$ value thus is a description of an atom possessing volume and electronegativity characteristics associated with the hydride group, which is treated as a single atom. The $\delta^v$ and $\delta$ values accurately reflect the volume of the hydrides as seen in Table II. The $\delta^v$ and $\delta$ values for hydride groups also correctly order the group electronegativities of OH, $NH_2$, SH, and $CH_3$, based on various estimates of these values. Thus, from Eq. 8, the predicted group electronegativities are $X_M(OH) = 15.07$, $X_M(NH_2) = 11.07$, $X_M(SH) = 10.63$, and $X_M(CH_3) = 9.07$, all on the Mulliken scale.

The uniform exclusion of hydrogen makes the electronegativity and the volume of this atom a reference point. Note that in Eq. 8 relating to Mulliken electronegativity, the $y$ intercept (when $\delta^v - \delta = 0$) is the electronegativity of hydrogen. Similarly in Eq. 4 relating to the Bondi fragment volume, the $y$ intercept (when $\delta^v = \delta = 0$) for methane is the value of the $sp^3$ carbon fragment plus all four hydrogen atoms.

**Index for a Molecule**—The index for the molecule, $^1\chi^v$, is written as a summation of the bond terms:

$$^1\chi^v = \Sigma(\delta_i^v\delta_j^v)^{-1/2} \qquad \text{(Eq. 10)}$$

This is the valence molecular connectivity index of first order since it is summed over all bonds that are single-path fragments of the molecule.

Valence molecular connectivity is built on the sigma electron or interjacent electron framework of the molecule. The presence of an atom, $i$, with nonsigma valence electrons, pi, or lone-pair electrons, which can be called exterjacent electrons, results in the fraction $1/\delta_i^v$ being smaller than $1/\delta_i$. The value of $^1\chi^v$ for the molecule containing atom $i$ with exterjacent electrons reflects the total number of bonds and their adjacency, but it also reflects the diminished value, $1/\delta_i^v$, due to the presence of exterjacent electrons on atom $i$.

With the data in Table V, a series of comparisons reveals the encoded structural information in $^1\chi^v$ values. Molecule 1, butane, is the reference structure where all $\delta_i^v = \delta_i$; hence, $^1\chi^v = {}^1\chi = 1.914$. There are no exterjacent electrons so $^1\chi - {}^1\chi^v = 0$.

Molecules 2 and 3 in Table V are four-atom amines (excluding hydrogens), each with two exterjacent electrons on the nitrogen. Since the positions of the nitrogen atoms in the chains are different in each case, the fractional contributions of valence electrons forming nonhydrogenic

**Table V—Information Encoded in $^1\chi^v$ and $\delta^v$ Values for Four-Atom Chains with $\delta$ Values of $A^1$–$B^2$–$C^2$–$D^1$**

| Number | Molecule | $A$ | $B$ | $C$ | $D$ | $^1\chi^v$ | Exterjacent Electrons | $^1\chi - {}^1\chi^v$ |

| Methanol | 0.447 | 32.80 |
| Water | 0 | 78.0 |

bonds are different. The nitrogen in Molecule 2 contributes one-third $[(1/\delta^v_N) = 1/3]$ of its nonhydrogenic valence electrons to form one sigma bond to carbon. The nitrogen in Molecule 3, contributes one-fourth $[(1/\delta^v_N) = 1/4]$ of its nonhydrogenic valence electrons to each of two sigma bonds with adjacent carbons. The indexes for bonds *B–C* and *C–D* thus are different for these cases. As a consequence, the $^1\chi^v$ indexes are different for Molecules 2 and 3, and each, in turn, is different and less than the value for Molecule 1.

Viewed in terms of valence electron structure information, it is obvious that in Molecule 2 the nitrogen bonds only once to a carbon and, therefore, participates only once as an amine group in an electronegativity equalization event (12). In Molecule 3, the nitrogen is located midchain and, therefore, participates in two bonds to carbons, with two opportunities to participate in electronegativity equalization. Clearly, electronically governed properties differ and are potentially correlated with the $^1\chi^v$ values. The formation of two sigma bonds by nitrogen in Molecule 3 leads to two electronegativity equalization events, resulting in a greater buildup of charge on the nitrogen in Molecule 3. Thus, Molecule 3 is more basic than Molecule 2. Within closely related amines, the $^1\chi - {}^1\chi^v$ difference appears to parallel this effect. It follows that $^1\chi - {}^1\chi^v$ for trimethylamine is 0.390, suggesting that it is more basic than Molecule 3. This is true in the gas phase.

The two amines, Molecules 2 and 3, have the same number and kind of atoms. They differ from the reference structure, butane, by having two exterjacent electrons on one atom. The calculated $^1\chi^v$ value reflects both the presence of the exterjacent electrons and the adjacency relationship of that atom (nitrogen) to other atoms in the molecule. The diminished value of $^1\chi^v$ for Molecule 3, relative to butane and to its positional isomeric amine, parallels structural differences that can be interpreted in electronic terms such as relative charge and basicity.

As a companion to the electronic interpretation of the information encoded by the different $^1\chi^v$ values, the volumes are expected to be different. Thus, properties governed by volume are expected to, and have been shown to, parallel the calculated $^1\chi^v$ values for a series of amines (1).

In Molecules 4 and 5 (Table V), oxygen is the atom contributing exterjacent electrons to the molecules. The same pattern of results is found as for the amines. The terminal oxygen in Molecule 4 with six valence electrons has a bonded hydrogen; hence, $\delta^v = Z^v - h = 6 - 1 = 5$. Thus, $(1/\delta^v) = 1/5$ describes the sigma electron fraction forming a hydroxyl oxygen bond to a carbon. Only one sigma bond involves the hydroxyl oxygen group. In Molecule 5, the $\delta^v$ for oxygen is 6; hence, $(1/\delta^v) = 1/6$ describes each of two sigma electrons bonding to two adjacent carbons. Electronegativity equalization and atom volume overlapping are possible through two bonds in Molecule 5 but only one in Molecule 4. The greater $^1\chi - {}^1\chi^v$ calculated for Molecule 5 reflects the consequences of this greater degree of adjacency. Note also that the $^1\chi^v$ for Molecule 4 is less than that of Molecule 2 (and 5 is less than that of 3), reflecting more exterjacent electrons on the oxygen-containing molecules. A physical manifestation mirroring this result is the lower ionization potentials of ethers relative to alcohols of the same size. A lone-pair electron is the one lost in this process.

**Table VII—Relative Benzene-Likeness of Hydrocarbons and Heterocycles**

| Molecule | $^1\chi^v$ | $^1\chi^v$/Bonds | $B^a$ |
|---|---|---|---|
| Benzene | 2.000 | 0.333 | 1.00 |
| Naphthalene | 3.405 | 0.310 | 0.93 |
| Phenanthrene | 4.815 | 0.301 | 0.90 |
| Anthracene | 4.808 | 0.300 | 0.90 |

[a] Benzene-likeness from [$^1\chi^v$/bonds (for molecule)]/[$^1\chi^v$/bonds (for benzene)].

Molecules 6 and 7 in Table V describe a different situation. In these isomeric alkenes, there are two exterjacent electrons but they are not paired on the same atom, as with the amines; they are located on adjacent atoms. Thus, the $\delta^v$ values for Molecule 6 are different from the reference butane structure in the case of two atoms. This situation is typical of an unsaturated bond. As a consequence, of the three bond indexes calculated for each alkene molecule, two differ from the reference molecule for Molecule 6 and all three differ for Molecule 7. Thus, the $^1\chi^v$ for Molecule 7 is lower than that for Molecule 6. The lower $^1\chi^v$ value for Molecule 7 relative to Molecule 6 presages a greater availability of the pi electrons. Thus, Molecule 7 reacts faster with electrophiles and has a lower heat of hydrogenation and a lower ionization potential.

By extending this list of four-atom molecules in Table V, it can be seen that with an increasing number of exterjacent electrons, $^1\chi^v$ decreases. The series might be called an increasing "exterjacency series." There is a parallel with physical experience relating to stability, polarity as a solvent, and chemical reactivity. Table VI ranks common solvents by polarity, expressed as the dielectric constant correlating with $^1\chi^v$. The relative exterjacency, encoded in the $^1\chi^v$ value, manifests itself as a structural description in another way. For benzene, for example, the simple $\delta$ values for the ring atoms are uniformly 2. The $^1\chi$ value is 3.000. In contrast, the $\delta^v$ values are uniformly 3, leading to a $^1\chi^v$ value of 2.000. The specific exterjacency (per bond) $(^1\chi - {}^1\chi^v)/6$ is 0.333. It is now possible to rank cyclic heterocycles relative to benzene to compare their likeness to it (Table VII).

The molecular volume information encoded in $^1\chi^v$ is easy to envision. A glance down the molecules in Table V reveals that $^1\chi^v$ decreases with decreasing bond lengths. Thus, the ranking closely parallels the molecular volume.

## SUMMARY

The valence molecular connectivity index ($^1\chi^v$) is derived from a cardinal number ($\delta^v$) enumerating the valence electrons on an atom not bonding to hydrogen. The $\delta^v$ number is used $\delta$ times in calculating $^1\chi^v$, where $\delta$ is the number of sigma electrons on an atom not bonding to hydrogen. These two cardinal numbers specify the hybrid states or valence states of any atom within a quantum level.

In this study, it was shown that the atomic fragment volume approximations used in assessing molecular volume are highly correlated with the value of $\delta^v + \delta$ for an atom in its valence state. It also was shown that the valence state electronegativity estimates of Mulliken correlate well with the value of $\delta^v - \delta$ for an atom in its valence state. These two relationships are general for atoms in at least the first three quantum levels.

The $\delta^v$ value, when formulated into the $^1\chi^v$ value for a molecule, carries with it information relating to both volume and electronic character. A simple analogy is the observation that the number 12 carries information about the space occupied by a dozen freshly laid eggs and the number of embryonic heartbeats. Thus, an $sp^3$ nitrogen atom has a $\delta^v = 5$. The cardinal number, 5, counts orbitals contributing to a spatial property, volume. The number 5 concurrently counts the number of valence electrons, which govern electronic characteristics. This duality in the information encoded in the cardinal number ($\delta^v$) leads to a duality of structural information encoded in the derived $^1\chi^v$ value.

The volume information encoded in $^1\chi^v$ values has been demonstrated on numerous occasions in the form of close correlations with volume-related physical properties (39). Other studies showed that properties largely governed by electronic composition also correlate with $^1\chi^v$ indexes. Inspection of the many studies using valence connectivity indexes (Table I) show both aspects of structure relating to these indexes.

In this study, for the first time, a derivation of $^1\chi^v$ from $\delta^v$ has been shown. It is based on the assignment of fractional parts of properties ascribed to the valence electrons of a bonding atom. The fractions $1/\delta^v$

for bonding atoms contribute to the bond so that the geometric mean of the fraction products characterizes the new physical environment. Thus, a bond index is born. The bond indexes $[(1/\delta_A^v)(1/\delta_B^v)]^{1/2}$ are summed to form the molecular connectivity index, $^1\chi^v$.

# Analysis of Drug Contamination from Parabens in Theophylline Olamine

**E. C. JUENGE ˣ, D. F. GURKA, and M. A. KREIENBAUM**

Received July 1, 1980, from the *National Center for Drug Analysis, Food and Drug Administration, 1114 Market Street, St. Louis, MO 63101.* Accepted for publication September 29, 1980.

**Abstract** □ Contaminants in a commercial enema sample of theophylline olamine were found to be derived from parabens and ethanolamine. These contaminants, whose presence was characterized by the loss of preservatives and solubilizing agent, were isolated directly from the drug sample and identified. A high-performance liquid chromatographic (HPLC) system was developed to separate completely and to measure quantitatively theophylline, the two impurities, 4-hydroxybenzoic acid and *N*-(2-hydroxyethyl)-4-hydroxybenzamide, and the remaining parabens. The material balance obtained from the results of quantitative HPLC indicated the formation of these impurities at the expense of parabens. TLC, IR, and UV spectrophotometry and NMR and mass spectrometric analyses were used for identification or for comparisons of the new compound and the known *N*-(2-hydroxyethyl)benzamide.

**Keyphrases** □ Theophylline olamine—contaminants, identification and quantitation, high-performance liquid chromatographic analysis □ Contaminants—identification and quantitation, theophylline olamine enema solutions, high-performance liquid chromatographic analysis □ Paraben preservatives—contamination in theophylline olamine enema solutions, high-performance liquid chromatographic analysis, identification and quantitation □ High-performance liquid chromatography—contamination from paraben preservatives in theophylline olamine enema solutions

During a survey of xanthine derivative drugs conducted by the National Center for Drug Analysis, assay of some enema solutions containing theophylline olamine was attempted with a high-performance liquid chromatographic (HPLC) method that had been used successfully for theophylline elixirs. The analysis showed that, in addition to theophylline and parabens, the sample contained two impurities. This paper discusses the identification and quantitation of these two substances.

## BACKGROUND

The approach followed in this laboratory study was dictated primarily by the small amounts of sample initially available. It involved, first, the original detection of the impurities 4-hydroxybenzoic acid (I) and *N*-(2-hydroxyethyl)-4-hydroxybenzamide (II) by HPLC and TLC, with characterization of their aromatic nature by UV spectrophotometry; and, second, identification by isolation of the impurities from the drug sample and direct comparison with standards by mixed melting-point determinations and IR and NMR analyses. Identities were confirmed by HPLC and TLC comparisons of the original drug solution with commercial and synthesized standards and by a wide collection of spectral data. Finally, the theophylline peak was displaced from the narrow region between the impurity peaks by adjusting the mobile phase to enable quantitative HPLC analysis.

The question of isomerism in the conventional syntheses used to prepare the amides arose because two materials whose elemental analyses were consistent for *N*-(2-hydroxyethyl)benzamide (III) showed different properties. The problem was resolved by purification that showed the materials to be identical; moreover, the mass fragmentations were consistent with the structures given for II and its structural analog, III.

This work demonstrates that parabens can interact chemically with amines used as complexing agents in the compounding of theophylline

for bonding atoms contribute to the bond so that the geometric mean of the fraction products characterizes the new physical environment. Thus, a bond index is born. The bond indexes $[(1/\delta_A^v)(1/\delta_B^v)]^{1/2}$ are summed to form the molecular connectivity index, $^1\chi^v$.

# Analysis of Drug Contamination from Parabens in Theophylline Olamine

**E. C. JUENGE ˣ, D. F. GURKA, and M. A. KREIENBAUM**

Received July 1, 1980, from the *National Center for Drug Analysis, Food and Drug Administration, 1114 Market Street, St. Louis, MO 63101.* Accepted for publication September 29, 1980.

**Abstract** □ Contaminants in a commercial enema sample of theophylline olamine were found to be derived from parabens and ethanolamine. These contaminants, whose presence was characterized by the loss of preservatives and solubilizing agent, were isolated directly from the drug sample and identified. A high-performance liquid chromatographic (HPLC) system was developed to separate completely and to measure quantitatively theophylline, the two impurities, 4-hydroxybenzoic acid and *N*-(2-hydroxyethyl)-4-hydroxybenzamide, and the remaining parabens. The material balance obtained from the results of quantitative HPLC indicated the formation of these impurities at the expense of parabens. TLC, IR, and UV spectrophotometry and NMR and mass spectrometric analyses were used for identification or for comparisons of the new compound and the known *N*-(2-hydroxyethyl)benzamide.

**Keyphrases** □ Theophylline olamine—contaminants, identification and quantitation, high-performance liquid chromatographic analysis □ Contaminants—identification and quantitation, theophylline olamine enema solutions, high-performance liquid chromatographic analysis □ Paraben preservatives—contamination in theophylline olamine enema solutions, high-performance liquid chromatographic analysis, identification and quantitation □ High-performance liquid chromatography—contamination from paraben preservatives in theophylline olamine enema solutions

During a survey of xanthine derivative drugs conducted by the National Center for Drug Analysis, assay of some enema solutions containing theophylline olamine was attempted with a high-performance liquid chromatographic (HPLC) method that had been used successfully for theophylline elixirs. The analysis showed that, in addition to theophylline and parabens, the sample contained two impurities. This paper discusses the identification and quantitation of these two substances.

## BACKGROUND

The approach followed in this laboratory study was dictated primarily by the small amounts of sample initially available. It involved, first, the original detection of the impurities 4-hydroxybenzoic acid (I) and *N*-(2-hydroxyethyl)-4-hydroxybenzamide (II) by HPLC and TLC, with characterization of their aromatic nature by UV spectrophotometry; and, second, identification by isolation of the impurities from the drug sample and direct comparison with standards by mixed melting-point determinations and IR and NMR analyses. Identities were confirmed by HPLC and TLC comparisons of the original drug solution with commercial and synthesized standards and by a wide collection of spectral data. Finally, the theophylline peak was displaced from the narrow region between the impurity peaks by adjusting the mobile phase to enable quantitative HPLC analysis.

The question of isomerism in the conventional syntheses used to prepare the amides arose because two materials whose elemental analyses were consistent for *N*-(2-hydroxyethyl)benzamide (III) showed different properties. The problem was resolved by purification that showed the materials to be identical; moreover, the mass fragmentations were consistent with the structures given for II and its structural analog, III.

This work demonstrates that parabens can interact chemically with amines used as complexing agents in the compounding of theophylline

drugs. As a result, foreign substances are introduced into the drug sample, the amount of active drug in the form of the absorbable soluble amine complex is reduced, and the bactericidal and fungicidal properties of the paraben preservative are reduced because of its consumption.

## EXPERIMENTAL

**Materials**—Distilled-in-glass chloroform[1], acetone[1], methanol[1], and acetonitrile[1] and reagent grade sodium bicarbonate, hydrochloric acid, acetic acid, ethanol, silver nitrate, and magnesium sulfate were used. Deionized water was used in preparing mobile phases and in extraction. Benzene[2] was 99 mole % pure, and ether[3] was anhydrous analytical reagent grade. The reactants, primary standard benzoic acid[3], organic reagent 4-hydroxybenzoic acid[3], reagent grade methyl and propyl *p*-hydroxybenzoate[4], and purified grade ethanolamine[4], were used as received.

Theophylline monohydrate[3] (USP grade), phenol[3] (analytical reagent grade), and ferric chloride[2] (certified ACS grade) were used. The spray reagents, ninhydrin[5] [0.2% in methanol–isopropanol (30:70)] and bromcresol green[6] (0.05% in isopropanol), were used as detection agents for TLC. Base-range[7] and short-range[8] pH paper, silica gel columns[9] (2.5 cm), and TLC plates[10] were used.

**Instruments and Parameters**—Grating IR spectrophotometers[11], a UV/near-IR spectrophotometer[12], a 60-MHz NMR spectrometer[13], a high-performance liquid chromatograph[14], and a double-focusing mass spectrometer[15] interfaced to a data system[16] were employed. Melting points were taken in a capillary melting-point apparatus[17].

Direct insertion by probe was used for mass spectrometry under the following conditions: acceleration voltage, 300 v; source temperature, 200°; electron energy, 70 ev; emission current, 1 mamp; scan rate (SR 22), 4 sec/mass decade, exponential; and multiplier, 16-stage dynode at 2.6 kv ($10^6$ gain, minimum).

Instrument parameters for HPLC included a UV detector with a fixed wavelength of 254 nm and a microparticulate reversed-phase column[18] (30 cm × 3.9 mm i.d.). The mobile phase was 0.1% acetic acid in 10% acetonitrile. A flow rate of 2.0 ml/min and an automatic injector with a 20-$\mu$l loop were used. Retention times were converted to capacity factors.

**TLC**—Substances were spotted as methanol solutions. The drug sample was spotted directly on silica gel plates (5 × 7.5 cm) or was acidified toward litmus with hydrochloric acid and extracted once or twice with equal volumes of chloroform before spotting. The chromatograms were developed with a mixed solvent (equal volumes of chloroform and acetone) by the equilibrated, ascending technique in a tank lined with filter paper.

Spots were placed 1 cm from the base of the plate, and the solvent was developed just to the top of the plate. Most spots were located by short-wave UV irradiation, but ethanolamine spots were developed either by spraying the plate with ninhydrin and placing it in an oven at 100° for 3 min or by spraying with bromcresol green.

**Detection of Impurities by HPLC and TLC–UV Characterization**—The mobile phase consisted of 0.1% acetic acid in 10% acetonitrile. A sample of the drug solution diluted with 10 volumes of absolute methanol was injected directly for HPLC analysis. To remove the parabens, another sample was made acidic to litmus with 6 *N* HCl and washed three times with equal volumes of chloroform prior to HPLC analysis. These aqueous layers also were analyzed by TLC. Materials represented by the outside halves of the two peaks of the impurities were collected during elution in the HPLC of the drug sample that previously had been washed free of parabens. These eluents were examined by TLC and then by UV spectrophotometry.

An authentic theophylline monohydrate sample was dissolved in a solvent consisting of 0.1% acetic acid in 10% acetonitrile and also was examined by UV spectrophotometry for comparison.

**Extraction of Drug Sample Impurities**—*Separation of Impurities from Theophylline and Parabens and Isolation of I*—A 10-ml portion of the basic (pH 8.8) enema solution was adjusted to pH 5.0 with short-range paper by dropwise addition of 6 *N* HCl and was extracted by shaking for 5 min with 60 ml of chloroform. The extraction was repeated three times to provide complete separation of theophylline and parabens from the aqueous solution as ascertained by TLC. The aqueous solution then was extracted twice with 40-ml portions of ether and saved for subsequent isolation of II.

The combined ether extracts, containing any free I, were dried over anhydrous magnesium sulfate and filtered. To obtain the product, the ether was removed from the solution on a steam bath under nitrogen; the residue was kept on the steam bath under nitrogen for 5 min to ensure complete solvent removal. The material was recrystallized from acetonitrile, dried at 55°/3 mm for 1 hr, and examined by IR and NMR analyses and melting-point determination.

*Isolation of II*—A 50-ml portion of the drug sample was treated as already described, and the aqueous solution remaining after chloroform and ether extraction was evaporated to dryness on a steam bath under a strong nitrogen flush. The solid residue was extracted twice with 15 ml of boiling acetonitrile to remove II. The undissolved portion of the residue remained fluid during the hot extraction but solidified immediately upon cooling, permitting solvent decantation. The undissolved residue was recrystallized from absolute ethanol and identified by comparison with a synthesized sample of ethanolamine hydrochloride, whose preparation will be described.

The acetonitrile solutions were combined and filtered, and a portion of the filtrate was tested by TLC for the presence of II and residual ethanolamine. The remaining filtrate was evaporated on a steam bath under a nitrogen flush to remove the solvent, leaving a semisolid residue. Amide II was detected on TLC plates by fluorescence diminution, and ethanolamine at the origin of the chromatogram was detected by pH-sensitive bromcresol green spray or by ninhydrin spray followed by a 3–4-min exposure to 100° heat.

A 2.5-cm silica gel cartridge[9] was preconditioned by passing 40 ml of chloroform through it. The semisolid residue from the acetonitrile evaporation was dissolved in the minimum amount (~4–5 drops) of absolute methanol, transferred with a capillary tube to the top of the column, and washed onto the cartridge three times with minimum portions of chloroform.

Chloroform (100 ml) was passed through the column to remove any impurities present in the forerun, and II then was eluted with chloroform–acetone (1:1). For product isolation and identification, the first few milliliters of eluate were evaporated to dryness by warming under a flush of nitrogen. The residue was used for subsequent identification of II.

In addition to characterizing the impurities directly in the drug sample through extraction, HPLC evidence was obtained by spiking the drug sample with additional amounts of reagent grade I and synthesized II.

**Preparation of Ethanolamine Hydrochloride**—An aqueous solution of ethanolamine containing 10% molar excess of hydrochloric acid was evaporated almost to dryness by boiling and completely to dryness by azeotropic removal of water with benzene. The white crystals obtained upon cooling were recrystallized from a small amount of absolute ethanol under a nitrogen atmosphere to preclude moisture, but they were not particularly deliquescent. The crystallized material was dried at 55°/3–4 mm for 3 hr, mp 83.0–83.8°.

*Anal.*—Calc. for $C_2H_8ClNO$: C, 24.68; H, 8.27; N, 14.36. Found: C, 24.81; H, 8.35; N, 14.29.

**Synthesis of II from Methylparaben and Ethanolamine**—Methyl 4-hydroxybenzoate (15.2 g, 0.10 mole) and 6.11 g of ethanolamine (0.10 mole) were placed in a round-bottom flask fitted with a vacuum adapter to a small 15-ml receiver. The system was flushed with nitrogen, and the reaction was carried out under a nitrogen atmosphere. The flask was immersed in an oil bath at 103–107° for 10.5 hr, with the clear melt being agitated by a magnetic stirring bar. Only a few drops of liquid collected in the receiver, but a hard, sticky semisolid formed in the reaction mixture upon cooling. The solid was triturated for 10 min with 60 ml of chloroform.

This process was repeated four times, during which the semisolid became tacky and hard. The solid was triturated twice with 40 ml of dry ether, which left a granular white solid. Crystallization from a small amount of absolute ethanol gave 6.00 g (33%) of white solid (II), mp 145–151°. Recrystallization two more times and drying at 100°/5 mm for 2 hr gave a sample, mp 155.3–156.3°, suitable for analysis. IR spectral

analysis showed prominent bands at 3370, 3240, 1610, 1570, 1510, 1320, 1290, 1240, 1185, 1080, 1065, 860, and 710 $cm^{-1}$. The product was insoluble in chloroform and ether and also could be crystallized from water, acetonitrile, and acetone. A sample also was submitted for mass spectrometric and elemental analyses.

*Anal.*—Calc. for $C_9H_{11}NO_3$: C, 59.66; H, 6.12; N, 7.72. Found: C, 59.80; H, 6.44; N, 7.52.

**Preparation of II by Reaction between I and Ethanolamine**—A very low yield of product was obtained in this procedure. A mixture of 13.8 g of I (0.10 mole) and 6.11 g of ethanolamine (0.10 mole) was heated gradually to 200° according to the procedure of Wenker (1). Vacuum distillation, after a small forerun, gave ~10 ml of a colorless liquid having a phenol odor, bp 77–79°/11 mm. This distillate had a boiling point corresponding to that of phenol but gave a negative test for phenol with 1% ferric chloride solution and with ferric chloride–urea reagent (2), and it gave a poor IR spectral match with pure phenol.

A developed TLC plate containing the material indicated the presence of ethanolamine when sprayed with bromcresol green. Approximately 4 drops of the distillate were dissolved in chloroform and placed on the top of a silica gel cartridge that had been conditioned previously with 40 ml of chloroform. When ethyl acetate was passed through the cartridge, pure phenol eluted within the first 2 ml and was identified by TLC after comparison with phenol spotted alongside the distillate ($R_f$ 0.68). When the chromatogram was sprayed with bromcresol green, no blue spot for ethanolamine appeared. The material purified by chromatography gave a deep-purple color with 1% ferric chloride solution and with ferric chloride–urea reagent, as expected for phenol. The IR spectrum also matched that of an authentic phenol sample.

A small amount of the desired product was obtained from the sticky, semisolid residue (2.3 g) left after the distillation. This residue was triturated twice with 10 ml of chloroform and once with 10 ml of anhydrous ether, leaving 2.13 g (11.8%) of light-brown granular solid. After two recrystallizations from absolute ethanol, the product melted at 155.2–156.2°. It was shown to be II by mixed melting point with the analytically pure sample of this substance prepared as already described and by comparison of the IR spectrum with that of the pure compound. TLC of the two synthesized samples and the isolated amide II showed identical $R_f$ values.

**Synthesis of III from Benzoic Acid and Ethanolamine**—Compound III was synthesized by the procedure of Wenker (1). In the present study, a reaction on a 0.1 *M* scale gave a forerun of ~1 g of sublimate upon distillation. This white solid was recrystallized twice from 95% ethanol (mp 143.5–144.5°) and dried at 55°/3 mm for 1.5 hr. Results of elemental analysis were consistent with the structure for β-hydroxyethylammonium benzoate.

*Anal.*—Calc. for $C_9H_{13}NO_3$: C, 59.00; H, 7.15; N, 7.65. Found: C, 59.12; H, 7.41; N, 7.57.

The identity of this substance was confirmed as follows. Known β-hydroxyethylammonium benzoate was obtained as a white solid, which crystallized on cooling from a hot acetone solution of equimolar amounts of benzoic acid and ethanolamine. No melting-point depression was observed from a mixture of the known and unknown materials.

Continued distillation yielded ~8 g of an oily product, which failed to give a dry crystalline product on attempted crystallization from common solvents; however, a crystalline product was obtained in two ways. First, in a crystal growth technique, a small amount of the oil was placed in an erlenmeyer flask with a small overlayer of dry ether; the flask was stoppered and stored in the freezer compartment of a refrigerator. Soft, fibrous, single needles, 3 cm long, grew out of the mass overnight, leaving at the origin only a very small amount of liquid unconverted to crystals. The product was collected quickly, washed with a small amount of dry ether, dried in air, and crushed to a white powder, $R_f$ 0.30, mp 63.5–65.8° [lit. (3) mp 66–67°].

The product (III) was dried over phosphorus pentoxide for 1 hr and then at 55°/4 mm for 1.5 hr. It then was submitted for mass spectrometric and elemental analyses.

*Anal.*—Calc. for $C_9H_{11}NO_2$: C, 65.44; H, 6.71; N, 8.48. Found: C, 65.20; H, 6.93; N, 8.31.

Some crystals were used to seed the crude distillate. On standing several hours, the distillate crystallized to a semisolid laced with needles. However, the needles were thixotropic, and the crystals became fluid and were adsorbed when collection on filter paper by filtration or by pressing on tile was attempted.

In the second purification procedure, a double silica gel cartridge (two silica gel cartridges[9] connected in tandem with an inserted small piece of glass tubing) was preconditioned with chloroform as already described. A portion of the crude distillate (119 mg) was dissolved in 0.2 ml of chloroform, applied to the top of the column, and washed into the column by two applications of a few drops of chloroform. Chloroform was used for development and elution. The first 10 ml of eluate contained only small amounts of impurities and was discarded.

The amide product (III) eluted completely in the next 70 ml. The solvent was removed from this fraction by warming under nitrogen, leaving a heavy oil. When scratched with a stirring rod, this oil formed a hard white solid, mp 63.8–64.5°. This product was free of ethanolamine, as determined by TLC and bromcresol green spray. The products isolated by the crystal growth and silica gel cartridge techniques were shown to be identical by mixed melting-point and IR analyses (3300, 3140, 1600, 1520, 1440, 1370, 1320, 1290, 1200, 1150, 1060, 1040, 870, 800, 760, and 690 $cm^{-1}$).

**Quantitative Study by HPLC**—*Mobile Phase*—Impurities II and I and theophylline were determined by HPLC, using a mobile phase of 0.5% acetic acid in 2.8% aqueous acetonitrile. Methylparaben was determined with 0.5% acetic acid in 10% aqueous acetonitrile, and propylparaben was determined with 0.5% acetic acid in 25% aqueous acetonitrile.

*Sample and Standard Solutions*—A stock solution of II (synthesized from paraben) was prepared by dissolving 22.1 mg of the recrystallized compound in 250.0 ml of methanol (88.4 μg/ml). This stock solution was diluted to 79.6, 44.2, and 26.5 μg/ml with methanol. A sample solution was prepared by diluting 5.0 ml of enema solution to 50.0 ml with methanol.

A solution of I was prepared by dissolving 60.0 mg in 200.0 ml of methanol (300 μg/ml) and was used directly. Another solution of I was prepared by dissolving 42.6 mg in 200.0 ml of methanol (213 μg/ml), and an aliquot of this solution was diluted to 102 μg/ml with methanol. A sample solution was prepared by diluting 5.0 ml of enema solution to 50.0 ml with methanol.

The stock methylparaben solution was prepared by dissolving 20.0 mg of methylparaben in 100.0 ml of methanol (200 μg/ml), and aliquots were diluted to 160, 80, 60, and 44 μg/ml with methanol. A sample solution was prepared by diluting 6.0 ml of enema solution to 50.0 ml with methanol.

The stock propylparaben solution was prepared by dissolving 20.0 mg of propylparaben in 100.0 ml of methanol (200 μg/ml). This stock solution was diluted to 128, 100, and 50 μg/ml with methanol. A sample solution was prepared by diluting 17.0 ml of enema solution to 50.0 ml with methanol.

A stock solution of theophylline was prepared by dissolving 153 mg of anhydrous theophylline in 100.0 ml of methanol (1.530 mg/ml), and aliquots were diluted to 1.150, 0.770, and 0.380 mg/ml with methanol. A sample solution was prepared by diluting 3.0 ml of enema solution to 50.0 ml with methanol.

*HPLC Method*—After the approximate concentration of each component of the sample solution was determined, standard solutions were prepared to range from ~50 to 150% of these concentrations. Each sample and standard solution was injected at least three times, and peak heights were measured manually. Each sample component was calculated by:

$$C_c = H_s/H_{std}C_sDF \qquad \text{(Eq. 1)}$$

where $C_c$ and $C_s$ are the concentrations (milligrams per milliliter) of each component of the sample solution and of the corresponding standard, respectively; $H_s$ and $H_{std}$ are the peak heights of the sample and standard solutions, respectively, such that the standard concentration is chosen to yield a standard peak height within 5% of the sample peak height; and $DF$ is the sample dilution factor.

The full-scale absorbance settings were: theophylline and I, 0.64; II and methylparaben, 0.16; and propylparaben, 0.08. The recorder chart was operated at 30.48 cm/hr.

**Ethanolamine**—Ethanolamine was determined by the official NF method (4).

## RESULTS AND DISCUSSION

The chromatogram obtained from the HPLC (0.1% acetic acid in 10% acetonitrile) determination of the diluted enema solution or the drug solution applied directly on the $C_{18}$ reversed-phase column showed a cluster of peaks reflecting capacity factors of 0.87 for II, the first impurity to elute, 1.62 for theophylline, and 2.25 for I, the second impurity to elute. The peak of the major impurity, I, was almost three times as large as that of the minor impurity, II, and the theophylline peak was the largest of the three. The parabens eluted much later than this cluster.

Acidification of the drug sample and subsequent extraction with chloroform completely removed the parabens and concentrated the im-

**Table I—$R_f$ Values for Isolated and Synthesized Compounds [a]**

| Compound | $R_f$ |
|---|---|
| Theophylline | 0.22 |
| I | 0.27 |
| II | 0.17 |
| III[b] | 0.30 |
| Methylparaben | 0.70 |

[a] Silica gel plates and solvent system composed of equal volumes of chloroform and acetone. [b] *N*-(2-Hydroxyethyl)benzamide. [c] Developed with bromcresol green spray or ninhydrin spray followed by heating at 100° for 3 min.

purities at the expense of theophylline. The completeness of this process was reflected in chromatograms of the extracted samples by the absence of peaks for parabens and the modification of peak heights in the cluster. Relative heights of the peaks for the impurities remained essentially unaltered and suggested repeated extractions of this type as a first step in the isolation of the impurities from the drug sample. The UV spectra of selected fractions eluted during HPLC showed a $\lambda_{max}$ of 252 nm for II and a $\lambda_{max}$ of 256 nm for I, indicating the aromatic nature of the compounds. The $\lambda_{max}$ of theophylline in the mobile phase was 272 nm, which suggested that the impurities were not simple derivatives of that substance. Methylparaben itself showed an absorption at 255 nm.

TLC confirmed that two impurities were present in the drug sample. The $R_f$ values for the smaller impurity (0.17), theophylline (0.22), and the larger impurity (0.27) (Table I) indicated a reverse order of migration for the substances on 7.5-cm silica gel TLC plates compared with that on $C_{18}$ reversed-phase HPLC, as expected. The $R_f$ values from 20-cm TLC plates were essentially the same as those from 7.5-cm plates.

After the acidified drug solution was washed repeatedly with chloroform, no theophylline could be detected by TLC. The first impurity (I) was isolated by ether extraction and was obtained as a white solid after removal of the ether solvent. Two such treatments involving chloroform and ether extractions of acidified drug sample gave 8.0 and 7.4 mg of this impurity, representing 4.8 and 4.4%, respectively, relative to the weight of the therapeutic component, theophylline. After recrystallization, the isolated impurity melted at 205.5–206.0°.

*Anal.*—Calc. for $C_7H_6O_3$: C, 60.86; H, 4.38; mol. wt. 138. Found: C, 60.91; H, 4.27; mol. wt. 142.

After analysis indicated that the extracted product was I, identification was confirmed by using an authentic sample of I in IR and NMR comparisons and by mixed melting-point determination.

Because limited sample was available and the impurities were present in a very dilute state, subsequent extractions leading to identification of II, which was present in an even smaller amount, seemed difficult without a reference standard. UV analysis of the isolated HPLC eluate suggested that II could have an aromatic structure similar to that of the parabens. In the search for a reference standard, various xanthines and uric acids were examined, as were heated reaction mixtures from methylparaben with theophylline and with ethanolamine. The latter reaction provided the desired source. Initial HPLC of the crude product indicated that the major product of the reaction was identical with the minor impurity (II) in the commercial sample. TLC also supported this identity.

After I was extracted from the aqueous residue, II was isolated by evaporation of the residue to dryness and preliminary extraction with acetonitrile to remove II from the insoluble ethanolamine hydrochloride. This procedure left 175 mg of residue which, after crystallization from absolute ethanol, yielded 122 mg of ethanolamine hydrochloride, mp 83.0–83.5°. This material appeared to be a dry, not readily deliquescent material, whereas the literature described the substance as deliquescent (5) and gave two melting points, 75–77° (5) and 100° (6). Therefore, the recrystallized substance was identified further as ethanolamine hydrochloride by comparing its IR and NMR spectra with those of synthesized ethanolamine hydrochloride. A mixture of known ethanolamine hydrochloride and the unknown gave no depression in melting point.

The acetonitrile extraction removed most of the amide impurity from the ethanolamine salt, and TLC examination of the extract by fluorescence diminution showed only II and no I or theophylline. Moreover, only a small amount of ethanolamine was detectable compared with a similar examination of the residue before the acetonitrile treatment. The ethanolamine showed little or no migration from the origin (Table I) and was detected as a blue spot with bromcresol green or as a red spot with ninhydrin followed by heat. This low migration allowed purification of II on a short silica gel column.

The residue remaining after acetonitrile evaporation was applied to the column; passage of a large volume of chloroform removed traces of impurities from II, which showed little migration with this eluent. When the solvent was changed to chloroform–acetone (1:1), II eluted immediately; elution was complete within the next 7 ml without release of any ethanolamine. An additional 40 ml of the solvent failed to elute any ethanolamine, attesting to the effectiveness of the method. Solvent removal from the 7-ml fraction of mixed solvent left 9.33 mg of dry white powder, mp 154.0–156.0°. The impurity was identified as II by IR and NMR comparisons with the analytically pure, synthesized compound. A mixture of the known and unknown compounds gave no depression in melting point.

Although I and II were detected initially by HPLC and TLC, these procedures allowed identification of the impurities by direct extraction from the drug sample.

In terms of the active ingredient, ~7.7 mg of I [4.6% by weight relative to the weight (166 mg) of theophylline expected by label declaration] and ~1.9 mg or 1.1% of II were obtained by extraction of 10 ml of the drug sample. Heavy losses were expected from the multiple extractions used in purification. Refinement of the HPLC technique, which allowed quantitative analysis and reflected chemical changes that resulted in formation of the contaminant, will be described.

The impurities in the drug sample were identified directly by extraction and the use of reference standards. Confirmatory identification was obtained from HPLC by spiking drug samples with the reference standards, resulting in enlargements of the peaks representing the impurities without any new peaks.

The problems associated with the isolation and identification of II were the lack of a preparation method for it and the high solubility of such amides in water, a property shared by ethanolamine, a possible contaminant of these amides. Ethanolamine can be removed by silica gel columns, onto which the ethanolamine is tenaciously adsorbed. A method (1) was described for the preparation of the structural analog, amide III, directly from I and the amine, but a more effective approach seemed to be a reaction between an ester and the amine. Moreover, the reaction between paraben esters and ethanolamine warranted study as a source for generation of II in the drug sample. The reaction gave a product that was identical with one impurity in the drug sample and whose identity was confirmed by elemental analysis.

Reported methods for preparation of III are not without discrepancies, but they were resolved. Prepared as already described, the compound was initially a water-soluble liquid, in accordance with the description of Wenker (1), who reported that the compound could not be obtained in crystalline form. However, Fränkel and Cornelius (3) reported that the compound was a crystalline solid when prepared by the Schotten–Baumann reaction followed by hydrolysis of the dibenzoyl derivative of ethanolamine. The structure of these two products rested on the reported elemental analysis for nitrogen.

In this laboratory, a reaction was attempted between I and ethanolamine by gradually heating the mixture to 200° under the conditions used by Wenker to prepare the liquid parent compound. The reaction gave phenol primarily, which resulted from the ease of decarboxylation attributed to resonance effects of the 4-hydroxy group. However, some II was generated and was identical with the product obtained by reaction of methylparaben and ethanolamine and with the impurity contained in the drug sample. The reaction of Wenker was repeated and yielded a liquid that could not be obtained as a crystalline solid by the usual procedures but was obtained in crystalline form by a crystal growth technique under dry ether or by use of a silica gel cartridge. The melting point of these crystals was essentially the same as that previously obtained (3), indicating that this amide and that of Wenker were identical. It is unlikely that I formed first in the drug sample and then partially reacted with ethanolamine to generate II. Even when these reactants were heated gradually to 200°, as already described, phenol was formed primarily by decarboxylation.

In view of the slight differences in reports describing the synthesis of the parent amide, both II and III were analyzed by mass spectrometry. A rather general similarity of fragmentation pattern was shown by these substances (Table II). The spectra for II and III showed molecular ions at *m/z* 181 and 165, respectively, and base peaks, as expected, at *m/z* 121 and 105, respectively. The odd *m/z* ratio of the molecular ion confirmed the odd number of nitrogen atoms in the compounds. Postulated structures for some major ions are given in Table II.

The NMR spectrum of II (methanol-$d_4$ solvent) showed essentially two doublets for the *ortho* and *meta* aromatic hydrogens centered at 6.75 and 6.90 ppm, splitting each other with a coupling constant of $J = 4.2$ Hz. Both I and methylparaben also had very similar pairs of doublets for

**Table II—Postulated Structures of Some Major Ions Generated in Mass Spectrometric Fragmentation of $RCONHCH_2CH_2OH$**

| Fragment Ion | R = $HOC_6H_4$[a] | | R = $C_6H_5$[b] | |

coupling between these two types of aromatic protons. Both III and II showed similarly shaped multiplets for the methylene protons, 3.48–3.78 ppm. The aromatic regions for these compounds were quite different, and aromatic absorptions for III with complicated multiplets centered at 7.26 and 7.82 ppm were identical with those in the spectrum of *N*-(2-hydroxyethyl)thiobenzamide previously reported (7).

Other investigators (8) recently reported a chemically related contamination resulting from a reaction between ethylenediamine complexing agent and a suppository base.

The high efficiency of the reversed-phase column produced a wide range of capacity factors, which necessitated the use of three mobile phases to separate the five components of the enema solution. Resolution to baseline was achieved for the analysis of each component. Acetic acid was added to the mobile phases to reduce peak tailing.

The original conditions (10% acetonitrile, Table III) used for detection of the impurities in the drug sample placed the peak for theophylline in a narrow region between the peaks for the impurities, leading to considerable overlap and precluding quantitative determination of the impurities. Fortunately, the capacity factor of theophylline on the lipophilic column was much more sensitive to the polar nature of the mobile phase than were the impurities. In general, the capacity factors increased as the percentage of acetonitrile declined. However, from 10.0 to 2.8% acetonitrile, the differential capacity factor $k'(I)-k'(T)$ for I relative to theophylline went through an inversion (Table III) from 0.2 to −4.8, *i.e.*, the separation factor [relative retention, $\alpha = k'(I)/k'(T)$] became fractional. This general trend was reflected by collection of data with a mobile phase containing no acetonitrile (Table III). The problem was resolved by removing the theophylline peak from its location between the peaks for the impurities, allowing quantitation of the impurities by use of 2.8% acetonitrile as the mobile phase. However, since retentions for the parabens were excessively long with this mobile phase, 10 and 25% acetonitrile were used for quantitation of methyl- and propylparabens, respectively.

Before the use of peak heights to measure sample concentrations, it was determined that injection volumes were reproducible to better than 1%. Standard calibration curves for each enema component demonstrated linearity of peak heights with concentrations between 50 and 150% of the actual component concentration in the enema sample. The mean peak height for at least three injections was used in all calculations. The concentration of each component of the enema solution is listed in Table IV.

These analytical data indicate that only 96 mg of total paraben remained from a label claim of 360 mg of total paraben/100 ml of enema solution. The residual parabens along with impurities accounted for 106% of the label claim for total parabens on a molar basis, indicating that 73.3% of the parabens had chemically decomposed. Thus, the fungistatic and bacteriostatic properties of the solution were seriously lowered. In addition, 6% (0.26 mg/ml) of the label quantity of ethanolamine was converted to II, decreasing the ethanolamine concentration to 23.6% of the labeled quantity of theophylline olamine; the official limits are 22–28% of label.

**Table III—Capacity Factors in Quantitative HPLC of Enema Solution**

| Acetonitrile[a], % | Amide Impurity $k'(II)$ | Theophylline $k'(T)$ | 4-Hydroxybenzoic Acid $k'(I)$ | Methylparaben | Propylparaben |

| 0 | 10.4 | 33.0 | 12.1 | — | — |
| 2.8 | 3.4 | 10.0 | 5.2 | — | — |
| 10.0 | 1.0 | 2.8 | 3.0 | 12.5 | — |
| 25.0 | — | — | — | — | 16.6 |

[a] Each mobile phase contained 0.5% acetic acid.

**Table IV—HPLC Analysis of Enema Solution**

| Component | Label Claim, mg/ml | Found, mg/ml | Percent of Label Claim |
|---|---|---|---|
| Methylparaben | 3.00 | 0.67 | 22.3 |
| Propylparaben | 0.60 | 0.29 | 48.3 |
| Theophylline | 12.61 | 12.96 | 103.0 |
| Ethanolamine | 4.28 | 3.92 | 91.6 |
| I | — | 1.95 | — |
| II | — | 0.77 | — |

By salt formation with xanthine drugs, *e.g.*, theophylline and theobromine, amines such as ethanolamine and ethylenediamine effectively solubilize these drugs. However, because they are rather reactive substances, esters such as parabens are chemically vulnerable, particularly toward attack by amines. These reactions of the complexing agent may reduce the amount of drug in solution and consume the preservative. Loss of preservative may result in drug biodegradation or in a health hazard through bacterial or fungal contamination of the dosage form; such loss also may create a source of chemical contamination by generation of foreign substances. Improper treatment, such as excessive temperatures and extremely high or low pH during formulation, packaging, and storage, may increase reaction rates and lead to such paraben reactions as acylation and hydrolysis. Hydrolysis of methylparaben in basic and acidic solutions (pH 6–8) was previously studied (9). Autoclaving at pH 9 (close to the measured pH of the sample used in this study) for 30 min left only 58% of the initial methylparaben concentration. The hydrolysis rates of methylparaben at 70, 80, and 85° were greater when the solutions were basic, as were the enema solutions investigated.

In this study, relative to theophylline, 4.6% by weight of II and 11.7% of I were found in the drug sample with a corresponding 73.3% loss of parabens in the solution. The corresponding amide from salicylic acid, *N*-(2-hydroxyethyl)-3-hydroxybenzamide, was described previously (10), but to the knowledge of the authors, II is unknown and its physiological effects are unexplored.

It should be noted that paraben losses may occur by direct chemical decomposition as well as by microbial degradation or complex formation with macromolecules. Despite their phenolic moiety, structures such as paraben esters are not resistant to all microbes and, like other phenols with electron-withdrawing substituents (*e.g.*, picric acid), may give complex formation with macromolecules. These factors may result in loss of the preservative effects of parabens in drug samples. This study shows that the ester functional group of parabens also may give rise to loss of preservative action by direct chemical decomposition. Interactions similar to those between parabens and ethanolamine described here also should apply to ethylenediamine complexing agent.

# Precaution on Use of Hydrochloride Salts in Pharmaceutical Formulation

**SHOZO MIYAZAKI ˣ, MIDORI OSHIBA, and TANEKAZU NADAI**

Received April 30, 1980, from the *Faculty of Pharmaceutical Sciences, Josai University, Sakado, Saitama 350-02, Japan.* Accepted for publication November 3, 1980.

**Abstract** □ Previous reports suggested that the formation of hydrochloride salts does not always enhance solubility due to the common ion effect. The extent of the common ion effect seems to be related to aqueous solubility, with slightly soluble hydrochlorides being more sensitive to the common ion, *i.e.*, chloride ion. The relationship between solubility in water and the extent of the common ion effect was examined, and a high correlation was found, suggesting that hydrochlorides possessing solubilities in water at least of the order observed for papaverine and demeclocycline hydrochlorides (~32 mg/ml at 25° and 42 mg/ml at 37°) are less soluble than the corresponding free base at gastric pH.

**Keyphrases** □ Hydrochlorides—effect on solubility, common ion effect □ Solubility—effect of hydrochlorides, common ion effect □ Common ion effect—effect of hydrochlorides on solubility □ Physicochemistry—effect of hydrochlorides on solubility, common ion effect

Salt formation is one of the first approaches used to modify drug solubility and dissolution rates. Because of simple availability and physiology, the monohydrochloride salts have been the most frequent choice of the available salts of basic drugs (1). However, previous reports (2–5) showed that hydrochloride salt formation does not necessarily enhance solubility and bioavailability. This finding is based on the common ion effect of chloride on the solubility product equilibrium of hydrochloride salts (6), which often is overlooked. Hydrochloride salts of the drugs frequently exhibit less than desirable solubility in gastric fluid because of the abundance of chloride ion.

## BACKGROUND

Unusual pH–solubility profiles containing maxima at pH 2–3 were reported previously (2) for chlortetracycline, demeclocycline, and methacycline hydrochlorides in sodium acetate–hydrochloric acid buffers. The decrease in solubility at lower pH values was attributed to the common ion effect of chloride on the solubility product equilibrium of the hydrochloride salts. The apparent dissolution rates and solubilities of these hydrochloride salts were less than those of the respective free base forms in chloride-containing media. Evidence was presented for greater bioavailability from the chlortetracycline and methacycline free bases compared to the hydrochloride salts (3). The common ion effect also influenced the solubilities and dissolution rates of the hydrochloride salts of papaverine, trihexyphenidyl, isoxsuprine, phenazopyridine, cyproheptadine, and bromhexine (4, 5).

On the other hand, tetracycline hydrochloride solubility, which increased with a pH decrease, showed a usual pH profile in chloride-containing buffers (2). Tetracycline hydrochloride exhibited a greater solubility than its free base in hydrochloric acid at pH 1.2 since the hydrochloride exhibited a low sensitivity to the chloride ion. The differences between tetracycline and the other drugs in sensitivity to the chloride ion may result because the aqueous solubility of tetracycline hydrochloride is much higher than that of the others.

The addition of a common ion often reduces the solubility of a slightly soluble electrolyte. Although the concept of solubility product equilibrium originated in inorganic chemistry, this principle can be applied to slightly soluble organic salts (7). The drugs under study are basic amino compounds and form slightly or sparingly soluble hydrochloride salts. Since the salt in solution is partially dissociated, further solubility suppression may be caused by the common ion effect. The equilibrium involved is shown in Scheme I.

From previous results, it seems that the extent of the common ion effect

$$BH^+Cl^-_{(solid)} \rightleftharpoons (BH^+)_{aq} + (Cl^-)_{aq}$$

*Scheme I*

is related to aqueous solubility, with slightly soluble salts being more sensitive to the chloride ion. In this study, an attempt was made to determine the relationship of solubilities in water and their sensitivities to the chloride ion of nine hydrochloride salts that showed unusual solution properties. The salting-out constant with sodium chloride, based on the Setschenow equation (8), was taken as the parameter of the extent of the common ion effect, *i.e.*, sensitivity to chloride ion. The Setschenow equation was found to be applicable to an amine hydrochloride (9).

## EXPERIMENTAL

The drugs studied are listed in Table I. Solubility measurements in distilled water were made at 25 and 37°. An excess of the drugs was placed into each vial containing the solvent, and the vials were equilibrated by shaking overnight. Equilibrated mixtures were filtered[1], and the filtrates were assayed spectrophotometrically.

The solubility of each drug in sodium chloride solutions also was determined as already described. Experimental salting-out constants were calculated according to the Setschenow equation (8):

$$\log S_0/S = kC \qquad \text{(Eq. 1)}$$

where $S$ and $S_0$ are the solubilities in the salt solution and in pure water, respectively; $C$ is the molar concentration of the electrolyte; and $k$ is the empirical salting-out constant.

## RESULTS

Table I summarizes the solubility data obtained for each hydrochloride salt and their experimentally determined salting-out constants with sodium chloride at 25 and 37°; the solution pH is also given. Setschenow plots for these drugs in sodium chloride at 25° are shown in Fig. 1. There appears to be a distinct relationship between the solubility in water and the salting-out constant with sodium chloride; as the solubility in water increased, the salting-out constant decreased. Thus, phenazopyridine, cyproheptadine, and bromhexine hydrochlorides, which had the smallest solubilities, were sensitive to the chloride ion to the greatest extent. The most soluble drugs, papaverine and demeclocycline hydrochlorides, were the least sensitive to the chloride ion.

Figure 2 shows the salting-out constant with sodium chloride as a function of solubility in water at 25 and 37°. A least-squares line was fitted to all points in each log–log plot. A high correlation coefficient ($r$) was obtained at both 25 ($r$ = 0.902) and 37° ($r$ = 0.946), indicating that the smaller the solubility in water, the larger the salting-out constant.

Furthermore, the data are interesting with regard to their general applicability to other slightly soluble organic hydrochlorides. For all drugs listed in Table I, much greater solubility and dissolution rates were obtained by the free bases than by hydrochloride salts in hydrochloric acid solution at pH 1.2. Perhaps this phenomenon applies to hydrochloride salts having water solubilities less than ~32 mg/ml at 25° and 42 mg/ml at 37°, which are the solubilities of papaverine and demeclocycline hydrochlorides.

## DISCUSSION

Comparison of the solubilities in water to the salting-out constant revealed an inverse relationship between these quantities. Although it would be desirable to develop this relationship further, a general statement concerning hydrochloride salt formation within the solubility range found in this study may be possible: hydrochloride salts having solubil-

[a] As reported in Refs. 2, 4, and 5. [b] The averaged result is reported where there were more than two determinations, followed by parentheses containing the number of determinations and the standard error. For two determinations, the average is followed by parentheses containing the individual values. All data are expressed as the free base equivalent. [c] The pH of a saturated solution. [d] Estimated from the initial slope. [e] Contained 3/2 mole of water. [f] Monohydrate.

ities in water at least of the order observed for papaverine and demeclocycline hydrochlorides are less soluble than the corresponding free base at gastric pH. This finding may be useful in predicting the most soluble form of similar drugs from known or readily determined water solubility values.

Lin *et al.* (9) illustrated a similar phenomenon that decreases the dissolution rate of the salt below that of its free base form. The free base of an experimental antihypertensive exhibited a greater dissolution rate

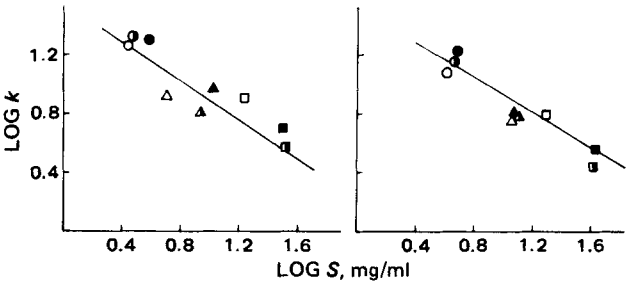

**Figure 2**—*Relationship between solubility in water and salting-out constant at 25 (left) and 37° (right). Key: see Fig. 1.*

than the monohydrochloride salt in 0.1 *N* HCl, and this finding was attributed to the common ion effect. The equilibrium solubility of the monohydrochloride at 37° was 16 mg/ml in water.

Because of the high aqueous solubility (133.7 and 164.4 mg/ml at 25 and 37°, respectively) and low sensitivity of tetracycline hydrochloride to the chloride ion ($k$ = 0.94 and 0.85, respectively), this antibiotic showed unusual solubility characteristics (2). The freely soluble hydrochlorides normally exhibit no serious problem.

Although doxycycline hydrochloride solubility in water at 25° is 50 mg/ml (10), the free base dissolved from the compressed pellet form about sixfold faster than the hydrochloride in 0.1 *N* HCl (11). Common ion equilibrium with chloride strongly reduces the dissolution rate of doxycycline hydrochloride from the pellet, while the free base is not affected. Dissolution of hydrochloride salts from crystalline powder in chloride-containing media probably represents a problem only with slightly or sparingly soluble hydrochlorides, but dissolution certainly may be a problem with the tablet dosage form when the hydrochloride is soluble.

The solubility of solids is a very useful parameter since an orally administered drug in solid dosage form must dissolve in the GI tract prior to absorption. The GI absorption of chlortetracycline and its hydrochloride was studied in rats and humans (3), and the results indicated that the free base was more efficiently absorbed than the hydrochloride from the GI tract. Similar results also were noted for methacycline and its hydrochloride. The differences between the bioavailability of the free base and the hydrochloride were attributed mainly to differences in solubility at gastric pH.

Since the absorption of basic drugs occurs chiefly from the intestine, these drugs should reach the intestine in a dissolved or readily soluble form. The solubility of the drugs in the stomach is of decisive importance for absorption since basic drugs have very low solubility in the alkaline environment of the intestine. Drug particles that do not dissolve in the stomach are emptied into the intestine and generally will be unabsorbed.

The pH of the gastric fluid usually ranges from 1 to 3; fasting tends to decrease the pH to 1.2–1.8 (12). In addition, the chloride ion is present in body fluids at a high level, which also is unfavorable for dissolution of the hydrochloride due to the common ion suppression of the solubility product equilibrium. These factors create conditions less favorable for hydrochloride dissolution in gastric fluid, thus affecting bioavailability. In such cases, selection of an alternative salt form or free base may improve dissolution and bioavailability.

Special precautions should be taken when drugs are used as hydrochloride salts in pharmaceutical formulation. Consequently, extensive and systematic preformulation studies of the physicochemical properties, including salt formation, of each new drug entity are necessary to determine the most suitable form for drug formulation by the pharmaceutical industry.

# Urinary Excretion of Methenamine and Formaldehyde: Evaluation of 10 Methenamine Products in Humans

**RAMACHANDER GOLLAMUDI, ARTHUR B. STRAUGHN, and MARVIN C. MEYER ˣ**

Received June 30, 1980, from the *Departments of Pharmaceutics and Medicinal Chemistry, College of Pharmacy, University of Tennessee Center for the Health Sciences, Memphis, TN 38163.* Accepted for publication November 5, 1980.

**Abstract** □ The urinary excretion of both methenamine and formaldehyde was measured for 48 hr after the oral administration of 10 different methenamine products to 10 human subjects in a crossover study. The following dosage forms were evaluated: a tablet of methenamine base, a methenamine hippurate tablet, and eight products containing methenamine mandelate, including six enteric-coated tablets, a suspension, and a granule dosage form. The nonenteric-coated dosage forms were absorbed more rapidly, based on maximum excretion rates that occurred within 3 hr after dosing. The enteric-coated tablets, which were designed not to release methenamine until reaching the intestinal tract, exhibited maximum excretion rates that did not occur until 7–17 hr after dosing. There were no significant differences ($p > 0.05$) among products in terms of total excretion of free formaldehyde in the urine. However, large differences ($p < 0.05$) were noted among products for urinary recovery of total methenamine, with the amount of administered dose recovered ranging from 16 to 83%.

**Keyphrases** □ Methenamine—evaluation of 10 products, urinary excretion of formaldehyde □ Bioavailability—methenamine in 10 products, humans □ Urinary tract antibacterials—evaluation of 10 methenamine products, excretion of formaldehyde □ Antibacterials, urinary tract—evaluation of 10 methenamine products, excretion of formaldehyde

Methenamine (hexamethylenetetramine) is a urinary tract antibacterial agent. It is absorbed from the intestinal tract, circulates unchanged in blood, and is excreted in the urine. Under acidic conditions in the urine, it undergoes hydrolysis to formaldehyde. Approximately 10–30% of the drug also is believed to be converted to formaldehyde in the acidic environment of the stomach (1). Enteric-coated preparations are designed to withstand such premature hydrolysis by releasing drug only in the intestine. With such dosage forms, drug absorption may be delayed due to slow gastric emptying or may be incomplete due to failure of the product to release methenamine in the intestine.

A crossover study was undertaken to evaluate the relative bioavailability of 10 methenamine products. The urinary excretion of both methenamine and formaldehyde was determined in 10 human volunteers who received all 10 dosage forms.

## EXPERIMENTAL

**Methenamine Products**—The 10 methenamine products evaluated are summarized in Table I. Products 1–3 were included as reference products for comparison with the hippurate tablet and the six enteric-coated tablets. All products were supplied by the U.S. Food and Drug Administration, except Products 1 and 2, which were purchased from a local pharmacy.

**Table I—Methenamine Products Tested**

| Product[a] | Dosage Form | Administered Dose | Calculated Methenamine Content, g |
|---|---|---|---|
| 1 | Methenamine tablets (0.5 g) | 1 tablet | 0.500 |
| 2 | Methenamine mandelate suspension (50 mg/ml) | 20 ml | 0.480 |
| 3 | Methenamine mandelate granules (0.5 g/package) | 2 packages | 0.480 |
| 4 | Methenamine mandelate tablets (0.5 g)[b] | 2 tablets | 0.480 |
| 5 | Methenamine mandelate tablets (0.5 g)[b] | 2 tablets | 0.480 |

maintained at a sufficient level to provide for adequate urine output. No food was permitted until 4 hr after drug administration.

Urine samples were obtained at 0, 1, 2, 3, 4, 6, 8, 12, 24, and 48 hr. The subjects were instructed to provide complete urine collections at each voiding. Immediately upon voiding, the urine volume and pH[3] were measured. A urine aliquot was diluted 15 times with water and stored at −18° until analysis, which was performed within 7 days. Samples voided at other times were collected similarly and stored. At the time of analysis, samples voided between sampling times were combined with the sample obtained at the next required sampling time. The samples were pooled using aliquot volumes proportional to the individual volumes of voided urine.

**Urine Analysis**—Urine formaldehyde and methenamine concentrations were determined in duplicate using a spectrophotometric method (3).

**Statistical Analysis**—Urine free formaldehyde concentrations, as well as free formaldehyde and total methenamine excretion rates and the cumulative amount and percent excreted, were subjected to an analysis of variance to determine the level of significance for differences among products, subjects, and weeks. The data were analyzed using a logarithmic transformation because of significant nonadditivity in the untransformed data. Where significant differences were found ($p < 0.05$), the Newman–Keuls *a posteriori* test was applied to identify where these differences occurred.

## RESULTS AND DISCUSSION

**Free Formaldehyde Concentrations**—The mean urine free formaldehyde concentrations at each sampling are presented in Table II. The maximum mean formaldehyde concentrations ranged from 34.2 (Product 7) to 55.8 (Product 3) μg/ml at 12 hr. Although this difference was not significant ($p > 0.05$), significant differences ($p < 0.05$) were evident at 1, 2, 4, and 24 hr. The Newman–Keuls *a posteriori* test indicated the enteric-coated formulations (Products 4–9) generally resulted in lower formaldehyde concentrations than the other products during the first 4 hr. This finding is consistent with the fact that an enteric-coated dosage form must reach the intestinal tract before drug can be released. Maximum mean free formaldehyde concentrations were attained between 6 and 12 hr with all products, except Product 8, which had a maximum mean concentration at 24 hr.

The minimum inhibitory concentration for formaldehyde in urine was reported to range from 13 (4) to 18 μg/ml (5). Mean free formaldehyde levels in this range were attained within 1–2 hr from the nonenteric-coated Products 1–3 and 10; the enteric-coated products required 4–12 hr to provide free formaldehyde concentrations in this range.

The therapeutic efficacy of a methenamine product is thought to be related to the formaldehyde concentration in the urine. Formaldehyde formation is governed mainly by the rate and extent of intestinal absorption and renal excretion of methenamine and by the volume and pH of the urine. The mean free formaldehyde concentrations exhibited high relative standard deviations, partially because fluid intake and urine pH were not controlled in these subjects. In general, the urine pH ranged from 5.5 to 6.8, and the fluctuations within and among individuals obscured any correlations between urine pH and the formaldehyde concentrations obtained with the different products.

The mean cumulative 48-hr excretion of formaldehyde from each dosage form, expressed as methenamine equivalents, ranged from 26.8 (Product 10) to 37.7 (Product 6) mg. This 29% difference among products was not significant ($p > 0.05$). Since the total amount of methenamine administered was not identical in all 10 products, the cumulative amount of formaldehyde excreted at each sampling also was calculated as a percent of the total methenamine dose. The cumulative percent of formaldehyde excreted at 48 hr (Fig. 1) ranged from 5.5 (Product 2) to 8.7% (Product 8), but this 37% difference among products also was not significant ($p > 0.05$).

**Cumulative Excretion of Total Methenamine**—Although the measurement of free formaldehyde provided useful information, the large variations in these levels precluded a meaningful evaluation of dosage form bioavailability. Thus, the excretion of total methenamine equiva-

[a] Mean values of 10 subjects with percent relative standard deviation in parentheses. See Table I for product number identification.

lents also was determined. The sum of the amount of methenamine excreted as free formaldehyde and as free methenamine was expressed as milligrams of total methenamine. Statistical analysis of the mean cumulative amounts of total methenamine excreted at various sampling times showed highly significant differences ($p < 0.001$) among products at all sampling times.

One hour after administration of Products 1, 3, and 10, the mean cumulative amount of total methenamine excreted was 42.2, 39.8, and 31.1 mg, respectively. These recoveries were significantly higher than those for the other products. The 17.4 mg excreted at 1 hr with Product 2 was significantly higher than the amount for the enteric-coated tablets. The lowest levels at 1 hr were found with Product 5 (0.1 mg). At 2 and 4 hr, the excretion of total methenamine was significantly higher ($p < 0.05$) for the nonenteric-coated products than for the other dosage forms. Among the enteric-coated preparations, Products 5 and 7 gave the lowest total methenamine recoveries. At subsequent collections, Product 5 resulted in cumulative total methenamine levels that were significantly lower than those for all other products. Product 7 gave significantly higher cumulative total methenamine levels than Product 5 at 4, 6, 8, and 12 hr, but the levels with this product were lower than those attained with any other product.

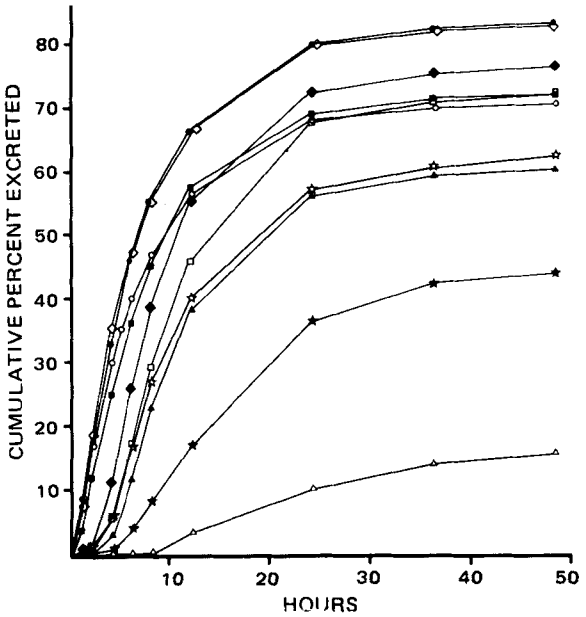

**Figure 2**—*Cumulative excretion of total methenamine, expressed as a percent of the administered dose. Each data point represents the mean of 10 subjects. Key:* ●, *Product 1;* ■, *Product 2;* ○, *Product 3;* ▲, *Product 4;* △, *Product 5;* □, *Product 6;* ☆, *Product 7;* ★, *Product 8;* ◆, *Product 9; and* ◇, *Product 10.*

The mean cumulative excretion of total methenamine, expressed as percent of administered dose at various collection times, is illustrated in Fig. 2. The results of the statistical evaluation are summarized in Table III. The percent of total methenamine excreted at 1 hr ranged from 0.03% for Products 5 and 7 to 8.4% for Product 1. At this sampling time, Products 1, 3, and 10 gave significantly higher total methenamine recoveries than did the other products. The 2-hr total methenamine values ranged from 0.06% for Product 7 to 18.6% for Product 1, with the values for Products 1, 3, and 10 being significantly higher than those for the other products.

The lowest cumulative total methenamine percentages at subsequent sampling times were with Product 5. Although the total methenamine excretion after Product 7 was significantly higher than after Product 5, it was lower than the values obtained with the other products at 4, 6, 8, 12, and 24 hr. The lowest cumulative percentage of total methenamine excreted at 48 hr was with Products 5 (16.2%) and 7 (44.2%). The total recoveries of all other products exceeded 60% at 48 hr.

**Excretion Rate of Total Methenamine**—The mean maximum excretion rates and times of the maximum excretion rate for total methenamine are summarized in Table IV. Statistically significant differences are indicated in Table III. The maximum excretion rate of total methenamine ranged from 4.8 mg/hr with Product 5 to 57.6 mg/hr with Product 1. The rates observed with Product 1 were significantly higher than those found with Products 4, 5, and 7. Product 5 exhibited significantly lower excretion rates compared to all others. The maximum excretion rate for Product 7 was higher than for Product 5 but was significantly lower than the rates for all other products.

In terms of percent of administered dose, the maximum excretion rate was highest for Product 10 (11.7%/hr) and lowest for Product 5 (1.0%/hr). The latter value was significantly lower than that observed after Product 7 (2.8%/hr). The times of the maximum excretion rate ($T_{max}$) were 1.6, 1.9, 2.3, and 2.9 hr for the nonenteric-coated Products 1, 3, 10, and 2, respectively. These times were significantly lower than those found for the other products. Products 5 and 7 yielded significantly longer $T_{max}$ values of 17.1 and 12.6 hr, respectively.

**Subject and Week Effects**—Each urinary excretion parameter also was statistically analyzed to determine the significance of differences observed among subjects and administration sequences (weeks). Since Subject 6 began the study several weeks after the other nine subjects and took the medication at 4-day intervals, the analysis of weekly differences actually related to differences that could have arisen because a dose was the first, second, third, *etc.*, dose administered.

Since there were no significant weekly differences, it may be concluded that the bioavailability of a particular dose of methenamine was not influenced by the previous administration of other dosage forms of the drug. Results of the analysis of the blank (zero time) urine samples also were monitored each week to determine if they showed any progressive increase, which would have occurred if the drug had been accumulating. No such trend was found in the blank readings. Furthermore, the statistical analysis did not indicate any significant differences among subjects in the excretion of either free formaldehyde or total methenamine.

## CONCLUSIONS

Methenamine compressed tablets, methenamine mandelate granules, and methenamine hippurate tablets showed the highest methenamine urinary recovery and were considered bioequivalent. The suspension dosage form exhibited adequate bioavailability but was less well absorbed than the other dosage forms. In general, the enteric-coated products exhibited delayed urinary excretion of methenamine, but Products 4, 6, 8, and 9 did not differ significantly from the nonenteric-coated products in most measurements. Two enteric-coated products (Products 5 and 7) were significantly less bioavailable than all other products tested. None of the 10 products differed significantly ($p > 0.05$) in urinary formaldehyde concentrations. However, the large intersubject variability precluded an accurate assessment of dosage form bioavailability using only free formaldehyde determinations.

# Effect of Antacid on Bioavailability of Theophylline from Rapid and Timed-Release Drug Products

**LEON SHARGEL ˣ, JUDY A. STEVENS, JOB E. FUCHS, and ANDREW B. C. YU ***

Received September 10, 1980, from the *College of Pharmacy and Allied Health Professions, Northeastern University, Boston, MA 02115.* Accepted for publication November 7, 1980. *Present address: Sterling-Winthrop Research Institute, Rensselaer, NY 12144.

**Abstract** □ Magnesium aluminum hydroxide suspension (an antacid) was given concurrently with either theophylline anhydrous tablets or theophylline anhydrous timed-release capsules to 13 volunteers using a four-way crossover design. Serum theophylline was measured by reversed-phase high-pressure liquid chromatography. The serum level–time curves were individually fitted to an oral absorption one-compartment open model. The pharmacokinetic parameters (mean ± *SD*) $K_A$, $K$, $AUC$, and $F/V$ for theophylline from the rapid release theophylline anhydrous tablets were 2.1 ± 1.3 $hr^{-1}$, 0.15 ± 0.06 $hr^{-1}$, 89.2 ± 30 μg hr/ml, and 0.0023 ± 0.002 kg/ml, respectively; from the anhydrous timed-release capsules, they were 0.27 ± 0.08 $hr^{-1}$, 0.20 ± 0.07 $hr^{-1}$, 79.0 ± 27 μg hr/ml, and 0.0030 ± 0.0007 kg/ml, respectively. The concurrent administration of 15 ml of antacid (magnesium aluminum hydroxide suspension) with the theophylline products did not significantly affect any of these pharmacokinetic parameters. The extent of theophylline bioavailability from all drug products was consistent and similar as shown by the $F/V$ and $AUC$ values.

**Keyphrases** □ Theophylline—effect of antacid on bioavailability, tablets and timed-release capsules □ Antacids—effects on theophylline bioavailability, tablets and timed-release capsules □ Pharmacokinetics—effect of antacid on theophylline, tablets and timed-release capsules □ Dosage forms—tablets and timed-release capsules, effect of antacid on theophylline bioavailability

Theophylline is used extensively in the treatment of various respiratory diseases (1–4). When taken in the recommended dosage, it relieves or prevents symptoms associated with asthma, bronchitis, and emphysema. The amount of relief produced is directly related to the serum drug concentration. Side effects (nausea, vomiting, headache, and restlessness) are usually associated with high blood theophylline levels (>20 μg/ml), although some individuals may experience side effects at lower levels (1–4).

Magnesium aluminum hydroxide suspension is a commonly used antacid for the symptomatic relief of hyperacidity, gastritis, and heartburn. However, antacids affect the bioavailability of various drugs (5–8). The object of this investigation was to determine the effect of concurrent antacid therapy on the rate and extent of theophylline absorption from theophylline anhydrous tablets and theophylline anhydrous timed-release capsules.

## EXPERIMENTAL

**Reagents and Chemicals**—All reagents and chemicals including theophylline anhydrous[1], sodium acetate[1], 7-(β-hydroxypropyl)theophylline[1], β-hydroxyethyltheophylline[1], 8-chlorotheophylline[1], theo-

[a] Volunteer withdrew from study after receiving Treatments B–D. [b] Volunteer withdrew from study after receiving Treatment A only.

bromine[2], caffeine[3], and acetonitrile[4] were of USP, NF, or analytical grade and were used as received. Normal serum samples[5] were obtained from healthy students. All other reagents and solvents were purchased from commercial sources and used without further purification.

**Design**—Fourteen male volunteers (18–26 years old), weighing an average of 77 kg, were judged healthy by physical examination. The volunteers refrained from all other medications, smoking, and theophylline-containing beverages such as coffee, tea, chocolate, and cola prior to and during the study. Each volunteer fasted overnight prior to and for 4 hr after receiving the theophylline formulation.

The following drug products were given to each volunteer in a four-way crossover Latin-square design with a 1-week interval between treatments: Product A, theophylline anhydrous tablets[6]; Product B, theophylline anhydrous timed-release capsules[7]; Product C, theophylline anhydrous tablets[6] with 15 ml of magnesium aluminum hydroxide suspension[8]; and Product D, theophylline anhydrous timed-release capsules[7] with 15 ml of magnesium aluminum hydroxide suspension[8].

All doses of theophylline were based on 5 mg/kg, and each drug product was given with 240 ml of water. Both serum and urine samples were obtained at zero time and periodically after medication. Serum samples were assayed for theophylline, and urine samples were tested for pH.

**Theophylline Assay**—Serum samples were assayed for theophylline concentrations by reversed-phase high-pressure liquid chromatography (HPLC) (9) with $\beta$-hydroxyethyltheophylline as the internal standard.

The high-pressure liquid chromatograph[9] was fitted with a UV (254 nm) absorbance detector and strip-chart recorder[10]. Samples were chromatographed on a reversed-phase HPLC column, 30 cm × 4 mm i.d., packed with 10-$\mu$m octadecyltrichlorosilane-coated silica beads[11]. The mobile phase was prepared by mixing 930 ml of a 10-mmole sodium acetate buffer (pH 4.0) with 70 ml of acetonitrile. The mobile phase was degassed and filtered[12] prior to use.

All determinations were performed at ambient temperature with a solvent flow rate of 2 ml/min. The detector sensitivity scale was 0.005, and the chart speed was 0.25 cm/min. Pressure was maintained at ~2200 psi. All sample injections were 10 $\mu$l.

A standard theophylline concentration curve was prepared daily by processing pooled serum samples spiked with known concentrations of theophylline concurrently with the unknown serum samples. A statistical least-squares fitting procedure was employed for calculating the standard curve by comparing the peak height ratio of theophylline to $\beta$-hydroxyethyltheophylline to the spiked serum theophylline concentrations. Assay sensitivity was ~0.5 $\mu$g/ml, which is adequate for measuring the expected serum theophylline concentrations. This HPLC procedure was validated using control human serum samples containing known concentrations of theophylline, which were unknown to the operator ($r$ 0.972).

**Table II—Effect of Antacid on Theophylline Pharmacokinetics from Rapid and Timed-Release Drug Products**

| Parameter | Product A | Product B | Product C | Product D |
|---|---|---|---|---|
| $K_A$, hr$^{-1}$ | 2.10[a] (1.31) | 0.27[b] (0.08) | 2.41 (1.77) | 0.24[b] (0.06) |
| $K$, hr$^{-1}$ | 0.15 (0.06) | 0.20 (0.07) | 0.16 (0.07) | 0.17 (0.06) |
| $F/V$, kg/ml | 0.0023 (0.0003) | 0.0030 (0.0007) | 0.0025 (0.0004) | 0.0024 (0.0005) |
| $AUC$, $\mu$g hr/ml | 89.2 (30.4) | 79.0 (27.4) | 87.3 (28.5) | 76.2 (32.5) |
| $t_{max}$[c], hr | 1.66 (0.67) | 4.45[b] (0.92) | 1.73 (0.91) | 5.04[b,d] (0.89) |

[a] Each value represents the mean for 13 volunteers with the standard deviation in parentheses. [b] $p < 0.01$ compared to Product A. [c] Obtained by calculation. [d] $p < 0.01$ compared to Product B.

## RESULTS

The patient data and doses of theophylline appear in Table I. The serum theophylline concentration–time curves obtained from each patient were fitted to an oral absorption one-compartment open model using a least-squares regression analysis program[13]. Preliminary parameter

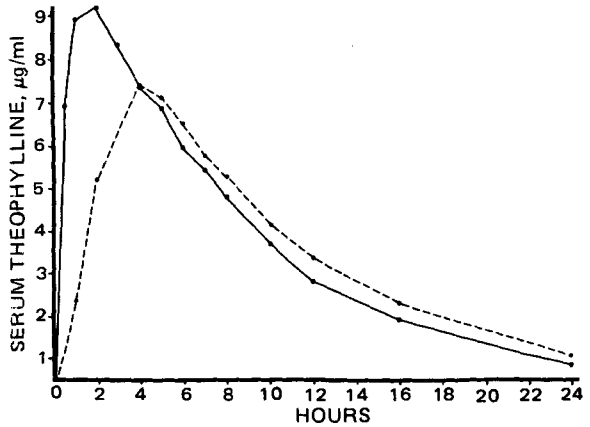

**Figure 1**—*Comparison of mean theophylline level–time curves in volunteers after receiving either Product A, theophylline anhydrous tablets (●—), or Product B, theophylline anhydrous time-release capsules (○- - -); n = 13.*

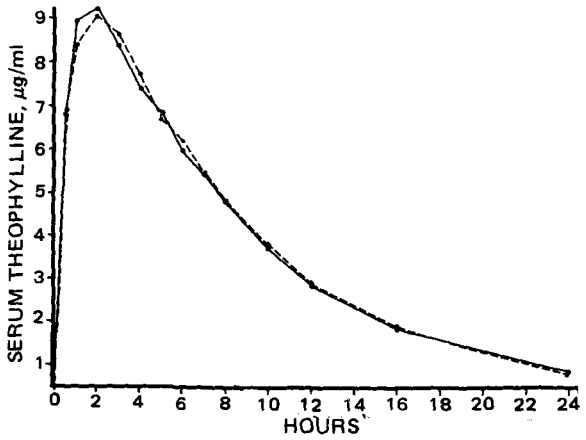

**Figure 2**—*Comparison of mean theophylline level–time curves in volunteers after receiving either Product A, theophylline anhydrous tablets (●—), or Product C, theophylline anhydrous tablets plus 15 ml of antacid (○- - -); n = 13.*

estimates were made using the Wagner–Nelson method (10). The one-compartment oral absorption model (Scheme I) is described by:

$$\xrightarrow{K_A} \boxed{V, C} \xrightarrow{K}$$

*Scheme I*

$$C = \frac{FDK_A}{(K_A - K)V}(e^{-Kt} - e^{-K_{at}}) \qquad \text{(Eq. 1)}$$

where $K_A$ is the first-order absorption rate constant, $K$ is the first-order elimination rate constant, $D$ is the dose, $C$ is the serum drug concentration, $V$ is the volume of distribution, $t$ is the time after drug adminstration, and $F$ is the fraction of drug absorbed.

The time for peak serum theophylline level ($t_{max}$) for each subject was calculated from:

$$t_{max} = \frac{\ln(K_A/K)}{K_A - K} \qquad \text{(Eq. 2)}$$

and the maximum serum theophylline level ($C_{max}$) was calculated by substitution of $t_{max}$ for $t$ in Eq. 1. Computer estimation of theophylline pharmacokinetic parameters for each patient and each drug product was obtained. Coefficients of correlation for the theophylline anhydrous tablets and the theophylline anhydrous timed-release capsules were 0.97–0.99 and 0.96–0.99, respectively, demonstrating excellent fit of the data. The $t_{max}$ is the time for peak serum theophylline concentration as calculated from $K_A$ and $K$.

The mean pharmacokinetic parameters obtained for the theophylline anhydrous tablets and theophylline anhydrous timed-release capsules are shown in Table II. As expected, the $K_A$ value (2.10 ± 1.31 $hr^{-1}$) for the theophylline bioavailability rate from the rapid release tablet was significantly larger than the $K_A$ (0.27 ± 0.08 $hr^{-1}$) for theophylline bioavailability from the timed-release capsules. Furthermore, the $t_{max}$ for rapid release theophylline anhydrous tablets (Product A) was 1.66 ± 0.67 hr, which was significantly shorter than the $t_{max}$ of 4.45 ± 0.92 hr for the theophylline anhydrous timed-release capsules (Product B). The corresponding serum theophylline level–time curves for Products A and B are shown in Fig. 1.

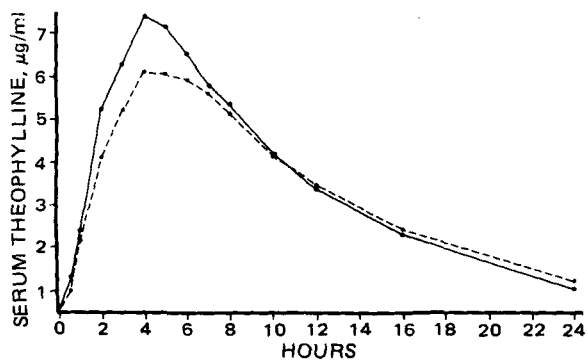

**Figure 3**—*Comparison of mean theophylline level–time curves in volunteers after receiving either Product B, theophylline anhydrous timed-release capsules (●—), or Product D, theophylline anhydrous timed-release capsules plus 15 ml of antacid (○- - -); n = 13.*

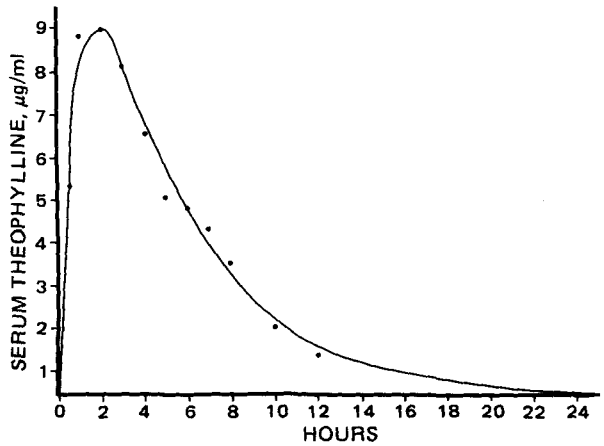

**Figure 4**—*Predicted serum theophylline level time–curve in Patient 1 after receiving Product A, theophylline anhydrous tablets. Experimental values are indicated.*

The medication of 15 ml of magnesium aluminum hydroxide suspension given concurrently with the theophylline products did not affect the $t_{max}$ for the rapid release theophylline tablets (Product C) but significantly ($p < 0.05$) increased the $t_{max}$ for the timed-release theophylline capsules (Product D) (Table II and Figs. 2 and 3). However, the apparent rate constant for absorption, $K_A$, for theophylline from the timed-release capsules was not affected by concurrent antacid administration.

The extent of theophylline bioavailability from both rapid release and timed-release forms was essentially similar as shown by the *AUC* values. Furthermore, there were no differences in the *F/V* values for both drug products, demonstrating that theophylline availability was similar and consistent. Moreover, the concurrent administration of 15 ml of magnesium aluminum hydroxide suspension with either the rapid release or timed-release theophylline drug products did not affect the *AUC* or *F/V* values (Table II).

The observed serum theophylline concentration–time curves and the theoretically calculated curves for each drug product in one patient are shown in Figs. 4–7. All curves from each patient demonstrated excellent correlation coefficients, indicating that the data were well described by the oral absorption one-compartment open model.

Urine pH was measured for each individual. No significant differences in urine pH due to antacid were apparent in the specimens collected during the entire 24 hr of sampling.

## DISCUSSION

Theophylline pharmacokinetics after an intravenous bolus have been described as a two-compartment open model with a very rapid distribution phase (3, 11–14). The results of this study confirm previous reports that the one-compartment open model may be used to describe the oral absorption of theophylline from a rapid release tablet or a timed-release capsule (3, 13, 14).

Concurrent administration of 15 ml of magnesium aluminum hy-

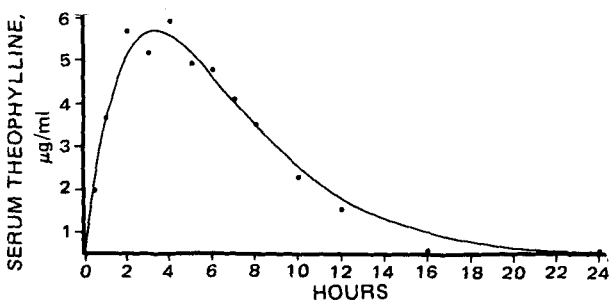

**Figure 5**—*Predicted serum theophylline level–time curve in Patient 1 after receiving Product B, theophylline anhydrous timed-release capsules. Experimental values are indicated.*

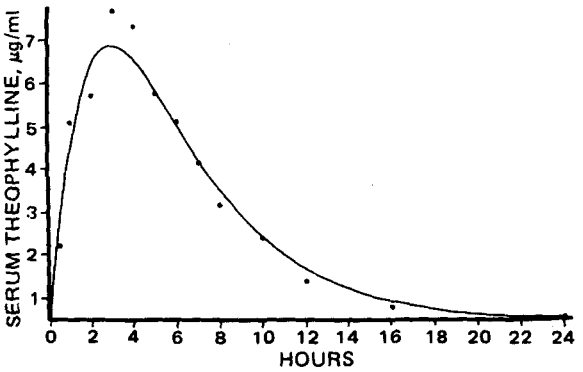

**Figure 6**—*Predicted serum theophylline level–time curve in Patient 1 after receiving Product C, theophylline anhydrous tablets plus 15 ml of antacid. Experimental values are indicated.*

droxide suspension with the rapid release theophylline anhydrous tablets did not affect theophylline bioavailability, as shown by the lack of any significant effect on the various pharmacokinetic parameters measured.

Antacid given with the theophylline anhydrous timed-release capsules increased the time for peak serum concentration, $t_{max}$, by ~13%. However, both the absorption rate constant, $K_A$, and the *AUC* for theophylline from the timed-release capsules were not affected by concurrent antacid administration. Therefore, the extent of theophylline bioavailability from the timed-release capsules was unaffected by antacid, and the theophylline bioavailability rate was affected only slightly.

A previous study (5) reported that 30 ml of magnesium aluminum hydroxide suspension significantly decreased the $K_A$ for theophylline in volunteers given a single 200-mg dose of aminophylline tablets. This decrease may have been due to the fact that theophylline was given as the ethylenediamine salt (aminophylline) and in smaller doses compared to the present study. In addition, 30 ml of antacid was given compared to the 15 ml used in this study. In both studies, the elimination rate constant, $K$, *AUC*, and $F/V$ values were in good agreement.

In conclusion, these data demonstrate that the concurrent administration of 15 ml of magnesium aluminum hydroxide suspension does not significantly affect the bioavailability of theophylline from theophylline anhydrous tablets or theophylline anhydrous timed-release capsules.

hypoglycemic activity. Therefore, two main series of *p*-(3-methyl-5-phenylpyrazole-1)benzenesulfonylurea and *p*-(4-bromo -3- methyl-5-phenylpyrazole-1)benzenesulfonylurea derivatives were synthesized. Some synthesized compounds were tested for hypoglycemic activity. Preliminary biological testing revealed that the compounds possess potent antidiabetic activity.

## DISCUSSION

The new pyrazoles are listed in Tables I and II. The antidiabetic activity of selected compounds is listed in Table III.

1-Phenylbutane-1,3-dione (1) reacts with aryl hydrazines to give a monohydrazone. On heating, this monohydrazone cyclizes to 1-aryl-3-methyl-5-phenylpyrazoles (9–12).

1-(*p*-Sulfamylphenyl)-3-methyl-5-phenylpyrazole (III) was prepared by treating *p*-sulfamylphenylhydrazine (II) with an equivalent amount of 1-phenylbutane-1,3-dione. Alkaline potassium permanganate oxidation of III afforded 1-(*p*-sulfamylphenyl)-5-phenylpyrazole-3-carboxylic acid (IV).

Bromination of III afforded 1-(*p*-sulfamylphenyl)-4-bromo-3-methyl-5-phenylpyrazole (VII). Acetylation of III with acetic anhydride afforded the monoacetyl derivative, as confirmed by microanalysis and IR and PMR spectra.

Substituted *p*-(3-methyl-5-phenylpyrazole-1)benzenesulfonylurea (V) and *p*-(4-bromo-3-methyl-5-phenylpyrazole-1)benzenesulfonylurea (VIII) derivatives were prepared by the reaction between III or VII and the appropriate isocyanate in dry acetone (13).

Substituted *p*-(3-methyl-5-phenylpyrazole-1)benzenesulfonylthiourea (VI) and *p*-(4-bromo-3-methyl-5-phenylpyrazole-1)benzenesulfonylthiourea (IX) derivatives were prepared by treatment of III or VII with the appropriate isothiocyanate.

## EXPERIMENTAL[2]

**1-(*p*-Sulfamylphenyl)-3-methyl-5-phenylpyrazole (III)**—A mixture of *p*-sulfamylphenylhydrazine (18.7 g, 0.1 mole) and 1-phenylbutan-1,3-dione (16.6 g, 0.1 mole) in ethanol (150 ml) was refluxed for

[2] Melting points were determined on a Kofler block and are uncorrected. IR spectra were determined as Nujol mulls with a Beckman IR-4210 spectrometer. PMR spectra were recorded on a Varian A-60 A spectrometer. Microanalyses were performed by the Microanalytical Unit, Faculty of Science, University of Cairo, Cairo, Egypt.

4–6 hr on a steam bath, concentrated, and allowed to cool. The crude product was separated and recrystallized (75% yield) from ethanol, mp 198°.

*Anal.*—Calc. for $C_{16}H_{15}N_3O_2S$: C, 61.3; H, 4.8; N, 13.4; S, 10.2. Found: C, 61.4; H, 4.5; N, 13.2; S, 10.1.

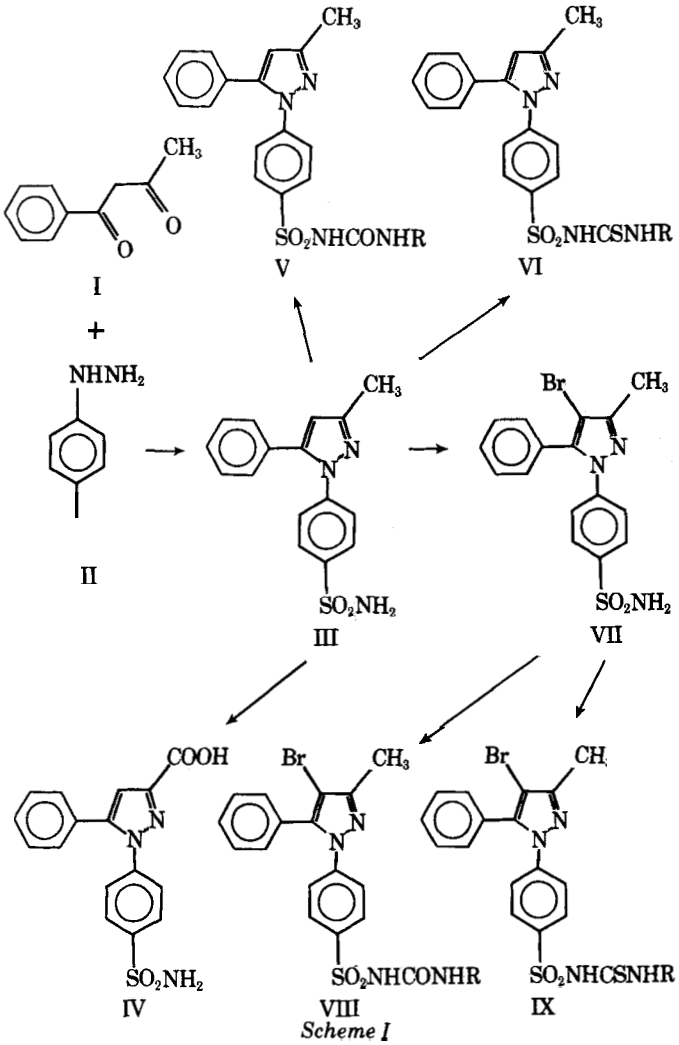
**1-(*p*-Sulfamylphenyl)-5-phenylpyrazole-3-carboxylic Acid (IV)**—A stirred mixture of III (0.1 mole) and sodium hydroxide (0.15 mole) in water (100 ml) was treated with powdered potassium permanganate (30 g) over 4 hr with stirring and cooling (temperature should not exceed 20°). Stirring was continued for 2 additional hr, and the mixture was left standing overnight. The mixture then was filtered and neutralized with 2 *N* HCl. The crude product was separated and crystallized from ethanol as colorless needles (65% yield), mp 185°.

*Anal.*—Calc. for $C_{16}H_{13}N_3O_4S$: C, 56.0; H, 3.8; N, 12.2; S, 9.3. Found: C, 55.7; H, 3.6; N, 12.0; S, 9.7.

**1-(*p*-Sulfamylphenyl) -4- bromo-3-methyl-5-phenylpyrazole (VII)**—A mixture of III (0.1 mole) in chloroform (100 ml) was stirred with bromine (0.1 mole) for 1 hr. The crude product that separated during stirring was filtered and recrystallized from ethanol as colorless needles (85% yield), mp 228°.

*Anal.*—Calc. for $C_{16}H_{14}BrN_3O_2S$: C, 49.0; H, 3.6; Br, 20.4; N, 10.7; S, 8.2. Found: C, 49.2; H, 3.4; Br, 20.6; N, 10.6; S, 8.4.

**1-(*p*-Acetamidosulfonylphenyl)-3-methyl-5-phenylpyrazole**—A mixture of III (0.01 mole), sodium acetate (0.02 mole), and acetic anhydride (10 ml) was refluxed for 3 hr. After cooling, the reaction mixture was poured onto water. The acetyl derivative was recrystallized from



*Scheme I*

methanol as white needles (65% yield), mp 172°.

*Anal.*—Calc. for $C_{18}H_{17}N_3O_3S$: C, 60.8; H, 4.8; N, 11.8; S, 9.0. Found: C, 61.1; H, 4.7; N, 11.5; S, 9.3.

The IR spectra of this acetyl derivative revealed a secondary carbonyl amide absorption at 1710 $cm^{-1}$ in addition to the two bands of the $SO_2N$ group at 1350 and 1170 $cm^{-1}$. The PMR spectra showed three singlets at δ 6.2, 2.3, and 1.8 for C-4, acetyl, and methyl protons, respectively, in addition to the aromatic protons at δ 7.9–7.1.

**Substituted *p*-(3-Methyl-5-phenylpyrazole-1)benzenesulfonylurea (V) and *p*-(4-Bromo-3-methyl-5-phenylpyrazole-1)benzenesulfonylurea (VIII) Derivatives**—A mixture of III or VII (0.05 mole) and anhydrous potassium carbonate (0.1 mole) in dry acetone (100 ml) was stirred and refluxed for 1.5 hr. At this temperature, a solution of the appropriate isocyanate (0.075 mole) in dry acetone (20 ml) was added dropwise. After the mixture was stirred and refluxed overnight, acetone was removed under reduced pressure, and the solid residue was dissolved in water. The crude product was isolated by acidification with 2 *N* HCl and purified by recrystallization from ethanol. The IR spectra of these compounds revealed two absorption bands at 1350–1330 and 1190–1170 $cm^{-1}$, indicative of the $SO_2N$ group as well as a urea carbonyl band at 1660 $cm^{-1}$.

**Substituted *p*-(3-Methyl-5-phenylpyrazole-1)benzenesulfonylthiourea (VI) and *p*-(4-Bromo-3-methyl-5-phenylpyrazole-1)benzenesulfonylthiourea (IX) Derivatives**—A mixture of III or VII (0.05 mole) and anhydrous potassium carbonate (0.1 mole) in dry acetone (100 ml) was stirred and treated with the appropriate isothiocyanate (0.06 mole). After the mixture was stirred and refluxed for 10 hr, acetone was removed under reduced pressure. The solid mass thus obtained was dissolved in water and acidified with 2 *N* HCl. The crude product was purified by recrystallization from dilute ethanol.

The IR spectra of these compounds revealed two absorption bands at 1350–1335 and 1180–1170 $cm^{-1}$, indicative of the $SO_2N$ group, and a band at 1200–1050 $cm^{-1}$, indicative of the C=S group, with the C–N absorption (III) at 1300 $cm^{-1}$.

**1-[*p*-(2-Pyrimidinylsulfamyl)phenyl]-3-methyl-5-phenylpyrazole**—A mixture of *p*-(2-pyrimidinylsulfamyl)phenylhydrazine (0.05 mole) and 1-phenylbutane-1,3-dione (0.05 mole) in ethanol (50 ml) was refluxed for 6 hr on a steam bath, concentrated, and allowed to cool. The crude product was recrystallized from ethanol as colorless crystals (75% yield), mp 265°.

*Anal.*—Calc. for $C_{20}H_{17}N_5O_2S$: C, 61.3; H, 4.3; N, 17.9; S, 8.2. Found: C, 60.9; H, 4.5; N, 17.5; S, 8.0.

**Biological Testing Method**—Compounds IV, V*b*–V*e*, VI*c*, VIII*d*, and IX*e* were tested for hypoglycemic activity using alloxan-treated female albino mice weighing 20 g. Alloxan, 100 mg/kg, was injected into the tail vein in a 10-mg/ml saline solution. Three days later, the mice were given the test compounds orally in suspension in 1% carboxymethylcellulose solution at the rate of 10 mg/kg.

Each day, a group of six mice was used as a control, and one group of six mice was given the standard, 100 mg of phenformin/kg. Up to six groups of six mice received the test compounds. Blood samples were collected into 0.04% NaF solution at 0, 1, and 3 hr.

Glucose was determined by the microcolorimetric copper reduction technique of Haslewood and Strookman (14). Results are expressed as a percentage reduction of the plasma glucose level compared to the control value.

Statistical significance was assessed by a Student *t* test. Statistical significance was accepted where the calculated *t* value exceeded the tabulated *t* value at $p = 0.05$.

From the data presented in Table III, it is obvious that V*b*–V*d* and VIII*d* possess marked hypoglycemic activity. The potency of these compounds is more than that of phenformin, and they are much more active than the parent compound, 3,5-dimethylpyrazole.

**Table III—Antidiabetic Activity of Substituted *p*-(3-Methyl-5-phenylpyrazole-1)benzenesulfonylurea Derivatives**

| Compound | Reduction in Plasma Glucose Level, % | *p* |
|---|---|---|
| Phenformin | 10 | <0.01[a] |
| 3,5-Dimethylpyrazole | 4 | <0.05[a] |
| IV | <1 | 0.05 |
| V*b* | 20 | <0.01[a] |
| V*c* | 21 | <0.01[a] |
| V*d* | 12.5 | <0.01[a] |
| V*e* | 4 | 0.05 |
| VI*c* | 2 | 0.05 |
| VIII*d* | 15 | <0.01[a] |
| IX*e* | 2 | 0.05 |

[a] Statistically significant.

# Preparation and Antidiabetic Activity of New Substituted 3,5-Diarylpyrazolesulfonylurea Derivatives

**RAAFAT SOLIMAN** *x, **HASSAN M. FEID-ALLAH** §, **SAMIR K. EL SADANY** §, and **HOSNY F. MOHAMED** ‡

Received August 18, 1980, from the *Department of Pharmaceutical Chemistry and the ‡Department of Pharmacology, Faculty of Pharmacy, and the §Department of Chemistry, Faculty of Science, University of Alexandria, Alexandria, Egypt. Accepted for publication September 26, 1980.

**Abstract** □ Four series of *p*-(3,5-diphenylpyrazole-1)-, *p*-[5-(*p*-chlorophenyl)-3-phenylpyrazole-1]-, *p*-[5-(*p*-chlorophenyl)-4-hydroxy-3-phenyl-2-pyrazolin-1-yl]-, and *p*-[5-(*p*-chlorophenyl)-4-hydroxy-3-phenylpyrazole-1]benzenesulfonylurea derivatives were prepared for evaluation as hypoglycemic agents. Preliminary biological testing revealed that the new compounds possess potent hypoglycemic activity.

**Keyphrases** □ 3,5-Diarylpyrazolesulfonylurea derivatives, substituted—preparation and evaluation for antidiabetic activity □ Structure–activity relationships—substituted 3,5-diarylpyrazolesulfonylurea derivatives and antidiabetic activity □ Antidiabetic activity—substituted 3,5-diarylpyrazolesulfonylurea derivatives synthesized and tested

Since several 3,5-dimethylpyrazoles possess hypoglycemic activities as great as 100 times that of tolbutamide in glucose-primed intact rats (1–5), studies have been conducted on the synthesis of new 3,5-disubstituted pyrazoles (6–9). In continuation of previous work (8, 9), many new substituted 3,5-diarylpyrazolesulfonylurea derivatives were prepared[1].

In light of the biological data reported in this paper and previously (8, 9), a possible structure–activity relationship for hypoglycemic activity may result.

Four series of *p*-(3,5-diphenylpyrazole-1)-, *p*-[5-(*p*-chlorophenyl)-3-phenylpyrazole-1]-, *p*-[5-(*p*-chlorophenyl)-4-hydroxy-3-phenyl-2-pyrazolin-1-yl]-, and *p*-[5-(*p*-chlorophenyl)-4-hydroxy -3- phenylpyrazole-1]benzenesulfonylurea derivatives were synthesized. Some compounds were tested for hypoglycemic activity. Preliminary biological testing revealed that the compounds showed potent antidiabetic activity.

## DISCUSSION

The new pyrazoles are listed in Tables I and II. The compounds listed in Table III were tested for antidiabetic activity.

1-(*p*-Sulfamylphenyl)-3,5-diphenylpyrazole (III) was prepared by treating *p*-sulfamylphenylhydrazine (I) with an equivalent amount of epoxybenzalacetophenone (II) (Scheme I). Acetylation of III with acetic anhydride afforded the monoacetyl derivative (IV*a*). Similarly, benzoylation of III with benzoyl chloride or *p*-methoxybenzoyl chloride in pyridine afforded the corresponding monobenzoyl (IV*b*) and the *p*-methoxybenzoyl (IV*c*) derivatives, respectively, as affirmed by microanalysis and IR spectra.

Condensation of I with an equivalent amount of epoxy-*p*-chlorobenzalacetophenone (VII) afforded a mixture of 1-(*p*-sulfamylphenyl)-5-(*p*-chlorophenyl)-3-phenylpyrazole (VIII) and 1-(*p*-sulfamylphenyl)-5-(*p*-chlorophenyl)-4-hydroxy-3-phenyl-2-pyrazoline (IX). Compound IX, on oxidation with bromine water, gave 1-(*p*-sulfamylphenyl)-5-(*p*-chlorophenyl)-4-hydroxy-3-phenylpyrazole (X). Benzoylation of VIII and IX afforded the corresponding benzamidosulfonyl derivatives (Scheme II).

Substituted *p*-(3,5-diphenylpyrazole-1)- (V), substituted *p*-[5-(*p*-chlorophenyl)-3-phenylpyrazole-1]- (XII), substituted *p*-[5-(*p*-chlorophenyl)-4-hydroxy-3-phenyl-2-pyrazolin-1-yl]- (XIII), and substituted *p*-[5-(*p*-chlorophenyl) -4- hydroxy-3-phenylpyrazole-1]benzenesulfonylurea (XIV) derivatives were prepared by the reaction between III, VIII, IX, or X and the appropriate isocyanate in dry acetone (10).

Substituted *p*-(3,5-diphenylpyrazole-1)- (VI), substituted *p*-[5-(*p*-chlorophenyl)-3-phenylpyrazole-1]- (XII), substituted *p*-[5-(*p*-chlorophenyl)-4-hydroxy-3-phenyl-2-pyrazolin-1-yl]- (XIII), and substituted *p*-[5-(*p*-chlorophenyl)-4-hydroxy -3- phenylpyrazole-1]benzenesulfonylthiourea (XIV) derivatives were prepared by the reaction between III, VIII, IX, or X and the appropriate isothiocyanates in dry acetone.

Substituted *p*-[5-(*p*-chlorophenyl)-4-hydroxy-3-phenylpyrazole-1]-benzenesulfonylurea and thiourea derivatives were also prepared by direct oxidation of the corresponding 2-pyrazoline derivatives (XIII*a*–XIII*f*) using bromine water.

## EXPERIMENTAL[2]

**1-(*p*-Sulfamylphenyl)-3,5-diphenylpyrazole (III)**—A mixture of *p*-sulfamylphenylhydrazine (I, 0.1 mole) and epoxybenzalacetophenone (II, 0.1 mole) in absolute ethanol (50 ml) was refluxed for 3 hr on a steam bath, concentrated, and allowed to cool. The crude product was filtered and recrystallized from ethanol as colorless prismatic needles (75% yield), mp 172°. The IR spectrum of III revealed two characteristic bands at 1365 and 1170 $cm^{-1}$, indicative of the $SO_2N$ group, and two bands at 3170 and 3350 $cm^{-1}$, indicative of the $NH_2$ group.

*Anal.*—Calc. for $C_{21}H_{17}N_3O_2S$: C, 67.2; H, 4.5; N, 11.2; S, 8.5. Found: C, 67.2; H, 4.4; N, 11.3; S, 8.4.

**1-(*p*-Acetamidosulfonylphenyl)-3,5-diphenylpyrazole (IV*a*)**—A mixture of III (0.01 mole), sodium acetate (0.02 mole), and acetic anhydride (10 ml) was refluxed for 4 hr. After cooling, the reaction mixture was diluted with water. The crude acetyl derivative was recrystallized from dilute methanol in yellow needles (65% yield), mp 98°. The IR spectrum of IV*a* revealed a secondary carbonyl amide absorption at 1720 $cm^{-1}$ and an NH band at 3090 $cm^{-1}$ in addition to the two bands of the $SO_2N$ group at 1365 and 1170 $cm^{-1}$.

*Anal.*—Calc. for $C_{23}H_{19}N_3O_3S$: C, 66.2; H, 4.6; N, 10.1; S, 7.7. Found: C, 66.0; H, 4.8; N, 10.3; S, 7.9.

**1-(*p*-Benzamidosulfonylphenyl)-3,5-diphenylpyrazole (IV*b*)**—A solution of III (0.001 mole) in pyridine (5 ml) was heated with benzoyl chloride (0.001 mole) for 20 min. The reaction mixture was left at room temperature for 6 hr and then diluted with ice-cold water. The crude product was purified by recrystallization from dilute methanol to give white needles (70% yield), mp 135°. The IR spectrum of IV*b* revealed a secondary carbonyl amide absorption at 1705 $cm^{-1}$ and an NH band at 3100 $cm^{-1}$, in addition to the two bands of the $SO_2N$ group at 1365 and 1170 $cm^{-1}$.

*Anal.*—Calc. for $C_{28}H_{21}N_3O_3S$: C, 70.1; H, 4.4; N, 8.8; S, 6.7. Found: C, 69.8; H, 4.2; N, 9.0; S, 6.7.

**1-[*p*-(*p*-Methoxybenzamido)sulfonylphenyl]-3,5-diphenylpyrazole (IV*c*)**—A solution of III (0.001 mole) in pyridine (5 ml) was heated with *p*-methoxybenzoyl chloride (0.001 mole) for 20 min. The reaction mixture then was left at room temperature for 6 hr and diluted with ice-cold water. The crude product was purified by recrystallization from dilute methanol to give white needles (70% yield), mp 225°. The IR spectrum of IV*c* revealed a secondary carbonyl amide absorption at 1700 $cm^{-1}$ and an NH band at 3090 $cm^{-1}$ in addition to the two bands of the $SO_2N$ group at 1365 and 1170 $cm^{-1}$.

[1] Application for a patent was made for compounds described in this report.

[2] Melting points were determined on a Kofler block and are uncorrected. IR spectra were determined as Nujol mulls with a Beckman IR-4210 spectrometer. PMR spectra were recorded on a Varian A-60 A spectrometer. Microanalyses were performed by the Microanalytical Unit, Faculty of Science, University of Cairo, Cairo, Egypt.

**1-(*p*-Benzamidosulfonylphenyl)-5-(*p*-chlorophenyl)-4-hydroxy-3-phenyl-2-pyrazoline**—A solution of IX (0.001 mole) in pyridine (5 ml) was heated with benzoyl chloride (0.001 mole) for 20 min. The reaction mixture then was left at room temperature for 6 hr and diluted with ice-cold water. The crude product was purified by recrystallization from methanol to give white needles (75% yield), mp 162°. The IR spectrum revealed a band at 3380 $cm^{-1}$, indicative of an OH group, a secondary carbonyl amide band at 1710 $cm^{-1}$, and an NH band at 3100 $cm^{-1}$.

*Anal.*—Calc. for $C_{28}H_{22}ClN_3O_4S$: C, 63.2; H, 4.1; Cl, 6.7; N, 7.9; S, 6.0. Found: C, 63.4; H, 4.5; Cl, 6.8; N, 7.7; S, 6.0.

**1-[*p*-(*p*-Methoxybenzamido)sulfonylphenyl] -5- (*p*-chlorophenyl)-4-hydroxy-3-phenyl-2-pyrazoline**—A solution of IX (0.001 mole) in pyridine (5 ml) was heated with *p*-methoxybenzoyl chloride (0.001 mole) for 20 min. The reaction mixture then was left at room temperature for 6 hr and diluted with ice-cold water. The crude product was purified by recrystallization from ethanol to give white needles (70% yield), mp 190°. The IR spectrum revealed a band at 3350 $cm^{-1}$, indicative of an OH group, a secondary carbonyl amide band at 1715 $cm^{-1}$, and an NH band at 3100 $cm^{-1}$.

*Anal.*—Calc. for $C_{29}H_{24}ClN_3O_5S$: C, 62.0; H, 4.3; Cl, 6.3; N, 7.5; S, 5.7. Found: C, 62.2; H, 4.3; Cl, 6.1; N, 7.6; S, 5.8.

**1 - (*p* - Sulfamylphenyl)-5-(*p*-chlorophenyl)-4-hydroxy-3-phenylpyrazole (X)**—A suspension of IX (0.01 mole) in water (10 ml) was treated with 5% bromine water until a faint-yellow color developed with stirring. Stirring continued for 2 hr, and the crude pyrazole was filtered and recrystallized from methanol as colorless needles (45% yield), mp 252°. The IR spectrum of X showed a band at 3400 $cm^{-1}$, indicative of an OH group, and two bands at 3230 and 3290 $cm^{-1}$, indicative of an $NH_2$ group.

*Anal.*—Calc. for $C_{21}H_{16}ClN_3O_3S$: C, 59.2; H, 3.8; Cl, 8.3; N, 9.9; S, 7.5. Found: C, 59.1; H, 3.9; Cl, 8.1; N, 10.1; S, 7.5.

**Substituted *p*-(3,5-Diarylpyrazole-1)benzenesulfonylurea (V, XII, and XIV) Derivatives**—A mixture of III, VIII, or X (0.01 mole) and anhydrous potassium carbonate (0.02 mole) in dry acetone (25 ml) was stirred and refluxed for 1 hr. At this temperature, a solution of the appropriate isocyanate (0.015 mole) in dry acetone (5 ml) was added dropwise. After the mixture was stirred and refluxed overnight, acetone was removed under reduced pressure, and the solid residue was dissolved in water. The crude product was isolated by acidification with 2 *N* HCl and purified by recrystallization from ethanol (Table I).

**Substituted *p*-(3,5-Diarylpyrazole-1)benzenesulfonylthiorea (VI, XII, and XIV) Derivatives**—A mixture of III, VIII, or X (0.01 mole) and anhydrous potassium carbonate (0.02 mole) in dry acetone (25 ml) was stirred and treated with the appropriate isothiocyanate (0.012 mole). After the mixture was stirred and refluxed for 10 hr, acetone was removed under reduced pressure, and the solid mass was dissolved in water and acidified with 2 *N* HCl. The crude product was purified by recrystallization from dilute ethanol (Table I).

**Substituted *p*-[5-(*p*-Chlorophenyl)-4-hydroxy-3-phenyl-2-pyrazolin-1-yl]benzenesulfonylurea and Thiourea (XIIIa–XIII*f*) Derivatives**—Compounds XIII*a*–XIII*f* were prepared by the same procedures used in the preparation of substituted *p*-(3,5-diarylpyrazole-1)benzenesulfonylurea and thiourea derivatives.

Substituted *p*-[5-(*p*-chlorophenyl)-4-hydroxy-3-phenylpyrazole-1]-benzenesulfonylurea and thiourea (XIV*a*–XIV*d*) derivatives could also be prepared by bromine water oxidation of their corresponding pyrazoline derivatives (XIII*a*–XIII*f*).

The IR spectra of V*a*–V*e* showed a band at 1660–1680 $cm^{-1}$, indicative of C=O, and a band at 3110–3080 $cm^{-1}$, indicative of an NH group. Compounds VI*a*–VI*e* showed a characteristic band in the region of 1100–1140 $cm^{-1}$, indicative of a C=S group, and a band in the region of 3100–3080 $cm^{-1}$, indicative of an NH group. Compounds XII*a*–XII*e* showed a characteristic band at 1660–1640 $cm^{-1}$, indicative of a secondary carbonyl amide, in addition to the two bands of the $SO_2N$ group at 1360–1330 and 1180–1150 $cm^{-1}$. Compounds XIII*a*–XIII*c* showed two characteristic bands at 3400–3380 $cm^{-1}$, indicative of an OH group, and at 1665–1650 $cm^{-1}$, indicative of a carbonyl group. Compounds XIII*d* and XIII*e* showed a characteristic band at 1100–1220 $cm^{-1}$, indicative of a C=S group, in addition to the band of an OH group at 3450–3400 $cm^{-1}$.

The PMR spectra of VI*c* showed aromatic protons at $\delta$ 7.2–8.0, a multiplet at $\delta$ 0.5–1.9 for the cyclohexyl protons, and a singlet at $\delta$ 6.9 due to the C-4 proton.

The PMR spectra of XIII*d* showed a multiplet in the region of $\delta$ 8.1–8.8 for the aromatic protons with the two NH protons, a triplet at $\delta$ 1.1 for the $CH_3$ of the ethyl group, and a quartet at $\delta$ 3.7 for the $CH_2$ of the ethyl group. The C-4 and C-5 protons appeared as a triplet and doublet at $\delta$

**Table III—Antidiabetic Activity of Substituted 3,5-Diarylpyrazole-1-benzenesulfonylurea Derivatives**

| Compound | Reduction in Plasma Glucose Level, % | *p* |

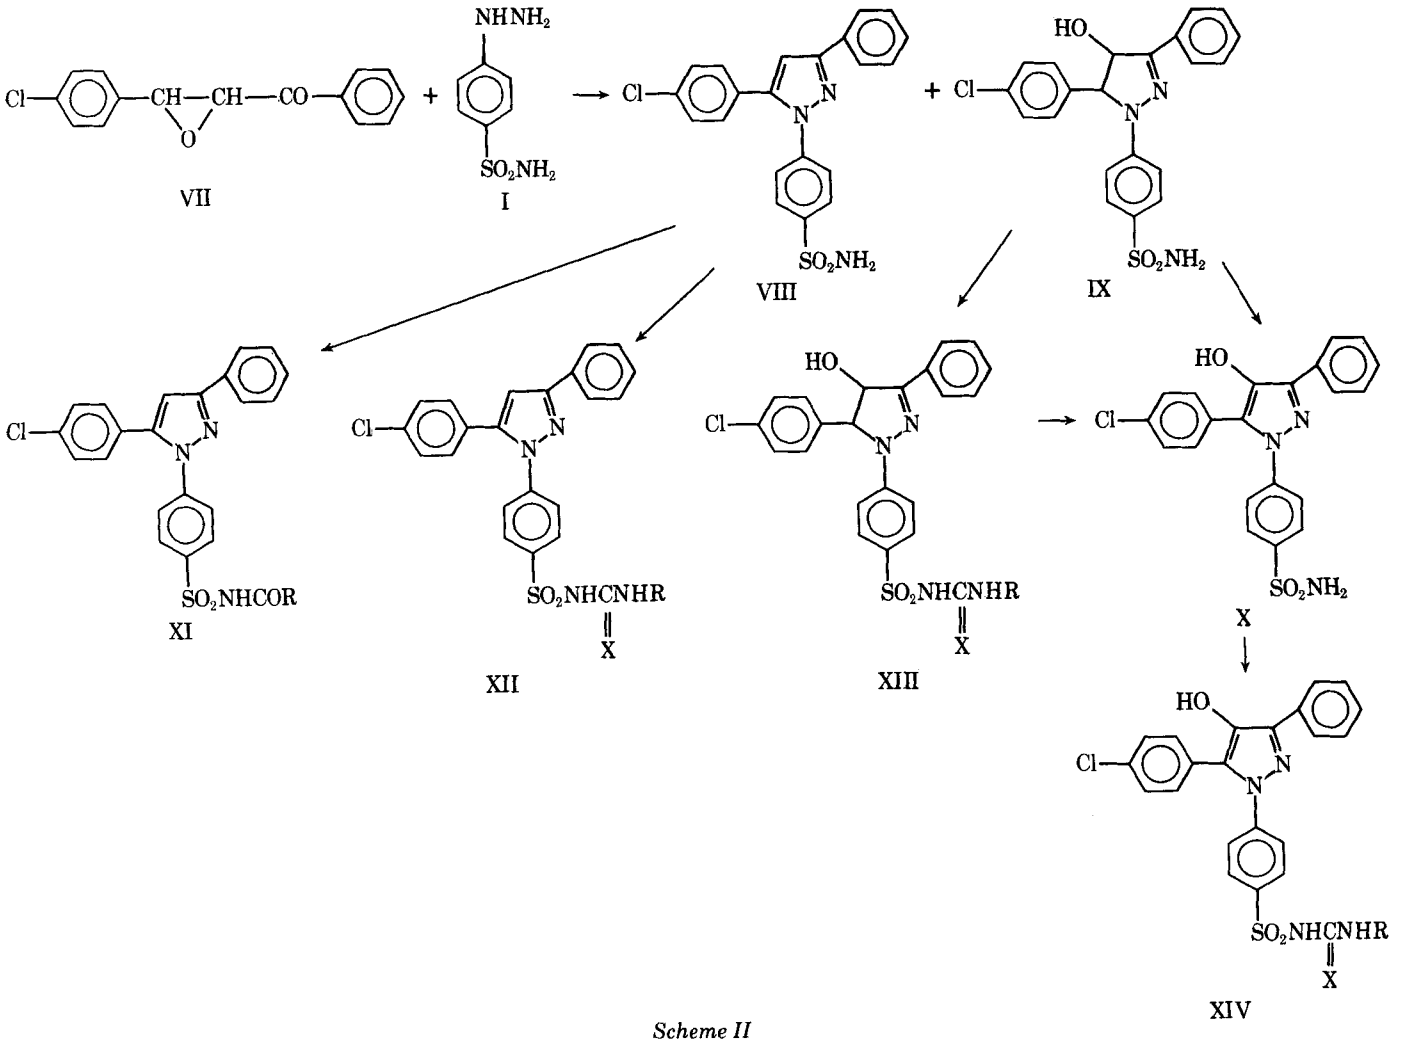
[a] Statistically significant.



*Scheme II*

3.3 and 1.5, respectively. The signal at $\delta$ 6.5 was due to the OH group.

**Biological Testing Method**—Compounds III, Vc, Vd, VIc, XIIc, XII*f*, XIII*b*, and XIV*b* were tested for hypoglycemic activity using alloxan-treated female albino mice weighing 20 g. Alloxan, 100 mg/kg, was injected into the tail vein in a 10-mg/ml saline solution. Three days later, the mice were given the test compounds orally in suspension in 1% carboxymethylcellulose solution at the rate of 0.2 mmole/kg.

Each day, a group of four mice was used as the control, and one group of four mice was given the standard, 100 mg (0.4 mmole) of phenformin/kg. Up to six groups of four mice received the test compounds. Blood samples were collected into 0.04% NaF solution at 0, 1, and 3 hr.

Glucose was determined by the microcolorimetric copper reduction technique of Haslewood and Strookman (11). Results are expressed as a percentage reduction of plasma glucose levels compared to the control value.

Statistical significance was assessed by the Student $t$ test. Statistical significance was accepted where the calculated $t$ value exceeded the tabulated $t$ value at the $p = 0.05$ level.

## RESULTS

Compounds Vc, Vd, VIc, XIII*b*, and XIV*b* possess marked hypoglycemic activity (Table III). The potency of these compounds, however, is more than that of phenformin (0.2 mmole of test compound/kg compared to 0.4 mmole of phenformin/kg) and much more active than 3,5-dimethylpyrazole.

From the data presented previously (8, 9) and in this study, it is obvious that many 3,5-disubstituted pyrazolebenzenesulfonylurea derivatives possess marked hypoglycemic activity. Thiourea derivatives are much less active. Introduction of a bromine atom at position 4 of the pyrazole ring increases the hypoglycemic activity of the sulfonylurea derivative. The 3-methyl-5-phenylpyrazole derivatives are much more active than their corresponding 3,5-dimethylpyrazole analogs. 3,5-Diarylpyrazolesulfonylurea derivatives are quite active as antidiabetic agents. 3,5-Diphenylpyrazole derivatives are much more active than their corresponding 3-phenyl-5-(*p*-chlorophenyl)pyrazole analogs. The presence of an hydroxy group in position 4 of the pyrazole ring of benzenesulfonylurea derivatives increases hypoglycemic activity.

# Carboxymethylcellulose: Effect of Degree of Polymerization and Substitution on Tablet Disintegration and Dissolution

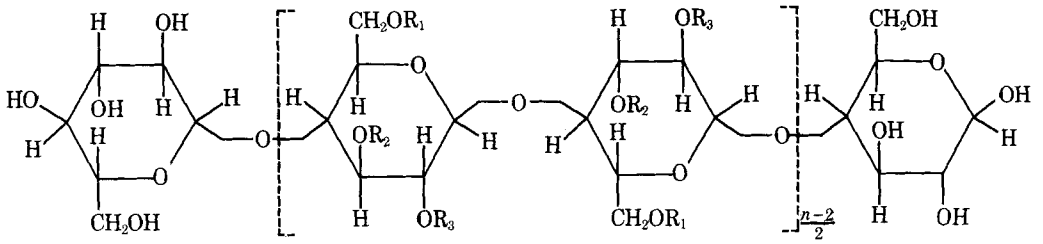
**N. H. SHAH *, J. H. LAZARUS *, P. R. SHETH *, and C. I. JAROWSKI ˣ**

Received January 21, 1980, from the *Department of Allied Health and Industrial Sciences, College of Pharmacy and Allied Health Professions, St. John's University, Jamaica, NY 11439.* Accepted for publication November 6, 1980. *Present address: Hoffmann-La Roche Inc., Nutley, NJ 07110.

**Abstract** □ Highly polymerized grades of carboxymethylcellulose sodium serve effectively as disintegrating agents for tablets. The preferred disintegrants have a high degree of polymerization with a small number of carboxymethyl groups. Grades with a low degree of polymerization are poor disintegrating agents irrespective of their degree of substitution. The dissolution rates of sulfamethoxazole tablets correlated with the disintegration times.

**Keyphrases** □ Carboxymethylcellulose—effect of polymerization and substitution on tablet disintegration and dissolution □ Disintegrants—carboxymethylcellulose, effect of polymerization and substitution on tablet disintegration and dissolution □ Binders—carboxymethylcellulose, effect of polymerization and substitution on tablet disintegration and dissolution □ Disintegration—tablets, effect of carboxymethylcellulose polymerization and substitution □ Dissolution—tablets, effect of carboxymethylcellulose polymerization and substitution

Carboxymethylcellulose sodium is the sodium salt of the polycarboxymethyl ether of cellulose. The cellulose molecule consists of repeating cellobiose units, which are composed of two anhydroglucose units. The structures of the cellulose and carboxymethylcellulose molecules are (1):



cellulose: $R_1 = R_2 = R_3 = H$
carboxymethylcellulose: degree of substitution = 1 when $R_1 = CH_2COOH$, $R_2 = R_3 = H$
degree of substitution = 3 when $R_1 = R_2 = R_3 = CH_2COOH$ ($n$ = number of anhydroglucose units or degree of polymerization)

The degree of substitution refers to the average number of carboxymethyl groups that are substituted per anhydroglucose unit. Thus, carboxymethylcellulose sodium has a degree of substitution of 0.7 when an average of seven carboxymethyl groups have been substituted per 10 anhydroglucose units; it has a degree of substitution of 1.2 when an average of 12 carboxymethyl groups have been substituted per 10 anhydroglucose units.

The average molecular weight of carboxymethylcellulose sodium is determined by the average chain length and the degree of substitution. The viscosity of carboxymethylcellulose sodium dispersions increases as the molecular weight increases and thus is used as a measure of the degree of polymerization.

The USP XX has a specification for sodium content calculated on a dry basis of not less than 6.5% and not more than 9.5% (2). The upper limit represents a degree of substitution of about 0.7. There is no specification for viscosity so the degree of polymerization can vary. As the degree of substitution decreases, the chemical structure of carboxymethylcellulose sodium approaches the chemical structure of natural cellulose.

For many years, carboxymethylcellulose sodium has been used in tablets as a binder and as a viscosity builder in aqueous solutions (1). Carboxymethylcellulose sodium with a low sodium content and a degree of substitution below 0.2 was reported to be a suitable tablet disintegrant (3). Although there are no reports on the effect of different grades of carboxymethylcellulose sodium having varying degrees of polymerization and substitution on tablet characteristics, the physicochemical properties of cellulose are altered significantly with changes in the degree of substitution and polymerization.

The present study evaluated the effect of various grades of carboxymethylcellulose sodium on the disintegration and dissolution rates of a sulfamethoxazole tablet.

## EXPERIMENTAL

**Materials**—Sulfamethoxazole[1], carboxymethylcellulose sodium[2] of various grades, pregelatinized starch[3], and magnesium stearate[4] were used.

**Equipment**—A single-punch tablet press[5], a friabilator[6], a hardness tester[7], a USP disintegration apparatus[8], a USP dissolution apparatus[9], a viscometer LVT[10], U.S. sieves numbers 14 and 20[11], and a mixer[12] were used.

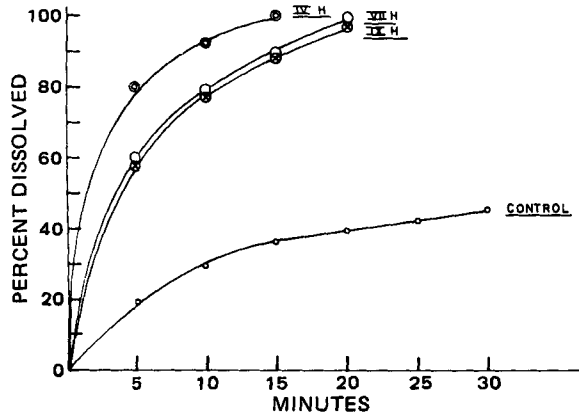

**Figure 1**—*Effect of the degree of substitution of highly polymerized carboxymethylcellulose sodium on the dissolution rate of sulfamethoxazole tablets.*

**Solubility Studies**—The solubility of the sulfamethoxazole in various solvents was determined by the method specified in USP XX (2).

**Viscosity Studies**—The viscosity of various carboxymethylcellulose sodium samples was determined in distilled water at 25° with a viscometer. The percentage concentration, spindle number, and speed recommended by the supplier were used.

**Manufacture of Tablets**—The raw materials were used as received. The formulations used in the study were as follows:

| | control formula, mg | experimental formula 1, mg | experimental formula 2, mg |
|---|---|---|---|
| sulfamethoxazole | 500 | 500 | 500 |
| pregelatinized starch | 25 | 25 | 25 |
| carboxymethylcellulose sodium | — | 15 | 25 |
| magnesium stearate | 2.5 | 2.5 | 2.5 |

The sulfamethoxazole was mixed with the pregelantinized starch and passed manually through a 20-mesh sieve. The mixture was remixed and granulated with water (240 ml of distilled water for 1000 tablets) and the granulation was placed on trays and dried overnight in an oven set at 54.4°. The dried granulation was screened manually through a 14-mesh screen. Then carboxymethylcellulose sodium was mixed with the dried granulation for 10 min. The granulation was lubricated with magnesium stearate by blending the mixture for 5 min. The tablets were compressed on a single-punch tablet press using 1.3-cm (0.5-in.) diameter flat-faced beveled-edge punches to a hardness of ~15 Strong–Cobb units.

**Assay**—The UV spectrum of sulfamethoxazole showed a maximum absorption at 265 nm. It obeyed Beer's law in 0.84 *N* HCl.

**Disintegration**—Tablet disintegration was carried out in simulated gastric and intestinal fluids at 37° using the USP XX disintegration apparatus without disks.

**Dissolution Rate**—The dissolution rate was measured by the USP XX method using the rotating basket at 100 rpm with 0.84 *N* HCl as the dissolution medium. The percentage of the drug released was determined as a function of time.

**Table I—Sulfamethoxazole Solubility in Various Solvents at 25°**

| Solvent | Solubility, mg/ml |
|---|---|
| 95% Ethanol | 30 |
| Methanol | 90 |
| 0.1 *N* NaOH | 16 |
| Water | 0.5 |
| 0.1 *N* HCl | 0.03 |
| 0.84 *N* HCl | 2.85 |

**Table II—Viscosities of Various Grades of Carboxymethylcellulose Sodium in Water at 25°**

| Degree of Substitution | Grade[a] | Concentration, % | Viscosity Range[b], cps | Actual Viscosity, cps |
|---|---|---|---|---|
| 0.4 | IVH | 1 | 400–1000 | 1080 |
| 0.4 | IVM | 2 | 300–600 | 350 |
| 0.4 | IVL | 2 | 24 maximum | 16 |
| 0.7 | VIIH | 1 | 1500–2500 | 1580 |
| 0.7 | VIIM | 2 | 300–600 | 320 |
| 0.7 | VIIL | 2 | 25–50 | 30 |
| 0.9 | IXH | 1 | 2500–4500 | 3200 |
| 0.9 | IXM | 2 | 400–800 | 360 |
| 1.2 | XIIM | 2 | 800–3100 | 850 |

[a] The first number represents the degree of substitution. Thus, IV, V, VII, IX, or XII represents the degree of substitution of 0.4, 0.5, 0.7, 0.9, or 1.2, respectively. The L, M, or H signifies low, medium, or high viscosity. [b] According to supplier.

## RESULTS AND DISCUSSION

Sulfamethoxazole was poorly soluble in distilled water as well as in 0.1 *N* HCl (Table I). Its solubility was markedly improved in 0.84 *N* HCl. As a consequence, the latter solvent was used in the dissolution studies.

The viscosities of the various grades of carboxymethylcellulose sodium are shown in Table II. In addition, the nomenclature for the various grades is explained.

All tablets manufactured met USP specifications for weight variation, content uniformity, and friability. They had a hardness range of 13–16 Strong–Cobb units. The data on the disintegration and dissolution rates of the various tablets are given in Table III and in Figs. 1–3. The results clearly show that the highly polymerized grades of carboxymethylcellulose sodium are good disintegrating agents. The disintegration properties were significantly influenced by the degree of substitution. The gums with a low degree of substitution together with a high degree of polymerization were excellent disintegrating agents. The disintegration properties of carboxymethylcellulose sodium decreased as the degree of substitution increased and the degree of polymerization decreased. Thus, carboxymethylcellulose sodium with a degree of substitution of 0.4 and a high degree of polymerization would be an excellent disintegrant. However,

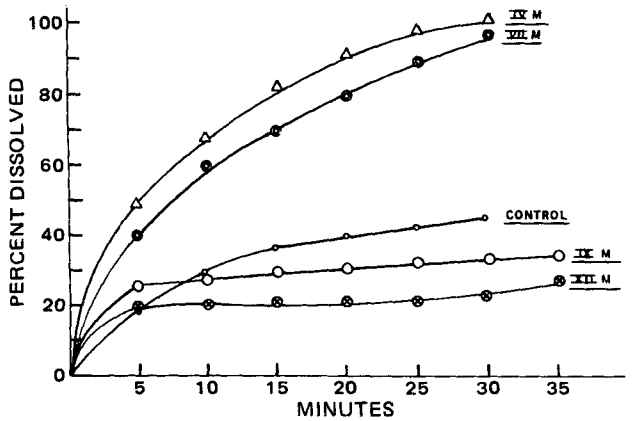

**Figure 2**—*Effect of the degree of substitution of carboxymethylcellulose sodium on the dissolution rate of sulfamethoxazole tablets.*

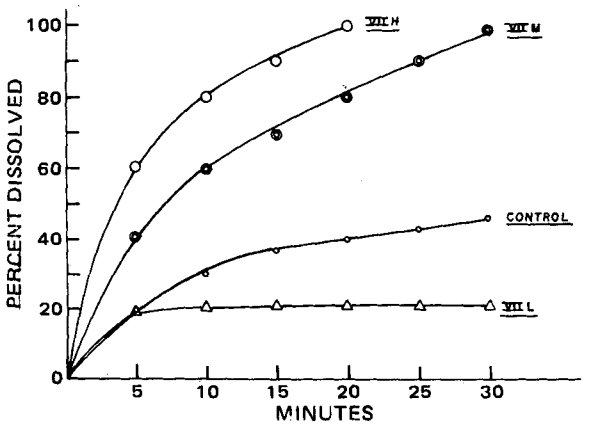

**Figure 3**—*Effect of the degree of polymerization of carboxymethylcellulose sodium on the dissolution rate of sulfamethoxazole tablets.*

Table III—Disintegration Rates of Sulfamethoxazole Tablets Containing 3% of Various Grades of Carboxymethylcellulose Sodium

| Grade | Degree of Substitution | Degree of Polymerization | Disintegration Time, sec: Simulated Gastric Fluid | Disintegration Time, sec: Simulated Intestinal Fluid |
|---|---|---|---|---|
| — | Control | — | >1800 | >1800 |
| IVH | 0.4 | High | 30 | 30 |
| IVM | 0.4 | Medium | 90 | 300 |
| IVL | 0.4 | Low | >1800 | >1800 |
| VIIH | 0.7 | High | 90 | 600 |
| VIIM | 0.7 | Medium | 100 | 900 |
| VIIL | 0.7 | Low | >1800 | >1800 |
| IXH | 0.9 | High | 100 | 900 |
| IXM | 0.9 | Medium | >1800 | >1800 |
| XIIM | 1.2 | Medium | >1800 | >1800 |

carboxymethylcellulose sodium with a degree of substitution of 1.2 and a low degree of polymerization would be a poor disintegrating agent. The results are summarized as follows:

1. The highly polymerized grades of carboxymethylcellulose sodium are good disintegrating agents. The preferred disintegrant has a high degree of polymerization together with a low degree of substitution. Type IVH is preferred over VIIH, which is preferred over IXH (Fig. 1).

2. The medium-polymerized carboxymethylcellulose sodium with a degree of substitution of 0.7 or less has moderate disintegrant properties; but as substitution increases from 0.7 to 1.2, the medium-polymerized grades of carboxymethylcellulose sodium are not as effective as tablet disintegrants. Thus, medium-viscosity carboxymethylcellulose sodium with a degree of substitution of 0.4 or 0.7 has moderate disintegrant properties. Those with a higher degree of substitution, such as 0.9 or 1.2, are poor disintegrants (Fig. 2). Highly substituted carboxymethylcellulose sodium can only be used as a disintegrant when the degree of polymerization is high.

3. With the same degree of substitution, the higher the degree of polymerization, the better are the disintegrant properties. The disintegrant efficacy improves directly with an increase in polymerization. Thus, VIIH is a better disintegrant than VIIM, which is better than VIIL (Fig. 3).

4. Carboxymethylcellulose sodium with a low degree of polymerization is a poor disintegrant irrespective of the degree of substitution. Thus, low-viscosity carboxymethylcelluloses with degree of substitution values of 0.4, 0.7, 0.9, and 1.2 are poor disintegrating agents.

5. The dissolution rate of the sulfamethoxazole tablets correlated with the disintegration times of the tablets.

6. There was no significant difference in disintegration time and in dissolution rate between the two experimental formulas.

Table IV—Minimum Viscosities for Good Disintegration Properties

| Degree of Substitution | Minimum Viscosity of 2% Aqueous Dispersion at 25° Using Propeller-Type Mixer, cps |
|---|---|
| 0.4 | >150 |
| 0.7 | >200 |
| 0.9 | >1500 |
| 1.2 | >3000 |

The minimum viscosity required for effective disintegration properties for the various grades of carboxymethylcellulose sodium is shown in Table IV. Aqueous dispersions of carboxymethylcellulose sodium with a degree of substitution of 0.4 should have a viscosity above 150 cps to have good disintegration properties. Similarly, the higher substituted carboxymethylcellulose sodium should meet the requirements for minimum viscosities to be considered a good disintegrant. Whenever a high degree of polymerization is mentioned, the viscosity will be much greater than the minimum stated in Table IV. Carboxymethylcellulose sodium with a low degree of polymerization will exhibit viscosities less than the minimum value in Table IV.

Further studies are in progress to evaluate the effect of carboxymethylcellulose sodium in solid dosage forms for: (*a*) disintegrants in tablets containing weak acids, weak bases, or neutral drugs; (*b*) comparisons with other presently available disintegrants; and (*c*) alteration of drug delivery systems through the utilization of the appropriate grade.

# Rotary Press Utilizing a Flexible Die Wall

**GREGORY E. AMIDON, DONALD P. SMITH, and EVERETT N. HIESTAND** ˣ

Received March 31, 1980, from *The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication November 7, 1980.

**Abstract** □ A die with a flexible wall was constructed and evaluated on a specially modified instrumented rotary tablet press. The design permits an inward deflection of the die wall by a side punch, which rolls past a side compression roll during compression–decompression. The side compression roll is instrumented to monitor the applied side compression roll forces. On decompression, return of the die wall to its original position permits release of residual die wall pressure. The decreased residual die wall pressure can decrease fracture and capping of tablets for problem formulations. The performance was tested on three experimental formulations. For these formulations, tablets made in a conventional die exhibited severe capping problems. However, most tablets compressed in the special die were superior. With proper adjustment of punch and die wall compression forces, excellent tablets could be manufactured. The merits of the special die and modified tablet machine are substantiated, although this initial design did not provide adequate die wall pressure for all formulations. Further engineering efforts could result in practical production equipment.

**Keyphrases** □ Tableting machine—tablets produced from modified tableting machine with flexible die wall compared with those compressed conventionally □ Tablets—compressed with modified tableting machine compared with those conventionally compressed □ Compressed tablets—produced from modified tableting machine with flexible die wall, compared with tablets produced conventionally

It is generally accepted that bonding in a compressed tablet is the result of establishing and maintaining sufficient true areas of contact between particles. Lamination or capping of tablets, therefore, may seem unexplained since significant portions of a laminated or capped tablet remain densely packed after compression–decompression.

# Rotary Press Utilizing a Flexible Die Wall

**GREGORY E. AMIDON, DONALD P. SMITH, and EVERETT N. HIESTAND** ˣ

Received March 31, 1980, from *The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication November 7, 1980.

**Abstract** □ A die with a flexible wall was constructed and evaluated on a specially modified instrumented rotary tablet press. The design permits an inward deflection of the die wall by a side punch, which rolls past a side compression roll during compression–decompression. The side compression roll is instrumented to monitor the applied side compression roll forces. On decompression, return of the die wall to its original position permits release of residual die wall pressure. The decreased residual die wall pressure can decrease fracture and capping of tablets for problem formulations. The performance was tested on three experimental formulations. For these formulations, tablets made in a conventional die exhibited severe capping problems. However, most tablets compressed in the special die were superior. With proper adjustment of punch and die wall compression forces, excellent tablets could be manufactured. The merits of the special die and modified tablet machine are substantiated, although this initial design did not provide adequate die wall pressure for all formulations. Further engineering efforts could result in practical production equipment.

**Keyphrases** □ Tableting machine—tablets produced from modified tableting machine with flexible die wall compared with those compressed conventionally □ Tablets—compressed with modified tableting machine compared with those conventionally compressed □ Compressed tablets—produced from modified tableting machine with flexible die wall, compared with tablets produced conventionally

It is generally accepted that bonding in a compressed tablet is the result of establishing and maintaining sufficient true areas of contact between particles. Lamination or capping of tablets, therefore, may seem unexplained since significant portions of a laminated or capped tablet remain densely packed after compression–decompression.

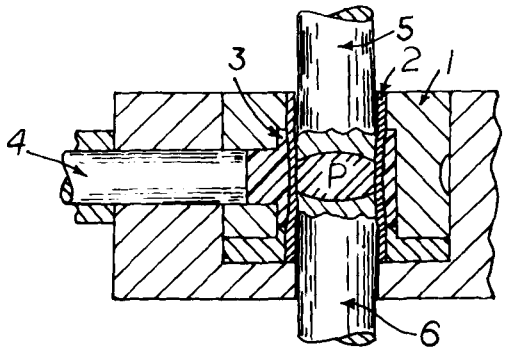

**Figure 1**—*Schematic diagram of specially designed triaxial die.*

A sufficient true area of contact apparently is established in these regions to bond ingredients together, yet the bonding is not sufficient to prevent fracture.

## BACKGROUND

Fracture is thought to be the result of inadequate plastic flow, resulting in highly stressed regions within the compact. A previous report (1) demonstrated that the die wall pressure for several materials is limited by the shear strength of the compacted material and that it changes with time (viscoelastic effects). Furthermore, it was concluded that the dynamic shear strength is exceeded over much of the compression–decompression cycle. When the shear strength is exceeded, either permanent deformation *via* plastic flow or fracture occurs.

Fracture need not occur if plastic flow occurs before stresses are high enough to cause fracture by crack propagation. Very brittle materials such as phenacetin, methenamine, and acetaminophen cannot relieve local stresses as easily as other materials by plastic deformation. Since high die wall pressure results, fracture is more likely to occur in compacts of these materials. These fractures may occur on decompression or on ejection where the die edge may concentrate stress and cause capping.

A decrease of die wall pressure (either by allowing the die wall pressure to decay with time or by relieving the pressure mechanically) should decrease the likelihood of fracture. A specially designed die was reported (2) that allowed the simultaneous release of punch and die wall pressure. The special square die, split along its diagonal, was placed in a frame holding the two halves together with a hydraulic cylinder. By fluid coupling of this hydraulic cylinder with the cylinder on the hand press that pushes the punches together, the die wall and punch pressures could be reduced simultaneously during decompression. In this manner, intact compacts of materials known to laminate on decompression or ejection (*e.g.*, phenacetin, erythromycin, methenamine, and acetaminophen) could be made.

Success with this split die led to the circular die with the flexible die wall reported in this investigation. The die was mounted into a modified rotary press. A specially designed side compression roll (3) and side punch permit pressure to be applied to the die wall, which contracts under compression. In this way, die wall pressure can be released as the die wall returns to its original shape during decompression. Three direct-compaction formulations were studied, and the capping tendencies of tablets formed in the special die were compared with those prepared in a conventional die on the same machine.

**Apparatus**—The special die is shown in cross-section in Fig. 1. The internal wall of the die, 1, is lined and defined by a sleeve, 2, made of thin steel to provide slight radial flexibility. The sleeve is surrounded by a pressure-transmitting material, 3, such as rubber, which evenly distributes pressure around the sleeve. Application of pressure through the side punch, 4, permits a slight (one thousandth or two thousandth inch) inward deflection of the steel sleeve. Proper timing of the movement of the radial punch and axial punches, 5 and 6, permit the simultaneous three-dimensional or triaxial compression of powders. Release of the side punch pressure, which is simultaneous with axial punch pressure release, permits the steel sleeve to return to its original position.

The side compression roll, 7, and mounting block are shown attached to the rotary press in Fig. 2. The side compression roll is positioned such that pressure is applied simultaneously to the upper, lower, and side punches by the upper, 8, lower, 9, and side compression roll. Appropriate measures were taken to prevent overloading of the machine parts due to the excessive stress conditions. Side compression roll pressure was

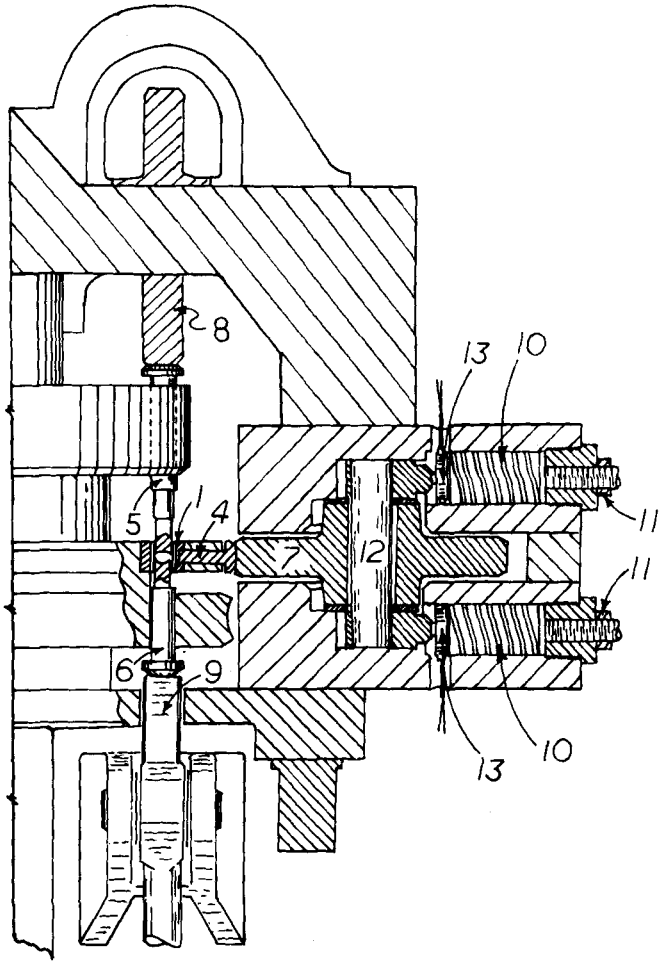

**Figure 2**—*Schematic diagram of modified rotary press showing details of the side compression roll.*

adjusted by incorporating two springs, 10, and adjusting nuts, 11, which apply pressure to each end of the side compression roll pin, 12. Strain-gauge sensors, 13, permit monitoring of the side compression force. Adjustable stops incorporated within the mounting block prevent application of excess pressure to the side punch when the die is empty.

The modified rotary press[1] is shown in Fig. 3. For the following experiments, only two of the 16 stations were used. One station consisted of a set of round 1.111-cm ($^7/_{16}$-in.) concave (0.075-cm deep cup) punches and die. On the opposite side of the table was the specially designed die. Similar round 1.106-cm ($^7/_{16}$-in.) concave punches were used in the special die. These punch diameters were reduced by 0.005 cm to allow enough clearance between the collapsed die wall and the punch during compression. The two types of tablets can be separated as they come off the machine, and direct comparisons can be made between them.

The axial punch pressure was monitored by a strain gauge attached to the lower roll support and calibrated with a known load. During operation, all three strain gauges were monitored so that the compression forces were known for both die types and the die wall–punch forces were known for the triaxial die.

**Limitations in Design**—Technical requirements placed important restrictions on the design and construction of the special die, particularly in the amount of die wall pressure that could be released by die wall flexing. Maximum flexing of the die wall on compression is desired to allow adequate die wall pressure release on decompression. However, the contraction of the die wall radius is limited by the upper and lower punches in the die. At the same time, an excessive gap between the punch and die wall is not acceptable since large weight variation due to powder slipping past the lower punch might occur.

Excessive powder between the punch and die wall also could cause sticking of the punches in the die and failure of the die wall to contract correctly. For these reasons, the punch diameters for the triaxial die were

reduced by 0.005 cm to permit this amount of flexing of the die wall. It was felt that this change would provide sufficient die wall radius contraction and, at the same time, minimize the amount of powder slipping past the lower punch. This limited flexibility of the special die, unlike the split die that allows complete release of the die wall pressure, is expected to release only a portion of the residual die wall pressure during decompression.

The present design requires enough side compression roll pressure to flex the steel die wall sleeve inward; therefore, the actual force applied to the compact is not equal to the side compression roll force. However, the observed values for the side compression roll force should be approximately proportional to the actual applied force in the radial direction. The efficiency of the pressure-transmitting material within the die at transferring the pressure from the side punch to the die wall and the elastic properties of the compression roll and mounting block also influence the actual pressure applied to the die wall.

Only one design, the initial effort, was used in these studies. Because the force for die wall contraction in the presence of powder in the die and of small amounts of powder between the die wall and punch could not be evaluated in advance, the choice of spring sizes and load cells for the die compression was conjecture. The experimental results indicate that the springs and load cells were somewhat undersize, which restricted the amount of die wall pressure that could be applied. Some of the experimental results may have been due to this limitation. This limitation results from the arbitrary choice of capacities and is not inherent in the application of the principle.

## EXPERIMENTAL

**Materials**—Ascorbic acid USP[2], phenacetin USP[3] (passed through a No. 64 tensile bolting cloth), and acetaminophen[4] were used as the primary ingredient in each formulation. Other excipients included microcrystalline cellulose NF[5], colloidal silicon dioxide NF[6], starch USP[7] (cornstarch passed through a No. 105 tensile bolting cloth), compressible sugar NF[8], FD&C Blue No. 2 Aluminum Lake[9], lactose USP[10] (hydrous spray process), and orange oil NF[11]. Magnesium stearate USP powder, food grade[12], was used as a lubricant.

**Methods**—Three direct-compression formulations were prepared as shown in Table I. The ascorbic acid and phenacetin formulations were similar and were prepared in the following manner. All ingredients except magnesium stearate were passed through a 20-mesh screen and blended in a V-blender for 10 min. Subsequently, a portion of this blend was passed through a 20-mesh screen with the magnesium stearate, and all powder was mixed for an additional 2 min. The acetaminophen formulation was prepared by blending, in a V-blender, a portion of a 75% acetaminophen–25% spray-dried lactose mixture with an appropriate amount of a blend of the remaining ingredients to obtain the desired percentage of acetaminophen.

These formulations were prepared to study differences in capping tendencies between conventionally compressed (uniaxially compressed) tablets and tablets compressed in the special triaxial compression die. Other properties such as disintegration and dissolution were not evaluated.

The primary means of assessing capping tendency was visual inspection of each tablet after the hardness test. Breaking strengths were obtained on at least five tablets using an electronic hardness tester[13]. Tablets classified as "capped" normally had the entire intact dome separated from the body of the tablet. Tablets that did not cap in the hardness tester were inspected and broken by hand to check for laminations. Tablets classified as "not capped" had no visible laminations. Friability[14] was determined occasionally but often did not adequately distinguish between capped and noncapped tablets when only small fracture lines were present.

The direct-compression formulations were compressed at various punch and side compression roll forces. Normal operation speed was 24.5 rpm, although one formulation was done at 31.5 rpm. Before operation of the tablet machine, sufficient material was added to fill the feed frame (50–100 g). Normal operation time was 30–60 sec at each die wall and punch pressure setting. This procedure produced ~25–50 tablets; half

were compressed in the standard die, and the other half were compressed in the triaxial die. The triaxially compressed tablets were marked with a felt pen as they came off the press to distinguish them from the uniaxially compressed tablets. Tablet weights, breaking strengths, and capping tendencies were checked immediately after completion of the run. Punch forces were set to ensure breaking strengths between 30 and 70 N, depending on the specific formulation.

## RESULTS

The results for three test formulations are shown in Tables II–V. These formulations showed a substantial difference between the uniaxially and triaxially compressed tablets. Several other formulations showed no capping or laminations for either kind of tablet. Two test formulations (containing materials known to induce capping) were tested in which both the triaxially and the uniaxially compressed tablets capped. Even with inadequate die wall pressure relief, the triaxially compressed tablets were at least as good as the uniaxially compressed ones. With some materials, adequate die wall pressure relief made the differences very dramatic: good tablets from the triaxial die and laminated ones from the uniaxial die.

The punch and side compression roll load cell outputs were monitored throughout each experiment. The punch force was obtained by multiplying the voltage output of the strain gauge by an experimentally determined calibration constant. This punch force was the same for both the uniaxially and triaxially compressed tablets under any given set of conditions. The side compression roll force is the sum of the calculated applied forces of the upper and lower load cells and was adjusted before each run to ensure even pressure on the side compression roll.

The average breaking strength of the tablets and the percentage of tablets that had visible laminations upon breaking were recorded. Friability is reported either as the percentage of the tablets that capped in the friabilator or as the percentage of the original weight lost after 4 min. All tablets were compressed at a speed of 24.5 rpm, except for the ascorbic acid tablets (Table II) which were made at 31.5 rpm.

## DISCUSSION

The results in Tables II–V demonstrate the differences in capping tendency between the uniaxially compressed and triaxially compressed tablets. Proper adjustment of the punch and side compression roll force generally resulted in triaxially compressed tablets that were superior to those compressed in the standard die.

The results for the ascorbic acid formulation (Table II) were obtained at a relatively constant punch force (24.4–25.5 kN) while the side compression roll force was varied. The uniaxially compressed tablets capped 100% of the time. With adequate die wall compression, the triaxially compressed tablets showed substantial improvement in quality, both in breaking strength and capping tendency. At lower side compression roll forces, the triaxially compressed tablets approached the poorer quality of the uniaxially compressed ones.

Apparently, as the side compression roll force increased, greater deflection of the triaxial die wall occurred. This deflection allowed greater release of die wall pressure on decompression and better relief of accumulated stresses. At lower side compression roll forces, less die wall deflection tended to produce tablets similar to the uniaxially compressed tablets. An apparent minimum side compression roll force is probably necessary for sufficient die wall deflection and adequate die wall pressure release. This minimum side compression roll force has to overcome the resistance of the die wall sleeve to deformation as well as any frictional resistances within the system. The applied punch pressure and the physical properties of the powders in the formulation (*i.e.*, tensile strength, shear strength, brittle fracture propensity, stress relaxation rate, *etc.*) also influence the minimum side compression roll force necessary to eliminate capping.

Similar success was obtained (*i.e.*, superior tablets) in the triaxial die for the phenacetin formulation (Table III). At moderate punch forces (12.0–13.0 kN), tablets compressed triaxially were obtained that showed no capping and that had tablet breaking strengths of 45–53 N. At this compression force, a range of side compression roll forces (16.1–26.1 kN) produced acceptable tablets. Conversely, the tablets compressed in the standard die showed a severe capping tendency, with some tablets capping upon ejection from the die. All uniaxially compressed tablets showed laminations that would make them unacceptable for production purposes. At higher punch forces, adequate release of residual die wall pressure could not be attained even with the maximum available compression roll force of 26.3 kN (*i.e.*, the design limitation), and the triaxially compressed tablets began to show capping.

The acetaminophen formulation (Table IV) showed the effect of varying the punch force without altering the side compression roll force. Only compressions at three punch forces were done, but differences between the tablets from the two dies were seen. Only at the high punch force was the quality of the triaxially compressed tablets reduced to become comparable to the uniaxially compressed tablets, *i.e.*, they showed excessive capping. Higher side compression roll force may have decreased capping in the triaxial die at the highest pressure, but this machine was incapable of such high forces. However, correct adjustment of the punch and side compression roll forces produced excellent tablets from the triaxial die.

The influence of machine speed on capping tendency can be seen by comparing the results for the ascorbic acid formulation in Tables II and V. A 30% increase in the machine speed changed the properties of both tablets. Uniaxially compressed tablets were of poor quality at both speeds. Although the triaxially compressed tablets were, in general, superior to the uniaxially compressed tablets at both rotation speeds, the triaxially compressed tablets showed evidence of capping at the higher speed. At the lower speed, a wide range of punch and side compression roll forces produced excellent tablets from the triaxial die (Table V). At the higher speed, capping was not eliminated completely with this material even at the maximum available side compression roll force, due perhaps in part to the time-dependent nature of stress relaxation.

The time-dependent nature of stress relaxation is an important mechanism of stress relief at the higher speed even in the triaxial die unless the stress relief rate of the punch and die wall is matched to minimize internal stress. Apparently, the longer time that the tablet spent in the die at the slower rotation speed allowed greater stress relief due to plastic flow within the compact. The large difference in the quality of the uniaxially and triaxially compressed tablets made at the lower speed shows that mechanical release of some die wall pressure by the triaxial die improves the tablet quality. At the higher speed, the mechanical release of the die wall pressure in the triaxial die was not sufficient by itself to eliminate capping. Future machines should have increased capacity and thus be capable of applying larger die wall forces, which would permit greater latitudes in the die wall forces applied. In this way, more die wall pressure could be released when the formulation and compression characteristics warrant it.

## SUMMARY

These preliminary investigations show that the mechanical release of die wall pressure, using a specially designed die with a flexible die wall, decreases or eliminates capping in three direct-compression formulations when compared to the same formulation compressed in a standard die. Correct adjustment of the applied side compression roll force and punch pressure allows sufficient release of residual die wall pressure on decompression to prevent or diminish capping due to the excessive stress concentrations within the compact during decompression or ejection. The force required for the side compression roll and for success in eliminating capping during decompression or ejection is dependent on the physical properties of the formulation, the applied punch pressure, the viscoelastic properties of the formulation materials, and the efficiency with which the applied force from the side compression roll is transmitted to the die wall.

This preliminary report (an outgrowth of the principles developed from basic research on the physical properties of materials) demonstrates the feasibility of designing and constructing equipment for the successful manufacture of otherwise troublesome formulations. This design offers the advantages of simultaneous and more uniform release of residual die wall pressure, as well as the capability of adjusting the pressure applied to the die wall. Further engineering efforts can result in practical production equipment design and utilization.

# Comparison of Anticonvulsant Potencies of Cyheptamide, Carbamazepine, and Phenytoin

GARY L. JONES ˣ, ROBERT J. AMATO, GARY H. WIMBISH, and GAYLON A. PEYTON

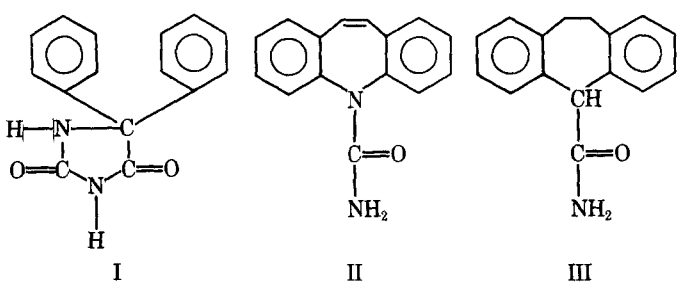
Received September 25, 1980, from the *Department of Pharmacology, Texas College of Osteopathic Medicine, Fort Worth, TX 76107.* Accepted for publication November 11, 1980.

**Abstract** □ Carbamazepine and cyheptamide have certain stereochemical features in common with phenytoin; when superimposed, two bulky hydrophobic groups in each permit the approximate apposition of two electron donor atoms. The anticonvulsant activity of each compound was determined in mice using a standard maximal electroshock procedure, and the relative potencies are expressed in terms of the blood and brain concentrations as well as the intraperitoneal dosage. Although cyheptamide was much less potent than carbamazepine or phenytoin on the basis of intraperitoneal dosage, the difference in potency was much less when blood or brain concentrations were compared. These data should be of value for quantitative structure–activity relationship studies.

**Keyphrases** □ Carbamazepine—anticonvulsant activity, intraperitoneal dosage, blood and brain concentrations □ Cyheptamide—anticonvulsant activity, intraperitoneal dosage, blood and brain concentrations □ Phenytoin—anticonvulsant activity, intraperitoneal dosage, blood and brain concentrations □ Anticonvulsant activity—carbamazepine, cyheptamide, phenytoin, blood and brain concentrations □ Structure–activity relationships—carbamazepine, cyheptamide, and phenytoin compared for anticonvulsant activity

A stereochemical basis of anticonvulsant drug action was described (1–5) for various chemically unrelated molecules. When brought into apposition, it becomes apparent that molecules as chemically unrelated as phenytoin (I) and diazepam not only have bulky hydrophobic groups with similar orientations in space but also have electron-donating groups in similar spatial positions. By using space-filling and Dreiding stereomodels, it can be seen that carbamazepine (II) and cyheptamide (III) (10,11-dihydro-5*H*-dibenzo[*a*,*d*]cycloheptene-5-carboxamide) also bear obvious structural similarities to phenytoin. The two phenyl rings in each, when approximately superimposed, permit the reasonable apposition of a carbonyl oxygen as well as a second electron donor, the imide nitrogen in phenytoin and the amide nitrogen in carbamazepine and cyheptamide.

Although several reports (6–8) have dealt with the pharmacological properties of cyheptamide, the procedures employed do not permit direct comparison of its anticonvulsant activity with that of carbamazepine, phenytoin, and other structurally related anticonvulsants. The present investigation presents such data for comparative purposes. In a preliminary experiment, the $ED_{50}$ of cyheptamide after intraperitoneal administration was 81.0 mg/kg (based on a maximal electroshock technique). According to Krall *et al.* (9), this value would represent a potential antiepileptic worthy of further study. Therefore, the relative potencies of cyheptamide, carbamazepine, and phenytoin were determined with respect to blood and brain concentrations in addition to intraperitoneal dosage. The results should be of value in quantitative structure–activity analysis involving the particular class of compounds known to conform to the previously mentioned stereochemistry.



I II III

## EXPERIMENTAL

Male CF1 mice[1], 30–32 days old when received, were allowed to acclimate for several days after possible food and water deprivation during transportation. They were permitted food and water *ad libitum* except during the short time when removed from their cages for testing.

Carbamazepine[2] and phenytoin sodium[3] were suspended in 30% aqueous polyethylene glycol 400, and cyheptamide[4] was suspended in 5% gum acacia. The suspensions were sonicated for ~5 min to produce a fine suspension. The drugs were administered intraperitoneally (0.01 ml/g) to mice weighing an average of 22 g.

Each compound was assayed at the time of its peak anticonvulsant effect. A maximal electroshock (MES) test (10) was employed for the peak time determinations as well as for subsequent dose–response experiments. Briefly, this test is a measure of the ability of a drug to abolish the hindlimb extensor component of the seizure pattern induced by a 60-Hz alternating current of 50 mamp delivered for 0.2 sec *via* corneal electrodes. The animal was restrained only by hand and was released at the moment of stimulation to permit observation of the seizure throughout its entire course. Protection against the extensor component beyond a 90° angle with the trunk was required for an anticonvulsant effect to be registered. An approximate $ED_{50}$ of the drug to be tested was given to groups of five mice, and the maximal electroshock test was performed 15 min after administration and at 30-min intervals thereafter until the time of peak effect had obviously passed (indicated by fewer animals being protected than at an earlier time). All subsequent dose–response determinations were based on assays of the drug at its established peak time.

Immediately after the maximal electroshock test, 100 μl of blood was collected in 2% sodium fluoride and the animal was decapitated. The entire brain was removed and blotted on filter paper, and the specimens (including blood) were stored at −80° until they were assayed. Blood and brains from 10 mice were pooled for each dose, and at least five doses were employed for each drug.

The blood and brain concentrations for each phenytoin dose were assayed by GLC with 5-(*p*-methylphenyl)-5-phenylhydantoin as an internal standard. The blood and homogenized whole brain specimens were saturated with ammonium sulfate, acidified, and extracted with toluene. The toluene layer was separated and back-extracted with tetramethylammonium hydroxide according to the procedure of Johnson *et al.* (11). The samples were analyzed on 3% OV-17 on 80–100-mesh Supelcoport at 230° and detected by flame ionization (injector port and detector temperature 300°).

Carbamazepine was extracted from alkalinized blood and homogenized whole brain specimens by *n*-butyl chloride. The *n*-butyl chloride was

**Table I—Anti-Maximal Electroshock Potencies of Phenytoin, Carbamazepine, and Cyheptamide**

| $ED_{50}$[a] | Phenytoin | Carbamazepine | Cyheptamide |
|---|---|---|---|
| Intraperitoneal, mg/kg | 7.1 (6.5–7.8) | 9.7 (8.5–11.0) | 81.0 (52.0–127.0) |
| Blood, μg/ml | 2.2 (1.8–2.8) | 2.4 (2.2–2.7) | 5.5 (3.9–7.8) |
| Brain, μg/g | 5.3 (4.7–5.9) | 4.9 (4.1–5.7) | 8.9 (7.5–10.6) |

[a] The $ED_{50}$ values are listed with 95% confidence intervals in parenthesis. Potencies are expressed in terms of the intraperitoneal dose and blood and brain concentrations.

evaporated to dryness, and the residue was derivatized with pentafluorobenzoyl chloride to increase sensitivity by electron capture. 10-Methoxycarbamazepine was added as an internal standard. The samples were analyzed by the method described by Schwertner *et al.* (12).

Cyheptamide was extracted from blood and brain specimens in the manner described for carbamazepine. The *n*-butyl chloride was evaporated to dryness and reconstituted in 50 μl of chloroform. Carbamazepine was used as an internal standard. The analysis was performed on 3% OV-17 on 80–100-mesh Supelcoport at 250° and detected by flame ionization (injector port temperature 270° and detector temperature 300°). A typical chromatogram for cyheptamide extracted from brain tissue is depicted in Fig. 1.

The anticonvulsant data were evaluated with 95% confidence limits by the statistical method of Litchfield and Wilcoxon (13). The relative anticonvulsant potencies ($ED_{50}$) are expressed in terms of the blood and brain concentrations as well as the intraperitoneal dosage.

## RESULTS AND DISCUSSION

The comparative times of peak anticonvulsant effect of carbamazepine, cyheptamide, and phenytoin were ~30, 45, and 60 min, respectively. Although the anti-maximal electroshock potency of carbamazepine was similar to that of phenytoin, the potency of cyheptamide was considerably less (Table I and Fig. 2). The dose of cyheptamide necessary to protect 50% of the mice from tonic hindlimb extension ($ED_{50}$) was 81.0 mg/kg (95% confidence limits of 52.0–127.0), expressed as the intraperitoneal dose. The respective $ED_{50}$ values (95% confidence limits) for carbamazepine and phenytoin were 9.7 (8.5–11.0) and 7.1 (6.5–7.8) mg/kg, respectively (Table I). However, when the blood and brain concentrations of the three drugs were compared, the relative potencies were not that

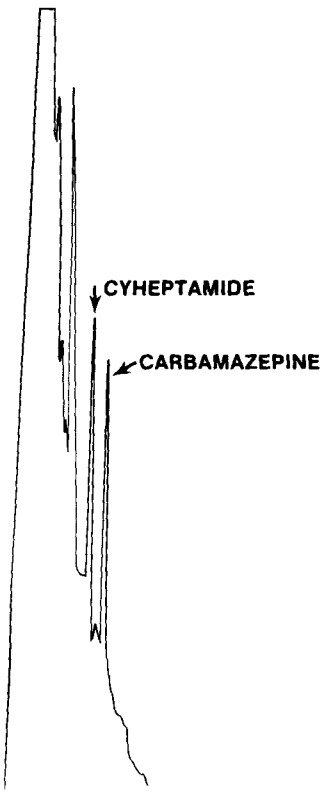

**Figure 1**—*Gas–liquid chromatogram of cyheptamide from brain extract. The internal standard was carbamazepine.*

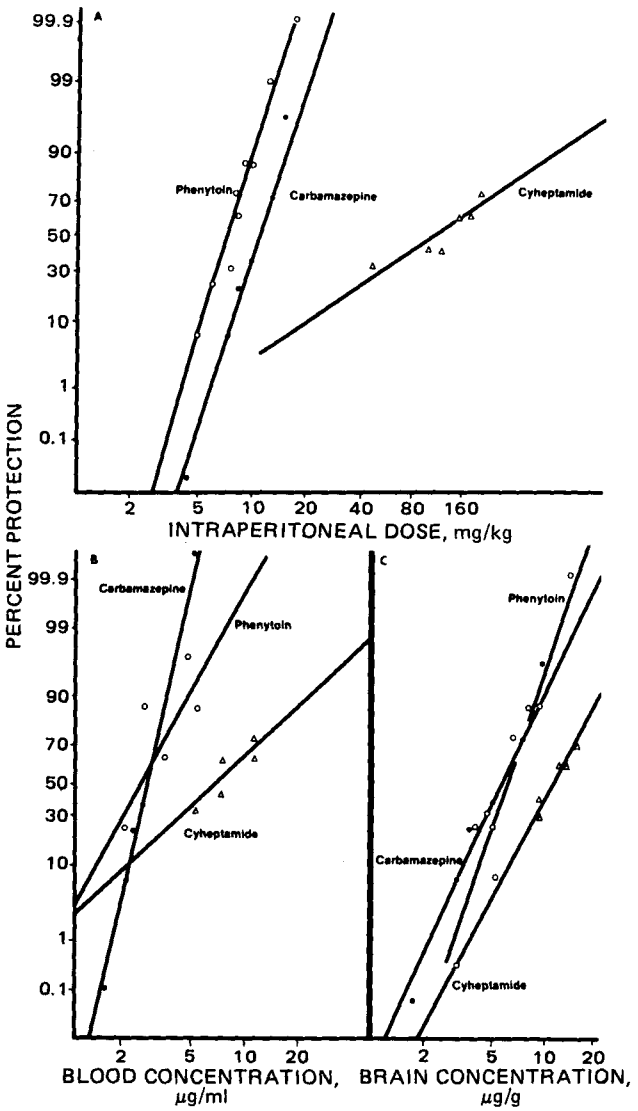

**Figure 2**—*Log dose–response curves for phenytoin, carbamazepine, and cyheptamide expressed in terms of the intraperitoneal dosage (A), blood concentration (B), and brain concentration (C).*

dissimilar. Cyheptamide again was the least potent (Table I). But the potency ratio (95% confidence limits) of cyheptamide to phenytoin, 11.4 (7.3–17.9) on a milligram per kilogram basis, was only 2.5 (1.6–3.8) when blood concentrations (micrograms per milliliter) were compared. When brain concentrations (micrograms per gram) were compared, the ratio was even less, 1.7 (1.4–2.1). In the comparison of cyheptamide to carbamazepine, the ratios were 8.3 (6.1–11.6) on a milligram per kilogram basis, 2.3 (1.7–2.9) for blood concentrations, and 1.8 (1.8–1.9) for brain concentrations. Phenytoin was only slightly more potent than carbamazepine on a milligram per kilogram basis ($p = 0.05$), but the difference was not significant based on blood or brain concentrations.

The large difference in the $ED_{50}$ (intraperitoneal) for cyheptamide might be explained by its lipophilicity. Calculations of log *P* based upon hydrophobicity constants (14) produce an estimated partition coefficient of 550[5] (log $P = 2.74$). The compound is so lipid soluble that it might not achieve the same aqueous dispersion as phenytoin or carbamazepine when given intraperitoneally; thus, absorption would be relatively less due to the smaller effective surface area to which the drug is exposed. The calculated partition coefficients[5] for phenytoin and carbamazepine were fairly similar, 170 (log $P = 2.23$) and 151 (log $P = 2.18$), respectively. This

[5] Log *P* calculations: cyheptamide, from log *P* $(C_6H_5)_2CH_2 + \frac{1}{3}\pi$(cyclohexane) + $\pi(CONH_2)$ = 4.14 + 0.84 + (−2.24) = 2.74; carbamazepine, from log *P* $(C_6H_5)_2NCONH_2 + \frac{1}{3}\pi(C_6H_5)$ = 1.53 + 0.65 = 2.18; phenytoin, from log *P* (hydantoin) + $2\pi(C_6H_5)$ = −1.69 + 3.92 = 2.23. Note that the calculated log *P* for phenytoin is slightly different than the experimental value of 2.47 (14). Only calculated values were used to maintain consistency.

result may explain their similar potencies when their $ED_{50}$ values are compared by any of the three criteria.

An alternative explanation of the potency difference, also based on relative lipophilicities, might be the parabolic dependence of potency on hydrophobicity described by Penniston *et al.* (15) and McFarland (16). Although potency among various compounds is known to increase with increasing lipophilicity, there is frequently an optimum hydrophobicity beyond which potency actually decreases. A quantitative description of this phenomenon is expressed according to (17):

$$\log \frac{1}{C} = -k(\log P)^2 + k' \log P + k'' \qquad \text{(Eq. 1)}$$

Although various explanations might account for such behavior, the following concept is popular. A certain degree of lipophilicity is necessary so that molecules may "dissolve" in and penetrate the lipid matrix of membranes. However, extremely lipophilic substances may actually take up "residence" within the lipid matrix of the membrane. Each membrane interposed along the path a drug might follow to its receptor thus lessens the probability that the drug will reach the receptor. The greatest reduction in such probability occurs at extreme values of the partition coefficient. Drugs with low partition coefficients may have difficulty entering the membrane, while those with high coefficients may not leave readily. Thus, the rather large increase in the partition coefficient of cyheptamide relative to phenytoin and carbamazepine might be responsible for its significantly lower potency. Furthermore, it might be assumed that fewer membranes are interposed between the bulk drug concentrations and the receptors when drug activity is expressed in terms of brain concentrations than when expressed as the intraperitoneal dose or blood concentration. Therefore, the smaller potency ratios observed for the brain concentrations are likely an expression of the smaller difference in probability permitted by fewer barriers separating the drug from its receptor.

The higher brain to blood concentration ratio for phenytoin (2.4) in comparison with carbamazepine (2.0) might reflect its slightly more lipophilic character, but a greater binding of carbamazepine to plasma protein also might be involved. Because cyheptamide is the most lipophilic of these compounds, its surprisingly low brain to blood ratio (1.6) is probably the result of substantial binding to plasma protein.

Previous investigations of cyheptamide produced significantly lower potency estimates than the present data indicate. The probable explanation for this difference points to the problem many investigators have when correlating anticonvulsant structure with activity, namely, the failure to apply a uniform experimental model of epilepsy. In the earliest study (6), mice were subjected to a maximal electroshock procedure in which 30 mamp of 60-Hz current was applied for 0.2 sec *via* corneal electrodes. The $ED_{50}$ value was $25 \pm 1$ mg/kg by the intraperitoneal route and $33 \pm 3.5$ mg/kg by the oral route. A later report cited an $ED_{50}$ (oral) of 38 mg/kg (7). In that study, the current was only 25 mamp (60 Hz), again delivered for 0.2 sec through corneal electrodes. The lower potency of cyheptamide determined in the present study is likely the result of the higher (50 mamp) current, as prescribed in the most thoroughly documented model of grand mal epilepsy (9, 18).

In summary, the relatively low anti-maximal electroshock potency described previously (6, 7) for cyheptamide has been verified. However, its potency is not so discrepant from that of structurally related carbamazepine and phenytoin as might be inferred from the intraperitoneal dosage. The $ED_{50}$ values expressed in terms of tissue concentrations might be of greater value in a quantitative structure–activity investigation than those values based on parenteral dosage.

# Effect of Antacids on Activity of Oral Hypoglycemics

S. A. SAID ˣ and M. E. ABDULLAH

Received February 5, 1980, from the *Department of Pharmaceutics, College of Pharmacy, University of Riyad, Riyad, Saudi Arabia.* Accepted for publication November 13, 1980.

**Abstract** □ The effect of some antacids on the dissolution and hypoglycemic activity of acetohexamide, tolazamide, and tolbutamide tablets was investigated, as was the adsorption of the three drugs onto the antacids. The dissolution rates of the three drugs in the presence of magnesium oxide, aluminum hydroxide, magnesium carbonate, and calcium carbonate increased (0.5–1 hr) and then plateaued or decreased (1–3 hr). Magnesium trisilicate directly suppressed the dissolution of the three drugs. The antacids reduced the hypoglycemic activity of tolbutamide in the following order: magnesium trisilicate > magnesium oxide > aluminum hydroxide > magnesium carbonate > calcium carbonate. The same order occurred for the first three antacids with acetohexamide and tolazamide. Decreased hypoglycemic activity of the drugs may have been due to their adsorption to the coadministered antacids.

**Keyphrases** □ Antacids—effect on oral hypoglycemics, dissolution, adsorption, hypoglycemic activity □ Hypoglycemics, oral—effect of antacids, dissolution, adsorption, hypoglycemic activity □ Dissolution—effect of antacids on oral hypoglycemics, adsorption, hypoglycemic activity □ Adsorption—effect of antacids on oral hypoglycemics, dissolution, hypoglycemic activity

The effect of antacids on the dissolution and bioavailability of drugs has been studied extensively (1–7). Drug–antacid interactions may be caused by several effects. Antacids can change the absorption rate by altering the ionization state of the drug molecule (1, 2), delaying stomach emptying (3), changing the fluid pH in the body (4), and adsorbing drugs (5–7). In addition to affecting bioavailability, a chemical or strong physical interaction between the antacid and drug can have important ramifications in therapy.

Since no information is available on the effect of coadministration of antacids on the bioavailability of oral hypoglycemics, the present study investigated the influence of commonly used antacids on the dissolution and hypoglycemic activity of acetohexamide, tolazamide, and tolbutamide. The adsorption of these drugs onto some antacids also was studied.

## EXPERIMENTAL

**Materials**—Acetohexamide[1], tolazamide[2], and tolbutamide[3] tablets were used in the dissolution studies. Powdered acetohexamide[1], tolazamide[2], tolbutamide[3], magnesium trisilicate[4], magnesium carbonate[5], magnesium oxide[6], aluminum hydroxide[7], and calcium carbonate[7] were used as supplied in the adsorption and hypoglycemic activity studies.

**Dissolution Testing**—The dissolution rates of acetohexamide and tolbutamide tablets were tested according to USP XIX (6) using the USP rotating-basket dissolution apparatus[8]. Tolazamide tablets were tested similarly, but the absorbance[9] was measured at 262 nm. Tablets of the three drugs were tested for dissolution in their respective medium containing one antacid (1%).

**Measurement of Blood Glucose in Rats**—The effect of orally administered acetohexamide, tolazamide, and tolbutamide with and without antacids on blood glucose levels of adult male albino rats[10] was studied. Rats (180–250 g) were fasted 24 hr before the experiment but were allowed free access to water.

The effect of antacids on the hypoglycemic activity of tolbutamide was studied using six groups of 15 rats each. One group was given tolbutamide suspension (1%) in water containing 0.2% methylcellulose in a 200-mg/kg dose. Five other groups were given equivalent doses of tolbutamide but in the presence of 1% of the antacid.

Each group of animals was divided into five subgroups, each containing three rats. Each subgroup was kept in a separate cage and allowed free access to water. At 0.5, 1, 2, 3, 4, and 5 hr, the animals were sacrificed. A blood sample was taken from each rat and analyzed for blood glucose content (8). One group of animals was used as the control. The mean blood glucose levels of each subgroup were compared, and the differences were tested for significance by analysis of variance and a Student $t$ test.

The effect of magnesium trisilicate, magnesium oxide, and aluminum hydroxide on the blood glucose level following administration of acetohexamide and tolazamide was tested in the same manner.

**Adsorption Experiments**—The drugs were dissolved in the fluid used for dissolution testing, and 50 ml of the solution containing 2.5–40 mg of the drug was placed in 100-ml glass-stoppered conical flasks containing the antacid (1%). The drug–antacid solution was equilibrated at 37 ± 0.1° and shaken mechanically for ~24 hr to reach equilibrium. After centrifugation, the drug concentration remaining in the supernate was determined spectrophotometrically at the respective wavelength used for dissolution testing against a blank. Three replicate runs were made, and the results were averaged.

***Desorption***—The desorption of adsorbed drugs was determined at 37 ± 0.5° in the fluid used for dissolution testing as described previously (6). Three experiments were performed in each case, and the average percent desorbed was calculated.

The least significant difference procedure was used to assess the difference between two means, and the completely randomized designs–analysis of variance technique was used to evaluate the level of significance between multiple determinations (9).

## RESULTS AND DISCUSSION

Figure 1 shows the effect of the five antacids on the dissolution rates of acetohexamide, tolazamide, and tolbutamide tablets. With the exception of magnesium trisilicate, the antacids exhibited a minor increase in dissolution (0.5–1 hr) and then a plateau with a slight decrease toward the end. Magnesium trisilicate moderately decreased the dissolution rates of the three drugs. After 3 hr, the amounts of tolbutamide in solution were 82.5, 81, 66, 60, and 10% in the presence of calcium carbonate, magnesium carbonate, aluminum hydroxide, magnesium oxide, and magnesium trisilicate, respectively, as compared to 100% in the absence of these antacids. The amounts of acetohexamide, tolbutamide, and tolazamide in solution at 3 hr were 4.5, 40, and 30%, respectively, in the presence of magnesium trisilicate; at that time, complete dissolution of the three drugs was attained in the absence of antacids.

Figure 2 illustrates the effect of the tested antacids on the hypoglycemic activity of acetohexamide, tolazamide, and tolbutamide. The mean blood glucose concentration of 24-hr fasted rats was 73.25 ± 2.55 mg/100 ml and was significantly higher than all treated groups (Student $t$ test, $p < 0.05$).

The reduction in blood glucose levels was lessened in the system containing the antacid (Fig. 2). At 2 hr, the mean blood glucose level of rats taking tolbutamide alone was 2.8 mg/100 ml; it increased to 18.3, 15.3,

[a] Significance at the 5% level.

12.5, 10.5, and 8.4 mg/100 ml in the presence of magnesium trisilicate, magnesium oxide, aluminum hydroxide, magnesium carbonate, and calcium carbonate, respectively. Analysis of variance for the results in Table I showed a highly significant difference ($p < 0.05$) in the 2-hr mean blood glucose levels among the tested dosage forms. At 2 hr, there was a significant difference (least significant difference procedure, $p < 0.05$) between the mean blood glucose when tolbutamide was administered alone and when it was administered with each tested antacid. This result indicates that a decreased absorption of tolbutamide occurred in the presence of each tested antacid.

The antacids reduced the hypoglycemic activity of acetohexamide and tolazamide in the order magnesium trisilicate > aluminum hydroxide. At 2 hr, the respective mean blood glucose levels of rats taking acetohexamide alone was 22.5 mg/100 ml, which increased to 45.5 and 37.5 mg/100 ml in the presence of magnesium trisilicate and aluminum hydroxide, respectively. At 2 hr, the mean blood glucose level of rats taking tolazamide was 6.5 mg/100 ml, which increased to 18 and 13 mg/100 ml in the presence of magnesium trisilicate and aluminum hydroxide, respectively.

Analysis of variance for the data of the 2-hr mean blood glucose levels of rats administered acetohexamide alone and with the tested antacids

[a] Significance at the 5% level.

showed that there was a significant difference ($p < 0.05$) among the tested dosage forms (Table II). There was a significant difference (least significant difference procedure, $p < 0.05$) between the mean blood glucose level when acetohexamide was administered alone and when it was administered with either magnesium trisilicate or aluminum hydroxide (Table II). Similarly, statistical comparison of the data in Table III indicated that there was a significant difference (analysis of variance, $p < 0.05$) among the tested tolazamide dosage forms as to the 2-hr mean blood glucose levels. There was also a significant difference (least significant difference procedure, $p < 0.05$) between the mean blood glucose level when tolazamide was administered alone and when it was administered with either magnesium trisilicate or aluminum hydroxide.

Figure 3 shows the plots of drug adsorption onto magnesium trisilicate (1% w/v). Preliminary experiments showed that equilibrium was attained within 6–24 hr, depending on the drug, its concentration, and the antacid. Antacid adsorption of the drugs followed the sequence magnesium trisilicate > magnesium oxide > aluminum hydroxide. These antacids adsorbed 95, 50, and 17.5% of tolbutamide, respectively. The extent of drug adsorption to antacids followed the sequence acetohexamide > tolbutamide > tolazamide. The three drugs possess varying relative polarity, and the extent of adsorption was increased with the more polar drug. This finding is concordant with the reported (10) conclusion that, for a given solvent, the more soluble solutes generally were adsorbed less strongly than the less soluble ones.

Table IV summarizes the extent of adsorption of the three drugs from the respective medium used for dissolution. These data illustrate a strong adsorption of the three drugs to magnesium trisilicate; only 5.17, 5.20, and 6.5% were desorbed from acetohexamide, tolbutamide, and tolazamide, respectively. The same sequence occurred with aluminum hydroxide and magnesium oxide. Analysis of variance of the data in Table IV showed that there was no significant difference among the tested antacids as to the extent of adsorption of the three hypoglycemics.

Statistical analysis of the data in Table IV (least significant difference procedure, $p < 0.05$) indicated that tolbutamide was adsorbed more significantly to magnesium trisilicate than to aluminum hydroxide. There appeared to be no significant differences between the extent of tolbutamide adsorption to magnesium trisilicate and magnesium oxide nor to aluminum hydroxide and magnesium oxide. Tolazamide was adsorbed more strongly to magnesium trisilicate than to the other two antacids. Acetohexamide exhibited a significantly higher adsorption to magnesium trisilicate than to aluminum hydroxide; however, no significant difference existed between the extent of its adsorption to magnesium oxide and magnesium trisilicate nor between its adsorption to aluminum hydroxide and magnesium oxide.

These results indicate that the tested antacids reduce the hypoglycemic activity of acetohexamide, tolazamide, and tolbutamide. The dissolution rates of the three oral hypoglycemics in the presence of the antacids, with the exception of magnesium trisilicate, increased (0.5–1 hr), plateaued, and then decreased. Increased dissolution in the 1st hr did not rise continually due to uptake of the dissolved drug by the antacid. Again, the earlier increased dissolution does not reflect increased hypoglycemic activity due to direct adsorption of drug by antacid decreasing the amount of free drug available for systemic absorption. Magnesium trisilicate, which showed the highest adsorption capacity for the three oral hypoglycemics, induced the paramount suppression in their hypoglycemic activity. Furthermore, the powerful adsorption of the drugs by this antacid, as indicated by minor desorption, illustrates this suppression.

From the present study, it may be concluded that the hypoglycemic activity of acetohexamide, tolazamide, and tolbutamide will be decreased considerably if these drugs are separately coadministered with the tested antacids. The extent of reduction will vary with the antacid.

# Stereospecific Radioimmunoassays for *d*-Pseudoephedrine in Human Plasma and Their Application to Bioequivalency Studies

**JOHN W. A. FINDLAY ˣ, JAMES T. WARREN, JOHN A. HILL, and RICHARD M. WELCH**

Received August 11, 1980, from *Wellcome Research Laboratories, Research Triangle Park, NC 27709.* Accepted for publication November 11, 1980.

**Abstract** □ Antiserum to *d*-pseudoephedrine was raised in New Zealand White rabbits in response to immunization with a conjugate of bovine serum albumin and *d*-pseudoephedrine-*N*-3-propionic acid. The hapten was prepared by reaction of methyl acrylate with *d*-pseudoephedrine, followed by ester hydrolysis. Sodium boro[$^3$H]hydride reduction of *dl*-ephedrone gave [$\alpha$-$^3$H]-*dl*-ephedrine, and a Welsh rearrangement with acetic anhydride followed by deacetylation gave [$\alpha$-$^3$H]-*dl*-pseudoephedrine, which was used as a radioligand in radioimmunoassay procedures for direct plasma analyses. Three sensitive radioimmunoassay procedures were developed, two using [$^3$H]pseudoephedrine as the radioligand and either adsorption on coated charcoal or polyethylene glycol precipitation for separation of antibody-bound from free radioligand. The third method used an [$^{125}$I]tyrosine methyl ester analog of pseudoephedrine and charcoal separation, preceded by extraction and derivatization of pseudoephedrine with methyl acrylate. All three assays could detect ≤2.5 ng of pseudoephedrine/ml. The antiserum was stereospecific, showing low cross-reactivities with *l*-pseudoephedrine and *d*- and *l*-ephedrines. *d*-Norpseudoephedrine and some other related compounds also had low cross-reactivity in these radioimmunoassay procedures. Excellent agreement was found between pseudoephedrine concentrations in human plasma determined by radioimmunoassay and by a standard GLC method. The utility of radioimmunoassay was illustrated by application of one of these procedures to an assessment of the bioequivalence of immediate- and sustained-release pseudoephedrine formulations in normal volunteers. A sustained-release preparation containing 120 mg of pseudoephedrine hydrochloride given every 12 hr was shown by *AUC* comparisons to be bioequivalent to an immediate-release tablet (containing 60 mg of pseudoephedrine hydrochloride) given every 6 hr.

**Keyphrases** □ Radioimmunoassay—*d*-pseudoephedrine, human plasma, bioequivalency studies, immediate- and sustained-release tablets □ *d*-Pseudoephedrine—radioimmunoassay, bioequivalency studies, immediate- and sustained-release tablets □ Bioequivalency studies—radioimmunoassays of *d*-pseudoephedrine in human plasma, bioequivalency studies, immediate- and sustained-release tablets □ Adrenergics—radioimmunoassays for *d*-pseudoephedrine in human plasma, bioequivalency studies, immediate- and sustained-release tablets

*d*-Pseudoephedrine was first isolated from the Chinese plant *Ma Huang* by Chou and Read (1) in 1926, and studies of its pharmacology started soon thereafter (2, 3). Although pseudoephedrine is in widespread use as a proven, clinically effective nasal decongestant (4–6), little published information is available on its disposition and pharmacokinetics in human plasma following administration of therapeutic doses. Studies have examined kinetics chiefly from the viewpoint of urinary excretion (7–9), which is liable to be influenced by alterations in urinary pH (8). Such indirect studies were necessitated by the lack of methods sufficiently sensitive to detect the relatively low circulating concentrations of pseudoephedrine in plasma following therapeutic doses.

Reported GLC procedures (7, 10, and 11) were capable of detecting only 0.3–0.5 μg of pseudoephedrine/ml. Even with nitrogen detection, Bye *et al.* (12) were able to lower the sensitivity limit only to 25 ng/ml. Kuntzman *et al.* (8) reported a procedure that involved esterification of isolated pseudoephedrine with tritiated acetic anhydride followed by separation and quantitation of the resulting radioactive product. Although capable of detecting 50 ng of pseudoephedrine/ml of plasma, this method is still relatively insensitive and time consuming. A study (13) of plasma pseudoephedrine levels relative to efficacy, using a GLC method for drug determination, was able to determine plasma concentrations up to 6 hr following a 60-mg oral dose of pseudoephedrine hydrochloride.

This report describes the development of a specific antiserum to pseudoephedrine and its application to three specific radioimmunoassay procedures for the drug. Two procedures are direct and employ a tritium-labeled radioligand; the third requires extraction and derivatization of the drug prior to assay but employs a $\gamma$-labeled radioligand. The sensitivity limits of these procedures are <2.5 ng of pseudoephedrine/ml in all cases. Their use for drug disposition studies following oral administration of both immediate- and sustained-release pseudoephedrine preparations is illustrated.

## EXPERIMENTAL

Melting points[1] are uncorrected. $^1$H-NMR spectra[2] were obtained in deuterochloroform with tetramethylsilane as the internal standard unless otherwise indicated. Low-resolution mass spectra[3] were obtained by

electron-ionization methods. TLC plates were precoated silica gel[4] with a layer thickness of 0.25 mm. Radiochemical purities were determined by scanning the TLC plates using a radiochromatogram scanner[5]. Bovine serum albumin (Cohn Fraction V), 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide hydrochloride, tyrosine methyl ester, and dicyclohexylcarbodiimide were purchased from a commercial supplier[6].

Radioimmunoassay grade charcoal[7] was used in the radioimmunoassay separation system. Sodium [$^{125}$I]iodide (carrier free) and sodium boro[$^{3}$H]hydride (specific activity 28 Ci/mmole) were obtained commercially[8]. Methyl acrylate[9], chloramine-T[9], Freund's complete adjuvant[10], and polyethylene glycol 6000[11] were commercial products. Quantitation of radioactivity was in liquid scintillation fluid[12]. Radioactivity was determined in a liquid scintillation counter[13] or $\gamma$-counter[14], as appropriate. Ephedrine, pseudoephedrine, and related compounds were commercially supplied[15].

**d-Pseudoephedrine-*N*-3-propionic Acid Methyl Ester (II)**—To *d*-pseudoephedrine free base (I, 1.65 g, 0.01 mole) in absolute ethanol (25 ml) containing triethylamine (1.03 g, 0.012 mole) was added methyl acrylate (1.03 g, 0.012 mole), and the sealed mixture was stirred at room temperature overnight. The volatile components were evaporated under reduced pressure, leaving an oily residue that slowly crystallized from *n*-pentane to give a colorless solid (2 g), mp 37°; NMR: $\delta$ 7.3 (s, 5H, aromatic H), 4.7 (d, 1H, $J$ = 1.5 Hz, $\alpha$-H), 3.6 (s, 3H, $COOCH_3$), 3.3 (m, 5H), 2.8 (s, 3H, N–$CH_3$), and 1.0 (s, 3H, C–$CH_3$) ppm; mass spectrum: $m/z$ 220 (M − $CH_3$), 178 (M − $CH_2COOCH_3$), and 144.

*Anal.*—Calc. for $C_{14}H_{21}NO_3$: C, 66.90; H, 8.42; N, 5.57. Found: C, 67.78; H, 8.57; N, 5.61.

**d-Pseudoephedrine-*N*-3-propionic Acid Sodium Salt (III)**—The crystalline ester II (2 g) was dissolved in warm 2 *N* NaOH (10 ml) and stirred for 2 hr. Upon cooling, the sodium salt of the acid derivative separated and was filtered. The yield was 1 g of amorphous powder, mp >200° dec.; NMR (deuterated dimethyl sulfoxide): $\delta$ 7.25 (s, 5H, aromatic H), 5.5 (s, 1H), 4.25 (d, 1H, $J$ = 1.5 Hz, $\alpha$-H), 2.5 (m, 6H), 2.2 (s, 3H, N–$CH_3$), and 0.6 (d, 3H, $J$ = 1.5 Hz, C–$CH_3$) ppm; mass spectrum: $m/z$ 282, (free acid anion$^{-1}$ · $Na^{2+}$)$^+$, 541 (L, N–$CH_3$), (anion$^{2-}$ · $Na^{3+}$)$^+$, and 800, (anion$^{3-}$ · $Na^{4+}$)$^+$.

**d-Pseudoephedrine-*N*-3-propionic Acid–Bovine Serum Albumin Amide (IV)**—The pH of a solution of the salt of acid III (0.1 g, 0.4 m*M*) and bovine serum albumin (0.1 g) in water (15 ml) was adjusted to 5.5 with dilute hydrochloric acid. 1-Ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride (0.1 g) was added, and the solution was stirred at room temperature for 20 hr. The immunogen was purified by ultrafiltration[16]. The solution was lyophilized, and the powdery protein residue was stored over desiccant at −80°.

**d-Pseudoephedrine-*N*-3-propionic Acid–Tyrosine Methyl Ester Amide (IV*a*)**—A solution of *d*-pseudoephedrine-*N*-3-propionic acid (0.6 g, 1.8 m*M*) and tyrosine methyl ester free base (0.35 g, 1.8 m*M*) was prepared in acetonitrile (3 ml) and dimethylformamide (1 ml). Sufficient water and dilute hydrochloric acid were added to achieve a homogeneous solution (pH 6). The solution was cooled to 0°, a solution of dicyclohexylcarbodiimide (0.49 g, 2.2 m*M*) in cold dimethylformamide (0.8 ml) was added, and the reaction mixture was stirred at 0° overnight. After filtration, the solution was added to a mixture of tetrahydrofuran (100 ml), acetic acid (15 drops), ethanol (15 ml), and triethylamine (1 ml) to destroy excess dicyclohexylcarbodiimide. Stirring was continued for 1 hr at room temperature. The solution was filtered, and the filtrate was evaporated under reduced pressure.

The residue was dissolved in chloroform (100 ml) and filtered, and the solution was extracted with 5% sodium bicarbonate (2 × 25 ml) and then with 0.1 *N* HCl (2 × 25 ml). The aqueous acid extract was made basic with excess sodium carbonate and extracted into chloroform (3 × 50 ml), and the solvent was dried with magnesium sulfate and clarified with charcoal prior to being evaporated. A methanol solution of the residue was applied to silica gel plates (0.5 mm, 20 × 20 cm) and developed in ethylene dichloride–methanol–ammonium hydroxide (100:30:4). The product band was visualized with fast blue B salt, scraped off, and eluted from the silica gel with methanol (2 × 5 ml).

The methanol solution was concentrated to 0.5 ml, and the preparative TLC purification was repeated. The amorphous residue (0.1 g), mp 162° dec., was stored over desiccant at −80°; NMR: $\delta$ 7.5 (s, 5H, aromatic H), 7.0 (q, 4H, $J$ = 1.0 Hz, aromatic H), 5.0 (d, 1H, $J$ = 1.0 Hz), 4.4 (d, 1H, $J$ = 1.5 Hz, $\alpha$-H), 3.8 (s, 3H, $COOCH_3$), 3.3–2.4 (m, 8H), 2.3 (s, 3H), and 0.7 (d, 3H, $J$ = 1.0 Hz, C–$CH_3$) ppm; mass spectrum: $m/z$ 307.1648, $C_{16}H_{23}N_2O_4$ (M − $CH_2C_6H_4OH$).

**[$^{125}$I]-*d*-Pseudoephedrine-*N*-3-propionic Acid–Tyrosine Methyl Ester Amide (V)**—Into a small test tube containing a glass bead was pipetted 70 $\mu$l of a solution of IV*a* (1.54 $\mu$g, 3.7 n*M*) in 0.5 *M* phosphate buffer, pH 7.7, followed by sodium [$^{125}$I]iodide (1 mCi, 0.56 n*M*) in 10 $\mu$l of dilute sodium hydroxide, pH 8.0. A freshly prepared solution of chloramine-T (25.2 $\mu$g, 89.6 n*M*) in 25 $\mu$l of 0.05 *M* phosphate buffer, pH 7.7, was added, and the mixture was agitated at room temperature for 1 min. A freshly prepared solution of sodium metabisulfite (341 $\mu$g, 1790 n*M*) in 100 $\mu$l of 0.05 *M* phosphate buffer, pH 7.7, was added immediately with mixing.

The mixture was set aside for 10 min at room temperature and then was applied to a silica gel plate (20 × 20 cm), which was developed in the solvent system described for IV*a*. X-ray film was exposed to the TLC plate, and the band ($R_f$ 0.6) corresponding to the main dark band on the X-ray film was scraped off, extracted with methanol (4 × 5 ml), and stored at −80° until used.

**[$\alpha$-$^{3}$H]-*dl*-Pseudoephedrine Hydrochloride (VI)**—dl-$\alpha$-*Bromopropiophenone*—Bromine (20.0 g, 0.125 mole) in methylene chloride (50 ml) was added dropwise to a stirred solution of propiophenone (13.42 g, 0.10 mole) in methylene chloride (80 ml) at 30–35°, and the mixture was heated under reflux for 60 min. Evaporation to dryness gave a pale-yellow oil, which was used in the next reaction without further purification.

dl-*Ephedrone Hydrochloride*—A solution of the crude propiophenone in ethanol (10 ml) was added dropwise under nitrogen to a stirred ice-cold solution of methylamine gas (10.0 g, 0.32 mole) in ethanol (130 ml) during 50 min, and the mixture was stirred at 0° for an additional 40 min. A mixture of 12 *N* HCl (30 ml) and ice was added to pH < 7, and the aqueous solution was extracted with ether and evaporated to dryness. The yellow solid was extracted with chloroform (4 × 50 ml), and the residual methylamine hydrochloride was discarded. Evaporation of the chloroform filtrates gave an off-white solid, which was recrystallized twice from ethanol–acetone to give 3.41 g (17.1%) of *dl*-ephedrone hydrochloride as off-white crystals, mp 176–179° [lit. (21) mp 176–177°]; NMR (dimethyl sulfoxide-$d_6$ + $D_2O$): $\delta$ 1.5 (d, 3H, C–$CH_3$), 2.7 (s, 3H, N–$CH_3$), 5.2 (q, 1H, $\alpha$-H), and 7.4–8.2 (m, 5H, aromatic H) ppm. TLC in chloroform–2-propanol–triethylamine (62:35:3) showed a single spot, $R_f$ 0.53.

*[$\alpha$-$^{3}$H]*-dl-*Ephedrine Hydrochloride*—To a stirred solution of ephedrone hydrochloride (90.1 mg, 0.45 mmole) in ethanol (12 ml) under dry argon was added dropwise a solution of sodium boro[$^{3}$H]hydride (8 Ci at 28 Ci/mmole, ~0.34 mmole) in ethanol (19 ml) during 2 min. After a further 60 min at room temperature, a solution of 12 *N* HCl (1.6 ml) in water (2.9 ml) was added dropwise. After stirring for 20 min, the colorless solution was diluted with water (90 ml) and ether (70 ml), and 1 *N* NaOH (30 ml) was added to pH > 10. The aqueous solution was extracted with ether (4 × 50 ml), and the combined ether solutions were washed with water (100 ml), evaporated to near dryness *in vacuo* at 0°, and treated with methanol (20 ml) and 12 *N* HCl (2.0 ml). Evaporation to dryness *in vacuo* yielded 89.9 mg (98.8%) of crude ephedrine as an off-white solid. TLC in chloroform–2-propanol–triethylamine (62:35:3) showed ephedrines ($R_f$ ~0.19) containing a trace of residual ephedrone ($R_f$ 0.53), and TLC in 2-butanone–2-propanol–ammonium hydroxide (6:3:1) showed mainly ephedrine ($R_f$ 0.49) containing a trace of pseudoephedrine ($R_f$ 0.82).

*[$\alpha$-$^{3}$H]*-dl-*Pseudoephedrine Hydrochloride*—A stirred mixture of crude ephedrine (89.9 mg) and acetic anhydride (3.0 ml) under dry argon was heated under reflux for 30 min. The cooled solution was evaporated to dryness *in vacuo*, water (2.0 ml) and 12 *N* HCl (0.6 ml) were added, and the mixture was distilled for 2 hr while fresh water was added continuously to the flask to replace the distillate, volume for volume. Evaporation to dryness *in vacuo* was followed by the addition of hot water (1.5 ml) and then the addition of 50% NaOH solution to the stirred ice-cold solution to pH > 13. The precipitate of [$\alpha$-$^{3}$H]-*dl*-pseudoephedrine was collected by filtration, washed with ice-cold water (1.0 ml), dissolved in methanol (10 ml), and treated with 12 *N* HCl (1.0 ml).

TLC in 2-butanone–2-propanol–ammonium hydroxide (6:3:1) showed

almost entirely pseudoephedrine ($R_f$ 0.82), no ephedrone and no ephedrine, and a small amount of unknown material ($R_f$ 0.0). Evaporation to dryness *in vacuo* yielded 58.2 mg (64.0% from ephedrone) of crude [$^3$H]pseudoephedrine hydrochloride as an off-white solid. Two recrystallizations from 3-methyl-1-butanol–tetrahydrofuran afforded 3.8 mg of pure [$\alpha$-$^3$H]-*dl*-pseudoephedrine hydrochloride as a colorless crystalline solid. TLC in 2-butanone–2-propanol–ammonium hydroxide (6:3:1) showed almost single-spot [$^3$H]pseudoephedrine ($R_f$ 0.82) with a trace of material at the origin. Radiochromatogram scanning showed ~0.4% [$^3$H]ephedrine in otherwise radiochemically pure [$^3$H]pseudoephedrine. TLC in chloroform–2-propanol–triethylamine (62:35:3) again showed almost pure [$^3$H]pseudoephedrine ($R_f$ 0.16) with a trace of material at the origin. Radioactive chromatogram scanning showed ~2.6% of the activity in the origin material in otherwise 97.4% radiochemically pure [$^3$H]pseudoephedrine. Autoradiograms showed the same distribution pattern of radioactivity as shown by plate scanning. The specific activity was determined by scintillation counting to be 5.0 Ci/mmole.

**[$\alpha$-$^3$H]-*dl*-Pseudoephedrine-*N*-3-propionic Acid Methyl Ester (VII)**—A methanol solution of [$\alpha$-$^3$H]-*dl*-pseudoephedrine (2.82 $\mu$g, 69 $\mu$Ci, 300 $\mu$l) containing triethylamine (36.3 mg, 358 $\mu M$, 10 $\mu$l) and methyl acrylate (47.8 mg, 555 $\mu M$, 50 $\mu$l) was sealed and mixed at room temperature overnight. The solution was gently evaporated (dry nitrogen stream), and the residue was dissolved in 300 $\mu$l of methanol. A TLC radiochromatogram in ethylene dichloride–methanol–ammonium hydroxide (100:20:4) showed a single band that migrated with the unlabeled compound.

**[$\alpha$-$^3$H]-*dl*-Pseudoephedrine-*N*-3-propionitrile (VIII)**—A methanol solution of [$\alpha$-$^3$H]-*dl*-pseudoephedrine (2.82 $\mu$g, 69 $\mu$Ci, 300 $\mu$l) containing triethylamine (36.3 mg, 358 $\mu M$, 10 $\mu$l) and acrylonitrile (40.3 mg, 760 $\mu M$, 50 $\mu$l) was sealed and mixed at room temperature overnight. The solution was gently evaporated (dry nitrogen stream), and the residue was dissolved in 300 $\mu$l of methanol. A radiochromatogram in the TLC system used for VII showed a single band that migrated with the unlabeled compound.

**[$\alpha$-$^3$H]-*dl*-Pseudoephedrine-*N*-acetyl Amide (IX)**—A methanol solution of [$\alpha$-$^3$H]-*dl*-pseudoephedrine (2.82 $\mu$g, 69 $\mu$Ci, 300 $\mu$l) containing triethylamine (36.3 mg, 358 $\mu M$, 10 $\mu$l) and acetyl chloride (55.2 mg, 703 $\mu M$, 50 $\mu$l) was sealed and mixed at room temperature overnight. The solution was gently evaporated (dry nitrogen stream), and the residue was dissolved in 300 $\mu$l of methanol. A radiochromatogram in the system used for VII showed a single band that migrated with the unlabeled compound.

**Immunization Procedures**—Male New Zealand White rabbits received a primary immunization of 1 mg of bovine serum albumin–drug conjugate in 1 ml of 0.9% saline emulsified with 1 ml of Freund's complete adjuvant as two intramuscular (*vastus lateralis*) and eight subcutaneous (along each side of the dorsal column) injections of 0.2 ml each. At intervals of 2, 4, and 6 weeks following the primary immunization and at monthly intervals thereafter, booster immunizations of 0.5 mg of immunogen in 0.5 ml of saline, emulsified with 0.5 ml of Freund's complete adjuvant, were administered at multiple subcutaneous sites. Following the second and all subsequent booster immunizations, blood samples were collected from the central ear artery and the serum was separated and stored at −80°.

**Human Study**—Seventeen healthy male subjects received, for 5 days, either an immediate-release tablet[17] containing 2.5 mg of triprolidine hydrochloride and 60 mg of pseudoephedrine hydrochloride every 6 hr or a sustained-release capsule[18] containing 5 mg of triprolidine hydrochloride and 120 mg of pseudoephedrine hydrochloride every 12 hr. The study followed a double-blind crossover design so that all subjects received both treatments with a 1-week period intervening to allow for removal of residual drugs from the plasma. At each drug administration, subjects received a tablet and a capsule, one of which contained active drug and the other contained placebo materials according to the planned treatment schedule. The sustained-release preparation was administered at 8 am and 8 pm, while the immediate-release tablets were given at 8 am, 2 pm, 8 pm, and 2 am.

In each phase of the study, blood samples were collected into glass tubes[19] containing the disodium salt of ethylenediaminetetraacetic acid at 8 am, 10 am, 8 pm, and 10 pm on Days 1–4, at 8 am, 9 am, 10 am, 12 noon, 2 pm, 3 pm, 4 pm, 6 pm, 8 pm, and 10 pm on Day 5, and at 8 am and 2 pm on Day 6. Plasma was separated by centrifugation and stored at −20° until analyzed for pseudoephedrine content. The participants had not ingested any drugs for at least 1 week prior to entering the study.

**General Radioimmunoassay Procedures**—The assay buffer contained 0.05 $M$ $NaH_2PO_4$–$Na_2HPO_4$ (pH 7.4), 0.15 $M$ NaCl, 0.01 $M$ ethylenediaminetetraacetic acid disodium salt, and 1% bovine serum albumin, except where otherwise indicated. The pH of this buffer, hereafter referred to as 1% bovine serum albumin–phosphate-buffered saline, was adjusted to 7.4. For separation of antibody-bound radiolabel from free radiolabel, a bovine serum albumin-coated charcoal suspension was prepared by dissolving 0.6 g of charcoal in 100 ml of ice-cold 2% bovine serum albumin–phosphate-buffered saline. The suspension was stirred for at least 30 min at 0° prior to use.

The alternative separation system consisted of 350 g of polyethylene glycol 6000 dissolved in 1 liter of phosphate-buffered saline. For use with this system, radioligand and rabbit antibody solutions were prepared in buffer containing 0.1% bovine serum albumin (0.1% bovine serum albumin–phosphate-buffered saline); bovine serum albumin was not added to phosphate-buffered saline for any other assay applications using the polyethylene glycol 6000 immunoglobulin precipitation.

All assay points were established in duplicate, and most unknown samples were analyzed at two dilutions.

**Antiserum Titration**—*Charcoal Separation*—[$^{125}$I]-*d*-Pseudoephedrine-*N*-3-propionic acid–tyrosine methyl ester amide (100,000 dpm/assay), [$^3$H]-*dl*-pseudoephedrine-*N*-3-propionic acid methyl ester (16,000 dpm/assay), [$^3$H]-*dl*-pseudoephedrine-*N*-3-propionitrile (16,000 dpm/assay), [$^3$H]-*dl*-pseudoephedrine-*N*-acetyl amide (16,000 dpm/assay), or [$^3$H]-*dl*-pseudoephedrine (16,000 dpm/assay) in buffer (0.1 ml) was incubated with varying dilutions of rabbit antiserum in buffer (0.1 ml) and additional assay buffer (0.8 ml) at 4° overnight. Tubes containing only radiolabeled solution and buffer added to obtain the same total incubation volume served as total count tubes and background tubes.

Ice-cold 2% bovine serum albumin–charcoal suspension (0.5 ml) was added to all tubes except the total count tubes; the contents of the tubes were mixed, incubated at 4° for 5 min, and centrifuged (≥1000×$g$, 10 min). The tritium-containing supernates were decanted into scintillant (10 ml) and mixed, and the antibody-bound radioactivity was quantitated. The radioiodine-containing supernates were decanted into plastic tubes (12 × 75 cm) and capped, and their radioactivity contents were quantitated. The dilution that bound 50% of the amount bound in the presence of excess antiserum was defined as the working titer of the antiserum.

*Polyethylene Glycol Separation*—To ensure maximal precipitation of the antibody–radiolabel complex in the radioimmunoassay procedure using polyethylene glycol 6000 as an immunoglobulin precipitant, carrier immunoglobulin protein in the form of 0.1 ml of filtered (0.22 $\mu$m) pooled normal human plasma was added to the assay mixture and the amount of added buffer was reduced by 0.1 ml. After the assay mixture was incubated overnight at 4°, 1 ml of the polyethylene glycol 6000 solution was added to each assay tube (polypropylene, 12 × 55 mm) at 0° in an ice bath. The tubes were thoroughly mixed, incubated at 0° for 30 min, and centrifuged at ≥1000×$g$ for 30 min. Supernates were decanted from the immunoglobulin pellet containing antibody-bound radiolabel, the inverted tubes were allowed to drain for 15 min, and then the assay tubes were pounded on paper towels to remove the remaining supernates quantitatively. The pellets were then resolubilized in phosphate-buffered saline (0.3 ml) with mixing over 30 min. Total count tubes received 0.2 ml of phosphate-buffered saline plus 0.1 ml of labeled solution. When a homogeneous solution was achieved, scintillation fluid (2 ml) was added to the assay tubes, which were capped and mixed. These tubes were placed in specially designed scintillation vials that kept them correctly positioned for scintillation counting.

**Radioimmunoassay of Standard, Control, and Unknown Plasma Samples**—*Direct Radioimmunoassay with [$\alpha$-$^3$H]-*dl*-Pseudoephedrine Label*—A series of *d*-pseudoephedrine hydrochloride standard solutions in filtered (0.22 $\mu$m), pooled, normal human plasma (0.1 ml) ranging in concentration from 1 to 250 ng/ml (free base equivalents) was incubated as already described (for the polyethylene glycol separation) with [$\alpha$-$^3$H]-*dl*-pseudoephedrine (16,000 dpm/assay, 0.1 ml), *d*-pseudoephedrine antiserum (1:100 dilution, 0.1 ml), and assay buffer (0.7 ml). A similar series of three control solutions of *d*-pseudoephedrine added to normal human plasma varying in concentration across the range of the standard curve served as controls of assay accuracy and reproducibility. Unknown human plasma samples (0.1 ml), diluted appropriately with normal human plasma to enter the range of the assay, were also incubated with [$\alpha$-$^3$H]-*dl*-pseudoephedrine, *d*-pseudoephedrine antiserum, and assay buffer as described. Total counts and background tubes were as already described, each containing 0.1 ml of normal human plasma and a total final volume of 1 ml.

IX: R = $^3$H, R′ = $COCH_3$

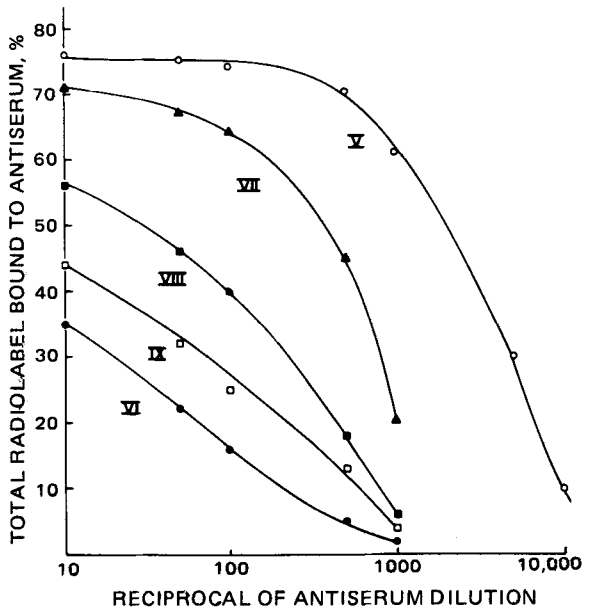

**Figure 1**—*Binding of various* d-*pseudoephedrine radioligands to increasing dilutions of* d-*pseudoephedrine antiserum.*

Separation of antibody-bound radiolabel from free radiolabel was achieved by charcoal adsorption of free radiolabel or polyethylene glycol 6000 precipitation of antibody-bound radiolabel as already described. Standard curves were expressed as % $B/B_0$ *versus* log *d*-pseudoephedrine free base concentration, where $B_0$ represents the amount (counts per minute) of [$\alpha$-$^3$H]-*dl*-pseudoephedrine bound in the absence of any unlabeled *d*-pseudoephedrine and $B$ is the amount bound at a given *d*-pseudoephedrine standard concentration (corrected for nonspecific binding).

*Indirect (Extracted and Derivatized) Assay Using [$^{125}$I]-*d*-Pseudoephedrine-*N*-3-propionic Acid–Tyrosine Methyl Ester Amide Label*—A similar series of *d*-pseudoephedrine standard solutions, control solutions, and appropriately diluted unknowns in filtered normal human plasma ranging in concentration from 0.2 to 50 ng/ml was prepared. One-milliliter aliquots of standards, controls, or unknown dilutions were pipetted into 15-ml glass centrifuge tubes with polytef-lined screw caps, followed by 2 *N* NaOH (0.5 ml, in saturated sodium sulfate). The basic plasma samples were shaken for 15 min with 7 ml of a mixture of cyclopentane–ether (1:1). After centrifugation, the lower aqueous layer was frozen in a dry ice–acetone bath and the solvent layer was decanted into a clean centrifuge tube.

The process was repeated with an additional 7 ml of solvent, and the combined extracts were evaporated under nitrogen at room temperature. The residue was taken up in methanol (2 ml) containing methyl acrylate (10 $\mu$l, 9.56 mg, 0.11 m*M*). The tubes were shaken gently overnight at room temperature, the contents were made acidic by the addition of 1 drop of a saturated solution of hydrogen chloride gas in methanol, and the tubes were shaken for 1 min. After evaporation under nitrogen at room temperature, the residues were dissolved in assay buffer (1 ml), and the tubes were shaken for 1 min.

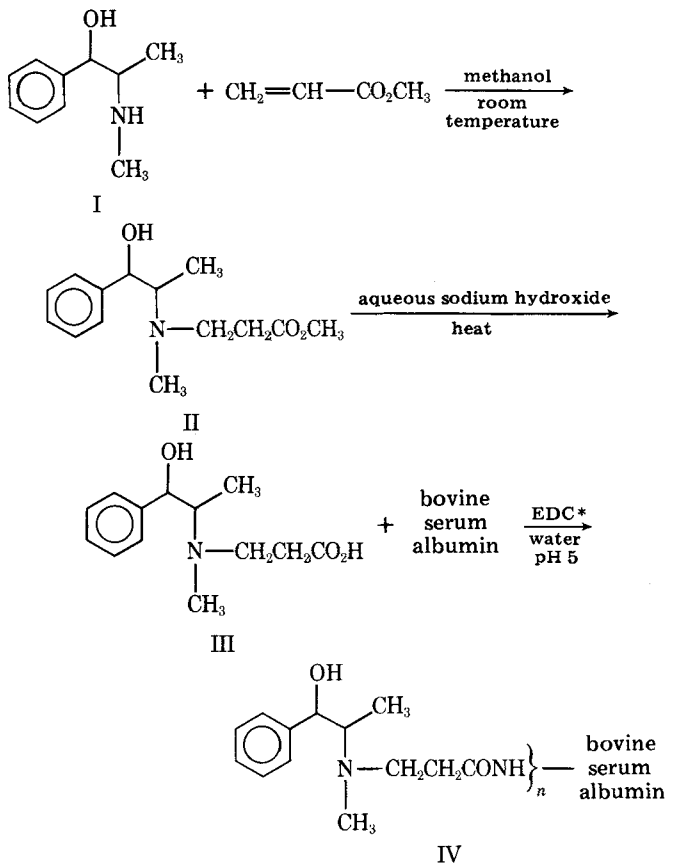
The radioimmunoassay incubation mixture was similar to that employing the tritium label and consisted of standards, controls, or unknown plasma dilutions, after extraction and derivatization, in assay buffer (0.5 ml), [$^{125}$I]-*d*-pseudoephedrine-*N*-3-propionic acid–tyrosine methyl ester amide (100,000 dpm) in assay buffer (0.1 ml), anti-*d*-pseudoephedrine serum (1:1500 dilution) in assay buffer (0.1 ml), and assay buffer (0.3 ml). After incubation for 2 hr at 0°, free radiolabel was adsorbed onto bovine serum albumin-coated charcoal as already described; the antibody-bound radiolabel contained in the supernates was quantitated. Data were reduced to standard curves, and control and unknown dilution concentrations were determined as already described.

*Cross-Reactivity Studies*—The procedure was similar to that described for the direct radioimmunoassay. A series of standard solutions of *d*-pseudoephedrine hydrochloride (0.2–100 ng of free base equivalents/ml) and some metabolites and structurally related compounds (1–100,000 ng/ml) in normal human plasma were incubated directly, or after extraction and derivatization, with antiserum and radiolabel and processed as described. Standard curves were drawn for each compound. Cross-reactivities were expressed as the percentage ratio of the *d*-pseudoephedrine concentration required to inhibit binding of the radiolabel to antiserum by 50% ($I_{50}$) to that of each respective compound (14).

## RESULTS

**Immunogen Synthesis**—The hapten used for the immunogen preparation, *d*-pseudoephedrine-*N*-3-propionic acid (III), was prepared by aqueous base hydrolysis of the ester product of a Michael addition of methyl acrylate to *d*-pseudoephedrine (Scheme I). The product was characterized by NMR and mass spectral analyses prior to coupling to bovine serum albumin *via* a carbodiimide-mediated amide bond formation using reaction conditions similar to those described by Cheng *et al.* (15).

**Radioligand Syntheses**—*[$\alpha$-$^3$H]-*dl*-Pseudoephedrine Hydrochloride (VI)*—This compound was prepared by a modification of the methods described previously (16–19) for the unlabeled compound. Bromination of propiophenone with bromine in refluxing methylene



*Scheme I—Synthesis of* d-*pseudoephedrine–bovine serum albumin conjugate (*EDC = 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride).*

[a] Pseudoephedrine was added to blank human plasma for all recovery studies. [b] Plasma samples were carried through the entire extraction–derivatization procedures. [c] All concentration values are nanograms per milliliter.

chloride solution gave *dl*-α-bromopropiophenone, which was condensed with methylamine gas in ethanol at 0° essentially by the method of Hyde *et al.* (20) to give, after purification, *dl*-ephedrone hydrochloride. Treatment of this compound with sodium boro[$^3$H]hydride in ethanol gave a quantitative yield of predominantly the *erythro* compound, [$^3$H]-*dl*-ephedrine hydrochloride. In the Welsh procedure (18, 19), this *erythro* compound undergoes an N → O acyl migration with inversion of configuration upon reaction with refluxing acetic anhydride while the *threo* isomer undergoes the same migration with retention of configuration.

Thus, acetylation of the crude ephedrine, followed by hydrolysis in aqueous hydrochloric acid, gave the free base [$^3$H]pseudoephedrine, which was converted to VI (64% yield from ephedrine). Two recrystallizations from isoamyl alcohol–tetrahydrofuran gave pure [$^3$H]pseudoephedrine hydrochloride for use in radioimmunoassay studies. Two useful methods for determination of the enantiomeric purity of the final product were developed during the synthetic work. TLC on silica gel layers in 2-butanone–2-propanol–ammonium hydroxide (6:3:1) clearly separated ephedrine ($R_f$ 0.49) and pseudoephedrine ($R_f$ 0.82). Also, the chemical shift of the α-proton doublet in the $^1$H-NMR spectrum could be used to detect ephedrine (δ 5.24, d, $J$ = 3 Hz) in the presence of pseudoephedrine (δ 4.62, d, $J$ = 10 Hz) and vice versa. The specific radioactivity of VI was estimated to be 5 Ci/mmole.

N-*Functionalized Radioligands*—Reaction of acetyl chloride, acrylonitrile, or methyl acrylate with VI, as described under *Experimental*, gave the *N*-acetyl amide (IX), *N*-propionitrile (VIII), or *N*-propionic acid methyl ester (VII) derivatives, respectively (Fig. 1). These radioligands were used to examine the affinity of the antiserum for radioligands bearing differing components of the bridge between hapten and bovine serum albumin in the immunizing conjugate.

$^{125}$*I-Labeled Radioligand*—A radioiodine-substituted ligand (V, Fig. 1) was prepared from *d*-pseudoephedrine-*N*-3-propionic acid–tyrosine methyl ester amide by reaction with sodium [$^{125}$I]iodide and chloramine-T by the general method of Hunter and Greenwood (21). The specific radioactivity of the ligand was estimated to be 270 Ci/m*M*.

**Comparative Binding of Radioligands by Antibody**—Figure 1 compares the ability of increasing dilutions of antiserum 515-1 to bind a constant amount of tritiated radioligands under identical incubation conditions. Since the specific activities of the tritiated radioligands were the same, the figure indicates the relative affinity of the antibody for pseudoephedrine and its various side-chain analogs. As the series progressed from underivatized [$^3$H]pseudoephedrine to *N*-acetyl-[$^3$H]-pseudoephedrine to the *N*-propionitrile analog and, finally, to the *N*-propionic acid methyl ester, the immediate precursor of the hapten derivative, higher dilutions of antiserum were capable of binding similar amounts of the radioligand. Clearly, the presence of the side chain was well recognized by this antiserum. The antiserum appeared to recognize the $^{125}$I-labeled radioligand well, although affinity comparisons with the $^3$H-labeled radioligands are difficult due to the higher specific activity of the iodinated compound.

**Assay Precision and Sensitivity**—Typical mean standard curves for the three individual radioimmunoassays are shown in Fig. 2. Each mean curve was constructed from four individual standard curves. The standard deviations on the curves indicate the excellent interassay precision. Further confirmation of interassay precision is shown by the assay data (means and standard deviations) for *d*-pseudoephedrine-spiked plasma controls that varied across the range of standard curve sensitivity for the separate radioimmunoassay procedures (Table I). The coefficient

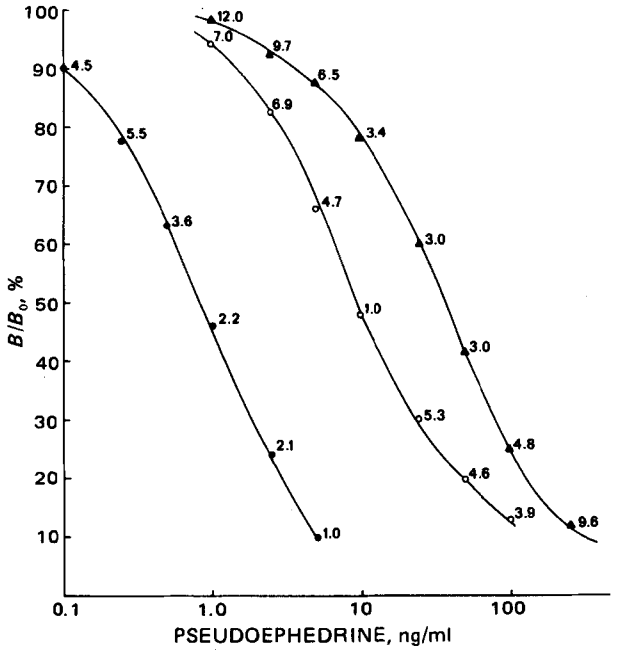

**Figure 2**—*Typical standard curves for* d*-pseudoephedrine radioimmunoassay procedures. Key:* ●, *iodine 125–derivatization–charcoal;* ○, *tritium–direct–charcoal; and* ▲, *tritium–direct–polyethylene glycol.*

of variation values did not exceed 8% for any control sample; for most samples, the coefficient of variation was <3%.

The indirect radioimmunoassay procedure, utilizing a radioiodine ligand and extraction and derivatization of *d*-pseudoephedrine prior to assay, is the most sensitive and specific technique, clearly able to detect 0.2 ng of *d*-pseudoephedrine/ml ($IC_{50}$ = 4.3 ng/ml). The direct radioimmunoassay procedure, utilizing a tritium radioligand and a bovine serum albumin-coated charcoal bound/free separation scheme, is the next most sensitive procedure with a detection limit of 1 ng of *d*-pseudoephedrine/ml ($IC_{50}$ = 10 ng/ml). However, due to the observed time-dependent tendency of the bovine serum albumin-coated charcoal to remove [$^3$H]-*dl*-pseudoephedrine from its binding sites on the antibody, the capacity of the assay (standards, controls, and unknowns) is limited.

For this reason, an alternative direct radioimmunoassay procedure using [$^3$H]-*dl*-pseudoephedrine was developed. Polyethylene glycol 6000 precipitates immunoglobulins (22) and, thus, antibody-bound radiolabel from the assay mixture. This precipitation achieves a separation of antibody-bound from free radiolabel that is relatively independent of time. The lower detection limit of this assay is 2.5 ng/ml ($IC_{50}$ = 35 ng/ml).

**Assay Specificity**—The relative specificities of the three radioimmunoassay procedures are shown in Table II. *d*-Norpseudoephedrine cross-reacted between 0.8 and 5.0%, with the indirect extraction–derivatization radioimmunoassay procedure being most specific and the direct–charcoal method being least specific. *l*-Ephedrine, the diastereomer of *d*-pseudoephedrine, was recognized by the antiserum 200–800 times less effectively than *d*-pseudoephedrine. In this case, while cross-reactivity was low in all three procedures, the direct–charcoal method was the most specific. *l*-Pseudoephedrine, the optical isomer of *d*-pseudoephedrine, had very low cross-reactivity in all assays (<0.003–0.01%).

More detailed cross-reaction studies were pursued using the polyethylene glycol 6000–direct procedure. The antibody was clearly able to distinguish the lack of a β-methyl group (*N*-methylphenylethanolamine, 0.26%), the lack of an α-hydroxy group (methamphetamine, 0.08%), oxidation of the α-hydroxy group (ephedrone, <0.003%), and hydroxylation of the aromatic ring (*p*-hydroxyephedrine, <0.003%). Endogenous phenylethanolamines, such as epinephrine, and drugs that may be coadministered with pseudoephedrine, such as triprolidine and codeine, cross-reacted <0.003%.

**Validation of Radioimmunoassays (Correlation with Standard GLC Assay)**—Final validation of the assays was achieved by comparative analysis by radioimmunoassay and GLC of human plasma samples containing *d*-pseudoephedrine (obtained from volunteers who had ingested a 60-mg tablet of *d*-pseudoephedrine hydrochloride). Figure 3 shows correlation diagrams relating plasma *d*-pseudoephedrine levels

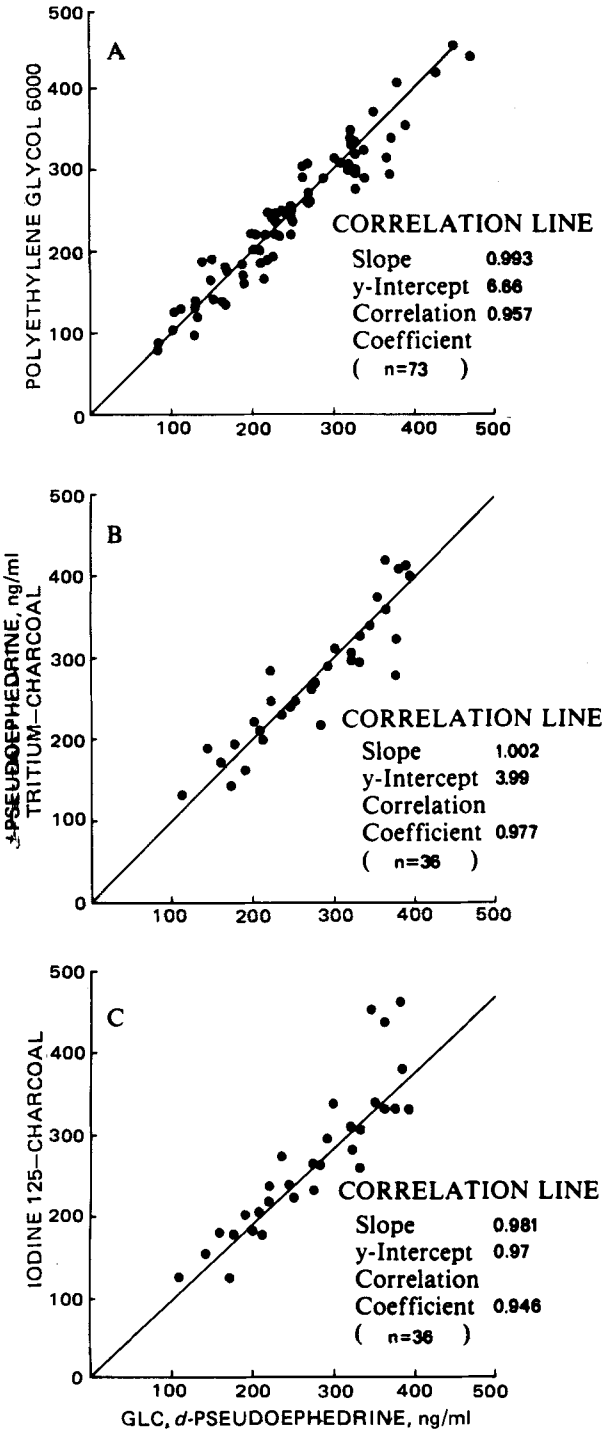

**Figure 3**—*Correlation of pseudoephedrine concentrations in human plasma samples as analyzed by a GLC procedure and tritium–direct–polyethylene glycol radioimmunoassay (A), tritium–direct–charcoal radioimmunoassay (B), or iodine 125–derivatization–charcoal radioimmunoassay (C).*

determined by a derivatization GLC procedure with electron-capture detection (10) to those determined by the three radioimmunoassays. In each case, linear regression analysis gave correlation coefficients between 0.946 and 0.977 and slopes of 0.981–1.002, indicating excellent agreement between all three radioimmunoassay procedures and the reference GLC assay.

**Disposition Studies in Humans**—For convenience and ease of operation, the direct radioimmunoassay utilizing [$^3$H]pseudoephedrine and the polyethylene glycol 6000 separation method was used in all human drug disposition studies. This assay was applied to a bioequivalence comparison of *d*-pseudoephedrine from a sustained-release preparation

**Table II—Cross-Reactivities (%) of Related Compounds in Pseudoephedrine Radioimmunoassay Procedures**

| Compound | Tritium–Direct–Charcoal | Tritium–Direct–Polyethylene Glycol 6000 | Iodine 125–Extraction–Derivatization |
|---|---|---|---|
| *d*-Pseudoephedrine | 100 | 100 | 100 |
| *d*-Norpseudoephedrine | 5.0 | 1.75 | 0.8 |
| *l*-Pseudoephedrine | 0.01 | 0.05 | <0.003 |
| *l*-Ephedrine | 0.13 | 0.44 | 0.32 |
| *l*-Norephedrine | — | 0.02 | — |
| *d*-Ephedrine | — | 0.35 | — |
| *N*-Methylphenylethanolamine | — | 0.26 | — |
| Methamphetamine | — | 0.08 | — |
| *dl*-*p*-Hydroxyephedrine | — | <0.003 | — |
| Ephedrone | — | <0.003 | — |
| Metaraminol | — | <0.003 | — |

| Codeine | — | <0.003 | — |

(containing 120 and 5 mg, respectively) and an immediate-release preparation (containing 2.5 and 60 mg, respectively) of *d*-pseudoephedrine hydrochloride and triprolidine hydrochloride in 17 healthy male subjects. The study extended over 126 hr in each of two separate periods, during which all subjects received both formulations (*Experimental*). Doses of sustained-release medication were administered at 12-hr intervals (8 am and 8 pm), while immediate-release tablets were given at 6-hr intervals (8 am, 2 pm, 8 pm, and 2 am) throughout the first 120 hr. Mean plasma pseudoephedrine levels in these subjects over the entire 126-hr study period as determined by the direct radioimmunoassay are shown in Fig. 4.

Steady-state concentrations were approached with both drug formulations by the 3rd day of treatment, with mean trough concentrations of 280–350 ng/ml and mean peak concentrations of 420–560 ng/ml for the two preparations. Additional blood samples were taken from 8 am to 8 pm on Day 5 to define more closely the plasma concentration–time profiles at steady state for immediate- and sustained-release preparations. The mean plasma concentration–time curves for all subjects during this period are shown in Fig. 5. The mean observed peak concentration following the first (8 am) dose of the immediate-release tablet (containing 60 mg of pseudoephedrine hydrochloride) was 565.8 ng/ml and that following the second (2 pm) dose was 554.6 ng/ml. The maximum concentration observed following administration (at 8 am) of the sustained-release preparation (which contained 120 mg of pseudoephedrine hydrochloride) was 550.6 ng/ml. Although the mean peak plasma concentrations achieved with the two formulations were not significantly different, mean plasma concentrations of pseudoephedrine were maintained for a considerably longer period with the sustained-release preparation.

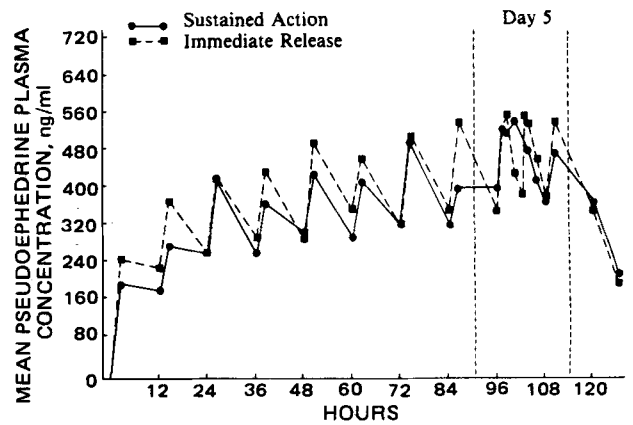

**Figure 4**—*Mean plasma pseudoephedrine concentrations over 126 hr in 17 healthy volunteers who received either a sustained-release preparation of pseudoephedrine every 12 hr or an immediate-release preparation every 6 hr for the first 5 days.*

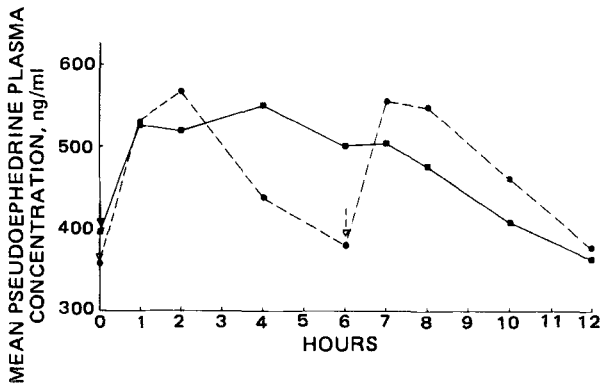

**Figure 5**—*Detailed presentation of the 8 am–8 pm period on Day 5 of the study presented in Fig. 4. Key: ■, sustained release; and ●, immediate release.*

## DISCUSSION

Previous investigations demonstrated the need for conjugation of drugs to macromolecules to render them immunogenic (23–25). In the present study, *d*-pseudoephedrine was easily derivatized *via* the nitrogen atom by reaction with methyl acrylate followed by alkaline hydrolysis to give the *N*-3-propionic acid derivative for coupling to bovine serum albumin for immunization purposes. Antiserum raised in response to this immunization procedure was used to develop three radioimmunoassay procedures. In one, a tyrosine methyl ester derivative of the original hapten, prepared by carbodiimide-mediated reaction with tyrosine methyl ester followed by iodination, provided a radioligand with the convenience of a $\gamma$-emitting radioisotope. However, since this ligand could not be displaced by *d*-pseudoephedrine at the required sensitivity level, this assay modification required prior extraction of all pseudoephedrine-containing samples and derivatization with methyl acrylate before their addition to the radioimmunoassay system.

[$\alpha$-$^3$H]-*dl*-Pseudoephedrine and unlabeled pseudoephedrine were used to demonstrate that the drug could be extracted and derivatized by this method with a mean overall recovery of >95% across the concentration range of 0.1–500 ng/ml when performed under the conditions specified under *Experimental*. This assay modification has better sensitivity and specificity than the other variations and may be useful in studies where maximal sensitivity is required, such as tissue distribution experiments. The assay variants employing [$^3$H]pseudoephedrine as the radioligand are somewhat less sensitive than the derivatization assay using the $^{125}$I-labeled radioligand and use the antiserum at a much lower titer, but these variations have the distinct advantage of providing reliable drug analyses directly on plasma, *i.e.*, without prior extraction. The assay using the polyethylene glycol 6000 method for separation of antibody-bound from free radioligand had the advantage of being less time dependent when compared to the bovine serum albumin-coated charcoal separation method. Thus, large assay runs were more reliably performed with the former system.

All three assay systems are accurate and precise (Table I), and have sensitivity limits in the range of 0.2–2.5 ng/ml for iodine 125–derivatized and tritium–polyethylene glycol methods, respectively (0.2–0.25-ng actual mass of pseudoephedrine, see *Experimental*). This sensitivity far exceeds that of the earlier GLC procedures for pseudoephedrine (7, 10, 11) and is better than that of a more recent GLC method using nitrogen detection that was capable of detecting a lower limit of 25 ng/ml (12). Acetylation of pseudoephedrine with [$^3$H]acetic anhydride provides a method capable of detecting 50 ng/ml of the drug in plasma (8). Recently, a pseudoephedrine pharmacokinetic study (26) was reported in the rat using an electron-capture GLC microtechnique capable of detecting 2 ng of drug. This method is still less sensitive and far more cumbersome than direct radioimmunoassay with the [$^3$H]pseudoephedrine radioligand described here. All three radioimmunoassay variants were validated by comparison with an accepted GLC analytical method (10), giving an excellent correlation in each case (Fig. 3).

The ability of drug antiserum to discern changes in molecular architecture is normally greatest for structural changes at sites distant from the site of attachment of the drug to the macromolecular carrier. Thus, *d*-norpseudoephedrine, which was reported to be a minor metabolite of pseudoephedrine (11) in humans, unexpectedly cross-reacted only to the extent of 0.8–5.0% (Table II). In the nor compound, a methyl group was lacking on the nitrogen atom on which the bridge to protein in the immunogen was attached. The low cross-reactivity in the derivatized assay with the $\gamma$ label is easier to understand in that norpseudoephedrine would presumably react with methyl acrylate in the derivatization step to give a bis adduct, which would then be recognized less effectively by the antiserum.

Several recent reports described the ability of antiserum to discern stereochemical differences in drug molecules. Cook *et al.* (27) described the development of stereoselective radioimmunoassay procedures for (*R*)- and (*S*)-warfarin, Gross and Soares (28) prepared antiserum to *d*-amphetamine, and Kawashima *et al.* (29) reported radioimmunoassay procedures for *l*- and racemic propranolol. The *d*-pseudoephedrine antiserum developed in the present study also possesses a high degree of stereospecificity, as shown by the very low cross-reactivities of *l*-pseudoephedrine, *d*- and *l*-ephedrines, and *l*-norephedrine. A change in the aromatic ring of the ephedrine series, such as in *dl*-*p*-hydroxyephedrine, essentially eliminates recognition by the antiserum. Changes in side-chain structure, as represented by ephedrine, *N*-methylphenylethanolamine, methamphetamine, metaraminol, methoxamine, phenylethylamine, and *l*-phenylephrine, are well recognized by the antiserum, resulting in very low cross-reactivities. A representative catecholamine, epinephrine, caused no inhibition of radioligand binding, nor did triprolidine and codeine, which may, on occasion, be coadministered with pseudoephedrine.

The pharmacokinetics of *d*-pseudoephedrine in humans have not yet been investigated in detail, although some data relating plasma levels to pharmacological effects were reported (12). A major limitation to the pursuit of such studies has been the lack of suitable analytical methodology. The applicability of the present radioimmunoassay technique to pharmacokinetic studies is shown by the data in Figs. 4 and 5. The day-to-day plasma levels in this bioequivalence study were measured easily with the direct radioimmunoassay procedure with polyethylene glycol 6000 as the separation system. As seen in Fig. 4, the assay demonstrated that steady-state plasma concentrations of pseudoephedrine were approached by Day 3 of dosing with either formulation.

The bioequivalence of the immediate- and sustained-release preparations in these subjects was demonstrated by the lack of significant difference between the mean area under their plasma concentration–time curve (*AUC*) values over the entire 126-hr period of the study [43,796 ± 2738 (*SEM*) ng/ml hr for the sustained release and 47,910 ± 3085 (*SEM*) ng/ml hr for the immediate release]. Since this *AUC* comparison was approximate due to the infrequent blood collections during Days 1–4, a similar *AUC* comparison was made for 8 am–8 pm on Day 5, when steady-state concentrations had been achieved and additional blood samples were collected. From these data (Fig. 5), *AUC* calculations again indicated bioequivalence of immediate- and sustained-release preparations [5744 ± 395 (*SEM*) ng/ml hr for the sustained release and 5674 ± 354 (*SEM*) ng/ml hr for the immediate release].

Figure 5 clearly shows that, although the observed maximum plasma concentrations following each formulation were not significantly different, the mean concentrations were maintained in the 450–550-ng/ml range for ~8 hr with the sustained-release preparation, thus avoiding the trough at 6 hr and the peak at 7–8 hr that occurred with the two-dose regimen of the immediate-release preparation. Thus, the radioimmunoassay has been used to demonstrate the rationale for this type of sustained-release preparation. Recently, studies of similar pseudoephedrine formulations have produced similar results (30, 31).

These radioimmunoassay procedures are being applied currently to detailed studies of the disposition of *d*-pseudoephedrine in animals and humans.

# Comparative Teratogenicity of Cortisone and Phenytoin in Mice

**JOSEPH M. McDEVITT, RONALD F. GAUTIERI ˣ, and DAVID E. MANN, Jr.**

Received September 2, 1980, from the *Department of Pharmacology, School of Pharmacy, Temple University, Philadelphia, PA 19140.* Accepted for publication November 13, 1980.

**Abstract** □ Single administrations of cortisone or phenytoin to pregnant mice on Days 11–14 of gestation caused similar skeletal and dissimilar soft tissue fetal anomalies. Cortisone reduced both maternal and fetal weight, whereas phenytoin only reduced fetal weight without adversely affecting maternal weight. A correlation between fetal weight reduction and cleft palate incidence was evident for each drug. Because probit analysis of dose–response regression lines did not deviate from parallelism after drug challenge, it was concluded that cortisone and phenytoin may produce palatal anomalies in the mouse fetus by a similar mechanism.

**Keyphrases** □ Teratogenicity—effects of cortisone and phenytoin on mice □ Cortisone—teratogenic effects on mice □ Phenytoin—teratogenic effects on mice □ Antiepileptics—teratogenic effects of phenytoin on mice

The experimental use of various agents to elicit and inhibit cleft palate has been pursued vigorously in recent years to determine its cause and to prevent its occurrence in human newborns. Although cortisone is the prototypal agent employed for the induction of this anomaly in lower species (1), phenytoin is of particular interest because of the purported link between its use as an antiepileptic drug during pregnancy and the appearance of cleft palate in offspring (2, 3).

The purpose of this investigation was to compare the teratogenic effects of phenytoin with those of cortisone by means of dose–response relationships in mice and to ascertain whether the mechanism involved in cleft palate inception by cortisone and phenytoin is similar.

## EXPERIMENTAL

**Animals**—CF-1 albino mice[1] (25–35 g) were used. Females were confined in groups of 10 to aggregate cages for at least 2 weeks prior to mating. Males were placed individually in metal cages (12.5 × 15 × 10 cm) with a wire mesh front and floor[2]. Adult mice were maintained on a commercial diet[3] and tap water *ad libitum*. The breeding room was equipped with an electrical system[4], which provided 12 hr of light (7:00 am–7:00 pm) and 12 hr of darkness. Room temperature was maintained between 22 and 26°.

**Preparation of Solutions**—Saline and cortisone acetate solutions were prepared commercially[5,6]. Fresh aliquots (10 ml) of phenytoin solution were prepared as needed on the day of injection by dissolving the drug[7] in a stock solution of 70% propylene glycol[8] (in saline). Phenytoin solutions were prepared containing 10, 14, 16, or 18 mg of phenytoin/ml of vehicle in injection volumes of 0.1–0.3 ml. All injections were made with a glass syringe[9]. The bone-staining solution was prepared by dissolving 18 mg of alizarin red-S in each liter of 1% KOH in distilled water. A 50:50 mixture of 70% ethyl alcohol and 100% glycerin was used to fix and clear the specimens. Fetuses chosen for soft tissue analysis were fixed in Bouin's solution.

**Breeding Procedure and Treatment Regimen**—The breeding procedure was previously described (4). Gravid females were randomly

[a] Eight mice per group. [b] I is cortisone acetate; II is phenytoin.

assigned to one of three control groups or one of two treatment sections: I, cortisone; and II, phenytoin, the latter being divided into five groups each (Table I). Each control group and each treatment group consisted of eight females. Of the three control groups, one received no further treatment while the other two served as vehicle controls. One group received saline solution in a fixed volume of 0.3 ml, which was administered in a manner identical to that of cortisone; the remaining control group received 0.3 ml of 70% propylene glycol solution in a manner identical to that of phenytoin.

The treatment groups received cortisone or phenytoin on Days 11–14 of gestation. The steroid was injected intramuscularly into the thigh muscles of the hindlegs, alternating between the right and left legs on successive days, in 25-, 50-, 75-, 100-, and 125-mg/kg doses per group. Phenytoin was administered subcutaneously into the ventroposterior or dorsoanterior quadrant close to the axilla, in alternate quadrants on successive days, in 10-, 30-, 50-, 70-, and 90-mg/kg doses per group. It soon became apparent that a threshold dose for phenytoin teratogenicity (cleft palate production) would be >50 mg/kg. Therefore, the two lower dosage schedules were deleted, and a group of eight mice receiving 80 mg of phenytoin/kg was substituted.

**Examination of Fetuses**—On Day 18, 1 day before term, the terminal weight was recorded for each mouse[10], which then was sacrificed by cervical dislocation. The number and position of fetuses and resorption sites (metrial glands) were ascertained and recorded. The fetuses were removed, tested for viability with a blunt probe, blotted dry, and weighed to the nearest hundredth of a gram[10]. They then were examined for gross external defects and sexed.

The specimens were prepared for macroscopic examination as follows. For skeletal examination, every second fetus was prepared according to the method of Staples and Schnell (5); the remaining fetuses were fixed and decalcified in Bouin's solution in preparation for freehand razor blade sectioning (6). The palatal shelves were observed prior to sectioning, and the urogenital organs were left intact. All specimens were examined for bone and soft tissue anomalies with a binocular dissecting microscope[11].

**Statistical Methods and Analysis**—The degree of significance of observed variations among the experimental groups was determined by the Student $t$ test (7). All $t$ values were calculated on a computer[12]. The dose–response relationships for cortisone- and phenytoin-induced cleft palate were compared by probit analysis (8).

## RESULTS AND DISCUSSION

**Maternal Effects of Drugs**—The female mice were unresponsive to intramuscular injections of saline or to initial cortisone challenges, but second and third administrations of the hormone caused lethargy that persisted for over 24 hr at the higher dosage levels. Mice injected subcutaneously with either 70% propylene glycol or phenytoin experienced excitement and discomfort. As the number of injections and dosages of the antiepileptic agent was increased, Straub tail reactions, excitement (cage circling), ataxia, and depression occurred. Ataxia and depression were most pronounced in the group receiving 90 mg of phenytoin/kg. At laparotomy, most mice that had received solutions containing the propylene glycol vehicle had inflamed injection sites, particularly in the scapular region. No deaths in gravid animals resulted from drug treatment.

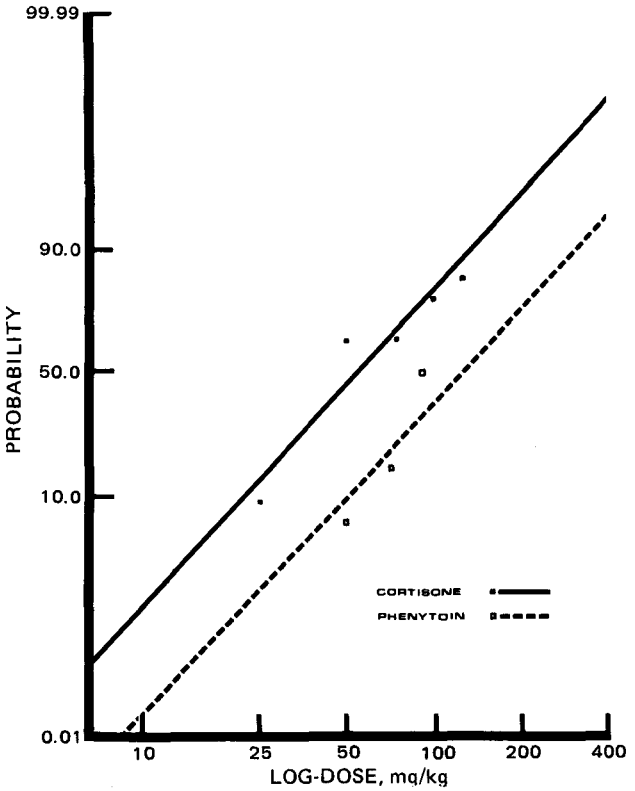

**Figure 1**—*Probit regression of the percent of cleft palate per litter on log-dose.*

Table II presents the mean values of maternal and fetal deviations of the test groups in relation to their respective saline or propylene glycol controls. Each group contained eight litters and ~100 fetuses.

**Maternal Weight**—The weight gain reflects the difference in maternal weight on Days 0 and 18 of gestation. The mean maternal weight gains among the cortisone-treated groups decreased as the dosage of the hormone was increased. Significantly lower weight gains, when compared with those in the saline group, occurred in all cortisone groups, except in the one receiving the 25-mg/kg dose. No significant differences were found when the mean maternal weight gains within the phenytoin-treated groups were compared with those of the group receiving the propylene glycol vehicle.

**Fetal Resorption**—Percent resorption is defined as the ratio of the number of resorption sites to the sum of the resorption sites and viable fetuses times 100. No significant differences were found among the control or cortisone-treated groups with respect to percent resorption. Within the phenytoin-treated groups, only mice that received 70- and 80-mg/kg doses had a significantly higher percent resorption ($p < 0.05$) than occurred in the group that received a dose of 50 mg/kg[13].

**Fetal and Sex Ratios**—No significant variations in the mean number of fetuses in either the right or left uterine horn were noted among the control or treated groups. There were no differences in the sex ratios of the phenytoin-treated and propylene glycol control groups. However, the group that received cortisone (75 mg/kg) had a significantly lower mean percentage of males when compared with the saline control.

**Mean Fetal Weight**—There were no significant differences in the mean fetal weight among the control groups. Within the cortisone-treated groups, an apparent dose-dependent reduction of this parameter occurred, with significant differences being evident with cortisone at 50, 100, and 125 mg/kg when compared with the saline control. In the phenytoin-treated group, a significant reduction in mean fetal weight was noted between the antiepileptic agent (90 mg/kg) and its propylene glycol control.

**Production of Soft Tissue and Skeletal Anomalies**—The occurrence and nature of the various soft tissue and skeletal defects representing significant deviations of the cortisone- and phenytoin-treated

groups from their saline and propylene glycol controls are presented in Tables III and IV, respectively.

With the exception of cleft palate, which appeared in the fetuses of both treatment groups, most soft tissue anomalies caused by single intramuscular injections of cortisone on Days 11–14 of gestation were unlike those observed after single subcutaneous administrations of phenytoin on the same days of gestation.

An inverse relationship between fetal weight and cleft palate incidence has been well documented for cortisone teratogenicity (9, 10). A similar association between reduced fetal weight and phenytoin-induced cleft palate also was reported (11). However, these are dose-dependent responses, as shown in the present study and others (11–14), which probably explain why fetal weight loss was not reported when low doses of phenytoin were used (15, 16).

An inverse relationship appeared to exist between the occurrence of a small protuberance on the forepaw and cortisone dosage, whereas a direct relationship was evident between the dosage level of the steroid and the emergence of other soft tissue anomalies, *i.e.*, cleft palate. The former situation demonstrates that the presence of one defect may be dependent on the presence or absence of another. This type of variable dependency may account for the nonlinear response observed for sternebral defects in the cortisone-treated group. The frequently appearing anomaly, crankshaft sternebrae, could positively influence the occurrence of fused sternebrae because sternebral ossification sites would be positioned closer to each other. Therefore, anomaly frequency in response to a given dose should be considered individually before conclusions concerning the teratogenic potential of a suspected agent are made.

Cryptorchidism seemed to be directly dependent on phenytoin dosage but was not related to cortisone dosage. Ovarian displacement after phenytoin treatment also appeared to be dose related. The reason why ectopic ovarian development occurred only on the left side of the fetus remains enigmatic.

In addition to the soft tissue defects listed in Table III, other soft tissue anomalies observed in the phenytoin-treated groups were curled tail, connective tissue infiltration of the cerebral hemispheres, cerebral hemorrhage, fused digit, ectrodactyly, malformed hindpaw, malformed kidney, and cleft lip. These soft tissue defects and those observed in the cortisone-treated groups, *i.e.*, curled tail, exencephaly, and fused digit, were not statistically significant when compared with the respective treatment or control groups.

Cortisone and phenytoin treatment produced fetuses with similar skeletal malformations that primarily involved the sternebral and cranial (supraoccipital) bones; this finding is in agreement with previous results (15). The following skeletal defects were observed at insignificant frequencies in their respective groups: missing sternebrae, malformed and split xiphoid processes (cortisone and phenytoin), ectopic sternebrae (cortisone, phenytoin, and untreated), and displaced sternebrae, *i.e.*, due to rotation of the sternebral ossification sites 30° off center (cortisone).

Phenytoin also interfered specifically with skeletal digit development. Delayed ossification of the digits was dose dependent (Table IV). Malformed and hypoplastic digits have been reported in human infants whose epileptic mothers were maintained on phenytoin therapy during pregnancy (17, 18).

Rugh (19) accumulated data that related organogenesis to gestational age in the mouse. Thus, from the results obtained in this and other studies that employed similar dosage schedules (12, 13, 15) of cortisone and phenytoin, it is evident that the majority of the skeletal abnormalities induced by these agents occur at sites where chondrification centers develop on Days 15–16 (supraoccipital bone, sternum, and distal phalanges). These findings indicate that the critical time for phenytoin- and cortisone-induced skeletal anomalies is several days prior to genesis of the affected tissue.

The critical periods reported for phenytoin- and cortisone-induced cleft palate are remarkably similar to those required for the production of sternebral, supraoccipital, and digital malformations. Single injections of cortisone (20) and phenytoin (12, 21) were most effective in producing cleft palate when given to mice on Day 12 of gestation, although maximum responses were obtained from multiple injections over Days 12–14. It has been determined (22) that murine palatogenesis begins on Day 14

[a] Mean percent of defects per litter. [b] Eight mice per group. Significance ($p < 0.05$) is indicated by superscripts as compared with controls: [c] untreated, [d] saline, and [e] propylene glycol, and with treated groups: cortisone, [f] 25 and [g] 50 mg/kg, and phenytoin, [h] 50 and [i] 70 mg/kg. D.O.P. = delayed ossification of the paws; Split Supraocc. = split supraoccipital bone, Stern. Dft. = occurrence of at least one sternebral defect, Crank St. = crankshaft sternebrae, Split St. = split sternebrae, and Fused St. = fused sternebrae.

and terminates on Day 15.

Several studies linked the alteration of events common to palatogenesis and bone formation, including glycosaminoglycan (23) and collagen formation (24, 25), and the activities of enzymes (alkaline phosphatase, acid phosphatase, and β-glucuronidase) (26) and hormones (parathyroid hormone and calcitonin) (27) to the production of cortisone-induced cleft palate. Because of these relationships and the similarities that exist between cortisone- and phenytoin-induced skeletal malformations, it can be concluded that, qualitatively, the teratogenic mechanism of action of these agents in the formation of skeletal anomalies is similar.

A graphical approximation of the regression lines of the mean percent of cleft palate per litter on log-dose for cortisone- and phenytoin-treated groups appears in Fig. 1. These lines are the result of the second iteration of the method of probit analysis described by Finney (8). The original iteration was performed on lines fitted independently from the results obtained from the test groups without constraint of parallelism. The results from the second stage were employed to calculate the common slope, which was used to construct the curves in Fig. 1. Heterogenicity and parallelism were both examined by $\chi^2$ tests. Because the dose–response regression lines for cortisone- and phenytoin-induced cleft palate did not deviate from parallelism, the teratogenic mechanism of action of these agents in causing this anomaly may be similar. The relative potency of phenytoin as a cleft palate-inducing teratogen was calculated, according to the method of Finney (8), to be from 14.54 to 69.18% that of cortisone.

# Oxidative Degradation of 6-Selenoguanosine in Aqueous Solutions

**A. J. REPTA ˣ and Y. A. BELTAGY ***

Received August 8, 1980, from the *Pharmaceutical Chemistry Department, School of Pharmacy, University of Kansas, Lawrence, KS 66044.* Accepted for publication November 17, 1980.

*Present address: Pharmaceutical Chemistry Department, Faculty of Pharmacy, University of Alexandria, Alexandria, Egypt.

**Abstract** □ The degradation of 6-selenoguanosine (NSC 137679)(I) in water and in various buffer systems was investigated. Drug degradation in aqueous media was monitored by high-pressure liquid chromatography. Some kinetic aspects of the degradation of I in various buffer systems at 25° also were studied spectrophotometrically. The degradation, which requires oxygen, involves autoxidation of I to the corresponding diselenide, which produces a selenide and metallic selenium in the presence of oxygen. This degradation pathway differs from that reported for the oxidation of related thio compounds.

**Keyphrases** □ 6-Selenoguanosine—oxidative degradation in aqueous solutions, kinetics □ Autoxidation, aqueous—6-selenoguanosine, selenium compounds, pharmacokinetics □ Kinetics—6-selenoguanosine, oxidative degradation in aqueous solutions, selenium compounds □ Antineoplastics—6-selenoguanosine, selenium compounds, oxidative degradation in aqueous solutions, kinetics

During a study of selenium analogs of physiologically active sulfur compounds, numerous selenium analogs were synthesized for biochemical investigation. 6-Selenopurine was synthesized (1) and found to be active as an antileukemic agent (2), but it was unstable and toxic to the host (3). Subsequently, 6-selenopurine-9-β-D-ribonucleoside was prepared, but it was even less stable than 6-selenopurine under the same conditions (3).

In a search for a more stable analog, 6-selenoguanosine (NSC 137679) (I) was synthesized (4); it was found to be an active inhibitor of several experimental tumors *in vitro* (5, 6) and *in vivo* (7, 8). Although I was reported to be more stable than preceding analogs (4, 9), it still undergoes sufficiently rapid degradation in aqueous solutions such that its formulation in a dosage form suitable for evaluation of anticancer activity presented serious problems (10).

# Oxidative Degradation of 6-Selenoguanosine in Aqueous Solutions

**A. J. REPTA ˣ and Y. A. BELTAGY ***

Received August 8, 1980, from the *Pharmaceutical Chemistry Department, School of Pharmacy, University of Kansas, Lawrence, KS 66044.* Accepted for publication November 17, 1980.

*Present address: Pharmaceutical Chemistry Department, Faculty of Pharmacy, University of Alexandria, Alexandria, Egypt.

**Abstract** □ The degradation of 6-selenoguanosine (NSC 137679)(I) in water and in various buffer systems was investigated. Drug degradation in aqueous media was monitored by high-pressure liquid chromatography. Some kinetic aspects of the degradation of I in various buffer systems at 25° also were studied spectrophotometrically. The degradation, which requires oxygen, involves autoxidation of I to the corresponding diselenide, which produces a selenide and metallic selenium in the presence of oxygen. This degradation pathway differs from that reported for the oxidation of related thio compounds.

**Keyphrases** □ 6-Selenoguanosine—oxidative degradation in aqueous solutions, kinetics □ Autoxidation, aqueous—6-selenoguanosine, selenium compounds, pharmacokinetics □ Kinetics—6-selenoguanosine, oxidative degradation in aqueous solutions, selenium compounds □ Antineoplastics—6-selenoguanosine, selenium compounds, oxidative degradation in aqueous solutions, kinetics

During a study of selenium analogs of physiologically active sulfur compounds, numerous selenium analogs were synthesized for biochemical investigation. 6-Selenopurine was synthesized (1) and found to be active as an antileukemic agent (2), but it was unstable and toxic to the host (3). Subsequently, 6-selenopurine-9-β-D-ribonucleoside was prepared, but it was even less stable than 6-selenopurine under the same conditions (3).

In a search for a more stable analog, 6-selenoguanosine (NSC 137679) (I) was synthesized (4); it was found to be an active inhibitor of several experimental tumors *in vitro* (5, 6) and *in vivo* (7, 8). Although I was reported to be more stable than preceding analogs (4, 9), it still undergoes sufficiently rapid degradation in aqueous solutions such that its formulation in a dosage form suitable for evaluation of anticancer activity presented serious problems (10).

While considerable information has been published

I

relative to the oxidation and other solution reactions of sulfur-containing compounds, including thiopurines and thionucleosides (11, 12), there is a lack of such information for related selenium compounds. The present work examined the nature of the degradation, including its reaction products, and investigated the factors affecting the degradation rate of I in solutions.

## RESULTS AND DISCUSSION

When I was dissolved in water (0.75 mg of I/ml of water) and air was continuously bubbled through the solution, cloudiness developed within 5 hr. The cloudy solution was filtered at 6 hr, and the solid dark-yellow residue was dissolved in methanol. When the methanolic solution was examined by high-pressure liquid chromatography (HPLC), a major peak was eluted at 21.5 ml (capacity factor $k' = 7.08$). An authentic sample of the diselenide of 6-selenoguanosine in methanol (II) also eluted at 21.5 ml. Results of the elemental analysis of the solid residue were in good agreement with those of the authentic II sample. Additionally, the UV spectra of methanolic solutions of the solid residue and authentic II also were identical. Thus, it was concluded that the cloudiness was due to II precipitation. When the filtrate of the cloudy solution at 5 hr was examined by HPLC, only a very small peak (D, Fig. 1) corresponding to II was observed; it was attributed to the fact that II is only very sparingly soluble in water (~0.1 μg/ml) and little remains in solution.

The compounds responsible for the remaining peaks in the filtrate chromatogram shown in Fig. 1 also were examined. Peak A ($k' = 1.46$) was due to I itself. Peak B ($k' = 3.92$), which was only present in small amounts, was characterized as guanosine (III) based on the fact that it coeluted with an authentic guanosine sample.

The compound responsible for peak C ($k' = 4.40$) was more difficult to characterize. In chromatograms of freshly prepared solutions of I, peak C was not observed. But on standing with exposure to molecular oxygen, peak C increased in intensity. After standing for ~10 days, the reaction appeared to reach completion; the chromatogram of the reaction mixture filtrate showed only a small peak B (corresponding to III) and a large peak C, with no remaining peak A or D. When a dilute aqueous suspension of II (0.2 mg of II/ml of water) was prepared and allowed to stand exposed to air, peak C again was formed at the expense of II. The sediment remaining after the aqueous solution of I was exposed to oxygen for 10 days was red. Separation and analysis of the solid demonstrated that it was selenium metal.

The filtrate obtained at 10 days was evaporated to dryness under reduced pressure, and the compound corresponding to peak C was isolated and recrystallized. HPLC analysis of the recrystallized solid indicated that recrystallization had not resulted in any significant compound degradation, although some contaminants, including III and selenium metal, appeared to be present in the final product. Subsequent attempts to purify the samples further resulted in some degradation, as evidenced by visual inspection and HPLC analysis. Elemental analyses of the samples obtained indicated 11–13% selenium. When the sample was treated with trimethylsilane and analyzed by chemical-ionization mass spectrometry, the parent ion ($MH^+ = 1190$) and the two major fragments (mass 635 and 555) suggested the structure of the silylated compound to be IV*a*.

While the carbon, hydrogen, and nitrogen analysis of the isolated material did not agree closely with that of IV, the discrepancy may be attributed to an inability to obtain a pure sample, even when recrystallization from various solvents was attempted. The UV spectrum of IV

III

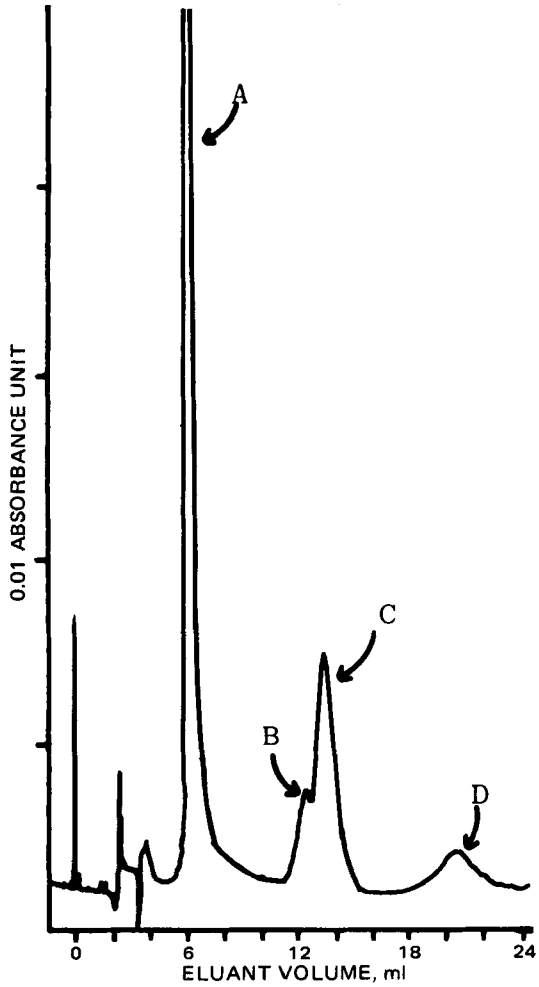

**Figure 1**—*Chromatogram (HPLC) of a solution of 6-selenoguanosine in water (pH ~4–5) after 5 hr at room temperature.*

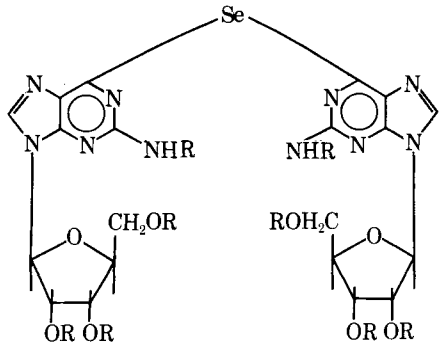


IV: R = H, bis(2-amino-9-β-D-ribofuranosyl-6-purinyl) selenide

IV*a*: R = trimethylsilyl

showed a maximum at 325 nm, indicating more conjugation in the purine ring system and the absence of the selenone group.

When I was dissolved in water that had been recently boiled and cooled (under argon or nitrogen) and the reaction mixture was kept under argon (or nitrogen), no degradation products were detected by HPLC and the solution remained clear for >6 days. Similarly, a II suspension in oxygen-free water stored under an inert gas showed no IV formation. However, when these same systems were subsequently exposed to oxygen, decomposition again was apparent within a few hours.

These data demonstrate the need for oxygen in conversion of I to II and of II to IV. These results support the following scheme:

$$2\mathrm{I} \xrightarrow{O_2} \mathrm{II} \xrightarrow{O_2} \mathrm{IV} + \mathrm{Se}$$

*Scheme I*

where the conversion of I to II involves a simple oxidation while the conversion of II to IV is a more complex transformation. While the production of IV from II appears to be a disproportionation reaction, the necessity of atmospheric oxygen precludes such a simple explanation.

Although a free radical process may be involved, available data do not provide a specific mechanistic interpretation of the conversion of the diselenide to the selenide and metallic selenium.

As already mentioned, in the degradation of I and II, traces of III were present in the solutions. It is not clear whether III occurs as a result of a minor side reaction of the decomposition of I and/or II or as a product of the slow degradation of IV. In any event, it represents only a small fraction of the products.

While II has a very low water solubility of ~1 μg/ml, both I and IV are much more soluble, with the solubility of I being ~2–3 mg/ml and that of IV being ~3.5 mg/ml.

Spectrophotometric changes observed during the described reaction also supported Scheme I. In simple aqueous solution (pH 4–5), the absorbance maximum of I was at 358 nm while in 0.1 *N* NaOH, $\lambda_{max}$ was ~330 nm. This marked change in $\lambda_{max}$ may be ascribed to tautomerization and ionization as shown in Scheme II.

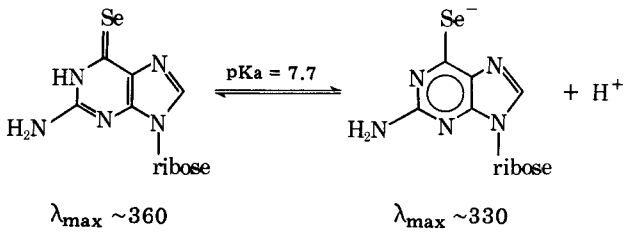
Methanolic solutions of I, II, and IV yielded $\lambda_{max}$ values of 365 (log a 4.29), 318 (4.30), and 327 (4.31) nm, respectively. The chemical structures of both II and IV are related more closely to Ia than to I and thus would be expected to exhibit $\lambda_{max}$ values similar to those of Ia. When oxidation of I in water was followed spectrophotometrically at pH <7, the reaction was accompanied by a substantial time-dependent decrease in absorbance at 350–360 nm and a corresponding increase at 315–330 nm. In alkaline media of pH >10, the maximum absorbance was at 315–330 nm; little change in absorbance occurred as the reaction proceeded (as monitored by HPLC).

Similar spectral behavior has been reported and rationalized for numerous related 6-thiopurine derivatives including the corresponding disulfides and the 6-alkylmercapto compounds (12–16). In all cases, loss of the thione or selenone form resulted in a hypsochromic shift.

The initial degradation studies were carried out on solutions prepared by dissolution of I in water. The resulting solutions were in the pH 4–6 range. Subsequent efforts were directed toward determining the effects of pH on the degradation rate of I.

The rates of loss of I from aqueous buffered solution exposed to air were studied at pH 2–11 using UV spectrophotometry and/or HPLC. Over this entire pH range, the degradation rate of I appeared to be a first-order process, with linear semilog plots obtained for more than two half-lives in all cases and for up to five half-lives in most instances.

The rate data are summarized in Table I; I apparently was most stable at pH 4–5. At values of pH 7–11, there appeared to be no significant change in the rate of loss of I, which is surprising since the pKa of I was found by spectrophotometric determination to be 7.68 ± 0.05. Normally, it might be expected that the ionization involving the selenium atom would alter the rate significantly. Table I also shows that the buffers used may substantially influence the degradation rate. This finding is particularly obvious at pH 5, where acetate and citrate buffers were used and the rate in citrate was more than fourfold greater than that in acetate at concentrations of $1 \times 10^{-2}$ *M*.



*Scheme II*

**Table I—Rate Data Obtained for the Loss of 6-Selenoguanosine [a] for Aqueous Buffered Solution at 25° and Various pH Values**

| pH | Buffer | $\lambda_{max}$, nm | $t_{1/2}$, hr | $k_{obs}$ (× $10^2$), $hr^{-1}$ |
|---|---|---|---|---|
| 11.0 | Sodium hydroxide[b,c] | 330 | 6.6 | 10.6 |
| 9.0 | 0.010 *M* borate[b] | 330 | 3.9 | 17.8 |
| 8.0 | 0.010 *M* borate[b] | 335 | 5.0 | 13.9 |
| 7.9 | 0.005 *M* phosphate | 335 | 2.5 | 27.7 |
| 7.0 | 0.005 *M* phosphate | 357 | 4.7 | 14.7 |
| 5.0 | 0.010 *M* acetate[b] | 358 | 40.8 | 1.7 |
| | | | (43.8)[c] | (1.6)[c] |
| 5.0 | 0.010 *M* citrate[b] | 358 | 10.1 | 6.9 |
| 4.0 | 0.010 *M* acetate[b] | 358 | 44.9 | 1.5 |
| | | | (49.3)[c] | (1.4)[c] |
| 2.0 | Hydrochloric acid | 360 | 27.7 | 2.5 |

[a] Initial concentration was ~$5 \times 10^{-5}$ *M*. [b] Solution contained 0.1 *M* KCl. [c] Data obtained by HPLC studies with initial concentration of I of $2 \times 10^{-4}$ *M*.

Additional absorbance studies were carried out to determine if citrate enhanced degradation or if acetate acted as a stabilizer. With both citrate and acetate buffers (pH 5), the rate of absorbance loss increased when the buffer concentrations increased, indicating that both buffer systems enhanced the rate of loss of I.

With acetate buffers, the rate enhancement due to buffer appeared to be rather small and a linear relationship appeared to exist between buffer concentration and the observed rate constant. The effect of total citrate concentration on the observed rate constant was nonlinear, exhibiting a decreasing rate dependence on citrate as the buffer concentration was increased from $1 \times 10^{-3}$ to 0.10 *M*. The precise cause for the observed asymptotic relationship is not understood but presumably involves a reversible interaction between I and citric acid (or citrate ion) to yield a species that is less stable than I itself. Studies on the effects of citrate on I degradation are continuing.

At pH 4 and 5 in acetate buffers, the rates of loss of I as determined by both spectrophotometry and HPLC appeared to accelerate at about two half-lives (60–90 hr). Whether this result was due to product catalysis or another competing side reaction was not determined. Such acceleration was not observed at other pH values or even at pH 4 and 5 when citrate buffers were used. However, in those cases, the half-lives of the reaction being monitored were much shorter and, consequently, the loss of I was largely complete in 50–60 hr.

While the oxidation of I in water is rather facile, the oxidation rates in dimethyl sulfoxide and dimethylacetamide were much faster. Within 1 hr at ambient temperature, complete conversion of I to II occurred. However, there did not appear to be any subsequent diselenide degradation in either of these organic solvents over the several days during which the solutions were monitored. Similar oxidation reactions in these solvents were reported for sulfur compounds (17).

## CONCLUSION

In a reaction analogous to the autoxidation of thiols and thionucleosides such as thioguanosine, 6-selenoguanosine (I) is oxidized in aqueous media in the presence of air to yield the corresponding diselenide. However, unlike the disulfides, which are relatively stable except in alkaline media or in the presence of potent oxidizing agents, the diselenide (II) of I undergoes a facile reaction to yield the more soluble selenide and selenium metal. Whether this is a general reaction of diselenides was not addressed in this study but may merit investigation as a simple means of preparing seleno ethers from organic selenols.

Previous reports that I was more stable than some of its analogs were based on absorption changes in aqueous solution (9). However, the comparisons made were between a solution of I in an alkaline medium (where loss of I is not accompanied by significant changes in absorption) and solutions of 6-selenopurine and related compounds at neutral pH (where loss of the parent substance is evidenced by large absorption changes). When solutions of I were studied at neutral pH values, relatively rapid and large absorbance changes were observed. Consequently, the stability of I clearly does not differ substantially from that of its closely related predecessors.

In the absence of oxygen, I was quite stable, and aqueous solutions gave no evidence of drug loss over several days. In the presence of oxygen, the minimum rates of oxidation appeared to occur at pH 4–5. Further sta-

bilization can be afforded by the incorporation of antioxidants such as ascorbic acid and dithioerythritol (10).

## EXPERIMENTAL

**Materials**—6-Selenoguanosine[1] (I) was purified by recrystallization from aqueous ascorbic acid as previously described (10). All other chemicals were analytical or chromatographic grades.

**Preparation of I Solutions for Kinetic Studies**—A stock solution of I was prepared by dissolving the drug (15–17 mg) in 100 ml of 0.1 *M* KCl. The solution obtained was filtered (0.45-μm membrane filter), and 10 ml of the clear filtrate was diluted to 100 ml with the selected buffer to yield I concentrations of $\sim 5 \times 10^{-5}$ *M*. The resulting solution was kept in a tightly closed flask and maintained at 25° in a water bath. Aliquots were withdrawn at intervals, and the UV absorption at $\lambda_{max}$ (358 nm in pH 4–5 acetate buffer, ~330 nm in more alkaline buffers, and 360 nm in acid buffers) was monitored spectrophotometrically[2].

For kinetic studies monitored by HPLC, solutions were prepared similarly, but the final concentrations of I were $\sim 2 \times 10^{-4}$ *M*. Aliquots (20 μl) were removed and analyzed by HPLC.

**pKa Determination of I**—The pKa was determined spectrophotometrically at 25° by the method of Albert and Serjeant (18). Buffers were 0.01 *M*, and calculations were based on absorbances monitored at 255, 330, and 358 nm. At all wavelengths, the value obtained was pKa = 7.68 ± 0.05.

**Chromatography**—HPLC was performed as described previously (10). Although the methodology used was unchanged, the elution volume and, consequently, the capacity factors were much smaller. These factors were observed to decrease as column use continued.

**Isolation and Characterization of Degradation Product (IV) of I in Aqueous Solution**—Compound I (300 mg) was dissolved in deionized water (400 ml). Air was continuously bubbled through the solution, and the degradation was followed chromatographically (1 ml of the reaction mixture was diluted to 10 ml with methanol and 10 μl of solution was injected) until the reaction was complete (~10 days). Water loss due to evaporation (which was accelerated by the passage of air through the solution) was compensated for by daily addition of water to a constant total volume. Such replacement of water was necessary to keep the reactants in solution.

After 10 days, the reaction mixture was filtered (0.45-μm filter), and the filtrate was evaporated to dryness under reduced pressure at ~40°. The residue was treated with absolute ethanol (30 ml, to facilitate the complete removal of water) and was again evaporated to dryness. The product was dissolved in boiling methanol (25 ml), filtered, and poured on cold ether (400 ml). The resulting liquid, containing a yellow precipitate, was kept in a refrigerator overnight. The precipitate was separated by filtration (glass filter, 4–4.5 μm), washed with cold ether (3 × 25 ml), and dried under vacuum for 24 hr to give 195 mg of IV (65% yield) as a yellow solid, which decomposed on melting at 220–222° (uncor.).

*Anal.*—Calc. for $C_{20}H_{24}N_{10}O_8Se$: C, 39.29; H, 3.96; N, 22.91; Se, 12.91. Found[3]: C, 37.77; H, 4.1; N, 21.09; Se, 11.92.

Chemical-ionization mass spectrometry[4] of the trimethylsilylated compound gave evidence of a molecular ion ($MH^+$) of 1190 and two major fragments at masses of 555 and 635, corresponding to fragmentation of the compound (IV*a*) between the selenium atom at position 6 of the purine rings. Both the parent ion and the mass 635 peaks exhibited the typical selenium cluster. These results agreed with the molecular weight of 612 for Structure IV*a*.

# Effect of Adsorbed Carbonate on Surface Charge Characteristics and Physical Properties of Aluminum Hydroxide Gel

JOSEPH R. FELDKAMP *, DHIREN N. SHAH ‡, SUSAN L. MEYER ‡, JOE L. WHITE *, and STANLEY L. HEM ‡x

Received October 6, 1980, from the *Department of Agronomy and the ‡Department of Industrial and Physical Pharmacy, Purdue University, West Lafayette, IN 47907. Accepted for publication November 14, 1980.

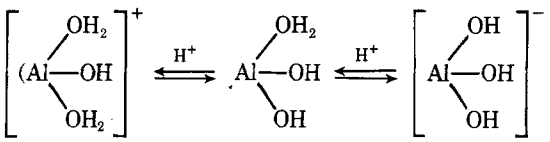
**Abstract** □ A titration procedure was used to determine the zero point of charge of a number of chloride-containing aluminum hydroxide gels and aluminum hydroxycarbonate gels. The surface charge characteristics of aluminum hydroxide gel were determined by both hydroxyls and the surface density of specifically adsorbed carbonate anion. The wide range of zero point of charge values reported for aluminum hydroxide is thought to be due to the presence of specifically adsorbed anions such as carbonate. The effect of ionic strength on the pH of aluminum hydroxide gel is important during washing since the ease of electrolyte removal is related to surface charge. Viscosity and sedimentation characteristics are related to the relationship between the zero point of charge and bulk pH. Maximum viscosity was observed when the bulk pH was adjusted to the zero point of charge.

**Keyphrases** □ Aluminum hydroxide gel—effect of adsorbed carbonate on surface charge and physical characteristics □ Carbonate, adsorbed—effect on surface charge and physical characteristics of aluminum hydroxide gel □ Physicochemistry—effect of adsorbed carbonate on surface charge and physical characteristics of aluminum hydroxide gel

Aluminum hydroxide gels exhibit a surface charge whose sign and magnitude depend on bulk pH, specific ion adsorption, and ionic strength. When no specific adsorption of ions other than protons or hydroxyls occurs, as with chloride- or nitrate-containing aluminum hydroxide gels (1), surface charge arises by the mechanism (2) shown in Schemes I and II (which are equivalent). For clarity, only the bonds associated with the charged site are shown, even though aluminum is in sixfold coordination in each structure.

$$(Al{-}OH_2)^+ \overset{H^+}{\rightleftharpoons} Al{-}OH \overset{H^+}{\rightleftharpoons} (Al{-}O)^-$$

*Scheme I*



*Scheme II*

When carbonate or any other specifically adsorbed anion (1) is present as in aluminum hydroxycarbonate gel, a second mechanism (Scheme III) contributes to the surface charge. Thus, the observed surface charge of aluminum hydroxycarbonate gel depends on the surface density of each type of site.

$$Al{-}OH + CO_3^{2-} \leftrightarrows Al{-}OCO_2^- + OH^-$$

*Scheme III*

An important property of colloidal systems that possess a pH-dependent surface charge is the zero point of charge, which is the pH at which the net surface charge is zero. At this pH, the densities of the positive and negative charges arising from Schemes I–III are equal (3).

A number of anions other than carbonate affect the zero point of charge of metal oxides through specific adsorption to metal oxide surfaces. These anions include orthophosphate, pyrophosphate, tripolyphosphate, silicate, selenite, and fluoride anions (4). In each case, the specifically adsorbed anion contributes additional negative charge to the surface, thereby displacing the zero point of charge to lower pH values. The major objective of this study was to determine the effect of specifically adsorbed carbonate on the zero point of charge. Another objective was to illustrate the effect of surface charge on important physical properties such as apparent viscosity and electrolyte removal by washing.

## EXPERIMENTAL

**Materials**—Two chloride-containing aluminum hydroxide gels were prepared in an identical manner, with precautions taken to minimize the specific adsorption of carbonate. A closed, baffled reaction vessel was used as well as freshly distilled water stored in a closed container. Potassium hydroxide (1 *M*) was added with continuous stirring to 0.5 *M* $AlCl_3$ at 1 ml/min through a submerged delivery tube having a pinhole-size orifice until pH 9.5 was reached. The resulting chloride-containing aluminum hydroxide gel was allowed to stand for 24 hr and was washed with five volumes of freshly distilled water using centrifugation.

An aluminum hydroxycarbonate gel was prepared by the addition of 0.5 *M* $AlCl_3$ to a solution of 0.5 *M* $NaHCO_3$ and 0.23 *M* $Na_2CO_3$ with agitation until pH 6.6 was reached (5). The aluminum hydroxycarbonate gel was allowed to stand for 24 hr and was washed with five volumes of water using centrifugation.

Nine aluminum hydroxycarbonate gels were obtained commercially.

**Analytical Procedures**—The titration technique (6) used to measure the zero point of charge was based on the principle that changes in the ionic strength produced by the addition of an indifferent electrolyte, such as potassium chloride, will have no effect on proton adsorption or release by the gel when the gel surface charge is zero. Thus, titration curves (moles of bound or released protons *versus* pH) obtained at several ionic strengths intersect at a common point, the zero point of charge.

The zero point of charge of the laboratory chloride-containing aluminum hydroxide gels and the laboratory aluminum hydroxycarbonate gel was determined by the following procedure. Aliquots of the gel containing ~1% equivalent aluminum oxide were prepared containing the appropriate quantities of potassium chloride and hydrochloric acid or potassium hydroxide, depending on the ionic strength and pH desired. The amount of hydrochloric acid or potassium hydroxide added and the resulting pH were recorded. A blank, *i.e.*, no gel present, also was treated similarly to correct for any acid or base that did not result in the adsorption or release of protons from the surface. Curves obtained at different ionic strengths intersect at the zero point of charge. A correction was rarely needed, and a more rapid and convenient continuous titration procedure was developed for routine use.

The zero point of charge of the commercial aluminum hydroxycarbonate gels were determined by a continuous titration procedure. An aluminum hydroxycarbonate gel sample, adjusted to the desired ionic strength with potassium chloride, was titrated with either acid or base, depending on the desired direction of pH change. A blank titration was not run since experience showed that no significant correction was needed. The recorded pH values and the corresponding quantity of acid

| Commercial aluminum hydroxycarbonate gel 9 | 6.94 | 5.63 | + |

or base added were plotted, and the intersection point of the different ionic strength curves was the zero point of charge, *i.e.*, the pH at which ionic strength has no effect.

The specific procedure was as follows:

1. A 100-ml aliquot containing ~1% equivalent aluminum oxide was transferred to a 250-ml beaker.
2. The initial pH was recorded with stirring after a stable value was achieved.
3. Sufficient 0.1 *N* KOH was added from a 10-ml buret to cause a pH change of 0.05–0.10 unit. Usually, increments of titrant ranging from 0.2 to 1.0 ml were required. When the pH was stable, the volume of titrant added and the pH were recorded.
4. Steps 1–3 were repeated but titration was performed with 0.1 *N* HCl.
5. A plot was constructed with micromoles of acid or base added on the ordinate and the resultant pH on the abscissa.
6. Steps 1–5 were repeated except that, in Step 1, 2 ml of 4 *M* KCl was added to the 100-ml volumetric flask before making the final dilution of the ~1% equivalent aluminum oxide aliquot. The data were plotted on the same graph.
7. Steps 1–5 were repeated except that, in Step 1, 10 ml of 4 *M* KCl was added to the 100-ml volumetric flask before making the final dilution of the ~1% equivalent aluminum oxide aliquot. The data were plotted on the same graph. The pH where the three curves intersected was the zero point of charge.

The equivalent aluminum oxide content was determined by the ethylenediaminetetraacetic acid titration (7).

Viscosity measurements were made on two of the commercial aluminum hydroxycarbonate gels after the gel pH was adjusted to selected values above and below the zero point of charge. The pH range of 5–9.5 was selected to avoid substantial solubilization of the aluminum hydroxycarbonate gel (8). Two hundred milliliters of a gel containing 9% equivalent aluminum oxide was adjusted to the desired pH by the addition of either 1 *N* HCl or KOH. The ionic strength of all samples was adjusted to 0.03 by adding 1 *M* KCl. The final volume of all samples was adjusted to 230 ml with distilled water. Each sample was vigorously stirred and transferred into the measuring vessel of the rotational viscometer[1] with the appropriate spindle in place. Each sample was allowed to set for 5 min before the viscosity was measured at 100 rpm.

## RESULTS AND DISCUSSION

Figure 1 illustrates the zero point of charge determination of the laboratory chloride-containing aluminum hydroxide gel 1. The value is concluded to be 9.65 because ionic strength did not affect the gel at pH 9.65. Triplicate determinations resulted in identical results (Table I), indicating the excellent precision of the individual sample adjustment method for determining the zero point of charge. The precipitation method also was very reproducible since the zero point of charge of laboratory chloride-containing aluminum hydroxide gel 2 was 9.68 (Table I). The surface charge of both gels was positive since the bulk pH was below the zero point of charge.

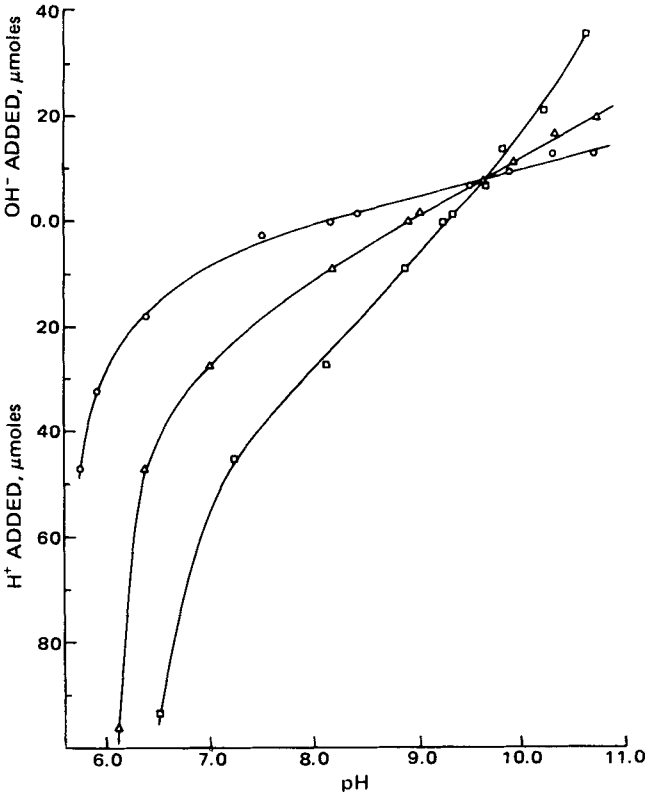

**Figure 1**—*Determination of the zero point of charge of laboratory chloride-containing aluminum hydroxide gel 1. Key:* ○, $\mu = 0.0005$; △, $\mu = 0.01$; *and* □, $\mu = 0.6$.

Specifically adsorbed carbonate had a substantial effect on the zero point of charge. The value of the laboratory aluminum hydroxycarbonate gel was 6.66 ± 0.01 based on triplicate determinations (Table I). The surface charge of this gel was negative since the bulk pH was above the zero point of charge.

The continuous titration method also measured precisely the zero point of charge; triplicate determinations on commercial aluminum hydroxycarbonate gel 1 gave identical results of 6.95 (Table I). The zero point of charge of the nine commercial aluminum hydroxycarbonate gels ranged from 6.3 to 7.3. These gels exhibited positive, neutral, and negative surface charges. The lower and more variable values obtained for the aluminum hydroxycarbonate gels in comparison to the chloride-containing aluminum hydroxide gels indicate that specifically adsorbed carbonate contributes to the surface charge characteristics as hypothesized in Scheme III.

The zero point of charge of the chloride-containing aluminum hydroxide gel was similar to values reported for highly crystalline forms of aluminum hydroxide (9), which would be expected to be largely free of specifically adsorbed carbonate. This finding suggests that chloride, like nitrate, is outside the coordination sphere of the aluminum cation and interacts by electrostatic forces (1). This observation agrees with an earlier observation that a chloride impurity in hydrous aluminum oxide does not affect the zero point of charge (9).

Thus, it appears that the wide range of zero point of charge values, *i.e.*, 3.8–10.0 (9, 10), reported for aluminum hydroxide is due to the presence of a specifically adsorbed anion such as carbonate that contributes to the surface charge characteristics (Scheme III) in addition to the contribution of surface hydroxyls (Schemes I and II). Direct adsorption of carbon dioxide from the atmosphere by aluminum hydroxide is likely to occur since carbon dioxide is known to be strongly adsorbed onto moist goethite surfaces as carbonate (11).

The effect of ionic strength on the pH of aluminum hydroxide is seen in Fig. 1. As the ionic strength increased, the pH of the aluminum hydroxide gel tended toward the zero point of charge. Conversely, lowering the ionic strength caused the pH to move away from the zero point of charge. This behavior must be considered during the washing of aluminum hydroxide gel or the final pH of the gel after washing will be un-

[1] Model RVT, Brookfield Engineering Laboratories, Stoughton, Mass.

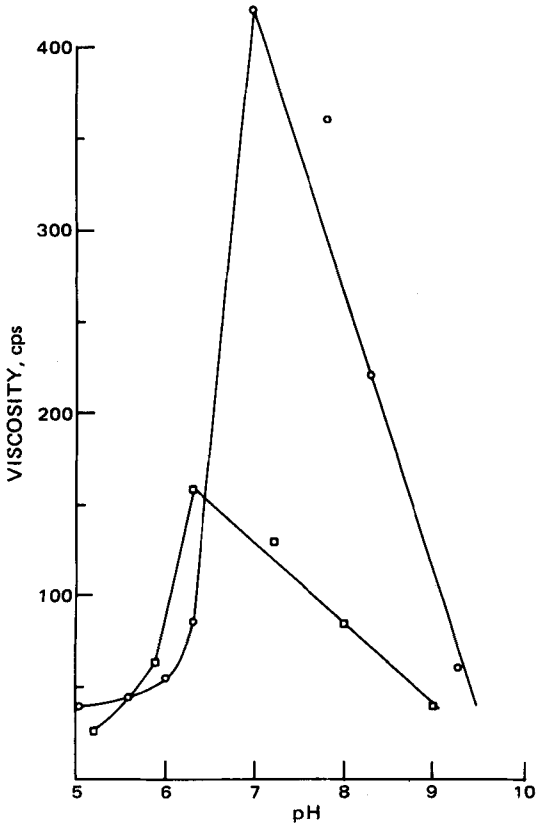

**Figure 2**—*Effect of bulk pH on apparent viscosity of commercial aluminum hydroxycarbonate gels 1 (○) and 4 (□). The zero point of charge of commercial aluminum hydroxycarbonate gels 1 and 4 are 6.95 and 6.30, respectively.*

predictable. Table I indicates that the bulk pH ranged from 5.63 to 6.60 and was as random as the zero point of charge. Figure 1 indicates that washing a gel whose pH was at the zero point of charge did not produce a pH change even though the ionic strength was reduced. Furthermore, because the gel surface is neutral when the pH is at the zero point of charge, electrolyte removal should be accomplished most readily when washing is performed under these conditions. Cations will be retained if washing occurs at pH conditions above the zero point of charge, and anions will be retained if the pH during washing is below the zero point of charge.

Physical properties of aluminum hydroxide gel such as viscosity and sedimentation characteristics are controlled largely by a sensitive interplay between the attractive and repulsive forces operating between the particles and aggregates. The coulombic repulsive force and the van der Waals attractive force are of prime importance. For molecules, van der Waals forces are weak and very short ranged, with the force being inversely proportional to the seventh power of the distance separating the molecules (12). Only in the absence of other forces and at sufficiently low temperatures do these forces manifest themselves between molecules. For particles, the situation is different. To find the magnitude of the force and the dependence on the separating distance, the assumption is often made that the individual forces operating between molecules may be summed pairwise to obtain the net force between macroscopic bodies (12). In the case of two flat slabs, where the separation distance is small compared to the thickness of either slab, the force varies inversely with the third power of the separating distance. The van der Waals force summed in this way has sufficient magnitude to be of relevance in colloidal systems. In fact, when the charge on the particle surfaces is sufficiently reduced (by adjustment of pH or ionic strength), the van der Waals forces are responsible for aggregation and associated phenomena (13). A result similar to that obtained for flat slabs also occurs for macroscopic spheres.

Another important result related to van der Waals forces is that the force between anisometric particles is a function of the relative orientations of the bodies (considering all orientations having the same center of mass separation). In particular, lath-shaped particles and needles interact most strongly when positioned end-to-end. Plates interact most strongly in an edge-to-edge orientation. For isometric particles, the same considerations apply since joining two isometric particles necessarily forms an anisometric aggregate which tends to orient itself end-on with a third particle (12).

The apparent viscosity of aluminum hydroxide gel is sensitive to the bulk pH because of particle interactions. When coulombic repulsion is sufficiently reduced by adjusting the bulk pH close to the zero point of charge or by increasing the ionic strength, the van der Waals forces cause the particles to agglomerate. Consequently, the apparent viscosity increases. The magnitude of the viscosity change depends on the aggregate structures. Figure 2 illustrates the effect of bulk pH on the apparent viscosity of commercial aluminum hydroxycarbonate gels 1 and 4. The viscosity of both aluminum hydroxycarbonate gels was at a maximum when the bulk pH was at the zero point of charge, *i.e.*, pH 6.95 and 6.30, respectively. The fact that a different maximum viscosity occurred for each aluminum hydroxycarbonate gel suggests that aluminum hydroxycarbonate gel 1 formed a more highly extended and cross-linked network of particles in comparison to aluminum hydroxycarbonate gel 4.

The apparent viscosity of aluminum hydroxycarbonate gel 1 increased eightfold as the pH increased from 5.95 to 6.95, and aluminum hydroxycarbonate gel 4 showed a sixfold increase in apparent viscosity between pH 5.30 and 6.30. A small pH change in the region of the zero point of charge produces large changes in apparent viscosity.

It is apparent from Fig. 2 that investigations of the factors affecting aggregate type will prove valuable because aluminum hydroxide gels whose apparent viscosity is not sensitive to small variations in bulk pH are more generally desirable. In addition, the pH changes that may occur when aluminum hydroxide gel is washed also may lead to changes in viscosity. Finally, the results suggest that the viscosity of aluminum hydroxide gels can be controlled by adjusting the relationship between the zero point of charge and the bulk pH to produce the desired degree of aggregation.

# Spectrofluorometric Determination of Acetylsalicylic Acid, Salicylamide, and Salicylic Acid as an Impurity in Pharmaceutical Preparations

**KENNETH W. STREET, Jr. *x, and GEORGE H. SCHENK**

Received September 8, 1980, from the *Department of Chemistry, Wayne State University, Detroit, MI 48202.* Accepted for publication December 2, 1980. *Present address: Department of Chemistry, Loyola University, Chicago, IL 60626.

**Abstract** □ Spectrofluorometry, either direct or in combination with a separation technique, provides a sensitive and accurate method for the determination of certain fluorescent analgesic drugs and the determination of impurities in many combination preparations. A critical examination of the UV spectra of common analgesics and related compounds indicates that the fluorescence inner filter effect should be negligible below $10^{-5}$ *M* and that selective excitation and emission wavelengths should minimize interference from other fluorescent species. Fluorometric procedures are presented for the determination of salicylamide, acetylsalicylic acid, and salicylic acid, as an impurity, in preparations containing salicylamide, acetylsalicylic acid, acetaminophen, caffeine, and phenacetin as major constituents. Inner filtering is the limiting factor only for the direct and indirect determination of salicylamide and the direct determination of acetylsalicylic acid. Results of fluorometric determinations compare favorably with other reference methods. Salicylic acid is determined in the $10^{-7}$ *M* concentration range after separation from salicylamide, acetaminophen, and caffeine.

**Keyphrases** □ Salicylic acid—analysis, spectrofluorometry, impurity in multicomponent analgesic tablets □ Salicylamide, aspirin—spectrofluorometry, as major constituent in multicomponent tablets □ Aspirin—spectrofluorometric determination of an impurity in drug combinations □ Spectrofluorometry—determination of salicylic acid, salicylamide, and acetylsalicylic acid in multicomponent analgesic tablets

Various methods for the determination of salicylamide, acetylsalicylic acid, and salicylic acid, as an impurity, are available. However, with the advent of new instrumentation, new drugs, and new drug combinations (Table I), many of these methods have become outmoded or are no longer specific. The present study developed new methods along with improvements in some older methods.

## BACKGROUND

**Methods for Acetylsalicylic Acid**—Fluorometric (8, 9) and phosphorimetric (10) methods for the determination of acetylsalicylic acid in pharmaceuticals were reported. Other fluorometric methods involve fluorophore formation by conversion to salicylic acid (11, 12). Many of these methods have never been examined for the effect of other constitcylates that interfere with the direct determination of salicylamide. Additional steps to eliminate fluoresence interference from salicylic acid are needed for the many preparations containing acetylsalicylic acid and other fluorescent salicylates. Analyses by direct UV (4, 5) and differential UV (6) spectrophotometry are both subject to interferences. One visible spectrophotometric method (7) involves a chromophore-producing reaction with ferric chloride reagent.

**Methods for Acetylsalicylic Acid**—Fluorometric (8, 9) and phosphorimetric (10) methods for the determination of acetylsalicylic acid in pharmaceuticals were reported. Other fluorometric methods involve fluorophore formation by conversion to salicyclic acid (11, 12). Many of these methods have never been examined for the effect of other constituents commonly found in recent preparations, such as other fluorescent salicylates and substances that absorb large amounts of exciting radiation. Direct UV methods for acetylsalicylic acid are based on prior separation from other components in the preparation (13–15).

**Methods for Salicylic Acid as Impurity**—The salicylic acid content in acetylsalicylic acid used for pharmaceuticals is limited to 0.3–0.75%, depending on the type of preparation relative to the acetylsalicylic acid content. The USP/NF (16) methods of analysis require separation of salicylic acid from acetylsalicylic acid *via* column chromatography after reaction with ferric chloride reagent. Other automated methods use ferric chloride reagent directly (17). Although this method works well for pure acetylsalicylic acid preparations, salicylamide also undergoes the same reaction with ferric reagents used for colorimetric determination (18). The salicylamide content of newer preparations often is as high as 40% of the total salicylate content.

Schenk *et al.* (8) proposed a direct fluorometric method for the determination of salicylic acid in acetylsalicylic acid. Unfortunately, in their solvent system, both salicylic acid and salicylamide excite and fluoresce at virtually the same wavelengths. Other methods involving chromophore-forming reactions (19) and high-pressure liquid chromatographic separations (20, 21) were proposed but never evaluated for interference by other sample constituents common in multicomponent preparations.

## EXPERIMENTAL[1]

**Solvents**—All fluorescence work was done with fluoro grade alcohol prepared by percolation through 30–40-cm columns of activated coconut charcoal[2] (40–80 mesh). After the first 50-ml portion (contaminated) was discarded, each column produced 5–10 liters of fluorescence quality alcohol.

The fluoro grade chloroform used was prepared by vigorous extraction with 0.45 *M* NaOH, two washings with small volumes of water, and filtration through chloroform-moistened filter paper.

**Organic Reagents**—The salicylamide[3] was freed from the salicylic acid impurity by recrystallization from hot concentrated chloroform solution. [Alternatively, salicylic acid could be extracted from salicylamide in chloroform by two washings with 5% sodium bicarbonate (22).]

The acetylsalicylic acid[4] was purified of an unacceptable amount of salicylic acid by two recrystallizations from hot saturated chloroform; fluorometric analysis (8) demonstrated that a third recrystallization was unnecessary.

Caffeine citrate[5] was freed from citric acid by extraction with chloroform from a nearly saturated aqueous solution at pH 8.0 (ammonia). After filtration, the evaporated chloroform gave a white powder with a UV spectrum comparable to that of Sunshine and Gerber (23).

Samples of acetaminophen[6] and phenacetin[7] were used without further purification.

**Determination of Salicylamide Alone**—To determine salicylamide in the absence of acetylsalicylic acid, salicylic acid, or buffers, a tablet, capsule, or powder (equivalent to 50–100 mg of salicylamide) was placed in a 100-ml volumetric flask, and ~50 ml of methanol was added. The sample tablet form was crushed, shaken, and diluted to volume with methanol. After insoluble materials settled, a 0.1-ml aliquot was diluted to 100 ml with methanol and filtered through medium-speed filter paper. The first 20 ml of the filtrate was discarded, and the fluorescence of the next 50 ml was measured using the instrument settings in Table II. A blank reading was subtracted from the sample fluorescence reading by running a methanol blank for each lot of filter paper. A standard curve

[1] Fluorescence measurements were taken on a Perkin-Elmer MPF-2A spectrofluorometer. Absorption spectra were taken on either a Beckman DK-2A spectrophotometer or a Cary-14 spectrophotometer; a Coleman Jr spectrophotometer was used for quantitative measurement in the visible region. GLC analysis was done on a Perkin-Elmer 3920 chromatograph (flame-ionization detector, glass column packed with 3% OV-17 on Gas Chrom Q, 100–120 mesh).

of fluoresence *versus* concentration was prepared using 0–1.4 × $10^{-5}$ *M* salicylamide in methanol.

**Determination of Salicylamide in Acetylsalicylic Acid, Salicylic Acid, or Buffers**—The tablet(s), capsule contents, or homogeneous powder (50–100 mg of salicylamide) was weighed into a 100-ml volumetric flask, and ~75 ml of chloroform was added. After agitation for 10 min, the solution was diluted to volume with chloroform and filtered through a medium-speed filter paper. [This solution also may be used to determine acetylsalicylic acid and salicylic acid (Scheme I).] A 10-ml aliquot was transferred to a 60-ml separator, and 20 ml of chloroform and 10 ml of pH 7.0 phosphate buffer (24) were added. Then the solution was extracted.

Before the chloroform extract was filtered, a filter paper blank was run by running 100 ml of chloroform through the filter paper and measuring the chloroform fluorescence (Table II). If the blank exceeded 3% of full scale, a different lot of filter paper[8] was used. The extracted chloroform layer was filtered through chloroform-wet filter paper into a 100-ml volumetric flask. The aqueous phase was extracted twice more with 30 ml of chloroform each time, and the extracts were combined and diluted to volume with chloroform. Dilution of 0.20 ml of chloroform solution to 25 ml with chloroform was performed, and the fluorescence was measured (Table II). The chloroform-wet filter paper blank was subtracted from each reading. A standard curve was prepared from standards of 0–10 × $10^{-3}$ *M* salicylamide treated in the same manner as the samples.

**Determination of Acetylsalicylic Acid**—The tablets or capsule contents were weighed and ground. The resulting homogeneous powder (50–300 mg of acetylsalicylic acid) was weighed into a 100-ml volumetric flask. Chloroform (75 ml) was added, and the solution was agitated for 10 min and diluted to volume with chloroform. The solution was filtered through medium-speed filter paper, and a 0.1-ml aliquot was diluted to 100 ml with 1% acetic acid–chloroform. The fluorescence was measured using the settings in Table II. A blank reading was subtracted from the sample fluorescence reading by running a chloroform blank for each lot of filter paper. A standard curve of fluorescence *versus* concentration was prepared using 0–1.7 × $10^{-5}$ *M* acetylsalicylic acid in 1% acetic acid–chloroform.

**Determination of Salicylic Acid in Salicylamide (No Acetylsalicylic Acid)**—Ten tablets or the contents of 10 capsules of samples without acetylsalicylic acid were weighed and ground to homogeneity. A portion of this powder (100 mg of salicylamide) was weighed into a 100-ml volumetric flask, and 75 ml of chloroform was added. The solution was agitated for 10 min and diluted to volume with chloroform. A suitable aliquot, such as 10 ml, was filtered through medium-speed filter paper and transferred to a 60-ml separator. Another 20 ml of chloroform was added with 10 ml of pH 7.0 phosphate buffer (24), the solution was extracted, and the chloroform layer was discarded. The process was repeated three more times with 30-ml chloroform volumes, and the chloroform was discarded.

The aqueous phase was extracted with 10 ml of chloroform and 2.0 ml of 2.0 *M* HCl. The chloroform layer was filtered through chloroform-wet filter paper into a 50-ml volumetric flask. The aqueous phase was extracted with two additional 10-ml portions of chloroform and filtered, and the three extracts were combined. The solution was diluted to volume, and the fluorescence of the solution was measured (Table II).

A blank was run on the filter paper using chloroform, and the blank reading was subtracted from the sample fluorescence reading. These readings were compared to a salicylamide control in the same concentration range as the sample (7.3 × $10^{-3}$ *M*) and salicylic acid standards (3.0–9.0 × $10^{-6}$ *M*), which were extracted in the same manner.

**Determination of Salicylic Acid in Salicylamide and Acetylsalicylic Acid**—The previous procedure was followed with the following changes: (*a*) the sample size contained 45 mg of acetylsalicylic acid; (*b*) on addition of the pH 7.0 buffer, the salicylic acid was extracted into chloroform as quickly as possible with a reproducible technique; (*c*) a suitable acetylsalicylic acid control in the 2.6 × $10^{-4}$ *M* range was substituted for the salicylamide control; and (*d*) salicylic acid standards in the 0.7–7.0 × $10^{-3}$ *M* range were used.

## DISCUSSION

**UV Absorption of Salicylates and Related Compounds**—The removal of a proton from salicylamide alters its UV spectrum. In alcohol, the salicylamide anion is produced by saturation of the solution with small quantities of sodium bicarbonate or sodium carbonate. In aqueous solution or in methanol, this anion has twice the molar absorptivity of molecular salicylamide, and its UV maximum shifts to 330 nm (23). In contrast, salicylic acid does not exhibit this effect in aqueous solutions (23).

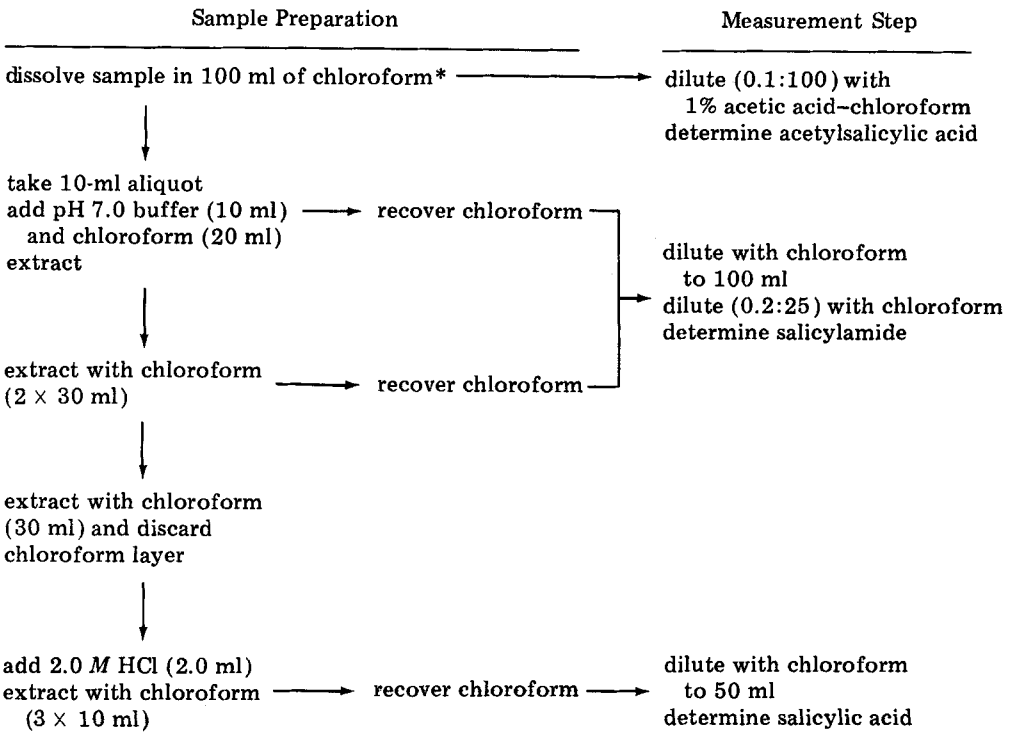
The molar absorptivities and wavelengths of maximum absorption of acetylsalicylic acid and salicylic acid in chloroform and 1% acetic acid–chloroform are not significantly different (8). Thus, the lowest energy electronic transition should be approximately the same in both solvent systems.

**Fluorescence of Salicylates and Related Compounds**—For salicylates and related compounds, emission in the 330–360-nm region of the spectrum has been postulated as arising from the neutral molecule (8, 25). Emission in the 400–450-nm region of the spectrum originates from the dipolar ion formed within the lifetime of the $S_1$ state *via* either inter- or intramolecular proton transfer (8, 25–28).

For salicylamide in methanol, the 340-nm emission is weak relative to that at 420 nm. The fluorescence emissions at 410 and 420 nm are postulated as arising from the zwitterion formed *via* intramolecular transfer within the lifetime of the $S_1$ state (26, 27). In methanolic solution, the 410-nm emission arising from the 333-nm excitation, which only occurs to a small extent, can be suppressed almost completely with small amounts of acid. In methanolic solution with traces of base, the UV maximum shifts from 300 to 330 nm and the emission at 410 nm is greatly enhanced because the 330-nm UV band is twice as intense as that of the neutral species and because the quantum yield for this form of the molecule is an estimated 20 times that of the neutral molecule. It then appears that the anion is more rigid than the molecular form of salicylamide,

**Table II—Instrumental Conditions for Spectrofluorometric Determinations**

| Ingredient Determined | Wavelength, nm | | Slit Width, nm | |
|---|---|---|---|---|
| | Excitation | Emission | Excitation | Emission |
| Salicylamide | | | | |
| In methanol | 300 | 425 | 10 | 10 |
| In chloroform | 315 | 445 | 10 | 20 |
| Acetylsalicylic acid | 280 | 335 | 10 | 20 |
| Salicylic acid | 315 | 445 | 10 | 10 |



*Scheme I—Determination of salicylamide, acetylsalicylic acid, and/or salicylic acid in a multicomponent sample that may contain salicylamide, acetylsalicylic acid, acetaminophen, caffeine, and/or salicylic acid as an impurity. (* Sample must contain appropriate amounts of salicylamide and acetylsalicylic acid for subsequent determination of salicylamide, acetylsalicylic acid, and salicylic acid as an impurity.)*

possibly because the negatively charged oxygen atom can form a strong hydrogen bond to the adjacent *ortho* group. The molecular form thus will be less rigid, allowing an increase in the overall rate of internal conversion to the ground state. In addition to fluorescing in methanol, salicylamide also fluoresces weakly at 325 nm and intensely at 445 nm in chloroform.

In designing a fluorometric method for salicylamide, excitation was done at 300 nm rather than at the 310-nm excitation maximum. Excitation at 300 nm seemed to produce more reliable fluorescence emission readings since the 310-nm excitation is more sensitive to small changes in the quality of methanol. At this wavelength, good quality spectrograde methanol (which gives a low fluorescence emission blank) could be substituted for fluorescent grade solvent. Partly because pharmaceutical preparations contain basic buffers to reduce GI bleeding from aspirin, a possible fluorometric method for salicylamide in basic methanol solvent was tested. Saturation of methanol with sodium bicarbonate produced only partial (75%) conversion to the highly fluorescent anion, while saturation of methanol with sodium carbonate produced complete conversion. Other buffers such as magnesium carbonate, dihydrogen citrate, and magnesium hydroxide, which frequently are incorporated in pharmaceutical preparations, probably also could cause large variations in the 425-nm fluorescence emission. Inner filtering by acetaminophen, caffeine, and phenacetin was negligible.

The methodology was tested on several preparations with sodium carbonate-saturated methanol and 330-nm excitation. A further dilution (1:10) of the samples was required to keep the fluorescence readings on scale and the UV absorbance at the excitation wavelength low enough for negligible inner filtering. Although salicylamide was 100% converted to its anion, acetaminophen was converted only partially to its anion in this buffer. Large variations in the acetaminophen content of the sample, particularly when in combination with other buffers, may alter the percent conversion of salicylamide and/or acetaminophen to their anionic forms even in sodium carbonate-saturated methanol. (The anion of acetaminophen absorbs strongly and at longer wavelengths than the neutral molecule.) In addition, a previous study (3) reported that salicylamide decomposes in strong alkaline solution.

For excitation of samples at 300 nm in methanol, all samples must be excited under uniform conditions. The fluorescence emission readings increased in a reproducible manner with respect to the excitation time. For the most reliable readings, the sample should not be excited unless the fluorescence emission is to be read immediately.

The fluorescence of acetylsalicylic acid in chloroform and chloroform–aliphatic acid mixtures was described prviously (8). In methanol and methanol–1% acetic acid, acetylsalicylic acid does not appear to fluoresce as in the chloroform–aliphatic acid solvent systems.

A single fluorescence emission peak in both chloroform and methanol was observed for salicylic acid. For salicylic acid, intramolecular proton transfer to the excited carbonyl oxygen occurs within the lifetime of the lowest excited singlet state (25). In chloroform, low concentrations (1%) of various aliphatic acids produce an additional fluorescence emission band in the 350–400-nm region. In methanol, the fluorescence emission at 400 nm is diminished almost completely by 0.5% acetic acid when excited at 295 nm.

**Methodology**—The National Formulary specifies that salicylamide-containing tablets contain 100 ± 5.0% of the labeled content. The acetylsalicylic acid content of acetylsalicylic acid-containing capsules (NF) must be within 100 ± 7.0% of the labeled content, and tablets (USP) must contain 100 ± 5% of the labeled content. Neither the USP nor the NF have established limits of purity for salicylamide with respect to salicylic acid as an impurity, but both specify limits for purity of acetylsalicylic acid with respect to salicylic acid as an impurity (0.3% in capsules and 0.75% in tablets).

**Factors Affecting Fluorescence Assay Procedures for Salicylamide in Preparations Containing No Acetylsalicylic Acid, Salicylic Acid Impurity, or Buffers**—The salicylamide excitation band at 330 nm is extremely sensitive to solvent conditions. Thus, excitation at 330 nm was attempted in methanol, and then the specimen was reexcited after a trace of acetic acid was added. The difference between the two readings was linear in the $10^{-5}$ *M* range. Actual tablets contain ingredients that make this effect less useful for analytical purposes.

Other solvents were tested for analytical use. Although salicylamide fluoresced with greater efficiency in *n*-propanol and ethanol, *n*-propanol is not purified as easily as methanol, and ethanol is not as readily available. Chloroform was found to quench fluorescence.

Since acetaminophen, caffeine, and phenacetin also absorb in the region of salicylamide excitation, the possibility of an inner filter effect from any or all of these compounds was evaluated. At the levels normally present in pharmaceutical preparations, acetaminophen, caffeine, and phenacetin did not cause an inner filter effect in the present spectrofluorometric method.

## RESULTS

Results of spectrofluorometric determinations compared favorably with those of several reference methods when corrections were applied and the reference methodology was modified for suitable sample handling

(Tables III–VI). Calibration curves were only linear to 100 mg/100 ml of salicylamide in the original sample ($7 \times 10^{-6}$ *M*) due to inner filtering; analytical results were most accurate when determined graphically with calibration standards that closely approximated the salicylamide concentration of the samples. When some of the same samples were excited at 313 nm in a filter fluorometer (mercury arc source), poor results were obtained due to the high amplification needed to measure the fluorescence emission.

**Determination of Salicylamide in Preparations Containing Acetylsalicylic Acid or Salicylic Acid Impurity**—If salicylic acid may be present, it is best to separate it from salicylamide before fluorescence analysis. Studies in this laboratory indicate that salicylamide is never completely recovered in chloroform at any pH by equal volume extractions (Fig. 1) and that better recoveries should result at a lower pH extraction than 5% sodium bicarbonate as previously reported (22). The behavior of acetylsalicylic acid and salicylic acid is similar; neither is extracted well with chloroform at pH > 5. At pH < 3, acetylsalicylic acid and salicylic acid extract significantly into chloroform. Therefore, any analytical separations must be done at pH 6–7.

The solubility of acetaminophen in chloroform is low (0.3 g/liter), and extraction into chloroform is not possible at any pH; therefore, accurate distribution ratio values, *D*, could not be determined. In contrast, caffeine is completely soluble in chloroform and is extracted so completely by chloroform over the pH range studied that accurate *D* values could not be determined for this compound either.

After three extractions, salicylamide was ~98% recovered from the aqueous phase. The salicylic acid, with ~50% of acetylsalicylic acid, remained in the aqueous phase at pH 7. After extraction with chloroform at this pH, all acetaminophen remained in the aqueous phase and all caffeine was in the chloroform with salicylamide. Solutions of molarities similar to those of the sample solutions were tested for inner filtering effects. No inner filtering by acetylsalicylic acid, acetaminophen, and caffeine was observed.

The effect of adding buffers to the pharmaceutical preparations was never critically evaluated. These compounds were assumed to be too insoluble in chloroform to alter the pH of the aqueous buffer (0.067 *M*) when equilibrated with it.

Although salicylamide has a larger molar absorptivity in chloroform than in methanol, it has a much lower quantum efficiency of fluorescence in chloroform. In spite of the former characteristic, accurate results are easily obtained in the 0–100-mg range. Self inner filtering begins at

concentrations of >3 × $10^{-6}$ *M* salicylamide in the final solution. For accurate results, samples should be compared to extracted standards of similar salicylamide content. Comparison to extracted standards eliminates the need for extraction efficiency corrections; the extracted standards serve as controls.

**Determination of Acetylsalicylic Acid in Preparations Containing Salicylamide, Acetaminophen, and Caffeine**—Many problems associated with the fluorometric determination of acetylsalicylic acid in aspirin tablets have been solved (8), including excitation and emission wavelengths, concentration ranges, choice of a suitable solvent (level of acetic acid for enhancement of fluorescence), and elapsed time between dissolution and analysis. However, the effects of other constituents found in recent complex pain-relief preparations were never evaluated fully.

For example, caffeine has its UV maximum at the same wavelengths as acetylsalicylic acid and the acetylsalicylic acid–acetic acid complex but has approximately six times the molar absorptivity. At low caffeine to acetylsalicylic acid ratios (expressed in milligrams) in pharmaceutical preparations, caffeine was not found to inner filter. However, at ratios greater than 1:1 in preparations containing large amounts of acetylsalicylic acid, the absorbance at 280 nm was so large that inner filtering became significant. The presence of acetaminophen was never a problem at low acetaminophen to acetylsalicylic acid ratios (expressed in milligrams) but became a problem at ratios greater than 2:1 where large amounts of aspirin were being determined. Typical content ratios for these compounds in newer preparations are 0.1 < acetaminophen (milligrams)/acetylsalicylic acid (milligrams) < 1.0 and 0.0 < caffeine (milligrams)/acetylsalicylic acid (milligrams) < 0.4.

For the determination of acetylsalicylic acid in the presence of sali-

[a] Triplicate analysis.

cylamide, several simultaneously competing effects are possible. Although salicylamide exhibits a UV minimum at 260 nm, it has a band at 270–340 nm with a molar absorptivity at 307 nm, which is approximately six times that of acetylsalicylic acid at its maximum. Hence, inner filtering of excitational radiation is possible where large amounts of acetylsalicylic acid are to be excited at 280 nm with a high weight ratio of salicylamide to acetylsalicylic acid. Since the 307-nm absorption band of salicylamide is extremely wide, inner filtering of the 335-nm acetylsalicylic acid emission also is possible. In addition, the 445-nm salicylamide emission band is broad so that a small positive interference from salicylamide emission actually is observed when measuring the acetylsalicylic acid emission at 335 nm. At smaller ratios of salicylamide to acetylsalicylic acid and small amounts of acetylsalicylic acid, the sum of these three effects is negligible. Typical content ratios in newer preparations are $0.2 \leq$ salicylamide (milligrams)/acetylsalicylic acid (milligrams) $\leq 1.3$.

Any pharmaceutical preparation containing acetaminophen and caffeine probably can be analyzed rapidly and accurately for acetylsalicylic acid content spectrofluorometrically. Any inner filtering can be avoided, at least in theory, by diluting the sample to <0.05 absorbance unit at 280 nm and using higher signal amplification. However, any positive error from salicylamide cannot be removed by dilution. At lesser content ratios, salicylamide does not contribute more than 1% positive error to the determination. Since the two emission peaks of the salicylamide–acetylsalicylic acid system are well resolved and can be read on approximately the same instrument sensitivity, multicomponent system calculations should be applicable if a large salicylamide to acetylsalicylic acid ratio is encountered.

Results of spectrofluorometric determinations compared favorably with nonaqueous titrations using chlorophenol red indicator. This indicator was not stable in the sample, and additional indicator was required as the titration proceeded; the end-point was still indistinct. In the end-point region, the kinetics of the titration became slow. The combination of these two titrimetric effects may have caused part of the overall positive error observed (Table VI). (Tablet Preparation F had the largest positive error but the lowest salicylamide to acetylsalicylic acid content ratio; the percent error due to salicylamide content was ~+0.3% for Preparations E and F and +0.6% for Preparations G and H.)

**Determination of Salicylic Acid in Salicylamide-Containing Pharmaceuticals**—Since salicylamide is separated so easily from salicylic acid, the salicylic acid content of salicylamide-containing pharmaceuticals should be negligible. Analysis of reagent grade salicylamide proved that the reagent contained significant amounts of salicylic acid; the salicylic acid content was not homogeneously distributed. Consequently, a method for the determination of salicylic acid content of salicylamide is necessary to ensure the purity of the salicylamide standard used for the direct spectrofluorometric analysis of salicylamide in methanol. This method also is applicable to pharmaceuticals containing salicylamide.

For the determination of salicylic acid in pharmaceuticals not containing acetylsalicylic acid, the only constituent of the sample solution prepared for analysis should be salicylic acid. In practice, small amounts of salicylamide appear in the final sample solution but can be compensated for by running a salicylic acid-free salicylamide control with the samples. The correction is linear from 50 to 300 mg of initial salicylamide content. Due to the reduced recovery of salicylic acid (89.4 ± 2.3%), samples should be compared to extracted standards to eliminate the need for percent recovery corrections. These standards also can serve as controls. With correction for residual salicylamide content, the detection limit for the determination of salicylic acid in samples containing 100 mg of salicylamide is ~0.05% of the total salicylamide content.

**Determination of Salicylic Acid in Pharmaceuticals Containing Salicylamide and Acetylsalicylic Acid**—One important problem in analyzing any preparation containing acetylsalicylic acid is that acetylsalicylic acid is hydrolyzed to salicylic acid in aqueous solution. At high pH, the acetylsalicylic acid is hydrolyzed immediately; in neutral and acid solution, the hydrolysis rate is slow enough that it can be compensated for accurately ($0.007 \pm 0.001_0$ mg/min and $0.001_2 \pm 0.000_3$ mg/min, respectively). In the present analyses, the hydrolysis rates were constant over the time required for the separation of acetylsalicylic acid from salicylamide, acetaminophen, and caffeine by extraction. The rates were not determined for various concentrations of acetylsalicylic acid so that the acetylsalicylic acid content of the initial sample in this method was limited to 45 ± 2 mg of acetylsalicylic acid. For best results, a previously analyzed USP grade acetylsalicylic acid control containing the same amount (within ±2 mg) of aspirin as in each sample should be processed with the samples and standards. Standards should be within the 0.01–0.1 mg of salicylic acid concentration range in the original sample. Any samples not within this range after extraction should be diluted and then remeasured.

In processing samples for salicylic acid determination, each sample must be extracted completely before the next sample is started rather than processing many samples simultaneously. (However, once in the final chloroform solution, the sample can be read within 1 hr.) This process keeps acetylsalicylic acid corrections small. The upper limit was set at 10 min for the extraction of each sample.

All of the preparations analyzed were within NF specifications with respect to the salicylic acid content.

## CONCLUSIONS

Fluorometric analysis of pharmaceutical preparations for salicylamide and acetylsalicylic acid and salicylic acid as an impurity in salicylamide-containing preparations is relatively free of interference from other associated compounds. This may not be the case with other reported methods that have never been evaluated for combination preparations. Analysis time is short, and results of determinations compare favorably with other reference methods for a wide variety of combination preparations.

# Continuous Flow Bead-Bed Dissolution Apparatus for Suppositories

**T. J. ROSEMAN ˣ, G. R. DERR, K. G. NELSON, B. L. LIEBERMAN, and S. S. BUTLER**

Received August 1, 1980, from the *Pharmacy Research Unit, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication December 2, 1980.

**Abstract** □ A bead-bed dissolution apparatus for suppositories was evaluated by measuring the release of benzocaine from various vehicles. During dissolution, suppositories soften, deform, disintegrate, and eventually pass through a phase change from a solid to an oil. The control of the interfacial area during dissolution is a key factor in obtaining experimentally reproducible release data. The proposed suppository dissolution apparatus was designed to provide greater constancy of the exposed suppository area for dissolution. The apparatus consisted of a glass bead-bed containing the suppository. A continuous flow of liquid was passed through the bead-bed at a constant rate. Direct contact of the suppository was maintained with the dissolution medium, confining the suppository within the beads.

**Keyphrases** □ Suppositories—evaluation of a bead-bed dissolution apparatus, drug release rate □ Dissolution—bead-bed apparatus for suppositories, evaluation, drug release rate □ Drug release—suppositories, evaluation of a bead-bed dissolution apparatus

Benzocaine was selected as a model compound with both a low melting (33.5–35.5°) and a high melting (37–39°) glyceride-type suppository base. *In vitro* release of benzocaine decreased as the melting point of the suppository increased. Reproducibility of the complete release curves was acceptable. Drug release also was affected by the temperature of the dissolution media, increasing, decreasing, and increasing again at certain temperatures. This finding was related to the ability of the beads to penetrate the surface of the suppository when the suppository softened. Release profiles, however, were reproducible at the temperature studied. The proposed bead-bed dissolution apparatus should offer an improved means for measuring drug release from suppositories.

## BACKGROUND

Suppositories, administered either vaginally or rectally, are utilized as a dosage form for various drugs (1). Recent reports investigated the use of vaginally administered prostaglandins for fertility control and also emphasized certain advantages of this mode of drug therapy, *e.g.*, self-administration and single-dose therapy (2–9). This continued interest in suppositories and suppository bases (10) has led to the recognition that a dissolution test would be helpful during the initial phase of dosage form design. In addition, such a test would provide valuable information on the effect of storage time and temperature on the subsequent *in vitro* release profile.

The methods used for testing drug release rate characteristics of suppositories *in vitro* can be classified in terms of five general types (Fig. 1). The first type consists of simple placement of the suppository in a flask or beaker (11–15). The second type utilizes an existing tablet dissolution apparatus that provides a wire mesh basket for holding the sample (16–22). The third and fourth types employ a membrane; the third consists of a sample chamber separated from a reservoir by a membrane (23–33), whereas the fourth employs dialysis tubing or a natural membrane (33–46). The fifth type involves a flow system in which the sample is placed on cotton or a wire screen (47, 48).

One basic problem in testing for drug release from a suppository is that the suppository softens, deforms, melts, or disintegrates during the test, exposing a variable interfacial area to the dissolution medium. Because the release rate is dependent on the interfacial area, the variability of this factor leads to poor test reproducibility.

Membranes have been used to control the interfacial area on the principle that when the suppository softens, it would spread over the entire membrane, restricting the area exposed to the dissolution fluid. Bhavnagri and Speiser (24) designed a type three apparatus with a relatively small sample chamber. Others (39, 42) used a relatively small bag in a type four apparatus to restrict the interfacial area.

The need to control the interfacial area is important, but the intro-

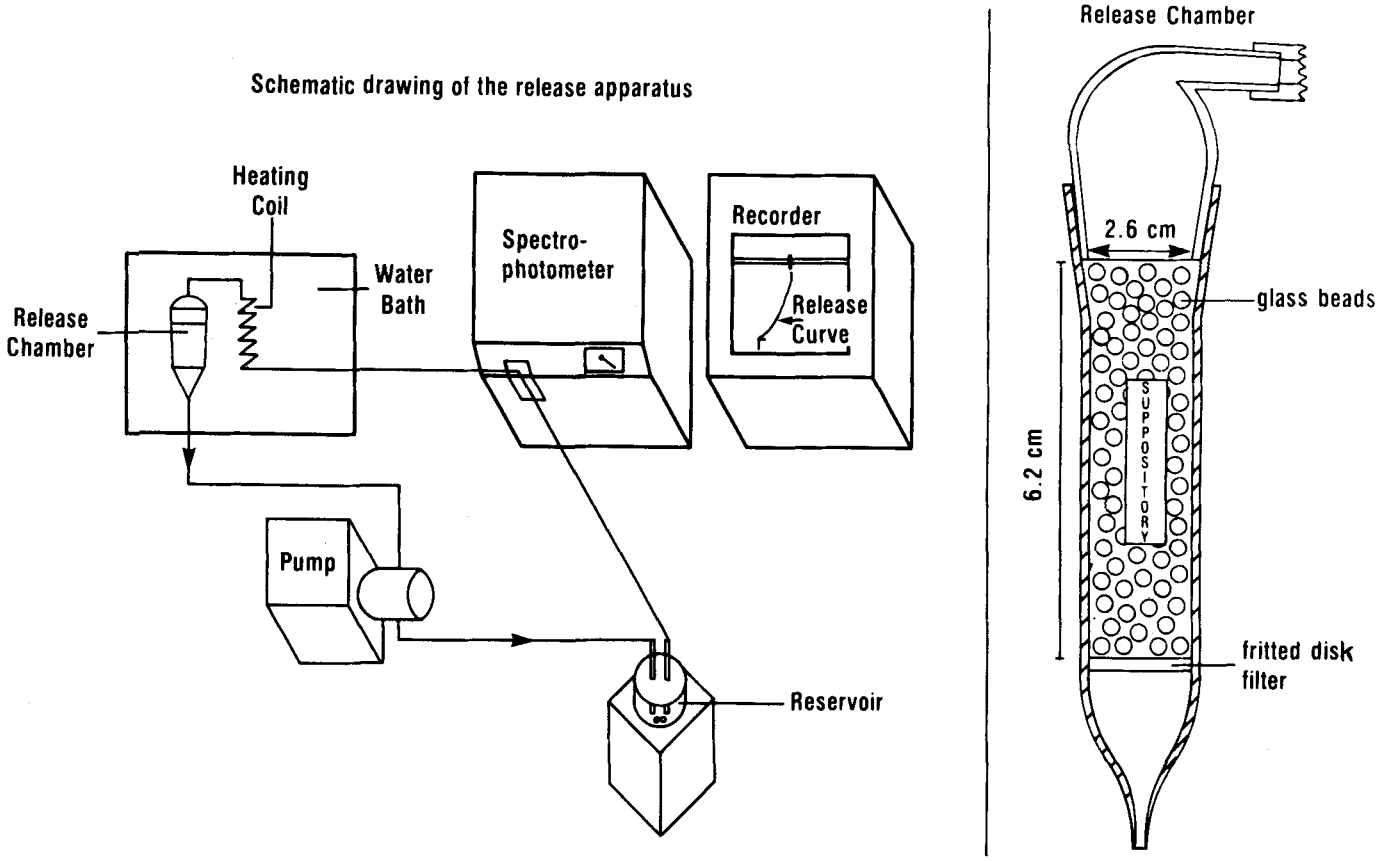

**Figure 2**—*Continuous flow bead-bed suppository dissolution apparatus.*

duction of an additional physical process, *i.e.*, membrane transport, complicates matters and may mask the real release characteristics for certain drug–suppository base combinations. Therefore, a flow-through technique was developed in which the suppository is secured in a bed of glass beads. This arrangement controls the interfacial area for most suppository bases, yet allows direct contact between the suppository and the dissolution medium.

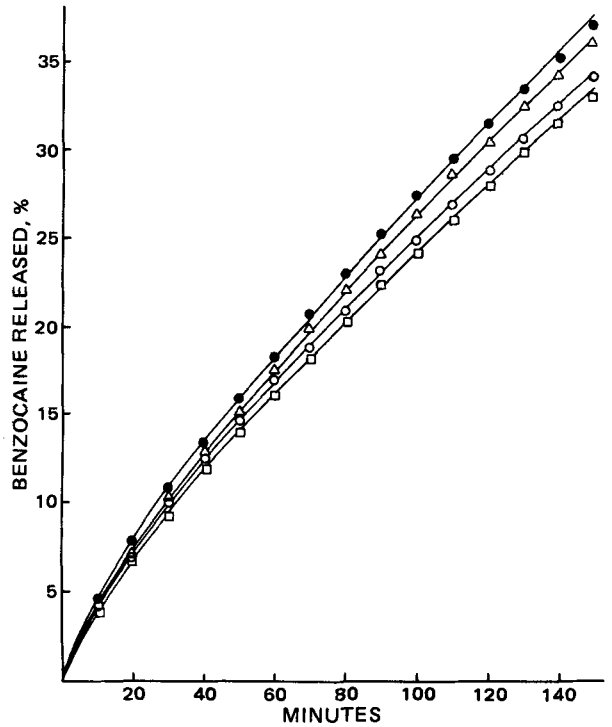

**Figure 3**—*Release of benzocaine from Base A suppositories on different days at 37° (original dissolution chamber). Key: ●, Day 1; ○, Day 2; □, Day 3; and △, Day 3.*

## EXPERIMENTAL

**Suppository Preparation**—The suppositories were prepared by first dissolving an appropriate amount of benzocaine[1] (ethyl *p*-aminobenzoate) in the melted base to yield a benzocaine concentration of 0.125% (w/w). The suppository bases, designated A[2] for the low melting (33.5–35.5°) and B[3] for the higher melting (37–39°), were melted at 5–10° above their melting points. The melt then was poured into aluminum suppository molds and allowed to cool at room temperature, and the excess base was scraped away after solidification. The molds were cooled further at room temperature (Base A) or in a refrigerator (Base B) for 30 min, and then the suppositories were ejected from the molds.

The molds consisted of tapered cavities drilled into an aluminum block. The taper permitted easy removal of the suppositories. The suppositories were 800 mg, 1.91 cm long, and 0.75 and 0.79 cm in diameter at the ends. The amount of benzocaine in each suppository was 1.0 mg.

**Design of Release Apparatus**—The release rate apparatus was designed to provide reasonable control over the interfacial area for drug dissolution (Fig. 2). A continuous eluent flow is maintained over the suppository contained in a bed of glass beads. The eluent starts in the 150-ml jacketed beaker, which is covered with an acrylic resin disk. When the pump[4] is started, water is drawn through polyethylene tubing (3 mm o.d. × 2 mm i.d.) from the 150-ml jacketed beaker to a 1-cm flowcell in the UV spectrophotometer[5]. From the spectrophotometer, the water is drawn into a preheating glass coil (glass automated analyzer coil, 1.5 cm in diameter × 16 cm in length). The glass coil is submerged in the water bath[6] to allow the water temperature to equilibrate before reaching the sample chamber, which also is submerged in the water bath. The water leaves the glass coil and enters the sample chamber from the top.

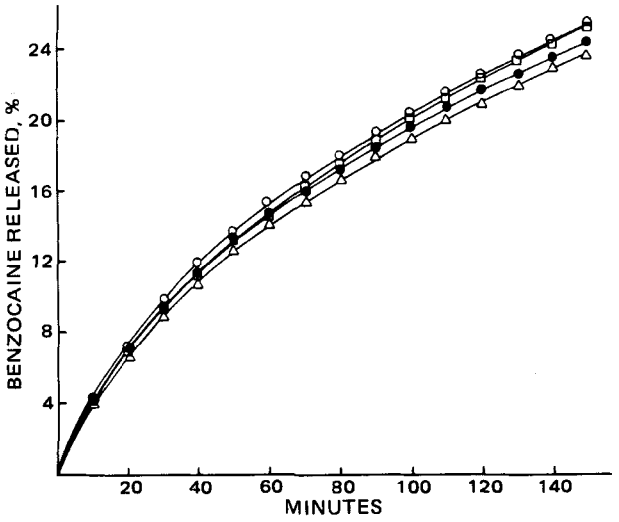

**Figure 4**—*Release of benzocaine from Base B suppositories on different days at 37° (original dissolution chamber). Key: ●, Day 1; ○, Day 1; □, Day 3; and △, Day 3.*

Originally, the chamber consisted of two 15-ml Büchner fritted disk filters connected at the top by Tygon tubing and a clamp. The present chamber consists of two sections. The bottom section is a 15-ml coarse Büchner fritted disk filter modified with a 24/40 glass joint at the top and an outlet tube narrowed to 4 mm o.d. × 2 mm i.d. The top half is a 24/40 hose-connecting joint modified with an inlet tube narrowed to 4 mm o.d. × 2 mm i.d. The water travels through the glass bead-bed (3-mm diameter, chemically resistant glass balls) and around the suppository. The dimensions of the cell containing the beads is 2.6 cm i.d. and 6.2 cm long. The original chamber was 2.3 cm i.d. and 4.6 cm long. The water leaves the test chamber, is drawn into the pump, and is pumped back into the 150-ml jacketed beaker, which is stirred by a magnetic stirrer.

**Procedure**—Before a release rate experiment was begun, a water baseline was established by adding 130 ml of deionized water to the 150-ml jacketed beaker. The water bath was adjusted to the appropriate temperature, and the system and water were allowed to equilibrate. Temperature was controlled within ±0.1°. The test chamber then was half-filled with glass beads. A weighed suppository was inserted into the center of the chamber, using a plunger assembly that allowed the operator to position the suppository reproducibly. The remainder of the chamber was filled with glass beads, and its upper section was connected. The chamber then was lowered into the water bath along with the glass coil and fixed into an upright position. The pump was started immediately in the reverse direction, allowing the water to fill the test chamber from the bottom up. As soon as the entire system was filled, the flow was reversed so that the water flowed from top to bottom in the chamber.

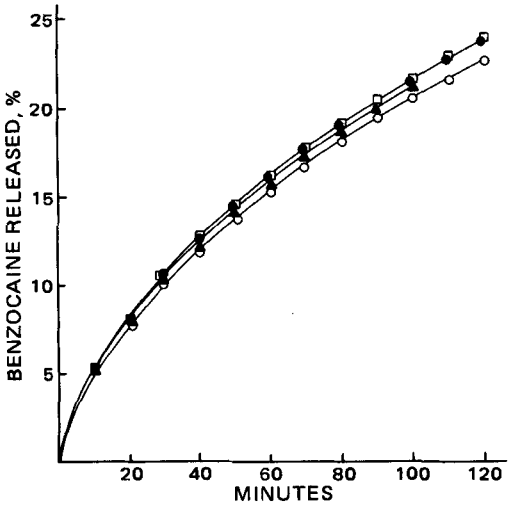

**Figure 5**—*Replicate 37° dissolution experiments for the release of benzocaine from Base B using the modified dissolution cell. Key: ○ and □, Day 1; and ▲ and ●, Day 2.*

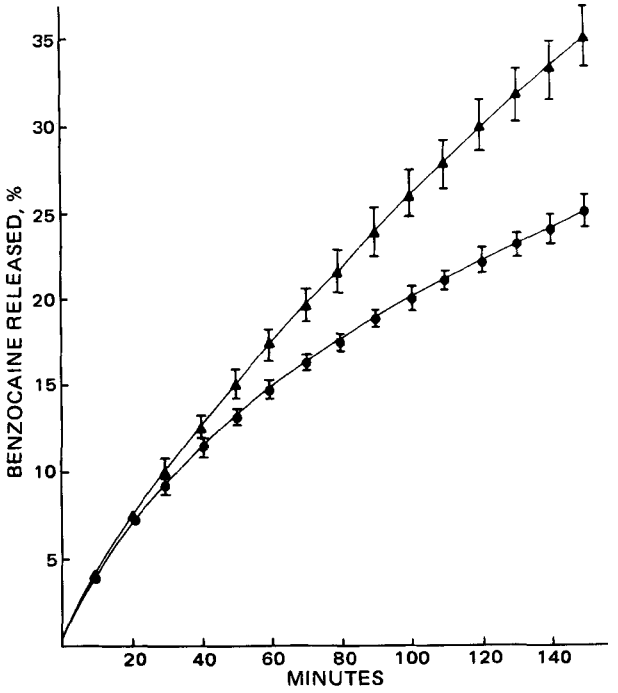

**Figure 6**—*Comparative release of benzocaine from Base A (▲) and B (●) suppositories at 37°.*

The flow rate was controlled at 30 ± 0.5 ml/min. Drug release was monitored with a UV spectrophotometer (282 nm) equipped with a recorder. The cumulative amount released with time was calculated from the recorder tracings by converting absorbance to concentration and multiplying by the volume of the dissolution medium. Before each run, the UV spectrophotometer was checked with two solutions of known benzocaine concentrations to assure that absorbance was linear with concentration.

## RESULTS AND DISCUSSION

The concept of a flow system employing a bed of beads was shown to be useful for studying dissolution rates of solids. A system for testing tablets and granules in which the sample is placed within the bed was described previously (49). Reproducible dissolution rates for drug powders were obtained (50) by mixing the powder with a diluent and placing the mixture between two layers of glass beads in a flowcell. Rippie and Huq (51) used a flowcell containing several layers of glass beads in which the bead size was reduced successively. Drug powder, introduced at the top, then migrated through the bed as dissolution occurred. These recent reports demonstrate the distinctness of this type of system opposed to the usual vessel and flow systems used for dissolution testing.

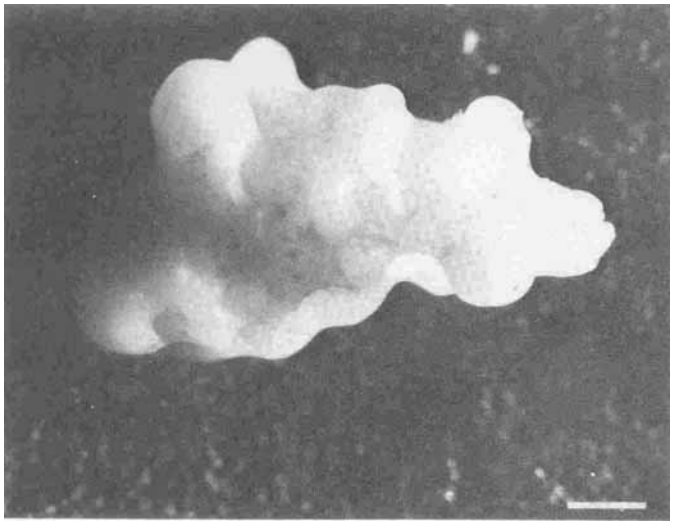
Suppository drug release is influenced by factors such as: drug–vehicle interactions; vehicle composition; crystalline form of the vehicle (polymorph); solubility, partition coefficient, and drug permeability in the vehicle; particle size of the drug (dispersed system); and drug concentration in the vehicle. Experimental parameters such as the temperature of the dissolution solvent and flow rate should influence the observed release patterns.

This report presents a preliminary evaluation of the continuous flow bead-bed concept using two types of suppository bases with benzocaine as the model compound. Benzocaine was selected because benzocaine suppositories are marketed and because it has a UV-absorbing chromophore that allows it to be easily assayed.

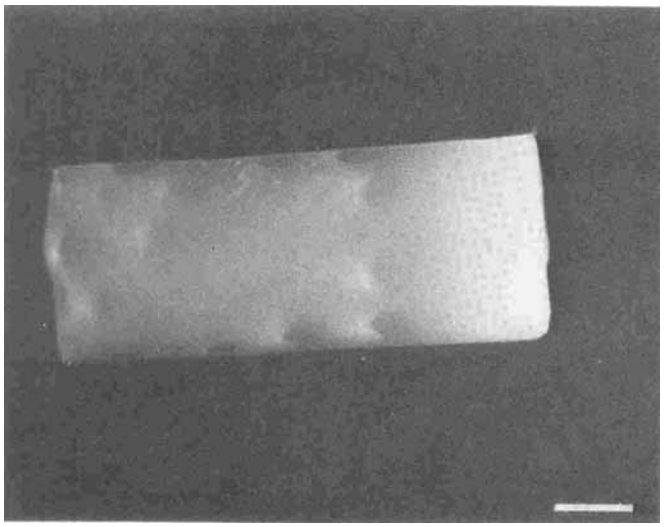
The two suppository bases (A and B) were mixtures of glycerides of fatty acids. They possess physicochemical properties representative of the many vehicles purchased from commercial suppliers (10) and have been studied with several different prostaglandins (3–5).

Figures 3 and 4 show the release profiles of benzocaine in duplicate from Bases A and B, respectively, on each of 2 different days, using the original dissolution chamber. Figure 5 gives the release profiles from the new chamber. These data indicate that there was no major difference between the two chambers (*i.e.*, within 10%).

The replicate runs were performed within 3 days to avoid any potential effects of a polymorphic change of the base on the drug release rate. The



BASE A



BASE B

**Figure 7**—*Photographs of suppositories after 2 hr (37°) in the bead-bed dissolution apparatus. Scale marker = 0.31 cm.*

thermal behavior of Base B (with benzocaine) was verified by differential scanning calorimetry; these scans were invariant with time[7]. The dissolution results indicate very good reproducibility of the data. Comparisons of the 15 time points on the curves from four runs gave an average relative standard deviation of 6.13% for Base A and 3.36% for Base B. Therefore, 95% of the time the complete release profile will be reproduced with a 13% variation for Base A and a 7% variation for Base B.

Release from the bases is compared in Fig. 6. The bars represent the standard deviation of the points. The percentages of benzocaine released during the first 30 min were similar, but the lower melting Base A exhibited a much faster release at later times. Figure 7 shows the physical form of the two bases after 2 hr in the bead-bed at 37°. They were allowed to solidify at room temperature before removal.

The low melting Base A softened and stayed within a confined region of the bead-bed. The higher melting Base B maintained its form, showing slight indentations from the beads. Suppositories of these types do not show complete melting at 37° but rather a softening of the suppository matrix. At temperatures well above their melting points, total liquefaction takes place. The degree to which the beads actually penetrate the suppository depends on the thermal behavior of a given suppository.

The similar early release of benzocaine from the two bases most likely results from the fact that they initially are both rigid. It requires time

[7] After ~1 month of storage at 25°, the differential scanning calorimetric curves began to change with a concomitant decrease in the release profiles. Alteration in the thermal behavior of semisynthetic bases was recently reported (52).

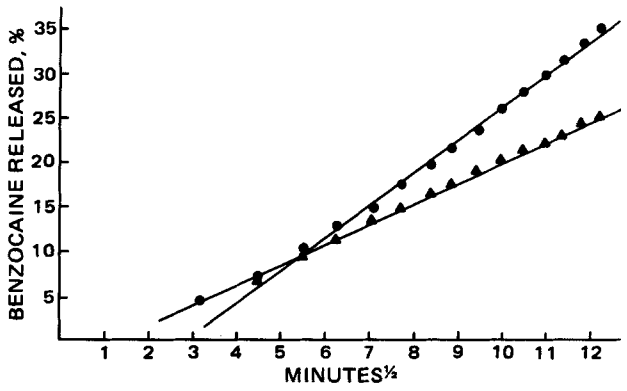


**Figure 8**—*Release of benzocaine, plotted as the square root of time, from Base A (●) and B (▲) suppositories at 37°.*

before the suppositories soften sufficiently to detect significant differences in release. Visual examination of Base A after 5 and 20 min supported this view. After this time, bead penetration restricts the area for drug release. Therefore, *in vitro* release from Base A is actually higher than observed. Plots of the percent released *versus* the square root of time were linear with correlation coefficients of 0.990 and 0.996, respectively (Fig. 8). This type of release kinetics follows the matrix-controlled release theory previously developed (53). It is particularly applicable to Base B, which maintained its shape (constant surface area) during the test period.

To investigate bead penetration further, the influence of temperature on the release of benzocaine from Base B was studied in more detail. Release curves as a function of temperature are presented in Fig. 9. The release profiles did not increase as a direct function of temperature. For example, release increased from 33 to 37°, with 39 and 40° data being comparable to the 33° run.

The fastest release profile was achieved at 45° where complete melting of the base occurred. At first, this overall temperature dependence seemed surprising. However, close examination of the physical state of the suppository in the beads provided the reason for this behavior. While the suppository was in the dissolution apparatus, it softened and eventually melted. As it softened, the beads became impressed within the suppository (Fig. 10). At 39 and 40°, the beads penetrated the surface of the suppository, thereby reducing the surface area available for drug release. Once the base melted completely (*e.g.*, 45°), release increased again due to the spreading of the oil in the bead-bed. At this temperature, oil globules were found floating at the top of the beads. Although release was temperature dependent, it was reproducible at the temperatures studied. This finding supports the continued evaluation and development of this apparatus, which is particularly well suited for suppositories that reasonably maintain their shape during the dissolution process.

In view of the influence of the beads on release at temperatures that

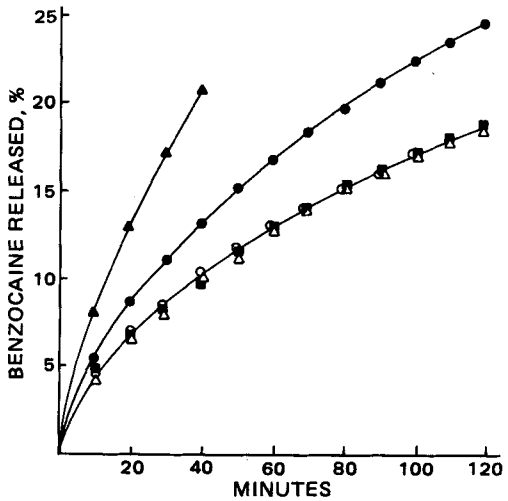

**Figure 9**—*Dependence of benzocaine release from Base B suppositories as a function of temperature. Key: ▲, 45°; ■, 40°; ○, 39°; ●, 37°; and △, 33°.*

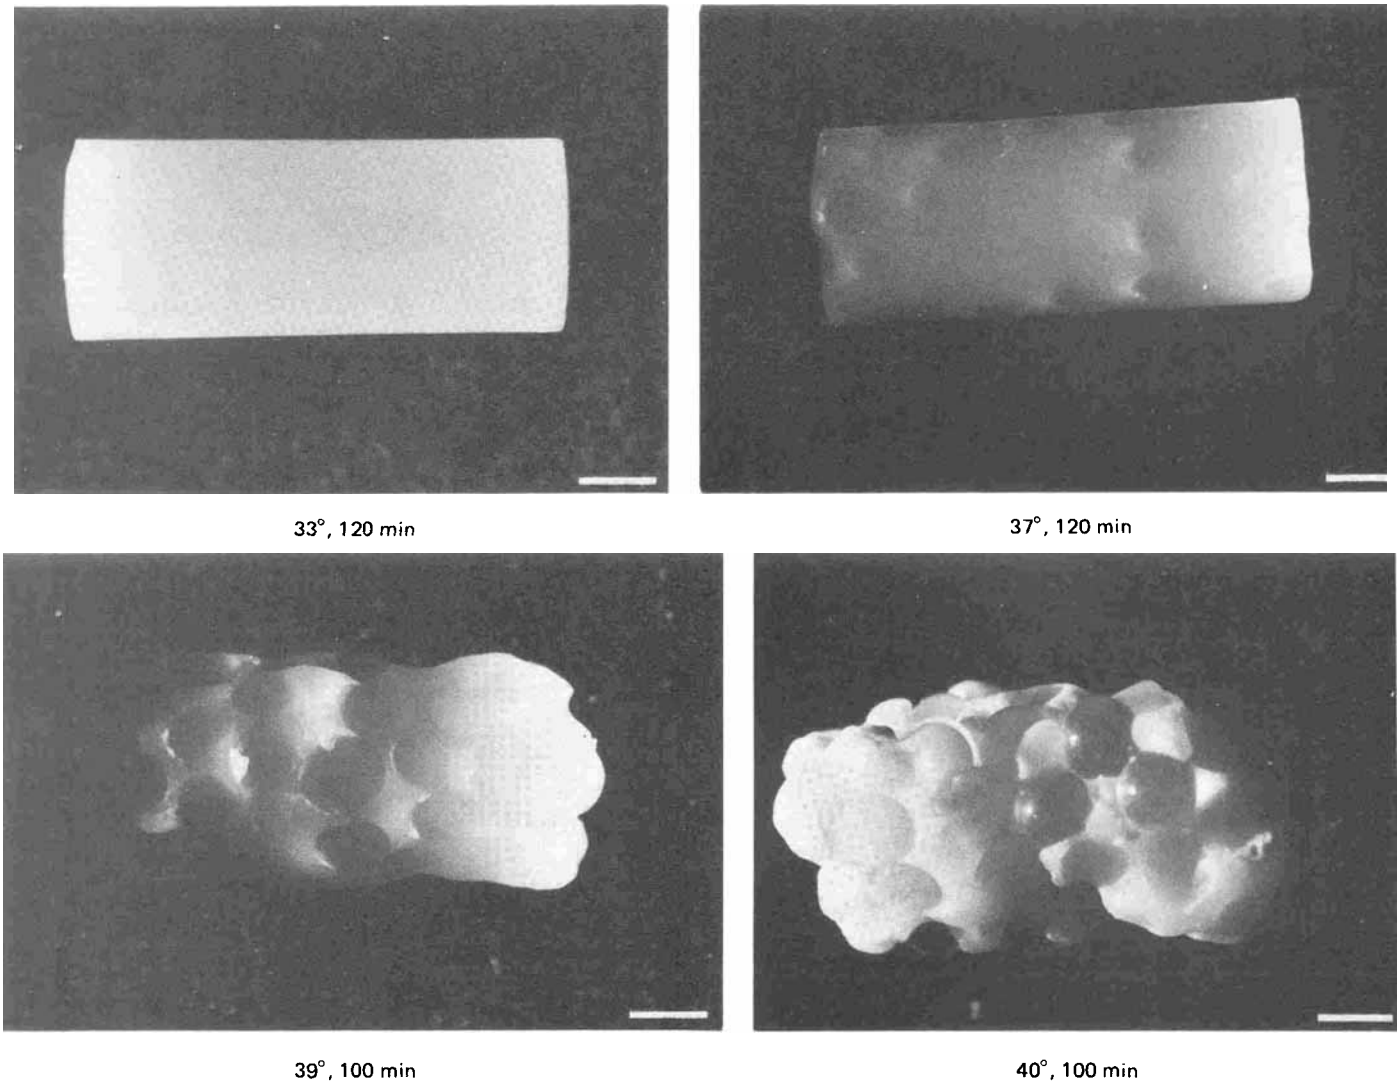

**Figure 10**—*Photographs of Base B suppositories after ~2 hr (37°) in the bead-bed dissolution apparatus. Scale marker = 0.31 cm.*

cause deformation of the base, further refinements of the bead-bed apparatus are anticipated. Consideration will be given to maintaining the beads in a stationary position, thereby eliminating the dynamics of bead penetration. This can be accomplished by using a preformed bead cavity as a mold or a porous gel instead of the beads.

# Effect of Caffeine on Ergotamine Absorption from Rat Small Intestine

**JOHN R. ANDERSON, GERTRUDE DREHSEN, and IAN H. PITMAN ˣ**

Received July 24, 1980, from the *Victorian College of Pharmacy Ltd., Parkville, Victoria, Australia 3052.* Accepted for publication December 2, 1980.

**Abstract** □ The effect of caffeine on the absorption of ergotamine from the rat small intestine was studied. The results of a series of experiments showed that caffeine significantly enhanced absorption of ergotamine from solutions of pH 5.0 when both substances were in solution and when an intact blood supply was either absent (*in vitro* everted sac experiments) or present (*in situ* experiments). Caffeine did not appear to influence the absorption rate of ergotamine in *in situ* experiments when the solution pH was 3.0. Isosorbide dinitrate, a vasodilator, enhanced ergotamine absorption when both substances were administered simultaneously into intestinal loops *in situ*. Isosorbide dinitrate probably exerts its effect by increasing blood flow to the intestine. The results are consistent with an hypothesis that the rate-determining step in ergotamine absorption is the transport of the drug from a lipid phase (GI membrane) into an aqueous phase (blood). Caffeine is thought to exert its rate-accelerating effect by increasing the water solubility of ergotamine neutral molecules.

**Keyphrases** □ Caffeine—effect on ergotamine absorption from rat small intestine, *in vitro* and *in vivo* studies □ Ergotamine—effect of caffeine on absorption from rat small intestine, *in vitro* and *in vivo* studies □ Absorption—ergotamine, effect of caffeine on absorption from rat small intestine, *in vitro* and *in vivo* studies □ Analgesics—ergotamine, effect of caffeine on absorption from rat small intestine, *in vitro* and *in vivo* studies

Ergotamine tartrate is widely used in the treatment of migraine (1, 2). When administered parenterally, it is effective in relieving migraine pain (3, 4), but oral administration often affords no relief (5, 6). Regardless of the route, ergotamine must be administered early in an attack to be effective (7). The frequent failure of oral ergotamine therapy appears to be related to its relatively low water solubility (1:500) and the fact that its absorption from the GI tract into the systemic circulation often is slow or impaired during a migraine attack (4–9).

Simultaneous oral administration of caffeine and ergotamine results in more effective therapy than ergotamine administered alone (10–12). Recent pharmacokinetic studies in humans indicated faster and more complete absorption of ergotamine after oral administration when it is combined with caffeine (13). Zoglio *et al.* (14) conducted *in vitro* experiments to elucidate the mechanism by which caffeine enhances ergotamine absorption; caffeine increased the solubility and dissolution rates of ergotamine in 0.1 *M* HCl and in 0.1 *M* phosphate buffer (pH 6.65) and was claimed to accelerate the partitioning of ergotamine from an aqueous (pH 6.65) to an organic (chloroform) phase. These observations led to the conclusion that the solubilizing effect of caffeine on ergotamine in water is the major factor in its enhancement of oral ergotamine migraine therapy.

The present study was undertaken to determine the effect, if any, that caffeine has on ergotamine absorption across the rat small intestine when both substances are dissolved.

## EXPERIMENTAL

**Ergotamine Assay**—Ergotamine concentrations were calculated from the results of reversed-phase high-performance liquid chromatographic (HPLC) assays (15). The mobile phase was acetonitrile–1% sodium acetate/acetic acid buffer (55:45) at pH 6.5. The stationary phase was a 10/25 ODS column, and ergotamine was detected by fluorescence spectrometry ($\lambda_{ex}$ = 325 nm; $\lambda_{em}$ = 407 nm).

***In Vitro* Studies (Everted Sac Technique)**—Adult male Hooded Wistar rats, 240–280 g, were fasted in cages designed to prevent coprophagy for at least 12 hr before sacrifice. Water was allowed *ad libitum*. The rats were killed by a blow on the head. The small intestine was removed immediately, rinsed with Krebs–Henselite solution, sleeved onto a glass rod, and everted carefully. The first 15 cm, beginning with the pylorus, was discarded, and the next 8-cm segment was used in the experiments.

The segment was attached to a cannula at the proximal end, trimmed to 7 cm, and ligated at the distal end so that 6 cm of the everted intestine

Recent pharmacokinetic studies in humans indicated faster and more complete absorption of ergotamine after oral administration when it is combined with caffeine (13). Zoglio *et al.* (14) conducted *in vitro* experiments to elucidate the mechanism by which caffeine enhances ergotamine absorption; caffeine increased the solubility and dissolution rates of ergotamine in 0.1 *M* HCl and in 0.1 *M* phosphate buffer (pH 6.65) and was claimed to accelerate the partitioning of ergotamine from an aqueous (pH 6.65) to an organic (chloroform) phase. These observations led to the conclusion that the solubilizing effect of caffeine on ergotamine in water is the major factor in its enhancement of oral ergotamine migraine therapy.

The present study was undertaken to determine the effect, if any, that caffeine has on ergotamine absorption across the rat small intestine when both substances are dissolved.

## EXPERIMENTAL

**Ergotamine Assay**—Ergotamine concentrations were calculated from the results of reversed-phase high-performance liquid chromatographic (HPLC) assays (15). The mobile phase was acetonitrile–1% sodium acetate/acetic acid buffer (55:45) at pH 6.5. The stationary phase was a 10/25 ODS column, and ergotamine was detected by fluorescence spectrometry ($\lambda_{ex}$ = 325 nm; $\lambda_{em}$ = 407 nm).

***In Vitro* Studies (Everted Sac Technique)**—Adult male Hooded Wistar rats, 240–280 g, were fasted in cages designed to prevent coprophagy for at least 12 hr before sacrifice. Water was allowed *ad libitum*. The rats were killed by a blow on the head. The small intestine was removed immediately, rinsed with Krebs–Henselite solution, sleeved onto a glass rod, and everted carefully. The first 15 cm, beginning with the pylorus, was discarded, and the next 8-cm segment was used in the experiments.

The segment was attached to a cannula at the proximal end, trimmed to 7 cm, and ligated at the distal end so that 6 cm of the everted intestine

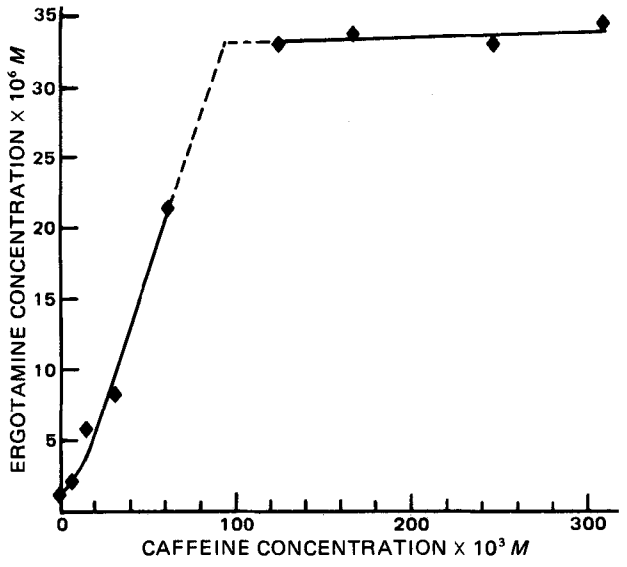

**Figure 1**—*Solubilizing effect of caffeine on ergotamine in pH 8.5 boric acid buffer. The shape of the diagram between* $[caffeine]_T = 60 \times 10^{-3}$ M *and* $120 \times 10^{-3}$ M *was not determined. The initial solid phase was ergotamine tartrate.*

was exposed to the drug solution. The intestinal sac was maintained in a vertical position during the experiment. The organ bath was filled with 60.0 ml of buffered drug solution (mucosal solution), which was maintained at 37.0 ± 0.1° and continuously gassed with 95% $O_2$–5% $CO_2$. The inner (serosal) solution consisted of 0.6 ml of buffer.

The buffer for the mucosal and serosal solutions consisted of Krebs–Henseleit solution–0.1 *M* sodium acetate (9:1), buffered to pH 5.0 with acetic acid. Quinine sulfate (0.5 mg/ml) was included to act as the internal standard in the ergotamine assay. In all experiments, the mucosal solution was the same as the serosal solution plus 0.1 mg of ergotamine tartrate/ml. In permeation experiments involving the rate of ergotamine transfer across the membrane in the presence of caffeine, 10 mg of caffeine/ml was included in the mucosal and serosal solutions.

During the experiments, 10-μl samples were withdrawn from the serosal solution at indicated times and assayed for ergotamine by the HPLC method described previously (15). The concentration of ergotamine transferred across the membrane was expressed as a percentage of the ergotamine concentration in the mucosal solution. The transfer rates were determined from the slope of a plot of log (100 − percent of ergotamine absorbed) *versus* time.

***In Situ* Studies**—Five loops of intestine (12 cm in length) were prepared in each rat according to the method described previously (16). The total volume of test solution introduced into each loop was 1.0 ml.

Two types of experiments were conducted: "time zero" studies, in which the intestine was removed from the rat immediately after the test solutions were placed in the loops, and "absorption" studies, in which the intestine remained *in situ* within the abdominal cavity of the rat for 2.5 hr before being removed.

The absorption characteristics of ergotamine tartrate were investigated in the presence of two additives, caffeine and isosorbide dinitrate. The caffeine experiments were conducted at pH 3 (0.1 *M* tartaric acid–sodium hydroxide buffer), 5 (sodium acetate–acetic acid buffer), and 6 (0.1 *M* citric acid–sodium hydroxide buffer). In the isosorbide dinitrate experiments, all test and control solutions introduced into the loops were prepared in the pH 5.0 acetate buffer, which also contained 10% dimethyl sulfoxide to solubilize the isosorbide dinitrate. The ergotamine tartrate concentration was 0.05, 0.1, or 0.2 mg/ml, the caffeine concentration was either 10 or 20 mg/ml, and the isosorbide dinitrate concentration was 2 mg/ml.

In the caffeine experiments, two loops contained an ergotamine tartrate solution at a particular concentration while another two loops contained ergotamine tartrate at the same concentration plus a particular concentration of caffeine. The remaining loop in each rat contained the appropriate buffer solution (blank loop) and served as a reference for the assay. The contents of the five loops were randomized on the basis of rows from a 5 × 5 Latin square. Five rats were used at each ergotamine tartrate and caffeine combination to complete the Latin square.

In the isosorbide dinitrate experiments, two different methods of allocating the solutions to particular loops were used. One was on the basis of a 5 × 5 Latin square, with two loops containing ergotamine tartrate solution, two loops containing ergotamine tartrate plus isosorbide dinitrate solution, and the remaining loop containing the reference solution. The second method involved placing only one type of test solution into all five loops of two rats.

At the end of each experiment, the small intestine was removed from the rat, trimmed of its mesentery and blood vessels, and rinsed in 0.9% (w/v) NaCl solution. The length of each loop was measured and recorded. The individual loops were placed in separate homogenization flasks and manually chopped as finely as possible. Five milliliters of 1.0% (w/v) tartaric acid solution was added to each flask, and the contents were homogenized for 10 min.

The homogenates were transferred quantitatively with 10 ml of absolute ethanol to centrifuge tubes. These homogenates were centrifuged at 2000×*g* for 10 min, and the supernates were decanted into 50-ml volumetric flasks. Each precipitate was resuspended and washed with three 10-ml portions of 70% ethanol and centrifuged as before, and the washings were combined with their corresponding supernates. Five milliliters of a 200-μg/ml quinine sulfate (HPLC assay internal standard) solution in 70% ethanol was added to each flask. The combined solutions were filtered through 0.80-μm membrane filters to remove solid material before they were assayed (15). Ergotamine that could not be recovered by this method was considered to have been absorbed.

A preliminary experiment was conducted to ensure that the rat intestinal secretions did not significantly alter the pH values of the test solutions during absorption. Five milliliters of the pH 5.0 acetate buffer was introduced into the rat small intestine. After 2.5 hr, the intestine was removed from the abdominal cavity, and the fluid in the lumen of the intestine was collected. The intestinal fluid was filtered through a 0.22-μm membrane filter, and the filtrate pH was measured.

**Solubility Studies**—Excess quantities of ergotamine tartrate (50 mg) were placed in 25-ml screw-capped vials together with varying, but accurately weighed, amounts of caffeine (0–480 mg) and 10 ml of pH 8.5 borate buffer (4.5 ml of 0.2 *M* boric acid and 5.5 ml of 0.05 *M* borax). The vials were placed in a constant-temperature water bath and shaken for 48 hr at 25°. Preliminary studies were conducted to determine the time required for the solutions to reach equilibrium.

The total amount of ergotamine in each equilibrated solution was determined by filtering the vial contents through a 0.22-μm membrane filter and analyzing for ergotamine concentration using the previously described HPLC method (15).

## RESULTS

**Solubility Studies**—The phase solubility diagram, obtained by saturation of caffeine solutions in pH 8.5 boric acid buffers with ergotamine tartrate, is shown in Fig. 1. The addition of 0.124 *M* caffeine increased ergotamine solubility at pH 8.5 from $1.25 \times 10^{-6}$ to $3.29 \times 10^{-5}$ *M*. Additional caffeine did not significantly alter ergotamine solubility.

***In Vitro* Studies (Everted Sac Technique)**—The absorption of ergotamine across the rat small intestine was initially studied using a modification of a reported everted sac technique (17). The volume of liquid and the concentration of quinine sulfate (internal standard) on both the serosal and mucosal sides of the everted intestine did not change appreciably during the experiment. Therefore, it was concluded that no net transfer of water or of quinine sulfate took place.

The transfer rates of ergotamine across the membrane were calculated from the slopes of plots of log (100 − percent of ergotamine absorbed) *versus* time (Fig. 2). A *t* test indicated that caffeine significantly increased the transfer rate of ergotamine from solution across the isolated rat intestine ($p < 0.001$).

***In Situ* Studies Involving Caffeine and Ergotamine**—The *in situ* technique used to measure the absorption[1] of ergotamine from the rat small intestine was based on a method developed in these laboratories by Admans *et al.* (16). It was a modification of the technique of Levine and Pelikan (18), which allows absorption of drugs from single or multiple intestinal loops to be measured.

Ergotamine solutions were introduced into four intestinal loops in an anesthetized rat, and a blank solution was introduced into a fifth loop. After 2.5 hr, the loops and their contents were homogenized separately and assayed for ergotamine. The amount of ergotamine absorbed was calculated from the difference between the amount administered and the amount remaining and was expressed as the percent absorbed.

A minor complication in calculating the amount of ergotamine remaining arose because HPLC chromatograms of ergotamine tartrate solutions that had been in the rat gut for 2.5 hr contained two more peaks than those observed for an ergotamine solution. The additional peaks

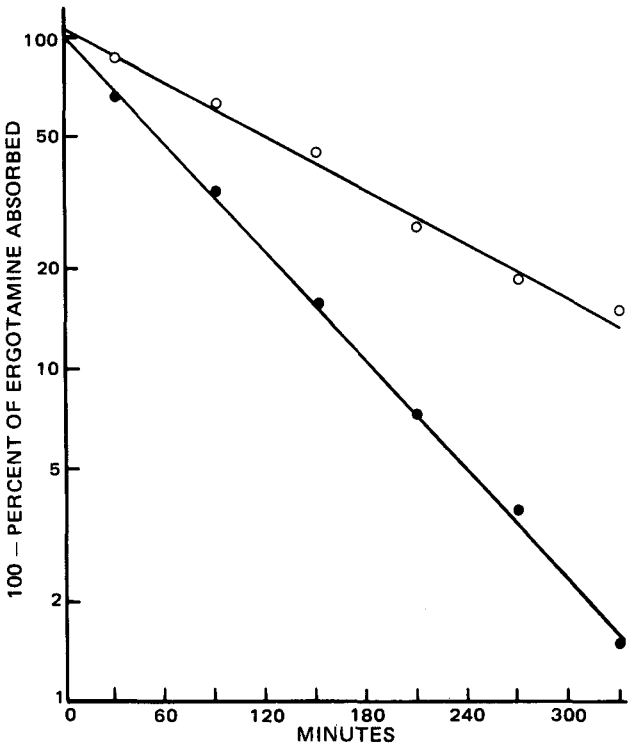

**Figure 2**—*Semilogarithmic plot against time of (100 − percent of ergotamine absorbed) in everted rat gut experiments. Key: ○, 0.1 mg of ergotamine tartrate/ml, slope = $-6.23 \times 10^{-3}$/min; and ●, 0.1 mg of ergotamine tartrate/ml plus 10 mg of caffeine/ml, slope = $-1.26 \times 10^{-2}$/min.*

had retention times of 6.5 and 7.5 min, whereas the ergotamine peak had a retention time of 9.0 min. Typical chromatograms that were measured from experiments conducted at pH 3 and 5 are shown in Fig. 3. In the experiments at pH 3.0, the metabolites or degradation product peaks were barely apparent. At pH 5.0, the metabolism was greater than at pH 3.0 but still relatively slight. When experiments at pH 6.0 were attempted, little ergotamine remained in the loops after 2.5 hr and the metabolites were significant, thereby making quantitation of absorption difficult.

Ergotaminine, an isomer of ergotamine that results from epimerization at C-8 (19), gave a peak with a retention time of 6.5 min. Thus, it was concluded that ergotaminine was one degradation product. Because fluorescence of ergotaminine is 2.5 times greater than that of ergotamine (20), it was estimated that the ratio of the amount of ergotaminine to the original amount of ergotamine after 2.5 hr at pH 5.0 was 0.03:1. Thus, conversion by metabolism of ergotamine to ergotaminine is unlikely to affect the results significantly.

The extraneous peak with a retention time of 7.5 min was twice as intense as that of ergotaminine. The nature of the compound causing this peak is uncertain, but it is likely to be *aci*-ergotamine or *aci*-ergotaminine, which is formed by the inversion of ergotamine or ergotaminine at the 2′-position (19). These compounds are more polar than ergotamine (21) and are expected to be eluted earlier with the mobile phase employed. Although the fluorescence intensity of the *aci* compounds is not known, it is unlikely that they would fluoresce much less strongly than ergotamine.

In the absence of more precise information, it was assumed that the fluorescence of the metabolites was similar to that of ergotamine. Hence, ergotamine concentrations that remained were derived by summing the areas under the peaks for ergotamine and its metabolites. This procedure should introduce a maximum error of ±10% into the results[1].

***In Situ* Studies**—*pH Value of Intestinal Contents*—The pH of the intestinal contents 2.5 hr after introduction of the pH 5.0 acetate buffer was 5.3. The pKa value of ergotamine is 6.4 (22). Therefore, at least 90%

[1] A reviewer pointed out that the above experiments do not distinguish between absorption and loss of ergotamine due to metabolism if the metabolites are themselves absorbed. This point is accepted but, in the absence of other information, the good correlations between the effect of caffeine on ergotamine absorption in *in vitro* and *in situ* experiments and the low probability that caffeine appreciably influences ergotamine metabolism are accepted as points that support the discussion in the manuscript.

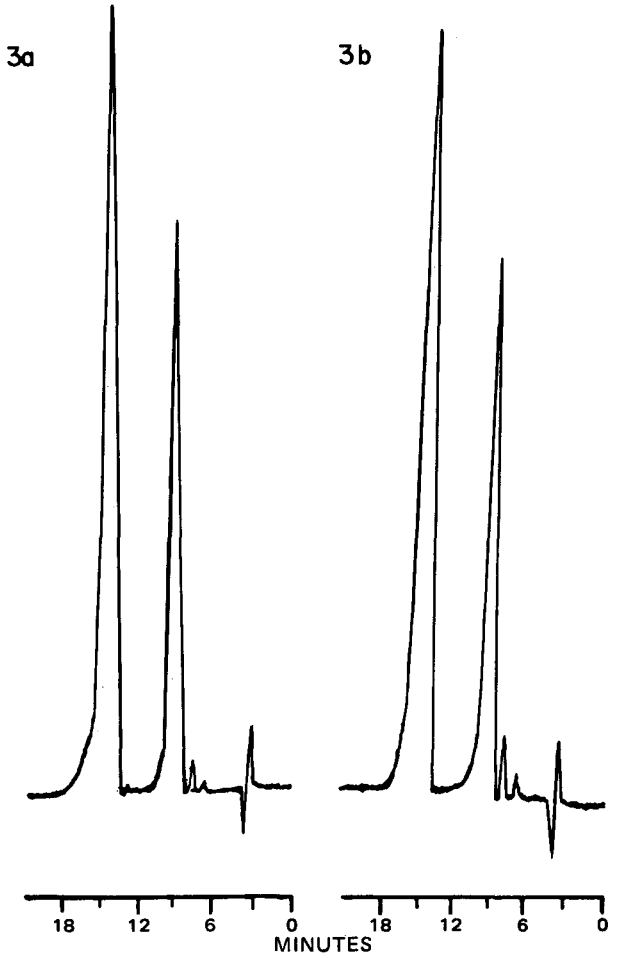

**Figure 3**—*Chromatograms of extracts from* in situ *rat intestinal homogenates. Experiments were conducted at pH 3.0 (a) and 5.0 (b). The peaks eluted after 9 and 15 min were ergotamine and quinine, respectively.*

of the ergotamine existed in the ionized form and remained in solution throughout the study. It also was found that a 0.2-mg/ml solution of ergotamine tartrate could be obtained at pH 5.3. Since the maximum concentration of ergotamine tartrate introduced into the intestinal loops was 0.2 mg/ml, all of the ergotamine in the intestinal loops, either by itself or in the presence of caffeine, probably remained in solution throughout the absorption experiments conducted at pH 5 or below.

*Significance of Blank Loop and Effect of Loop Length*—Ergotamine could disappear from a loop by either absorption into the blood or lymphatic system or by leakage into an adjoining loop. Ergotamine also could possibly be reabsorbed from the blood into the lumen of a loop. However, no ergotamine was detected in the loop containing the blank solution. Hence, it was concluded that ergotamine that had disappeared from a loop was absorbed.

An analysis of variance of the results indicated that the variation in loop length that occurred with this technique had no significant effect on the percentage of the administered amount of ergotamine absorbed from the loops ($p > 0.1$).

*Effect of Caffeine*—In the experiments designed to test the reliability of the recovery process (time zero studies), loops containing either 0.2 mg of ergotamine tartrate/ml alone or 0.2 mg of ergotamine tartrate/ml plus 20 mg of caffeine/ml were removed and assayed immediately after introduction of the test solutions into the loops. At pH 5.0, the mean recovery of ergotamine from 10 loops (five rats) was 97 ± 3%. The mean recovery of ergotamine in the presence of caffeine from 10 loops (five rats) was 98 ± 3%. At pH 3.0, the recoveries were 95 ± 6% for ergotamine tartrate solution (four loops) and 96 ± 1% for ergotamine tartrate and caffeine solution (four loops).

Analysis of variance conducted on these results indicated that caffeine had no significant effect on the recovery of ergotamine from loops at pH 3.0 ($p > 0.1$) or 5.0 ($p > 0.1$) and that the loop position (*i.e.*, distance from the pylorus) had no significant effect on the amount of ergotamine re-

**Table I—Extent of Ergotamine Absorption from *In Situ* Rat Small Intestinal Loops after 2.5 hr in the Presence and Absence of Caffeine**

| pH | Ergotamine Tartrate, mg/ml | Caffeine, mg/ml | Absorption of Ergotamine[a], % Without Caffeine | Absorption of Ergotamine[a], % With Caffeine |
|---|---|---|---|---|
| 5.0 | 0.2 | 20 | 21 (6) | 61 (6) |
| | 0.2 | 10 | 24 (9) | 49 (5) |
| | 0.1 | 10 | 25 (9) | 53 (6) |
| 3.0 | 0.2 | 10 | 47 (14) | 47 (12) |

[a] Each value is the mean of 10 loops from five rats. Standard deviation is in parentheses.

covered ($p > 0.1$). Because of the near complete recovery of ergotamine at time zero, no correction to the results obtained at 2.5 hr was necessary.

The results of the absorption studies are shown in Table I. Analysis of variance indicated that in each of three sets of experiments at pH 5.0, the presence of caffeine in the loops caused a highly significant increase in the extent of ergotamine absorption ($p < 0.001$). A $t$ test conducted on the results of the 0.2-mg/ml ergotamine tartrate experiments indicated that 20 mg of caffeine/ml had a significantly greater effect on ergotamine absorption than did 10 mg of caffeine/ml ($p < 0.001$). No significant difference was found in the percentage of ergotamine absorbed from loops containing ergotamine tartrate alone at 0.1 or 0.2 mg/ml ($p > 0.1$).

At pH 3.0, analysis of variance indicated that the presence of 20 mg of caffeine/ml in the loops had no significant effect on the extent of absorption of ergotamine ($p > 0.05$).

The position of the loop relative to the pylorus also had no significant effect on the amount of ergotamine absorbed at pH 3.0 or 5.0 ($p > 0.1$).

*Effect of Isosorbide Dinitrate*—The efficiency of the recovery process was demonstrated in the time zero experiments. The mean recovery of ergotamine from 10 loops (five rats) containing 0.2 mg of ergotamine tartrate/ml was 82 ± 5%; in the presence of 2 mg of isosorbide dinitrate/ml, it was 83 ± 5%. Analysis of variance demonstrated that neither the presence of isosorbide dinitrate nor loop position had a significant effect on ergotamine recovery ($p > 0.1$).

In the caffeine experiments, the recovery of ergotamine from loops containing 0.2 mg of ergotamine tartrate/ml alone was 97 ± 3%. The major difference between the caffeine and isosorbide dinitrate recovery experiments was the inclusion, for solubility, of 10% dimethyl sulfoxide in the pH 5.0 acetate buffer in the latter experiments. Comparison of the results using a $t$ test showed that dimethyl sulfoxide significantly affected ergotamine recovery ($p < 0.001$), but the reason for this effect is not known. The results are listed in Table II.

The ergotamine absorption figures are corrected by the factor "100/percentage of ergotamine recovered in time zero studies." This correction was necessary since the time zero studies indicated that extraction did not produce complete recovery of the ergotamine remaining in the loop. Analysis of variance indicated that isosorbide dinitrate had a significant effect on ergotamine absorption at the 5% confidence level ($0.05 > p > 0.01$) when ergotamine alone and when ergotamine plus isosorbide dinitrate were administered to the same rats. Loop position had no significant effect on absorption ($p > 0.1$).

In the second series of isosorbide dinitrate experiments, all five loops of a rat contained only one test solution. The corrected figures for the mean percentage absorption of ergotamine from loops containing ergotamine tartrate alone and from loops containing ergotamine tartrate plus isosorbide dinitrate were 19 ± 12 and 39 ± 8%, respectively. A $t$ test indicated that ergotamine absorption in rats in which all loops contained ergotamine tartrate plus isosorbide dinitrate was significantly greater than in rats in which all loops contained only ergotamine tartrate ($p < 0.001$).

The effect of isosorbide dinitrate in loops adjacent to those containing ergotamine tartrate alone was tested by comparing ergotamine absorption from the rats in the first series of experiments, where the adjacent loops contained isosorbide dinitrate, with the rats in the second series of experiments where all loops contained ergotamine tartrate only. The absorption in these two cases was 34 ± 7 and 19 ± 12%, respectively. A $t$ test indicated that isosorbide dinitrate in intestinal loops adjacent to the loops under study significantly increased ergotamine absorption, compared to similar loops in rats in which no isosorbide dinitrate was present ($0.01 > p > 0.002$).

## DISCUSSION

It was established previously that caffeine and ergotamine form one or more molecular complexes in water, but no attempt was made to calculate equilibrium constants for these reactions (14, 23).

Figure 1 shows the phase solubility diagram of ergotamine neutral molecule (E) in solutions of neutral caffeine (C). Measurements were made at pH 8 5. Caffeine was within its solubility when its concentrations were between 0 and $7 \times 10^{-2}$ $M$ (24). Solutions to which $12 \times 10^{-2}$ $M$ or more caffeine had been added were saturated with respect to caffeine. These results are consistent with ergotamine and caffeine forming 1:1 (EC) and 1:2 ($EC_2$) complexes (Schemes I and II):

$$E + C \overset{K_1}{\rightleftharpoons} EC$$

*Scheme I*

$$EC + C \overset{K_2}{\rightleftharpoons} EC_2$$

*Scheme II*

where:

$$K_1 = \frac{[EC]}{[E][C]} \qquad \text{(Eq. 1)}$$

$$K_2 = \frac{[EC_2]}{[EC][C]} \qquad \text{(Eq. 2)}$$

According to this model, the total amount of ergotamine in solution under any set of conditions, $[E]_T$, would be:

$$[E]_T = [E] + [EC] + [EC_2] \qquad \text{(Eq. 3)}$$

and the total amount of caffeine in solution, $[C]_T$, would be:

$$[C]_T = [C] + [EC] + 2[EC_2] \qquad \text{(Eq. 4)}$$

Because $[E]_T$ only varied between 1 and $34 \times 10^{-6}$ $M$ when the added caffeine concentration was varied between 0 and $6 \times 10^{-2}$ $M$, it could be assumed that $[C]_T \equiv [C]$ in all experiments performed.

On the ascending portion of the curve (*i.e.*, where the solutions were saturated with respect to ergotamine but not with respect to caffeine), [E] is the value of $[E]_T$ when [C] = 0.

Substitution of Eqs. 1 and 2 in Eq. 3 and rearrangement yield:

$$\frac{[E]_T - [E]}{[E][C]} = K_1 + K_1K_2[C] \qquad \text{(Eq. 5)}$$

Hence, if the model is compatible with the data, a plot of the left side of Eq. 5 against [C] should be linear. The value of the intercept of this line when [C] = 0 would be $K_1$, and the slope to intercept ratio would be $K_2$.

The results in Fig. 4 show that this plot is essentially linear. A least-

**Table II—Absorption of Ergotamine from the Rat Small Intestine in the Presence and Absence of Isosorbide Dinitrate at pH 5.0**

| Test Solution | Mean Percentage of Ergotamine Extracted from Loops after 2.5 hr | Mean Corrected Percentage of Ergotamine Remaining in Loops after 2.5 hr | Mean Percent Absorption of Ergotamine after 2.5 hr |
|---|---|---|---|
| Ergotamine tartrate, 0.2 mg/ml | 54.0 ± 6.0[a] | 65.9 ± 7.3[a] | 34.1[a] |
| | 66.4 ± 9.8[b] | 81.0 ± 12.0[b] | 19.0[b] |
| Ergotamine tartrate, 0.2 mg/ml, plus isosorbide dinitrate, 2 mg/ml | 48.2 ± 6.2[a] | 57.9 ± 7.5[a] | 42.1[a] |
| | 50.6 ± 9.8[b] | 61.0 ± 8.0[b] | 39.0[b] |

[a] Both solutions were administered to each rat. [b] Either ergotamine tartrate alone or ergotamine tartrate plus isosorbide dinitrate was administered to each rat.

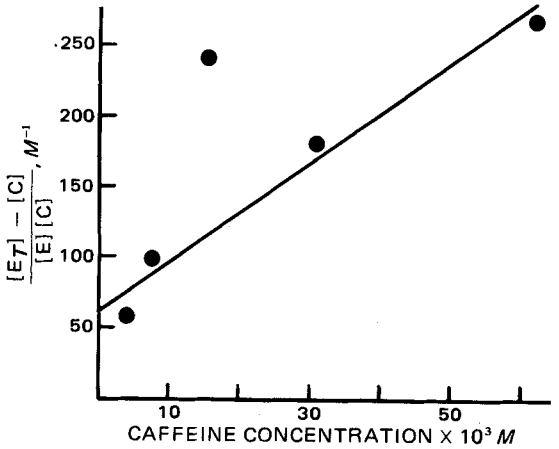

**Figure 4**—*Plot of $([E]_T - [E])/[E][C]$ against [C] for complexation of caffeine and ergotamine at pH 8.5.*

squares linear regression ($r^2 = 0.974$) of the results yielded values for $K_1$ and $K_2$ of 62 and 55 $M^{-1}$, respectively.

One test of the validity of this model comes from consideration of the results obtained in solutions saturated with caffeine (*i.e.*, when the concentration of added caffeine was greater than $12 \times 10^{-2}$ *M*). Under these conditions, a rearranged form of Eq. 5 suggests:

$$[E]_T = [E](1 + K_1[C]_S + K_1K_2[C]_S^2) \qquad \text{(Eq. 6)}$$

where $[C]_S$ is the caffeine solubility. It can be seen from Fig. 1 that, as required by Eq. 6, the value of $[E]_T$ is essentially independent of the concentration of added caffeine when the solubility of caffeine is exceeded. Solution of Eq. 6 for the solubility of caffeine yields a value of 8–9 $\times 10^{-2}$ *M*. Previous studies (24) showed that caffeine has a solubility of $1.8 \times 10^{-1}$ *M* in water but that this value was depressed by increasing the ionic strength (*e.g.*, $4.5 \times 10^{-2}$ *M* at pH > 8.5 when the ionic strength was adjusted to 3.0 *M* with sodium chloride). Hence, a value for caffeine solubility between 8 and $9 \times 10^{-2}$ *M* in a solution containing buffer salts and saturated with respect to ergotamine appears to be reasonable.

A similar analysis was made of the phase solubility diagram of ergotamine in caffeine solutions at pH 2.0 (23). Under these conditions, ergotamine is essentially completely protonated ($EH^+$), and caffeine is essentially present as a neutral molecule. The 1:1 ($ECH^+$) and 1:2 ($EC_2H^+$) complexes probably also would be essentially completely protonated (Schemes III and IV). Hence, the relevant reactions would be:

$$EH^+ + C \overset{K_3}{\rightleftharpoons} ECH^+$$

*Scheme III*

$$ECH^+ + C \overset{K_4}{\rightleftharpoons} EC_2H^+$$

*Scheme IV*

By similar reasoning to that outlined for reactions at pH 8.5, this model requires that a plot of $([E]_T - [EH^+])/([EH^+][C])$ against [C] should be linear with the intercept when [C] = 0 is equal to $K_3$ and the slope to intercept value is equal to $K_4$. A linear regression analysis of the results in Fig. 5 (which were computed from data in Ref. 23) yielded values of $K_3$ and $K_4$ of 204 and 44 $M^{-1}$, respectively. The standard deviation of the line was 0.98.

Consideration of the values of $K_1$, $K_2$, $K_3$, and $K_4$ gives some insight into the nature of the complexation reaction. Hence, the strongest complexation reaction involves caffeine and ergotamine cation ($K_3$ = 204 $M^{-1}$). The positive charge in the complex that is formed ($ECH^+$) apparently must be largely neutralized or buried since the complexation of caffeine with $ECH^+$ ($K_4$ = 44 $M^{-1}$) is a similar reaction to that of caffeine with the ergotamine neutral molecule ($K_1$ = 62 $M^{-1}$) or the neutral caffeine–ergotamine complex ($K_2$ = 55 $M^{-1}$).

***In Vitro* Absorption of Ergotamine**—The results in Fig. 2 show clearly that caffeine (10 mg/ml) significantly increased the rate at which ergotamine (initially 0.1 mg/ml) passed from the mucosal to the serosal side of the rat intestine when the pH of the contents of the former side was 5.0.

One important feature is that ergotamine was in solution on the mucosal side of the membrane. Hence, caffeine could not exert its accelerating effect on ergotamine absorption by increasing the dissolution rate of solid ergotamine. Caffeine's role in this latter process was suggested as its major role in enhancing ergotamine absorption following its administration as a solid (14).

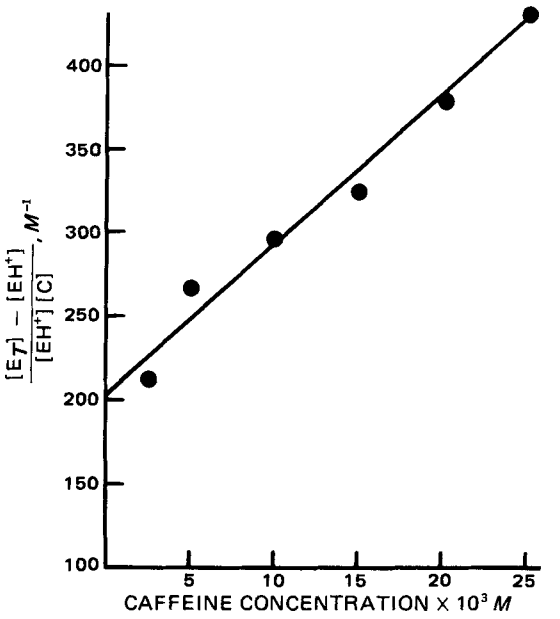

**Figure 5**—*Plot of $([E]_T - [EH^+])/[EH^+][C]$ against [C] for complexation of caffeine and ergotamine cation at pH 2.0.*

Another feature is that no blood supply was available to the intestine. Consequently, caffeine could not exert its effect by changing the blood flow rate. These results will be discussed in conjunction with the results of the *in situ* studies.

***In Situ* Absorption of Ergotamine**—The *in situ* experiments differed from the *in vitro* experiments in that an intact blood supply was present. However, as in the former experiments, ergotamine was in solution in the intestinal lumen, so the dissolution rate could not be a rate-determining factor in absorption. The results of experiments at pH 3 and 5 in both the absence and presence of caffeine are presented in Table I.

One point of interest concerns the effect, or apparent lack of effect, that varying the pH from 3 to 5 had on the absorption of the weakly basic ergotamine (pKa of conjugate acid = 6.4). Hence, although the absorption rate of ergotamine was similar at pH 3 and 5, the percent composition of the ergotamine neutral molecule in solution varied approximately 100-fold, from 0.04% at pH 3 to 3.8% at pH 5. Throughout the same pH range, the composition with respect to ergotamine cation varied from 99.96 to 96.2%.

The results in Table I also show that, at pH 3.0, the absorption rate of ergotamine (initial concentration of ergotamine tartrate 0.2 mg/ml) was the same in either the absence or the presence of caffeine (10 mg/ml). The solutions that did not contain caffeine contained 99.96% ergotamine cation and 0.04% ergotamine neutral molecule. The composition of the solutions with respect to ergotamine species are shown in Table III. Values of $K_1$, $K_2$, $K_3$, and $K_4$ for the reactions shown in Schemes I–IV, respectively, and a $K_a$ value for ergotamine of $3.98 \times 10^{-7}$ *M* were used to compute these results. Hence, while the concentration of ergotamine cation decreased from 99.96% in the absence of caffeine to 2.8%, the total concentration of ergotamine cation plus protonated complexes remained essentially constant.

The situation at pH 5.0 was quite different, because caffeine (10 or 20 mg/ml) significantly increased the absorption rate of ergotamine. The extent to which caffeine increased the absorption rate in the *in situ* experiments was similar to that in the *in vitro* experiments.

**Table III—Composition [a], as a Percentage of Total Ergotamine Species, of Solutions Containing Ergotamine (0.2 mg/ml) and Caffeine (10 mg/ml) at pH 3.0 and 5.0**

| | Concentration, % | | | | | |
|---|---|---|---|---|---|---|
| pH | $EH^+$ | $ECH^+$ | $EC_2H^+$ | E | EC | $EC_2$ |

[a] Calculated as described in the text.

These results are consistent with a model for GI absorption of basic drugs described earlier (25). The appropriate model (Model A in Ref. 25) assumes that neutral molecules, but not ions, rapidly pass from the aqueous environment of the lumen into the lipoidal GI membrane and that equilibrium between these two phases is established rapidly. The slow step in overall absorption is the transport of neutral molecules from the lipoidal membrane into the aqueous blood compartment. The model for ergotamine absorption is shown schematically in Scheme V. According to this model, the rate of drug appearance in the blood is proportional to the concentration of neutral drug molecules in the membrane. Hence:

$$\text{absorption rate} = k_E[E]_m V_m + k_{EC}[EC]_m V_m + k_{EC_2}[EC_2]_m V_m \quad \text{(Eq. 7)}$$

where the terms in brackets with subscript $m$, $[\ ]_m$, refer to the concentration of the various species in the membrane and $V_m$ is the volume of the membrane. By definition:

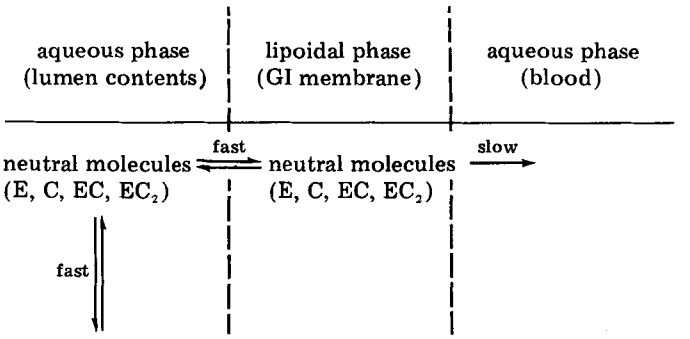
$$P_E = \frac{[E]_m}{[E]_w} \quad \text{(Eq. 8)}$$

$$P_{EC} = \frac{[EC]_m}{[EC]_w} \quad \text{(Eq. 9)}$$

$$P_{EC_2} = \frac{[EC_2]_m}{[EC_2]_w} \quad \text{(Eq. 10)}$$

where the $P$ symbols are the intrinsic partition coefficients for the three ergotamine species between the aqueous contents of the lumen and the membrane and the terms in brackets with subscript $w$, $[\ ]_w$, refer to the concentrations of the various species in water.

Substitution of Eqs. 8–10 in Eq. 7 and expression of the various concentration terms as fractions of the total amount of ergotamine in the lumen contents and in the membrane $E_T$ yield:



*Scheme V*

$$\text{rate of absorption} = \frac{(k_E P_E K_a + k_{EC} P_{EC} K_1 K_a [C]_w + k_{EC_2} P_{EC_2} K_1 K_2 K_a [C]_w^2) E_T}{\frac{V_w}{V_m}[K_a + 1 + K_3[C]_w + K_3 K_4 [C]_w^2 [H^+] + K_1 K_a [C]_w + K_1 K_2 K_a [C]_w^2] + K_a (P_E + P_{EC} K_1 [C]_w + P_{EC_2} K_1 K_2 [C]_w^2)} \quad \text{(Eq. 11)}$$

where $V_w$ is the volume of the aqueous lumen contents and $[C]_w$ is the concentration of caffeine in the lumen contents. If transport of a species, $i$, from the lipoidal membrane across an aqueous barrier and into the blood is the rate-determining process, then, from Fick's first law:

$$k_i = \frac{D_i A_i P_i}{h_i} \quad \text{(Eq. 12)}$$

where $D_i$ is the diffusion coefficient of the $i$ species in an aqueous barrier of surface area $A_i$ and thickness $h_i$, and $P_i$ is the partition coefficient of the species $i$ from the lipoidal membrane into the aqueous phase. This model assumes transport into a sink. If the following additional assumptions are made:

1. The values of the diffusion coefficients for the species E, EC, and $EC_2$ are equal and have the value $D$
2. The partition coefficients of the species from the lipoidal membrane into blood are the inverse of the $P$ values in Eq. 11, which were for partitioning from the aqueous lumen contents into the membrane

then substitution of the terms defined in Eq. 12 into Eq. 11 and rearrangement lead to:

$$\text{rate of absorption} = \frac{\frac{DA}{h} E_T}{\frac{V_w}{V_m} + \frac{V_w}{V_m}\frac{[H^+]}{K_a}\left\{\frac{1 + K_3[C]_w + K_3 K_4 [C]_w^2}{1 + K_1[C]_w + K_1 K_2 [C]_w^2}\right\} + P_E\left\{\frac{1 + \frac{P_{EC}}{P_E} K_1 [C]_w + \frac{P_{EC_2}}{P_E} K_1 K_2 [C]_w^2}{1 + K_1[C]_w + K_1 K_2 [C]_w^2}\right\}} \quad \text{(Eq. 13)}$$

where $A$ and $h$ are the surface area and thickness of the barrier.

When caffeine is absent, Eq. 13 reduces to:

$$\text{rate of absorption} = \frac{\frac{DA}{h} E_T}{\frac{V_w}{V_m} + \frac{V_w}{V_m}\frac{[H^+]}{K_a} + P_E} \quad \text{(Eq. 14)}$$

Hence, the model would be consistent with the data that showed that the absorption rate did not change as $[H^+]$ increased from $10^{-5}$ to $10^{-3}$ $M$ if the value of $P_E \gg (V_w/V_m)\ 2.5 \times 10^3$. This seems reasonable since $P_E$ is expected to be very large. The Merck Index (26) states that ergotamine is "freely soluble in chloroform" and "only slightly soluble in water."

The approximate doubling of the rate of ergotamine absorption in the presence of caffeine ($5.15 \times 10^{-2}$ $M$) when the pH was increased from 3 to 5 needs to be explained. The model would be consistent with this result if, in the presence of caffeine, the term in the denominator that contained $[H^+]$ and the term containing $P_E$ were of comparable value at pH 3. But if the term containing $P_E$ was much greater than the term containing $[H^+]$ at pH 5, although still being slightly less than the value of $P_E$, knowledge of the values of the equilibrium constants $K_1$, $K_2$, $K_3$, and $K_4$ indicate that the term containing $[H^+]$ would be greater in the presence of $5.15 \times 10^{-2}$ $M$ caffeine than in its absence by a factor of 2.7. The value of the term containing $P_E$ is not known precisely, but it is reasonable to expect that it would be less than $P_E$. This situation would arise if the values of the partition coefficients $P_{EC}$ and $P_{EC_2}$ were smaller than $P_E$. Although the values of these terms are not known, the phase solubility study (Fig. 1) reveals that the complexes EC and $EC_2$ have significantly higher water solubility than ergotamine. Hence, it is not unreasonable to assume that they will have a smaller tendency than ergotamine to partition into a lipoidal phase.

This model leads to the conclusion that the water-solubilizing effect of caffeine on ergotamine neutral molecules is a major factor in its accelerating effect on ergotamine absorption.

Zoglio and coworkers (14, 27, 28), in discussing the rate-accelerating effect of caffeine on the partitioning of ergotamine and related alkaloids from water to chloroform at pH 6.5, but not at pH 1.0, proposed that it did so by "preventing precipitation" of ergotamine prior to its absorption. In the present study, precipitation was not possible because solutions were not saturated with respect to ergotamine. However, the two theories are consistent in that both credit caffeine's role to the increased water solubility that it confers on the ergotamine neutral molecule.

**Effect of Isosorbide Dinitrate on Ergotamine Absorption**—Isosorbide dinitrate significantly increased the rate of ergotamine absorption. However, the nature of its effect was quite different than that of caffeine. For example, the presence of caffeine in intestinal loops adjacent to loops in the same rat that only contained ergotamine did not significantly increase the rate of ergotamine absorption. On the other hand, the presence of isosorbide dinitrate in any intestinal loop increased the rate of ergotamine absorption in other loops in the rat that did not contain isosorbide dinitrate.

Since isosorbide dinitrate is a vasodilator (29), it probably increases the rate of ergotamine absorption by increasing the rate of intestinal blood flow. This conclusion is consistent with the earlier postulate that the rate-determining step in ergotamine absorption is its rate of passage from the membrane into the blood rather than its passage into or through the membrane.

Caffeine is also a vasodilator (30); at a concentration of 2 mg/ml, it increased intestinal blood flow by 166% in anesthetized rats and increased the rate of absorption of tritiated water, urea, and antipyrine at pH 8.0 and of salicylic acid at pH 6 (31). Hence, while part of the effect that caffeine has on increasing the absorption of ergotamine at pH 5.0 may be due to its effect on the blood flow rate, this effect is thought to be minor because it does not affect absorption rates at pH 3, it does not affect absorption rates at pH 5 from adjacent loops that do not contain caffeine, and it exerts an accelerating effect on ergotamine absorption in *in vitro* experiments where no blood supply is present.

## CONCLUSION

1. Caffeine increases the rate of ergotamine absorption from the rat small intestine when the pH of the intestinal contents is 5.0 but not when it is 3.0. This effect is independent of the effect that caffeine exerts on the dissolution rate of ergotamine because, in the experiments performed, ergotamine was administered as a stable solution.

2. Although caffeine increases intestinal blood flow, this property only plays a minor role in its absorption-accelerating effects at pH 5.0. Vasodilation and increased blood flow are likely to explain the rate-accelerating effect of isosorbide dinitrate on ergotamine absorption.

3. The rate-determining step in the absorption of ergotamine appears to be transport from the intestinal membrane into the blood.

# Effect of Poly-2-vinylpyridine-*N*-oxide and Sucrose on Silicate-Induced Hemolysis of Erythrocytes

**DENNIS W. OSCARSON *, GEORGE E. VAN SCOYOC ‡x, and JAMES L. AHLRICHS ‡**

Received May 9, 1980, from the **Saskatchewan Institute of Pedology, University of Saskatchewan, Saskatoon, Saskatchewan, Canada S7N 0W0,* and the ‡*Department of Agronomy, Purdue University, West Lafayette, IN 47907.* Accepted for publication November 19, 1980.

**Abstract** □ The biological activity of montmorillonite, palygorskite, kaolinite, chrysotile, and silica was examined using *in vitro* hemolysis of erythrocytes. The hemolytic potency was in the order montmorillonite > silica > palygorskite > chrysotile > kaolinite. The polymer poly-2-vinylpyridine-*N*-oxide inhibited hemolysis caused by montmorillonite, palygorskite, kaolinite, and silica, but it was less effective with chrysotile. The extent of polymer binding to the silicates and red blood cells was measured by UV spectroscopy. When sucrose was substituted for the saline solution as the incubating medium, hemolysis was eliminated in all systems except chrysotile–erythrocyte, where it was enhanced. The results indicate that both hydrogen bonding and ionic interactions between silicate surfaces and the erythrocyte membrane are important in the hemolytic process.

**Keyphrases** □ Silicates—effect of poly-2-vinylpyridine-*N*-oxide on silicate-induced hemolysis □ Hemolysis—effect of poly-2-vinylpyridine-*N*-oxide, silicates □ Suspending agents—effect of poly-2-vinylpyridine-*N*-oxide on silicate-induced hemolysis

Inhaled silicate particles cause various pathological disorders (1). In addition to pulmonary tissue damage, the particles can potentially damage other body tissues because silicates such as montmorillonite, kaolinite, and palygorskite are used in many pharmaceuticals and cosmetics (primarily as fillers, stabilizers, and suspending

# Effect of Poly-2-vinylpyridine-*N*-oxide and Sucrose on Silicate-Induced Hemolysis of Erythrocytes

**DENNIS W. OSCARSON *, GEORGE E. VAN SCOYOC ‡x, and JAMES L. AHLRICHS ‡**

Received May 9, 1980, from the **Saskatchewan Institute of Pedology, University of Saskatchewan, Saskatoon, Saskatchewan, Canada S7N 0W0,* and the ‡*Department of Agronomy, Purdue University, West Lafayette, IN 47907.* Accepted for publication November 19, 1980.

**Abstract** □ The biological activity of montmorillonite, palygorskite, kaolinite, chrysotile, and silica was examined using *in vitro* hemolysis of erythrocytes. The hemolytic potency was in the order montmorillonite > silica > palygorskite > chrysotile > kaolinite. The polymer poly-2-vinylpyridine-*N*-oxide inhibited hemolysis caused by montmorillonite, palygorskite, kaolinite, and silica, but it was less effective with chrysotile. The extent of polymer binding to the silicates and red blood cells was measured by UV spectroscopy. When sucrose was substituted for the saline solution as the incubating medium, hemolysis was eliminated in all systems except chrysotile–erythrocyte, where it was enhanced. The results indicate that both hydrogen bonding and ionic interactions between silicate surfaces and the erythrocyte membrane are important in the hemolytic process.

**Keyphrases** □ Silicates—effect of poly-2-vinylpyridine-*N*-oxide on silicate-induced hemolysis □ Hemolysis—effect of poly-2-vinylpyridine-*N*-oxide, silicates □ Suspending agents—effect of poly-2-vinylpyridine-*N*-oxide on silicate-induced hemolysis

Inhaled silicate particles cause various pathological disorders (1). In addition to pulmonary tissue damage, the particles can potentially damage other body tissues because silicates such as montmorillonite, kaolinite, and palygorskite are used in many pharmaceuticals and cosmetics (primarily as fillers, stabilizers, and suspending

*© 1981, American Pharmaceutical Association*

agents); consequently, silicate particles are ingested in relatively large quantities or applied directly to the skin. Palygorskite (attapulgite) also has a fibrous morphology somewhat similar to chrysotile asbestos.

The effect of silicates on cellular membranes may be studied by *in vitro* hemolysis of erythrocytes. Silica (2, 3), the chrysotile variety of asbestos (4, 5), sepiolite and palygorskite (5, 6), kaolinite (7), and montmorillonite and illite (7) are known to induce *in vitro* hemolysis.

The weakly basic polymer poly-2-vinylpyridine-*N*-oxide (I) is an effective preventative against experimental silicosis (8). It also protects erythrocytes against the hemolytic action of various silica forms (9, 10) but is less effective in preventing chrysotile-induced hemolysis (5). Little is known about the effect of I on hemolysis caused by other silicates.

The purposes of this study were to determine the effect of I and sucrose on hemolysis caused by montmorillonite, kaolinite, and palygorskite and to compare these systems with the silica- and chrysotile–erythrocyte systems, which have been the most extensively studied systems. In addition, the extent of I binding to the silicates and erythrocytes was determined.

## EXPERIMENTAL

**Silicates**—Montmorillonite[1], kaolinite[1], and palygorskite[2] samples were passed through a 300-mesh sieve, and the 50-$\mu$m fraction was used for all studies. Crude chrysotile fibers were separated partially by hand and then ground[3] for 2 min. The silica[4] was a synthetic, amorphous material and was used as received. Samples of the silicates[5] were suspended in deionized water and sonicated[6] for 5 min at 80 w to assure separation and dispersion.

**Erythrocytes and Media**—Bovine blood was drawn by venipuncture directly into a sterile 60-ml polyethylene tube coated with heparin. The red blood cells were washed three times with isotonic phosphate-buffered saline solution (0.106 *M* NaCl, 0.030 *M* $Na_2HPO_4 \cdot 7H_2O$, and 0.008 *M* $KH_2PO_4$). After the final wash, a 3% (v/v) suspension of red blood cells was prepared.

Phosphate buffer (pH 7.3) was used throughout, except for the chrysotile–erythrocyte system. It was reported (10) that phosphate inhibits the hemolytic activity of chrysotile, an observation confirmed in this laboratory. The pH of the chrysotile–erythrocyte system was monitored closely, however, and remained at 7.2 ± 0.1 for the concentration of chrysotile used.

To study the effect of sucrose on silicate-induced hemolysis, 0.250 *M* sucrose (0.250 *M* sucrose is isotonic with 0.145 *M* NaCl) was substituted for the saline solution as the incubating medium.

**Hemolysis Technique**—Glass test tubes (10 × 75 ml) were used for all hemolysis studies. The silicate–red blood cell suspensions consisted of the following and were prepared in the order given: 1 ml of a silicate suspension, 3 ml of the phosphate-buffered saline solution (sodium chloride alone for the chrysotile–erythrocyte system), and 1 ml of the 3% suspension of red blood cells. For the study of the effect of I on silicate-mediated hemolysis, the polymer was added to the described mixture immediately after the silicate suspension. The total volume of the mixture was always 5 ml. A sample consisting of 4 ml of the phosphate-buffered saline solution and 1 ml of the 3% suspension of red blood cells served as a control for the possible fragility of the erythrocytes.

The test tubes were sealed[7] and gently rotated end-over-end for 1 hr at room temperature. The suspensions then were centrifuged at 1500×*g* for 5 min, and the absorbance of the supernatant solution was measured spectrophotometrically[8] at 541 nm with the control sample as the reference. The degree of hemolysis was expressed as a percentage of a totally lysed sample.

**Table I—Percentage Hemolysis Produced by the Silicates in the Presence of I**

| Silicate[a] | I Concentration, $\mu M$/ml | |
|---|---|---|
| | 0.2 | 1.0 |
| Montmorillonite | 23 ± 2[b] | ND[c] |
| Palygorskite | 20 ± 3 | 3 ± 2 |
| Kaolinite | 50 ± 2 | 20 ± 5 |
| Silica | 7 ± 4 | ND |
| Chrysotile | 50 ± 1 | 42 ± 4 |

[a] The $HC_{50}$ concentrations of the silicates were used (see text). [b] Mean ± *SD*, % ($n = 4$). [c] No detectable hemolysis.

**Binding of I**—The UV spectrum of I gives a $\lambda_{max}$ equal to 260 nm in water (11); therefore, the extent of polymer binding to the silicates and erythrocytes can be measured conveniently.

Twenty milligrams of a silicate or 10 ml of a 6% suspension of red blood cells and 1 mg of I were added to 20 ml of the phosphate-buffered saline solution in 100-ml volumetric flasks. The flasks then were brought to volume with deionized water (phosphate-buffered saline solution was used for the erythrocyte–I mixture). After 5 min of periodic shaking, a sample was removed from the flasks, placed in polypropylene centrifuge tubes, and centrifuged at 40,000×*g* for 10 min. A sample of the supernate was transferred to a quartz cell, and the absorbance was measured[9] at 260 nm.

The following formula was used to calculate the percentage of 1 mg of I bound to 20 mg of the silicate or 10 ml of a 6% suspension of red blood cells:

$$\% \text{ bound} = [A_p - (A_s - A_m)/A_p] \times 100 \qquad \text{(Eq. 1)}$$

where $A_p$ is the absorbance of a 0.001% (w/v) solution of I, $A_s$ is the absorbance of the supernate after centrifugation of a mixture of 0.001% I and a 0.02% (w/v) silicate or 0.6% (v/v) erythrocyte suspension, and $A_m$ is the absorbance of the supernate after centrifugation of a 0.02% silicate or 0.6% erythrocyte suspension.

## RESULTS AND DISCUSSION

To facilitate meaningful comparisons between the silicates, the concentration of the silicate that caused 50% hemolysis when incubated with 1 ml of a 3% suspension of erythrocytes was determined. This concentration[10] (in milligrams of silicate per milliliter of silicate–erythrocyte-buffer suspension) was as follows for the five silicates examined: montmorillonite, 0.006; silica, 0.03; palygorskite, 0.06; chrysotile, 0.1; and kaolinite, 0.6. The use of the $HC_{50}$ concentration partially compensated for physical as well as chemical differences in the untreated silicates. There appeared to be a correlation between the specific surface area of the silicates [montmorillonite > silica ≥ palygorskite > kaolinite ≥ chrysotile (12–14)] and their hemolytic activity.

It was confirmed that I is very effective in inhibiting hemolysis caused by silica, but it was much less effective with chrysotile (Table I). The polymer also decreased hemolysis produced by montmorillonite, palygorskite, and kaolinite, although its effect was somewhat less than on silica-induced hemolysis (Table I).

Two hypotheses concerning the mechanism of interaction between silica and the erythrocyte membrane have been proposed: (*a*) hydrogen bonding (9) of the silanol groups on the silica surface with the phosphate ester linkages of phospholipids and the amide groups of proteins, and (*b*) ionic interaction (15) between dissociated silanol groups on the silica surface and positively charged species on the erythrocyte membrane surface.

Compound I is a strong hydrogen bonding material; therefore, its effectiveness in preventing silica-induced hemolysis suggests that hydrogen bonding is the predominant mode of interaction between silica and the erythrocyte membrane during hemolysis. The polymer apparently bonds to the silanol groups on the silica surface and thus prevents these groups from contacting the red blood cell membrane.

Because I also inhibits hemolysis caused by montmorillonite, paly-

**Table II—Amount of I Bound to the Silicates and to Erythrocytes**

| Material | I Bound[a], % |
|---|---|
| Montmorillonite | 100 |
| Palygorskite | 97 ± 2[b] |
| Kaolinite | 48 ± 3 |
| Silica | 96 ± 1 |
| Chrysotile | 37 ± 4 |
| Erythrocytes | 4 ± 1 |

[a] One milligram of I was added to 20 mg of the silicates or 10 ml of a 6% suspension of erythrocytes in a total volume of 100 ml. [b] Mean ± *SD*, % ($n$ = 4).

gorskite, and kaolinite (Table I), a hydrogen bonding mechanism probably is at least partially involved in these systems. The three silicates, montmorillonite, palygorskite, and kaolinite, have many surface hydroxyl groups bound to the cations (predominantly silicon, aluminum, and magnesium exposed at crystal edges) (16, 17); these hydroxyl groups could function as hydrogen donors. Furthermore, montmorillonite has a high cation-exchange capacity (12), and the water of hydration of the exchangeable cations also can function as hydrogen donors (18).

Chrysotile, on the other hand, is a fibrous, tubular magnesium silicate with the silica sheets on the inner side and the magnesium hydroxide sheets exposed at the surface. Since the pK of chrysotile is close to 11 (19), it has a positive surface charge at physiological pH values. Compound I is relatively ineffective in preventing chrysotile-induced hemolysis (Table I), while many anionic species such as phosphate and ethylenediaminetetraacetic acid are effective inhibitors (10, 20). This fact suggests that little hydrogen bonding is involved in the chrysotile–erythrocyte system. An ionic interaction between chrysotile and the red blood cell membrane has been proposed (21).

The effect of I on silicate-induced hemolysis previously has not been clearly interpretable; it could affect the surface of the silicate, the erythrocyte membrane, or both. The data in Table II clearly show that erythrocytes bind very little of the polymer while it is readily bound to montmorillonite, palygorskite, and silica and to a lesser extent to kaolinite and chrysotile. Therefore, I probably exerts its protective action by blocking the lytic sites on the surfaces of the silicates.

When sucrose was substituted for the saline solution as the incubating medium, no hemolysis was observed when the $HC_{50}$ concentrations of montmorillonite, palygorskite, kaolinite, and silica were incubated with erythrocytes. The sucrose molecule has many potential hydrogen-accepting sites, so it can form preemptive hydrogen bonds with the hydrogen-donating surface groups of montmorillonite, palygorskite, kaolinite, and silica. Consequently, these hydrogen-donating groups cannot contact the erythrocyte membrane and hemolysis cannot occur.

In contrast, erythrocytes incubated in sucrose underwent increased lysis (65% ± 4, $n$ = 4) when the $HC_{50}$ concentration of chrysotile was used. If the chrysotile–erythrocyte interaction is predominantly ionic, the interaction would be enhanced in a medium of relatively low dielectric constant such as sucrose, and this reaction is what was observed.

A recent report indicated a correlation between hyperplastic changes in isolated hamster trachea segments and *in vitro* hemolysis of erythrocytes by chrysotile asbestos and montmorillonite (22). Elucidation of the mechanism by which various silicate minerals interact with the erythrocyte membrane *in vitro* may lead to a better understanding of silicate–membrane interactions *in vivo*.

# Acute Hemodynamic Effects and Blood Pool Kinetics of Polystyrene Microspheres following Intravenous Administration

JOHN D. SLACK *§, MOTOKO KANKE ‡, GUY H. SIMMONS *, and PATRICK P. DeLUCA ‡x

Received June 23, 1980, from the *Colleges of *Medicine and ‡Pharmacy, University of Kentucky, and the §Cardiology Section, Veterans Administration Medical Center, University of Kentucky, Lexington, KY 40506. Accepted for publication October 29, 1980.

**Abstract** □ The acute hemodynamic effect of intravenous administration of polystyrene microspheres was investigated and correlated with their distribution pattern and kinetics. Microspheres of three diameters (3.4, 7.4, and 11.6 μm) were administered. The 7.4- and 11.6-μm diameter microspheres were filtered by the pulmonary capillary network following intravenous administration, the majority during the first pass. There was no significant hemodynamic effect following administration of the 7.4- and 11.6-μm diameter microspheres in doses as high as $3.0 \times 10^9$ and $6.1 \times 10^8$, respectively (total cross-sectional area of $1.3 \times 10^{11}$ and $6.4 \times 10^{10}$ $\mu m^2$, respectively). Intravenous administration of 3.4-μm diameter microspheres produced significant dose-dependent systemic hypotension and depression of myocardial performance at dosages as low as $1.0 \times 10^{10}$ (cross-sectional area of $9.1 \times 10^{10}$ $\mu m^2$). These differences in acute hemodynamic effect from the 7.4- and 11.6-μm diameter microspheres may be due to the differences in distribution kinetics and fate of the 3.4-μm diameter microspheres, which readily pass through the lungs to the systemic circulation, with late disposition primarily in the liver and spleen. Although elimination of the smaller spheres from the blood during the first 6–8 min was rapid, *i.e.*, $t_{1/2} = 1.62$ and 1.72 min from the venous and arterial blood circulation, respectively, levels of $10^3$ spheres/g of blood were present in the circulation for >1 hr. These findings must be considered in the planning of intravenous administration of microspheres as a drug delivery system to target organs.

**Keyphrases** □ Microspheres, polystyrene—acute hemodynamic effects and blood pool kinetics following intravenous administration to dogs, drug delivery system to target organs □ Drug delivery system—polystyrene microspheres, acute hemodynamic effects and blood pool kinetics following intravenous administration, dogs □ Kinetics—polystyrene microspheres, distribution and clearance in dogs following intravenous administration, drug delivery system □ Radionuclide imaging agents, potential—$^{141}$Ce-labeled polystyrene microspheres, acute hemodynamic effects and blood pool kinetics evaluated in dogs following intravenous administration

Systemic toxicity of pharmaceutical agents, particularly those used in the chemotherapy of malignancy, has prompted a search for alternative drug delivery methods. Ideally, these methods should be safe, comfortable, and convenient to the patient. To date, attempts at local therapy with surgical implants or chronic catheter placement have achieved only limited success. Intravascular administration of radioactive microspheres has been utilized safely in animals and humans for many years to assess blood flow patterns (1). Detailed investigation regarding their distribution patterns (2, 3), hemodynamic effects (4–6), and induced pathological changes (7, 8) has begun only recently, stimulated by evidence that pharmaceutical agents may be incorporated into subvisible particulates for intravenous administration, with subsequent local release after the particle lodges in the microcirculation (9–11).

While some deaths were recorded in previous studies on microsphere size, distribution time, and distribution pattern in beagle dogs (2, 4, 8), there was little evidence of tissue damage that could be attributed to the microspheres in specific organs. Due to the lack of significant clinical changes, the present study was undertaken to assess the influence of particle size on the hemodynamic changes associated with the intravenous administration of relatively large aggregate-weight bolus injections of microspheres.

## EXPERIMENTAL

**Administration of Microspheres**—Polystyrene divinylbenzene microspheres labeled with cerium 141 were obtained as a suspension in physiological saline from a commercial supplier[1]. The specific activity was ~50 mCi/g; ~500 μCi was administered to each dog. The number of radioactive spheres was calculated from:

$$\text{number of spheres/mg} = \frac{1.55 \times 10^9}{D^3} \qquad \text{(Eq. 1)}$$

where $D$ is the mean sphere diameter in microns. The nonradioactive spheres[2] were obtained as a 10% suspension in saline. The actual size and number of the microspheres were determined microscopically[3] and with an electronic particle counter[4], respectively. The appropriate dose of microspheres was drawn into a syringe, and an accurate radioactivity count was determined by a radioisotope calibrator[5]. The microspheres then were injected intravenously using a three-way stopcock. After thorough flushing of the syringe and stopcock with saline, the syringe was analyzed to exclude significant retention of the microspheres. Immediately prior to dosage administration, the vial of microspheres was placed in an ultrasonic bath for 15 min to ensure dispersion of the spheres. A surfactant, polysorbate 80, was not used in the preparation of the microspheres due to its adverse hemodynamic effect (12).

**Preparation of Animals**—Female beagle dogs, 13.0–15.0 kg, were randomly assigned to receive 3.4, 7.4, or 11.6-μm diameter microspheres. Following endotrachael intubation, anesthesia was maintained with a mixture of 1–2.5% halothane (depending on the blood pressure response and desired level of anesthesia) and oxygen delivered by a mechanical respirator. A left thoracotomy was performed, and a micromanometer-tipped catheter[6] was inserted into the left ventricle to measure systolic pressure. The rate of change of the left ventricular pressure ($dp/dt$) was derived electronically. A pair of ultrasonic piezoelectron crystals was implanted in the left ventricular subendocardial wall to measure regional myocardial wall motion and, by inference, left ventricular volume.

Micromanometer-tipped catheters[7] were inserted into the pulmonary artery and descending aorta to measure pulmonary artery pressure. A thermistor-tipped catheter[8] also was placed in the pulmonary artery to enable serial thermodilution cardiac output determinations. Catheters were positioned in the right atrium and descending aorta to allow ease in blood sampling from the venous and arterial circulation, respectively. The surface ECG was monitored continuously. The micromanometer-tipped catheters were referenced to zero and calibrated with a mercury manometer before insertion. Correction for micromanometer transducer drift was performed by superimposing electronically derived mean

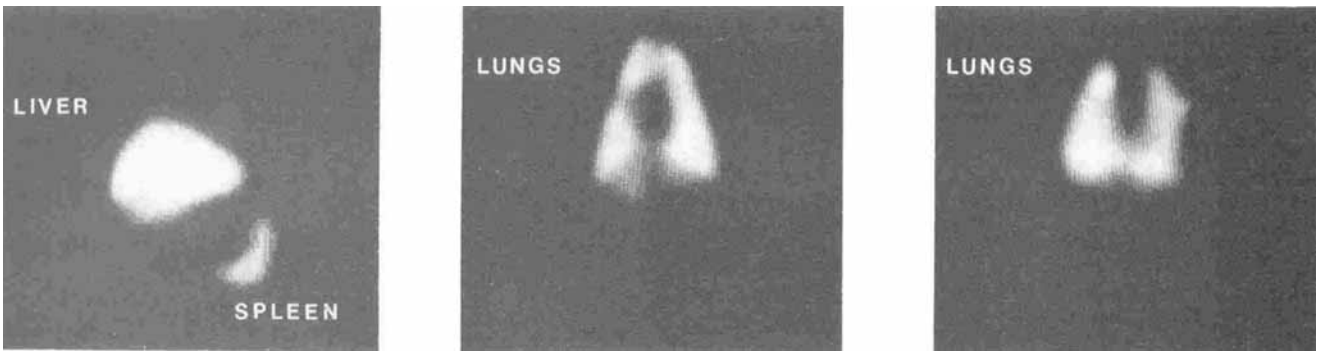

**Figure 1**—*Distribution of $^{141}$Ce-labeled microspheres as determined by external nuclear imaging 3.5 hr following intravenous administration. The larger microspheres (7.4 μm in Dog 6 and 11.6 μm in Dog 4) were localized in the lungs, whereas the smaller (3.4 μm in Dog 1) microspheres distributed to the liver and spleen.*

pressure against that of a fluid-filled catheter system connected to a pressure transducer[9] positioned at midchest level.

**Hemodynamic Protocol**—Following the surgical instrumentation, each animal was monitored for 30 min to ensure hemodynamic stability. Continuous direct measurements of the surface ECG, pulmonary artery pressure, systemic artery pressure, left ventricular pressure, rate of change of left ventricular pressure ($dp/dt$), and left ventricular segmental wall motion were recorded on magnetic tape[10]. Data were printed at predetermined intervals[11]. Serial duplicate cardiac output determinations were recorded at 20-min intervals[12]. Maximum values of $+dp/dt$ and $-dp/dt$ were determined from electronic differentiation of the left ventricular pressure waveform.

The systolic shortening fraction, which is a measure of the left ventricular regional wall motion, was calculated with ultrasonic segment-length measurement *via* the piezoelectron crystals implanted in the left ventricular subendocardium using the following expression: (end diastolic length − end systolic length)/end diastolic length. All animals were stable throughout the 30-min control period. A control animal was monitored for 3 hr following a placebo injection of physiological saline; this animal remained stable.

Following the 30-min control period, a measured number of $^{141}$Ce-labeled microspheres of a given size (Table I) was administered as a bolus injection into the right atrium. Two dogs received the 3.4-μm diameter size, two received the 7.4-μm diameter size, and two received the 11.6-μm diameter size microspheres. Hemodynamic measurements and venous and arterial blood samples were taken every 2 min for 40 min, every 5 min for 20 min, and then every 10 min for the next 2 hr.

At the conclusion of the 3-hr monitoring period, a second bolus injection of nonradioactive microspheres of the same diameter (Table I) was administered slowly (~8 ml/min) to assess possible hemodynamic effects of larger doses. Then 3.5 hr after administration of the radioactive microspheres, each animal was sacrificed and sent for nuclear scanning. Two additional dogs were instrumented similarly for additional dosing with nonradioactive 3.4-μm diameter microspheres to complete the dose–response curve.

**Scanning of Dogs**—With a digital computer[13] attached to a scintillation camera[14], distribution of the radioactive microspheres was assessed by whole body scanning.

**Blood Level of Spheres**—Blood samples removed during the 3-hr study were analyzed for radioactivity using a well-type γ-counter[15]. Application of the appropriate calibration equation yielded results in microspheres per gram of blood.

## RESULTS

**Nuclear Scanning**—Consistent with previous results, the radioactivity was confined principally to the lungs (>90%) in animals administered $^{141}$Ce-labeled 7.4- and 11.6-μm diameter microspheres. The animals given 3.4-μm diameter microspheres had little activity (~12%) remaining in the lungs 3.5 hr following administration, the majority (~83%) of the radioactive particles having accumulated in the liver and spleen (Fig. 1). Table II summarizes the results of external analysis of these organs and demonstrates the clear tendency of the microspheres to distribute in a size-dependent organ-specific pattern.

**Table I—Dosing Information**

| Dog | Microsphere Size, μm | Number | CSA[a], μm² | Weight, mg |
|---|---|---|---|---|

| 8NR | 3.4 | $9.55 \times 10^{10}$ | $8.67 \times 10^{11}$ | 2388 |

[a] CSA = cross-sectional area. [b] NR = dose of nonradioactive spheres. [c] LNR = large dose of nonradioactive spheres.

**Blood Pool Kinetics**—Serial measurements of circulating microsphere levels from venous and arterial sites drawn following intravenous administration of $^{141}$Ce-labeled microspheres are shown graphically by blood level profiles in Fig. 2. The elimination rate of the initial stage following intravenous administration is summarized in Table III. The elimination rate constant was determined by the least-squares method using first-order kinetics. These data, along with the ratios of venous and arterial blood levels presented in Table IV, demonstrate that few of the 7.4- and 11.6-μm spheres reached the arterial circulation; 98% of the 7.4- and 11.6-μm spheres were eliminated from the circulating blood pool in the first 2 min. For the 3.4-μm spheres, 10–12 min was required before 98% was eliminated. Within 10 min, the concentrations of the 11.6, 7.4, and 3.4-μm spheres in venous circulation were <10, ~10, and ~$10^3$–$10^4$ spheres/g of blood, respectively. Therefore, a ratio of 0.81 for venous to arterial circulation for the 3.4-μm spheres indicates that the smaller spheres passed readily from the venous to arterial circulation, with high arterial levels present virtually immediately after administration. The

**Table II—Microsphere Distribution in Specific Organs 3.5 hr after Intravenous Administration Determined by External Imaging**

| Size, μm | Lungs, % | Liver, % | Spleen, % | Total in the Three Organs, % |

**Table III—Elimination of Microspheres from Blood at Initial Stage following Intravenous Administration [a]**

| Sphere Size, μm | Elimination Rate, $min^{-1}$ | | $t^{1/2}$, min | |
|---|---|---|---|---|
| | Venous Blood | Arterial Blood | Venous Blood | Arterial Blood |
| 3.4 | −0.426 ± 0.078 | −0.403 ± 0.053 | 1.62 | 1.72 |
| 7.4 | −0.810 ± 0.168 | −0.776 ± 0.140[b] | 0.86 | 0.89 |
| 11.6 | −1.33 ± 0.320 | — | 0.52 | — |

[a] Average of two dogs in each size. [b] Essentially all 11.6-μm spheres and >95% of the 7.4-μm spheres were removed from the systemic circulation during the first pass. Therefore, this elimination rate is for a relatively small number of spheres that reached the arterial circulation.

blood level profiles show that the venous and arterial levels of 3.4-μm spheres remained essentially the same over ~3 hr, suggesting that these spheres recirculate rather freely. Even after 2 hr, the level in the circulation was $10^2$–$10^3$/g of blood.

**Hemodynamic Data**—The 7.4- and 11.6-μm diameter microspheres were not associated with significant hemodynamic changes in the dosage ranges administered. The 3.4-μm diameter microspheres, administered at a similar total cross-sectional area dosage, induced significant dose-dependent deterioration in some of the hemodynamic parameters monitored (Fig. 3). These changes are illustrated more clearly in Fig. 4, which depicts a slow continuous recording of the first 7 min following intravenous administration of $1.41 \times 10^{11}$ 3.4-μm diameter microspheres. A profound drop in the systemic blood pressure, with associated deterioration in $-dp/dt$, $+dp/dt$, and systolic segment shortening, occurred within several minutes of microsphere administration. A later secondary elevation in pulmonary artery pressure also occurred, probably due to a neurohumoral reflex response to the severe systemic hypotension.

These acute changes are most consistent with peripheral vascular collapse, not unlike those seen in anaphylactic shock. That direct myocardial depression occurs, but is not the predominant cause of shock, is evidenced by the lack of elevation in left ventricular end diastolic pressure and the reduction in end diastolic segment length. Only after a period of profound hypotension was there evidence of depressed myocardial function, *i.e.*, decreased $+dp/dt$ and decreased systolic segment shortening. Sustained ventricular tachycardia developed late following administration of 3.4-μm diameter microspheres in one animal. Cardiac output also was well maintained initially, dropping only after sustained hypotension, with its deleterious effect on the myocardium, had been present. Progressive increases in dosage of these 3.4-μm diameter microspheres resulted in progressive worsening of the severity (Fig. 5) and duration of the systemic hypotension.

## DISCUSSION

Intravascular injection of particulate matter has been performed to image organs and assess blood flow characteristics. Early investigators utilized distribution kinetics of different size microspheres to assess the physical dimensions and biological characteristics of the microcirculation of various organs (1). As early as 1961, it was reported that the majority of microspheres less than 4.0 μm in diameter injected into the femoral vein passed through the pulmonary capillary network, whereas only a relatively small portion of similarly injected microspheres of >8.0 μm diameter passed into the systemic circulation (13). Previous work in our laboratories amplifies these points and, along with the present results, demonstrates that localization of the 7.4- and 11.6-μm diameter microspheres in the lungs, presumably by mechanical filtration, occurs in the first 2 min. This rapid localization suggests passive filtration and is consistent with ultrastructure studies of the pulmonary capillary network (14, 15) and the results of other investigators working with similarly sized microspheres (13, 16). The localization in the lungs appears to be complete for the 11.6-μm spheres, but there is evidence of gradual clearance and relocation in the liver and spleen of the 7.6-μm spheres.

Because of the recirculation characteristics of the microspheres of <4.0-μm diameter, their use was generally abandoned since they were of little value in organ imaging or assessing blood flow patterns. Of considerable interest is the recent documentation (2, 8) that, following intravenous administration, the 3.4-μm diameter microspheres pass through the pulmonary circulation and distribute in a pattern consistent with reticuloendothelial system uptake. This localization of the 3.4-μm diameter microspheres in the liver and spleen requires considerably more time than localization of the larger (≥7.4-μm diameter) microspheres in the lungs, suggesting a biologically active process, *e.g.*, phagocytosis (17) rather than passive filtration. The prolonged time course required for the 3.4-μm diameter microsphere clearance from the circulating blood pool correlates well with the duration of their acute hemodynamic effects (*vide supra*) and suggests some association with blood cells, a gradual release from the lungs, or a combination of the two.

Allen *et al.* (18) suggested that pulmonary hypertension is the most sensitive sign of hemodynamic deterioration following intravenous injection of microspheres larger than 13.5-μm in diameter. These authors also demonstrated a dose–response curve that correlated the increase in pulmonary artery pressure with increasing dosage and increasing sizes of administered microspheres (5). As expected from their dose–response curve, no significant pulmonary artery pressure rise was observed following intravenous administration of 7.4- and 11.6-μm diameter microspheres. While these particles are smaller than those that Allen utilized, they are nearly completely filtered by the pulmonary capillary network during the first pass through the pulmonary circulation.

The number of 3.4-μm diameter microspheres required to produce serious hemodynamic compromise is much smaller than would be predicted using the formula suggested by Allen *et al.* (5). This result appears due to the demonstrated ability of these small microspheres to pass through the pulmonary vascular network. Indeed, the period of hemodynamic compromise coincides with the time during which the 3.4-μm

**Table IV—Ratio of Microsphere Levels in Venous and Arterial Blood (VBC/AVC) Samples following Intravenous Administration**

| Minutes | VBC/AVC | | |
|---|---|---|---|
| | 3.4 μm | 7.4 μm | 11.6 μm |
| 2 | 0.81 | 6.4 | 85 |
| 4 | 0.69 | 3.1[a] | 18[a] |
| 10 | 0.81[b] | —[c] | —[c] |
| 20 | 1.0 | — | — |
| 30 | 1.1 | — | — |

[a] Approximate venous concentration is <50 spheres/g of blood. [b] Venous concentration is $10^3$–$10^4$ spheres/g of blood. [c] Venous concentration is <10 spheres/g of blood.

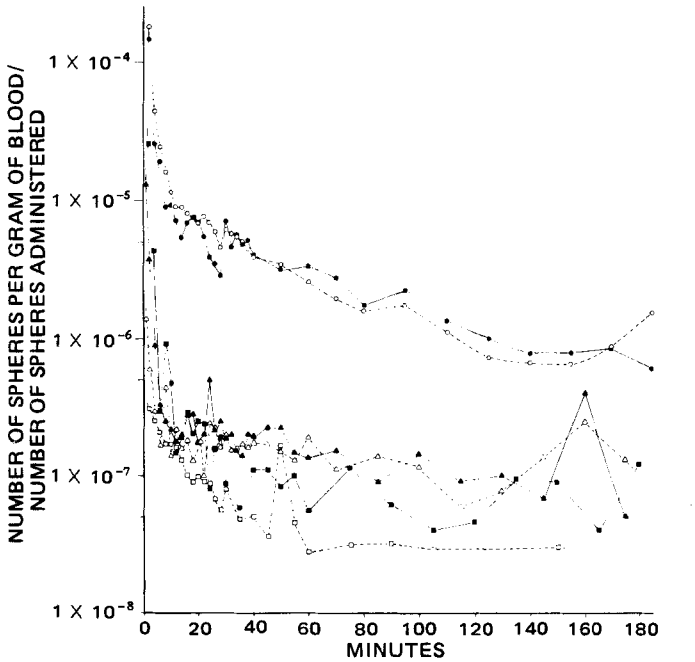

**Figure 2**—*Level of $^{141}Ce$-labeled microspheres in venous and arterial samples following intravenous administration in beagle dogs. Key: ●, 3.4 μm, venous; ○, 3.4 μm, arterial; ▲, 7.4 μm, venous; △, 7.4 μm, arterial; ■, 11.6 μm, venous; and □, 11.6 μm, arterial.*

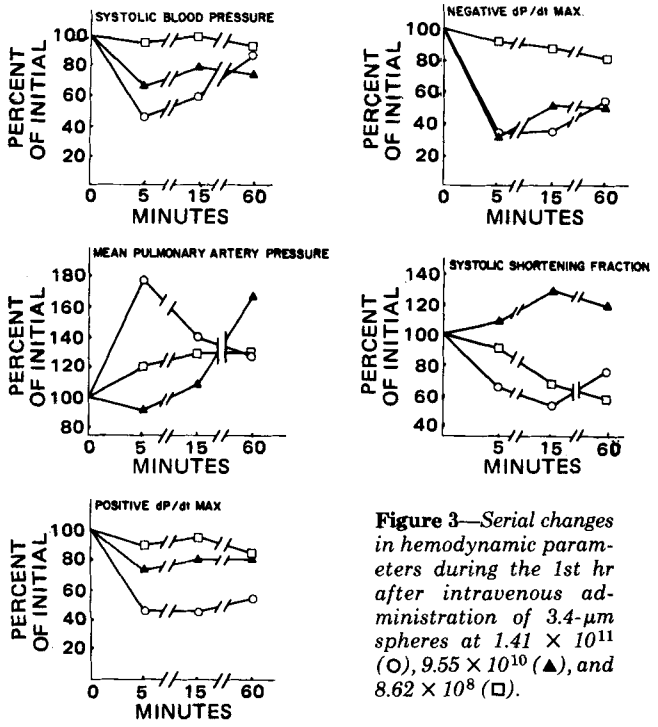

**Figure 3**—*Serial changes in hemodynamic parameters during the 1st hr after intravenous administration of 3.4-μm spheres at 1.41 × $10^{11}$ (○), 9.55 × $10^{10}$ (▲), and 8.62 × $10^{8}$ (□).*

diameter microspheres are numerous in the circulating blood pool (Figs. 2–4).

At present, the cause of the observed acute hemodynamic deterioration is unknown. Because of its similarity to anaphylaxis, a possible explanation would be the liberation of vasoactive amines as the microspheres pass through the pulmonary and peripheral vascular networks (19, 20). Alternatively, the hypotension could reflect a neurogenic reflex caused by high levels of the microspheres entering the central nervous system (21, 22). The former appears more likely based on the sequence of hemodynamic changes and the platelet clumping that occurred only around the 3.4-μm diameter microspheres upon histological examination (8, 23). The possibility that toxic monomers leaching from the smaller microspheres could promote vasomotor instability and initiate anaphylaxis was considered and discarded when injection of 20 ml of supernate from the sphere suspension into a dog caused no change in blood pressure over 0.5 hr. Furthermore, *in vitro* analyses of the supernate included UV spectra devoid of any peaks characteristic of monomer and a clean TLC analysis of a chloroform extract. The amount of residue left after drying the chloroform extract was too small to quantitate or to obtain an IR spectrum.

Incorporation of pharmacotherapeutic agents into microspheres for intravascular administration appears feasible from a technological standpoint and may have the advantages of achieving locally high drug concentrations in the target organ. Larger size (7.4- and 11.6-μm diameter) microspheres lodge in the pulmonary capillary network whereas 3.4-μm diameter microspheres appear to be taken up by the reticuloendothelial system. These differences in distribution fate following intravenous administration may be of significance in planning future chemotherapy of disease of the lungs and reticuloendothelial system.

## CONCLUSION

This study demonstrates that intravenous administration of particulate matter may be associated with significant acute hemodynamic deterioration in the experimental animal and reveals that very small microspheres (3.4-μm diameter) have a different distribution fate and time course than larger microspheres (≥7.4-μm diameter). Since the difference in distribution is associated with a more severe, acute hemodynamic effect than would be expected based on size and number alone, the limitation of particulate material for target organ drug administration may be the ability to incorporate a therapeutic dose in a finite number of particles

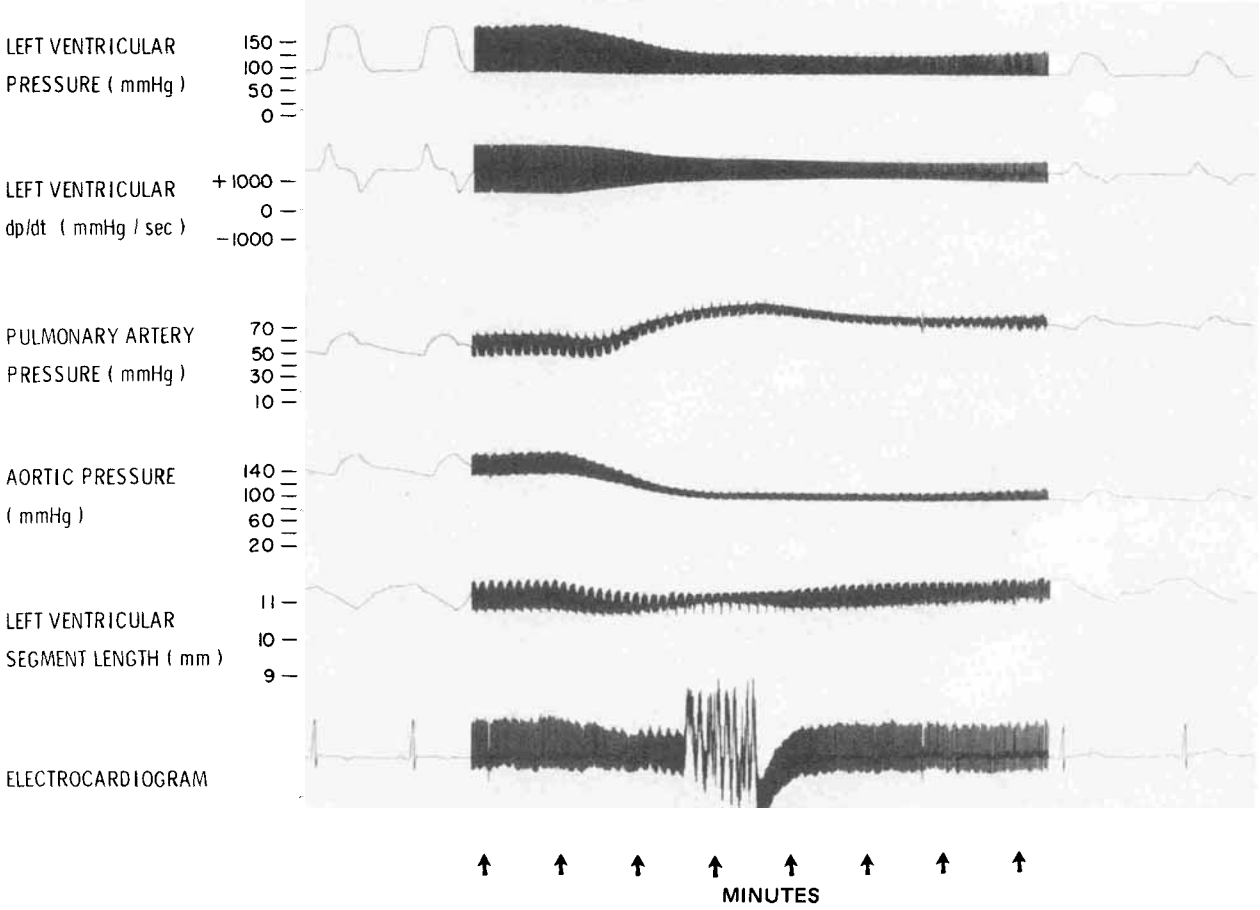

**Figure 4**—*Continuous display of the hemodynamic changes in the first 7 min following intravenous administration of 1.41 × $10^{11}$ microspheres of 3.4-μm size (area = 1.28 × $10^{12}$ μm² and weight = 3525 mg). A short lead and exit strip at chart speed of 25 mm/sec are provided to allow appreciation of individual waveforms.*

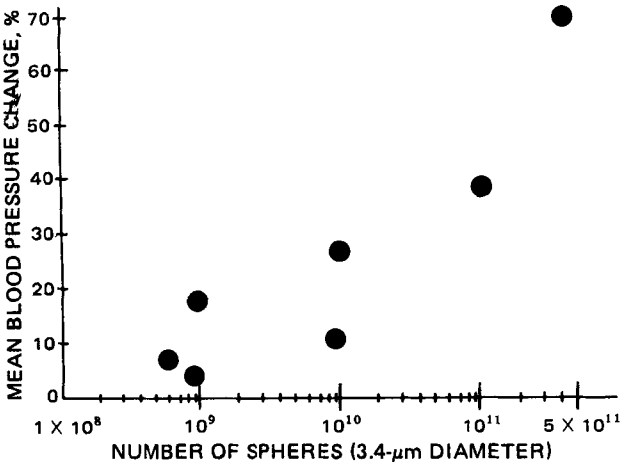

**Figure 5**—*Acute effect of intravenously administered 3.4-μm spheres on mean blood pressure as a function of concentration (r = 0.82).*

determined by their hemodynamic effect. Nevertheless, bolus intravenous injections of ~1 g of microspheres were administered to beagle dogs (13–15 kg) without serious consequences.

Therefore, the potential exists to incorporate sufficient amounts of drug into the microsphere during manufacture to provide therapeutic dosages. The influences of particle composition, surface charge, dissolution rate, and antigenicity will need to be determined. Furthermore, the acute hemodynamic effect evidenced following administration of the 3.4-μm diameter microspheres was consistently brief and reversible in the smaller dosage range. This finding suggests that a different dosage pattern, *i.e.*, smaller, more frequent administrations rather than a large bolus injection, or slower administration could avoid the risks of hemodynamic effects, thereby delivering a selected chemotherapeutic agent in relatively high local tissue concentrations to the target organ with safety.

Finally, both histological and hemodynamic studies of the long-term effects of repeated intravascular injections of microspheres must be performed to exclude the possibility of irreversible tissue damage with chronic administration.

# High-Performance Liquid Chromatographic Analysis of Captopril in Plasma

**B. JARROTT ˣ, A. ANDERSON, R. HOOPER, and W. J. LOUIS**

Received September 18, 1980, from the *Clinical Pharmacology and Therapeutics Unit, Department of Medicine, University of Melbourne, Austin Hospital, Heidelberg 3084, Victoria, Australia.* Accepted for publication November 17, 1980.

**Abstract** □ A sensitive assay is described for quantitating plasma captopril levels. Captopril is an orally active inhibitor of angiotensin-converting enzyme. Blood from patients taking this drug was collected into tubes containing edetate and ascorbic acid, and the plasma was separated by centrifugation. After addition of an internal standard, the plasma was deproteinized and the supernate was adjusted to pH 6.5. *N*-(1-Pyrene)-maleimide was added to derivatize captopril and an internal standard to fluorescent adducts. These derivatives then were extracted into ethyl acetate–benzene (1:1) and separated from other derivatized thiols by high-performance liquid chromatography. The sensitivity of the assay was 150 pmoles/ml. Preliminary pharmacokinetics were obtained in patients taking captopril chronically for essential hypertension. After administration of 100 mg of captopril to patients who had fasted overnight, the plasma levels rose rapidly; peak levels were obtained at ~37 min. Thereafter, the plasma levels declined rapidly, and the terminal half-life was ~40 min. In these patients, the time course of the plasma levels did not reflect changes in blood pressure, so there appeared to be no direct relationship between plasma levels of the parent compound and blood pressure changes.

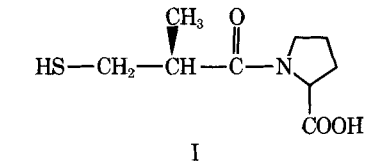
**Keyphrases** □ High-performance liquid chromatography—analysis of captopril in plasma □ Captopril—analysis using high-performance liquid chromatography □ Antihypertensives—high-performance liquid chromatographic method for captopril

Captopril (D-3-mercapto-2-methylpropanoyl-L-proline, I) is a potent and selective inhibitor of angiotensin-converting enzyme (kininase II) (1). Oral captopril administration lowers blood pressure in laboratory animals with experimental hypertension (2, 3) and in hypertensive humans (4, 5). Since the reductions in blood pressure apparently are related to the inhibition of angiotensin-converting enzyme (5), captopril appears to be the prototype of a new class of antihypertensive drug.

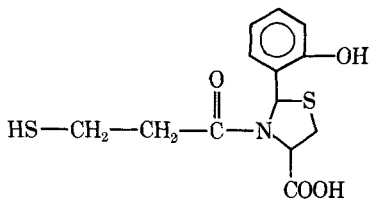
The disposition of captopril has been reported only in normotensive subjects taking an oral formulation of $^{35}S$-labeled captopril (6). The present paper reports the development of a sensitive high-performance liquid chromatographic (HPLC) assay for quantitating captopril in plasma and its application to a preliminary study of captopril pharmacokinetics in patients undergoing a clinical trial for the management of essential hypertension.

## EXPERIMENTAL

**Instrumentation**—Assays were carried out using a constant-flow, high-performance liquid chromatograph[1]. It consisted of a solvent delivery system[2], a universal injector[3], a radial compression module[4] with a reversed-phase permanently bonded octadecylsilane cartridge[5] (10 cm long × 8 mm i.d.), and a spectrophotofluorometer[6] equipped with a 20-μl flow-through quartz cell and a 150-w xenon arc lamp with excitation and emission monochromators set at 340 and 390 nm, respectively.



I



II

**Reagents**—Captopril[7] and an internal standard[8] [(4*R*)-2-(2-hydroxyphenyl)-3-(3-mercaptopropionyl)-4-thiazolidinecarboxylic acid, II] were used. The derivating reagent was *N*-(1-pyrene)maleimide[9]. Ethyl acetate and benzene[10] were analytical reagent grade, and methanol[1] was liquid chromatographic grade. All other reagents were the highest grade purity.

**Standard Solutions**—Standard solutions of captopril (1 m*M*) and II (1 m*M*) were prepared by dissolving pure drug in an aqueous solution of edetate disodium (1 m*M*) previously bubbled with nitrogen. These solutions were stored at 4° and were stable for at least 7 days. The *N*-(1-pyrene)maleimide derivatizing reagent (2 m*M*) was prepared by dissolving the powder in acetone and was stored at 4° for at least 14 days.

**Patient Sampling Procedure**—Four patients who had been taking captopril (100 mg, three times a day) for essential hypertension were studied. After an overnight fast, 100 mg of captopril was given; the patients then continued to fast for 4 hr. Immediately prior to dosing and at 0.25, 0.5, 0.75, 1.0, 1.5, 2, 3, and 4 hr, a 5-ml blood sample was taken from an indwelling catheter in a forearm vein and added to a heparinized tube containing 50 μl of a solution of edetate disodium (0.1 *M*) and ascorbic acid (0.1 *M*). After mixing, the samples were centrifuged immediately at 2000×*g* for 10 min to separate the plasma.

**Extraction Procedure**—The internal standard (10 nmoles) was added to 1.0 ml of plasma in a polypropylene tube (9.5 × 2 cm), and then 200 μl of perchloric acid (2 *M*) was added. After centrifugation at 2000×*g* for 10 min, 0.5 ml of the supernate was removed and its pH was adjusted to 6.5 with tribasic potassium phosphate (1 *M*). The derivatizing reagent was added (50 nmoles), and the solution was left at room temperature for 15 min. The solution then was extracted with 3 ml of ethyl acetate–benzene (1:1) by vortex mixing for 30 sec. Following centrifugation to separate the phases, the upper layer was transferred to a clean glass-stoppered conical tube and evaporated to dryness under nitrogen. The residue was dissolved in 100 μl of methanol and was either subjected immediately to liquid chromatography or stored overnight at 4°.

**Chromatography**—Ten-microliter injection volumes were used. The mobile phase was methanol–potassium phosphate buffer (5 m*M*, pH 6.5) (52:48), and the flow rate was maintained at 2 ml/min at a back pressure of ~1000 psi.

**Quantitation**—Since captopril is known to oxidize spontaneously into disulfides, ascorbic acid and edetate were added to the blood immediately upon sampling. Preliminary experiments demonstrated that this procedure prevented any loss of captopril when it was added to control blood and analyzed as already described.

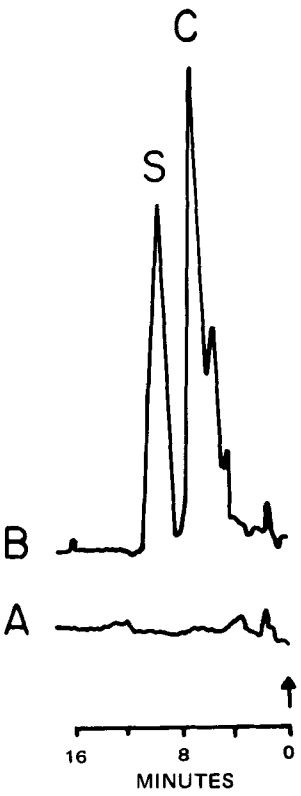

**Figure 1**—*Elution of fluorescent material from HPLC column after derivatization and extraction of control plasma (A) and plasma from a patient who had taken 100 mg of captopril 1 hr previously (B). Key: C, captopril (I); and S, internal standard (II).*

A calibration curve was constructed by adding varying amounts of captopril and a constant amount of internal standard to 1 ml of control plasma and analyzing the samples as already described. To assess linearity, the peak height ratio of captopril to the internal standard was plotted against the added captopril.

Recoveries of sulfhydryl compounds were calculated by first adding the same amount of each compound to plasma and then deproteinizating, derivatizing, extracting, evaporating, and reconstituting in methanol. The methanol extract then was injected, and the peak height was calculated. The same amount of sulfhydryl compound in phosphate buffer was derivatized and directly injected, and the peak height was measured. The percent recovery was calculated by dividing the peak height after solvent extraction by the peak height without solvent extraction and multiplying by 100.

**Pharmacokinetic Analysis**—Plasma captopril level–time data were fitted to a polyexponential equation using the nonlinear least-squares regression analysis computer program AUTOAN 2 (7). The estimated parameters were obtained assuming first-order absorption and elimination.

## RESULTS AND DISCUSSION

Captopril disposition in humans (6) and laboratory animals (8) has only been studied using a single dose of radiolabeled captopril. Thus, a sensitive and specific assay is needed for measuring blood levels of captopril in patients so that its pharmacokinetics can be defined for developing an optimal dosage regimen.

Since captopril has no prominent absorption properties in the UV or visible spectrum, methods were examined for derivatizing captopril through its thiol group to yield a suitable fluorophore. A suitable reagent

**Table I—Summary of Captopril Pharmacokinetics in Patients** [a]

| Patient | $T_{max}$, hr | $C_{max}$, nmoles/ml | $AUC$, nmoles hr/ml | $T_{1/2}$, hr |
|---|---|---|---|---|
| 1 | 0.75 | 18.5 | 18.66 | 0.92 |
| 2 | 0.67 | 20.8 | 20.12 | 0.52 |
| 3 | 0.58 | 18.3 | 17.34 | 0.70 |
| 4 | 0.50 | 9.9 | 10.99 | 0.52 |
| Mean | 0.63 | 16.9 | 16.77 | 0.66 |
| *SE* | 0.05 | 2.4 | 2.01 | 0.09 |

[a] $T_{max}$ = time when maximum plasma concentration, $C_{max}$, is reached. $AUC$ = area under curve, and $T_{1/2}$ = elimination half-life.

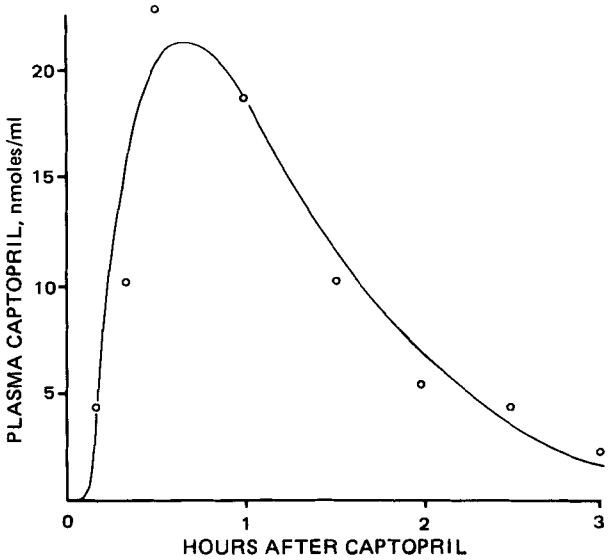

**Figure 2**—*Time–plasma concentration curve for captopril after oral administration of 100 mg to a hypertensive patient.*

was *N*-(1-pyrene)maleimide since this reagent did not fluoresce in aqueous solution but formed fluorescent adducts, under mild conditions, with thiol compounds or proteins containing such groups (9, 10). While this reagent has been used for fluorescence polarization studies of high molecular weight proteins, in the present study it formed a fluorescent adduct with captopril. However, other low molecular weight thiols such as cysteine, *N*-acetylcysteine, and glutathione also formed fluorescent derivatives that were indistinguishable from each other by their excitation and emission spectra.

Since glutathione and cysteine are present in the blood, it was apparent that an HPLC technique would be necessary to separate these derivatized thiols. Since such an assay could be improved by the incorporation of an internal standard, another thiol angiotensin-converting enzyme inhibitor (II) was included in initial studies to define the HPLC conditions for separation of the fluorescent adducts of glutathione, cysteine, captopril, and II. The conditions given under *Experimental* achieved satisfactory separations with retention times of 2.4, 3.2, 5.6, and 7.6 min, respectively. Further specificity was obtained by examining various solvents to extract the fluorescent adducts differentially after derivatization. The most suitable solvent was an equal mixture of ethyl acetate and benzene (3 ml), and the percent recovery of the succinimide derivatives at pH 6.5 was as follows: cysteine, 3%; glutathione, <1%; captopril, 68%; and II, 91%.

Figure 1 illustrates a typical chromatogram obtained after extraction of drug-free plasma (curve A) and of plasma from a patient who had taken captopril 1 hr earlier (curve B). The peak at 5.6 min represents captopril, and the peak at 7.6 min was the internal standard (II). The minor peak on the shoulder of the captopril peak was always seen when captopril was derivatized and chromatographed on the radial compression column. However, it was not seen in earlier studies when a $C_{18}$ reversed-phase column was used, presumably due to the lower efficiency of this column. Since the former column has a higher number of plates (~5000) than the latter column (~2000 plates) and, therefore, achieves a higher resolution, this minor component could be an isomer of captopril.

The threshold of captopril detection in plasma corresponding to a peak height approximately three times that of baseline noise was 150 pmoles/ml. A calibration curve for the peak height ratio of captopril to the internal standard was linear over the concentration range of 150–10,000 pmoles/ml. The within-run precision of the assay (coefficient of variation) at a concentration of 1.5 nmoles/ml was 8.1% ($n$ = 4), and the between-run precision was 9.0% ($n$ = 6).

Because of recent reports of toxicity, including neutropenia (11) and proteinuria (12), permission has not been given for single-dose pharmacokinetic studies in normotensive subjects. A limited study of captopril kinetics in patients taking this drug chronically for essential hypertension was made. Patients fasted overnight, and a predose blood sample was taken; no captopril could be detected in any predose blood sample. After the administration of a standard dose of 100 mg of captopril, absorption was very rapid in all patients; the average time for achieving peak plasma concentrations of captopril was 37 min (Table I). In two patients, the appearance rate of captopril in the blood was so rapid that it did not appear to be following a first-order process. Further experiments with

sampling at closer time intervals are needed to confirm these observations. The data for all patients could be described approximately by the sum of two exponentials, and the mean elimination half-life was ~40 min. The plasma concentration–time profile for one subject is shown in Fig. 2.

The pharmacokinetics of captopril in the four patients taking the drug chronically indicate that changes in plasma captopril concentrations do not reflect blood pressure changes. In all patients, captopril was undetected in their plasma 3–4 hr after dosing, yet blood pressure had not risen at this time. Blood levels of captopril metabolites, such as the disulfide, possibly may be a more useful index of the hemodynamics of this drug.

In conclusion, it was demonstrated that plasma captopril can be assayed with high sensitivity and specificity by first derivatizing this thiol compound to a fluorophore using *N*-(1-pyrene)maleimide and then separating the fluorescent adducts by HPLC. This procedure can also be used for assaying another thiol angiotensin-converting enzyme inhibitor, II, using captopril as the internal standard. This derivatization procedure should be suitable for assaying the mucolytic drug *N*-acetylcysteine after modification of the HPLC conditions to retard its elution.

# Pharmacokinetics of [$^{14}$C]Bretylium Tosylate in Rats

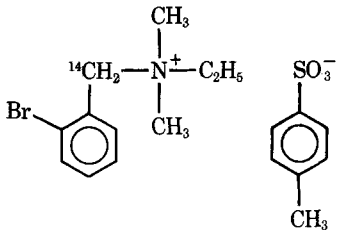
**BURDE L. KAMATH ˣ, HERMAN F. STAMPFLI, CHII-MING LAI, and AVRAHAM YACOBI**

Received August 29, 1980, from the *Pharmaceutical Development Department, Research & Development, American Critical Care, McGaw Park, IL 60085.* Accepted for publication November 20, 1980.

**Abstract** □ The pharmacokinetics of bretylium tosylate were investigated in eight male Charles River rats. Each animal received an intravenous dose (10 mg/kg) of [$^{14}$C]bretylium tosylate. Serial blood samples, urine, and feces were collected for up to 72 hr. Bretylium concentrations in plasma and amounts excreted in urine and feces were determined by scintillation counting. On the average, 88 and 95% of the dose were recovered in urine and feces in 24 and 72 hr, respectively. Urinary recovery accounted for 65.6% of the dose while 29.7% was excreted in the feces. Bretylium concentrations in plasma declined triexponentially and were fitted to a three-compartment open model. Bretylium has a very high apparent volume of distribution (15 liters/kg), and its $\beta$ half-life averaged 5.5 hr. Mean values of the apparent volume of the central compartment, plasma clearance, renal clearance, and excretion rate constants of bretylium in rats were 1 liter/kg, 1.93 liters/hr/kg, 1.27 liters/hr/kg, and 1.24 $hr^{-1}$, respectively. The results indicate that: (*a*) bretylium is strongly bound to the tissues and is eliminated by active urinary secretion and by biliary excretion in rats, and (*b*) there are strong similarities between the pharmacokinetics of bretylium in humans and rats and that this animal model might be suitable for interaction studies with other drugs.

**Keyphrases** □ Bretylium tosylate—pharmacokinetics, rats, compared with human studies □ Pharmacokinetics—bretylium tosylate, rats, compared with human studies □ Antiarrhythmic agents—bretylium tosylate, pharmacokinetics studied in rats, compared with human studies

Bretylium is a quaternary ammonium compound [(*o*-bromobenzyl)ethyldimethylamine] used clinically as the tosylate salt in the treatment of arrhythmias. Bretylium tosylate suppresses ventricular fibrillation in patients within minutes following intravenous administration (1). Suppression of ventricular tachycardia and other ventricular arrhythmias develops more slowly, usually 20–120 min following parenteral administration (2).



[$^{14}$C]bretylium tosylate

## BACKGROUND

In humans, bretylium is eliminated intact mainly through the renal route (3, 4). No metabolites have been identified following administration of bretylium tosylate in humans and rats (3). The biological half-life of bretylium in normal subjects was 5.5 hr (3). Romhilt *et al.* (2) reported a half-life of 9.75 hr (range 4.2–16.9) in eight patients with cardiac disease. More recently, Adir *et al.* (4) reported a half-life of 8.1 hr for a normal subject and of 16.0 and 31.5 hr for two patients with renal impairment. In the normal subject, the renal clearance of bretylium was 1 liter/min, indicating extensive active secretion, and the urinary excretion of unchanged drug accounted for 80% of the dose (4).

A previous study in the rat (3) demonstrated that 63% of the intramuscular dose (5 mg/kg) was excreted unchanged in the urine and that 31% was excreted in the feces. Most radioactivity was excreted within 24 hr. An average of 16% of the intravenous dose (2.5 mg/kg) in four rats was excreted in the bile within 5 hr.

This investigation studied the pharmacokinetics of distribution and elimination of bretylium in the rat following an intranveous dose of ra-

0022-3549/81/0600-0667$01.00/0

© 1981, American Pharmaceutical Association

sampling at closer time intervals are needed to confirm these observations. The data for all patients could be described approximately by the sum of two exponentials, and the mean elimination half-life was ~40 min. The plasma concentration–time profile for one subject is shown in Fig. 2.

The pharmacokinetics of captopril in the four patients taking the drug chronically indicate that changes in plasma captopril concentrations do not reflect blood pressure changes. In all patients, captopril was undetected in their plasma 3–4 hr after dosing, yet blood pressure had not risen at this time. Blood levels of captopril metabolites, such as the disulfide, possibly may be a more useful index of the hemodynamics of this drug.

In conclusion, it was demonstrated that plasma captopril can be assayed with high sensitivity and specificity by first derivatizing this thiol compound to a fluorophore using *N*-(1-pyrene)maleimide and then separating the fluorescent adducts by HPLC. This procedure can also be used for assaying another thiol angiotensin-converting enzyme inhibitor, II, using captopril as the internal standard. This derivatization procedure should be suitable for assaying the mucolytic drug *N*-acetylcysteine after modification of the HPLC conditions to retard its elution.

# Pharmacokinetics of [$^{14}$C]Bretylium Tosylate in Rats

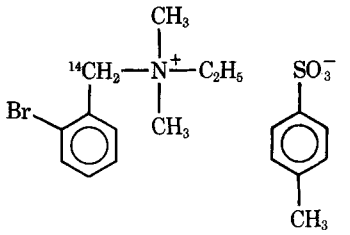
**BURDE L. KAMATH ˣ, HERMAN F. STAMPFLI, CHII-MING LAI, and AVRAHAM YACOBI**

Received August 29, 1980, from the *Pharmaceutical Development Department, Research & Development, American Critical Care, McGaw Park, IL 60085.* Accepted for publication November 20, 1980.

**Abstract** □ The pharmacokinetics of bretylium tosylate were investigated in eight male Charles River rats. Each animal received an intravenous dose (10 mg/kg) of [$^{14}$C]bretylium tosylate. Serial blood samples, urine, and feces were collected for up to 72 hr. Bretylium concentrations in plasma and amounts excreted in urine and feces were determined by scintillation counting. On the average, 88 and 95% of the dose were recovered in urine and feces in 24 and 72 hr, respectively. Urinary recovery accounted for 65.6% of the dose while 29.7% was excreted in the feces. Bretylium concentrations in plasma declined triexponentially and were fitted to a three-compartment open model. Bretylium has a very high apparent volume of distribution (15 liters/kg), and its $\beta$ half-life averaged 5.5 hr. Mean values of the apparent volume of the central compartment, plasma clearance, renal clearance, and excretion rate constants of bretylium in rats were 1 liter/kg, 1.93 liters/hr/kg, 1.27 liters/hr/kg, and 1.24 $hr^{-1}$, respectively. The results indicate that: (*a*) bretylium is strongly bound to the tissues and is eliminated by active urinary secretion and by biliary excretion in rats, and (*b*) there are strong similarities between the pharmacokinetics of bretylium in humans and rats and that this animal model might be suitable for interaction studies with other drugs.

**Keyphrases** □ Bretylium tosylate—pharmacokinetics, rats, compared with human studies □ Pharmacokinetics—bretylium tosylate, rats, compared with human studies □ Antiarrhythmic agents—bretylium tosylate, pharmacokinetics studied in rats, compared with human studies

Bretylium is a quaternary ammonium compound [(*o*-bromobenzyl)ethyldimethylamine] used clinically as the tosylate salt in the treatment of arrhythmias. Bretylium tosylate suppresses ventricular fibrillation in patients within minutes following intravenous administration (1). Suppression of ventricular tachycardia and other ventricular arrhythmias develops more slowly, usually 20–120 min following parenteral administration (2).



[$^{14}$C]bretylium tosylate

## BACKGROUND

In humans, bretylium is eliminated intact mainly through the renal route (3, 4). No metabolites have been identified following administration of bretylium tosylate in humans and rats (3). The biological half-life of bretylium in normal subjects was 5.5 hr (3). Romhilt *et al.* (2) reported a half-life of 9.75 hr (range 4.2–16.9) in eight patients with cardiac disease. More recently, Adir *et al.* (4) reported a half-life of 8.1 hr for a normal subject and of 16.0 and 31.5 hr for two patients with renal impairment. In the normal subject, the renal clearance of bretylium was 1 liter/min, indicating extensive active secretion, and the urinary excretion of unchanged drug accounted for 80% of the dose (4).

A previous study in the rat (3) demonstrated that 63% of the intramuscular dose (5 mg/kg) was excreted unchanged in the urine and that 31% was excreted in the feces. Most radioactivity was excreted within 24 hr. An average of 16% of the intravenous dose (2.5 mg/kg) in four rats was excreted in the bile within 5 hr.

This investigation studied the pharmacokinetics of distribution and elimination of bretylium in the rat following an intranveous dose of ra-

diolabeled bretylium and examined the suitability of the rat model for further *in vivo* investigation of the drug.

## EXPERIMENTAL

Bretylium tosylate (labeled at benzyl carbon with carbon 14, specific activity 27.3 μCi/mg) was obtained commercially[1]. The radioactive drug was diluted with the cold drug[2] to a final specific activity of 3.242 μCi/mg.

Eight male Charles River CD[3] rats, 390–460 g, were kept in individual metabolism cages during the study. One day before the drug administration, a cannula was inserted surgically into the jugular vein of each rat under light ether anesthesia to allow intravenous dosing and systemic blood sampling. The preparation of the cannulas and the surgical procedure were described previously (5). At time zero, a 10-mg/kg dose of [$^{14}$C]bretylium tosylate in solution was given intravenously through the jugular vein cannula after an overnight fast. The cannula was flushed with 0.5 ml of heparinized saline.

Food was withheld for 3 hr after drug administration, but water was freely available at all times. Serial blood samples (0.4 ml) were drawn at 0 (just before drug administration), 0.25, 0.5, 0.75, 1, 1.5, 2, 3, 4, 6, 8, and 10 hr following dosing and were placed in heparinized microcentrifuge tubes; the plasma was separated immediately. The blood volume withdrawn from the rat was replaced with an equal volume of heparinized saline. Urine and feces were collected for 72 and 48 hr, respectively.

The total radioactivity in plasma was determined by counting an aliquot of the plasma or urine in a liquid scintillation counter[4]. The total radioactivity in the feces was measured after homogenization and combustion of an aliquot of the homogenate by a sample oxidizer[5].

Plasma concentration *versus* time data of each rat were fitted to a three-compartment open model (6), with elimination from the central compartment, using the NLIN procedure available in SAS[6] package (7). Marquardt's iterative method was used with a convergence criterion of $10^{-4}$. Each observation was weighted by the reciprocal of its square to estimate the $\beta$-phase parameters, $B$ and $\beta$, which were used to estimate $P$, $\pi$, $A$, and $\alpha$ without weighing. Derived constants and parameters then were calculated from the estimated parameters using standard equations (6).

## RESULTS AND DISCUSSION

Table I summarizes the recovery of bretylium measured as radioactivity in urine and feces following intravenous administration of [$^{14}$C]-bretylium tosylate to eight rats. On the average, >95% of the dose was recovered in urine and feces in 72 hr. Urinary recovery was 65.6% of the dose, and the recovery in the feces was 29.7%. These values are in good agreement with the previously reported data for rats (3). An average of 88% of the dose was excreted within the first 24 hr. In humans, however, the urinary excretion of unchanged drug in 3 days accounted for 80–90% of the dose (3).

The method used in this study to fit the plasma concentration data to the exponential curve represented by the three-compartment open model was modified slightly. Because of wide and prolonged distribution of the drug, the $\beta$ phase (4 hr after drug administration) consisted of only three or four data points. It was found that simultaneous determination of all six least-squares parameters may lead to a bias in the characterization

of the pharmacokinetic parameters of bretylium. This problem could be overcome by first fitting only the points in the $\beta$ phase to the monoexponential equation and by weighing each observation by the reciprocal of its square. The influence of the $\alpha$ phase thus was minimized, and the best possible estimates of the $\beta$-phase parameters, $B$ and $\beta$, were obtained. By using these two predetermined parameters, all data points, including those in the $\beta$ phase, were simultaneously fitted again to the triexponential equation. This time no weighting factor was used. Through this procedure, the nonlinear least-squares estimates of $P$, $\pi$, $A$, and $\alpha$ were found, describing the distribution phase.

The mean values of the pharmacokinetic parameters estimated by this procedure, as well as the derived parameters calculated from the estimated parameters, are presented in Table II. The standard deviation and coefficient of variation of each parameter also are listed. A representative semilogarithmic plot of the plasma concentration *versus* time data from an individual rat is shown in Fig. 1.

In rats, bretylium is distributed rapidly in the body into two peripheral

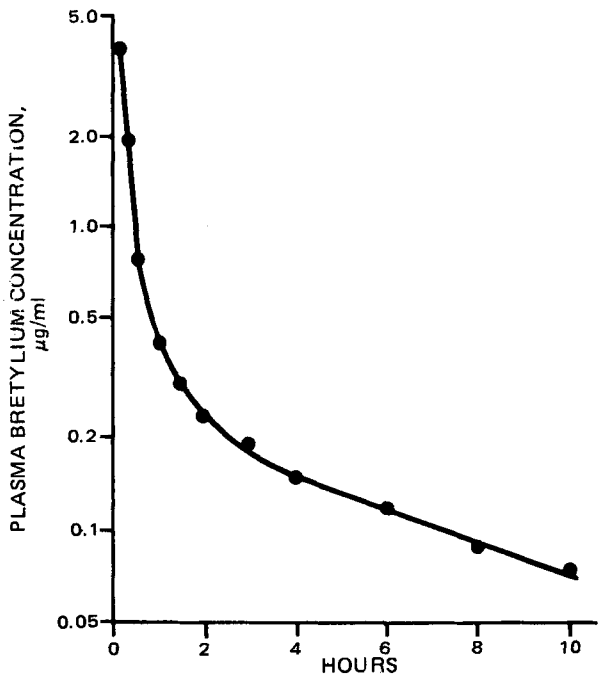

**Figure 1**—*Representative semilogarithmic plot of concentration of bretylium in plasma* versus *time following intravenous administration of bretylium tosylate (10 mg/kg) to a rat. The curve represents the data fitted to the three-compartment open model.*

compartments. The apparent equilibrium between the compartments was achieved within 3 hr. The apparent volume of the central compartment ($V_c$) was 1 liter/kg. The distribution half-life of the shallow and deep compartments (Compartments 2 and 3) were 6.14 and 32.5 min, respectively. In the postdistribution phase, the plasma levels declined with a terminal half-life of 5.45 hr (range 4.0–7.4). The plasma clearance ($Cl_p$) and the apparent volume of distribution ($V_{d,\beta}$) averaged 1.93 liters/hr/kg and 15 liters/kg, respectively. This unusually high apparent volume of distribution and the significant drop in plasma levels from 3–4 μg/ml at 6 min after injection to <200 ng/ml within 3 hr indicated extensive tissue uptake of bretylium in rats. Similar binding characteristics of bretylium were demonstrated in humans (8).

The intercompartmental distribution rate constants ($k_{12}$ and $k_{21}$) between the central compartment and Compartment 2 in the same rat were close to each other and ranged from 0.8 to 5.1 $hr^{-1}$ between rats. However, the transfer rate constant ($k_{31}$) from the third compartment to the central compartment was considerably smaller (mean 0.288 $hr^{-1}$) than either $k_{13}$ (the intercompartmental rate constant in the opposite direction, 1.97 $hr^{-1}$) or the elimination rate constant ($k_{10}$, 1.89 $hr^{-1}$). This finding suggests that tissue binding in Compartment 3 (the deep compartment) is rate limiting in the elimination of bretylium from the body.

The excretion rate constant ($k_{ex}$) and the renal clearance ($Cl_r$) of bretylium in rats were 1.24 $hr^{-1}$ and 1.27 liters/hr/kg, respectively. This renal clearance corresponds to 21 ml/min/kg and represents 66% of the total body clearance; it is about three times greater than the glomerular filtration rate of 6.64–8 ml/min/kg reported for normal rats (9, 10). It also indicates that active secretion is the major mechanism of urinary excretion of bretylium in rats. A similar mechanism of active secretion of bretylium in urine also was demonstrated for humans (4).

The major portion of the nonrenal excretion of bretylium probably occurs through the bile, as indicated by the recovery of ~30% of the dose in feces in 48 hr. If excretion in the bile is rapid immediately after dosing, there is a possibility of enterohepatic cycling. The extent of biliary excretion of bretylium has not been investigated in humans. However, on the basis of urinary excretion data, a much smaller quantity is expected to be eliminated *via* the biliary route.

In summary, these results indicate that bretylium is extensively distributed in rats, bound to the tissues, and excreted mainly unchanged in the urine, mostly by active secretion, similar to the findings in humans. Biliary excretion is the second major route of elimination of bretylium in rats. The data also show striking similarity in the pharmacokinetics of distribution and elimination of bretylium in humans and rats. This similarity might allow the use of the animal model for further *in vivo* investigations, including efficacy and drug–drug interaction studies in the rat.

# High-Performance Liquid Chromatographic Measurement of Cloprednol in Human Plasma

**C. LEE ˣ, B. AMOS, and S. B. MATIN**

Received October 6, 1980, from the *Department of Analytical and Metabolic Chemistry, Syntex Research, Palo Alto, CA 94304.* Accepted for publication December 2, 1980.

**Abstract** □ A rapid and specific high-performance liquid chromatographic method for the quantitative determination of cloprednol in human plasma is described. Samples were extracted using methylene chloride–ether (40:60) and then purified further by solvent and pH partitioning techniques. Cloprednol was analyzed using normal-phase chromatography and UV detection at 254 nm. The final recovery after losses during the cleanup procedure for cloprednol from human plasma was 80.8%. The lowest concentration that could be measured with confidence was 8 ng/ml.

**Keyphrases** □ Cloprednol—high-performance liquid chromatographic analysis, human plasma □ High-performance liquid chromatography—analysis, cloprednol in human plasma □ Anti-inflammatory agents—cloprednol, high-performance liquid chromatographic analysis, human plasma

Cloprednol (6-chloro-11β,17α,21-trihydroxypregna-1,4,6-triene-3,20-dione, I) is a fast-acting corticoid used in the treatment of collagen and allergic diseases (1).

Recently published analytical techniques for the quantitative determination of 17-hydroxycorticoids in

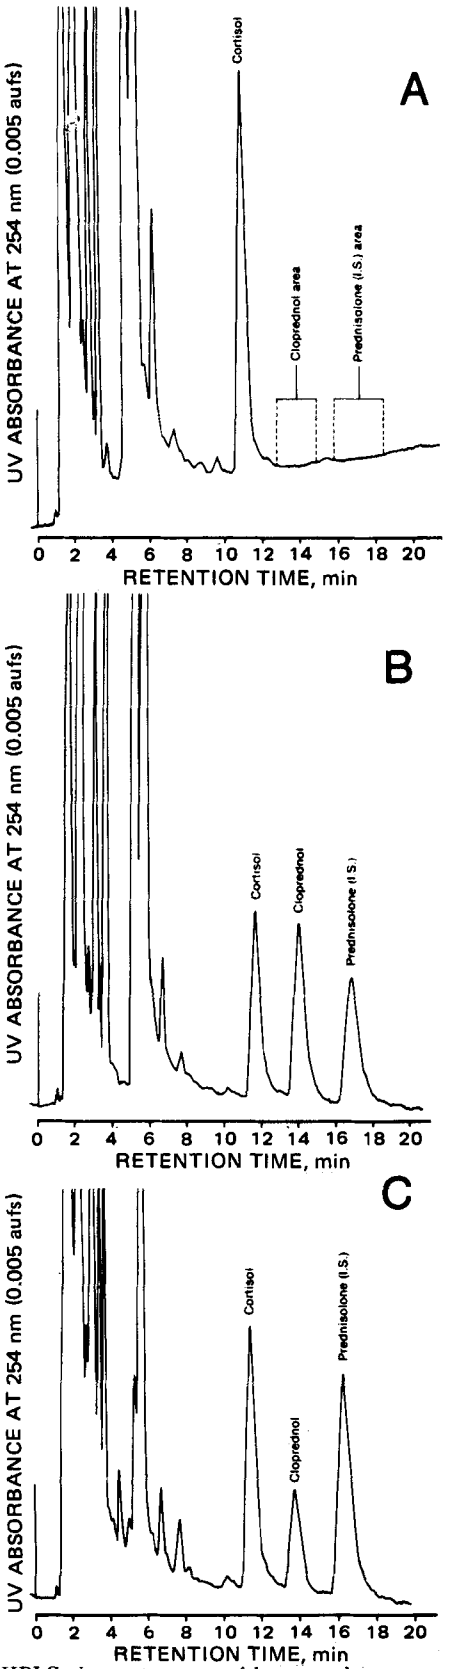

**Figure 1**—*HPLC chromatograms of human plasma assayed as described. Key: A, chromatogram from 3 ml of blank human plasma; B, chromatogram from 3 ml of human plasma spiked with 300 ng of cloprednol (100 ng/ml) and 200 ng of prednisolone (66.7 ng/ml) as the internal standard; and C, chromatogram of extracted human plasma sample (1 ml) 4 hr after an oral dose of 12.5 mg of cloprednol was diluted with blank human plasma to 3 ml and 200 ng of prednisolone (66.7 ng/ml) as an internal standard was added.*

**Table I—Extraction Efficiency of [$^3$H]Cloprednol from 3.0 ml of Human Plasma**

| Extraction Step | Percent of Spiked [$^3$H]Cloprednol |
|---|---|
| Methylene chloride–ether extraction | 88.7 |
| Methanol–water layer | 83.4 |
| Methylene chloride–ether after washing (overall extraction) | 80.4 |

requires extensive sample cleanup and time-consuming derivatization (9, 10).

A simple, sensitive, and specific HPLC method for the measurement of cloprednol in human plasma without derivatization is described here. By utilizing normal-phase chromatography, it was possible chromatographically to resolve structurally related endogenous corticoids like cortisol and drugs like prednisone. This method was applied to determine plasma concentrations in humans after the oral administration of 12.5 mg of cloprednol.

## EXPERIMENTAL

**Reagents and Materials**—Cloprednol[1], [$^3$H]cloprednol[1], prednisolone[2], and a complete oxidizer cocktail[3] were used as received. Distilled-in-glass grade[4] methanol, hexane, and methylene chloride and absolute ethanol[5] were used. All other chemicals and reagents were reagent grade and were used as received.

**Apparatus**—Analyses were performed on a high-performance liquid chromatograph[6] at ambient temperature. The chromatograph was equipped with a fixed-wavelength (254 nm) spectrophotometer[7]. A commercial 4.6-mm × 25-cm prepacked normal-phase column[8] with a precolumn[9] (2 mm × 7.1 cm) was used. Samples were introduced onto the column through a septumless injector[10] with a 100-μl syringe.

A liquid scintillation spectrometer[11] was used for [$^3$H]cloprednol counting.

**Chromatographic Conditions**—The mobile phase was methylene chloride–ethanol–acetic acid (96:4:0.01) with the flow rate adjusted to 2.0 ml/min (1300 psi) at 0.005 aufs. The solvent mixture was degassed by stirring under vacuum before use. Prednisolone was the internal standard.

**Extraction**—Sample aliquots, 0.1–3 ml, were diluted with blank plasma to 3 ml. A 200-μl spiking solution of prednisolone, used as the internal standard [equivalent to 1 ng/μl of methanol–water (1:9)], was added. Additional water was added to bring the total volume to 3.5 ml. The mixture was extracted with 10 ml of 40% methylene chloride in ether by shaking on a reciprocal shaker for 10 min. After centrifugation, the organic layer was transferred to another tube and evaporated to dryness under nitrogen at 37°.

To the dry residue was added 2 ml of methanol containing 10% water. After the tubes were vortexed, the methanol–water layer was washed three times with hexane (3 ml). The hexane washings were discarded, and the remaining methanol–water layer was dried at 37° under nitrogen. The dry residue was reconstituted in 10 ml of 40% methylene chloride in ether, and the organic layer was washed with 2 ml of 0.1 *N* HCl.

After centrifugation, the acidic layer was pipetted out, and the organic layer was washed with 3 ml of 0.1 *N* NaOH. After centrifugation, the organic layer was transferred to a 15-ml conical centrifuge tube and evaporated to dryness under nitrogen at 37°. The residue was redissolved in 100 μl of methylene chloride by vigorous vortexing, and 50–75 μl was injected for quantitation.

**Extraction Efficiency**—To drug-free pooled plasma (3 ml) were

added a known amount of [$^3$H]cloprednol and 100 ng of cloprednol. The spiked pooled plasma sample was processed through the entire procedure. At each extraction step, an aliquot of the organic layer was taken; the amount of radioactivity extracted was determined by counting the aliquot in 10 ml of scintillation fluid[3].

## RESULTS AND DISCUSSION

Cloprednol, a compound structurally similar to prednisolone, is a synthetic derivative of glycosteroids. It has an anti-inflammatory therapeutic potency twice that of prednisone and prednisolone on a milligram per kilogram basis (1).

The method described permits the analysis of underivatized cloprednol, thus making analysis simple and rapid. Cloprednol has three UV absorption peaks at 228, 256, and 299 nm with $E_{max}$ values of 11,200, 10,400, and 10,400, respectively. In this method, cloprednol was analyzed at 254 nm because of the commercial availability of the filter for the UV detector.

Under the described chromatographic conditions, the retention times of cloprednol and prednisolone (internal standard) were 14 and 17 min, respectively. Blank plasma samples not spiked with cloprednol or internal standard were processed through the entire procedure. The chromatogram shown in Fig. 1A clearly indicates that there was no interference from endogenous substances at the retention times of cloprednol and the internal standard. The chromatogram of an extracted human plasma sample spiked with 300 ng of cloprednol and 200 ng of the internal standard is shown in Fig. 1B.

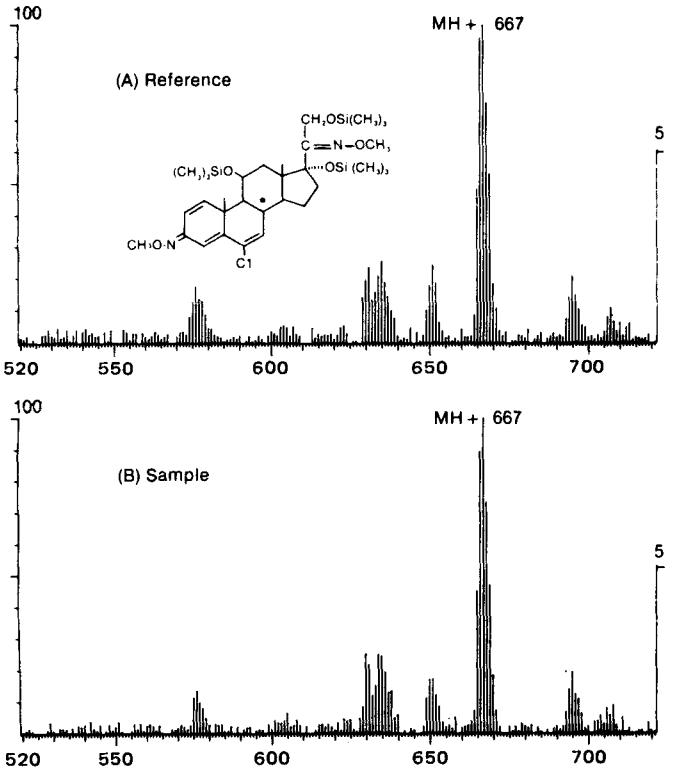

**Figure 2**—*Methane chemical-ionization mass spectra of methoxyimino trimethylsilyl derivative of cloprednol reference standard (A) and plasma extract (B).*

Plasma samples were extracted utilizing methylene chloride–ether (40:60). The extraction efficiency of cloprednol from 3.0 ml of human plasma was 88.7%. The extracts were purified further by solvent and pH partitioning techniques. Hexane was used to remove lipophilic substances, and acid–base washes were used to remove interference by endogenous substances.

The recovery of [$^3$H]cloprednol at each step during extraction was determined (Table I). The final recovery after losses during the cleanup procedure was 80.8%.

Linearity was established by preparing four calibration curves. The coefficients of variation (intraassay) at concentrations of 25, 50, 100, 200, and 300 ng/3.0 ml of plasma were 4.44, 7.37, 7.53, 4.72, and 2.40%, respectively (Table II). The calibration curve, as constructed by plotting the peak height ratio of cloprednol to the internal standard *versus* the amount of cloprednol spiked, was linear ($y$ = 0.9997) over the range (25–300 ng/3 ml) studied.

The specificity of the method was confirmed by chemical-ionization mass spectral studies. The HPLC-eluted peak of cloprednol from a dosed plasma sample was collected and derivatized as reported previously (18). The mass spectrum obtained from the cloprednol standard and that from the substance eluted in the chromatographic peak were identical (Figs. 2A and 2B). Based on this information, the peak was identified as cloprednol.

To show the applicability of the described method, a plasma sample obtained 4 hr after oral administration of cloprednol (12.5 mg) was processed. The chromatogram of the extracted sample is shown in Fig. 1C.

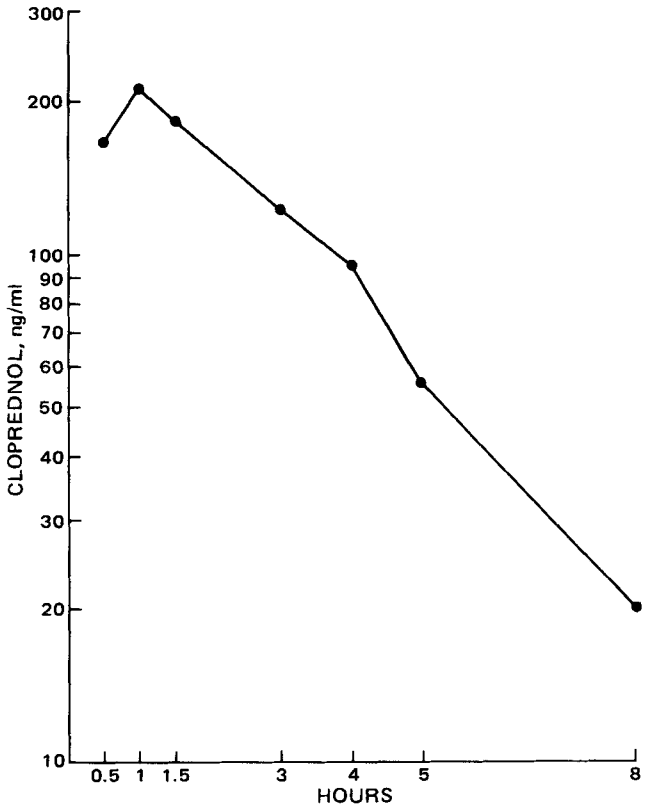

**Figure 3**—*Plasma cloprednol level–time profile of a human volunteer given a 12.5-mg oral dose.*

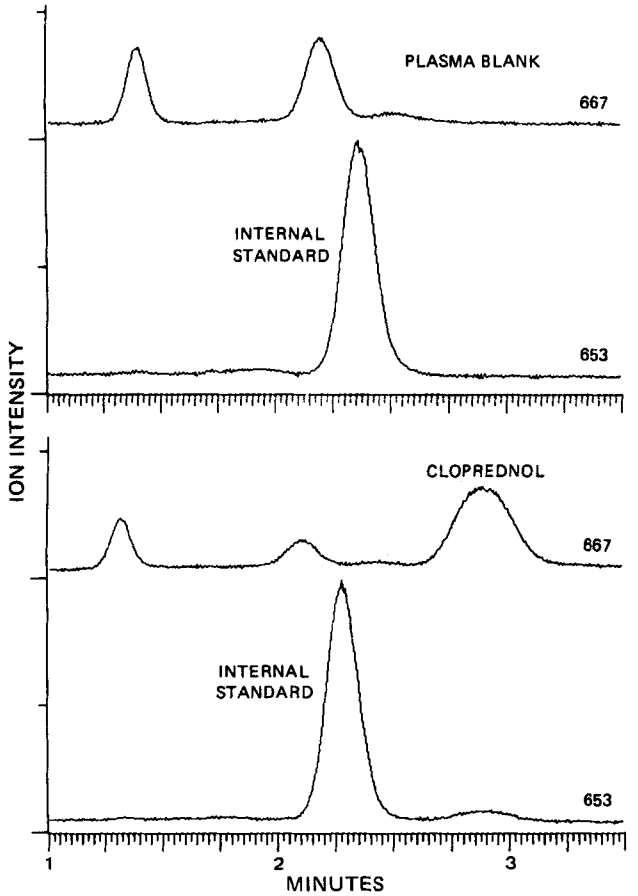

**Figure 4**—*Selected ion chromatograms of blank plasma (3 ml) spiked with the internal standard (top) and a plasma sample obtained 90 min after the administration of a 12.5-mg oral dose of cloprednol (bottom).*

The developed method also established a plasma level–time profile of a normal human volunteer following an oral dose of 12.5 mg of cloprednol (Fig. 3).

To validate the present HPLC method, plasma specimens were assayed by both HPLC and GLC–mass spectrometric[12] methods. To analyze the plasma samples by chemical-ionization mass spectrometry, the samples were extracted with ether and the extracts were cleaned by using miniature adsorption columns. A structural analog was used as an internal standard. The corticoids were converted to their methoxyimino trimethylsilyl derivatives to render them stable to analysis by GLC–mass spectrometry. A typical ion chromatogram obtained using GLC–mass spectrometry is shown in Fig. 4.

Numerous plasma samples from volunteers dosed with cloprednol were analyzed by both procedures. The excellent correlation between the two methods is indicated by the slope of 1.04 obtained from the scatter diagram shown in Fig. 5.

# Statistical Simulation Study of New Proposed Uniformity Requirement for Bioequivalency Studies

JOHN D. HAYNES

Received February 19, 1980, from the *Medical Research Division, Lederle Laboratories, American Cyanamid Company, Pearl River, NY 10965.* Accepted for publication November 19, 1980.

**Abstract** □ The results of a statistical simulation study of the FDA-proposed 75/75 requirement for some bioequivalency studies are presented. The study used test drug products with the same true average bioavailability as the corresponding reference drug products but with various degrees of uniformity as measured by the coefficient of variation. The performance of the 75/75 requirement indicated that the probability of the test product passing was greater if both products had identical small coefficients of variation than if both had identical large coefficients of variation. Moreover, a test product compared to a reference product with equal variability had less probability of acceptance than an equally variable test product for another drug for which the reference product had less variability. Both results indicate that the 75/75 requirement should be withdrawn. An alternative uniformly most powerful, unbiased test, the Pitman–Morgan $F$ test, is presented.

**Keyphrases** □ Bioequivalency studies—statistical simulation of the proposed 75/75 requirement □ Uniformity—statistical simulation of the proposed 75/75 requirement □ Bioavailability—statistical simulation of the proposed 75/75 requirement

The proposed rules for bioequivalency studies of tricyclic antidepressants (1), carbonic anhydrase inhibitors (2), probenecid (3), phenothiazine (4), and quinidine (5) all have a requirement dealing with the blood level results for individual subjects in addition to the usual requirement dealing with the average rate and extent of bioavailability. The new requirement essentially is that the relative bioavailability of the test product (compared to the study results for the clinically proven reference product for each subject) must be ≥75% for 75% of the subjects (or 70% for 70% of the subjects in Ref. 4).

The performance of this new 75/75 specification was found in the present study to have very undesirable characteristics for test and reference products that have equal true averages. Examination of bioequivalency studies of six hypothetical drugs indicated that the performance of the 75/75 specification sometimes can be irrelevant and inverse in practice. A different test is proposed here, consisting of the ratio of standard deviations with an adjustment for correlation.

## BACKGROUND

Until recently, the only required proof of bioequivalence of two drug products has consisted of showing that any differences in the calculated averages for rate and/or extent of bioavailability were medically and/or statistically insignificant. The study must have a number of subjects sufficient to ensure a large probability, commonly 0.80, of detecting a true difference that would be large enough to be clinically important.

The proposed rules (1–5) for bioequivalency studies of five drug types have an additional requirement on the relative bioavailability for the subjects. This requirement pertains to both the average and the range, the latter being a characteristic mentioned only recently in such guidelines. Specifically, the relative bioavailability of the test product must be ≥75% for at least 75% of the subjects (or 70/70 in Ref. 4).

This specification is similar in some respects to the content uniformity specifications on individual capsules and tablets in Ref. 6, which require almost all assay values to fall within 15% of the stated potency. Among the differences, one is very important; in place of the fixed stated potency (usually the labeled amount), the 75/75 specification requires the use of an estimate of the reference drug product potency (*e.g.*, the area under the serum drug level curve) in each subject.

While other specifications deal with the average test product results, this proposed specification places a requirement on the range, uniformity, or homogeneity of individual results. (For some drugs, but not all, this requirement may be reasonable.) There are two obvious ways to compare the test product and the reference product in this respect; one is the 75/75 approach and the other is the ratio of the standard deviations for the two products. Both methods were examined in the present study.

The performance characteristics of the 75/75 specification in the special case in which the true averages are practically equal (as they are for most well-formulated products) were examined. This study examined the success of the 75/75 specification in the detection of poor and superior uniformity of blood drug levels following administration of the test product. Its performance was considered in studies involving six hypothetical drugs with some important parameter, such as the area under the serum curve, for the test products and reference products with various intersubject coefficients of variation (Table I). In all studies, the design was a two-way crossover. The intrasubject coefficients of variation in Table I were taken as 30%, a value often obtained from the error mean square of the crossover analysis of variance, and in Table II were taken as 20%, also a common value.

## EXPERIMENTAL

**Studies with Drug D1**—Both drug products, *i.e.*, reference product and test product, have a true intersubject coefficient of variation of 60% (a common value in bioavailability studies), and the true averages are equal. Since both products are tested in the same subjects, there is usually a degree of correlation; *i.e.*, for a given subject, if the area under the serum drug curve on the reference product is above its 24-subject average, then on the test product the subject's area under the serum drug curve also is likely to be above its average.

The computerized, stochastic simulation procedure described in the *Appendix* was used to generate 1000 studies of 24 subjects (*i.e.*, 24,000 subjects) with a true correlation of 0.00 to serve as a baseline. Of these studies, 140 met the 75/75 criterion. The same procedure was followed for a range of correlation coefficients, $\rho = 0.30$–$0.90$ (Table I). The proportion increased toward 1.00 (the fair, just value for these two products) as rho increased.

**Studies with Drug D2**—Both of the products have an intersubject coefficient of variation of 40% (also a common value in bioavailability studies), and the true averages are equal. Table I shows that the proportion of D2 studies meeting the 75/75 criterion at any given $\rho$ value was notably greater than the corresponding one for Drug D1. Although for both drugs the test products are just as good as the corresponding reference product in this respect, Drug D1 test product is at a disadvantage simply because the intersubject coefficient of variation is large (although equal) for both products. The probability of accepting the test product is greater for D2 than for D1, although both test products really are equally acceptable as substitutes for their respective reference products.

**Studies with Drug D3**—The intersubject coefficient of variation is 60% for the test product and 40% for the reference product, and the true averages are equal. The proportions in Table I are intermediate to those for D1 and D2 at any given $\rho$ value except 0.80 and 0.90, where it is less than the D1 proportion. By comparing the results obtained with D1 and D3, it is seen that, according to the 75/75 specification, a test product with a range of $AUC$ values that is 50% greater than the range of the reference product $AUC$ values (D3: 60% for test product and 40% for reference product) usually has a greater chance of being declared bioequivalent, in this respect at least, than does a test product with the same range as the reference product (D1: 60% test product and 60% reference product).

**Other Drugs**—The determination of how many subjects should

[a] The values in these two columns are the same as for Drugs D1–D3.

participate in a bioequivalency study was made with the conventional equation involving Type I and II error rates, intrasubject coefficient of variation, and the size of the difference, *e.g.*, in average area under the curve, which is considered clinically important, often 20%. When a study is being planned, generally the variation of only the reference product is known. Therefore, that is what is used in the equation.

Table II shows the results of the simulation procedure for drugs with a smaller intrasubject coefficient of variation of 20%. The statistical power of detection of differences in average blood level *AUC* values in the studies is substantially the same for each of the three drugs and the same as that for the first three drugs.

**Studies with Drug D5**—The D5 proportions have been brought slightly closer to those for D4 than for D1 and D3, but the conclusions are unchanged. The probability of accepting the test product is greater for D5 than for D4, although both test products really are equally acceptable as substitutes for their respective reference products.

**Studies with Drug D6**—The D6 proportions also have been reduced but exceed the D4 proportions for $\rho$ of $\leq 0.80$. The picture is less unreasonable than for D3 but still is not reasonable. The conclusion given relating to D3 must be changed slightly for Drug D6; a test product with a range of *AUC* values that is 50% greater than the range of the reference product *AUC* values usually has a greater chance of being declared bioequivalent, in this respect at least, than does a test product with the same range as the reference product.

**Independent Confirmation**—The logic of the calculation procedure and the numerical results reported in Tables I and II were checked using the distribution theory provided by Marsaglia (7). The numbers agreed exactly to two decimals or were only 1, 2, or 3 low in the second decimal place.

**Results in "Equal Means" Situations**—For test products that give blood levels just as uniform as those obtained with the corresponding reference products (*e.g.*, D1 and D2), the probability of meeting the 75/75 specification is inversely proportional to the intersubject coefficient of variation for the reference product. Thus, the specification is unfair to those particular test products that must be compared to reference products with large intersubject coefficients of variation.

For test products giving blood levels that differ significantly in uniformity from those obtained with the corresponding reference products (*e.g.*, D3), the 75/75 specification is irregular; the inferior test product, that for D3, is either more likely or just as likely to be accepted as the equivalent test product, that for D1.

## DISCUSSION

**Generalization**—The present study dealt with cases where the true means for the two products were equal, as they are for most well-formulated products. When the true means were unequal, the performance characteristics of the 75/75 specification were not investigated here; in those cases, the performance of the 75/75 requirement involves the differences in averages as well as ranges. The findings here are pertinent also in cases where the true means are almost equal. The lack of a broader generalization does not preclude a conclusion about the 75/75 specification. The results indicate that in some common situations, *i.e.*, where the means for the test and reference products are practically equal, the 75/75 requirement is unfair to some particular test products and is irregular in its disposition of test products of various qualities in other studies. Therefore, the 75/75 requirement should be dropped.

The performance (*i.e.*, the probability of accepting the test product) of the 75/75 specification when the test and reference products were truly practically identical (with only random variation operating) depended on the magnitude of the variation, an irrelevant factor. The performance was the inverse of what it should be when the test product's variability is large; with a given, fixed degree of variation for a test product, the smaller the reference product's variation (*i.e.*, the more divergent the two products), the greater the probability of acceptance of the test product.

**Pitman–Morgan *F* Specification Procedure**—A procedure for comparing the uniformity, range, or standard deviation of blood levels of the test product to the uniformity of those of the reference product is the use of intersubject standard deviations for the two products. However, since the standard deviations are determined in the same subjects (*i.e.*, in a crossover study), the usual Fisher $F$ ratio of variances must be adjusted. This adjusted $F$, which is one form used to represent the Pitman–Morgan results, was shown (8) to be a uniformly most powerful, unbiased test.

Let:

$$F = (s_2/s_1)^2 \qquad \text{(Eq. 1)}$$

where the standard deviations $s_1$ and $s_2$ are for the reference product and test product, respectively. (If $F$ is <1.00, no further calculations are necessary because the uniformity of blood levels of the test product is estimated to be as good as that of the reference product or better.)

Then:

$$\text{adjusted } F = [(F-1)^2(n-2)]/[4F(1-R^2)] \qquad \text{(Eq. 2)}$$

where $R$ is the correlation coefficient for the pairs of values for each subject. If this correlation is zero or negative, then the unadjusted $F$ test is appropriate with $N-1$ and $N-1$ degrees of freedom. The adjusted $F$ has the same distribution as the tabulated $F$ with 1 and $N-2$ degrees of freedom. The 0.05 probability level seems appropriate.

The results of one study[1] serve to illustrate the use of these equations for the area under the serum drug concentration–time curve for 18 subjects. The standard deviation of the area was 129.8 for the reference product and 156.3 for the test product. The intersubject correlation coefficient between the area values was 0.90. The Fisher $F$ ratio was 1.45, leading to a Pitman–Morgan $F$ value of 2.94 as calculated from $[(1.45-1)^2(18-2)]/[4(1.45)(1.0-0.90^2)]$. This value has 1 and 16 degrees of freedom and the associated probability is 0.11. It was concluded that the two standard deviations do not differ significantly.

The same Monte Carlo simulation data used for Drugs D1–D6 were used for the Pitman–Morgan $F$ test with the critical $F$ at the 0.05 probability level. The proportions of acceptable studies were as follows: D1 and D2, 0.992 at all $\rho$ values; D4 and D5, 0.986 at all $\rho$ values; D3 ($N$ = 24), 0.743–0.749; and D6 ($N$ = 12), 0.869–0.874. These results are reasonable.

**Statistical Power**—If the true (population) correlation coefficient were 0.80 (chosen here because it is tabulated in Ref. 9), if the Pitman–

[1] Unpublished data.

Morgan $F$ test result in a study would be declared significant at the unilateral probability level of 0.01, if the study used 18 subjects, and if the power of detection of a difference in test and reference product standard deviations were set at 0.80, then the statistically detectable ratio would be (by rough extrapolation of the data in Ref. 9) >2 or 3. In other words, a test product standard deviation that is truly more than double or triple that of the reference product is likely to be detected in a study under these conditions. Any increase in sample size to improve the detection of differences in the standard deviations is believed to be unwarranted since, in view of other sources of inherent variation known in posology but not considered further here and in view of the desirability of minimizing the use of human subjects in bioequivalency studies, the power seems ample.

## APPENDIX

It was assumed that the test product values and the reference product values followed a bivariate normal distribution with both means equal to 100, with certain chosen standard deviations and with correlation coefficients (Table I) modified to allow for the intrasubject variability which, among other things, reduces the estimated value of $\rho$ (10).

The assumption that all actual bioequivalency data follow the bivariate normal distribution may be questioned; therefore, it is noted that very large intersubject coefficients of variation for *AUC*, *e.g.*, 150%, are symptomatic of drug products with either a very skewed distribution or some outliers. In such cases, the mean and standard deviation are not sufficient to describe the bivariate nonnormal distribution. However, if differences in only means are tested, the analysis of variance has been found to be a very robust procedure that is practically undisturbed by such things. Remedies after the fact include transformation of the data (*e.g.*, logarithmic) or identification of assignable causes for outliers; remedies *a priori* consist of controlling factors that have been found to cause aberrant results for the particular drug. In cases where the log transformation is used, the 75/75 rule also must be transformed. The performance of that transformed rule would be investigated differently than here, but intuitively the deficiencies of the rule would be substantially the same. The findings in the present study are appropriate for bioavailability parameters that are normally distributed.

The Monte Carlo simulation proceeded according to a FORTRAN program[2], which used a multivariate normal random deviate generator subroutine, GGNRM[3], and a local subroutine, CALC, which applied the 75/75 rule to each of the 1000 studies in turn. The main program then tallied up the number of studies that "passed." One run was made to obtain each cell in Tables I and II. The Pitman–Morgan $F$ (9) was calculated for the identical sets of data.

# Assignment of Conformation and Configuration to Potassium Permanganate Oxidation Products of Quinidine

**YEHUDA YANUKA, SHIMONA YOSSELSON-SUPERSTINE *, ARTOUL GERYES, and EDWARD SUPERSTINE *x**

Received August 8, 1980, from the *Department of Pharmacy, School of Pharmacy, Faculty of Medicine, Hebrew University–Hadassah Medical Center, Jerusalem, Israel.* Accepted for publication December 2, 1980. *Present address: College of Pharmacy, University of Utah, Salt Lake City, UT 84112.

**Abstract** □ Two epimeric aldehydes [(*R*)- and (*S*)-quinidinals] and the corresponding acids [(*R*)- and (*S*)-norhydroquinidinoic acids] were prepared by the oxidation of quinidine. The $\pi$–$\pi$ interactions of the carbonyl group and the aromatic moiety, as reflected in the NMR spectra, were compared with those of quinidine. NMR spectroscopic analyses made it possible to assign both the stable conformation and their configuration at C-3 to these molecules. The free hydroxyl group at C-9 must be present for the chemical shift values to be concentration dependent. These findings provide more information on association in the parent molecules.

**Keyphrases** □ Quinidine—oxidation products prepared, conformation and configuration assigned, NMR analyses □ Oxidation products—quinidine, conformation and configuration assigned to oxidation products, NMR analyses □ NMR spectroscopy—analyses, quinidine and oxidation products, conformation and configuration assigned

Previous work showed that the NMR spectra of quinidine (I) and hydroquinidine (1) differ significantly. The unique features encountered in the I molecule were attributed to $\pi$–$\pi$ interactions. If changes in these $\pi$–$\pi$ interactions are reflected in the NMR spectra of new compounds compared to the parent substances, it must be determined whether there is any correlation between the NMR data obtained and the biological activity of the compound. The antiarrhythmic activity of I and quinine differ greatly because of differences in configuration at C-8 and C-9. Comparison of the NMR data of I and quinine may provide information on the origin of these differences. Intraatomic distances in the molecules play an important role in their respective biological activities. NMR analyses may be valuable in assessing such differences and thus evaluating their possible therapeutic potential.

NMR analysis was used in the present work to measure the extent of $\pi$–$\pi$ interaction by changing the intensity of

Morgan $F$ test result in a study would be declared significant at the unilateral probability level of 0.01, if the study used 18 subjects, and if the power of detection of a difference in test and reference product standard deviations were set at 0.80, then the statistically detectable ratio would be (by rough extrapolation of the data in Ref. 9) >2 or 3. In other words, a test product standard deviation that is truly more than double or triple that of the reference product is likely to be detected in a study under these conditions. Any increase in sample size to improve the detection of differences in the standard deviations is believed to be unwarranted since, in view of other sources of inherent variation known in posology but not considered further here and in view of the desirability of minimizing the use of human subjects in bioequivalency studies, the power seems ample.

## APPENDIX

It was assumed that the test product values and the reference product values followed a bivariate normal distribution with both means equal to 100, with certain chosen standard deviations and with correlation coefficients (Table I) modified to allow for the intrasubject variability which, among other things, reduces the estimated value of $\rho$ (10).

The assumption that all actual bioequivalency data follow the bivariate normal distribution may be questioned; therefore, it is noted that very large intersubject coefficients of variation for *AUC*, *e.g.*, 150%, are symptomatic of drug products with either a very skewed distribution or some outliers. In such cases, the mean and standard deviation are not sufficient to describe the bivariate nonnormal distribution. However, if differences in only means are tested, the analysis of variance has been found to be a very robust procedure that is practically undisturbed by such things. Remedies after the fact include transformation of the data (*e.g.*, logarithmic) or identification of assignable causes for outliers; remedies *a priori* consist of controlling factors that have been found to cause aberrant results for the particular drug. In cases where the log transformation is used, the 75/75 rule also must be transformed. The performance of that transformed rule would be investigated differently than here, but intuitively the deficiencies of the rule would be substantially the same. The findings in the present study are appropriate for bioavailability parameters that are normally distributed.

The Monte Carlo simulation proceeded according to a FORTRAN program[2], which used a multivariate normal random deviate generator subroutine, GGNRM[3], and a local subroutine, CALC, which applied the 75/75 rule to each of the 1000 studies in turn. The main program then tallied up the number of studies that "passed." One run was made to obtain each cell in Tables I and II. The Pitman–Morgan $F$ (9) was calculated for the identical sets of data.

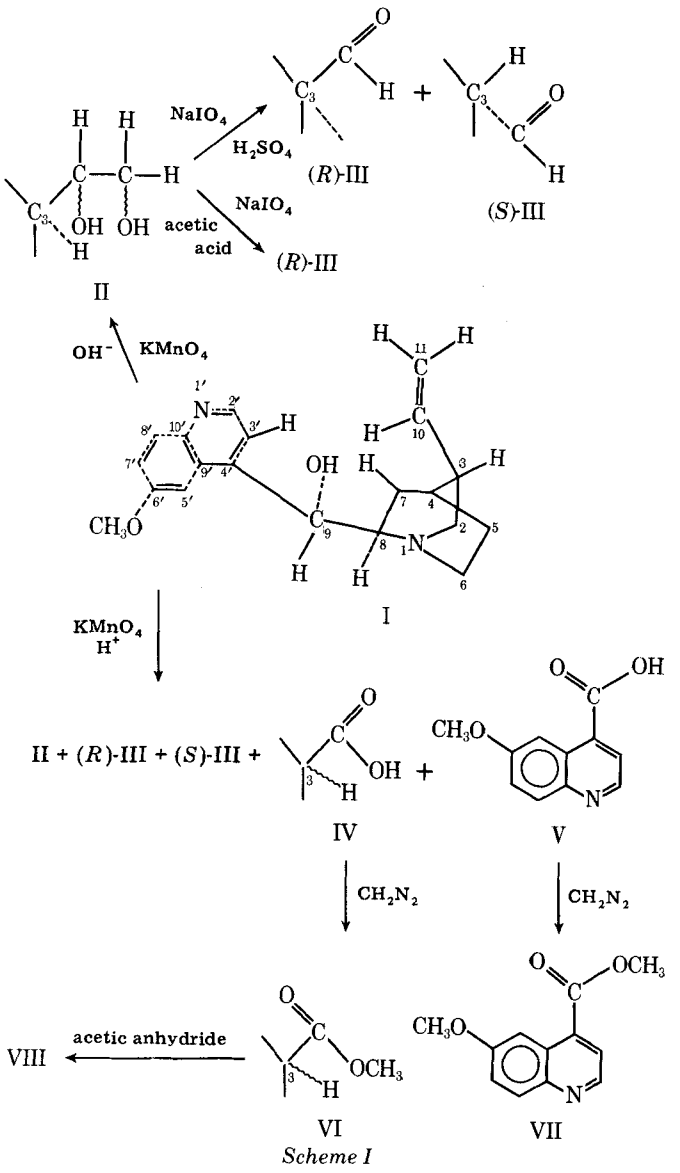

*Scheme I*

the $\pi$ system in the side chain at C-3. For this purpose, quinidinal[1] (III, a C-10 aldehydic derivative of I) and the corresponding acid norhydroquinidinoic acid (quitenidene, IV) were prepared by potassium permanganate oxidation of the vinylic group of I. Although preparation of III from I by the ozonization route was reported previously (2), the alternative method utilizing potassium permanganate was selected. With the latter method, it was possible to obtain the diol (II), the epimeric aldehydes (*R*)- and (*S*)-III, the corresponding acid (IV), and a fragmentation product (V) in one step (Scheme I). NMR analyses and TLC of the isolated products made it possible to study the characteristics and nature of the new compounds and the details of the experimental conditions.

## EXPERIMENTAL

NMR spectra were obtained at 300 MHz using an analytical NMR spectrometer[2] equipped with an automatic recorder. Tetramethylsilane in deuterochloroform was the internal standard. IR spectra were measured in potassium bromide disks on a grating IR spectrophotometer[3]. Mass spectra were recorded on a mass spectrometer[4] provided with an electric-impact and field-desorption ion source. Pure I was obtained from commercial quinidine sulfate USP[5]. TLC and preparative TLC were carried out on aluminum oxide GF 254[6] plates.

[a] In parts per million. [b] Increasing overlap with the hydrogen of chloroform with concentration.

**Oxidation of I by Potassium Permanganate and Dilute Sulfuric Acid**—Quinidine (I) (1 g), as the sulfate salt, was dissolved in 20 ml of dilute sulfuric acid (2 *N*), and two equivalents of potassium permanganate (0.95 g) in aqueous solution was added. The reaction mixture was stirred for 2 hr at room temperature. Sodium bisulfite in a 10% aqueous solution was added dropwise until the precipitated manganese dioxide was dissolved. TLC revealed a mixture of polar and nonpolar products. Separation of these products was accomplished by extraction and chromatography.

**Isolation of II and III**—The clear solution obtained after the addition of sodium bisulfite was transferred to a separator and made alkaline by the addition of sodium carbonate. The mixture was extracted completely with chloroform containing 10% methanol. After evaporation of the solvents, TLC revealed the presence of hydroquinidine, a small amount of unchanged I, and two new compounds, a diol (II) appearing as two isomers and the aldehyde (III).

The mixture was chromatographed on aluminum oxide plates. The fluorescing material was viewed under UV light and divided into three fractions. The upper strip was scraped and dispersed in 20 ml of 0.1 *N* $H_2SO_4$. Sodium bicarbonate (240 mg) was added, the mixture was transferred to a separator, and I and hydroquinidine were extracted with chloroform. The middle strip containing III was treated in the same manner but was extracted with chloroform containing 10% methanol. Its melting point was nonspecific; $R_f$ 0.20 (ethyl acetate–ethanol, 9:1); IR: 1720 (CO) $cm^{-1}$; mass spectrum: *m/z* 326. The chemical shifts of III, which consisted of two epimers (*R*)-III and (*S*)-III at various concentrations, are summarized in Table I.

The lower strip, containing a 1:1 mixture of the diastereomeric diols (II), was scraped; the powder obtained was extracted directly with chloroform containing 20% methanol. The two diastereomers were separated by repeated preparative TLC on aluminum oxide plates. The more polar diol, $R_f$ 0.13 (ethanol), yielded crystals from acetone and was sparingly soluble in chloroform. When attempting to determine its melting point, the crystals began to discolor at ~200°, becoming brown (similar to the caramelization of sugar) and forming a solid lump, which eventually liquified at 225–227°. The less polar diol, $R_f$ 0.36 (ethanol), was much more soluble in acetone and chloroform and could not be induced to crystallize. Upon the addition of ether to an acetone solution of the less polar diol, an amorphous material settled out. The melting

point of this amorphous material was nonspecific; at ~200°, it became brown and finally turned into a viscous liquid.

**Isolation of VI and VII**—The alkaline solution was made acidic by the addition of acetic acid. The mixture was extracted with chloroform–isopropyl alcohol (3:1). After evaporation of the solvents, the residue was treated with diazomethane, and the methyl esters of IV and V (VI and VII, respectively) were separated by preparative TLC. The mixture was chromatographed on aluminum oxide plates. The fluorescing material was viewed under UV light and divided into two fractions. The upper strip was scraped, and the powder obtained was extracted directly with chloroform containing 10% methanol. It contained the methyl ester of quininic acid (VII), $R_f$ 0.80 (ethyl acetate), mp 80–81°; IR: 1715 (CO) $cm^{-1}$. Table II lists the NMR data.

The lower strip was treated as was the upper strip and was found to contain the methyl ester of norhydroquinidinoic acid (VI), $R_f$ 0.14 (ethyl acetate) and $R_f$ 0.70 (ethyl acetate–ethanol, 1:1). Recrystallization from methanol gave crystals, mp 140–141°. However, there was a softening of the material at 137°, suggesting that VI consisted of two diastereomers, (*R*)-VI and (*S*)-VI. The IR spectrum showed 1725 (CO) $cm^{-1}$ with a shoulder at 1740 (CO) $cm^{-1}$, implying the existence of another diastereomer. The chemical shifts at various concentrations are summarized in Table III.

**Methyl Ester of 9-Acetyl Norhydroquinidinoic Acid (VIII)**—Pure VI (60 mg) was dissolved in 1 ml of pyridine and 1 ml of acetic anhydride, and this mixture was allowed to stand overnight for ~24 hr at room temperature. The solvents were removed with an air stream, and the solid residue was dissolved in 30 ml of chloroform. The chloroform solution was transferred to a separator, washed with 20 ml of water, and filtered without delay through anhydrous sodium sulfate since the acetylated product was prone to hydrolysis, $R_f$ 0.5 (ethyl acetate); IR: 1726, 1736, and 1746 (CO) $cm^{-1}$. The NMR data are included in Table III.

**Oxidation of I by Potassium Permanganate under Basic Conditions**—Five grams of I was dissolved in 30 ml of tetrahydrofuran. To this solution was added 40 ml of aqueous 1 *N* KOH followed by two equivalents of potassium permanganate (4.75 g) in aqueous solution. The reaction mixture was stirred magnetically for 7 days at room temperature and then was transferred in its entirety to a separator and extracted with chloroform containing 20% methanol until complete extraction was achieved. Upon removal of the solvents, a substance was readily crystallized. It proved to be a mixture of two diastereoisomers (II), which were identical to those obtained by oxidation of I under acidic conditions.

**Oxidation of II by Sodium Periodate**—*Method A: Dilute Aqueous Strong Acid*—One gram of II was dissolved in 20 ml of 1 *N* $H_2SO_4$. A 10.7% aqueous sodium periodate solution (6.5 ml) was added to the acidic solution of II, and this mixture was stirred at room temperature overnight. The solution was then transferred to a separator, made alkaline with sodium carbonate, and extracted thoroughly with chloroform containing 20% methanol. After evaporation of the solvents, an amorphous material was obtained that would not crystallize. This material was identical in all respects to the amorphous mixture of (*R*)-III and (*S*)-III obtained under acidic conditions.

*Method B: Dilute Aqueous Weak Acid*—One gram of II was dissolved in 1 ml of acetic acid and diluted with 20 ml of water. The sodium periodate was added, and the reaction mixture was stirred overnight. Once again the solution was made alkaline and extracted as for Method A. After evaporation of the solvents, a crystalline material was obtained and recrystallized from acetone, mp 205°, $R_f$ 0.20 (ethyl acetate–ethanol, 9:1). NMR analysis revealed only the natural epimer (*R*)-III (Table I).

**Epimerization of (*R*)-III**—Attempts to purify (*R*)-III by chromatography on aluminum oxide plates brought about complete epimerization, and NMR analysis showed that the final product contained a 1:1 mixture of (*R*)-III and (*S*)-III. On the other hand, NMR analysis of a freshly prepared sample of pure (*R*)-III in deuterated chloroform showed only pure (*R*)-III. After 24 hr, the same sample showed small amounts of the epimeric aldehyde (*S*)-III; after a 7-day standing period, the sample showed equal amounts of (*R*)-III and (*S*)-III.

## RESULTS AND DISCUSSION

**Assignment of Conformation and Configuration to Oxidation Products of I**—The data summarized in Table I show clearly that the chemical shift values of (*R*)-III and (*S*)-III in a mixture depend not only on the concentration of the mixture but also on the relative amounts of these epimers in the mixture. Therefore, to assign the configuration at C-3 in these molecules, NMR analysis was carried out on a mixture containing (*R*)-III and (*S*)-III in a 2:1 ratio.

*NMR Analysis of (R)-III*—The aldehydic proton resonated as a singlet at δ 9.85 ppm. The H-2′ proton appeared as a broad singlet at δ 8.54 ppm, H-3′ appeared as a doublet at δ 7.45 ppm ($J$ = 4 Hz), and H-8′ appeared as a doublet at δ 7.90 ppm ($J$ = 9 Hz). The H-5′ and H-7′ protons resonated between δ 7.28 and 7.25 ppm. The H–C-9–OH proton appeared as a doublet at δ 5.60 ppm ($J$ = 3.0 Hz). The methoxy protons absorbed at δ 3.87 ppm.

*NMR Analysis of (S)-III*—The aldehydic proton resonated as a singlet at δ 9.76 ppm, at a higher field compared to the crystalline aldehyde. The H-2′ proton appeared as a broad singlet at δ 8.54 ppm. The H-3′ proton resonated at δ 7.50 ppm ($J$ = 4 Hz), at a lower field compared to the crystalline aldehyde; H-8′ appeared at δ 7.90 ppm ($J$ = 10 Hz), the same as in the crystalline aldehyde. Both H-5′ and H-7′ appeared separately; the former proton shifted to a higher field at δ 7.11 ppm and the latter proton absorbed at almost the same frequency compared to (*R*)-III. The proton alpha to the hydroxyl group at C-9 (H–C-9–OH) appeared as a slightly broadened singlet at δ 5.71 ppm, at a lower field than (*R*)-III. The peak of the methoxy protons appeared at δ 3.81 ppm, at a slightly higher field than (*R*)-III.

While some protons were less shielded in (*R*)-III compared to those of (*S*)-III, other protons in (*R*)-III experienced more shielding than the same protons of (*S*)-III. In addition, the aldehydic protons in both epimers appeared as singlets while the coupling constants between the aldehydic proton and the proton alpha to the carbonyl group generally ranged between 1 and 3 Hz and in some cases reached a value of 6 Hz (3, 4). This finding indicates that a single rotamer prevails in the aldehydic groups with a dihedral angle of ~90° between the aldehydic proton and the proton alpha to the carbonyl group at C-3.

In a previous work based on NMR analyses (1), we assumed a stable

preferred conformation for I. On the basis of the data presented for the two aldehydes, we concluded that the molecules of each epimer exist as a stable rotamer and the structure of the rotamers depends mainly on steric and $\pi$–$\pi$ interactions in the molecule. As a result of this latter interaction, the coplanar H–C=O group in (*R*)-III is in close proximity to the nitrogen-containing aromatic ring, and this involves rotation about the C-4′–C-9–C-8 bonds, making the dihedral angle between the protons of C-9 and C-8 <90°. In (*S*)-III, the steric interaction of the proton at C-3 and the nitrogen-containing aromatic ring causes rotation in the opposite direction, bringing about a change in the dihedral angle between the protons of C-9 and C-8 from <90° to ~90°. At the same time, the H–C=O group is positioned at a greater distance from the nitrogen-containing aromatic ring as compared to (*R*)-III.

The ups and downs of the chemical shifts of some of the protons could be explained on the basis of the proposed assumption. In (*R*)-III, the close proximity of the H–C=O group to the nitrogen-containing aromatic ring places H-3′ within the positive zone of the carbonyl cone and H-2′ near its border. Consequently, H-3′ shifts to a higher field, and H-2′ appears as a broad singlet. For the same reason, the aldehydic proton in (*R*)-III is under the deshielding influence of the aromatic ring and absorbs at a lower field compared to the aldehydic proton of (*S*)-III. In (*S*)-III the nitrogen atom of the quinuclidine ring is in closer proximity to H-5′ than in (*R*)-III and, consequently, H-5′ experiences a shielding effect [due to a long-range shielding by the nitrogen atom (5, 6)].

Whereas the oxidation of I under basic conditions was relatively slow, the oxidation under acidic conditions was much faster and more complex. Its value was in the ability to: (*a*) prepare, in one reaction, carbonyl-containing compounds other than the aldehydes [(*R*)-III and (*S*)-III]; (*b*) study, with the help of NMR analyses of these additional carbonyl-containing compounds, the intensity of the $\pi$–$\pi$ interaction when the side-chain $\pi$ system varied from vinyl to aldehydic carbonyl to ester carbonyl; (*c*) explore, at the same time, their influence on the chemical shifts of some important protons in the molecule; and (*d*) determine whether they were concentration dependent.

The NMR data of (*R*)-III and (*S*)-III made it possible to assign the configuration at C-3. As the carbonyl group departed from the aromatic ring, certain apparent changes took place. The intensity of these changes depended on the mutual $\pi$–$\pi$ interactions between the aromatic ring and the side-chain $\pi$ systems. In Table IV, three $\pi$ systems (aldehyde, methoxycarbonyl, and vinyl) are compared; differences in intensity were measured by the chemical shifts experienced by H-2′, H-3′, and H-8′. For comparative purposes, hydroquinidine was also introduced. Since H-2′ is at a greater distance from the side-chain $\pi$ systems, H-3′ is more sensitive to both the intensity of the $\pi$ systems and the stable conformation of the molecule. As can be seen in Table IV, the shielding of H-3′ increased in the following order: (*R*)-III > VI ≈ I. With regard to H-2′, the order of shielding was as follows: (*R*)-III = I > VI.

These differences may be explained on the basis of different orientations of the carbonyl group of the aldehyde and methoxy functions. Since the methoxy group in VI is more bulky than the proton in the aldehydic group, rotation about C-10 takes place and makes the distance between the carbonyl group and H-3′ of the aromatic ring greater and thus lowers the shielding effect. Consequently, VI resembles hydroquinidine while (*R*)-III is closer to I with respect to the shielding effects on H-2′ and H-3′. Therefore, it is concluded that the aldehydic and vinylic groups are more appropriate for assignment of the C-3 configuration than the methoxy group, which brings about steric disturbances.

**Origin of $\pi$–$\pi$ Interaction**—The nitrogen-containing ring is relatively more $\pi$ deficient due to the electronegative character of the nitrogen atom. This $\pi$-deficiency is reflected in the chemical shifts of the protons in the two rings of the quinoline structure. The protons of the nitrogen-containing ring generally are deshielded to a greater extent than the protons of the sister ring. The $\pi$–$\pi$ interactions may be visualized as a donor–acceptor system. Thus, the $\pi$-deficient aromatic ring is the acceptor while the side-chain $\pi$ system is the donor.

**Epimerization at C-3**—Oxidation of II under weakly acidic conditions for a short time (as in Method B) yields pure natural (*R*)-III. Under more acidic conditions (as in Method A), rapid epimerization at C-3 takes place, mainly due to the tertiary nature of the carbon at C-3. In addition, the ease of epimerization suggests that, in the natural configuration (*R*)-III, the aldehydic derivative III is under steric strain and that this strain is partially relieved in the process of epimerization. An equilibrium is reached between the two epimers. The 1:1 ratio obtained at equilibrium suggests that the energy content of (*R*)-III and (*S*)-III is approximately equal. In (*R*)-III, the energy gained by the $\pi$–$\pi$ interaction is partially offset by the steric interaction developed in the vicinity of C-8–C-9. In (*S*)-III, the release of steric strain in the vicinity of C-8–C-9 is counteracted by a decrease in the $\pi$–$\pi$ interaction. Complete epimerization was also found when (*R*)-III was subjected to chromatography or dissolved in chloroform. Therefore, the enhanced sensitivity is due not only to the tertiary character of C-3 but also to the energy content of the molecule.

**Concentration Dependence of Chemical Shifts**—The concentration dependence of the chemical shifts of I and hydroquinidine were observed previously (1). It was suggested that this concentration dependence is a result of molecular association. In the present study, the same phenomenon was observed in III and IV (Tables I and III). Since the natural epimer (*R*)-III was only sparingly soluble in deuterochloroform, a mixture of (*R*)-III and (*S*)-III, which was much more soluble, was used. Compound IV was almost insoluble in deuterochloroform; therefore, the NMR analysis of its methyl ester (VI) was made. Quininic acid (V) was converted to its methyl ester (VII), which was much more soluble. Practically, no concentration dependence was observed in this compound (Table II).

These observations clearly imply that changes in the chemical shifts at different concentrations occur only when the quinuclidine moiety is connected to the quinoline moiety through the carbon atom at C-9 to which a hydroxyl group is attached. Thus, the previous suggestion that molecular association is initiated by hydrogen bonding of the hydroxyl groups has additional support. Aside from its importance in understanding the origin of the association in the molecules, the NMR data of the fragmentation derivative (VII) reveal some interesting features. Theoretically, the carbonyl group of the methoxycarbonyl moiety may be directed toward either H-5′ or H-3′ if there is no inhibition of resonance in the molecule as a whole. On the other hand, the inhibition of resonance could cause rotation about the C-4′–C-9 bond and bring about a departure of the bulky methoxy group from either H-3′ or H-5′. The NMR data of VII unambiguously show that the carbonyl group is positioned near H-5′ and that the methoxy group is in the vicinity of H-3′. The model of this molecule reveals that reversing the positions of the carbonyl group and the methoxy is associated with intensified steric strain. On the basis of this assumption, the NMR data may be rationalized. Furthermore, the concentration-independence of its chemical shifts implies that the molecule has one, and only one, stable rotamer.

When the hydroxyl group was replaced by acetoxy in VI, it was found that there was no concentration dependence in the acetyl derivative (VIII) (Table III). This result was in full agreement with previous findings (1) suggesting the absence of molecular association in the acetyl derivative of I. As expected, the presence of the acetoxy group caused a paramagnetic shift of H-2′ and a diamagnetic shift of H-3′. Another consequence of the concentration independence of this molecule was clearly shown in its NMR spectrum, namely, the presence of a second epimer (*S*)-VIII in addition to (*R*)-VIII. Since the oxidation of I under acidic conditions yielded two epimers, (*R*)-III and (*S*)-III in a 1:1 ratio, one might expect that the acids of the same oxidation reaction would also consist of two epimers (*R*)-IV and (*S*)-IV in a 1:1 ratio. The NMR data showed that this was not the case; rather, the ratio of the two epimers was ~3:1 in favor of the natural configuration. This observation suggests that I is mainly oxidized directly to an acidic product without the mediation of an aldehyde. The presence of (*S*)-IV was due to slow oxidation of the epimeric aldehydes (*R*)-III and (*S*)-III. The presence of this second epimer was not revealed in the NMR spectrum of VI but only in that of the acetylated product (VIII); this result is a consequence of the lack of molecular association.

# Impact of Stable Conformation of Cinchona Alkaloids on Protonation Site

**YEHUDA YANUKA, SHIMONA YOSSELSON-SUPERSTINE *, ARTOUL GERYES, and EDWARD SUPERSTINE *x**

Received August 8, 1980, from the *Department of Pharmacy, School of Pharmacy, Faculty of Medicine, Hebrew University–Hadassah Medical Center, Jerusalem, Israel.* Accepted for publication December 2, 1980. *Present address: College of Pharmacy, University of Utah, Salt Lake City, UT 84112.

**Abstract** □ NMR analyses of quinidine and other cinchona alkaloids and their monoprotonated salts in deuterium oxide and in deuterochloroform revealed that the molecules assume new conformations in polar and nonpolar media, affecting the protonation site and hydrophilic–lipophilic characteristics. The ion-pair feature of the salts is lost and the molecules assume a neutral feature when they are transferred from an aqueous to a lipoid phase. Hydrophobic bonds between the molecules and their environment and within the molecule itself may affect the binding of cinchona alkaloids to membranes in biological fluids.

**Keyphrases** □ Quinidine—impact of stable conformation on protonation site, effect of polar and nonpolar solvents on conformation, NMR analyses □ Alkaloids, cinchona—impact of stable conformation on protonation site, effect of polar and nonpolar solvents on conformation, NMR analyses □ Conformation—impact on protonation site of quinidine and other cinchona alkaloids, effect of polar and nonpolar solvents, NMR analyses □ NMR spectroscopy—analyses of quinidine and other cinchona alkaloids, impact of stable conformation on protonation site, polar and nonpolar solvents

The protonation site on the quinidine molecule (I) might have an important bearing on its disposition, protein binding, and activity in the body. When the nitrogen of the quinuclidine ring of I is uncharged at pH 10, the number of receptor areas in albumin increases from one to three, possibly because the polar effect of the positively charged nitrogen is lost (1). At pH 7.4, however, the quinuclidine ring apparently does not play a great part in the binding of I to albumin, as was demonstrated in the competitive inhibitory effects of related quinoline compounds on the binding of I to albumin (2). It was postulated (3) that the cardiac action of I may result from special orientation of the molecule at interfaces, with binding of the quinoline ring to membrane lipoprotein and with the charged quinuclidine ring in the aqueous phase affecting ion movement across the cardiac cell (Fig. 1).

Any factors that may change the protonation site in I, such as the polarity of the surrounding medium and the dependence of conformation on this polarity, might affect the binding of I to plasma or cell or enzyme protein and, hence, its distribution, activity, and metabolism. This study explored the dependence of hydrophilic–lipophilic and structural properties of the salts of I and other cinchona alkaloids on solvent polarity. NMR analyses of the alkaloids and their salts were utilized.

conducted in a pressure reaction apparatus[5]. Pure quinoline (IX) and quinoline hydrochloride (X) were obtained from commercially available quinoline[6]. TLC and preparative TLC were carried out on aluminum oxide GF 254[7] plates.

For NMR spectra measurements of the salts in deuterium oxide, an internal standard such as tetrahydrofuran (the chemical shifts of which were determined relative to 2,2,3,3-tetradeutero-3-(trimethylsilyl)propionic acid sodium) had to be used since the NMR spectra of the samples containing 2,2,3,3-tetradeutero-3-(trimethylsilyl)propionic acid sodium did not completely match the spectra without an internal standard. These discrepancies may originate from a proton transfer from the nitrogen to the carboxylate group of 2,2,3,3-tetradeutero-3-(trimethylsilyl)propionic acid sodium or from its influence on the mode of association of the cinchona salts. Since tetrahydrofuran was not completely without effect on association between molecules, except in the spectra of X, the absolute chemical shift values were eventually determined by matching the spectra in the presence and absence of the two different internal standards. This technique was possible because most chemical shifts, especially those on the margins, coincided.

**Purification of Commercial I and V**—Purification was carried out according to a procedure described previously (4). Table I lists the NMR data.

**Reduction of I to III**—Compound I (1 g) was dissolved in ethanol (50 ml) in a suitable vessel. Palladium-on-carbon (5%, 0.1 g) was added, and the hydrogenation was allowed to proceed for 1.5 hr at room temperature in the pressure reaction apparatus. The catalyst was removed by filtration through very retentive filter paper, the ethanol was evaporated, and III was readily crystallized. Table I lists the NMR measurements. Compound III was purified by preparative TLC (4).

**Reduction of V to VII**—Hydrogenation and purification were conducted as already described. Table I lists the NMR data.

**Purification of IX**—Purification was carried out according to a known procedure (5).

**Preparation of Hydrochloride Salts**—Each free base (I, III, V, VII, and IX) was dissolved in an accurate amount of dilute aqueous solution of hydrochloric acid. Water was removed under reduced pressure or allowed to evaporate spontaneously, and the residue of each salt was dried to constant weight.

## RESULTS

Comparison of the NMR data of I and II in deuterochloroform revealed that the aromatic protons of the pyridine ring in II moved to a lower field. The deviation of H-2′ was 0.01 ppm, and that of H-3′ was 0.15 ppm. This result is to be expected in protonated pyridine (6). In contrast, the protons of the benzene ring in II experienced a shielding effect and shifted upfield: H-8′ to 0.25 ppm, H-5′ to 0.37 ppm, and H-7′ to 0.38 ppm. In X (Table II), all aromatic protons absorbed at a lower field under the influence of the protonated nitrogen. These differences are attributable partly to the methoxy group at C-6′.

An outstanding deshielding effect on the proton H–C-9–OH, which appeared as a singlet, was observed in II when it moved 0.89 ppm downfield. This shift is in agreement with the reported value for a proton that is alpha to protonated nitrogen or for vinylogous hydrogen. It probably applies also to a proton alpha to a positively charged carbon (or to vinylogous hydrogen) such as C-2′ and C-4′ in the quinoline cation.

These deviations observed in the chemical shifts may be rationalized if the protonation site is assumed to be on the quinoline nitrogen and not on the quinuclidine nitrogen, which has a much higher pKa value. Had the protonation taken place on the quinuclidine nitrogen, the proton H–C-9–OH would have been deshielded to a lesser extent (0.35 ppm).

NMR data of II in deuterochloroform and in deuterium oxide showed that the proton H–C-9–OH, appearing as a singlet, shifted downfield only by 0.42 ppm in the latter, indicating that this proton could not be at a position alpha to protonated nitrogen. Other evidence was provided when the chemical shift values of the aromatic protons of the salts in the different solvents were compared. In deuterium oxide, the H-2′ and H-3′ protons and some protons of the benzene moiety resonated at lower fields (Table II). These observations imply that the protonation site is on the quinuclidine nitrogen in deuterium oxide.

Table II also shows that in II in deuterium oxide, as compared to the free base in deuterochloroform, the methoxy protons and all aromatic protons, except H-8′, experienced a paramagnetic effect.

NMR analyses of III, V, and VII and their salts (IV, VI, and VIII) in the two different solvents (Table II) demonstrated the same trend in chemical shifts, although they varied in their intensity. This finding indicated that the protonation site in these molecules is the same as that observed in I, *i.e.*, on the quinoline nitrogen in the nonpolar solvent and on the quinuclidine nitrogen in the polar solvent.

## DISCUSSION

Theoretically, protonation on the quinoline nitrogen should cause a paramagnetic effect on all aromatic protons, as was observed in X. In II in deuterochloroform, the diamagnetic effect observed on the benzene ring protons was attributed to the methoxy group at C-6′. The electron-releasing ability of this group, the capability of the molecule to pass to another conformation, and the concomitant bonding of a proton to the quinoline nitrogen in the neutral molecule increase the probability of protonation on this nitrogen. In VI in deuterochloroform, the paramagnetic effect on the pyridine protons was more pronounced than in II whereas the diamagnetic effect on the benzene protons was reduced (Table II). This result is expected when the conformations and pKa values of the two molecules are compared.

Protonation on the quinoline nitrogen causes the molecules to assume a new stable conformation in which the steric requirements for protonation on the quinuclidine nitrogen are more severe since it is now less exposed. This change is reflected in the change in the dihedral angle between the C-8 and C-9 protons. In the salts, this angle approaches 90° and is caused by rotation about the C-8–C-9 bond. The arrangement of the protons alpha to the quinuclidine nitrogen with respect to the aro-

matic rings is greatly dependent on the dihedral angle; therefore, their chemical shifts in the salts will differ from those in the free bases. The extent of these differences helps to establish the nature of the new rotamers. Four of the five protons alpha to the quinuclidine nitrogen in II in deuterochloroform moved ~0.33 ppm downfield in comparison to the same protons in the free base as a result of being closer to the pyridine ring. Proton H-8 in II was ~1 ppm downfield in comparison to its chemical shift in I as a result of facing the pyridine ring instead of the benzene ring. In V, the proton alpha to the quinuclidine nitrogen that was the most deshielded was one of the C-6 protons (Table III) since the new conformation placed it closer to the pyridine ring.

Supporting evidence for differences in conformation was provided by the analysis of the chemical shifts of vinylic and the methoxy protons in deuterochloroform. In II, the methylene protons at C-11 appeared at a field lower than that of their counterparts in the free base, and the chemical shift of the methine proton at C-10 was practically unchanged. In VI, the reverse behavior was observed when compared to its free base. This finding suggests that, in I, the vinylic moiety is arranged as in A and, in V, it is arranged as in B (Fig. 2). The protons of the methoxy group in the salts (II, VI, and VII) resonated at a higher field than in the free bases. Protonation on the quinoline nitrogen should have caused a deshielding effect on these protons. The fact that a diamagnetic effect was observed instead implies that the conformation of the molecules had changed greatly; *i.e.*, a rotation of 180° around the C-4′–C-9 bond had occurred. In this new conformation, the protons of the methoxy groups are within the shielding zone of the vinyl and ethyl cone, the nonpolar hydrophobic moieties are on one side of the molecule, and the two nitrogens are on the opposite side. In IV, the protons of the methoxy group experienced the expected paramagnetic effect since the suggested rotation did not take place because of severe steric requirements of the ethyl group at C-3.

NMR analysis of II in deuterium oxide revealed that the protonation site was on the quinuclidine nitrogen, as expected in such a polar solvent, since the positive charge on this nitrogen is stabilized by solvation. It further showed that the molecule assumed a new conformation. This change was best reflected in the pronounced paramagnetic effect on the methoxy, vinylic, and some aromatic protons in this solvent *versus* deuterochloroform.

Changes in conformation also were reflected in the NMR data of II in deuterium oxide and of the free base in deuterochloroform. The paramagnetic effect observed on almost all protons of II in deuterium oxide could be rationalized if strong hydrogen bondings between the solvent and polar groups in the molecule took place. These enhanced hydrogen bondings are a result of the lipophilic nature of the cinchona alkaloids and the high free energy content of these molecules in aqueous solution. The hydrogen bonding between the methoxy group and the solvent nullifies the electron-releasing ability of this group; consequently, the aromatic protons in the benzene ring do not move to higher field. Hydrogen bonding between the pyridine nitrogen and the solvent caused the observed shift in the protons of this group. To account for the pronounced shift of H-8′ to a higher field in the salt in deuterium oxide, the anisotropy of the quinoline nitrogen lone pair has to be invoked. This effect is present in the free base in the nonpolar solvent and is eliminated in the salt in deuterium oxide as a result of hydrogen bonding (solvation). Since neutral moieties are involved in hydrogen bonding (7, 8), only the anisotropic effect of the nitrogen lone pair on the neighboring protons

**Table III—Chemical Shift Values [a] of the Protons Alpha to the Quinuclidine Nitrogen of I and V (20 ± 1 mg/0.5 ml)**

| Proton | I | Proton | V |
|---|---|---|---|
| H-8 | 3.47 (q) (1H) | H-6 | 3.49 (m) (1H) |
| H-2 | 3.07 (m) (1H) | H-6 + H-8 | 3.06 (q) (2H) |
| H-2 + H-6 | 2.93 (q) (2H) | H-2 | 2.65 (m) (2H) |
| H-6 | 2.80 (m) (1H) | | |

[a] m = multiplet, and q = quartet. Values are expressed in parts per million.

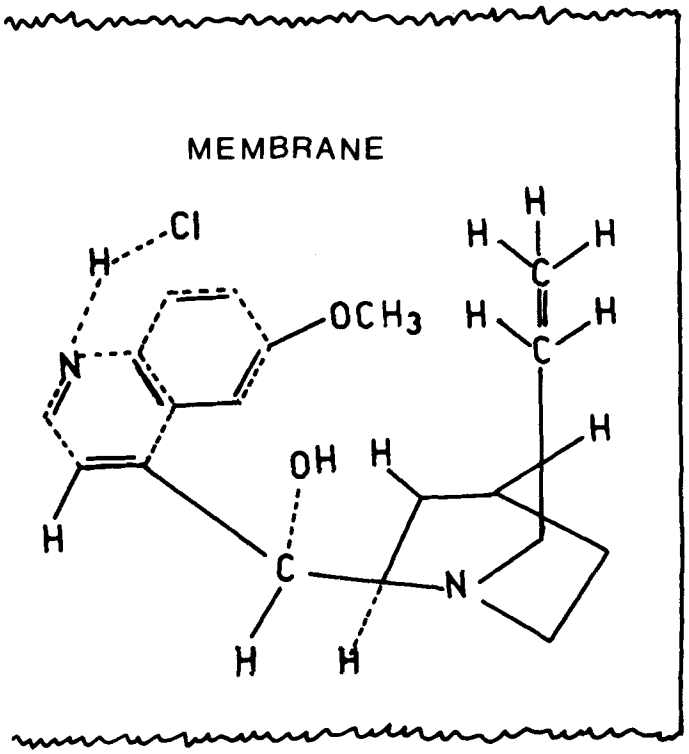

**Figure 3**—*Penetration of the monohydrochloride salt of I (II) through a membrane.*

comes into play. In the ion-pair counterpart, such as may exist in the protonated molecule, additional effects appear.

## CONCLUSION

On the basis of NMR analyses of the salts of some cinchona alkaloids, it was concluded that the protonation site on these molecules varies with their spatial orientation and the nature of the solvent. In the process of changing the conformation, when moving from a polar to nonpolar solvent, the basicity of the quinuclidine nitrogen is reduced as the quinuclidine and quinoline moieties get closer to each other. The proton is transferred from the quinuclidine nitrogen to the quinoline nitrogen, the ion-pair feature, which enhances hydrophilic capacity, is lost, and the molecule assumes a neutral feature with stronger hydrophobic bonds. As a result of this process, the hydrophilic–lipophilic properties of the molecule change in favor of a more lipophilic character.

These findings may have an important bearing on the passage of I and its congeners from an aqueous to a lipoid phase. Thus, the molecule not only is adsorbed to a membrane, as suggested in Fig. 1, but also penetrates the membrane (Fig. 3). Given the opportunity, the solute will forsake the aqueous solution for the organic environment.

The variation in conformation found in the studied cinchona alkaloids and their salts may contribute to their differences in biological activity.

# NOTES

# Biological and Phytochemical Investigation of Plants XVI: *Strumpfia maritima* (Rubiaceae)

**C. C. HSU *, R. H. DOBBERSTEIN *§, A. S. BINGEL *, H. H. S. FONG *, N. R. FARNSWORTH *x, and J. F. MORTON ‡**

Received May 15, 1980, from the **Department of Pharmacognosy and Pharmacology, College of Pharmacy, University of Illinois at the Medical Center, Chicago, IL 60612*, and the ‡*Morton Collectanea, University of Miami, Coral Gables, FL 33124.* Accepted for publication November 5, 1980. §Present address: Stevia Company, Arlington Heights, IL 60005.

**Abstract** □ An aqueous extract of the flowering tops of *Strumpfia maritima* exhibited antifertility activity in female rats. The extract also contained the flavonol glycoside narcissin. This article represents the first reported isolation of this flavonoid from the Rubiaceae, as well as the first reported phytochemical and pharmacological investigation of the genus *Strumpfia*.

**Keyphrases** □ *Strumpfia maritima*—biological and phytochemical investigation, isolation of narcissin ■ Narcissin—isolation from *Strumpfia maritima* (Rubiaceae) □ Antifertility activity—narcissin, flavonoid isolation from *Strumpfia maritima*

*Strumpfia maritima* Jacq. (Rubiaceae) is a low, maritime shrub found in southern Florida (1), the Bahamas (2), Venezuela (3), and Curacao[1]. The plant has a folkloric use as a mosquito repellent (2) and contraceptive[1]. *In vivo* testing of aqueous methanol extracts showed that the roots were devoid of antimalarial activity (4). This paper describes a preliminary screening of extracts of *S. maritima* for antifertility activity, as well as the isolation of narcissin from one of these extracts.

## RESULTS AND DISCUSSION

The powdered, defatted flowering tops of *S. maritima* were extracted with methanol. A phytochemical screening of this extract for alkaloids, saponins, sterols, cardenolides or bufadienolides, flavonoids, tannins or polyphenols, anthraquinones, and cyanogenic glycosides (5) revealed the presence of sterols, tannins and/or polyphenols, and flavonoid glycosides.

A methanolic extract was concentrated to dryness and partitioned between chloroform and water. Preliminary antifertility experiments showed that the aqueous extract administered daily (100 mg/kg ip) to rats significantly decreased the number of implantation sites relative to the number of corpora lutea of pregnancy ($p = 0.023$). No such decrease was seen in control rats treated simultaneously with the vehicle, 10% polysorbate 20. Furthermore, no such effect was seen in rats treated with either the petroleum ether or chloroform extracts, tested simultaneously with the 10% polysorbate 20 vehicle and sterol diluent control groups, respectively. These results are listed in Table I.

To isolate the biologically active compound(s) from the aqueous extract, the fraction was extracted with water-saturated 1-butanol, and the resulting organic extract was chromatographed over polyamide. Elution with distilled water and water–methanol afforded a yellow, microcrystalline flavonoid glycoside as a major component.

The UV spectrum of the isolate using standard shift reagents (7) indicated the presence of free 5-, 7-, and 4′-hydroxyl functions on the flavonoid nucleus. Hydrolysis of the glycoside with dilute acid (7) yielded isorhamnetin (melting point, mixed melting point, and UV, IR, PMR, and mass spectra were identical to the authentic compound) and two sugars. The sugars, present in equal proportions, were identified as glucose and rhamnose by TLC (8). A comparison of the UV spectra for the isolate and its aglycone in the presence of shift reagents indicated that the sugars were attached at position 3 of the aglycone. The PMR spectrum of the isolate as the trimethylsilyl ether showed signals for the rhamnosyl C-1 proton at 4.25 ppm and for the rhamnosyl methyl protons as a broad peak at 0.85 ppm, indicating that the rhamnoglucoside contains a rutinosyl rather than a neohesperidosyl moiety (7). Finally, the isolate

[a] Portions of these data were presented at the 17th annual meeting of the American Society of Pharmacognosy, Cable, Wis., July 1976 (Abstract 34). [b] A significant difference in this column means that the difference between the number of corpora lutea and the number of live fetuses could not be accounted for by the presence of dead, degenerating products of conception. [c] Sterol diluent consisted of 9 mg of benzyl alcohol, 4 mg of polysorbate 80, 5 mg of carboxymethylcellulose sodium, and 9 mg of sodium chloride/ml of distilled water (6). [d] Not significant. [e] The sixth rat was not pregnant at autopsy, presumably due to a failure to mate.

was found to be identical in all respects (TLC, melting point, mixed melting point, and UV, IR, and PMR spectra) to authentic narcissin.

The paucity of narcissin isolated did not permit testing for antifertility activity. Attempts are underway to obtain additional narcissin for biological evaluation. This work represents the first reported phytochemical and pharmacological investigation of *Strumpfia*, as well as the first isolation of narcissin from the Rubiaceae.

## EXPERIMENTAL[2]

**Extraction and Chromatography**—Dried, powdered flowering tops of *S. maritima*[3] (5 kg) were defatted by continuous extraction with petroleum ether, air dried, and extracted continuously with methanol. The methanolic extract was concentrated *in vacuo* to a thick syrup (1.1 kg), which was partitioned between water (2.5 liters) and chloroform (6 × 2 liters). After drying (sodium sulfate), the chloroform extract was evaporated *in vacuo* to give a residue (171.2 g). The water extract was lyophilized to yield 333 g of a light powder. Aliquots of the petroleum ether, chloroform, and aqueous extracts were screened for antifertility activity.

A portion of the lyophilized aqueous extract (133.2 g) was redissolved in water (2 liters) and extracted with water-saturated 1-butanol (5 × 2 liters). Evaporation of the butanol extract *in vacuo* gave 22 g of a brown gum, which was dissolved in distilled water (200 ml) and applied to the top of a polyamide column[4] (550 g).

**Isolation and Identification of Narcissin**—Elution was initiated with distilled water (5.4 liters), followed by water–methanol at ratios of 24:1 (1.4 liters), 47:3 (1 liter), 23:2 (3.2 liters), 21:4 (1.8 liters), 7:3 (2 liters), and 1:1 (10.8 liters). After elution with 5.7 liters of water–methanol (1:1), a 500-ml fraction was obtained, which gave a yellow residue on drying *in vacuo*. Crystallization and recrystallization from warm methanol afforded 184 mg of yellow microcrystals, mp 179–180° dec., which gave a positive flavonoid test (7); TLC on cellulose[5] gave an $R_f$ of 0.45 with 5% aqueous acetic acid; UV: $\lambda_{max}$ (methanol) 356 (log $\epsilon$ 4.18), 300 (sh), 265 (sh), and 253 (4.26) nm; IR: $\nu_{max}$ 3330 (br), 2920, 1660, and 1605 $cm^{-1}$; PMR (trimethylsilyl ether[6] in carbon tetrachloride): $\delta$ 0.85 (broad, 3H, rhamnosyl $CH_3$), 3.2–4.0 (m, 10H, sugar H), 3.87 (s, 3H, C-3′ methoxyl), 4.23 (broad s, 1H, rhamnosyl H-1), 5.90 (m, 1H, glucosyl H-1), 6.10 (d, 1H, $J$ = 2 Hz, H-6), 6.46 (d, 1H, $J$ = 2 Hz, H-8), 6.86 (d, 1H, $J$ = 8 Hz, H-5′), 7.41 (d, 1H, $J$ = 2 Hz, H-2′), and 7.42 (dd, 1H, $J$ = 2 and 8 Hz, H-6′).

Narcissin (20 mg) was hydrolyzed by mixing with 6% HCl (50 ml) and heating on a steam bath for 45 min. After cooling, the precipitated aglycone was filtered, and the filtrate was extracted three times with ether. The combined precipitate and ether extracts were recrystallized twice from ethanol. The aqueous filtrate was lyophilized and subjected to cellulose TLC in three solvent systems: ethyl acetate–pyridine–water (2:1:2), butanol–acetic acid–water (3:1:1), and pyridine–ethyl acetate–acetic acid–water (36:36:7:21) (8). Sugars were detected with *p*-anisidine phthalate spray reagent (8).

**Antifertility Screening**—Eight-week-old virgin female Sprague–Dawley rats were housed in environmentally controlled quarters, which provided 14 hr of light (5 am to 7 pm) per 24-hr period. After the animals had 1 week to acclimate to the environment, daily vaginal smears were initiated to provide information concerning their estrous cycles. On the 12th day of taking smears, intraperitoneal injections were begun and continued daily throughout the experiment. Groups of six rats were each administered 100 mg/kg of one of the extracts (the chloroform extract suspended in sterol diluent or the petroleum ether or aqueous extract suspended in 10% polysorbate 20). Control groups, six rats each, were treated simultaneously with the respective vehicle at 1 ml/kg.

On the 12th day of dosing, proven breeded males were placed in cages of the individually housed females. The day on which sperm were found in the smear or on which a plug was found in the vagina was defined as Day 1 of pregnancy. Rats were autopsied on Day 20 of pregnancy. The number of implantation sites in the uterus, equaling the number of live plus degenerating fetuses, was counted and compared with the number of corpora lutea of pregnancy found in the ovaries.

[2] Melting points were determined using a Kofler hot-stage instrument and are uncorrected. UV and IR spectra were recorded using a Beckman model DB-G grating spectrophotometer and a Beckman model IR-18A spectrophotometer with polystyrene calibration at 1601 $cm^{-1}$, respectively. PMR spectra were recorded at 60 MHz on a Varian T-60A instrument with a Nicolet model TT-7 Fourier attachment, using tetramethylsilane as the internal standard. Mass spectral data were obtained on a Hitachi Perkin-Elmer model RMU-6D spectrophotometer.

[3] The flowering tops of *S. maritima* Jacq. were collected (July 1971) in Curacao and identified by J. F. Morton. A voucher specimen was deposited at the Morton Collectanea, University of Miami, Coral Gables, Fla.

# Prolongation of Effect of Asparaginase by Implantation in Polyacrylamide in Rats

**PETER EDMAN and INGVAR SJÖHOLM** ˣ

Received May 15, 1980, from the *Department of Pharmaceutical Biochemistry, Biomedical Center, University of Uppsala, S-751 23 Uppsala, Sweden.* Accepted for publication October 23, 1980.

**Abstract** □ L-Asparaginase was immobilized in spherical polyacrylamide microparticles, which were inserted in polyacrylamide gel for implantation in rats. Intraperitoneal implantation of this gel depressed systemic L-asparagine for the same duration as was achieved with microparticles, *i.e.*, 8–10 days. The duration of the effect was prolonged up to about 25 days when the gel with the enzyme was implanted subcutaneously on the back of the rat. In both cases, a collagenous capsule formed around the gel, eventually preventing contact with the circulation. The effect of a second implantation was of the same magnitude as the first one.

**Keyphrases** □ L-Asparagine—polyacrylamide microparticles, prolongation of effect by implantation of immobilized enzyme, rats □ Polyacrylamide—microparticles containing L-asparaginase, prolongation of effect by implantation, rats □ Microparticles—L-asparaginase-containing polyacrylamide microparticles, prolongation of effect by implantation of immobilized enzyme, rats

L-Asparaginase has been used to control and depress the growth of L-asparagine-dependent tumors (1–3), and its administration in immobilized form offers some advantages (4). L-Asparaginase was immobilized in polyacrylamide microspheres (mean diameter of about 0.3 μm) in such a way that the enzymatic properties were retained. When these microspheres (1000 IU of L-asparaginase/kg) were administered in a single dose intraperitoneally, the effect on the serum L-asparagine level was prolonged from 4 to 14 days when compared with the effect of soluble enzyme. Moreover, the acrylic microspheres were cleared readily from the abdominal cavity and circulation by the reticuloendothelial system (5).

The enzyme is still active in the microparticles after the endocytosis but cannot control the systemic L-asparagine level. The duration of the effect thus is directly dependent on the time the particles stay in contact with the systemic circulation. In the present paper, data show that L-asparaginase given in polyacrylamide implants can depress L-asparagine for up to about 25 days.

## EXPERIMENTAL

**Materials**—L-Asparaginase[1] (EC 3.5.1.1) was isolated from *Escherichia coli* (ATCC 9637 and ATCC 11303). Polyacrylamide microparticles with L-asparaginase were prepared as described previously (4, 6).

**Polyacrylamide Gel Preparation for Implantation**—Microparticles of polyacrylamide containing L-asparaginase (20 and 100 IU) were suspended in 0.7 ml of monomeric acrylamide (T − C = 16–25[2]) in a cylinder with a height of 0.7 cm and a radius of 0.6 cm. A catalyst system of *N,N,N′,N′*-tetramethylethylenediamine (50 μl) and 50 μl of ammonium peroxydisulfate (500 mg/ml of water) then was added to the monomer suspension. The polymerization started immediately and was completed in 10 min. The gel tablet was washed with physiological saline for 7 days to free it from any remaining catalysts.

Determination of L-asparagine was done according to Cooney *et al.* (8).

L-Asparaginase was determined according to Yellin and Wriston (9) as described previously (4).

**Animals**—Sprague–Dawley male rats were used.

## RESULTS AND DISCUSSION

**L-Asparaginase Implanted Intraperitoneally**—Figure 1 shows the changes in the serum L-asparagine concentration in rats given single doses (20 IU) of L-asparaginase in soluble and immobilized forms. The enzyme was immobilized in polyacrylamide microspheres (T − C = 8–25), which subsequently were inserted in polyacrylamide gel (T − C = 16–25). The gel was prepared in the form of a cylinder with a height of 0.7 cm and a radius of 0.6 cm. The gel tablet was implanted in the abdominal cavity of a 110-g male rat.

The serum L-asparagine level was measured intermittently in the rats as well as in an untreated control taken from the same litter. The soluble enzyme had a short effect on the L-asparagine level, which was essentially normalized after 2 days (Fig. 1). When the enzyme was given in the polyacrylamide gel, L-asparagine immediately dropped to a level corresponding to ~25–30% of the initial value. After 8 days, the L-asparagine level was normalized.

The effect seen after intraperitoneal implantation of the gel was comparable to the effect obtained after intraperitoneal injection of L-asparaginase in microparticles (4). However, the dose in the implant corresponded to 182 IU/kg, while there were 1000 IU/kg in the microparticles.

On the 31st day, the abdominal cavity was opened. The gel was surrounded by a nonvascularized tough ligamentous capsule. No capillaries had penetrated the polyacrylamide implant, and the gel could be removed easily from the capsule. A significant amount of L-asparaginase activity still remained in the implant.

**L-Asparaginase Implanted Subcutaneously**—For subcutaneous administration, polyacrylamide gels (T − C = 16–25) were prepared containing 100 IU of L-asparaginase in microparticles (T − C = 8–25). The cylinders formed were about the same size as those used for intraperitoneal implantation. The gel implants (dose of ~700 IU/kg) were placed subcutaneously in the scapular line in two male rats weighing 147 g. The L-asparagine level was followed and compared to that in an untreated rat (Fig. 2).

A significant depression of the L-asparagine level was seen for at least 25 days, and the level was normalized on the 31st day. On the 61st day when the rats weighed 350 g, the implants were removed and a new gel tablet containing 100 IU of L-asparaginase (~300 IU/kg) was implanted in the other side of the back in the scapular line. The effect of this second implantation lasted for about 19 days (Fig. 2). In these cases also, the systemic effect of L-asparaginase was interrupted by encapsulation.

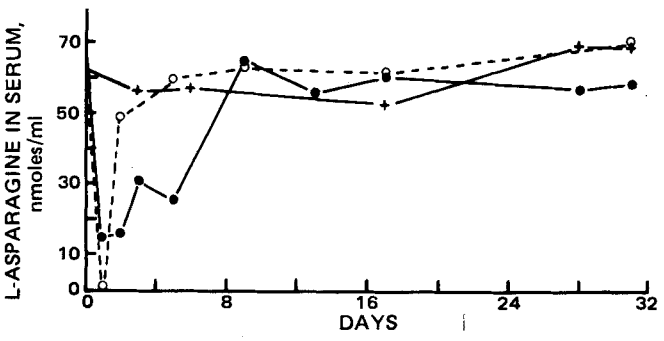

**Figure 1**—*L-Asparagine concentration in serum (nanomoles per milliliter) after intraperitoneal implantation of 20 IU of L-asparaginase (182 IU/kg) in rats (●) or after injection of the same amount in soluble form (○). The normal L-asparagine concentration (+) was obtained from an untreated rat taken from the same litter.*

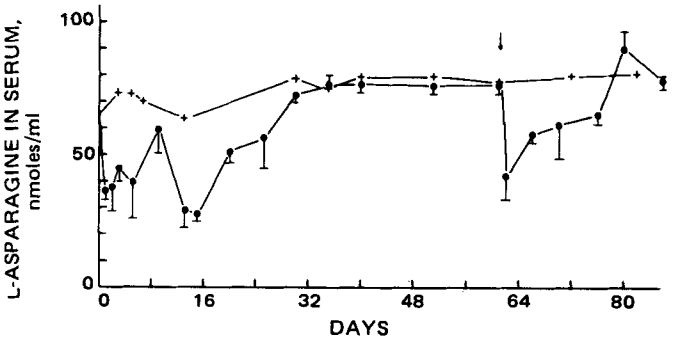

**Figure 2**—*L-Asparagine concentration in serum after subcutaneous implantation of 100 IU of L-asparaginase (700 IU/kg) in rats (●). The arrow shows the time when the implant was removed and a new gel tablet containing 100 IU of L-asparaginase (300 IU/kg) was inserted. Each point represents samples drawn from two rats and shows the mean and the range. The normal L-asparagine level (+) was obtained from an untreated rat from the same litter.*

The decrease of the serum L-asparagine concentration was of the same magnitude after the second implantation as that found initially, in spite of the lower dosage of L-asparaginase. This finding indicates that no significant amounts of antibodies were produced in the rats during the first 60 days of exposure to the implants. This conclusion is in accordance with earlier findings that proteins immobilized in highly cross-linked polyacrylamide are stably bound in the gel (6). Thus, it is feasible to assume that not enough of the immunogenic enzyme leaks out of the gel to activate the immune system.

By subcutaneous administration of L-asparaginase in implants of polyacrylamide, the effect can be substantially prolonged compared to the duration obtained by administration of soluble enzyme or by enzyme immobilized in microspheres. Although duration of the systemic effect *in vivo* was not limited by denaturation, the formation of a collagenous capsule around the implant effectively prevented the contact between the enzyme and the circulating L-asparagine. The encapsulation is a normal reaction to the presence of a foreign body. The same effects were detected after implantation of other acrylic polymers in rats (10, 11).

Updike *et al.* (12) also increased the duration of L-asparaginase by immobilizing the enzyme in resealed red blood cell ghosts. Undetected or very low levels of circulating L-asparagine lasted twice as long after the intravenous injection in monkeys of ghost-entrapped enzyme than after injection of the same amount of free enzyme. In this case, the duration of the enzymatic effect was limited by the survival of the red blood cell ghosts in the circulation.

Chang *et al.* (13) also showed that L-asparaginase entrapped in semipermeable microcapsules (~80 μm in diameter) can deamidate L-asparagine *in vitro*. When given intraperitoneally in mice, the entrapped enzyme (3.5 IU) was more efficient than native enzyme and cured 50% of the treated mice bearing an L-asparagine-dependent lymphoma cell line, 6C3HED (14).

The L-asparaginase implants thus were able to depress the systemic L-asparagine level significantly for prolonged periods. However, as is evident from the figures, the concentration of L-asparagine never reached zero. Therefore, it is not possible to predict whether the decreased level would influence the proliferation of L-asparagine-dependent tumors. Such tests may be performed with the 6C3HED cell line growing in mice.

# Fluorometric Determination of All-*trans* Retinol in Rat Serum

**SU-CHEN WU, A. C. CAPOMACCHIA ˣ, and J. C. PRICE**

Received May 21, 1980, from the *Department of Pharmaceutics, School of Pharmacy, University of Georgia, Athens, GA 30602.* Accepted for publication October 23, 1980.

**Abstract** □ A rapid, specific, and sensitive fluorometric assay for retinol in rat serum is reported. Serum retinol is extracted into cyclohexane after dilution of the serum sample with aqueous acetonitrile. Sample volumes as small as 0.2 ml can be used with a limiting detectable concentration of $2.5 \times 10^{-8}$ *M* for retinol.

**Keyphrases** □ Vitamin A—fluorometric determination in rat serum □ Retinol, all-*trans*—fluorometric determination in rat serum □ Fluorometry—determination of all-*trans* retinol in rat serum

Vitamin A (all-*trans* retinol) is well known for its importance in general growth, the growth and differentiation of epithelial tissues, visual function, and reproduction (1–4). A number of retinoids prevent or inhibit the growth of epithelial tumors (5–9). As early as 1926, it had been noticed that vitamin A deficiency leads to carcinomas in

# Fluorometric Determination of All-*trans* Retinol in Rat Serum

**SU-CHEN WU, A. C. CAPOMACCHIA ˣ, and J. C. PRICE**

Received May 21, 1980, from the *Department of Pharmaceutics, School of Pharmacy, University of Georgia, Athens, GA 30602.* Accepted for publication October 23, 1980.

**Abstract** □ A rapid, specific, and sensitive fluorometric assay for retinol in rat serum is reported. Serum retinol is extracted into cyclohexane after dilution of the serum sample with aqueous acetonitrile. Sample volumes as small as 0.2 ml can be used with a limiting detectable concentration of $2.5 \times 10^{-8}$ *M* for retinol.

**Keyphrases** □ Vitamin A—fluorometric determination in rat serum □ Retinol, all-*trans*—fluorometric determination in rat serum □ Fluorometry—determination of all-*trans* retinol in rat serum

Vitamin A (all-*trans* retinol) is well known for its importance in general growth, the growth and differentiation of epithelial tissues, visual function, and reproduction (1–4). A number of retinoids prevent or inhibit the growth of epithelial tumors (5–9). As early as 1926, it had been noticed that vitamin A deficiency leads to carcinomas in

© 1981, American Pharmaceutical Association

the stomach of rats (10) and later to hyperkeratosis of the skin and to metaplastic changes in epithelia of the GI, respiratory, and urogenital tract (11–14).

In the late 1960's, several scientists showed that the induction of benign and malignant epithelial tumors in animals could be retarded or even prevented by systemically applied retinol or retinol palmitate (5, 6). The use of these compounds for cancer chemoprevention was reviewed previously (15, 16). These nutritional surveys and cancer prevention studies required a method for measuring micromolar to nanomolar amounts of retinol in small volumes of serum, a method whereby numerous analyses could be performed without undue analytical time. For these reasons, there is an intense search for exact, sensitive, and simple methods for determining retinol in biological material.

The innate sensitivity and speed of fluorescence measurements as an analytical technique have been demonstrated (17–26). However, current methodology is still not as sensitive as some recently reported high-pressure liquid chromatographic (HPLC) procedures (27–31). The present paper reports an improved fluorometric assay for retinol in rat serum that is more sensitive than reported methods and compares favorably with HPLC procedures.

## EXPERIMENTAL

**Apparatus**—All fluorescence measurements were made with a fluorescence spectrophotometer[1] equipped with an $x$–$y$ recorder. Quartz cells of a 1-cm light path were used. Daily variation in instrumental response was corrected with a dilute quinine bisulfate standard solution ($5 \times 10^{-5}$ $M$ in 0.1 $N$ $H_2SO_4$).

Since organic solvents were found to extract fluorescent substances from plastic caps, tubes, and bottles (25), a glass apparatus was used during all analytical manipulations. Glass culture tubes[2] were used to collect serum samples and extract retinol from serum.

A high-speed centrifuge[3] was used for centrifugation, and a vibrating mixer[4] was used for mixing and extraction.

**Reagents and Solutions**—Retinol[5] (all-*trans*, crystalline, synthetic Type X) and retinyl acetate[5] (all-*trans*, crystalline, synthetic Type I) were used as received. Solid samples were stored at −10° under nitrogen and protected from light. All solvents were the highest grade commercially available; they were checked for fluorescent impurities before use. A buffer solution ($\mu$ = 0.15, pH 7.4) was prepared from analytical grade monobasic sodium phosphate[6], dibasic sodium phosphate, and distilled, deionized water.

**Standard Solutions**—Sufficient retinyl acetate was weighed into a 10-ml amber volumetric flask and dissolved in 10 ml of acetonitrile to yield a standard stock solution (~$1 \times 10^{-3}$ $M$). Serial dilutions of this solution yielded working standard solutions with concentrations ranging from $1 \times 10^{-4}$ to $1 \times 10^{-6}$ $M$. All solutions were stored at −10° and protected from light. The purity of the solutions was checked by comparing their absorption spectra with their corrected fluorescence excitation spectra. Retinyl acetate was used as a standard because it has long been accepted as a standard for retinol determination by fluorometric analysis. The reported quantum efficiencies for each compound are identical, and the stability of retinol acetate solutions is much better (32–34). All experimental manipulations were conducted under yellow light and in amber glassware.

**Solvent Pair Selections**—A water-miscible–water-immiscible solvent pair was selected based on the following criteria.

1. The fluorescence of retinyl acetate in 14 nonpolar and nine polar solvents was examined.

2. The nonpolar solvents were used to extract blank rat serum to detect extractable, fluorescent serum components. The nonpolar solvents were carbon tetrachloride, chloroform, methyl chloride, methylene chloride, ethylene dichloride, tetrachloroethylene, $n$-pentane, $n$-hexane, $n$-heptane, cyclohexane, ethyl acetate, octanol, benzene, and toluene. The polar solvents were dimethyl sulfoxide, acetonitrile, dimethylformamide, formamide, ethylene glycol, water, methanol, ethanol, and dioxane.

3. Various ratios of polar solvent to water-diluted serum were examined with regard to decreasing the quantity of endogenous serum components extracted into the nonpolar solvent. For these comparisons, the serum was spiked with retinoid, diluted with water, and then diluted further with the polar solvent. The resulting aqueous solution was extracted with the nonpolar solvent.

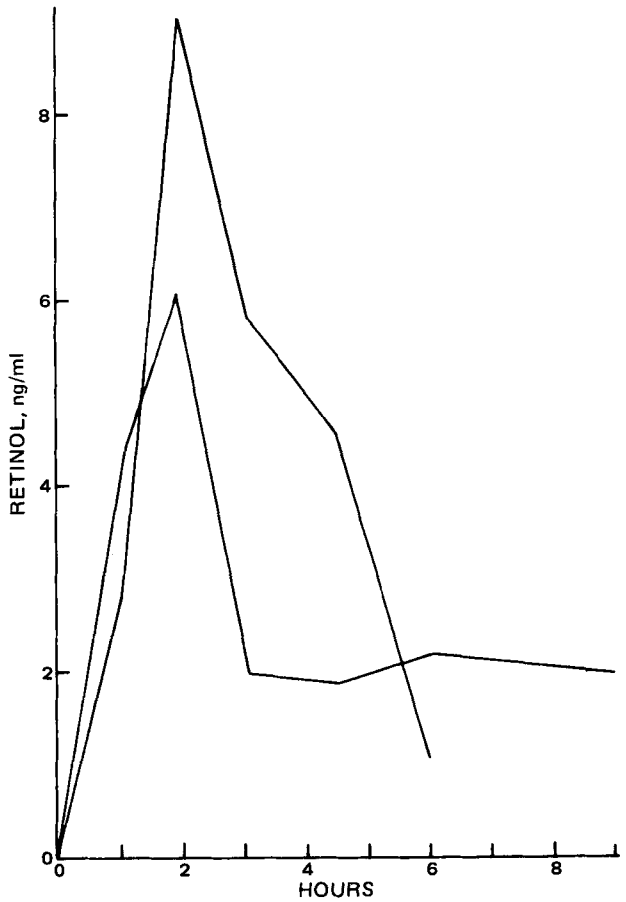

**Figure 1**—*Serum retinol blood profiles obtained from two rats after a single oral dose of 10 mg of retinyl acetate/kg. All points were corrected for blank fluorescence.*

**Serum**—Male and female rats[7] (300–400 g) were fasted for 19 hr before sacrifice. After the animal was anesthetized with ether, the rib cage was cut open to expose the heart. Total exsanguination from the left ventricle was accomplished with a 10-ml disposable plastic syringe. Approximately 10 ml of blood was obtained from each rat. The serum was obtained after centrifugation at 2500 rpm for 10 min in a glass culture tube.

The native fluorescence of the serum extracts was examined by mixing 0.2 ml of serum with 0.2 ml of phosphate buffer. To this mixture was added 2 ml of acetonitrile. After mixing, 2 ml of cyclohexane was added and shaken by a vibrating mixer for 30 sec. After this mixture was centrifuged at 2500 rpm for 5 min, the cyclohexane layer was removed for direct fluorometric measurement. The fluorescence intensity of each sample was measured at the excitation maximum of 327 nm and the emission maximum of 480 nm. This procedure was repeated with 15 different rat serum samples without drug. The average fluorescence intensity measured from these 15 blank serum samples was used as the blank.

Buffer and serum samples (0.2 ml) spiked with varying concentrations of retinyl acetate were extracted in the same manner as the blank serum extracts. Second extractions of the spiked samples were performed by adding 2 ml of cyclohexane to the aqueous mixture from which the first

[a] Optimum solution conditions.

cyclohexane layer had been removed. Since the fluorescence intensity of the second sample extract was the same as that of the blank, the fluorescence intensity of each sample recorded was from the first extract.

*In vivo* experiments were performed using three sets of four rats each, administered a 2-, 4-, or 10-mg/kg dose of retinyl acetate by stomach intubation. Each dose was prepared by dissolving an appropriate quantity of drug in ethanol. Before drug administration, each rat was fasted for 19 hr. The blood was withdrawn from the heart 2 hr postadministration.

Two more rats with body weights of 390 g were given 10 mg/kg of retinyl acetate orally. Blood samples of each rat were withdrawn from the tail at 0, 1, 2, 3, 4.5, 6, and 9 hr. All samples were centrifuged, and the serum was removed and kept frozen until assayed (Fig. 1).

## RESULTS AND DISCUSSION

Cyclohexane–acetonitrile was the best solvent pair when acetonitrile was added to the water-diluted serum samples (1:1) so that the final ratio of acetonitrile to aqueous sample was 1:0.17. The validity of using these proportions was checked (Table I). Methanol and ethanol also can be used as the water-miscible component as reported previously (22, 25, 35). However, they did not decrease the cyclohexane extraction of endogenous fluorescent substances in the serum as well as did acetonitrile. The other water-miscible solvents did not demonstrate this effect, the mechanism of which is not known. However, it appears to be a specific solvation effect, dependent on the solvent concentration as well as on the water concentration in the final solution (Table I). Simple dilution of the serum sample with water, with no acetonitrile added, resulted in a lower fluorescence intensity than under optimum conditions. Dilution with acetonitrile produced the same result. Sample fluorescence was maximized only after dilution with both acetonitrile and water in the given proportions.

Standard curves were constructed at six concentration points for retinol in (*a*) cyclohexane, (*b*) cyclohexane-extracted phosphate buffer, and (*c*) cyclohexane-extracted serum. Curves *a–c* were linear from $2.5 \times 10^{-8}$ to $1.0 \times 10^{-4}$ *M*. For *a* and *b*, each point was the mean of three determinations; for *c*, each point was the mean of 15 determinations. The correlation coefficients were 0.9998, 0.9997, and 0.9995 for *a–c*, respectively.

The extraction efficiencies of retinyl acetate from buffer solution and serum were 97.1 ± 1.2 and 91.4 ± 2.9%, respectively (mean ± *SD*). The results clearly show that a standard curve of this agent in cyclohexane-extracted buffer should not be used for extracted serum samples without a correction factor. Therefore, fluorometric procedures that do not include a correction factor will consistently report lower concentration values than are really present (22–26).

The procedure reported in this study is at least 10-fold more sensitive than current fluorometric procedures (22–26). However, sample volume and precision are essentially the same with both fluorometric and HPLC procedures now in use (22–26, 28–31). The method is applicable to bioavailability and pharmacokinetic studies, as demonstrated by the data in Fig. 1 and Table II.

**Table II—Rat Serum Concentrations of Retinol Obtained 2 hr after a Single Oral Dose of Retinyl Acetate**

| Dose, mg/kg | Number of Rats and Total Samples | Serum Concentration $\times 10^7$ *M* (mean ± *SD*) |
|---|---|---|
| 2 | 4 and 16 | 4.1 ± 0.9 |
| 4 | 4 and 16 | 7.6 ± 1.1 |
| 10 | 4 and 20 | 7.3 ± 1.0 |

The mean serum retinol concentration in 12 rats (52 samples) 2 hr after a single oral dose of retinyl acetate is shown in Table II. The data indicate a nonlinear correlation between dose and serum concentration. A 4-mg/kg dose produced a serum concentration nearly equal to that of the 10-mg/kg dose. An analysis of variance on the mean serum concentrations in Table II, using a Student procedure, showed that if the mean values differed by $1.82 \times 10^{-7}$ or more, then they were different ($p \leq 0.05$). Therefore, since oral doses of 4 and 10 mg/kg produced the same serum retinol concentration, a dose-dependent saturation of some part of the absorption or metabolic network may be occurring.

# High-Performance Liquid Chromatographic Determination of Propranolol and 4-Hydroxypropranolol in Plasma

**M. T. ROSSEEL** ˣ **and M. G. BOGAERT**

Received July 24, 1980, from the *J. F. & C. Heymans Institute of Pharmacology, University of Ghent, De Pintelaan, 135, B-9000 Gent, Belgium.* Accepted for publication November 7, 1980.

**Abstract** □ A high-performance liquid chromatographic method for the simultaneous determination of propranolol and 4-hydroxypropranolol in plasma is presented. The method involves plasma extraction at basic pH with ethyl acetate, two brief back-extractions, chromatography on a reversed-phase column, and fluorescence detection. The within-run coefficients of variation were 3.0–7.1% for propranolol and 5.8–8.3% for 4-hydroxypropranolol. The day-to-day variations were 4.6 and 8.2% for propranolol and 4-hydroxypropranolol, respectively. The method can detect 1 ng of each compound/ml of plasma.

**Keyphrases** □ High-performance liquid chromatography—propranolol and 4-hydroxypropranolol, human plasma □ Propranolol—analysis, high-performance liquid chromatography, human plasma □ 4-Hydroxypropranolol—analysis, high-performance liquid chromatography, human plasma □ β-Adrenergic antagonists—propranolol and 4-hydroxypropranolol, high-performance liquid chromatography, human plasma

Propranolol, a β-adrenergic antagonist, is used to treat angina pectoris, cardiac arrhythmias, and hypertension. 4-Hydroxypropranolol, a metabolite of propranolol in humans and animals (1), is equipotent with propranolol as a β-adrenergic antagonist (2) and is present in human plasma after acute and chronic treatment with propranolol (3–7).

Several methods for the simultaneous determination of both substances have been proposed, including mass fragmentography (3), direct fluorometry (4), and reversed-phase high-pressure liquid chromatography (HPLC) with fluorescence detection (5), but none of these methods is entirely satisfactory. In other methods, the standard curve for 4-hydroxypropranolol was not linear (8) and no internal standard was used (9).

This paper describes a specific and sensitive HPLC method for the simultaneous determination of propranolol and 4-hydroxypropranolol in plasma. The procedure has been used for the analysis of plasma samples of patients taking propranolol.

## EXPERIMENTAL

**Chemicals and Reagents**—1-Heptanesulfonic acid[1] in acetic acid was used. Propranolol, 4-hydroxypropranolol, and 4-methylpropranolol were supplied as the hydrochloride salts[2]. Methanol was Lichrosolv quality[3], and all other reagents were analytical grade.

**Instrumental Conditions**—The microprocessor-controlled high-performance liquid chromatograph[4] was equipped with a fluorescence detector[5]. The fluorometer was set at an excitation wavelength of 290 nm, with an emission cutoff filter allowing 90% transmission at 340 nm.

Chromatography was done on a reversed-phase column 250 mm long × 4.6 mm i.d.[6]. The helium degassed mobile phase was pumped through the column at a flow rate of 1.5 ml/min, which required pressures of 600–1000 psi, depending on column age. The column temperature was 40°. Samples were injected using an automatic injector[7] equipped with a 10-μl loop. Quantitation was done by peak area measurement[8].

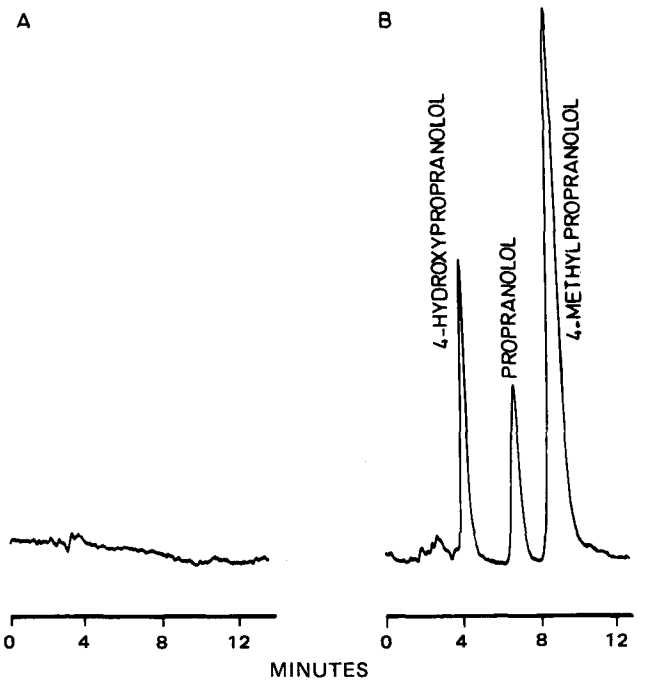

**Figure 1**—*(A) High-performance liquid chromatogram of the extract of 1 ml of blank plasma. (B) Chromatogram of an extract of 1 ml of blank plasma spiked with 20 ng of 4-hydroxypropranolol, 50 ng of propranolol, and 60 ng of the internal standard 4-methylpropranolol.*

**Mobile Phase**—1-Heptanesulfonic acid in acetic acid (25.0 ml) was mixed with 1000 ml of distilled water (Solvent A), and 25.0 ml of the same acid solution was mixed with 1000 ml of methanol (Solvent B). The mobile phase was Solvent A–Solvent B (34:66, v/v).

**Assay Standards**—Standard solutions of propranolol and of 4-hydroxypropranolol (10 mg/100 ml each, calculated as the base) were prepared in methanol and stored at −20°. For each assay, 100-fold aqueous dilutions of the standard solutions were made. The internal standard was 10 μg of 4-methylpropranolol/ml of methanol and was stored at −20°.

**Extractions**—To 1 ml of the spiked plasma or the unknown sample in a 10-ml glass-stoppered centrifuge tube, 20 mg of sodium hydrogen sulfite (20% in distilled water), 6 μl of the internal standard solution, 50 μl of 0.05 *M* triethylamine, and 500 μl of 2.5 *N* NaOH were added successively. The mixture was extracted with 4 ml of ethyl acetate by shaking horizontally for 10 min.

After centrifugation for 10 min at 6000 rpm, the organic phase was transferred with a Pasteur pipet to a 6-ml glass-stoppered conical tube. To the ethyl acetate layer, 100 μl of 0.2 *N* $H_2SO_4$ was added and the solution was mixed with a vortex mixer for 30 sec. After centrifugation the ethyl acetate layer was discarded and 100 μl of 2.5 *N* NaOH was added.

The basic solution was extracted immediately with 1 ml of ethyl acetate by mixing with a vortex mixer for 30 sec and centrifuging. The supernate was transferred with a Pasteur pipet to another 6-ml glass-stoppered conical tube, and the organic phase was removed under a gentle nitrogen stream at room temperature to near dryness. The residue was dissolved in 15 μl of the mobile phase and stored at −20° until analysis, *i.e.*, within a few hours.

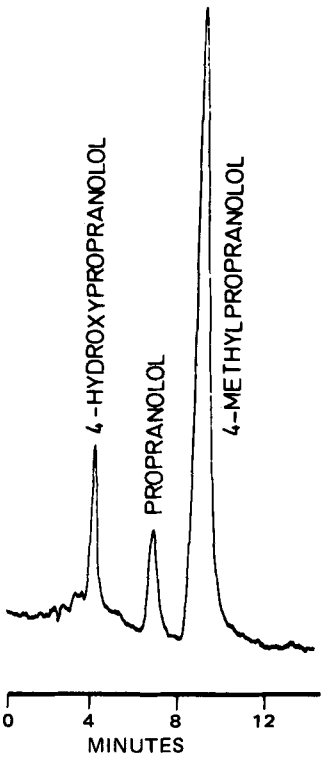

**Figure 2**—*High-performance liquid chromatogram of an extract of 1 ml of plasma of a patient receiving propranolol. To 1 ml of plasma, 60 ng of methylpropranolol was added as the internal standard.*

**Quantitation**—Human plasma samples spiked with increasing concentrations of propranolol (5–300 ng/ml) and 4-hydroxypropranolol (1–100 ng/ml) were carried through the whole procedure. Peak area ratios of propranolol or 4-hydroxypropranolol to the internal standard were plotted *versus* their concentrations, and an unweighted least-squares linear regression analysis was performed. Unknown drug concentrations were estimated from the calibration curve.

## RESULTS AND DISCUSSION

Blank plasma extracts yielded no interfering peaks from endogenous plasma components (Fig. 1A). Propranolol, 4-hydroxypropranolol, and 4-methylpropranolol were separated and eluted in ~12 min (Fig. 1B). Sensitivity limits were 1 ng/ml for each compound when the entire 1-ml plasma extract was injected. The detector response was linear for plasma propranolol concentrations of at least 5–300 ng/ml and plasma 4-hydroxypropranolol concentrations of at least 1–100 ng/ml. Typical calibration curve data are listed in Table I. Over 3 weeks, the slopes of the calibration curves demonstrated little change ($CV$ = 4.8 and 5.6% for propranolol and 4-hydroxypropranolol, respectively, $n$ = 13). The results of accuracy and precision, both within run and day to day, are shown in Table II. 4-Hydroxypropranolol is stable in plasma, if frozen, for at least 3 weeks (Table II). This stability also was reported by others (6).

Uncorrected recovery, as assessed by comparing peak areas of extracted standards with those of unextracted compounds, was 75 ± 6% ($n$ = 5) for 4-hydroxypropranolol and 80 ± 5% ($n$ = 5) for propranolol.

Figure 2 illustrates a chromatogram of the plasma extract from a patient receiving 40 mg of propranolol four times a day. The blood sample was taken 10 hr after the last dose.

There was no interference of the commonly used cardiac drugs quinidine, lidocaine, procainamide, and disopyramide added *in vitro*. *N*-Desisopropylpropranolol, another reported metabolite of propranolol (10), eluted just before propranolol, but no measurable amounts were found in the plasma of patients treated with propranolol.

**Table I—Calibration Curve Data ($y = c + mx$)**

| Compound | Range, ng/ml | Slope ($m$) | Intercept ($c$) | $r$ |
|---|---|---|---|---|
| Propranolol | 5–300 | 0.0098 | 0.0031 | 0.9990 |
| 4-Hydroxy-propranolol | 1–100 | 0.0127 | 0.0006 | 0.9992 |

**Table II—Accuracy and Within-Run and Day-to-Day Precision for Propranolol and 4-Hydroxypropranolol**

| Compound | Level, ng/ml | Mean Assay, % | $CV$, % |
|---|---|---|---|
| | Within Run ($n$ = 5) | | |
| Propranolol | 10 | 106.3 | 7.1 |
| | 50 | 99.6 | 3.0 |
| | 100 | 100.6 | 5.1 |
| 4-Hydroxypro-pranolol | 5 | 98.2 | 8.3 |
| | 20 | 101.9 | 5.8 |
| | 40 | 97.4 | 6.4 |
| | Day to Day ($n$ = 10)[a] | | |
| Propranolol | 50 | 103.7 | 4.6 |
| 4-Hydroxypro-pranolol | 15 | 98.5 | 8.2 |

[a] Pooled plasma standards, analyzed over 3 weeks.

The brief cleanup steps before chromatography, involving successive back-extractions into acid and ethyl acetate at basic pH, resulted in cleaner chromatograms than those previously reported (4, 5, 8). These cleanup steps were necessary particularly to obtain the assay sensitivity of 1 ng/ml for 4-hydroxypropranolol. In comparison to other HPLC methods for propranolol and 4-hydroxypropranolol (5, 8, 9), the described HPLC method is more sensitive, specific, and precise, particularly for the 4-hydroxypropranolol determination.

# Spectrophotometric Determination of Dimenhydrinate with Reinecke Salt

**A. KAR ˣ and G. I. ANIUHA**

Received August 9, 1979, from the *Department of Pharmaceutical Chemistry, Faculty of Pharmaceutical Sciences, University of Nigeria, Nsukka, Nigeria.* Accepted for publication November 13, 1980.

**Abstract** □ A convenient spectrophotometric method was developed for the determination of dimenhydrinate in bulk drug and dosage forms and in 1:1 combinations with aspirin, acetaminophen, meprobamate, phenylephrine, and tolbutamide. The method consisted of reacting dimenhydrinate with reinecke salt in an acidic medium at 27 ± 2°. The purple precipitate was filtered and dissolved in acetone, and the maximum color absorption attained in 15 min was measured at 540 nm. Evidence is provided to establish the optimal experimental parameters. The stoichiometric balance of the precipitate was determined. Reasonably ideal adherence of the color absorption pattern to the Beer–Lambert law permitted microdetermination of dimenhydrinate in pure form, commercial formulations, laboratory-made combinations, and recovery experiments with good accuracy and repeatability. No interference was observed with any of the drugs or tablet adjuvants.

**Keyphrases** □ Dimenhydrinate—spectrophotometric determination with reinecke salt □ Spectrophotometry—determination of dimenhydrinate with reinecke salt □ Reinecke salt—determination of dimenhydrinate, spectrophotometry

Dimenhydrinate is assayed by official methods (1–3) by estimating diphenhydramine and 8-chlorotheophylline individually. It also has been determined in pharmaceuticals by gas-phase chromatography (4), an argentometrical method (5), UV absorption (6), complexation with phosphomolybdic acid followed by reduction with ascorbic acid in acetone to molybdenum blue (7), and a silicotungstic acid method followed by gravimetry (7).

The present study investigated reinecke salt as a useful precipitant (8) for the spectrophotometric estimation of dimenhydrinate in pure forms, dosage formulations, and laboratory-made combinations. The study investigated color stability, effect of temperature on the colored precipitate, influence of pH on absorbance of the precipitate in acetone solution, determination of the stoichiometric balance, establishment of an absorbance–wavelength relationship, and recovery with various combinations. Adherence to Beer's law was found within a range of 200–1000 μg/ml.

## EXPERIMENTAL

**Instruments and Materials**—A single-beam spectrophotometer[1], a pH meter[2] fitted with a sealed calomel electrode, a shielded glass electrode, and a suitable thermostated[3] water bath were used.

Pharmaceutical grade dimenhydrinate, aspirin, acetaminophen, meprobamate, phenylephrine, and tolbutamide were employed as the working standards.

The commercial preparation analyzed was dimenhydrinate tablets[4]. For drug combinations, aspirin, acetaminophen, meprobamate, phenylephrine, and tolbutamide were mixed with dimenhydrinate in a 1:1 ratio.

The following reagents were used: ammonium nitrate solution[5] (10% w/v). Saturated reinecke salt solution[6] ($3 \times 10^{-3}$ *M*), ammonium thiocyanate[6] (0.01 *M*), ferric ammonium sulfate solution indicator[5], hydrochloric acid[5] (0.1 and 0.01 *M*), methylene blue solution indicator[6], silver nitrate solution[5] (0.01 *M*), and sodium hydroxide solution[6] (0.1 and 0.01 *M*, 20% w/v).

For the standard solution, dimenhydrinate (0.5 g) was dissolved in 100 ml of methanol[6] (analytical reagent).

**Sample Preparation**—An equivalent weight of a single-powdered tablet from a composite of 20 tablets was placed in a 50-ml volumetric flask and dissolved in 20 ml of methanol; then 0.5 ml of concentrated hydrochloric acid was added. The mixture was allowed to stand for 20 min with intermittent shaking. It was filtered through filter paper[7] into a dry 50-ml volumetric flask and brought to volume by rinsing with methanol.

**Procedure**—Twenty milliliters of the standard (or of the appropriately prepared sample) solution was transferred to a 100-ml volumetric flask. To it was added 0.5 ml of hydrochloric acid followed by 50 ml of saturated reinecke salt solution. The contents were shaken vigorously for 5 min. The precipitate was filtered through a sintered-glass crucible ($G_4$) and washed with 10 ml of chilled 0.02% (w/v) aqueous solution of reinecke salt. Then the precipitate was dried in a vacuum desiccator, dissolved in acetone, and transferred quantitatively to a 50-ml volumetric flask. It was brought to volume with acetone (stock). Appropriate dilutions were made, and the solution was transferred into a cell. Absorbance was determined at 540 nm *versus* a blank prepared from 20 ml of methanol and treated identically.

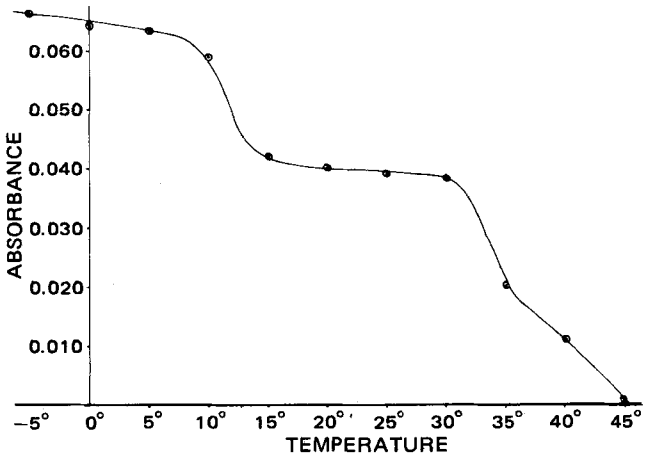

**Figure 1**—*Plot showing the absorbance* versus *temperature of dimenhydrinate with reinecke salt at 540 nm between −5 and +45°.*

## RESULTS AND DISCUSSION

Dimenhydrinate purity was ascertained by BP methods (1) and found to be 97.5 ± 0.5%. The absorbances of the colored precipitate were measured at various wavelengths ranging from 400 to 650 nm. The maximum absorbance was at 540 nm. The stability of the dimenhydrinate–reinecke salt precipitate determined at 27 ± 2° was >2 hr.

The effect of temperature on the formation of the colored precipitate was investigated using a constant-temperature water bath ranging from −5 to +5°; a $1.5 \times 10^{-3}$ *M* methanolic solution of dimenhydrinate and a $1.5 \times 10^{-3}$ *M* aqueous solution of reinecke salt (Fig. 1) were employed. Figure 1 shows two near-plateau regions, one from −5 to 7.5° and the other from 15 to 30°. The experiments were carried out at room temperature (27 ± 2°).

**Table I—Average Percentage of Dimenhydrinate in Laboratory-Made Mixtures and in Commercial Samples by Proposed Method and BP Method**

| Mixture (M) (1:1) | Proposed Method Mean, %[a] | ±SD | BP Method Mean, %[a] | ±SD |
|---|---|---|---|---|
| Dimenhydrinate + aspirin ($M_1$) | 99.32 | 0.82 | 98.48 | 1.06 |
| Dimenhydrinate + acetaminophen ($M_2$) | 99.76 | 0.36 | 98.93 | 0.31 |
| Dimenhydrinate + meprobamate ($M_3$) | 98.88 | 0.39 | 98.70 | 0.65 |
| Dimenhydrinate + phenylephrine ($M_4$) | 99.76 | 0.37 | 98.82 | 0.08 |
| Dimenhydrinate + tolbutamide ($M_5$) | 99.32 | 0.31 | 99.71 | 0.19 |
| Commercial tablet[b] $T_1$ | 101.86 | 0.64 | 101.16 | 0.80 |
| Commercial tablet[b] $T_2$ | 100.53 | 0.47 | 100.44 | 0.48 |

[a] Average of four determinations. [b] Each tablet contained 50 mg of dimenhydrinate.

The effect of pH (1.60–11.20) on the absorbance of the colored precipitate (in acetone) was studied. Hydrochloric acid was used to vary the pH from 4.10 to 1.60, and dilute ammonia solution was used to vary it from 4.10 to 11.20. However, absorbance was not affected within a pH range of 2.85–8.30.

The stoichiometric balance was determined by Job's method of continuous variation (9) and a slope-ratio method (10). In Job's method, the maximum absorbance was obtained when $V_1/(V_1 + V_2) = 0.33$, which indicated the formation of the dimenhydrinate–reinecke salt precipitate in a 1:2 molar ratio. In the slope-ratio method, the $slope_1$ and $slope_2$ values were 0.0027586 and 0.0014210 $ml^{-1}$, respectively. Hence, $slope_1/slope_2$ for the precipitate was nearly equal to 2, thereby suggesting a 1:2 molar ratio.

Reinecke salt had a solubility in water of 1 in 52. Therefore, 50 ml of a saturated aqueous solution of reinecke salt was added to a 20-ml aliquot of a methanolic solution of dimenhydrinate to establish the 1:2 molar ratio requirement for maximum precipitation of dimenhydrinate.

**Table II—Recovery Experiments by Proposed Method**

| Mixture or Tablet | Quantity of Dimenhydrinate Added, g | Corresponding Concentration of Dilution Measured, g % | Mean, %[a] | ±SD |
|---|---|---|---|---|
| $M_1$ | 0.600 | 0.096 | 99.36 | 0.40 |
| $M_2$ | 0.025 | 0.075 | 99.12 | 0.66 |
| $M_3$ | 0.020 | 0.072 | 99.01 | 0.76 |
| $M_4$ | 0.055 | 0.093 | 99.36 | 0.12 |
| $M_5$ | 0.035 | 0.081 | 98.69 | 0.52 |
| $T_1$ | 0.005 | 0.033 | 99.93 | 1.17 |
| $T_2$ | 0.010 | 0.036 | 99.41 | 0.64 |

[a] Average for four determinations.

After the optimal experimental conditions for the maximal precipitation of dimenhydrinate–reinecke salt were established, the Beer's plot was obtained by employing the stock solution of the dimenhydrinate–reinecke salt precipitate in acetone. It obeyed Beer's law in the concentration range of 200–1000 μg/ml. With the least-squares method, the calibration curve from the data obtained can be described by the following regression equation: $A = 0.0045 + 1.905C$, where the regression coefficient is 0.999.

Five laboratory-made mixtures and two commercial tablet samples containing dimenhydrinate were subjected to analysis by the proposed method and the BP method (1) (Table I).

The activity of phenylephrine was checked directly with the reagent under identical experimental conditions and was found not to react.

To justify the repeatability of the proposed method, known amounts of pure dimenhydrinate were added to preanalyzed samples of mixtures and dosage forms and reassayed by the proposed method (Table II).

The presence of either pure drugs, *i.e.*, aspirin, acetaminophen, meprobamate, phenylephrine, and tolbutamide, or tablet adjuncts like starch, lactose, talc, and magnesium stearate in the quantities used caused no detectable interference in the proposed method. The analyses of two commercial products and the efficient percentage recoveries and significant reproducibility obtained suggest the feasibility of utilizing the proposed method for the quantitation of dimenhydrinate.

# Characteristics of Equilibrium Reaction of Zolazepam

**WEN-HAI HONG * and DALE H. SZULCZEWSKI ‡x**

Received September 18, 1980, from **Analytical Research and ‡Product Development, Warner-Lambert Pharmaceutical Research Division, Warner-Lambert Company, Morris Plains, NJ 07950.* Accepted for publication November 17, 1980.

**Abstract** □ The equilibrium reaction of zolazepam, a pyrazolodiazepinone, was studied and analyzed using the approach used previously for other pyrazolodiazepinone derivatives. The intrinsic ring closure equilibrium constant for this reaction was ~100 times larger than that observed for pyrazolodiazepinones studied previously. This study illustrates that the diazepinone ring can dominate in equilibrium mixtures formed at pH values far below the pKa of the corresponding open form.

**Keyphrases** □ Zolazepam—analysis of equilibrium reaction □ Structure–activity relationships—equilibrium reaction of zolazepam □ Pyrazolodiazepinones—equilibrium reaction of zolazepam □ Equilibrium—analysis of zolazepam in reaction

The characteristics of the equilibrium reaction of certain pyrazolodiazepinones were reported previously (1). This study was an extension of that work and concerned the equilibrium behavior of zolazepam, 4-(*o*-fluorophen-

The effect of pH (1.60–11.20) on the absorbance of the colored precipitate (in acetone) was studied. Hydrochloric acid was used to vary the pH from 4.10 to 1.60, and dilute ammonia solution was used to vary it from 4.10 to 11.20. However, absorbance was not affected within a pH range of 2.85–8.30.

The stoichiometric balance was determined by Job's method of continuous variation (9) and a slope-ratio method (10). In Job's method, the maximum absorbance was obtained when $V_1/(V_1 + V_2) = 0.33$, which indicated the formation of the dimenhydrinate–reinecke salt precipitate in a 1:2 molar ratio. In the slope-ratio method, the $slope_1$ and $slope_2$ values were 0.0027586 and 0.0014210 $ml^{-1}$, respectively. Hence, $slope_1/slope_2$ for the precipitate was nearly equal to 2, thereby suggesting a 1:2 molar ratio.

Reinecke salt had a solubility in water of 1 in 52. Therefore, 50 ml of a saturated aqueous solution of reinecke salt was added to a 20-ml aliquot of a methanolic solution of dimenhydrinate to establish the 1:2 molar ratio requirement for maximum precipitation of dimenhydrinate.

**Table II—Recovery Experiments by Proposed Method**

| Mixture or Tablet | Quantity of Dimenhydrinate Added, g | Corresponding Concentration of Dilution Measured, g % | Mean, %[a] | ±SD |
|---|---|---|---|---|
| $M_1$ | 0.600 | 0.096 | 99.36 | 0.40 |
| $M_2$ | 0.025 | 0.075 | 99.12 | 0.66 |
| $M_3$ | 0.020 | 0.072 | 99.01 | 0.76 |
| $M_4$ | 0.055 | 0.093 | 99.36 | 0.12 |
| $M_5$ | 0.035 | 0.081 | 98.69 | 0.52 |
| $T_1$ | 0.005 | 0.033 | 99.93 | 1.17 |
| $T_2$ | 0.010 | 0.036 | 99.41 | 0.64 |

[a] Average for four determinations.

After the optimal experimental conditions for the maximal precipitation of dimenhydrinate–reinecke salt were established, the Beer's plot was obtained by employing the stock solution of the dimenhydrinate–reinecke salt precipitate in acetone. It obeyed Beer's law in the concentration range of 200–1000 μg/ml. With the least-squares method, the calibration curve from the data obtained can be described by the following regression equation: $A = 0.0045 + 1.905C$, where the regression coefficient is 0.999.

Five laboratory-made mixtures and two commercial tablet samples containing dimenhydrinate were subjected to analysis by the proposed method and the BP method (1) (Table I).

The activity of phenylephrine was checked directly with the reagent under identical experimental conditions and was found not to react.

To justify the repeatability of the proposed method, known amounts of pure dimenhydrinate were added to preanalyzed samples of mixtures and dosage forms and reassayed by the proposed method (Table II).

The presence of either pure drugs, *i.e.*, aspirin, acetaminophen, meprobamate, phenylephrine, and tolbutamide, or tablet adjuncts like starch, lactose, talc, and magnesium stearate in the quantities used caused no detectable interference in the proposed method. The analyses of two commercial products and the efficient percentage recoveries and significant reproducibility obtained suggest the feasibility of utilizing the proposed method for the quantitation of dimenhydrinate.

# Characteristics of Equilibrium Reaction of Zolazepam

**WEN-HAI HONG * and DALE H. SZULCZEWSKI ‡x**

Received September 18, 1980, from **Analytical Research and ‡Product Development, Warner-Lambert Pharmaceutical Research Division, Warner-Lambert Company, Morris Plains, NJ 07950.* Accepted for publication November 17, 1980.

**Abstract** □ The equilibrium reaction of zolazepam, a pyrazolodiazepinone, was studied and analyzed using the approach used previously for other pyrazolodiazepinone derivatives. The intrinsic ring closure equilibrium constant for this reaction was ~100 times larger than that observed for pyrazolodiazepinones studied previously. This study illustrates that the diazepinone ring can dominate in equilibrium mixtures formed at pH values far below the pKa of the corresponding open form.

**Keyphrases** □ Zolazepam—analysis of equilibrium reaction □ Structure–activity relationships—equilibrium reaction of zolazepam □ Pyrazolodiazepinones—equilibrium reaction of zolazepam □ Equilibrium—analysis of zolazepam in reaction

The characteristics of the equilibrium reaction of certain pyrazolodiazepinones were reported previously (1). This study was an extension of that work and concerned the equilibrium behavior of zolazepam, 4-(*o*-fluorophen-

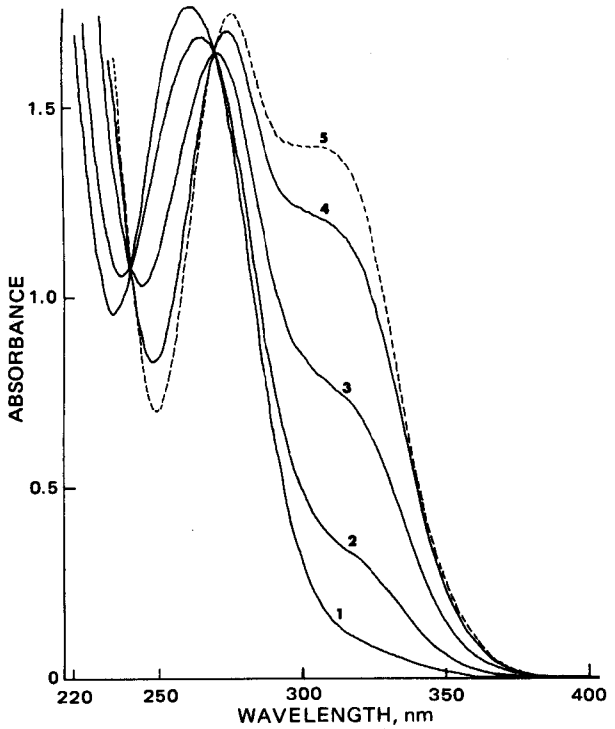

**Figure 1**—*Sequential spectra obtained for the equilibration of II at pH 3.70, 27°. Spectra 1, 2, 3, and 4 were obtained after 1, 7, 24, and 265 hr, respectively. Spectrum 4 corresponds to complete equilibration. Spectrum 5 is what would be obtained if conversion of II to I were complete.*

yl) - 6,8 - dihydro-1,3,8-trimethylpyrazolo[3,4-*e*][1,4]diazepine-7(1*H*)-one hydrochloride (I). While the nature of the reaction that occurred here was similar to that described previously, quantitative aspects differed.

## EXPERIMENTAL

**Reagents**—All chemicals used for the 0.1 and 0.05 *M* citrate and phosphate buffers of known pH values were reagent grade and were used without further purification. The hydrochloric acid solutions were prepared from prestandardized volumetric solutions[1]. The solvents, including hydrochloric acid solutions and buffers of varying pH used for kinetic studies, were adjusted to an ionic strength of 0.3 with potassium chloride. 5-(*N*-Methylaminoacetamido)-1,3-dimethyl-4-*o*-fluorobenzoylpyrazole sulfate (IIc) was used as received[2].

**Instrumentation**—The pH measurements were made using direct reading, digital pH meters[3]. UV spectra were obtained using a recording UV spectrophotometer[4].

**Equilibrium Studies**—Approximately 0.05 mEq of IIc was weighed accurately and transferred quantitatively to a 25-ml volumetric flask, using 1 ml of water to dissolve the compound. The reaction was initiated by diluting to volume with thermally equilibrated (27°) buffer with an ionic strength of 0.3 (potassium chloride). After mixing, the volumetric flasks were placed immediately in a constant-temperature water bath (27°). At appropriate intervals, 2-ml aliquots were removed, diluted to 25 ml with 0.1 *N* HCl, and mixed.

The UV spectra of the resulting solutions were obtained immediately following their preparation over 400–230 nm, using 1-cm silica cells and 0.1 *N* HCl as a blank. Samples were removed, and their spectra were obtained until redundancy was reached. The fraction of total II at equilibrium, $f_{II_T}$, was calculated by the formula: $(0.85A_i - A_{310})/0.781A_i$, where $A_i$ and $A_{310}$ are the absorbances at 271 (isosbestic point) and 310 nm, respectively. In this formula, $0.85A_i$ represents the theoretical absorbance at 310 nm for complete conversion from II to I, and $0.781A_i$ represents the expected absorbancy difference at 310 nm for complete conversion of II to I.

## RESULTS AND DISCUSSION

Typical sequential UV spectra obtained during equilibration are shown in Fig. 1. The starting material was the open form of I, 5-(*N*-methylaminoacetamido)-1,3-dimethyl-4-*o*-fluorobenzoylpyrazole (II). When II was the reactant, the spectra changed irrespective of the solution pH. When I was the starting material, changes in spectra with time were seen only at pH values of ≤6.0. As seen in Fig. 1, the spectrum of II changed to a spectrum closely resembling the spectrum of I. Isosbestic points at 240 and 271 nm were clear and sharp. At a given pH, the same redundant spectrum was produced irrespective of whether I or II was the starting material. The terminal spectra produced at pH values of ≤6.0 corresponded to the spectrum expected for mixtures of I and II containing up to 18% of II and 82% of I. The quantitative composition of equilibrium mixtures formed at various pH values is given in Table I.

The fraction of the open form ($f_{II_T}$) present at equilibrium for these systems is given by (1):

$$f_{II_T} = \frac{K_a^{IIb} + a_{H^+}}{K_a^{IIb} + a_{H^+} + K_a^{IIb}K^{*\prime}(K_a^{Ib} + a_{H^+})} = \frac{(II_T)}{(I_T) + (II_T)} \quad \text{(Eq. 1)}$$

where $I_T = (Ia) + (Ib)$, $II_T = (IIa) + (IIb)$, and:

$$K_a^{Ib} = \frac{(Ia)(H^+)}{(Ib)} \quad \text{(Eq. 2)}$$

$$K_a^{IIb} = \frac{(IIa)(H^+)}{(IIb)} \quad \text{(Eq. 3)}$$

In Eq. 1, $f_{II_T}$, $K_a^{IIb}$, and $K_a^{Ib}$ are experimentally determined known quantities (Tables I and II). Equation 1 can be rearranged so that the intrinsic ring closure constant $K^{*\prime}$ is in terms of these known quantities:

$$K^{*\prime} = \frac{(K_a^{IIb} + a_{H^+})(1 - f_{II_T})}{K_a^{IIb}(K_a^{Ib} + a_{H^+})f_{II_T}} = \frac{(Ib)}{(IIa)(H^+)} \quad \text{(Eq. 4)}$$

The value of $K^{*\prime}$ for this system was determined using Eq. 4 together with the values of $f_{II_T}$ given in Table I. The resulting values of $K^{*\prime}$ are given in Table III. As seen, the intrinsic ring closure constant for this system was ~100 times greater than it was for the ripazepam system studied previously (1).

When the values of $K^{*\prime}$, $K_a^{Ib}$, and $K_a^{IIb}$ given in Tables II and III are substituted in Eq. 1 and the values of $f_{II_T}$ are generated, the solid line shown in Fig. 2 is obtained. The calculated values correlate well with those determined by spectroscopic analysis of the equilibrium mixtures.

**Table I—Composition of Equilibrium Mixtures of I and II in Terms of $f_{II_T}$**

| pH | $f_{II_T}$[a] |
|---|---|
| 3.70 | 0.18 |
| 4.26 | 0.15 |
| 4.83 | 0.09 |
| 5.35 | 0.04 |
| 6.04 | 0.01 |

[a] These values were determined by analysis of the redundant, terminal UV spectrum obtained when equilibration was complete.

**Table II—Dissociation Constants**

| Compound | pKa | $K_a$, *M* |
|---|---|---|
| Ib[a] | 4.69 | $2.04 \times 10^{-5}$ |
| IIb[b] | 7.52 | $3.02 \times 10^{-8}$ |

[a] Determined spectrophotometrically. [b] Determined titrimetrically.

**Table III—Calculation of $K^{*\prime}$ Using Eq. 4**

| pH | $K^{*\prime}$, $M^{-1}$ |
|---|---|
| 3.70 | $1.70 \times 10^8$ |
| 4.26 | $1.48 \times 10^8$ |
| 4.83 | $1.13 \times 10^8$ |
| 5.35 | $1.14 \times 10^8$ |
| 6.04 | $1.45 \times 10^8$ |
| Average | $1.38 \times 10^8$ |

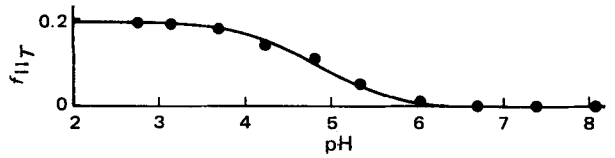

**Figure 2**—*Plot of* $f_{II_T}$ versus *pH*.

As indicated previously, at pH values below the pKa values of open and closed forms, Eq. 1 reaches a limit:

$$\lim f_{II_T}^{a\,H^+\to\infty} = \frac{1}{1 + K^{*\prime}K_a^{IIb}} \qquad \text{(Eq. 5)}$$

As seen from Eq. 5, the maximum concentration of the open form (II) that can exist in these systems depends not only on the pKa of the open form ($K_a^{IIb}$) but also on the value of the ring closure constant ($K^{*\prime}$). If, as is the case here, the value of $K^{*\prime}$ is very large ($1.38 \times 10^8\ M^{-1}$), then the maximum concentration of the open form at equilibrium is small irrespective of the solution's pH. The ring form then dominates. This situation is best understood by considering the reaction shown in Scheme I. An increase in hydrogen-ion activity serves not only to convert II to its unreactive protonated form but also to promote dehydration.

The marked increase in the value of the ring closure constant observed here may be attributed to a methyl group in position 4 of the diazepinone ring (1). Also important is the electronic distribution around the imino carbon atom (position 8). Zolazepam is a stronger base than ripazepam by a factor of 10 (1). This finding suggests that electron withdrawal from this carbon is less here than in the previous system. Attack by water would be hindered, and the ring form would be stabilized.

# Improved Assay for Mixtures of Citrate and Citric Acid in Systemic Alkalizer Solutions

**HENRY S. I. TAN ˣ, DIANNE M. McKIBBEN, and ARTHUR C. GLASSER**

Received May 30, 1980, from the *College of Pharmacy, University of Cincinnati–Medical Center, Cincinnati, OH 45267.* Accepted for publication November 4, 1980.

**Abstract** □ A modification of the USP method for the assay of systemic alkalizer solutions containing mixtures of citrate and citric acid is presented; it involves two titrations and ion-exchange chromatography. A diluted sample is titrated with 0.02 *N* NaOH to find the free citric acid content. The eluate from cation-exchange chromatography of an equal volume of diluted sample is titrated with 0.02 *N* NaOH to assay for total citric acid. Subtracting the results of the first titration from the second provides the citrate content. Synthetic mixtures of potassium citrate–citric acid, potassium citrate–sodium citrate–citric acid, and sodium citrate–citric acid were prepared and assayed. The method was applied to commercially available preparations. The proposed method eliminates some significant errors of the compendial method, and the accuracy and reproducibility are equal or better than those obtained with the compendial method. Theoretically, the result obtained by the compendial method does not necessarily give the citrate content.

**Keyphrases** □ Citrate–citric acid mixtures—improved assay of systemic alkalizer solutions □ Citric acid–citrate mixtures—improved assay of systemic alkalizer solutions □ Alkalizer—improved assay of citrate–citric acid mixtures

The compendial method for the assay of mixtures of citrate and citric acid solutions is a combination of an electrometric and visual titration (1). Direct application of this compendial method for the assay of citrate and citric acid to recently available commercial systemic alkalizer solutions such as potassium citrate–citric acid oral solution (I), potassium citrate–sodium citrate–citric acid oral solution (II), and sodium citrate–citric acid oral solution (III) is not practical since the preparations are generally colored and are assayed in undiluted form. Moreover, the titrants used are 1 *N* in strength. Since these difficulties allow for many sources of error, a more appropriate assay is desired for the quality control of these commercial preparations.

Alkali salts of organic acids have been analyzed by passing an aqueous solution of the salt through an ion-exchange column followed by titration of the eluate with a base (2, 3). The ion-exchange principle is included in the analysis of commercial systemic alkalizer solutions containing mixtures of citrate and citric acid. The method is simple, and the reproducibility and accuracy are equal or better than those obtained with the USP method.

## EXPERIMENTAL

**Reagents and Chemicals**—Citric acid monohydrate[1], potassium citrate monohydrate[1], sodium citrate dihydrate[1], a sulfonated polystyrene copolymer strong cation-exchange resin in the hydrogen form[2] (medium porosity), a 0.02 *N* NaOH volumetric solution obtained by quantitative dilution of 1 *N* NaOH (4), and phenolphthalein indicator solution were used. All other chemicals were reagent grade and were used without purification.

**Cation-Exchange Column**—Ten grams of cation-exchange resin was hydrated by mixing with 50 ml of glass-distilled water in a 100-ml beaker. The resin was allowed to settle, and the excess water was decanted until a slurry of resin remained in the beaker. The slurry was poured into a 15-mm i.d. × 300-mm long glass column, provided with a fritted disk and polytef stopcock, and the resin beads were allowed to settle into a homogeneous bed. Approximately 100 ml of glass-distilled water was used to wash the resin bed. The stopcock was closed when the water level was 1–2 mm above the resin bed.

**Assay for I and II**—A 15.0-ml aliquot of sample was transferred to a 250-ml volumetric flask and diluted to volume with distilled water.

*Free Citric Acid*—Five milliliters of the diluted sample was pipetted into a 250-ml erlenmeyer flask, and 25 ml of distilled water and 5 drops of phenolphthalein were added. The contents of the flask were swirled and titrated with 0.02 *N* NaOH. The quantity, in milligrams per milliliter, of citric acid monohydrate in the original sample was found using the formula $233.50 \times A$, where $A$ is the number of milliequivalents of sodium hydroxide[3] consumed in the titration.

*Total Citric Acid*—Five milliliters of the diluted sample was added carefully to the top of the resin bed in the column. A 250-ml erlenmeyer flask was placed below the column, and the stopcock was opened until the sample entered the resin bed. The sample was eluted with 60 ml of distilled water at a flow rate of ≃5 ml/min, and ~65 ml of eluate was collected. Then 5 drops of phenolphthalein was added to the eluate, and the contents were swirled and titrated with 0.02 *N* NaOH.

*Calculation of Citrate Content*—The quantity in the original sample, in milligrams per milliliter, of potassium citrate monohydrate in I was calculated using the formula $360.46 \times (B - A)$, or the quantity of total citrate ($C_6H_5O_7$) in II was calculated using the formula $210.10 \times (B - A)$, where $A$ is as defined previously and $B$ is the number of milliequivalents of sodium hydroxide[3] consumed in the titration of the cation-exchange column eluate.

**Assay for III**—Ten milliliters of the sample was transferred to a 100-ml volumetric flask and diluted to volume with distilled water. The directions given for the assay for I and II, beginning with *Free Citric Acid*, were followed with the exception of the calculation formulas. The quantity in the original sample, in milligrams per milliliter, of citric acid monohydrate was calculated using the formula $140.10 \times A$, and the quantity of sodium citrate dihydrate was calculated using the formula $196.07 \times (B - A)$, where $A$ and $B$ are as defined previously[4].

[3] Milliequivalents of sodium hydroxide equal milliliters of sodium hydroxide consumed in the titration × normality of sodium hydroxide. Constant equals equivalent weight × dilution factor. Dilution factor = (250 ml/5 ml) (1 ml/15 ml). Equivalent weight for citric acid monohydrate is 70.05; for potassium citrate monohydrate, it is 108.14; and for $C_6H_5O_7$, it is 63.03.

[4] Dilution factor = (100 ml/5 ml) (1 ml/10 ml). Constant equals equivalent weight times dilution factor. Equivalent weight of sodium citrate dihydrate is 98.04.

## RESULTS AND DISCUSSION

In the assay of citrate, the sample solution was passed through a strong cation-exchange resin. In the process, the cations such as potassium and sodium ions of the citrate were replaced by protons from the resin, resulting in an eluate containing citric acid. Since the sample also contained free citric acid, the titration of the eluate with base gave the total citric acid concentration. The free citric acid of the sample was titrated directly with base. When equal volumes of samples were used for the determination of free citric acid and of total citric acid, the difference in titrant consumption was equivalent to the quantity of citric acid derived from citrate. Studies indicated that citrate did not interfere in the direct titration of free citric acid with 0.02 *N* NaOH. Quantitative results also were obtained when pure potassium or sodium citrate solutions were passed through the column and the eluate was titrated with base.

Recovery data for synthetic mixtures containing mixtures of potassium and/or sodium citrate and citric acid are shown in Table I. The accuracy and precision were identical to those obtained by the compendial method. The proposed method was applied to the assay of commercial systemic alkalizer solutions (Table II). The compendial assay of these commercial preparations is usually subject to greater variations between individual samples, particularly in determining the end-point of the citric acid titration with base. The commercial preparations are generally colored and are analyzed in undiluted form. For example, one commercial product is a wine-red solution. As the wine-red solution is titrated with base to the phenolphthalein end-point, the color change to pink (or red) at the equivalence point is difficult to observe and a sharp end-point cannot be obtained. Since a 1 *N* NaOH titrant is used, each drop (~0.05 ml) of titrant from the equivalence point is equivalent to 3.5 mg of citric acid monohydrate. The coloring agent present in other commercial products also masks the color change at the equivalence point. This problem accounts for the relatively larger standard deviations for the compendial results as compared to those obtained by the proposed method (Table II). No problems were encountered in the titrations following the proposed method since a sharp end-point was obtained in each case.

The compendial assay for the citrate content in the mixture involves an electrometric titration to a predetermined pH of 1.55. Since the product of this titration is citric acid, the pH at the equivalence point is simply the pH of a solution of the total citric acid, which includes citric acid formed from citrate plus free citric acid already in the sample. Theoretically, the compendial method does not necessarily give the actual citrate content. A preparation containing the correct quantity of citrate but an incorrect amount of citric acid (as stated on a label claim) would give a wrong citrate content when the titration is conducted to a predetermined pH. Titration gives a true indication of the citrate content only when the quantity of free citric acid is correct. An electrometric titration to a predetermined pH is useful if the species analyzed is the only one that determines the end-point pH. The proposed method eliminates this

problem because the citrate assay and subsequent calculation directly reflect the citrate content, regardless of the original free citric acid concentration.

Approximate calculation of the pH at the equivalence point of the compendial citrate titration showed that the value differed markedly from the stated pH of 1.55. The calculated value of 1.81 was obtained when the preparation was assumed to contain the labeled quantities of citrate and citric acid, using a $K_{a_1}$ value of $7.45 \times 10^{-4}$ and a $K_{a_2}$ value of $1.73 \times 10^{-5}$ at 25° for citric acid (5) and assuming that the third dissociation was negligible. Applying the same approximate calculation to compute the pH at the equivalence point of a similar electrometric titration of citrate in anticoagulant citrate–dextrose solution gave a value of 2.07. This value was relatively close to the stated pH of 1.98 ± 0.02 (6).

Since commercial systemic alkalizer solutions contain additives such as preservatives, flavoring, and coloring agents, the assay of a solution placebo is recommended. The placebo should be subjected to the same analytical steps as the sample, and necessary corrections should be made for titrant consumption, if any, by the placebo. In contrast, the compendium directs the use of water as a blank in the electrometric titration of citrate and no blank runs for the titration of citric acid.

# Effect of Elevated Blood Glucose Levels on Hepatic Microsomal Enzyme System in Rats

**MARTIN B. SIDEMAN**

Received August 21, 1980, from the *Division of Pharmacotherapeutics, Arnold & Marie Schwartz College of Pharmacy and Health Sciences, Long Island University, Brooklyn, NY 11201.* Accepted for publication November 11, 1980.

**Abstract** □ Elevated blood glucose levels attained by *ad libitum* drinking of 20% glucose solution inhibited *in vivo* *O*-dealkylation associated with the hepatic microsomal enzyme system. Significant inhibition of biotransformation was demonstrated after 1 day, with the maximum occurring at 3 days. Inhibition was followed by a tendency to return to normal activity. Serum levels of substrate and product were determined by liquid chromatographic techniques using 55% acetonitrile and 45% 0.1 *M* acetic acid as the mobile phase.

**Keyphrases** □ Glucose levels, blood—effect of elevation on hepatic microsomal enzyme system, rats □ Microsomal enzyme system—effect of elevated blood glucose levels, rats □ Enzyme systems—effect of elevated blood glucose levels on hepatic microsomal enzymes, rats □ Biotransformation—effect of elevated blood glucose levels on hepatic microsomal enzyme system, rats

The following reactions (1) are catalyzed by the mixed-function oxidase enzymes of the hepatic microsomal system: *N*- and *O*-dealkylation, aromatic ring side-chain hydroxylation, sulfoxide formation, *N*-oxidation, *N*-hydroxylation, deamination of primary and secondary amines, and replacement of a sulfur by an oxygen atom. Previous investigators showed that elevated blood glucose levels have inhibitory effects on several of the biotransformations mentioned in addition to depressing the cytochrome P-450 levels of the system. Hartshorn *et al.* (2) demonstrated, by *in vitro* microsomal studies in rats, the inhibition of *N*-demethylation of ethylmorphine and aniline hydroxylase as well as depression of the cytochrome P-450 content. *In vitro* microsomal studies in mice (3) showed the inhibition of hexobarbital biotransformation, primarily oxidation of the side chain at C-5, and the *N*-dealkylation of benzphetamine in addition to cytochrome P-450 depression. Strother *et al.* (4), using the *in vivo* technique of increased sleep time, also showed that elevated blood glucose levels delayed the biotransformation of various barbiturates in mice.

This investigation established, by direct measurements in blood using liquid chromatography, that elevated blood glucose levels inhibit *O*-dealkylation associated with the hepatic microsomal system.

## EXPERIMENTAL

**Animals**—Adult male Sprague–Dawley rats, 180–200 g, were individually housed in temperature-, light-, humidity-, and air-controlled quarters. Commercial laboratory chow and drinking liquid, either water or 20% glucose solution, were given *ad libitum*.

**Liquid Chromatography**—A liquid chromatographic system containing a $C_{18}$ column and an absorbance detector fixed at 254 nm was used isocratically[1]. The mobile phase consisted of 55% acetonitrile (HPLC grade) and 45% of 0.1 *M* acetic acid. Prior to use, the mobile phase was passed through a solvent-clarification apparatus to remove gases and particulates which might affect the column. Solvent delivery was at a rate of 1 ml/min. Recordings were made at a chart speed of 0.5 cm/min.

**Reagents**—Five liters of 20% glucose solution was prepared at one time and stored in the refrigerator until needed. Methanol (HPLC grade) was used as a solvent for the internal standard and as a protein precipitant.

Indomethacin[2] (I) [1-(*p*-chlorobenzoyl)-5-methoxy-2-methylindole-3-acetic acid] was used as a substrate for biotransformation and as a reference standard.

*O*-Desmethylindomethacin[3] (II) was used as a reference standard for the biotransformation product. Compound II is a major product of the

biotransformation of I in humans (5) and in various laboratory animals (6).

1-(*p*-Fluorobenzoyl)-5-methoxy-2-methylindole-3-acetic acid[4] (III) was used as the internal standard for chromatography.

***In Vivo* Biotransformation**—The animals drank the 20% glucose solution for varying times (1, 3, 5, 7, and 10 days). Each experimental group consisted of six rats chosen at random from the pool. The control group contained eight rats. To reduce the workload on the day of sacrifice, each group was divided in half, with the second half starting 1 day later. All groups in each half were sacrificed the same day. Controls were started at the same time as the 10-day experimental group. The glucose solutions were replaced daily to avoid bacterial growth and contamination. On the morning of the day of sacrifice, all animals were tested for glucose in their urine.

Following the urine test, the animals were weighed and injected with a saline solution of I (10 mg/kg ip) solubilized by titrating to pH 7.6–8.0. The animals then were returned to their cages and sacrificed by decapitation 30 min later. The blood was collected, allowed to clot, and centrifuged; the serum was stored at from −10 to −20° until analyzed. During collection, an aliquot of whole blood was removed and tested for glucose with glucose reagent strips[5] and a reflectance colorimeter[6].

A preliminary study of blood I and II levels *versus* time showed an increase in concentration of both to a maximum at 15 min. The succeeding fall in concentration was measurable to at least 2 hr. The 0.5-hr point was chosen because of relatively high I and II concentrations. It was also assumed that little if any I was removed from the injection site and that the blood levels were the result of cellular uptake, biotransformation, and excretion on the maximum levels, in short, normal metabolic pathways.

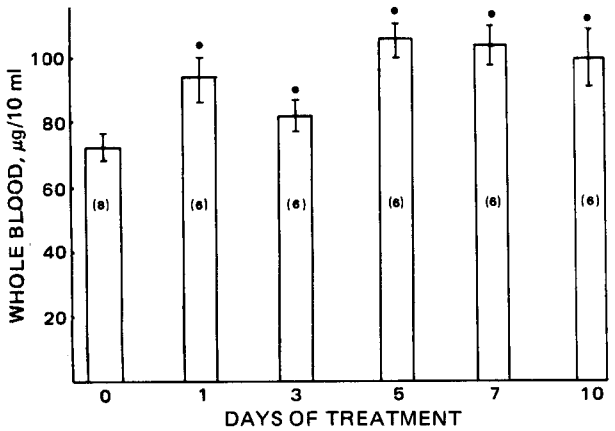

**Figure 2**—*Serum glucose levels. Key: ●, significant differences from control, p < 0.05, as determined by the Student t test.*

[5] Dextrostix, Ames Division of Miles Laboratories, Elkhart, Ind.

[6] Eyetone, Ames Division of Miles Laboratories, Elkhart, Ind.

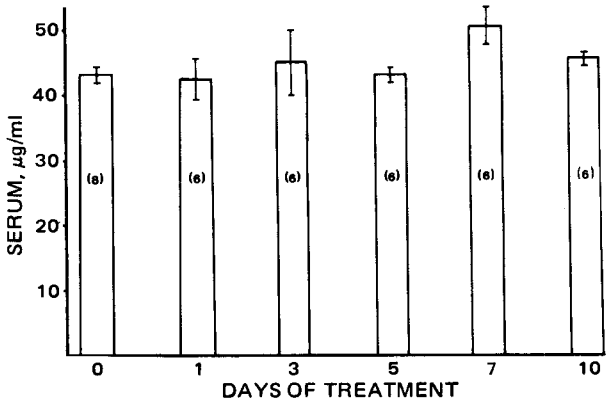

**Figure 3**—*Serum indomethacin levels.*

**Analysis**—To analyze the serum for I and II properly, substances that would interfere with the proper function of the column, principally protein, had to be removed. Methanol was added to the serum to precipitate the protein. Furthermore, methanol increased the solubility of the compounds under investigation and reduced the number of transfers needed to put them on the column. Four volumes of methanol served adequately.

The procedure used 0.5 ml of serum and 2 ml of methanol containing a fixed concentration of III. The mixture was agitated on a vortex mixer to ensure complete mixing and was centrifuged for 10 min, and the supernate was filtered to remove any particulate material. A 10-μl aliquot was placed on the column, and the peak areas were determined from standard curves.

Standard curves were prepared by plotting the ratio of the peak area produced by I or II divided by the peak produced by III *versus* the standard concentration. Recovery experiments showed that there was no loss of the three compounds if the 0.5-ml portion was methanol, water, or serum. Thus, no corrections for recovery had to be made. Figure 1 shows chromatograms of substrate, product, and internal standard added to either water or serum from a rat receiving no injections, the differences being the substances present in serum that do not interfere with the compounds under investigation. A complete chromatogram required 7 min.

All data are reported as the group mean ± *SE*. Significance to $p < 0.05$ was determined by the Student *t* test.

## RESULTS AND DISCUSSION

All animals showed good growth patterns with no significant difference in body weight. The average weight at sacrifice ranged from 263 ± 6 to 278 ± 5 g; the control group was not one of the extremes. Whole blood

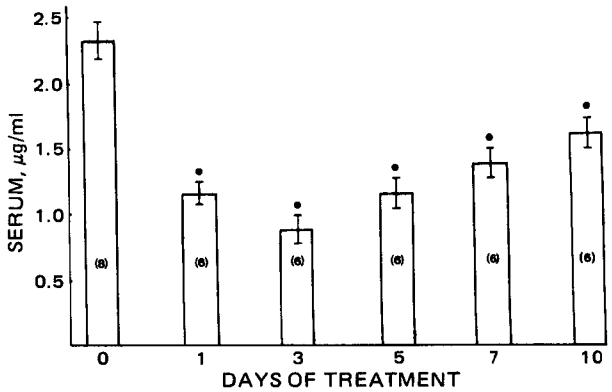

**Figure 4**—*Serum desmethylindomethacin levels. Key: ●, significant differences from control, p < 0.05, as determined by the Student t test.*

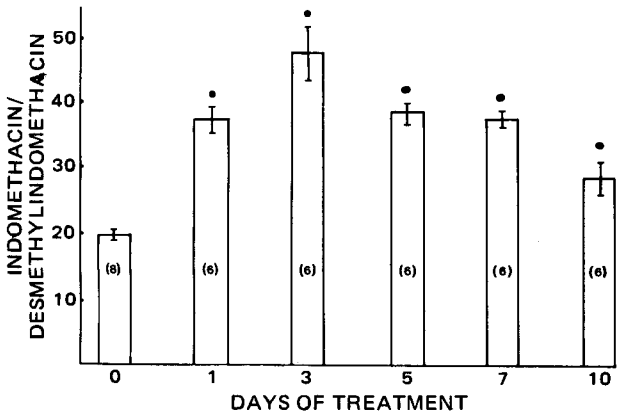

**Figure 5**—*Ratio of indomethacin divided by desmethylindomethacin. Key: ●, significant differences from control, p < 0.05, as determined by the Student t test.*

glucose levels (Fig. 2) were significantly elevated after 1 day and remained so. Although their blood levels were higher than those of the controls, none of the experimental animals had glucose in their urine on the day of sacrifice.

Figures 3 and 4 represent the serum levels of I and II, respectively. There were no significant differences in the substrate during the experiment. However, there were significant differences in the product level from Day 1 on. The maximum inhibition occurred at Day 3, followed by a tendency toward control levels as time progressed.

Elevated blood glucose levels obtained by oral administration of the 20% glucose solution rapidly led to inhibition of the hepatic microsomal mixed-function oxidase, which catalyzed *O*-dealkylation within 1 day. Although serum insulin levels were not measured, it can be projected from the urine levels at sacrifice and from the data presented by Hartshorn *et al.* (2) that the results were not due to hypoinsulinemia. Inversion of the inhibition after the maximum level at Day 3 confirmed earlier findings (7) that inhibition is short lived and returns to normal even though glucose administration is prolonged.

Since there were no significant differences in the blood substrate levels, the biotransformation inhibition could only be accounted for by the glucose affecting enzymatic activity. Kinetic studies (3) indicated that glucose caused mixed inhibition (competitive and noncompetitive) and altered the enzyme at the active site and at an allosteric site. The inversion of inhibition may have been caused by induction of new enzyme as well as displacement of old enzyme, freeing more active sites. Figure 5 shows the ratio of substrate to product, representing the biotransformation of I to II under the influence of glucose and time.

# Simultaneous Determination of Hydroxyzine Hydrochloride and Benzyl Alcohol in Injection Solutions by High-Performance Liquid Chromatography

**G. N. MENON and B. J. NORRIS** ˣ

Received January 18, 1980, from the *Department of Analytical Research, Abbott Laboratories, North Chicago, IL 60064.* Accepted for publication November 19, 1980.

**Abstract** □ A stability-indicating, high-performance liquid chromatographic method was developed for the simultaneous determination of hydroxyzine hydrochloride and benzyl alcohol in injection solutions. Separation was achieved using a μBondapak $C_{18}$ column and the eluent [60% water, 25% acetonitrile, and 15% methanol containing 0.06% (v/v) sulfuric acid, 0.5% (w/v) sodium sulfate, and 0.02% (w/v) heptanesulfonic acid sodium salt] at a flow rate of 2 ml/min. Isobutyrophenone and *p*-nitroacetophenone were used as internal standards. The UV detector response at 257 nm was linear for hydroxyzine hydrochloride in the 3–10-mg/ml range and for benzyl alcohol in the 0.54–1.8-mg/ml range under analysis conditions. The method is accurate, simple, and precise.

**Keyphrases** □ High-performance liquid chromatography—simultaneous determination of hydroxyzine hydrochloride and benzyl alcohol, injection solutions □ Analysis, simultaneous—high-performance liquid chromatographic method for hydroxyzine hydrochloride–benzyl alcohol injection solutions □ Injection solutions—high-performance liquid chromatographic method for simultaneous determination of hydroxyzine hydrochloride and benzyl alcohol

Hydroxyzine hydrochloride is usually formulated with benzyl alcohol as a preservative (bacteriostatic) in injection solutions. Depending on conditions such as pH, light exposure, and temperature, photolysis occurs in solution, resulting in the formation of *p*-chlorobenzophenone, *p*-chlorobenzaldehyde, *p*-chlorobenzoic acid, and 1-[2-(2-hydroxyethyl)ethyl]piperazine dihydrochloride (1, 2). The compendial assay for hydroxyzine hydrochloride injection, based on titration of the free base with perchloric acid, is not indicative of drug stability in solution (3). From an analytical standpoint, a simple, rapid, and precise method is desirable for the simultaneous determination of both the drug substance and the preservative in the formulation.

This paper describes the development of a high-performance liquid chromatographic (HPLC) method for hydroxyzine hydrochloride and benzyl alcohol in an injectable formulation. The method is stability indicating of both ingredients in solution.

## EXPERIMENTAL

**Instrumentation**—The chromatographic system was equipped with a dual-piston reciprocating pump[1], a universal injector[2], and a vari-

**Keyphrases** □ High-performance liquid chromatography—simultaneous determination of hydroxyzine hydrochloride and benzyl alcohol, injection solutions □ Analysis, simultaneous—high-performance liquid chromatographic method for hydroxyzine hydrochloride–benzyl alcohol injection solutions □ Injection solutions—high-performance liquid chromatographic method for simultaneous determination of hydroxyzine hydrochloride and benzyl alcohol

Hydroxyzine hydrochloride is usually formulated with benzyl alcohol as a preservative (bacteriostatic) in injection solutions. Depending on conditions such as pH, light exposure, and temperature, photolysis occurs in solution, resulting in the formation of *p*-chlorobenzophenone, *p*-chlorobenzaldehyde, *p*-chlorobenzoic acid, and 1-[2-(2-hydroxyethyl)ethyl]piperazine dihydrochloride (1, 2). The compendial assay for hydroxyzine hydrochloride injection, based on titration of the free base with perchloric acid, is not indicative of drug stability in solution (3). From an analytical standpoint, a simple, rapid, and precise method is desirable for the simultaneous determination of both the drug substance and the preservative in the formulation.

This paper describes the development of a high-performance liquid chromatographic (HPLC) method for hydroxyzine hydrochloride and benzyl alcohol in an injectable formulation. The method is stability indicating of both ingredients in solution.

## EXPERIMENTAL

**Instrumentation**—The chromatographic system was equipped with a dual-piston reciprocating pump[1], a universal injector[2], and a vari-

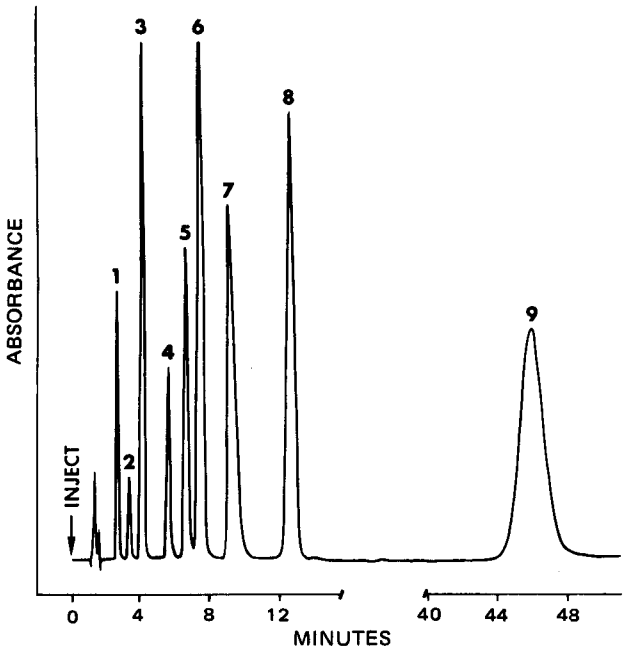

**Figure 1**—*Synthetic mixture of formulation ingredients, potential degradation products, and internal standards for quantitation. Key: 1, benzyl alcohol (0.81 mg/ml); 2, benzoic acid (0.093 mg/ml); 3, benzaldehyde (0.041 mg/ml); 4,* p-*nitroacetophenone (0.024 mg/ml); 5,* p-*chlorobenzoic acid (0.19 mg/ml); 6,* p-*chlorobenzaldehyde (0.073 mg/ml); 7, hydroxyzine hydrochloride (5.0 mg/ml); 8, isobutyrophenone (0.269 mg/ml); and 9,* p-*chlorobenzophenone (0.18 mg/ml).*

able-wavelength UV detector[3]. The separation was performed on a 30-cm × 4-mm i.d. column containing microparticulate (10-μm) bonded octadecylsilane material[4]. The chromatographic peaks were electronically integrated and recorded[5].

**Eluent**—The eluent was 60% water, 25% acetonitrile[6], and 15% methanol[6] containing 0.06% (v/v) sulfuric acid, 0.5% (w/v) sodium sulfate, and 0.02% (w/v) heptanesulfonic acid sodium salt[7]. The eluent pH was 2.6.

**Internal Standard Solution**—A methanolic solution of 0.2 mg of *p*-nitroacetophenone[8]/ml and 2.5 mg of isobutyrophenone[8]/ml was used as the internal standard solution.

**Standard Preparation**—The standard solution for analysis was prepared by dissolving 250 mg of hydroxyzine hydrochloride NF reference standard in 5 ml of water. Five milliliters of a 9-mg/ml methanolic solution of benzyl alcohol NF reference standard and 5.0 ml of the internal standard solution were pipetted into the hydroxyzine hydrochloride reference standard solution; this mixture was diluted to 50 ml with methanol.

**Sample Preparation**—The method was developed utilizing a formulation of 50 mg of hydroxyzine hydrochloride/ml containing 9 mg of benzyl alcohol/ml. The analysis sample was prepared by mixing 5.0 ml of formulation and 5.0 ml of internal standard solution and diluting the mixture to 50 ml with methanol.

**Analysis**—The following chromatographic conditions were used: flow rate, 2 ml/min; detector wavelength, 257 nm; absorbance, 0.2 aufs; and injection volume, 10 μl. Duplicate analyses were performed for both the standard and sample preparations.

## RESULTS AND DISCUSSION

A chromatographic method that is stability indicating of hydroxyzine hydrochloride was outlined previously (4); the chromatography was performed on a Bondapak phenyl/corasil column using a 5:3 mixture of 0.25% $(NH_4)_2CO_3$–acetonitrile as the eluent. A similar system using a 45:55 mixture of 0.01 *M* phosphate buffer (pH 7.8)–acetonitrile as the eluent and a μBondapak $C_{18}$ column also was used successfully to monitor hydroxyzine hydrochloride stability[9]. In both methods, a high proportion of acetonitrile is needed to elute the drug substance as the free base. Benzyl alcohol, another component in the formulation, could not be analyzed with hydroxyzine hydrochloride in either chromatographic system; it could not be retained on either column due to the high acetonitrile concentration in the eluent.

**Table I—Statistical Data Resulting from Simultaneous Analyses of Hydroxyzine Hydrochloride and Benzyl Alcohol in Hydroxyzine Hydrochloride Injection** [a]

| Parameter | Hydroxyzine Hydrochloride | Benzyl Alcohol |
|---|---|---|
| Number of analyses | 7 | 7 |
| Milligrams per milliliter (mean) | 48.7 | 8.47 |
| *SD*, mg/ml | ±0.44 | ±0.09 |
| *RSD*, % | ±0.9 | ±1.0 |

[a] Abbott Laboratories, North Chicago, Ill.; stored at 25° for 2 years.

The ion-pair reversed-phase chromatography used in this method allowed benzyl alcohol and hydroxyzine hydrochloride to be determined simultaneously. The acidity of the eluent was adjusted to a pH at which hydroxyzine hydrochloride and heptanesulfonic acid sodium salt are ionized, resulting in ion-pair formation. The ionic strength of the eluent was increased by the addition of sodium sulfate, which generally decreases the retention of compounds being chromatographed *via* the ion-pairing mechanism (5). Although the proportion of organic solvent in the eluent is high, the polarity of organic solvent was increased by using a mixture of methanol and acetonitrile. Therefore, benzyl alcohol was retained on the $C_{18}$ column; it was unaffected by the addition of heptanesulfonic acid sodium salt and sodium sulfate to the eluent, as it did not form an ion-pair.

This analysis is stability indicating of both hydroxyzine hydrochloride and benzyl alcohol (Fig. 1). A synthetic mixture of benzyl alcohol, hydroxyzine hydrochloride, several potential degradation products (benzoic acid[8], benzaldehyde[8], *p*-chlorobenzoic acid[8], *p*-chlorobenzaldehyde[8], and *p*-chlorobenzophenone[8]), and the internal standards used for quantitation, *p*-nitroacetophenone and isobutyrophenone, were separated under analytical conditions.

The detector wavelength of 257 nm was selected for maximum response for both hydroxyzine hydrochloride and benzyl alcohol. The linearity of the detector response under analytical conditions was established for hydroxyzine hydrochloride in the 3–10-mg/ml range (*y* intercept, −0.001; *r*, 0.9999) and for benzyl alcohol in the 0.54–1.8-mg/ml range (*y* intercept, 0.003; *r*, 0.9999). Since the resulting standard curves for both hydroxyzine hydrochloride and benzyl alcohol were linear and passed through the origin, sample analysis could be performed *versus* a single standard preparation.

Experiments were performed to demonstrate the accuracy of the method. Six solution mixtures were prepared ranging from 60 to 200% of the theoretical concentrations of the two components. Recoveries of benzyl alcohol varied from 99.4 to 103.0% with an average recovery of 101.0 ± 1.35%; recoveries of hydroxyzine hydrochloride varied from 99.8 to 100.7% with an average recovery of 100.2 ± 0.34%.

The reproducibility of the method was demonstrated by replicate analyses of hydroxyzine hydrochloride and benzyl alcohol in a commercial product which had been stored at 25° for 2 years. The statistical data are presented in Table I.

# Synthesis and Vasodepressor Screen of a Series of 2-(2-Alkylaminoalkylamido)-3-carbamyl-4-methyl-5-benzylpyrroles

**L. D. WANG *, J. W. SOWELL, Sr. *, J. J. FREEMAN ‡, and J. W. KOSH ‡x**

Received September 15, 1980, from the **Division of Medicinal Chemistry and the* ‡*Division of Pharmacology, College of Pharmacy, University of South Carolina, Columbia, SC 29208.* Accepted for publication November 19, 1980.

**Abstract** □ A series of 2-(2-alkylaminoalkylamido)-3-carbamyl-4-methyl-5-benzylpyrroles was synthesized and screened for vasoactivity. The compounds were administered intraperitoneally as a suspension to approximate the oral route of administration and intravenously when solubilization could be affected with suitable solvents. The most active compound following intravenous or intraperitoneal administration lowered blood pressure 73 and 35.5 mm Hg at doses of 4 mg/kg iv and 100 mg/kg ip, respectively. It also exhibited the longest duration of vasodepressor activity (25 min). Several other compounds exhibited vasodepressor activity following intraperitoneal administration. Several hydrochloride salts appeared to be more potent vasoactive agents than the corresponding bases.

**Keyphrases** □ Lidocaine analogs—synthesis, analysis of vasoactivity, intraperitoneal and intravenous administration □ Vasoactive agents—synthesis, analysis, intraperitoneal and intravenous administration, lidocaine analogs □ Synthesis and analysis—vasoactive agents, lidocaine analogs, intraperitoneal and intravenous administration □ Administration routes—effect on vasoactivity, lidocaine analogs, vasoactive agents

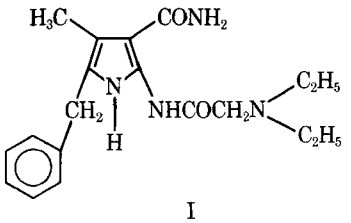
Several series of 2-aminopyrrole analogs of lidocaine recently were investigated as local anesthetic and antiarrhythmic agents (1–3). From one series, the hydrochloride salt of the benzylcarbamyl analog [2-(diethylaminoacetamide)-3-carbamyl-4-methyl-5-benzylpyrrole, I] was found to possess potent hypotensive activity following intravenous administration at doses of 2–4 mg/kg (4, 5). Compound I was more active than lidocaine with respect to antiarrhythmic activity, local anesthetic activity, and rectal temperature and respiratory depression.

Since I exerted its potent hypotensive property following intravenous administration, its structure was utilized as a basis for designing and synthesizing amine analogs that would have hypotensive activity following oral administration. Intraperitoneal administration was chosen to simulate oral activity since the drugs must cross biological membranes prior to exerting a hypotensive action.

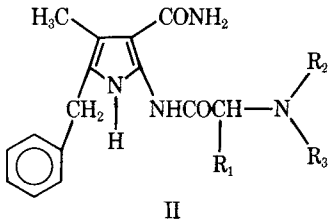
The present article reports the synthesis and vasoactivity of a series of 2-(alkylaminoalkylamido)-3-carbamyl-4-methyl-5-benzylpyrroles (II) following intraperitoneal and intravenous administration.

## EXPERIMENTAL

**Chemistry**[1]—*2-[(*N*-Ethyl-*N*-2-hydroxyethyl)amino]acetamido-3-carbamyl-4-methyl-5-benzylpyrrole (IIa)*—The procedure given for the synthesis of IIa is representative of that used for IIb–IIh. A suspension of 2-chloroacetamido-3-carbamyl-4-methyl-5-benzylpyrrole (7.0 g, 0.023 mole) (1) in absolute ethanol (160 ml) and 2-(ethylamino)ethanol (10.2



I



II

g, 0.115 mole) was refluxed with stirring for 8 hr. The ethanol was removed *in vacuo* to yield an orange solid. The residue was suspended in water (350 ml), and the insoluble product was collected by filtration and dried.

The crude product (6.0 g, 73.1%) was recrystallized from ethanol–water (7:3) to yield off-white crystals, mp 182.5–183.5°; IR (KBr): 3480, 3315, 3180, 2960, 1660, 1630, 1570, 1380, and 720 $cm^{-1}$; NMR (dimethyl sulfoxide-$d_6$): δ 0.97 (t, 3H, $CH_3$ of ethyl), 2.07 (s, 3H, $CH_3$ at $C_4$), 2.40–2.70 (m, 4H, α methylenes of amino radical), 3.13 (s, 2H, $-COCH_2-$), 3.25 (s, 1H, $-CH_2OH$), 3.45 (q, 2H, methylene of $-CH_2OH$), 3.80 (s, 2H, benzylic methylene), 6.57 (s, 2H, $-CONH_2$), 7.07 (s, 5H, aromatic H), 10.60 (2, 1H, NH), and 11.54 (s, 1H, NH) ppm (Table I).

*2-[(*N*-2-Hydroxyethyl-*N*-ethyl)amino]acetamido-3-carbamyl-4-methyl-5-benzylpyrrole Hydrochloride (IIIa)*—The procedure given for the synthesis of IIIa is representative of that used for IIIb and IIIc and IIIe–IIIh. A stirred suspension of IIa (1.20 g, 0.0033 mole) in acetone (25 ml) was treated with 0.4 ml of concentrated hydrochloric acid. The resulting suspension was stirred for 30 min at ambient temperature, and the white precipitate was collected by filtration, washed with acetone (25 ml), and dried. The hydrochloride salt (1.1 g, 83.0%) was homogeneous on TLC, mp 175–177° dec.; IR (KBr): broad absorption between 3400 and 2600 (with absorptions at 3400, 3320, 3120, and 3000), 1680, 1640, 1610, 1550, 1480, 1380, and 960 $cm^{-1}$ (Table I).

**Solution Preparation**—Compounds I, IIa–IIh, and IIIa–IIIh were prepared for intraperitoneal administration by suspending 50 mg/ml in 0.9% saline containing 0.5% polysorbate 80[2] and 0.5% acacia. Compound I was solubilized in 0.9% saline by adjusting the pH to 2.2 with 2 *N* HCl prior to intravenous injection. A solution of IIId (3.6 mg/ml) was prepared by adding 20 mg of IId to 5 ml of 20% dimethyl sulfoxide in saline and 0.5 ml of 10% sorbitol in saline, followed by adjustment of the pH to 2.0 with hydrochloric acid. Solubilization was effected after slight warming of the resulting solution. A solution of IIIh (4.0 mg/ml) was prepared using 20% dimethyl sulfoxide in saline.

**Blood Pressure Determination**—Male Sprague–Dawley (Spd: Sprague–Dawley, DS) rats, 300–400 g, were administered pentobarbital sodium (30 mg/kg) and urethan (950 mg/kg) intraperitoneally prior to surgery for blood pressure determination. After anesthetization, the animal was positioned on its back and the trachea, carotid artery, and jugular vein were exposed. The jugular vein was cannulated with polyethylene tubing[3]. The trachea was cannulated with a tracheal tube[4] as necessary and connected to a respirator[5] with 100% oxygen at 50 psi. The respirator was adjusted to deliver a respiratory rate of 60/min at an inspiratory pressure of 12–15 cm $H_2O$.

The carotid artery was cannulated with polyethylene tubing[3] containing 100 units of heparin/ml. Blood pressure was monitored *via* a pressure transducer[6], channel amplifier[7], and recorder[8]. Test compounds

[1] Melting points were determined on a Thomas-Hoover apparatus (capillary method) and are uncorrected. NMR spectra were determined on a Varian EM360A NMR spectrometer with tetramethylsilane as an internal standard. IR spectra were determined on a Beckman Acculab 4 spectrophotometer using the potassium bromide technique. Elemental analyses were performed by Atlantic Microlabs, Atlanta, Ga.

[a] $n = 2$ or 3. [b] Compound I refers to the benzylcarbamyl analog of lidocaine previously reported (4) and examined (5). Compound II refers to the free base and III refers to the hydrochloride salt of the amine analogs of the benzylcarbamyl derivative. [c] Blood pressure analysis was started 5 min after the intraperitoneal administration of the compound to avoid vehicle artifacts. [d] Duration was defined as the time required for the blood pressure to return to within 95% of the predrug value.

**Table III—Blood Pressure Response to Intravenously Administered 2-(2-Alkylaminoalkylamido)-3-carbamyl-4-methyl-5-benzylpyrroles**

| Compound | Dose, mg/kg | Blood Pressure Response[a] Average Change, mm Hg | Average Duration[b], min | n |
|---|---|---|---|---|
| Ic | 4 | −54.3 | 7.5 | 5 |
| III*d* | 4 | −73 | 30.0 | 3 |
| III*h* | 4 | −43.5 | 2.25 | 2 |

[a] Blood pressure recording was started immediately after the intravenous administration of the compound. [b] Duration was defined as the time required for the blood pressure to return within 95% of the predrug value. [c] Compound I is the benzylcarbamyl analog of lidocaine previously reported (4) and examined (5).

and the vehicle control were administered either intravenously through the jugular cannula or intraperitoneally. Saline (0.1 ml) was used to flush the cannula following each injection of the test compound or vehicle control solution.

Since the average vehicular vasodepressor response lasted 3–4 min following intraperitoneal administration, the maximal response and duration were recorded for each compound between 5 and 30 min. The blood pressure duration response was defined as the time required for the blood pressure to return to within 95% of the predrug value. Data collection of blood pressure activity for the intravenous studies began with the injection of the compound and lasted for 30 min.

## RESULTS

The blood pressure effects of the derivatives of the benzylcarbamyl analog of lidocaine following intraperitoneal administration (60 or 100 mg/kg) appear in Table II. Compounds II*a*–II*h* represent the free base forms, and III*a*–III*h* represent the corresponding hydrochloride salt forms. The most potent agents exhibiting vasodepressor activity were II*d* and III*d*. Compound II*d* lowered the blood pressure an average of 31 mm Hg with a duration of 25 min. Compound III*d* was slightly more active, depressing the blood pressure 35.5 mm Hg with a similar duration (25 min). Other compounds exhibiting vasodepressor activity were III*e* and II*g*, lowering the blood pressure 22 and 21.6 mm Hg with a duration of 15 and 21.7 min, respectively. For comparison, hydralazine, 5 mg/kg, lowered blood pressure 75 mm Hg with a duration of 25 min.

Two compounds (III*b* and III*f*) appeared to exhibit a vasopressor effect, elevating the blood pressure 16 and 10.5 mm Hg with durations of action of 21.5 and 17.5 min, respectively. The remaining compounds in Table II were inactive with respect to vasoactivity or produced inconsistent blood pressure effects.

One of the more potent vasodepressor compounds (III*d*) and one of the more variable compounds (III*h*) from Table II were administered intravenously (Table III) to compare hypotensive activity as a function of administration route. Both III*d* and III*h* exhibited a greater vasodepressor activity when administered intravenously. Compound III*d* was the most active, lowering blood pressure 73 mm Hg with a duration of 30 min.

## DISCUSSION

The present series of amine derivatives of the benzylcarbamyl analog of lidocaine was synthesized to obtain vasodepressor activity following intraperitoneal administration. The derivatives exhibited variable blood pressure effects (Table II). The vasodepressor response obtained following intraperitoneal administration indicates that the compounds can cross biological membranes prior to exerting a hypotensive action. Although the amine derivatives exerted vasodepressor activity, the most active (II*d* and III*d*) appeared to be only one-fortieth as active as hydralazine administered under similar experimental conditions. Comparison of Tables II and III indicates that intravenous administration of III*d* and III*h* produced a greater vasodepressor response than intraperitoneal administration. The decreased activity may be explained by reduced solubility, decreased absorption, or increased metabolism.

The lack of solubility of the compounds as one explanation was supported by the fact that among the active compounds (compounds *d*, *e*, and *h*) the salt was more active than the base in producing vasodepression. The compounds may not have been absorbed well into the blood following intraperitoneal administration since they were not very soluble in common solvents. An alternative explanation may be that the compounds were metabolized at an increased rate following intraperitoneal administration due to first-pass phenomena (6).

In the original series of 2-aminopyrrole analogs of lidocaine (1, 2), the benzylcarbamyl analog was the most potent vasodepressor agent (4). This fact established the structural requirements of the carbamyl function at position 3 and the benzyl group at position 5 of the pyrrole ring for maximal vasodepressor activity. Comparison of the compounds from a structure–activity relationship in the present series indicates that the secondary amines were devoid of vasodepressor activity. The most potent vasodepressors (compounds *d* and *e*) were substituted alpha to the tertiary amino functional group. From the limited data available, it appears that a benzyl substitution on the amino group enhances vasodepressor activity.

The activity of II*d* and III*d* represents an improvement over the parent compound (I), which does not appear to exert hypotensive activity following intraperitoneal administration. Additional structural modifications will be necessary to improve hypotensive activity following intraperitoneal (or oral) administration.

# Simple High-Performance Liquid Chromatographic Assay for Norethindrone–Mestranol in Combination Tablets

GLORIA M. SUNDARESAN, THOMAS J. GOEHL ˣ, and VADLAMANI K. PRASAD

Received August 21, 1980, from the *Biopharmaceutics Laboratory Branch, Division of Biopharmaceutics, Food and Drug Administration, Washington, DC 20204.* Accepted for publication November 19, 1980.

**Abstract** □ A simple, sensitive, and specific high-performance liquid chromatographic procedure was developed to assay norethindrone–mestranol combination tablets. The method involves a chloroform extraction of a single pulverized tablet. After centrifugation, an aliquot of the supernate was injected into a modular high-performance liquid chromatograph. The effluent from the silica column was monitored serially with a fixed-wavelength UV detector (254 nm) for norethindrone quantitation and a fluorescence detector (230 nm for excitation and 280-nm cutoff filter for emission) for mestranol quantitation. Progesterone was used as an internal standard. The method was employed successfully in content uniformity studies of several brands of commercially available tablets.

**Keyphrases** □ High-performance liquid chromatography—norethindrone–mestranol tablets, content uniformity studies □ Contraceptives—norethindrone–mestranol tablets, high-performance liquid chromatography, content uniformity studies □ Hormones, synthetic—norethindrone–mestranol tablets, high-performance liquid chromatography, content uniformity studies □ Norethindrone–mestranol combinations—high-performance liquid chromatography, content uniformity studies

Two widely used synthetic hormonal contraceptive steroids are norethindrone and mestranol, and various methods have been reported for their assay. Norethindrone was determined by spectrophotometry (1–3), fluorometry (4, 5), and GLC (3, 6). Mestranol also was determined by spectrophotometry (7), fluorometry (8), and GLC (9, 10). Simultaneous analysis of norethindrone and mestranol in combination tablets was achieved by GLC (11), quantitative TLC (12), and high-pressure liquid chromatography (13). The official compendial method (14) for the combination tablets is an automated method utilizing a spectrophotometer and a fluorometer to quantitate norethindrone and mestranol, respectively.

Each published chromatographic method has certain disadvantages. The TLC method requires scanning the plates at two different wavelengths with intervening spraying. The GLC method results in chromatograms with the undesirable characteristic of widely divergent peak heights for the two steroid components. A similar peak height disparity is observed with the reported high-pressure liquid chromatographic method, and the sample preparation technique sometimes results in the solubilization of excipients that interfere in the chromatography.

The present study reports a rapid high-performance liquid chromatographic (HPLC) method for the simultaneous analysis of norethindrone and mestranol in combination tablets using peak height determinations.

## EXPERIMENTAL

**Apparatus**—The modular high-performance liquid chromatograph consisted of a constant flow pump[1], an automated injector[2], a fixed-wavelength UV detector[3] (254 nm), a fluorescence detector[4] (excitation, 230 nm; emission, 280-nm cutoff filter), and a strip-chart recorder[5] (0.5 cm/min). Stainless steel columns[6] (4.6 mm i.d. × 250 mm), packed with fully porous, irregularly shaped 5-μm silica, were obtained commercially. Sample filtration was achieved by employing a syringe-type 25-mm filter holder[7] and 0.5-μm filters[8]. [An oversized filter (47 mm) was used so that it could be wrapped around the holder to improve the seal.]

**Chromatographic Conditions**—The mobile phase was ethylene dichloride–butanol–water (97.5:2.4:0.1). A flow rate of 1.3 ml/min was established (1500 psig), and the column was conditioned initially for 16 hr.

**Reagents and Materials**—Mestranol[9], norethindrone[9], and progesterone[10] were obtained commercially. Solvents were all HPLC grade[11]. Individual stock solutions of mestranol, norethindrone, and progesterone were prepared by dissolving 10, 100, and 400 mg, respectively, in 10 ml of chloroform.

**Glassware Preparation**—All glassware including pipets and syringes were silanized by immersion into a solution of 5% trimethylchlorosilane in toluene for at least 1 hr. Then the glassware was rinsed with toluene, methanol, water, methanol, and chloroform.

**Assay**—A single tablet was crushed to a fine powder in a folded sheet of weighing paper. The powder was transferred into a 15-ml test tube, and 4 ml of chloroform was added. Then 30 μl of the progesterone internal standard solution was added with a 50-μl syringe[12]. The sample was vortexed for ~30 sec, followed by 5–10 min of standing, and then was vortexed again for 1 min. The samples then were centrifuged and filtered through a 0.5-μm filter. The filtrate was transferred to a silanized vial for subsequent loading into the automated injector, which was programmed to inject 2 μl.

The amounts of mestranol and norethindrone in the tablets were determined from standard curves prepared by plotting peak height ratios (mestranol–progesterone or norethindrone–progesterone) *versus* the concentrations of the direct standards. These direct standards were prepared by spiking, into chloroform, both mestranol and norethindrone and then bringing each to a final volume of 4 ml. The amounts of mestranol and norethindrone spiked were 0 and 0, 30 μg and 0.5 mg, 50 μg and 1.0 mg, 100 μg and 2 mg, 150 μg and 2.5 mg, and 500 μg and 7.5 mg, respectively. In some cases, an additional standard (60 μg of mestranol, 10 mg of norethindrone) was included. To each standard was added 30 μl of the internal standard solution.

**Recovery**—Five tablets were ground together to a fine powder. Four aliquots, corresponding to the weight of a single tablet, were placed into individual test tubes. Standard mestranol and norethindrone were added to two of these test tubes. The amounts of the standards added were one-half of the tablet strength of each component. All samples then were assayed. This study was conducted on seven different products[13].

**Precision**—Fifteen tablets of Product F were ground to a fine powder; then 10 aliquots, equivalent to the weight of one tablet, were transferred to 10 test tubes. All samples then were assayed.

**Content Uniformity**—Seven drug products were assayed for content uniformity.

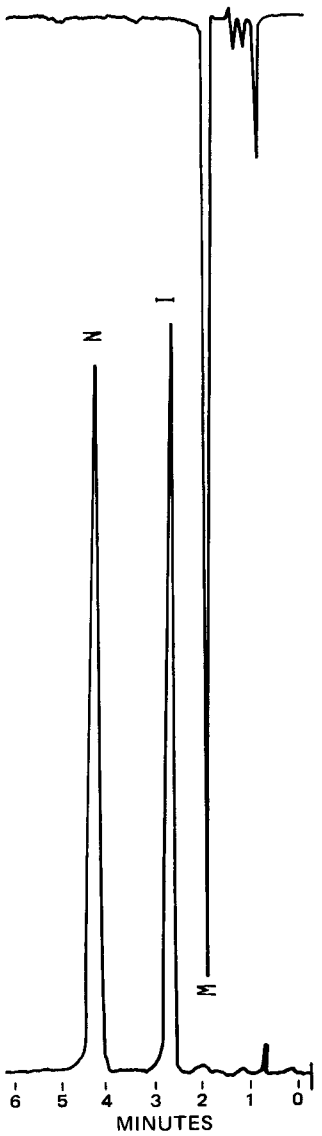

**Figure 1**—*Chromatogram obtained from HPLC assay of Product F. Column effluent was monitored for mestranol (M) using a fluorescence detector (1.0 μA range sensitivity) and for internal standard (I) and norethindrone (N) using an absorbance detector (0.05 aufs).*

## RESULTS AND DISCUSSION

The simultaneous analysis of combination drug products that contain widely different amounts of active components presents unique problems. All of the components of the drug product must be extracted quantitatively, and the detection techniques must give adequate sensitivity for even the lowest level component.

In norethindrone–mestranol tablets, the components are present in ratios from 12:1 to 160:1. Since the solubilities of both components were high in chloroform, this solvent was used for the extraction. The key to resolving the problem of adequate sensitivity for mestranol, the low level component, was the observation that estrogens possess native fluorescence (15) whereas norethindrone does not fluoresce (4). Thus, it seemed plausible to develop an HPLC method that employed a fluorescence detector and an absorbance detector to monitor the column effluent. Initial studies showed that excellent resolution of the tablet components could be obtained using a microparticulate silica column.

A chromatogram obtained in the analysis of Product F is shown in Fig. 1. By using two detectors, it was possible to optimize the response for each steroid component. The retention times for mestranol, progesterone (the internal standard), and norethindrone were 4.0, 5.6, and 8.8 min, respectively.

Initial studies indicated that drug adsorption onto the glassware was occurring. To overcome this problem, all glassware was silanized before use.

A standard linear calibration curve was obtained for direct standard solutions equivalent to 30–100 μg of mestranol/tablet and 0.5–10 mg of norethindrone/tablet. These ranges span those found in all commercially available tablets. The recovery studies were performed on spiked samples of seven drug products. The results (Table I) show excellent recovery in all cases. No interferences from any tablet excipient were observed in the resulting chromatograms. Precision was determined by multiple analyses of aliquots of a Product F composite. The means and coefficients of variation for the assay of mestranol and norethindrone were 101 μg ± 1.8% and 1.94 mg ± 2.0%, respectively. These results demonstrate excellent assay precision. An additional estimate of the precision was obtained by the evaluation of multiple direct standard curves. The values for the slopes were 0.0140 ± 1.6% (coefficient of variation) for mestranol and 0.5543 ± 1.25% for norethindrone.

The USP XX specified that coated tablets and tablets containing 50 mg or less of active ingredient must pass a content uniformity test. The newly developed HPLC assay was used in content uniformity studies of the same seven products examined in the recovery studies. The results established that the batches of the seven formulations met the compendial requirements (Table II). The methodology will be modified and used in planned dissolution studies.

# Optical Crystallographic Properties of Drugs of Abuse: Commonly Used Amine Street Drugs

**EDWARD A. JULIAN *x and ELMER M. PLEIN ‡**

Received July 1, 1980, from the **School of Pharmacy, University of Wyoming, Laramie, WY 82071*, and the ‡*School of Pharmacy, University of Washington, Seattle, WA 98195.* Accepted for publication November 21, 1980.

**Abstract** □ The optical crystallographic properties of the diliturate derivatives of amine drugs found in illicit street drug preparations known as "white crosses," "mini-bennies," or "whites" were determined. The crystallographic properties, especially the crystal morphology, extinction angles, and indexes of refraction, identify the drug substances found in the white cross suite. These data can be used with UV and IR spectroscopic and chromatographic evaluations for drug identification.

**Keyphrases** □ Drugs of abuse—substance identification by optical crystallographic properties of diliturate derivatives of amine drugs □ Optical crystallography—substance identification of diliturate derivatives of amine drugs □ Amphetamines—drugs of abuse, identification of drug substance by optical crystallographic properties

Optical chemical crystallography is a physical method for rapid drug identification (1–3). Microchemical properties of amine drug salts have been determined with various reagents (4), but few studies (5, 6) concentrated on the optical crystallographic properties.

The present study reports the optical crystallographic data and constants for the diliturate derivatives of amine drugs found in illicit street drug preparations entitled "white crosses" or "mini-bennies." These preparations are so termed because of the physical shape of the small, white, cross-scored tablets purported to contain 2–8 mg of *d*-methamphetamine (7, 8). However, other drugs have been freely substituted for dextroamphetamine in these street preparations since the 1970 Drug Enforcement Administration Controlled Substances Act made the amphetamines difficult to procure for the street market (8).

## EXPERIMENTAL

houses. The index of refraction standards[1,2] and the dilituric acid[3] (5-nitrobarbituric acid) used to prepare the crystalline derivatives also were purchased commercially.

**Methods**—The method utilized to prepare dilituric acid derivatives of the amine salts was that of Plein and Dewey (9). Briefly, 100 mg of the amine salt was dissolved in a minimum of water, and 10 ml of a hot, 1% aqueous solution of dilituric acid was added. The dilituratates of the amines crystallized out upon cooling in most cases, and the crystalline derivatives were recrystallized from water one to several times until compounds with sharp melting points were obtained. The purity of the salts was established by determination of percent nitrogen. All compounds analyzed for nitrogen were within 0.3% of the calculated theoretical values.

The optical data for the dilituratates of the white cross amines were determined using literature methods (9–11). The highest index of refraction liquid standard in the authors' sets of liquids was 1.785, so no value above this figure is reported. Crushed specimens were necessary to obtain some refractive indexes.

In this study, the $2V$ values were determined by a nomogram method (11). Briefly, the nomogram was utilized as a base upon which the three known refractive indexes were used to determine the fourth variable $V$ ($V = \cos^2 \theta$).

## RESULTS AND DISCUSSION

The crystallographic properties of the amine dilituratesare reported in Table I and are shown in Figs. 1 and 2. Many of the crystal derivatives are so flattened that they tend to assume a common orientation when immersed in the index oils on the microscope slide. The apparent properties of habit, optical orientation, and extinction angle of each crystalline derivative as observed on the most frequently occurring orientation are listed in Table I. The optical orientations designated as acute, obtuse, and optic normal indicate that a "centered" interference figure was observed upon an uncrushed crystal in its most frequently occurring orientation. The descriptive term "inclined" denotes that centered figures were not observed on the usual orientation of the crystal; therefore, one or both refractive indexes of the front face of the crystal would be variable.

Additional optical crystallographic properties reported in Table I are the three refractive indexes, crystal system, optic sign, elongation, and optic axial angle ($2V$). The $2V$ value is an optical parameter that can distinguish between two or more similar crystals, *e.g.*, *dl*-chlorpheniramine ($2V = 52°$) and diphenhydramine ($2V = 75°$).

Figures 1 and 2 present orthographic projection drawings of the crystals showing the front, side, and top views. These drawings supplement the data appearing in Table I and the text, and they facilitate the identification of the crystalline derivatives. Dashed lines represent the vibration directions, and refractive indexes are recorded for crystals that show consistent indexes in these directions. An asterisk indicates the higher index value on views in which consistent refractive indexes could not be obtained. Crystal angles measured microscopically are shown in the corners of the diagrams.

Additional discussion of properties of the reagent and derivatives will

facilitate identification by optical crystallographic methods. Dilituric acid rarely crystallized out of the reaction solution in the concentration utilized; however, dilituric acid crystals appeared as small square- to rectangular-shaped tablets with a low $\alpha$ index ($n$ = 1.388), running parallel to the crystal length and showing a low extinction angle (9°) on the top face.

Dextroamphetamine crystallized out as thin rectangular platelets that showed bright first- to second-order polarization colors under crossed nicols as compared to its *dl*-isomer, which was observed as poorly formed acicular prisms showing a high birefringence. *d*-Methamphetamine appeared as large, well-formed, lamellar platelets twinned on 001, showing bright polarization colors and a front face extinction angle of 33°. Its *dl*-isomer occurred as bundles of elongated rods with a notably small $2V$ = 8°. Both isomers are monoclinic crystals as compared to the two amphetamine isomers which show orthorhombic symmetry.

Derivatives of *l*-ephedrine, racephedrine, *dl*-chlorpheniramine, methapyrilene, and diphenhydramine crystallized out as six-sided platelets. The two ephedrine isomers crystallized out as large hexagonal platelets. *l*-Ephedrine showed orthorhombic symmetry, while racephedrine crystallized out as a large, yellow, triclinic platelet with a 38° extinction angle on the front face. *dl*-Chlorpheniramine had a crystal size smaller than the ephedrines and also showed monoclinic symmetry with an extinction angle of 15° on the top face. Methapyrilene and diphenhydramine appeared as monoclinic crystals with extinction angles of 33 and 42°, respectively, on the top face. However, diphenhydramine occurred as stellate rosettes, and the crystals showed a large $2V$ = 75°; methapyrilene appeared as a diamond-shaped crystal with a moderate $2V$ = 48°.

Propoxyphene dilituate occurred as long, acicular, monoclinic crystals that crystallized out in stellate rosettes. The side face of this crystal showed a 15° extinction angle. The mephentermine derivative was a long, acicular, monoclinic crystal with an extinction angle of 27° appearing on the top face; the phentermine dilituate, which was of the same crystal habit, showed orthorhombic symmetry.

Pseudoephedrine, phenylephrine, and papaverine dilituates crystallized out as prisms. Derivatives of both pseudoephedrine and phenylephrine were elongated in form but were distinguished easily from each other since pseudoephedrine had an orthorhombic symmetry and a low $2V$ = 36° while phenylephrine appeared as a triclinic crystal with a $2V$ = 70° and a front face extinction angle of 42°. The papaverine dilituate was observed as an almost equant triclinic prism with multifaceted sides.

# High-Pressure Liquid Chromatographic Analysis of Phenylpropanolamine in Human Plasma following Derivatization with *O*-Phthalaldehyde

**WILLIAM D. MASON ˣ and EDWIN N. AMICK ***

Received August 12, 1980, from the *Pharmacokinetics Laboratory, Schools of Pharmacy and Medicine, University of Missouri–Kansas City, Kansas City, MO 64108.* Accepted for publication December 2, 1980. *Present address: Kansas City Analytical Services, Kansas City, MO 64127.

**Abstract** □ A high-pressure liquid chromatographic analysis of phenylpropanolamine in human plasma following extraction, back-extraction, and *O*-phthalaldehyde derivatization is presented. Using fluorescence detection, the method was sufficiently sensitive to quantitate as little as 5 ng of drug/ml of plasma; the coefficient of variation below 100 ng/ml ranged between 5.7 and 2.8%. Plasma concentration data following a single 25-mg dose of phenylpropanolamine hydrochloride in 12 healthy volunteers demonstrate the application of the analytical method.

**Keyphrases** □ High-pressure liquid chromatography—phenylpropanolamine analysis in human plasma, *O*-phthalaldehyde derivatization □ Phenylpropanolamine—high-pressure liquid chromatographic analysis in human plasma, *O*-phthalaldehyde derivatization □ Derivatization—*O*-phthalaldehyde, high-pressure liquid chromatographic analysis in human plasma

There is great interest in measuring plasma phenylpropanolamine concentrations following single therapeutic doses (25 mg of phenylpropanolamine hydrochloride) of this sympathomimetic agent. GLC following formation of a heptafluorobutyryl derivative (1) was used previously (2, 3) to study phenylpropanolamine pharmacokinetics and was adequate when doses of 60 mg or more were administered or when plasma concentrations were >40 ng/ml and 2 ml of plasma was available for each determination. TLC following acetylation with tritiated acetic anhydride (4) suffers from a high coefficient of variation and nonlinearity.

After preliminary studies of GLC and liquid chromatography with absorbance detection were found to have inadequate specificity and sensitivity, the present method was developed. Previous investigators (5–7) showed that *O*-phthalaldehyde, in the presence of 2-mercaptoethanol, reacts with primary amines to form highly fluorescent products, 1-alkylthio-2-alkyl-substituted isoindoles (8). Replacing 2-mercaptoethanol with ethanethiol was reported to provide a more stable product (9), but the latter is difficult to work with due to its unpleasant odor.

A procedure for extraction of phenylpropanolamine and an internal standard from plasma, derivatization with *O*-phthalaldehyde, separation by high-pressure liquid chromatography (HPLC), and detection by fluorescence

is presented in this report. The procedure can differentiate plasma with as little as 1 ng/ml from a blank and can quantitate plasma concentrations above 5 ng/ml with accuracy and precision suitable for pharmacokinetic studies.

## EXPERIMENTAL

**Materials**—UV grade butyl chloride[1], 1-butanol[1], methanol[1], and acetonitrile[1] were employed without further preparation. Reagent grade ammonium acetate[2], boric acid[3], and ACS grade acetic acid[3] also were used as received. A derivatization solution was prepared by dissolving 50 mg of crystalline *O*-phthalaldehyde[4] in 2 ml of methanol, adding 0.2 ml of 2-mercaptoethanol[5], and diluting to 100 ml with 0.4 *M* borate buffer (pH 10.5). Phenylpropanolamine hydrochloride[6] and viloxazine hydrochloride[7] [2-(2-ethoxyphenoxymethyl)tetrahydro-1,4-oxazine hydrochloride, ICI-58,834] were used as received.

**Apparatus**—The HPLC system consisted of a pump[8], an injector[9], a 5-μm ODS column[10], and a fluorescence detector[11]. Excitation was at 230 nm (sensitivity, photomultiplier tube voltage setting, at 380 and time constant of 2.0 sec), and no filters were employed between the flowcell and photomultiplier tube. The window of the photomultiplier served as a 280-nm cutoff filter. The detection range was set at 0.2 with the recorder[12] input set to provide tracings corresponding to 0.2 and 0.02 and a chart speed of 0.5 cm/min.

**Plasma Extraction**—One milliliter of plasma, 0.1 ml of 0.1 *N* NaOH, and 8.0 ml of extraction solution (10% v/v 1-butanol in butyl chloride with 0.60 μg of viloxazine/ml as the internal standard) were placed in a 15-ml centrifuge tube. This mixture was vortexed for 60 sec and centrifuged for 5 min, and the organic layer (upper) was transferred to a second 15-ml centrifuge tube containing 300 μl of 1% acetic acid.

Back-extraction was effected by vortexing for 60 sec, and the layers were separated by centrifugation. The organic layer (upper) was discarded by aspiration, leaving the aqueous layer for derivatization. This acetic acid back-extract was stable for several days.

**Derivatization**—A 50-μl syringe was used to transfer 40 μl of a 1% acetic acid back-extract into a 4.0-ml glass tube to which 20 μl of the *O*-phthalaldehyde reagent then was added, and the solution was vortexed for 10 sec. The reaction was allowed to proceed exactly 60 sec, and then 200 μl of 1% acetic acid was added. The solution was vortexed, and 100 μl was injected immediately into the HPLC system.

**Chromatography**—A mobile phase was prepared by dissolving 10.4 g of ammonium acetate in 2400 ml of water and adding 8.0 ml of acetic acid and sufficient acetonitrile to obtain a 40% solution by volume (pH 5.6). With a flow rate of 1.8 ml/min in the HPLC system, a pressure of 2000 psig resulted. The retention times of viloxazine and the phenylpropanolamine derivative were 5.8 and 8.2 min, respectively.

**Clinical Study**—As part of a bioavailability study, 12 normal healthy subjects received single 25-mg doses of phenylpropanolamine hydrochloride in solution following an overnight fast. Blood samples were collected at 0, 0.5, 1, 1.5, 2, 3, 4, 6, 8, 12, and 24 hr in heparin-containing vacuum containers[13]. The plasma was separated immediately by centrifugation and frozen within 20 min. All samples were maintained frozen at −10° until assayed.

**Table I—Precision and Accuracy of Phenylpropanolamine Analysis**

| Actual Concentration[a], ng/ml | Number of Samples | Mean Concentration, ng/ml | *SD* | *CV*, % |
|---|---|---|---|---|
| 17.3 | 12 | 17.2 | 0.98 | 5.7 |
| 20.0 | 12 | 20.1 | 1.13 | 5.7 |
| 40.0 | 10 | 38.8 | 1.72 | 4.4 |
| 50.0 | 20 | 49.8 | 2.13 | 4.3 |
| 80.6 | 12 | 80.3 | 2.22 | 2.8 |
| 100 | 20 | 101 | 3.20 | 3.2 |
| 150 | 10 | 148 | 6.33 | 4.3 |
| 200 | 24 | 201 | 7.68 | 3.8 |

## RESULTS AND DISCUSSION

Figure 1 presents chromatograms for plasma containing 0, 5, and 10 ng of phenylpropanolamine/ml. Analysis of predose plasma samples from 22 human subjects and several batches of pooled human plasma presented no chromatographic peaks that interfered with the internal standard or phenylpropanolamine derivative. A previous report (10) suggested that no significant metabolism of phenylpropanolamine occurs, so *in vivo* interference by metabolites probably was not a problem. The ratio of the peak height of the phenylpropanolamine derivative to the viloxazine peak height varied linearly with the plasma phenylpropanolamine concentration range studied (*i.e.*, <200 ng/ml). A typical standard curve (20 points between 5 and 200 ng/ml), with the peak height ratio as the abscissa and plasma phenylpropanolamine as the ordinate, had a slope of 27.94 ng/ml and an intercept of −0.32 ng/ml with a correlation coefficient of 0.9976.

Table I demonstrates the precision and accuracy of the method following a single therapeutic dose. These data were collected over several weeks and thus demonstrate reproducibility. The lowest tabulated standard was 17.3 ng/ml; however, the method can be employed for concentrations of 5 ng/ml with slightly less precision (*i.e.*, coefficient of variation of 8%).

Figure 2 presents the mean plasma concentration–time data for the 12 subjects who received 25 mg of phenylpropanolamine hydrochloride. The concentrations were within the quantitative range of the described method. The samples were assayed in duplicate with 2 weeks between duplicate determinations of each sample. The precision of these assays is indicated by the mean coefficient of variation of 3.0% for duplicates. A repeated analysis of 24 samples after 6 months at −10° revealed no significant differences, thus indicating sample stability.

The general approach presented in this report produced very clean chromatograms and thus should be considered for other primary amines.

## Drug–Disintegrant Interactions: Binding of Oxymorphone Derivatives

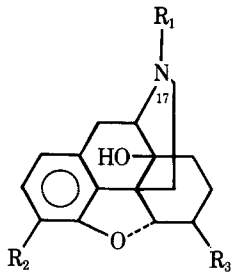
**Keyphrases** □ Drug-disintegrant interactions—binding of oxymorphone derivatives to disintegrating agents, dissolution testing, Freundlich adsorption isotherm □ Disintegrating agents—carboxymethylcellulose sodium, sodium starch glycolate, povidone, and modified cornstarch, binding to oxymorphone derivatives compared □ Oxymorphone derivatives—binding to disintegrating agents compared, Freundlich adsorption isotherm □ Freundlich adsorption isotherm—binding of oxymorphone derivatives to disintegrating agents compared, dissolution testing □ Analgesics, narcotic—oxymorphone, binding to disintegrating agents compared, dissolution testing

*To the Editor:*

Since the USP first established a disintegration standard in 1948, the search for good disintegrating agents for tablet formulations has intensified. Starch had been used as the primary tablet disintegrant and, in most cases, was relatively effective. However, recognition of the importance of bioavailability and compendial dissolution test requirements spurred the search for new disintegrants. An ideal disintegrant would improve both disintegration and dissolution and be effective in small amounts.

The search has produced several new disintegrating agents, most notably internally cross-linked carboxymethylcellulose sodium[1], sodium starch glycolate[2], cross-linked polyvinyl pyrrolidone[3] (povidone), and modified cornstarch[4].

During the development of a tablet formulation with a rapid disintegration/dissolution rate profile for a synthetic narcotic agonist–antagonist analgesic with the general structure of oxymorphone (I), extensive binding was noted between I and cross-linked carboxymethylcellulose sodium, and lower recovery resulted during dissolution testing. However, the binding to sodium starch glycolate was substantially less extensive, and no binding was detected for carboxymethylcellulose sodium, cornstarch, and modified cornstarch.



I

The binding of I to cross-linked carboxymethylcellulose sodium and sodium starch glycolate followed the Freundlich adsorption isotherm as shown in Fig. 1. The binding was sensitive to variation in solution pH (Fig. 2). Maximum binding was achieved for both cross-linked carboxy-

Figure 2 presents the mean plasma concentration–time data for the 12 subjects who received 25 mg of phenylpropanolamine hydrochloride. The concentrations were within the quantitative range of the described method. The samples were assayed in duplicate with 2 weeks between duplicate determinations of each sample. The precision of these assays is indicated by the mean coefficient of variation of 3.0% for duplicates. A repeated analysis of 24 samples after 6 months at −10° revealed no significant differences, thus indicating sample stability.

The general approach presented in this report produced very clean chromatograms and thus should be considered for other primary amines.

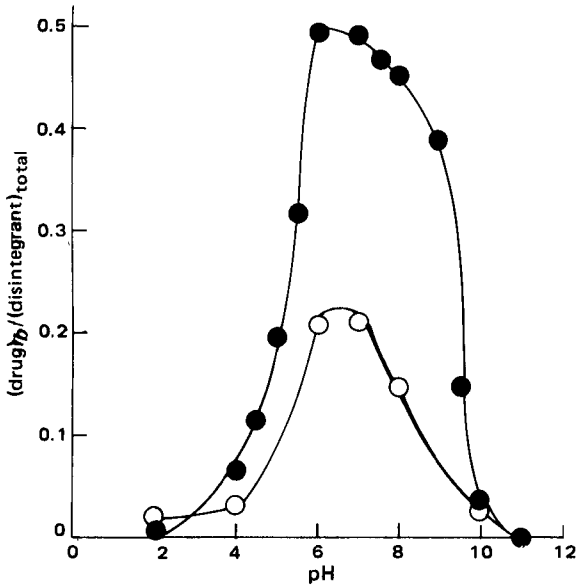

**Figure 2**—*Effect of solution pH on the interaction of oxymorphone derivative (I) with cross-linked carboxymethylcellulose sodium (●) and sodium starch glycolate (○).*

methylcellulose sodium and sodium starch glycolate at pH 6–7. However, the interaction of I with cross-linked carboxymethylcellulose sodium was twice that with sodium starch glycolate.

The interaction was believed to depend on the tertiary amine group at position 17 of I. Adsorption studies were extended to examine the interaction of cross-linked carboxymethylcellulose sodium with four derivatives of I, where substituents $R_1$, $R_2$, and $R_3$ varied and pKa values ranged from 7.9 to 8.7. Results indicated that the binding of I derivatives with cross-linked carboxymethylcellulose sodium can be described by the Freundlich adsorption isotherm as expressed by:

$$\log \frac{(\text{drug})_b}{(\text{disintegrant})} = \log k + \frac{1}{n} \log (\text{drug})_{eq} \qquad \text{(Eq. 1)}$$

where $n$ and $k$ are Freundlich adsorption constants that can be estimated from the slope and intercept of the linear portion of $\log[(\text{drug})_b/(\text{disintegrant})]$ *versus* $\log(\text{drug})_{eq}$ plots (Fig. 1); $(\text{drug})_{eq}$ is the equilibrium drug concentration in solution. Results obtained for the four I derivatives show $n$ values of 1.43–1.75 and $k$ values of 0.219–0.243. The data suggest that the structural variation of functional group $R_1$ at the tertiary amine group at position 17 of I does not greatly affect the Freundlich adsorption isotherm. All four I derivatives interacted with cross-linked carboxymethylcellulose sodium in a similar manner and to a significant extent.

The biological significance of these interactions is not known.

# X-Ray Crystal Structure Analysis of 14-Hydroxycaryophyllene Oxide, a New Metabolite of (−)-Caryophyllene, in Rabbits

**Keyphrases** □ Caryophyllene—X-ray crystal structure analysis of 14-hydroxycaryophyllene in rabbits □ Metabolites—of caryophyllene by X-ray crystal structure analysis, 14-hydroxycaryophyllene □ Terpenoids—caryophyllene, new metabolite, X-ray crystal structure analysis of 14-hydroxycarophyllene

*To the Editor:*

The metabolic studies of diet or crude drugs containing potentially toxic terpenoids may have significant implications for human toxicology. (−)-Caryophyllene (I), a sesquiterpene hydrocarbon having a *gem*-dimethyl group on the four-membered ring, often is found in crude drugs. For toxicological evaluation, I, $[\alpha]_D$ −10.6° (*c*, 5.64 in chloroform) (12 g), was administered to six male rabbits by a previously described method (1). The neutral metabolites (2.37 g) obtained from urine were chromatographed directly on silica gel to give crude alcohols, followed by acetylation with acetic anhydride in pyridine. The crude acetates also were chromatographed on silica gel impregnated with 5% silver nitrate to yield a pure acetate (II) (48% for total acetates).

Compound II, mp 71.5–72.5°, $[\alpha]_D$ −36.5° (*c*, 2.74 in chloroform), $C_{17}H_{26}O_3$ ($M^+$, 278), showed the presence of an acetoxymethyl group [1730 and 1240 $cm^{-1}$; δ 2.08 (s, 3H)[1] and 3.85 (s, 2H)] and an exocyclic methylene group [895 $cm^{-1}$; δ 4.90 and 5.03 (each bs, 1H)]. The PMR spectrum also contained the signals of one proton [δ 2.80 (m)] and one tertiary methyl group [δ 1.22 (s)] on carbons bearing an ether oxygen. This spectral evidence indicated that one of the *gem*-dimethyl groups on the four-membered ring might be hydroxylated. This assumption was supported further by the $^{13}C$-NMR spectrum of II, which showed the presence of two $CH_3$ groups (δ 17.0 and 17.2 ppm), five $CH_2$ groups (27.6, 28.8, 29.9, 30.3, and 34.8 ppm), two CH groups (45.8 and 48.1 ppm), a trisubstituted oxirane ring [59.4 (s) and 63.5 (d)], a tetrasubstituted $sp^3$ carbon (36.7), an exomethylene group [113.5 (t) and 151.4 (s) ppm], and an acetoxymethyl group [20.8 (q), 71.6 (t), and 170.9 (s) ppm].

Hydrolysis of II regenerated an alcohol, $[\alpha]_D$ −25.4° (*c*, 1.66 in chloroform); $C_{15}H_{24}O_2$ ($M^+$, 236); δ 1.07 and 1.25

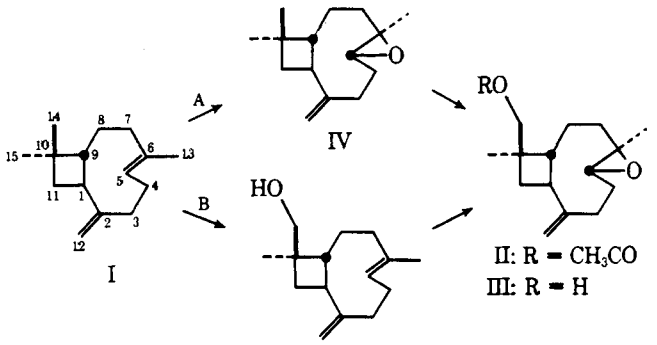

*Scheme I*

(each s, 3H), 2.92 (m, 1H, O–C–H), 3.55 (bs, 2H, $CH_2OH$), and 4.87 and 5.00 (each bs, 1H); 3450 $cm^{-1}$ (OH). These results showed that the metabolic product and its acetate were represented best as III and II, respectively. The absolute configuration of the metabolized methyl group on a four-membered ring of I was established by X-ray study of II: [a = 9.624(4) Å, b = 8.599(4) Å, c = 10.214(4) Å, $\beta$ = 105.47(3)°, space group $P2_1$, Dc = 1.13 g/$cm^3$, and z = 2]. The diffraction intensities were collected in the $\omega$-scan mode, using graphite monochromated MoK$\alpha$ radiation on a diffractomer[2], and corrected for Lorenz polarization and background effects. The structure was resolved by direct methods using a Multan program (2) and was refined by full matrix least-squares calculations. The final R value was 0.092 for 1008 reflections. The relative stereostructure of II is shown in Fig. 1.

Two metabolic pathways may be present in the biotransformation of I (Scheme I). In this connection, (−)-caryophyllene oxide (IV), $[\alpha]_D$ −35.2° (*c*, 2.19 in chloroform), also was administered to rabbits by the method already described. After being acetylated, II was obtained as the major product from the neutral metabolites. Thus, route A was confirmed. Although the presence of route B remains to be clarified, route A may be more favorable than B since IV was found in some essential oils (3–5). According to biotransformation, the hydroxylation of the *gem*-dimethyl group on the three-, four-, five-, and six-membered rings was established for 3-carene (6, 7) and carane (7); caryophyllene; camphor (8) and fenchone (9); and retinoic acid (10), respectively. The stereoselective hydroxylation of *gem*-dimethyl on the four-membered ring in mammals was not reported previously.

## Relationship between Flow Rates of Granular Powders through Stationary and Moving Orifices

**Keyphrases** □ Powders, granular—relationship between flow rates of granular powders through stationary and moving orifices □ Flow rates—of powder granulations, prediction of dynamic flow rate from static flow measurements □ Models, mathematical—prediction of dynamic flow rates of powder granulations from static flow measurements

*To the Editor:*

Since the compressed tablet is the most common dosage form manufactured, the ability to predict scale-up properties of tablet formulations for high-speed processing is needed. To manufacture tablets on a rotary tablet machine, flow of granular material through a stationary orifice (*i.e.*, efflux tube on the granulation hopper) followed by flow into moving orifices (*i.e.*, tablet dies) is required. Since little data have been reported (1, 2) that characterize the latter process of dynamic flow, data from static flow measurements have been used to predict dynamic flow properties of solids. Takieddin *et al.* (3) reported that dynamic flow rates were not predicted successfully from measurements of solid flow through a stationary orifice (static flow), noting that an apparatus suitable for the study of dynamic flow was not available.

An apparatus was constructed to study the dynamic flow of granular materials (4, 5). Although the instrument does not provide an exact duplication of events that occur within the feed frame of a tablet machine, it provides a reasonable means to obtain dynamic flow data. A slight modification of the apparatus also provides a means to study static flow rates.

Dynamic flow measurements of a lactose–cornstarch wet granulation (6) were reported (7). Six measurements were obtained for each combination of granulation mesh cut (20–40, 40–60, and 60–80), orifice size [3/16 (0.48), 1/4 (0.63), 5/16 (0.8), 3/8 (0.95), and 1/2 (1.3) in. (cm)], and five die ve-

Although the instrument does not provide an exact duplication of events that occur within the feed frame of a tablet machine, it provides a reasonable means to obtain dynamic flow data. A slight modification of the apparatus also provides a means to study static flow rates.

Dynamic flow measurements of a lactose–cornstarch wet granulation (6) were reported (7). Six measurements were obtained for each combination of granulation mesh cut (20–40, 40–60, and 60–80), orifice size [3/16 (0.48), 1/4 (0.63), 5/16 (0.8), 3/8 (0.95), and 1/2 (1.3) in. (cm)], and five die ve-

Table I—Static and Dynamic Flow Rates for Three Granulation Mesh Cuts

| Mesh Cut[a] of USP Sieves | Average Particle Diameter[b], cm | Orifice Diameter, in. (cm) | Static Flow Rate ($W_s$), g/sec | Dynamic Flow Rate ($W_2$)[c], g/sec |
|---|---|---|---|---|
| 20–40 | 0.0630 | 3/16 (0.48) | 0.74 | 0.53 |
| | | 1/4 (0.63) | 1.71 | 1.24 |
| | | 5/16 (0.8) | 3.11 | 2.74 |
| | | 3/8 (0.95) | 5.65 | 4.75 |
| | | 1/2 (1.3) | 12.7 | 12.4 |
| 40–60 | 0.0335 | 3/16 (0.48) | 1.13 | 0.88 |
| | | 1/4 (0.63) | 2.43 | 1.99 |
| | | 5/16 (0.8) | 4.25 | 3.97 |
| | | 3/8 (0.95) | 7.44 | 7.02 |
| | | 1/2 (1.3) | 15.5 | 17.1 |
| 60–80 | 0.0214 | 3/16 (0.48) | 1.31 | 1.07 |
| | | 1/4 (0.63) | 2.73 | 2.34 |
| | | 5/16 (0.8) | 4.45 | 4.48 |
| | | 3/8 (0.95) | 8.19 | 7.84 |
| | | 1/2 (1.3) | 14.7 | 18.3 |

[a] Particle density measurements (5) for the three mesh cuts are: 20–40, $\rho$ = 1.45 g/ml; 40–60, $\rho$ = 1.49 g/ml; and 60–80, $\rho$ = 1.52 g/ml. [b] Average particle diameter is defined as the arithmetic mean of the sieve openings for each pair of USP sieves; this value is an approximation (12). [c] Values of dynamic flow rates reported by Carstensen and Laughlin (7) were incorrect.

locities (between 3 and 12.5 cm/sec); average dynamic flow rates ($W_2$), as defined by Carstensen and Laughlin (7), are listed in Table I. For static flow measurements, the movable slide of the apparatus was stationary; an aluminum tube (2.54 cm i.d.) centered above the die held the granular material. Measurement of static flow rates was made with the same three granulation mesh cuts and the same five orifice sizes as used during dynamic flow studies. Five measurements with each combination of orifice and particle size were made; mean data are reported as static flow rates ($W_s$) in Table I. An apparent difference is noted between pairs of values for each set of experimental conditions; the dynamic flow rate is smaller in most cases.

Equations developed for modeling static flow often are based on the Brown–Richards equation (8) and are written in the following form:

$$W_s = f(d)P^{n(d)} \qquad \text{(Eq. 1)}$$

where $f$ and $n$ denote "function of" and $n$ is generally 2.5, a constant. However, $n$ also has been shown to be a function of particle diameter $d$ (9, 10).

Ahmad and Pilpel (9) studied the static flow properties of six different materials. Their mathematical model was based on the Brown–Richards equation and contained a bulk density term and a particle-shape factor term. They reported (9) that one equation could predict the static flow of all six materials with an overall accuracy of ~±7%.

Danish and Parrott (10) studied the static flow properties of a crystalline solid and a granular material and derived separate equations to describe the static flow rate of each material. The Brown–Richards equation was the basis for the derivations; a true density term was included but no particle-shape factor term. They reported a 10% variation between experimental and calculated values for each of the two models.

The Brown–Richards equation can be used to describe static flow for situations where: (*a*) the flow rate decreases as the particle size is increased, (*b*) the orifice size is at least six times greater than the particle size, (*c*) the granulation height is at least two times greater than the orifice diameter, and (*d*) the ratio of orifice diameter to granulation hopper diameter is <0.5. Therefore, it should be possible to write an equation in the form of Eq. 1 that can describe the static flow data shown in Table I. Such an equation, which describes static flow as a function of orifice size ($P$), particle diameter ($d$), acceleration due to gravity ($g$), and particle density[1] ($\rho$), has been derived; measurements of static flow through the largest orifice were excluded since they failed to meet the fourth criterion for applicability of the Brown–Richards equation. The derivation approach suggested by Danish and Parrott (10) was used (5) and resulted in:

$$W_s = \frac{\pi\rho\sqrt{g}}{4}\left(\frac{P}{1.65 + 2.34d}\right)^{\left(\frac{1}{0.24-0.038\ln d}\right)} \qquad \text{(Eq. 2)}$$

The flow rates predicted with Eq. 2 were larger than the experimentally measured values in eight of 12 cases; the average of the differences between calculated and experimental values (expressed as a percent of experimental data) for static flow was +3.5%.

Dynamic flow rate is not a function of orifice velocity (5). This fact can be concluded from study of Fig. 3 and Eq. 7 in Ref. 7; values for $W_2$ are calculated from the intercept of each line. Thus, each dynamic flow rate is related to the orifice size and particle diameter but is independent of the orifice velocity. These relationships suggest that dynamic flow also can be expressed in the form of the Brown–Richards equation. Measurements of dynamic flow through the largest orifice were excluded since they apparently failed to meet the first criteria for applicability of the Brown–Richards equation. Previous work indicated that, for dynamic flow, if the exponent $n$ is a constant, it should have a value of 2.9–3.4. Dynamic flow data, collected using the four smallest orifice sizes, were used to derive:

$$W_2 = \frac{\pi\rho\sqrt{g}}{4}\left(\frac{P + 0.0009d^{-1.25}}{2.11 + 0.12\ln d}\right)^{3.33} \qquad \text{(Eq. 3)}$$

The flow rates predicted with Eq. 3 were larger than experimentally measured values in eight of 12 cases. The average of the differences between calculated and experimental values (expressed as a percent of experimental data) for dynamic flow rates was +1.4%.

[1] Brown and Richards (11) reported that it is inappropriate to relate static flow rate to bulk density of the solid material, because bulk density is a combined measurement of the true or particle density and the packing characteristics of the material. They noted that $W_s$ is a function of the voidage at the orifice; this voidage is related to the true density of a crystalline material or to the particle density of a granular material. Since the particle densities of the three granulation mesh cuts are different, it seemed most appropriate to include particle density as the parameter in the equations.

A second equation for prediction of dynamic flow rates was developed, similar in form to Eq. 2 for static flow:

$$W_2 = \frac{\pi\rho\sqrt{g}}{4}\left(\frac{P}{1.52 + 4.12d}\right)^{(2.79+6.68d)} \quad \text{(Eq. 4)}$$

Again, measurements of dynamic flow through the largest orifice were excluded. Now, the exponent $n$ is a function of the particle diameter. The flow rates predicted with Eq. 4 were larger than experimentally measured values in five of 12 cases. The average of the differences between calculated and experimental values (expressed as a percent of experimental data) for dynamic flow rates was −0.4%.

In Eqs. 2–4, which are based on the Brown–Richards equation, the static and dynamic flow rates are expressed in terms of orifice diameter, particle diameter, and particle density. If static and dynamic flow rates are not dependent on any dimensions of the apparatus except the orifice size, it should be possible to combine the relationships. Then dynamic flow rate can be expressed as a function of static flow. If Eqs. 2 and 3 are combined, dynamic flow rates can be predicted using:

$$W_2 = \frac{\pi\rho\sqrt{g}}{4}\left[\left(\frac{1.65 + 2.34d}{2.11 + 0.12\ln d}\right)\left(\frac{4W_s}{\pi\rho\sqrt{g}}\right)^{(0.24-0.038\ln d)} + \left(\frac{0.0009d^{-1.25}}{2.11 + 0.12\ln d}\right)\right]^{3.33} \quad \text{(Eq. 5)}$$

If the predicting power of Eq. 5 is good:

1. There should be the same number of positive and negative differences between calculated and experimental values (+5 and −7).
2. The average of the differences (expressed as a percent of experimental data) should be close to zero (−1.2%).
3. The arithmetic mean of the absolute value of these differences should be small (6.0%).

Thus, Eq. 5 appears to be appropriate for predicting dynamic flow rates for the granular material studied.

When Eqs. 2 and 4 are combined, another algebraic expression is obtained that describes dynamic flow rate as a function of static flow:

$$W_2 = \frac{\pi\rho\sqrt{g}}{4}\left(\frac{1.65 + 2.34d}{1.52 + 4.12d}\right)^{(2.79+6.68d)} \times \left(\frac{4W_s}{\pi\rho\sqrt{g}}\right)^{(0.67+1.60d-0.11\ln d-0.25d\ln d)} \quad \text{(Eq. 6)}$$

If the predicting power of Eq. 6 is good:

1. There should be the same number of positive and negative differences between calculated and experimental values (+0 and −12).
2. The average of the differences (expressed as a percent of experimental data) should be close to zero (−6.2%).
3. The arithmetic mean of the absolute value of these differences should be small (6.2%).

Thus, Eq. 6 appears to have fair predicting power for dynamic flow rates of the granular materials studied, although it is somewhat less accurate than Eq. 5. The limited amount of data precludes selection of the more appropriate general form for an equation to predict dynamic flow rates from static flow data.

The form of Eqs. 2–4 for static and dynamic flow is comparable to equations reported by other investigators (9, 10). While Eqs. 5 and 6 are more cumbersome, they also are of a similar form; the orifice diameter ($P$) was written implicitly as a function of the static flow rate ($W_s$). An important observation of Eqs. 5 and 6 is that dynamic flow is not first order in static flow ($W_s$) if the exponents on the $(4W_s/\pi\rho\sqrt{g})$ term are different than unity. In Eq. 5, the exponent $[(0.24 - 0.038\ln d)\ (3.33)]$ is greater than unity for all $d$ values of <0.21 cm. Similarly, for Eq. 6, the exponent $(0.67 + 1.60d - 0.11\ln d - 0.25d\ln d)$ has a value greater than 1 for all particles sizes ($d$) of <598 cm. Therefore, for particle sizes commonly found in tablet formulations, both equations predict that the dynamic flow is not first order in static flow. In addition, the dynamic flow is nonlinear with respect to both preexponential terms, which are related indirectly (*i.e.*, through particle density) or directly to the particle diameter.

The direct applicability of Eqs. 5 and 6 to other granulations and dynamic flow systems is questionable. However, the form of the equations explains why the dynamic flow rates are not easily predicted from static flow data. The relationships also suggest that static and dynamic flow rates are dependent on many of the same measurable parameters; these parameters should be considered in the development of other mathematical models for dynamic flow rates.

lesterol gallstones (1–4). The clinical efficacy of I is curious since *in vitro* it is a relatively poor solubilizer of cholesterol, either alone or as mixed bile acid–lecithin micelles (5–8).

The contradiction between the poor solubilization of cholesterol monohydrate by I *in vitro* and yet its successful use for the dissolution of human gallstones *in vivo* led us to investigate the dissolution behavior of cholesterol monohydrate in media containing I conjugates (9, 10). The data showed that initial dissolution rates of cholesterol monohydrate in powder and pellet forms were always lower in lecithin–ursodeoxycholylglycine (III) solutions than in the corresponding lecithin–chenodeoxycholylglycine (IV) solutions. This finding is in agreement with previous investigations (5–8). However, in these experiments, cholesterol release into the lecithin–III-containing medium continued far beyond the apparent equilibrium solubility in the isotropic phase by formation of a turbid, liquid crystalline phase (mesophase).

These experiments were extended to determine whether such mesophase formation might occur during the *in vitro* dissolution of cholesterol gallstones.

Gallstones were obtained at surgery from two patients. The first group of stones (Fig. 1A) was removed from the gallbladder of a patient 40 years old, and the second group (Fig. 1B) was obtained from a patient 85 years old with a typical history of recurrent biliary colic. All stones were washed and kept moist in water until the dissolution studies were begun. Preoperative oral cholecystograms revealed radiolucent stones, and chemical analyses of both groups of stones showed the cholesterol contents to be close to 100%.

A single stone was placed in a test tube containing either 2 or 2.5 ml of solution. The tubes were shaken at 37°, and samples were taken at suitable time intervals. Cholesterol was assayed enzymatically[1], and an organic phosphate assay (11) was employed for lecithin.

Figure 1A shows the dissolution behavior of two stones, removed from the same patient, in lecithin–III medium. The dotted line shows the apparent equilibrium solubility of cholesterol monohydrate from pellet studies[2] in the corresponding medium. The arrows in Fig. 1 show the beginning of turbidity in the media. Microscope observations under cross-polarized light of a sample of the turbid medium revealed liquid crystals. In one experiment, the entire solution was replaced by 2.0 ml of fresh medium on the 10th day, and mesophase formation was observed to continue perhaps even at a higher rate. In these experiments, the total amount of cholesterol released far exceeded the thermodynamic micellar saturation value for cholesterol monohydrate.

Figure 1B shows data for the dissolution behavior of cholesterol gallstones from another patient; the difference in behavior for stone dissolution in III and IV solutions is clearly illustrated. For IV, the initial micellar dissolution rate was relatively rapid and the curves leveled off close to the apparent solubility value for cholesterol monohydrate[2]. In contrast, the stone dissolution in III initially proceeded much more slowly (as in Fig. 1A), and the dissolution curve did not level off at the apparent solubility

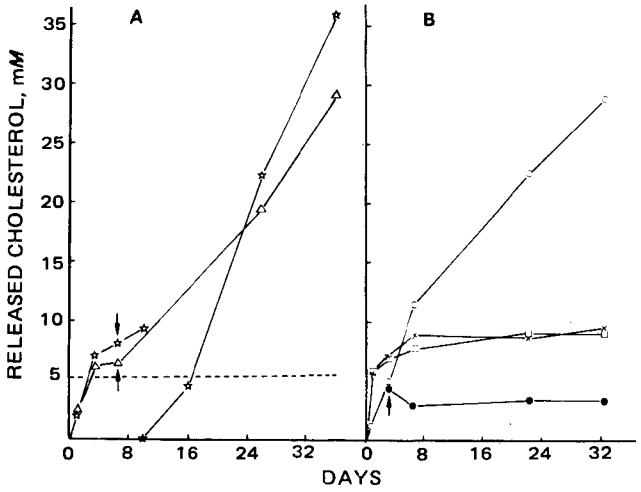

**Figure 1**—*Effect of bile acid type on cholesterol gallstone dissolution in 32 mM lecithin, 0.1 M NaCl, and 0.01 M phosphate buffer at pH 7.4 and 37°. Key: △, 126-mg stone in 2 ml of solution containing 87 mM III; ☆, 172-mg stone in 2 ml of solution containing 87 mM III (old medium was replaced by fresh medium on the 10th day); ○, 873-mg stone in 2.5 ml of solution containing 87 mM III; ×, 891-mg stone in 2.5 ml of solution containing 87 mM IV; □, 910-mg stone in 2.5 ml of solution containing 87 mM IV; and ●, 873-mg stone in 2.5 ml of solution containing 87 mM III (after centrifugation of the supernate).*

but proceeded to much higher values. In III solution, the beginning of turbidity was observed after about 3 days (see arrows), but cholesterol released from the stone continued far beyond the apparent solubility value. As in Fig. 1A, the polarizing microscope examination of the mesophase (which separates to the top of the isotropic solution after centrifugation) showed liquid crystal properties. Solid circles in Fig. 1B show the supernatant (isotropic phase) cholesterol levels after centrifugation (8000×*g* for 10 min).

Table I shows that the lecithin levels in the experiments involving IV remained relatively constant with and without centrifugation. In the experiments with III, the lecithin levels in the supernate (isotropic phase) obtained after centrifugation decreased greatly with time. Calculations based on the lecithin data in Table I and the cholesterol data in Fig. 1B showed that the separated phase(s) possessed an average cholesterol to lecithin ratio of 1:1 to 3:1. In addition, the cholesterol level obtained for the supernate (isotropic phase) after centrifugation was somewhat lower than the value corresponding to the dotted line in Fig. 1A. This finding is consistent with observed lecithin depletion from the media during mesophase formation.

Other gallstones, which are under investigation in these

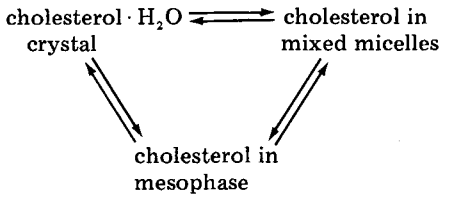
**Table I—Data Showing Lecithin Concentration (Millimolar) Changes during *In Vitro*[a] Cholesterol Gallstone Dissolution in Solutions Containing III**

| Days | Lecithin–IV | | Lecithin–IV | | Lecithin–III | |
|---|---|---|---|---|---|---|
| | Before[b] | After | Before | After | Before | After |
| 0 | 32.0 | 32.0 | 32.0 | 32.0 | 32.0 | 32.0 |
| 3.1 | 33.3 | 33.2 | 28.3 | 29.8 | 25.2 | 22.0 |
| 7.0 | 32.6 | 29.4 | 27.6 | 30.6 | 25.0 | 12.6 |
| 22.5 | 32.8 | 29.8 | 27.0 | 27.4 | 25.2 | 11.8 |
| 32.7 | 31.0 | 31.5 | 28.1 | 31.0 | 25.2 | 12.0 |

[a] Changes in cholesterol concentration are shown in Fig. 1. The initial concentration of lecithin was 32 m*M*; the concentrations of IV and III were 87 m*M*. [b] The concentration of lecithin before centrifugation denotes lecithin in both the mesomorphic and isotropic phases; after centrifugation, the lecithin concentration refers to the isotropic phase because the mesophase has risen to the top of the tube.

[1] Bio-Dynamics, Indianapolis, Ind.
[2] Manuscript in preparation.

laboratories, also show that the cholesterol release in media containing III and lecithin may follow the pattern described in Scheme I.



*Scheme I*

The process effectively represents a substantial mass transfer rate of cholesterol from the gallstone into the medium. Although this process is significantly slower than the micellar dissolution rate of a cholesterol gallstone in a lecithin–IV solution, after some time (several days in these experiments) the extent of dissolution and disintegration by this process may be greater.

These studies imply that the phase equilibria in III–lecithin–cholesterol–water differ from that in IV–lecithin–cholesterol–water. Conjugates of ursodeoxycholic acid apparently have a much weaker tendency to disperse mixed lecithin–cholesterol bilayers than those of chenodeoxycholic acid. The data do not answer directly the question of whether mesophase formation may occur during gallstone dissolution induced by ursodeoxycholate in humans since biliary bile acids become only moderately enriched in ursodeoxycholic acid (60–70%) during continuous ursodeoxycholate administration; therefore, further studies are needed. Mesophase formation during gallstone induction does occur in the cholesterol-fed prairie dog (12) whose bile contains predominantly cholate conjugates, and mesophases were reported to occur in some samples of human bile (13, 14).

# BOOKS

## REVIEWS

**Pharmaceutical Calculations, 7th Ed.** By MITCHELL J. STOKLOSA and HOWARD C. ANSEL. Lea & Febiger, 600 Washington Square, Philadelphia, PA 19106. 385 pp. 15 × 23 cm. Price $15.00.

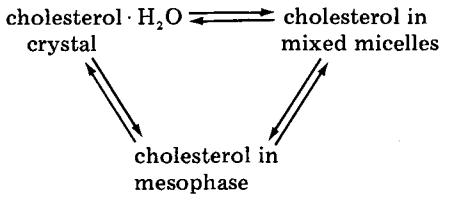
The seventh edition is in the same format as earlier ones but contains an expanded chapter on dosage calculations and additional chapters on interpreting the prescription and calculations involving parenteral admixtures. The material from the "Chemical Problems" chapter in the 6th edition is found in the appendix of the new edition. Many new practice problems have been added to appropriate chapters.

The addition of a new chapter, "Interpretation of the Prescription or Medication Order," is very good. The interpretation presented is aimed specifically at helping the student solve problems presented in the prescription, medication order, or formula and does not duplicate information given in other chapters, as one might expect. The subject matter is presented in a direct manner with enough examples to be easily understood.

Additions to the "Calculation of Doses" chapter include an expansion of the surface area method with the two DuBois and DuBois nomograms for finding body surface areas for children and adults. This is a considerable improvement over the 6th edition which contained a table of body weights and surface areas. Unfortunately, the reference to the use of this method (Harry Shirkey) uses the West nomogram, which gives results different from that of DuBois. Perhaps an expanded discussion could cover this point in the next edition.

The inclusion of calculations involving lean body mass, loading dose, maintenance dose, and the use of creatinine clearance rate is an excellent choice of subject to update the book. The explanations and examples are all clear and precise except for the calculation and use of creatinine

laboratories, also show that the cholesterol release in media containing III and lecithin may follow the pattern described in Scheme I.



*Scheme I*

The process effectively represents a substantial mass transfer rate of cholesterol from the gallstone into the medium. Although this process is significantly slower than the micellar dissolution rate of a cholesterol gallstone in a lecithin–IV solution, after some time (several days in these experiments) the extent of dissolution and disintegration by this process may be greater.

These studies imply that the phase equilibria in III–lecithin–cholesterol–water differ from that in IV–lecithin–cholesterol–water. Conjugates of ursodeoxycholic acid apparently have a much weaker tendency to disperse mixed lecithin–cholesterol bilayers than those of chenodeoxycholic acid. The data do not answer directly the question of whether mesophase formation may occur during gallstone dissolution induced by ursodeoxycholate in humans since biliary bile acids become only moderately enriched in ursodeoxycholic acid (60–70%) during continuous ursodeoxycholate administration; therefore, further studies are needed. Mesophase formation during gallstone induction does occur in the cholesterol-fed prairie dog (12) whose bile contains predominantly cholate conjugates, and mesophases were reported to occur in some samples of human bile (13, 14).

## REVIEWS

**Pharmaceutical Calculations, 7th Ed.** By MITCHELL J. STOKLOSA and HOWARD C. ANSEL. Lea & Febiger, 600 Washington Square, Philadelphia, PA 19106. 385 pp. 15 × 23 cm. Price $15.00.

The seventh edition is in the same format as earlier ones but contains an expanded chapter on dosage calculations and additional chapters on interpreting the prescription and calculations involving parenteral admixtures. The material from the "Chemical Problems" chapter in the 6th edition is found in the appendix of the new edition. Many new practice problems have been added to appropriate chapters.

The addition of a new chapter, "Interpretation of the Prescription or Medication Order," is very good. The interpretation presented is aimed specifically at helping the student solve problems presented in the prescription, medication order, or formula and does not duplicate information given in other chapters, as one might expect. The subject matter is presented in a direct manner with enough examples to be easily understood.

Additions to the "Calculation of Doses" chapter include an expansion of the surface area method with the two DuBois and DuBois nomograms for finding body surface areas for children and adults. This is a considerable improvement over the 6th edition which contained a table of body weights and surface areas. Unfortunately, the reference to the use of this method (Harry Shirkey) uses the West nomogram, which gives results different from that of DuBois. Perhaps an expanded discussion could cover this point in the next edition.

The inclusion of calculations involving lean body mass, loading dose, maintenance dose, and the use of creatinine clearance rate is an excellent choice of subject to update the book. The explanations and examples are all clear and precise except for the calculation and use of creatinine

clearance rate for females, which is hampered somewhat by insufficient practice problems of this type at the end of the chapter.

"Some Calculations Involving Parenteral Admixtures" is another new chapter. The material covers the application of the milliequivalent and millimole concepts to the use of additive solutions in parenteral therapy. The use of various solutions obtained from ampuls or vials and the constituting of total parenteral nutrition or hyperalimentation fluids are included, as are computations of the flow rates of intravenous solutions.

"Pharmaceutical Calculations" has been a standard text for many years. Its clear but concise explanations, numerous examples, and various practice problems have made it so. The new materials are good additions to an already excellent book.

**Sustained Release Medications.** Edited by J. C. JOHNSON. Noyes Data Corp., Mill Rd. at Grand Ave., Park Ridge, NJ 07655. 1980. 412 pp. 15 × 23 cm. Price $54.00.

In the foreword, the editor gives an excellent and precise description of the information contained in the book. The information is based on U.S. patents issued since January 1974 in the field of sustained-release medications. The editor indicates that the book is a data-based publication, providing information retrieved and made available from the U.S. patent literature. Thus, it serves a double purpose in that it supplies detailed technical information and can be used as a guide to the patent literature in this field. By indicating all the significant information and eliminating legal jargon and juristic phraseology, this book represents an advanced, commercially oriented review of recent developments in the field of sustained-release medications. The book is composed of 14 chapters; it contains 263 patents covering 204 processes.

The first chapter deals with patents describing the preparation of excipients used in the manufacture of these medications. Included are controlled-release tableting media (talc, ethylcellulose, methyl stearate mixtures, hydrated hydroxyalkylcellulose plus aliphatic alcohol, and salts of polymeric carboxylates), polymer gels (chelated hydrogels and water-insoluble hydrophilic copolymers), enteric-coating materials (cellulose ether compositions, partial esters of acrylate-unsaturated anhydride copolymers, and water-soluble coating resins), and polyesters (polymers with oxyacycloalkane units, polymers with alkoxy or oxacycloalkane substituents, bioabsorbable polyglycolic acid polyester condensates, and bioerodable partial esters of polycarboxylic acids).

Patented processes involved in the preparation and coating of microcapsules is covered in Chapter 2. Chapter 3 includes processes for preparing capsules as well as tablet cores and tablet coatings. Patents dealing with films and webs are discussed in Chapter 4. The fifth chapter describes 10 processes utilized in the design of diffusion devices containing medications soluble to some extent in the polymeric material. Chapter 6 includes 16 processes involved in the preparation of osmotic devices that use polymeric materials permeable to water and body fluids but not permeable to the drug.

The next four chapters describe devices such as implants, ocular inserts, intravaginal and intrauterine inserts, and devices for use in the GI tract. These devices utilize bioerodable polymers selected so that the device and the medication are absorbed by the body. Chapters 11–13 deal with various sustained-release medications such as heart and circulatory drugs, antispasmodics, antibiotics, aspirin, and analgesics and GI tract drugs. The final chapter describes veterinary preparations.

The book is a must for individuals interested in sustained-release technology. It is well written and would be a great timesaver and a source of many excellent ideas.

The book is composed of 14 chapters; it contains 263 patents covering 204 processes.

The first chapter deals with patents describing the preparation of excipients used in the manufacture of these medications. Included are controlled-release tableting media (talc, ethylcellulose, methyl stearate mixtures, hydrated hydroxyalkylcellulose plus aliphatic alcohol, and salts of polymeric carboxylates), polymer gels (chelated hydrogels and water-insoluble hydrophilic copolymers), enteric-coating materials (cellulose ether compositions, partial esters of acrylate-unsaturated anhydride copolymers, and water-soluble coating resins), and polyesters (polymers with oxyacycloalkane units, polymers with alkoxy or oxacycloalkane substituents, bioabsorbable polyglycolic acid polyester condensates, and bioerodable partial esters of polycarboxylic acids).

Patented processes involved in the preparation and coating of microcapsules is covered in Chapter 2. Chapter 3 includes processes for preparing capsules as well as tablet cores and tablet coatings. Patents dealing with films and webs are discussed in Chapter 4. The fifth chapter describes 10 processes utilized in the design of diffusion devices containing medications soluble to some extent in the polymeric material. Chapter 6 includes 16 processes involved in the preparation of osmotic devices that use polymeric materials permeable to water and body fluids but not permeable to the drug.

The next four chapters describe devices such as implants, ocular inserts, intravaginal and intrauterine inserts, and devices for use in the GI tract. These devices utilize bioerodable polymers selected so that the device and the medication are absorbed by the body. Chapters 11–13 deal with various sustained-release medications such as heart and circulatory drugs, antispasmodics, antibiotics, aspirin, and analgesics and GI tract drugs. The final chapter describes veterinary preparations.

The book is a must for individuals interested in sustained-release technology. It is well written and would be a great timesaver and a source of many excellent ideas.

# Dissolution Rate Behavior of Solid Cholesterol Preparations in Bile Acid Solutions

KENNETH M. FELD and WILLIAM I. HIGUCHI ˣ

Received April 28, 1980, from the *College of Pharmacy, University of Michigan, Ann Arbor, MI 48109.* Accepted for publication January 6, 1981.

**Abstract** □ Recent work in these laboratories showed that different preparations of cholesterol monohydrate and anhydrous cholesterol had different dissolution rates under the same conditions. A method was developed by which both the thermodynamic contribution ($C_s$) and the interfacial kinetic contribution ($P$) to dissolution could be determined from experimental data. The rotating-disk dissolution method was used with the Levich theory to assess the data. Dissolution rates were determined in solutions partially saturated with cholesterol. Dynamic solubilities were determined by plotting dissolution rates ($J/A$) *versus* bulk concentration ($C_b$) and extrapolating to zero $J/A$. By using a best-fit analysis, it was possible to determine solubility as well as the interfacial transport constant independently. When this method was used to study differences in dissolution behavior of different solid preparations of cholesterol, the differences could be accounted for primarily by variations in the interfacial transport constant rather than by solubility variations.

**Keyphrases** □ Cholesterol—dissolution rate behavior in bile acid solutions, comparison of solid preparations □ Dissolution—cholesterol, comparison of solid preparations in bile acid solutions □ Bile acids—cholesterol dissolution, comparison of solid preparations □ Gallstones—cholesterol dissolution, comparison of solid preparations in bile acid solutions

Most dissolution rate experiments have been interpreted satisfactorily by diffusion–convection models (1). However, recent studies (2, 3) of the dissolution rate behavior of cholesterol in bile acid solutions showed that interfacial resistance is often the dominant factor to mass transfer.

Preliminary studies in these laboratories showed that different preparations of solid cholesterol result in large variations in dissolution rate behavior. A method was needed to determine both the thermodynamic contribution and the kinetic contribution to dissolution from experimental data for different solid preparations.

The rotating-disk method was used with the accompanying Levich theory (4) to analyze results since it is well suited for quantifying the contributions of the diffusion–convection mass transfer resistance and the contributions of the interfacial barrier and/or solubilization kinetics in the diffusion layer to the overall kinetics. The purpose of this paper was to demonstrate how dissolution rate data can be analyzed when interfacial kinetics and the thermodynamic driving force for various solid phases of a substance vary simultaneously. The method was applied to the problem of cholesterol dissolution in bile acid solutions.

## THEORETICAL

According to the Nernst diffusion layer theory, the total resistance for the transfer of a solute into the solution immediately adjacent to the solid surface and then into the bulk solution is given by $h/D$, a diffusion term. Both convection and diffusion are expected to be important in most dissolution situations. Therefore, for the rotating-disk method, the effective diffusion resistance ($h/D$) may be equated to an appropriate function that considers both processes. Thus, when both diffusion and convection are important, the mass flux as given by Levich (4) is:

$$J = 0.62AD^{2/3}\nu^{-1/6}\omega^{1/2}(C_s - C_b) \qquad \text{(Eq. 1)}$$

where:

$A$ = apparent surface area of the pellet
$D$ = diffusion coefficient
$\nu$ = kinematic viscosity
$\omega$ = angular velocity of rotation
$C_s$ = saturation solubility
$C_b$ = bulk concentration

The effective diffusion layer thickness is given as:

$$h = 1.612D^{1/3}\nu^{1/6}\omega^{-1/2} \qquad \text{(Eq. 2)}$$

For the region of dissolution in which both diffusion and a first-order interfacial resistance are important, the flux as given by Levich (4) is:

$$J = \frac{A(C_s - C_b)}{1.612D^{-2/3}\nu^{1/6}\omega^{-1/2} + 1/P} \qquad \text{(Eq. 3)}$$

where $P$ is the permeability coefficient (interfacial transport constant).

In the case of pure bulk transport, the observed dissolution rate should be essentially equal to the calculated flux (Eq. 1). However, if the observed reaction rate is much lower than the calculated diffusion–convection flux, it may be concluded that dissolution is taking place in the interfacially controlled region, *i.e.*, $1/P$ has become rather large (Eq. 3).

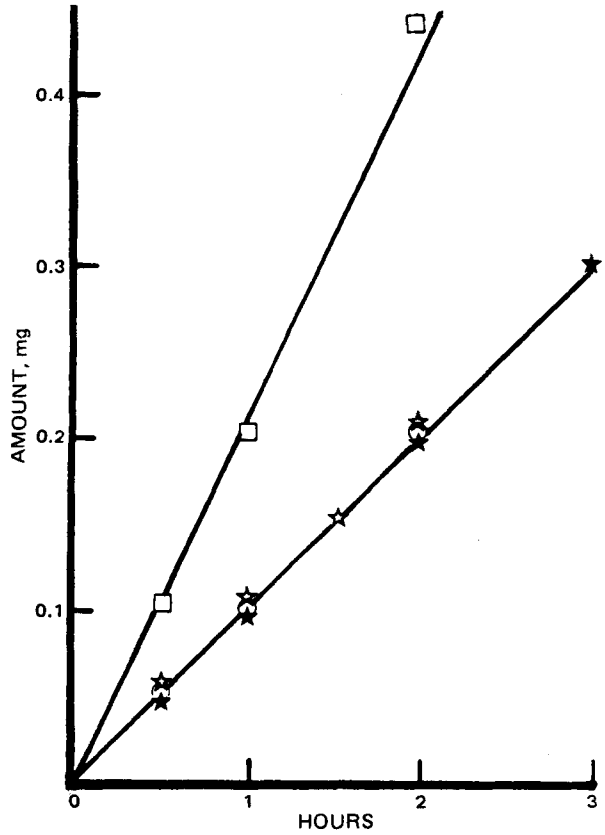

**Figure 1**—*Effect of pH on the dissolution rate of cholesterol in 5% sodium cholate solutions (pH was adjusted by addition of sodium hydroxide). Key:* □, *pH 7.1;* ★, *pH 7.4;* ○, *pH 8.02; and* ☆, *pH 11.08.*

## EXPERIMENTAL

**Solutions**—Sodium cholate test solutions were prepared by titrating equivalent amounts of cholic acid[1] with sodium hydroxide. The solution pH then was adjusted to 8.0. While this value was not the physiological pH, it was at a region where $J/A$ would experience minimum variability because of pH variations (Fig. 1). The solutions were allowed to equilibrate for at least 1 day before use.

**Materials**—Commercial cholesterol[2] was recrystallized three times from 95% ethanol. Radioactive cholesterol monohydrate was prepared by mixing [4-$^{14}$C]cholesterol[3] with a known amount of the recrystallized cholesterol at 60° (specific activity of ~10 μCi/g). The solutions then were allowed to stand undisturbed for 48 hr at room temperature. The cholesterol crystals were filtered and dried overnight *in vacuo*. The cholesterol monohydrate crystals were stored in the dark in a desiccator saturated with water vapor at room temperature.

**Preparation of Solid Phases**—Cholesterol samples that gave different dissolution rates under the same conditions were obtained. Two preparations of cholesterol monohydrate were obtained. One sample (I) was prepared by mixing 5 g of recrystallized cholesterol and 50 μCi of [4-$^{14}$C]cholesterol with 400 ml of 95% ethanol at 60°. Another sample (II) was prepared by mixing 10 g of recrystallized cholesterol and 100 μCi of [4-$^{14}$C]cholesterol with 400 ml of 95% ethanol at 60°. During the crystallization of I and II, the crystallization rates were significantly different. Crystals were first noticed ~12–15 and ~3–4 hr after dissolution[4] in I and II, respectively.

In addition, two nonhydrated forms of cholesterol were obtained by pretreatment of I. One sample (III) was prepared by melting a small amount of I at 160° for 5 min. Another preparation (IV) was obtained by heating I at 100° for 24 hr.

To check the hydrated nature of the two monohydrates and the nonhydrated nature of the melt and the heated sample, weight loss experiments were conducted on each solid form. For all of these preparations, ~1 g of the cholesterol was weighed into a vial and then heated at 100° for 15 min. After heating, the samples were reweighed. This process was repeated until the weight of the vial plus the cholesterol was constant. Any weight loss during this process was attributed to the loss of the solvation molecule (water).

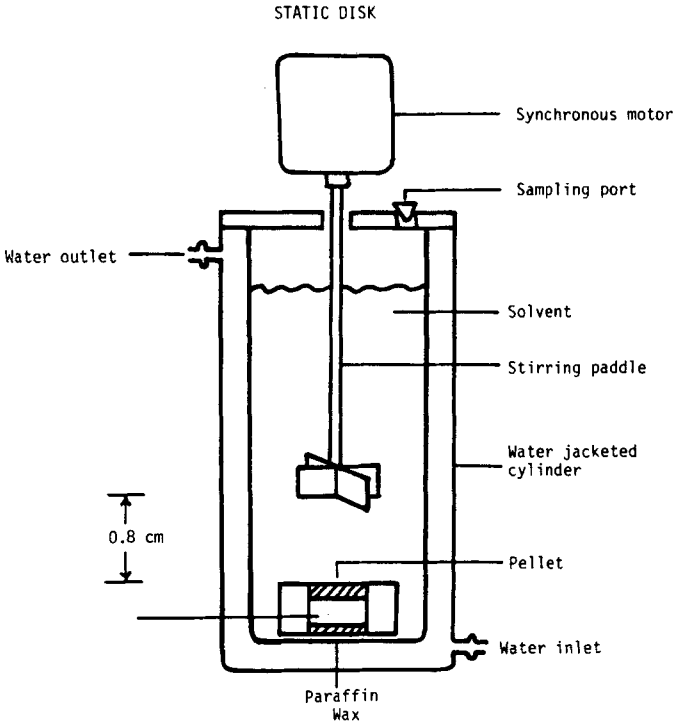

**Figure 2**—*Diagrammatic representation of the static-disk dissolution apparatus.*

For the two monohydrate samples, the loss in weight corresponded to 1.0 ± 0.3 mole of water for each mole of cholesterol. However, for the melt and the heated sample, no weight loss was detected after further heating. This finding demonstrates the monohydrate nature of the two hydrated forms and the anhydrous nature of the two heated preparations.

In addition to weight loss determination, it also was important to check for decomposition products. TLC plates were prepared and placed into tanks with chloroform–acetone (90:10) as the solvent (5). For all solid preparations, one spot with an $R_f$ value of 0.62 was found.

**Equilibrium Solubility Determination**—The solubility of each cholesterol monohydrate sample was determined by adding an excess of radiolabeled cholesterol monohydrate to a few milliliters of solvent. The tube containing the slurry then was shaken by a wrist-action shaker in a water bath maintained at 37°. Samples were taken periodically, 10 ml of scintillation fluid was added to the sample, and the amount of cholesterol dissolved was calculated from the radioactivity determined in a liquid scintillation counter[5]. When the amount of dissolved cholesterol reached a constant level, this limiting value was used to calculate the equilibrium solubility (2).

**Diffusion Coefficient Determination**—The diffusion coefficient was determined in a small-volume diaphragm cell at 37°. The apparatus and the procedure were described previously (6). The apparatus consisted of two well-stirred reservoirs separated by a silver filter membrane. Both reservoirs contained 3.4 ml of the solvent medium, and each was stirred at 150 rpm with a magnetic bar in the bottom chamber and a paddle in the upper chamber. At the end of the run, the concentration in each reservoir was determined.

**Method**—For the initial portion of this investigation, the static-disk dissolution apparatus was employed (Fig. 2). Approximately 200 mg of the various solid preparations was compressed[6] into pellets [compression load of 1362 kg (3000 lb)] with a diameter of 1.27 cm. The pellets then were placed into the dissolution setup. Exactly 10 ml of the sodium cholate solution was added, and the system was stirred with a 150-rpm stirrer[7].

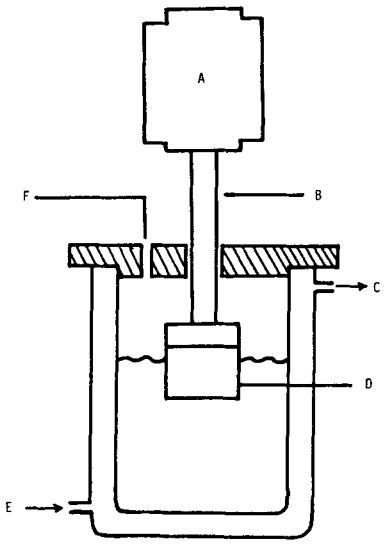

**Figure 3**—*Diagrammatic representation of the rotating-disk dissolution apparatus. Key: A, constant-speed motor; B, rotating shaft; C, water outlet; D, disk with pellet; E, water inlet; and F, sample port.*

Samples were taken at different times, and the amount dissolved was measured in a liquid scintillation counter.

For the more detailed analysis, the rotating-disk apparatus was used (Fig. 3). This apparatus consisted of three main parts: the outside water-jacketed beaker, the removable disk, and the controlled-rotating device[8]. Deviation of the experimental results from theory was assessed using benzoic acid as a model solute since benzoic acid dissolution is diffusion–convection controlled (6).

Fifty milliliters of solvent was pipetted into the water-jacketed beaker maintained at 37° for each dissolution run. The rotating disk containing the pellet then was centered at ~1 cm below the solvent level so that the distances from the disk wall to the inner surface of the beaker exceeded 0.5 cm. Samples were taken at appropriate times and assayed for the amount dissolved. All experiments were concluded early enough so that sink conditions were always maintained. Rotation speeds varied between 20 and 450 rpm. Partially saturated solutions of 5% sodium cholate and 0.1 *M* phosphate buffer at pH 8.0 were prepared by adding nonradioactive

cholesterol to the solutions and allowing the cholesterol to dissolve completely. Bulk concentrations of cholesterol varied from 0 to ~1.0 mg/ml.

## RESULTS AND DISCUSSION

As already stated, different solid preparations of cholesterol give different dissolution rates under the same conditions. These differences may be caused by variations in $P$ and/or $C_s$ (Eq. 3) between the different preparations. By varying $C_b$ (bulk concentration) and $\omega$ (rotational speed), it was possible to determine $C_s$ and $P$ values for all solid preparations.

Since cholesterol dissolution is essentially surface controlled, $1/P$ is much larger than $1.612D^{-2/3}\nu^{1/6}\omega^{-1/2}$ (Eq. 3). Therefore, the actual value of $D$ is not required for the present analysis. However, as an independent check, $D$ was determined and compared to the value obtained in the later analysis.

**Dissolution Results of Benzoic Acid**—The results of benzoic acid dissolution were the same as those previously reported (6). Benzoic acid dissolution was linear at all rotation speeds. When these dissolution rates

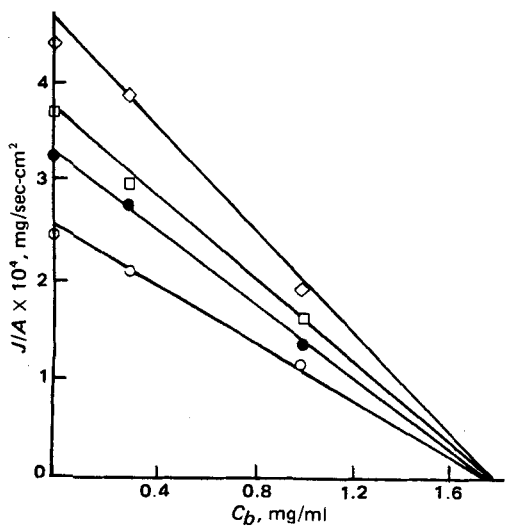

**Figure 8**—*Dissolution rate* versus *bulk concentration for the melt (III) pellets in 5% sodium cholate and 0.1* M *phosphate buffer at pH 8.00. Key:* ○, *20 rpm;* ●, *50 rpm;* □, *150 rpm; and* ◇, *450 rpm.*

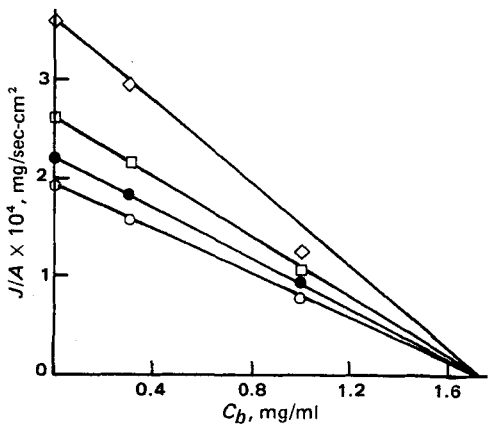

**Figure 9**—*Dissolution rate* versus *bulk concentration for the pellets (IV) prepared from I heated at 100° for 24 hr in 5% sodium cholate and 0.1* M *phosphate buffer at pH 8.00. Key:* ○, *20 rpm;* ●, *50 rpm;* □, *150 rpm; and* ◇, *450 rpm.*

were plotted *versus* the square root of the rotation speed, a linear relationship was obtained. This relationship was compared to the dissolution rates predicted by the Levich theory (4) (Eq. 1). The experimental dissolution rates were 15% lower than those predicted by the Levich theory. This discrepancy is consistent with the views of Gregory and Riddiford (7) regarding the performance of rotating-disk geometrics of the type used in the present study.

**Dissolution of Cholesterol Solid Preparations Using Static-Disk Setup**—Measurement of dissolution rates of the cholesterol solid phases showed significant differences (Fig. 4 and Table I). Sample II gave a dissolution rate that was ~70% higher than that of I. The heated preparation gave a dissolution rate ~3.6 times as great as did I, while the melt gave an increase in the dissolution rate by a factor of 5. The results of several pellets of each preparation were reproducible to ±10%. Because the differences in dissolution rates were significant, it was necessary to determine whether these differences were due to variations in $C_s$ (solubility) or $P$ (interfacial transport constant).

**Dissolution of Cholesterol Solid Preparations in Rotating-Disk Setup**—For each solid preparation, initial dissolution rates in the rotating-disk apparatus were obtained in the same manner as for the static-disk experiments. Figure 5 shows the results of some typical experiments for the various solid preparations in solutions of 5% sodium cholate and 0.1 $M$ phosphate buffer at pH 8.0 with bulk cholesterol concentrations equal to zero. As was found with the static disk, these results were reproducible to ±10%. Plots such as these were prepared under all conditions to obtain the initial dissolution rates.

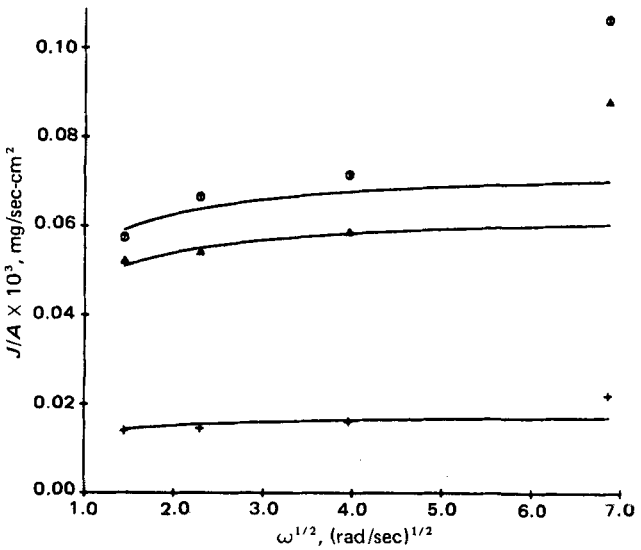

**Figure 10**—*Best-fit analysis of the normal pellets (I) in 5% sodium cholate and 0.1* M *phosphate buffer at pH 8.00. Key* ($C_b$ *in milligrams per milliliter):* ○, *0.0 mg/ml;* ▲, *0.2 mg/ml; and* +, *1.1 mg/ml.*

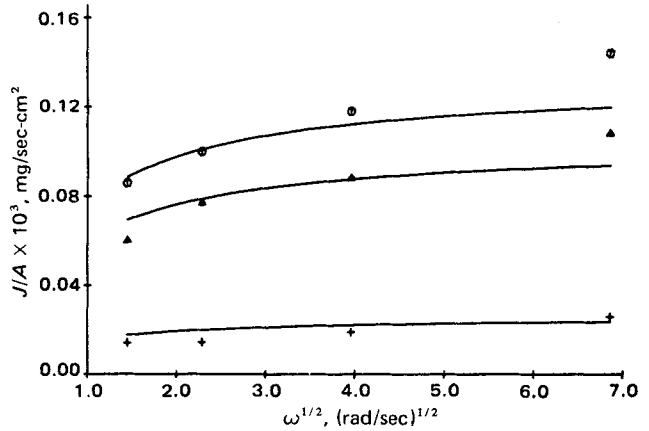

**Figure 1**—*Best-fit analysis of the rapid pellets (II) in 5% sodium cholate and 0.1* M *phosphate buffer at pH 8.00. Key* ($C_b$ *in milligrams per milliliter):* ○, *0.0 mg/ml;* ▲, *0.3 mg/ml; and* +, *1.1 mg/ml.*

To determine the dynamic solubility ($C_s$), initial dissolution rates were determined and then plotted against $C_b$ (bulk concentration). Figures 6–9 show the results of experiments carried out in 5% sodium cholate and 0.1 *M* phosphate buffer solutions at pH 8.0. The extrapolations of these data to zero $J/A$ gave the dynamic solubilities.

As was predicted, Figs. 6–9 show a linear decrease in the cholesterol monohydrate dissolution rate as saturation was approached. This finding indicates that dissolution kinetics are proportional to the change in concentration ($\Delta C$) over the entire saturation range. The dynamic solubilities for both cholesterol monohydrate samples were found by extrapolation to be ~1.40 mg/ml (Figs. 6 and 7). The $C_s$ value for the two anhydrous preparations was ~1.75 mg/ml (Figs. 8 and 9).

To look at the data in a more meaningful way, plots of $J/A$ *versus* $\omega^{1/2}$ were prepared. Figures 10–13 clearly show the important involvement of the interfacial barrier. If the interfacial barrier was not significant (*i.e.*, diffusion-controlled case), a plot of $J/A$ *versus* $\omega^{1/2}$ would give a straight line through the origin. If the interfacial barrier is significant in dissolution, a slope of <1 and a deviation from linearity should be obtained.

From a least-squares best-fit analysis, using Eq. 3 with a 15% correction, it was possible to obtain values for $C_s$, $P$, and $D$, where $P$ is the interfacial transport constant and $D$ is the diffusivity. The calculated dissolution rates using the best-fit values from Eq. 3 were compared to the experimental dissolution rates (Figs. 10–13). A good fit between experiment and theory is seen. The points at 450 rpm ($\omega^{1/2} = 6.86$) were not weighted in this analysis.

Tables II–V summarize the results of the partial saturation, the least-squares analyses, and the solubility determined by the slurry method (2). The tables show good agreement among the $C_s$ values obtained by all three methods for both I and II and nearly equivalent $C_s$ values between the samples. However, the interfacial transport constant ($P$) differed by a factor of 1.90 between the samples. Therefore, the differences in the dissolution rates between I and II can be accounted for primarily by a difference in their $P$ values.

The $C_s$ value from the partial saturation experiments for the melt-prepared and heat-prepared pellets was ~1.75 mg/ml. This value is ~20% greater than the $C_s$ value obtained from either monohydrate sample. Again, the big difference was seen in the interfacial transport constant ($P$). The $P_{IV}$:$P_I$ ratio was 3.99, while the $P_{III}$:$P_I$ ratio was 6.53. As was the case with I and II, the difference in the dissolution behavior between the anhydrous preparations can be accounted for primarily by a difference in $P$. The variations in the dissolution rates between the hydrated preparations and the nonhydrated preparations can be attributed to small changes in $C_s$ and large changes in $P$.

Experimental determination of $D$ (diffusivity) agreed well with the

values of $D$ determined from the best-fit analysis. From the small-volume diaphragm cell, $D$ was determined to be $1.52 \times 10^{-6}$ cm²/sec; from the best-fit analysis, $D$ was $\sim 1.25 \times 10^{-6}$ cm²/sec.

As already stated, the data at 450 rpm ($\omega^{1/2} = 6.86$) was not weighted in the best-fit analysis. The points at 450 rpm deviate substantially from the theoretical curve (Figs. 10–13). A possible explanation for this deviation can be found in the single-crystal experiments performed previously (8). Individual cholesterol crystals were mounted in a cell containing the bile acid solution, and the cell then was placed into a 37° chamber. Microscopic examination of the crystal under static conditions showed that surface etching occurred. Within 2 hr, a definite saw-tooth pattern developed along the edge of the crystal (Fig. 14). At 450 rpm in the rotating-disk experiments, the effective surface area might possibly have increased or some shearing of the peaks along the crystal surface may have occurred. This phenomenon, along with the normal micellar dissolution, could result in a positive deviation in the apparent dissolution rate from that expected from the theory.

These findings are consistent with those of Shefter and Higuchi (9). They showed that the dissolution behavior of hydrated and nonsolvated forms of cholesterol was indeed different. The initial dissolution rate was shown to be three times greater for the nonsolvated cholesterol as for the hydrated form at 25°. They also showed that the maximum concentration reached with the nonsolvated form was 1.4 times as great as the solubility of the hydrate at 25°.

**Implications in Cholesterol Gallstone Research**—Higuchi *et al.* (2, 3) proposed that cholesterol monohydrate pellets may be employed as a model for cholesterol gallstones in *in vitro* dissolution rate experiments. Borgren and Larsson (10) examined biliary calculi from humans immediately after removal. In all cases, the cholesterol present was cholesterol monohydrate. These investigators also showed that the monohydrate can lose water to give the anhydrous form. Other investigators (11, 12) found both forms of cholesterol in gallstones, but their studies were conducted on stones that had been removed several years earlier. The authors suggested that the anhydrous cholesterol was formed from the monohydrate and that cholesterol monohydrate was formed *in vivo*.

The present investigation demonstrated that large variations in results among studies may occur if the solid phase of cholesterol is not prepared in the same manner from study to study. There was approximately a fivefold difference between the highest (melt preparation) and lowest (I) rates observed. Even two preparations of the monohydrate (I and II) may show differences in pellet dissolution rates as great as 80%. Thus, the potential for problems should be recognized and the proper cautions exercised when comparing data from different studies (especially from different laboratories).

A rather subtle but important situation concerns the study of dissolution rate accelerators. The large difference in the dissolution rates between the melt (or the anhydrous preparation) and I was due mainly to the difference in $P$ values rather than to a difference in solubility ($C_s$). Thus, for example, the $P$ value for the anhydrous cholesterol pellet prepared by heating I was approximately four times larger than that for I itself. Thus, for the same hydrodynamic (convective–diffusion) situation, the anhydrous pellet can be up to four times less sensitive than a pellet of I to agents that may influence the interfacial kinetics.

From their studies, Tao *et al.* (13) concluded that convective diffusion rather than interfacial kinetics is the major determinant of the dissolution rate and that greatly accelerating the dissolution of cholesterol gallstones could be difficult. These investigators, however, prepared their cholesterol by evaporating a cholesterol–benzene solution to dryness and, consequently, their material was anhydrous cholesterol[9]. This procedure, at least in part, may account for their experimental results being closer to convective diffusion control than those results obtained by Higuchi *et al.* (2, 3).

# Variability in Dissolution Rates of Cholesterol Pellets in Bile Acid Solutions

**KENNETH M. FELD and WILLIAM I. HIGUCHI ˣ**

Received April 28, 1980, from the *College of Pharmacy, University of Michigan, Ann Arbor, MI 48109.* Accepted for publication January 6, 1981.

**Abstract** □ Large variations in dissolution rate behavior of cholesterol monohydrate pellets may result from small changes in experimental procedures. For example, when cholesterol monohydrate pellets were stored overnight prior to a dissolution run, the initial dissolution rates varied by more than a factor of 2. It is well known that cholesterol monohydrate is converted to anhydrous cholesterol; cholesterol may be unstable toward light, heat, and other radiation in the presence of air, leading to its decomposition. To determine the cause of the variable dissolution rates, experiments were conducted with pellets "aged" under various conditions. The data show that the probable cause of the variations is the pellet surface conversion of the monohydrate to anhydrous cholesterol, which may take place during pellet storage. The combined effects of temperature and humidity seem to be important. A uniform experimental procedure is needed if investigators hope to reproduce results within their own laboratories as well as reproduce the findings of others.

**Keyphrases** □ Cholesterol—dissolution rate behavior in bile acid solutions □ Dissolution—rate behavior of cholesterol in bile acid solutions □ Gallstones—cholesterol, dissolution rate behavior in bile acid solutions

Cholesterol monohydrate has been used as a model substance in gallstone dissolution research (1). In earlier work in this laboratory, it was noticed that small changes in the experimental procedure resulted in significant variations in the dissolution rate behavior of cholesterol pellets. In some experiments when the pellet was stored overnight at 35° prior to a dissolution run, the initial dissolution rate was two to three times greater than the dissolution rate of freshly made pellets. Since it is desirable to limit the variations to ~10–15% in many mechanistic studies on cholesterol dissolution kinetics (1–4), the cause of dissolution rate variability was investigated.

## EXPERIMENTAL

Initially, the static-disk dissolution method was used, while the more quantitative rotating-disk dissolution method was used in the later analysis. The experimental procedures were described previously (5). All dissolution rate experiments were run at 37° in 5% sodium cholate and 0.1 *M* phosphate buffer at pH 8.00.

Pellets of radiolabeled cholesterol were prepared as described previously (5). Pellets placed in the dissolution cell without solvent for varying times at ambient (room) humidity or humidity of <100% at 35° will be referred to as aged pellets. The pellets kept at 100% humidity at ambient temperature for 24 hr will be referred to as normal pellets. This latter treatment was shown to give the same dissolution rate as that of freshly made pellets.

One hundred percent humidity containers were prepared by adding water to a desiccator until it completely filled the area under the plate. The other constant-humidity chambers were prepared by making saturated aqueous solutions (6) of 80% sodium bromide and of 40% calcium chloride which then were placed in an oven at 35°.

## RESULTS AND DISCUSSION

**Static-Disk Apparatus**—When small changes in the normal experimental procedure were introduced, significant differences in dissolution behavior resulted (Fig. 1 and Table I). Figure 2 shows the effects of exposing the pellets to ambient humidity at 35° for varying periods (aging). The normally treated pellet and the pellet aged for 1 hr gave the same dissolution rate as well as the same dissolution pattern (linear). However, aging the pellet for 12 or 24 hr markedly increased the initial dissolution rate (Table II). After a few hours of dissolution, these pellets showed a definite curvature in their dissolution profiles.

Figure 3 shows the effects of varying the humidity as well as varying

the exposure time. All pellets exposed to <100% humidity at 35° for 12 or 24 hr had an initial dissolution rate greater than that of the normally treated pellet. Table III summarizes the dissolution rates as a function of time and humidity.

At this point, it was felt that these results could be due to either dehydration of cholesterol monohydrate or to chemical decomposition (oxidation) of cholesterol. Bergstrom and Wintersteiner (7) showed that cholesterol in colloidal aqueous dispersions is attacked easily by oxygen. Weiner and coworkers (8–10) showed that monomolecular films also undergo autoxidation under different conditions. Dauben and Payot (11) showed that $^{14}C$-labeled cholesterol is unstable when stored in the presence of air. They found that the decomposition required both radiation and oxygen since unlabeled cholesterol was stable in air when stored under the same conditions and labeled material was stable when stored *in vacuo*. Thus, several factors are involved: oxygen concentration, wavelength of light, storage temperature, and surface area of the cholesterol sample. Cholesterol monohydrate is known to be converted to anhydrous cholesterol (12), although this conversion generally occurs at elevated temperatures (80–100°).

To determine the effects of temperature, humidity, and light on cholesterol dissolution, a series of experiments was run in the static-disk apparatus. By varying temperature and humidity and running the experiments in the presence and absence of room light, the contribution of each variable to the change in dissolution behavior was assessed. The effects of the variables at 100% humidity were relatively small, if any (Table IV). However, at ambient humidity, the effects on the dissolution rate of raising the temperature to 35° were large (dissolution rates varied

by approximately two times). Therefore, the combined effect of humidity and temperature appeared to be the primary cause for the aging effect.

Because it was felt that pellet aging might lead to cholesterol decomposition, samples of bile acid–cholesterol solutions were spotted onto TLC plates. These samples were obtained during the first 30 min of actual dissolution experiments; if decomposition products were causing the large rate of dissolution, it would be possible to determine this by TLC. The plates then were placed into a tank with acetic acid–carbon tetrachloride–isopropyl ether–isoamylacetate–*n*-propanol–benzene (5:20:30:40:10:10) as the solvent (13). Good separation of the bile acids and cholesterol was obtained. For both normal and aged pellet samples, one spot for cholesterol was found ($R_f$ 0.71). To confirm that the samples obtained for TLC were from differently dissolving pellets, another sample was drawn from each dissolution cell and counted on a liquid scintillation counter[1]. The radioactivities for the aged and normal pellets were 2346.2 and 1235.2 cpm, respectively. It can be concluded that the differences in pellet behavior were not due to cholesterol decomposition during aging.

To check the dehydration hypothesis, aged pellets then were soaked in double-distilled water at 37° for 24 hr. Figure 4 shows the comparison of normal pellets, aged pellets, and aged pellets followed by soaking. Soaking an aged pellet lowered the dissolution rate, but this decrease was much greater than expected and will be discussed later.

**Rotating-Disk Method**—Since minor procedural changes resulted in significant differences in the dissolution behavior of cholesterol pellets, an in-depth study was undertaken to determine if these differences were due to changes in solubility and/or interfacial transport. It was hoped that a better understanding of the changes would be gained. The pellets chosen for study were those shown in Fig. 4. As already seen, major differences were present in the dissolution rates.

To determine the dynamic solubility, initial dissolution rates were determined (5) and plotted against bulk concentration. Figures 5–7 show the results of the experiments carried out in 5% sodium cholate and 0.1 *M* phosphate buffer at pH 8.00. By extrapolating to a dissolution rate ($J/A$) of zero, it was possible to obtain the dynamic solubility. Figures 5–7 show a linear decrease in the dissolution rate as partial saturation is increased. This decrease indicates that the dissolution kinetics are proportional to the change in concentration ($\Delta C$) over the entire saturation range. From these figures, it can be seen that the solubility for the normal and soaked pellets was ~1.40 mg/ml while that for the aged pellet was ~1.73 mg/ml. The solubility obtained for the aged pellet was the same as that previously obtained (5) for the anhydrous pellets, which indicates that dissolution from the aged pellet occurs from the same phase as from the anhydrous pellets.

To look at the data in a slightly different way, plots of ($J/A$) *versus* the square root rotational speed ($\omega^{1/2}$) were prepared. Figures 8–10 show

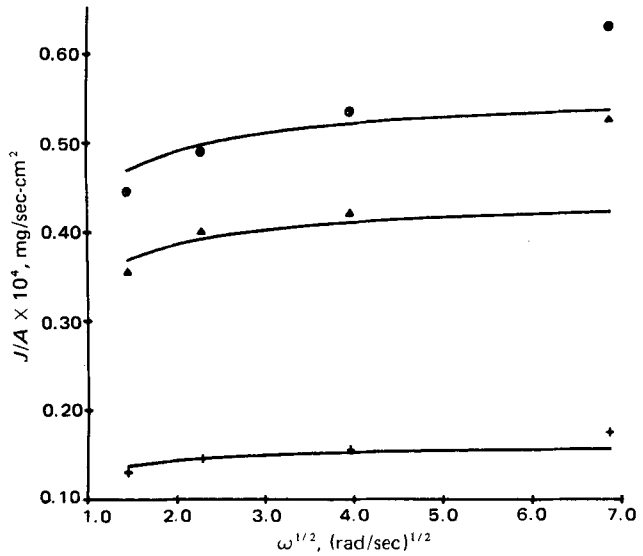

**Figure 10**—*Best-fit analysis of the soaked pellets in 5% sodium cholate and 0.1* M *phosphate buffer at pH 8.00. Key ($C_b$ in milligrams per milliliter): ●, 0.0; ▲, 0.3; and +, 1.0.*

| 1.45 | 150 | | | |
| 1.42 | 450 | | | |

[a] From extrapolation of partial saturation data.

clearly the important involvement of the interfacial barrier in dissolution. If the interfacial barrier was not significant in dissolution, a plot of $J/A$ *versus* $\omega^{1/2}$ would give a straight line through the origin.

Based on a best-fit analysis using the equation previously reported (5), $J = A(C_s - C_b)/[1.612D^{-2/3}\nu^{1/6}\omega^{-1/2} + 1/P]$, it was possible to obtain values for $C_s$, $P$, and $D$, where $P$ is the interfacial transport constant and $D$ is the diffusivity. The calculated dissolution rates using the best-fit values were compared to the experimental dissolution rates; there was a good fit between experiment and theory (Figs. 8–10). The points at 450 rpm ($\omega^{1/2} = 6.86$) were not weighted in this analysis (5).

Tables V–VII summarize the results of the partial saturation experiments and the best-fit analysis. The $P_{aged}$:$P_{normal}$ ratio was ~2.71, while the $P_{soaked}$:$P_{normal}$ ratio was ~0.78. Therefore, the differences in the dissolution rates can be accounted for primarily by significant changes in $P$.

Figure 11 shows a plot of the amount of cholesterol dissolved *versus* time for the normal and aged pellets at 150 rpm using the rotating-disk apparatus. The pattern of dissolution from the normal pellet was linear while that from the aged pellet showed a definite curvature after 1 hr (Figs. 2 and 4). The fact that the normal pellet showed a linear dissolution pattern indicates that dissolution occurs from a single phase (monohydrate). The curved dissolution pattern indicates that more than one phase probably takes part in the dissolution.

Because the solubilities for the aged and anhydrous pellets (5) are

similar, leaving the pellet at 35° and ambient humidity for 24 hr may effectively dehydrate the outer surface layer, thereby making the pellet anhydrous. After initial dissolution removes the outer layer, dissolution again is controlled by the more slowly dissolving monohydrate layers.

Another possible explanation for this dissolution pattern is that pellet dehydration is not just a phenomenon of the outer surface layer but that the internal portions of the pellet also dehydrate. When the pellet contacts the dissolution medium, the more rapidly dissolving anhydrous material is removed from the surface. Dissolution from the internal portions of the pellet now is controlled by both anhydrous cholesterol and cholesterol monohydrate. The deeper the dissolution goes into the pellet, the less anhydrous material is present. As the curvature becomes greater, more cholesterol monohydrate probably is exposed; thus, dissolution slows and begins to approach the dissolution rate of a normal pellet.

As shown in Fig. 4, pellets exposed to ambient humidity for 24 hr at 35° and then soaked in double-distilled water at 37° for 24 hr showed linear dissolution, which indicates that soaking of an aged pellet effectively rehydrates the pellet. This rehydration is seen in the fact that the solubilities for the soaked and normal pellets are similar. However, the reformation of the monohydrate is probably not to the original state, perhaps because of precipitation of cholesterol onto the pellet surface. The newly formed crystals might be another polymorph of cholesterol monohydrate or they might be more perfect crystals (fewer defects) with fewer effective sites available for dissolution. The lower dissolution rate seen for the soaked pellet can be accounted for by either explanation. If dissolution of the soaked pellet is studied for a long period (~24 hr), a second linear portion is seen in the dissolution profile. Its slope is closer to that of the normal pellet.

## CONCLUSION

From this analysis, the need for a uniform experimental procedure can be seen. If investigators hope to reproduce results within their own laboratories as well as reproduce other investigators' findings, standard experimental procedures must be defined and used.

# High-Pressure Liquid Chromatographic Analysis of Sennosides A and B Purgative Drugs

**OLUSEGUN OLUWOLE KOMOLAFE**

Received January 21, 1980, from the *Pharmaceutical Analysis Unit, Department of Pharmaceutical Chemistry, University of Ife, Ile-Ife, Nigeria.* Accepted for publication September 10, 1980.

**Abstract** □ Procedures are described for the analysis of the main anthraquinone glycosides of senna powder, senna fruit tablets, and sennoside tablets by high-pressure liquid chromatography (HPLC). In one HPLC analysis, TLC was used to separate the glycosides prior to elution on a strong anion-exchange column with 0.1 *M* ammonium nitrate solution (pH 9.0) as the mobile phase. In another HPLC analysis, separation was effected using a weak anion-exchange column with 0.1 *M* ammonium nitrate solution (pH 5.7) as the mobile phase.

**Keyphrases** □ Sennosides A and B—high-pressure liquid chromatographic analysis, separation of isomers from crude drug and pharmaceutical preparations □ Anthraquinone glycosides—high-pressure liquid chromatographic assay, separation of isomeric sennosides A and B from crude drug and pharmaceutical preparations □ High-pressure liquid chromatography—analysis, anthraquinone glycosides, separation of isomeric sennosides A and B from crude drug and pharmaceutical preparations □ Cathartics—anthraquinone glycosides, isomeric sennosides A and B, high-pressure liquid chromatographic analysis

The pods and leaves of senna as well as the pharmaceutical preparations containing sennosides A and B are widely used in medicine because of their laxative properties. An accurate, simple, and easy method is needed for estimation of sennosides A and B individually.

The most commonly used approach involves removal

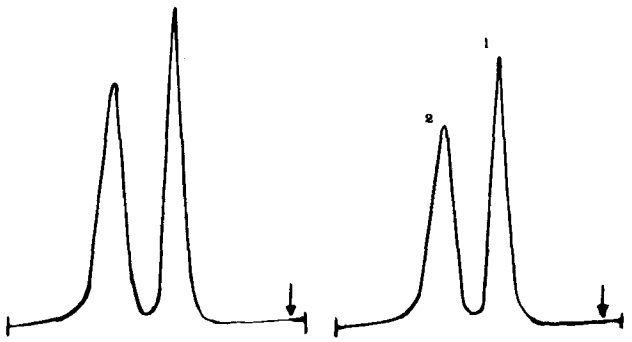

**Figure 1**—*Chromatogram of sennosides A (2) and B (1). The column was 600 × 2 mm i.d. (DuPont), strong anion exchange (30–40 μm). The mobile phase was ammonium nitrate solution (0.1 M, pH 9.0). UV detection was at 254 nm.*

of free aglycones by partitioning into an organic layer, hydrolysis and oxidation of the glycosides into aglycones and sugars, formation of colored derivatives by the action of aqueous alkali on the liberated aglycones, and absorption spectrophotometry (1–6). This procedure is not specific since it does not distinguish between the isomeric sennosides A and B but gives only a total sennoside content. Moreover, the procedure is ineffective since bianthrones such as the sennosides are not oxidized completely to anthraquinones (7, 8). The presence of several bianthrones in senna, rhubarb, cascara, and frangula suggested the need for a new assay.

The low concentrations of highly labile glycosides in their pharmacologically active forms in purgative drugs make liquid chromatography at ambient temperatures an attractive choice. Application of high-pressure liquid chromatography (HPLC) to the detection and separation of free and combined anthraquinone compounds has been reported (9–14), but HPLC has not been extended to the quantitation of anthraquinone glycosides in drugs and pharmaceutical preparations. This work attempted such a quantitation.

## EXPERIMENTAL

**Materials**—The authentic glycosides used were sennosides A and B. The drugs analyzed include powdered senna pods, senna fruit tablets[1] (each tablet contained sennosides A and B equivalent to 7.5 mg of sennoside B per tablet), and sennoside tablets[2] (each tablet contained 12 mg of sennosides A and B as calcium salts).

The HPLC eluates were monitored by UV detection at 254 nm. The strong anion-exchange columns used were 600 × 2 mm i.d., 30–40-μm particle size[3], and 125 × 4 mm i.d., 10-μm particle size[4]. The weak anion-exchange column was 600 × 2 mm i.d., 30–40-μm particle size[5]. An electronic integrator[6] was used for peak area measurement.

Silica gel was used for TLC. Precoated plastic sheets of silica gel (0.25 mm) containing a fluorescent indicator for UV detection at 254 nm also were used.

*n*-Propanol, ethyl acetate, ammonium hydroxide, nitric acid, and ethanol were analytical reagent grade. Aqueous reagents were prepared in deionized water, and all glassware was scrupulously cleaned.

**TLC**—The reference solution was prepared by dissolving sennoside A (~2 mg, accurately weighed) in the TLC mobile phase (1 ml) with gentle warming to effect complete dissolution. A reference solution of sennoside B was prepared similarly.

The test solution of senna powder, senna fruit tablets, or sennoside tablets was prepared by putting the powdered drug (~0.4 g of senna powder or senna fruit tablet powder or 0.2 g of sennoside tablet powder, accurately weighed) in a round-bottom flask and adding 5 ml of ethanol–water (50:50 v/v). The flask was weighed with its contents, a reflux condenser was attached, and the flask was heated in a boiling water bath for 15 min. Then the flask was cooled and adjusted to the original weight with ethanol (50% in water), and the contents were transferred to a centrifuge tube and centrifuged. The clear supernate was used for TLC spotting.

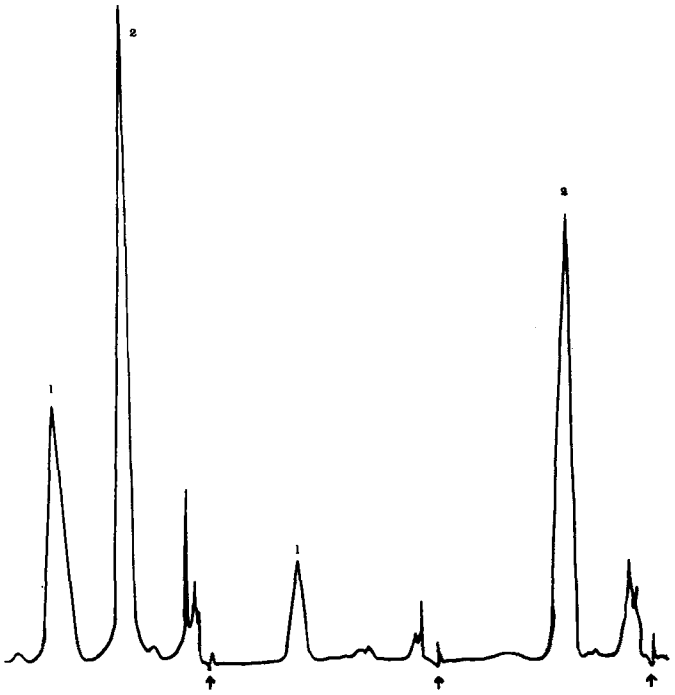

**Figure 2**—*Chromatogram of sennosides A (2) and B (1). The column was 125 × 4 mm i.d. (Partisil), strong anion exchange (10 μm). The mobile phase was ammonium nitrate solution (0.1 M, pH 7.5) and 15% ethanol. UV detection was at 254 nm.*

Aliquots (10 μl) of each standard and test solution were applied to the same chromatoplate, allowed to dry, and developed over a path of ~10 cm using *n*-propanol–ethyl acetate–water (40:40:30 v/v/v) as the developing solvent. The solvent was allowed to evaporate at room temperature, and the chromatoplate was examined under UV light to determine the spots corresponding to those of the standards.

**HPLC of TLC Spots**—Ten TLC spots from each authentic sennoside

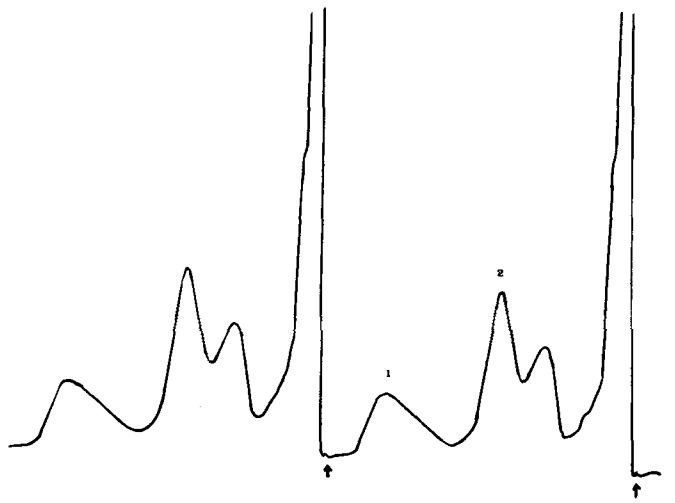

**Figure 3**—*Chromatogram of the aqueous extract of senna. The column was 600 × 2 mm i.d. (AL Pellionex), weak anion exchange (30–40 μm). The mobile phase was ammonium nitrate solution (0.1 M, pH 5.7). UV detection was at 254 nm. Key: 1, sennoside B; and 2, sennoside A.*

**Table I—Sennosides A and B Content [a] of Purgative Drugs as Determined by HPLC**

| Sample | Sennoside A Content, mg (SAX[b]) | Sennoside B Content, mg SAX[b] | Sennoside B Content, mg WAX[c] | Label (Colorimetric Assay) |
|---|---|---|---|---|
| Senna (per gram) | 14.2 | 13.9 | 14.3 | 28.6 |
| Senna fruit tablets (per tablet) | 3.5 | 3.3 | 3.62 | 7.5 |
| Sennoside tablets (per tablet) | 5.9 | 5.8 | 6.05 | 12.0 |

[a] Mean of three determinations. [b] SAX = strong anion-exchange column (30–40 μm) with 0.1 *M* ammonium nitrate solution (pH 9.0) as the mobile phase. [c] WAX = weak anion-exchange column (30–40 μm) with 0.1 *M* ammonium nitrate solution (pH 5.7) as the mobile phase.

spot were extracted with the HPLC mobile phase (1 ml), and a 10-μl portion was injected into the chromatograph and eluted under the following conditions. Column 1 was Zipax, strong anion exchange (30–40 μm), with a mobile phase of 0.1 *M* ammonium nitrate solution (pH 9.0). Column 2 was Partisil, strong anion exchange (10 μm), with a mobile phase of 0.1 *M* ammonium nitrate solution (pH 7.5) and 15% ethanol. The flow rate was 1 ml/min. UV detection was at 254 nm, and attenuation was set at ×16.

Ten TLC spots of the crude senna drug corresponding to sennoside A were extracted with the HPLC mobile phase (1 ml) and eluted under the same experimental conditions as for the authentic sennosides.

Similarly, 10 TLC spots corresponding to sennoside B in the crude senna drug were extracted with the HPLC mobile phase (1 ml) and eluted under the same experimental conditions as for the authentic sennosides. The sennosides A and B content of senna fruit tablets and sennoside tablets also was determined using the same experimental procedure and conditions as outlined for crude senna drug.

**Direct HPLC Analysis**—Sennosides A and B were dissolved in 0.1 *M* ammonium nitrate (pH 5.7) containing a trace of ammonia solution to give a concentration of ~1 mg/ml each. Aliquots (10 μl) were injected into the chromatograph under the following conditions. The column was AL Pellionex weak anion exchange (30–40 μm), with a mobile phase of 0.1 *M* ammonium nitrate (pH 5.7) at a flow rate of 1 ml/min. UV detection was at 254 nm, and attenuation was set at ×16.

Senna pods or senna fruit tablets (~0.5 g of each drug powder, accurately weighed) was placed in a round-bottom flask with deionized water (10 ml). After the flask was weighed with its contents, it was refluxed in a boiling water bath for 15 min, cooled, and adjusted to the original weight with deionized water. The aqueous extract was centrifuged, and portions of the clear supernate (10 μl) were chromatographed or were mixed with the authentic sennoside solutions and then chromatographed. The same elution conditions were used as for the standard solutions.

In the assay of sennoside tablets, one tablet was ground to a fine powder and then triturated with the mobile phase (5 ml). The suspension obtained was centrifuged and 10-μl portions of the clear supernate were chromatographed or were mixed with the authentic sennoside solutions and then chromatographed under the same conditions used for the standard solutions.

## RESULTS AND DISCUSSION

Preliminary investigations showed that the use of different solvents for extraction did not affect the yield or form of the sennosides. This finding is in agreement with the observation of previous workers (15, 16) who found that hot water or water containing up to 70% methanol, ethanol, or acetone effects extraction of most glycosidal contents in a drug–percolate ratio of 1:6. Comparison of the high-pressure liquid chromatograms of the drug extracts containing authentic sennosides with those that did not confirmed the presence of the sennosides in the drugs.

Variations of the HPLC elution parameters (pH and ionic strength)

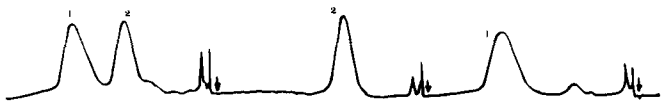

**Figure 4**—*Chromatogram of sennosides A (2) and B (1). The column was 600 × 2 mm i.d. (AL Pellionex), weak anion exchange (30–40 μm). The mobile phase was ammonium nitrate solution (0.1* M, *pH 5.7). UV detection was at 254 nm.*

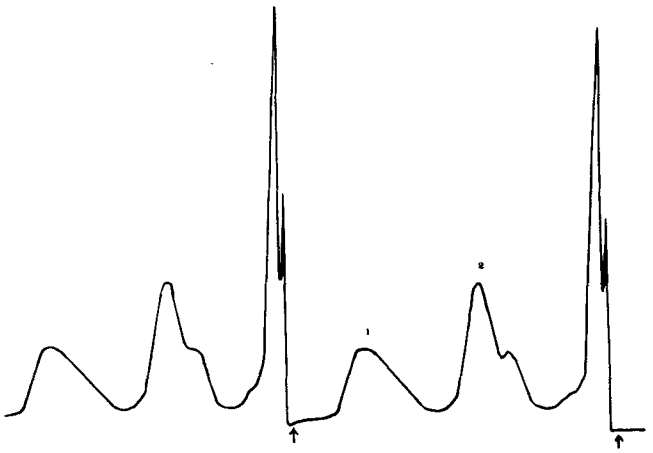

**Figure 5**—*Chromatogram of the ammonium nitrate extract of sennoside tablets. The column was 600 × 2 mm i.d. (AL Pellionex), weak anion exchange (30–40 μm). The mobile phase was ammonium nitrate solution (0.1* M, *pH 5.7). UV detection was at 254 nm. Key: 1, sennoside B; and 2, sennoside A.*

showed that the optimum conditions for the elutions of sennosides A and B in the two strong anion exchangers included 0.1 *M* ammonium nitrate (pH 9.0) in the larger particle chromedium and 0.1 *M* ammonium nitrate (pH 5.7) containing 15% ethanol in the 10-μm chromedium. At the optimum operational conditions, pure sennosides A and B had symmetrical peaks with good peak width and retention times, and they were well separated from each other. However, the resolution obtained on the larger particle chromedium was better than that obtained on the smaller particle chromedium (Figs. 1 and 2). Ethanol had to be added to the ammonium nitrate mobile phase to obtain elution of the glycosides on the 10-μm ion exchanger within a reasonable time. Alcohol molecules probably block the active adsorption sites on the chromedium, resulting in faster elution of the glycoside molecules.

The chromatogram obtained for senna fruit tablets was similar to that for senna pods on both the strong and weak anion-exchange columns (Fig. 3). This result was expected since senna fruit tablets are made from powdered senna pods. It was anticipated that the 10-μm strong anion exchange chromedium would produce better resolution than the larger particle chromedium (30–40 μm) and that the resolution might free the sennosides from unwanted matter. However, both strong anion-exchange systems, at the optimum elution conditions, did not achieve this end, making direct quantitation of the sennosides A and B content of the drug extracts impossible. However, elutions on the strong anion-exchange column (30–40 μm) with ammonium nitrate (pH 9.0) as the mobile phase gave improved separation of peaks with a decrease in the ionic strength of the mobile phase. The chromatogram of a 0.02 *M* ammonium nitrate solution showed that sennoside A was completely separated from all other peaks, although the retention time was very long (48 min) and the peak width was broad (3 cm). Therefore, direct HPLC quantitation of sennoside A in the crude purgative drug and pharmaceutical preparations might be possible using solvent programming.

TLC of pure sennoside A showed a major spot of $R_f$ 0.31 and a minor spot of $R_f$ 0.51 due to an impurity. TLC of pure sennoside B showed a major spot of $R_f$ 0.16 and two minor spots of $R_f$ 0.34 and 0.048 due to impurities (6, 8). Sennosides A and B in the drug samples were well separated by TLC. The results of the assay based on HPLC of the TLC spots are shown in Table I.

In the direct HPLC elutions of the aqueous extracts of senna pods, senna fruit tablets, and sennoside tablets using the weak anion-exchange column, only sennoside B was well separated from all other components of the drug constituents. Thus, it was possible to estimate only the sennoside B content of the drug by comparison of the peak area with that of authentic sennoside B solution of known concentration (Table I and Figs. 3–5).

The ion-exchange chromatographic separation of the sennosides from the other drug constituents is based on the presence of a carboxylic acid functional group on the sennoside molecules. Since sennosides A and B have the same functional groups and the same molecular configuration, the separation of one from the other on the ion-exchange column must include some other phenomenon (*e.g.*, hydrogen bonding, polar interaction, adsorption, or van der Waals forces) in addition to the reversible exchange of ions between the solute and the electrolyte gel.

# Dosage Form Design for Improvement of Bioavailability of Levodopa IV: Possible Causes of Low Bioavailability of Oral Levodopa in Dogs

**KUNIHIRO SASAHARA ˣ, TAKASHI NITANAI, TAEKO HABARA, TOSHIMASA KOJIMA, YUKINORI KAWAHARA, TADASHI MORIOKA, and EIICHI NAKAJIMA**

Received April 11, 1980, from the *Product Development Laboratories, Sankyo Company, Ltd., 1-2-58, Hiromachi, Shinagawa, Tokyo, Japan.* Accepted for publication September 30, 1980.

**Abstract** □ Several potential mechanisms for reduced levodopa bioavailability following oral administration to dogs and humans were investigated by studying the influence of the administration route on plasma levodopa levels after intravenous, hepatoportal, and duodenal administrations to dogs. The observed average areas under the plasma concentration–time curves (*AUC*) of levodopa following hepatoportal injection and intravenous injection were virtually identical; but following duodenal administration a decrease in the *AUC* of levodopa was observed with a concomitant increase in the *AUC* of total dopamine. The possible involvement of intestinal microorganisms in levodopa metabolism was explored in dogs that had been administered a combination of paromomycin and kanamycin to reduce intestinal microflora. Similar patterns of plasma level profiles and urinary excretion were observed between control and treated dogs. As measured by the release of [$^{14}$C]carbon dioxide from [$^{14}$C]levodopa, the distribution of levodopa decarboxylase enzyme activity in various parts of the intestine was studied in homogenates prepared from isolated intestinal segments of the duodenum and upper, middle, and lower parts of the jejunum and ileum. The jejunum showed the highest decarboxylase activity followed by the ileum and duodenum. These data indicate that the reduced bioavailability of orally administered levodopa occurs as a result of metabolism by levodopa decarboxylase enzyme in the gut wall.

**Keyphrases** □ Levodopa—bioavailability, effect of administration route, metabolism, intestinal microorganisms, levodopa decarboxylase □ Bioavailability—levodopa, effect of administration route □ Antiparkinsonian agents—levodopa, effect of administration route on bioavailability

Previous studies (1, 2) reported that, based on the measurement of levodopa and its metabolites recovered in the urine, the total amount absorbed, including levodopa metabolites, was 80–90% of the administered dose. However, the measurements of plasma levodopa concentrations after intravenous and oral administrations indicated that 20–40% of the administered dose reached the fluids of distribution intact.

The present study with levodopa was carried out in dogs to elucidate the mechanisms responsible for the low bioavailability of orally administered levodopa.

## EXPERIMENTAL

**Influence of Administration Route on Plasma Levodopa Levels and Its Metabolites in Dogs**—Nine healthy male beagle dogs, 10.5–13.2 kg, were fasted for ~16 hr and divided into three groups. They were anesthetized with 25 mg of pentobarbital sodium/kg iv. The first group was administered 20-mg doses of levodopa[1] into their brachial vein over 30 sec. After the dogs in the second group were fixed on their backs, a laparotomy was performed and levodopa solution[1] was administered directly into the hepatoportal veins over 30 sec. A laparotomy was performed in the third group, a 20-cm segment of the duodenum was ligated, and levodopa solution was administered into the ligated loop.

Blood samples were withdrawn from each animal with a heparinized syringe from the femoral or brachial vein at the time intervals indicated in Fig. 1. The blood specimens obtained were processed as described previously (1, 3). The third group was killed by exsanguination immediately after the last blood sample was collected, and the ligated duodenal loops were removed to determine residual levodopa and its metabolites in the duodenal loops where levodopa was administered. The contents of the duodenal loops were washed with saline and then three times with 0.04 *N* $HClO_4$ solution. The irrigating solutions were assayed for residual levodopa and its metabolites.

**Influence of GI Microorganisms on Oral Levodopa Absorption**—Two healthy male mongrel dogs, 6.0 and 11.8 kg, were orally administered a single capsule containing 110 mg of paromomycin and 100 mg of kanamycin. Two control dogs also were used. The dogs were anesthetized with intravenous injection of 25 mg of pentobarbital sodium/kg. After anesthetization, a laparotomy was performed and a series of intestinal loops were made by ligating segments of the stomach, duodenum, and jejunum. The contents of each segment were suspended in saline solution and diluted with 0.1% phosphate buffer (pH 7.2). The

# Dosage Form Design for Improvement of Bioavailability of Levodopa IV: Possible Causes of Low Bioavailability of Oral Levodopa in Dogs

**KUNIHIRO SASAHARA ˣ, TAKASHI NITANAI, TAEKO HABARA, TOSHIMASA KOJIMA, YUKINORI KAWAHARA, TADASHI MORIOKA, and EIICHI NAKAJIMA**

Received April 11, 1980, from the *Product Development Laboratories, Sankyo Company, Ltd., 1-2-58, Hiromachi, Shinagawa, Tokyo, Japan.* Accepted for publication September 30, 1980.

**Abstract** □ Several potential mechanisms for reduced levodopa bioavailability following oral administration to dogs and humans were investigated by studying the influence of the administration route on plasma levodopa levels after intravenous, hepatoportal, and duodenal administrations to dogs. The observed average areas under the plasma concentration–time curves (*AUC*) of levodopa following hepatoportal injection and intravenous injection were virtually identical; but following duodenal administration a decrease in the *AUC* of levodopa was observed with a concomitant increase in the *AUC* of total dopamine. The possible involvement of intestinal microorganisms in levodopa metabolism was explored in dogs that had been administered a combination of paromomycin and kanamycin to reduce intestinal microflora. Similar patterns of plasma level profiles and urinary excretion were observed between control and treated dogs. As measured by the release of [$^{14}$C]carbon dioxide from [$^{14}$C]levodopa, the distribution of levodopa decarboxylase enzyme activity in various parts of the intestine was studied in homogenates prepared from isolated intestinal segments of the duodenum and upper, middle, and lower parts of the jejunum and ileum. The jejunum showed the highest decarboxylase activity followed by the ileum and duodenum. These data indicate that the reduced bioavailability of orally administered levodopa occurs as a result of metabolism by levodopa decarboxylase enzyme in the gut wall.

**Keyphrases** □ Levodopa—bioavailability, effect of administration route, metabolism, intestinal microorganisms, levodopa decarboxylase □ Bioavailability—levodopa, effect of administration route □ Antiparkinsonian agents—levodopa, effect of administration route on bioavailability

Previous studies (1, 2) reported that, based on the measurement of levodopa and its metabolites recovered in the urine, the total amount absorbed, including levodopa metabolites, was 80–90% of the administered dose. However, the measurements of plasma levodopa concentrations after intravenous and oral administrations indicated that 20–40% of the administered dose reached the fluids of distribution intact.

The present study with levodopa was carried out in dogs to elucidate the mechanisms responsible for the low bioavailability of orally administered levodopa.

## EXPERIMENTAL

**Influence of Administration Route on Plasma Levodopa Levels and Its Metabolites in Dogs**—Nine healthy male beagle dogs, 10.5–13.2 kg, were fasted for ~16 hr and divided into three groups. They were anesthetized with 25 mg of pentobarbital sodium/kg iv. The first group was administered 20-mg doses of levodopa[1] into their brachial vein over 30 sec. After the dogs in the second group were fixed on their backs, a laparotomy was performed and levodopa solution[1] was administered directly into the hepatoportal veins over 30 sec. A laparotomy was performed in the third group, a 20-cm segment of the duodenum was ligated, and levodopa solution was administered into the ligated loop.

Blood samples were withdrawn from each animal with a heparinized syringe from the femoral or brachial vein at the time intervals indicated in Fig. 1. The blood specimens obtained were processed as described previously (1, 3). The third group was killed by exsanguination immediately after the last blood sample was collected, and the ligated duodenal loops were removed to determine residual levodopa and its metabolites in the duodenal loops where levodopa was administered. The contents of the duodenal loops were washed with saline and then three times with 0.04 *N* $HClO_4$ solution. The irrigating solutions were assayed for residual levodopa and its metabolites.

**Influence of GI Microorganisms on Oral Levodopa Absorption**—Two healthy male mongrel dogs, 6.0 and 11.8 kg, were orally administered a single capsule containing 110 mg of paromomycin and 100 mg of kanamycin. Two control dogs also were used. The dogs were anesthetized with intravenous injection of 25 mg of pentobarbital sodium/kg. After anesthetization, a laparotomy was performed and a series of intestinal loops were made by ligating segments of the stomach, duodenum, and jejunum. The contents of each segment were suspended in saline solution and diluted with 0.1% phosphate buffer (pH 7.2). The

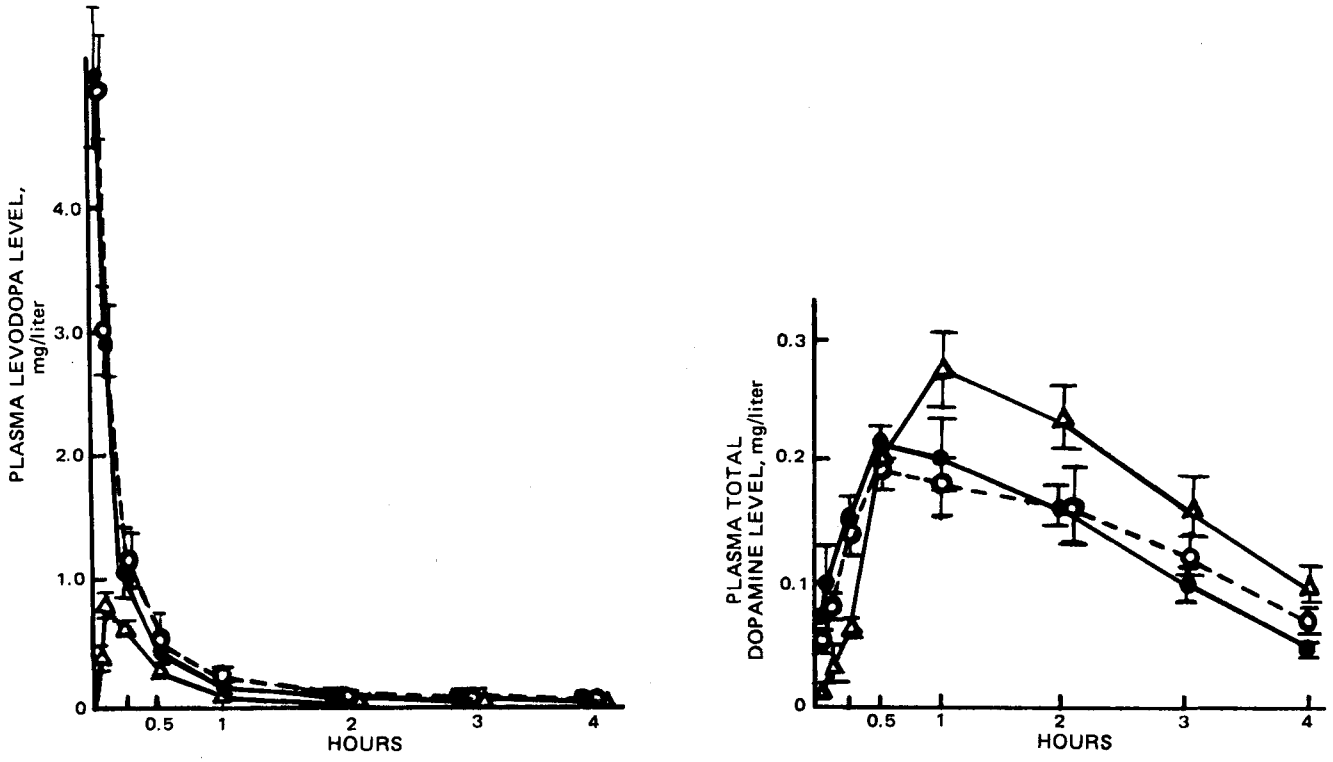

**Figure 1**—*Average plasma levels of levodopa (±SE) and total dopamine (±SE) following intravenous (●), hepatoportal (○), and duodenal (△) administrations of single 20-mg doses of levodopa to three dogs.*

diluted solution was smeared on the selective medium and cultured according to the conditions listed in Table I. After cultivation, the numbers of colonies were counted.

Following this initial study, six healthy male beagle dogs, 10.1–12.5 kg, were fasted for ~16 hr; levodopa in capsule form[2] was administered orally at a dose of 100 mg/dog with 10 ml of warm water. After 1 week, the same dogs were administered a single dose of the antibiotics as before, and levodopa in capsule form[2] was administered as previously described. Emesis was prevented by keeping the dogs' mouths closed by hand. Blood samples were obtained with a heparinized syringe at the intervals indicated in Fig. 2. The urine also was collected before and over 48 hr. The blood and urine samples were processed as previously described (1, 3).

**Distribution of Levodopa Decarboxylase Enzyme Activity in Intestinal Tract of Dogs**—Three healthy male mongrel dogs, 13.0–15.0 kg, were fasted for ~16 hr, anesthetized with 25 mg of pentobarbital sodium/kg iv, and then killed by exsanguination. Their abdomens were opened immediately, and sections of the duodenum and upper, middle, and lower parts of the jejunum and ileum were removed. The contents in each section were removed by washing three times with saline.

An homogenate of each section of the intestinal tract was prepared in 0.05 *M* phosphate buffer (pH 6.8) cooled to 0°. The volume was adjusted to reflect the final wet tissue concentration of 100 mg/ml. Then 0.2–0.5 ml of each homogenate was added to the reaction mixture consisting of 0.2 ml of 0.2 *M* phosphate buffer (pH 6.8), 0.05 ml of 0.5% (w/v) pyridoxal phosphate solution, 0.1 ml of 8.1% levodopa solution [1 g of levodopa dissolved with 0.2% (w/v) sodium bicarbonate and 0.5% (w/v) polyvinyl acetate] and $^{14}$C-labeled DL-levodopa (0.05 $\mu$Ci/410 nmoles) and then incubated for 30 min at 37°. At 30 min after incubation, the reaction was stopped by adding 0.2 ml of 30% (w/v) $HClO_4$ solution into the reaction mixture.

The [$^{14}$C]carbon dioxide evolved from decarboxylation of [$^{14}$C]levodopa by levodopa decarboxylase in the homogenate was trapped completely in filter paper impregnated with benzethonium chloride solution[3]. The filter paper was immersed in a toluene scintillation mixture of 8 g of 2,5-diphenyloxazole and 0.2 g of 1,4-bis[2-(4-methyl-5-phenyloxazoly)]-benzene dissolved in 1000 ml of toluene. The trapped radioactivity was measured by the standard procedure.

**Assay of Levodopa and Its Metabolites in Plasma and Urine**—The assay of levodopa and its metabolites in plasma and urine was carried out as previously reported (3).

**Assay of Levodopa and Its Metabolites at Administration**—Residual levodopa and its metabolites were determined in the same manner as urine.

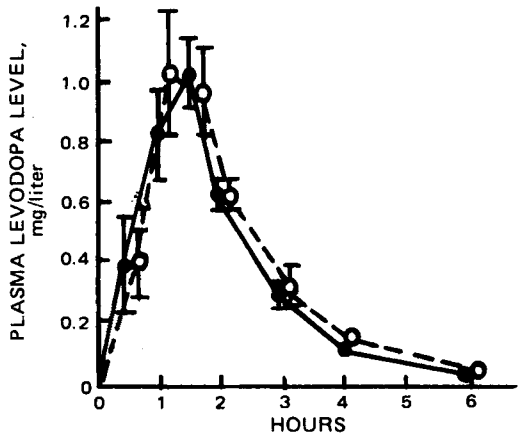

**Figure 2**—*Average plasma levodopa levels following oral administration of 100-mg doses of levodopa to six dogs treated with antibiotics (○) and to six control dogs without antibiotics (●) in a crossover fashion.*

## RESULTS

**Influence of Administration Route on Plasma Levels of Levodopa and Its Metabolites in Dogs**—The average plasma levels of levodopa and total dopamine, one of the main metabolites of levodopa, are shown in Fig. 1 following intravenous, hepatoportal, and intraduodenal administrations to dogs. Visual inspection of average plasma levodopa level curves following intravenous and hepatoportal administrations indicates that their overall disposition profiles appear similar. However, the average plasma levodopa level curves following duodenal administration were lower than observed following intravenous or hepatoportal administra-

[2] Levodopa in capsule form was prepared in the same prescription as Dopaston capsules, Sankyo Co., Tokyo, Japan.

[3] This benzethonium chloride solution was prepared from a 10-fold dilution of Hyamine, Sankyo Co., Tokyo, Japan.

**Table I—Selective Medium and Cultivation Conditions**

| Bacteria | Medium | Cultivation Conditions |
|---|---|---|
| *Enterobacteriaceae* | MacConkey agar | 37°/24 hr |
| *Streptococcus* | Endo agar | 37°/48 hr |
| *Staphylococcus* | Mannitol salt agar | 37°/48 hr |
| *Lactobacillus* | LBS agar | 37°/72 hr |

tion. On the other hand, the average plasma total dopamine levels following duodenal administration were higher than following other routes.

The average *AUC* of levodopa and total dopamine and the average ratio of the *AUC* of total dopamine to the *AUC* of levodopa are summarized in Table II. The *AUC* plots of levodopa following intravenous and hepatoportal administrations were approximately identical, but the *AUC* of levodopa following duodenal administration was significantly different from that after the other forms of administration ($p < 0.05$, $t$-test); for the *AUC* of total dopamine, the situation was inverse. The higher ratio of the *AUC* of total dopamine to the *AUC* of levodopa following duodenal administration lends evidence for the postulation that this organ is involved in levodopa metabolism. In contrast, the hepatoportal ratio did not differ significantly from that observed after intravenous administration. In addition, the residual amounts of levodopa and the total of all its metabolites at 4 hr after administration in the duodenal site were <1%. Since only insignificant levels of levodopa and its metabolites were observed, levodopa was absorbed almost completely from the duodenum.

**Influence of GI Microorganisms on Oral Levodopa Absorption**—The aerobic bacterial counts in each part of the GI tract, including the stomach, duodenum, and jejunum, in dogs treated with a single dose of paromomycin and kanamycin in contrast to control dogs are compared in Table III. The treatment led to a decrease in the number of aerobic organisms in the gut tested.

The average plasma levodopa levels following oral administration to antibiotic-treated dogs and to control dogs in crossover fashion are shown in Fig. 2. Visual inspection of average plasma levodopa level curves following oral administration to those dogs indicates that their overall disposition profiles were essentially identical. Table IV summarizes the average urinary excretion of levodopa and its metabolites after oral administration of levodopa to those dogs.

These results show that there was no difference between the dogs with and without antibiotics. Unfortunately, the results are ambiguous since the observed reduction in intestinal bacterial flora may not have been sufficient to affect levodopa metabolism, and only the reduction in aerobic organisms in the stomach, duodenum, and jejunum was observed[4]. However, the flora in these areas are thought to be predominantly aerobic.

**Distribution of Levodopa Decarboxylase Enzyme Activity in Intestinal Tract of Dogs**—Figure 3 shows the distribution of levodopa decarboxylase activity responsible for levodopa metabolism in the different parts of the intestinal tract of dogs. The jejunum showed the highest decarboxylase activity, as measured by the release of [$^{14}$C]carbon dioxide from labeled levodopa, followed by the ileum and then the duodenum.

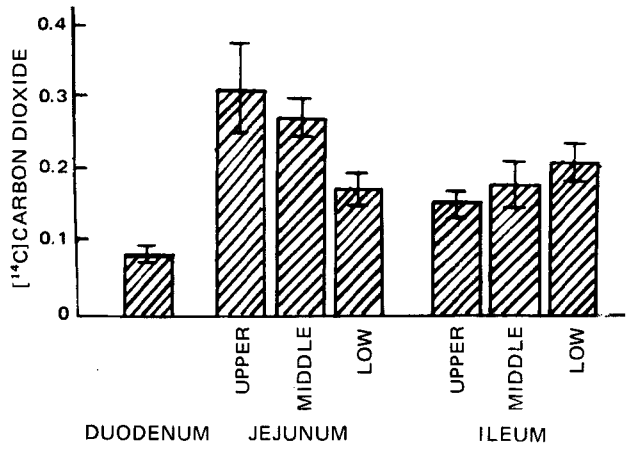

**Figure 3**—*Average distribution of levodopa decarboxylase activity in the different parts of the intestinal tract of dogs.*

[4] The duodenum will be shown to be the major absorption site in the next paper of this series.

**Table II—Average *AUC* of Levodopa and Total Dopamine and Ratio of *AUC* of Total Dopamine to Levodopa following Intravenous, Hepatoportal, and Duodenum Administrations to Dogs [a]**

| Route | *AUC* of Levodopa, (mg hr)/liter | *AUC* of Total Dopamine, (mg hr)/liter | Ratio of *AUC* of Total Dopamine to Levodopa |
|---|---|---|---|
| Intravenous | 1.70 ± 0.09[b] | 0.56 ± 0.14 | 0.34 ± 0.02 |
| Hepatoportal | 1.85 ± 0.10 | 0.57 ± 0.03 | 0.31 ± 0.01 |
| Duodenum | 0.65 ± 0.06 | 0.78 ± 0.07 | 1.20 ± 0.10 |

[a] The *AUC* from 0 to 4 hr was calculated using the trapezoidal rule. [b] Average ± *SE*.

## DISCUSSION

It was previously reported (1, 2) that the dose-dependent bioavailability of levodopa after oral administration to dogs and parkinsonian patients was probably due to metabolism during levodopa absorption. The plasma level profiles of levodopa and total dopamine were compared subsequent to intravenous, hepatoportal, and duodenal administrations to dogs. Analysis of the residual levels of levodopa and its metabolites in the duodenal loop indicated virtually complete levodopa absorption. However, plasma levodopa levels following duodenal administration were lower and plasma total dopamine levels were higher than those found after administration by other routes, leading to the highest ratio of the *AUC* of total dopamine to levodopa following duodenal administration. At the same time, the plasma level profiles of levodopa and total dopamine, the *AUC* of levodopa and total dopamine, and the ratio of the *AUC* of total dopamine to levodopa following the hepatoportal vein administration and intravenous administration were virtually identical.

These observations indicate that the first-pass metabolism of levodopa probably involves intestinal wall metabolism and, to a small extent, liver metabolism. This result is consistent with the conclusion reported previously (4, 5). Utilizing the isolated perfused rat liver technique, Mearrick *et al.* (4) reported that the major site of levodopa metabolism was the small intestine. Cotler *et al.* (5) administered [$^{14}$C]levodopa to dogs *via* hepatoportal, intravenous, and oral administrations on three separate occasions in crossover fashion. Comparisons of plasma levodopa level profiles *via* these administration routes led to the result that the physiologically impaired bioavailability of orally administered levodopa occurs virtually exclusively in the GI tract.

These results suggest the importance of levodopa metabolism in the intestine or the mucosal wall.

In addition, a similar degree of absorption and metabolism of levodopa was observed between control dogs and dogs whose numbers of intestinal bacteria decreased by treatment with antibiotics. Unfortunately, the results are not conclusive. Bakke (6) reported that levodopa was me-

Table IV—Average Urinary Excretion of Levodopa and Its Metabolite after Oral Administration of Levodopa to Sterilized Dogs and Control Dogs

| Dogs | Total Levodopa[a] | Total Dopamine[b] | Total 3,4-Dihydroxyphenylacetic Acid[c] | Total Homovanillic Acid[d] | Total[e] |
|---|---|---|---|---|---|
| Control | 0.47 ± 0.07[f] | 8.9 ± 1.2 | 9.3 ± 1.4 | 30.4 ± 2.3 | 49.1 ± 2.4 |
| Sterilized | 0.47 ± 0.07 | 9.5 ± 1.6 | 10.1 ± 1.3 | 30.7 ± 2.5 | 50.7 ± 2.7 |

[a] Total levodopa = unconjugated levodopa + conjugated levodopa. [b] Total dopamine = unconjugated dopamine + conjugated dopamine. [c] Total 3,4-dihydroxyphenylacetic acid = unconjugated 3,4-dihydroxyphenylacetic acid + conjugated 3,4-dihydroxyphenylacetic acid. [d] Total homovanillic acid = unconjugated homovanillic acid + conjugated homovanillic acid. [e] Sum of total levodopa, total dopamine, total 3,4-dihydroxyphenylacetic acid, and total homovanillic acid. [f] Percent of dose excreted in 0–48-hr urine (average ± *SE*).

tabolized by intestinal microorganisms *in vitro* to *m*-hydroxyphenylacetic acid, 4-methylcatechol, and 4-methylguaiacol. Furthermore, levodopa was reported to be metabolized by intestinal microorganisms to *m*-hydroxyphenylacetic acid *in vivo* in conventional rats but not in germ-free rats (7–9). However, the small amount of metabolites formed by intestinal microorganisms reported by Bakke (6) and the fast absorption of levodopa from dogs observed in an *in situ* experiment[5] support the hypothesis that bacterial metabolism of levodopa may be insignificant.

The levodopa decarboxylase enzyme was widely distributed in the dog intestinal tract, with the greatest activity in the jejunum and the least activity in the duodenum. Taubin and Landsberg (10) suggested that catechol *O*-methyltransferase also played an important role in levodopa metabolism in the rat intestine. Administration of the levodopa inhibitor or benzerazide [*N*-*dl*-seryl-*N*-(1,2,3-trihydroxybenzyl)hydrazine], which cannot inhibit catechol *O*-methyltransferase, increased plasma levodopa levels (11–14). This finding implies that catechol *O*-methyltransferase plays a far less important role in intestinal metabolism of levodopa than levodopa decarboxylase.

The data presented here indicate that the reduced bioavailability of orally administered levodopa is due to metabolism of levodopa by levodopa decarboxylase in the intestine, with the greatest activity in the jejunum and the least activity in the duodenum.

# Computational Problems of Compartment Models with Michaelis–Menten-Type Elimination

**CARL M. METZLER *x and D. D. M. TONG ‡**

Received April 8, 1980, from **PR&D Biostatistics, The Upjohn Company, Kalamazoo, MI 49001*, and ‡*Western Michigan University, Kalamazoo, MI 49008.* Accepted for publication December 2, 1980.

**Abstract** □ The Michaelis–Menten equation has been applied successfully in the study of enzyme kinetics. It usually is used to estimate $v_{max}$ and $k_m$ from observations of the initial rate of reaction, $v$, at various substrate concentrations, $C_s$. A variation of this expression recently was used in pharmacokinetics, where it was assumed that the elimination rate of drug from some compartment is $VC(t)/[K + C(t)]$, where $C(t)$ is the drug concentration. The meaning of $V$ and $K$ in this context is not clear. Attempts were made to estimate $V$, $K$, and other model parameters by fitting the model to observed drug concentrations at sampling times after dosing. This paper discusses the ill-conditioning of the estimation of parameters of a differential equation that includes the so-called Michaelis–Menten output. The solution of the equation is bound by the solutions to two first-order differential equations. Parameter values in an infinite region of the parameter space are shown to have solutions also lying within these two bounds. Simulations show that a minor change in the data (observations) or in the initial estimate of the parameters may cause a large change in the final estimates. In many cases, estimation and comparison of parameter values are meaningless.

**Keyphrases** □ Models, mathematical—compartment models with Michaelis–Menten-type elimination, computational problems, parameter estimation □ Michaelis–Menten equation—computational problems of compartment models, parameter estimation □ Compartment models—computational problems of models with Michaelis–Menten-type elimination, parameter estimation □ Pharmacokinetics—analysis, computational problems of compartment models with Michaelis–Menten-type elimination, parameter estimation

Linear compartment models have been used successfully in pharmacokinetics for the past 40 years. Like all mathematical models, they are an abstraction from the real biological system to a mathematical system and thus are

## ACKNOWLEDGMENTS

Presented in part at the Pharmaceutical Section, Pharmaceutical Society of Japan, Tokyo meeting, April 1977.

The authors thank Dr. T. Higuchi for valuable discussions, Dr. H. Negoro, Dr. S. Akagi, and Dr. T. Miki for the promotion of the research project, Dr. S. Riegelman for constructive comments on the manuscript, and Mrs. S. Tsutsumi for typing the manuscript.

# Computational Problems of Compartment Models with Michaelis–Menten-Type Elimination

**CARL M. METZLER *x and D. D. M. TONG ‡**

Received April 8, 1980, from **PR&D Biostatistics, The Upjohn Company, Kalamazoo, MI 49001*, and ‡*Western Michigan University, Kalamazoo, MI 49008.* Accepted for publication December 2, 1980.

**Abstract** □ The Michaelis–Menten equation has been applied successfully in the study of enzyme kinetics. It usually is used to estimate $v_{max}$ and $k_m$ from observations of the initial rate of reaction, $v$, at various substrate concentrations, $C_s$. A variation of this expression recently was used in pharmacokinetics, where it was assumed that the elimination rate of drug from some compartment is $VC(t)/[K + C(t)]$, where $C(t)$ is the drug concentration. The meaning of $V$ and $K$ in this context is not clear. Attempts were made to estimate $V$, $K$, and other model parameters by fitting the model to observed drug concentrations at sampling times after dosing. This paper discusses the ill-conditioning of the estimation of parameters of a differential equation that includes the so-called Michaelis–Menten output. The solution of the equation is bound by the solutions to two first-order differential equations. Parameter values in an infinite region of the parameter space are shown to have solutions also lying within these two bounds. Simulations show that a minor change in the data (observations) or in the initial estimate of the parameters may cause a large change in the final estimates. In many cases, estimation and comparison of parameter values are meaningless.

**Keyphrases** □ Models, mathematical—compartment models with Michaelis–Menten-type elimination, computational problems, parameter estimation □ Michaelis–Menten equation—computational problems of compartment models, parameter estimation □ Compartment models—computational problems of models with Michaelis–Menten-type elimination, parameter estimation □ Pharmacokinetics—analysis, computational problems of compartment models with Michaelis–Menten-type elimination, parameter estimation

Linear compartment models have been used successfully in pharmacokinetics for the past 40 years. Like all mathematical models, they are an abstraction from the real biological system to a mathematical system and thus are

approximations. Nevertheless, their successful use indicates that they are a good approximation with many drugs. For other drugs, they are not a good approximation, and attempts have been made to find nonlinear compartment models that are better.

## THEORETICAL

One class of nonlinear models assumes that elimination of drug from the system, rather than being a first-order process, is a Michaelis–Menten process. The well-known Michaelis–Menten equation has been used widely and successfully in enzyme kinetic studies despite difficulties in the theoretical derivation (1, 2). The Michaelis–Menten equation:

$$v = v_{max}C_s/(k_m + C_s) \qquad \text{(Eq. 1)}$$

is used to estimate $v_{max}$ and $k_m$ from observations of the initial reaction rate, $v$, at various substrate concentrations, $C_s$. It was adapted to pharmacokinetic models by assuming that the elimination rate from a compartment has a form similar to the right side of Eq. 1. Thus, if $C(t)$ is the drug concentration in a compartment, then the rate of change of $C(t)$ is:

$$\frac{dC(t)}{dt} = f(t, \theta) - VC(t)/[K + C(t)] \qquad \text{(Eq. 2)}$$

where $f(t, \theta)$ is a function determined by the input into the compartment. In the usual pharmacokinetic application of Eq. 2, attempts are made to estimate $V$ and $K$ along with the other model parameters, $\theta$, by fitting the model to observed drug concentrations at $n$ sampling times after dosing. Although Michaelis–Menten-type elimination models had been used previously, a detailed description and analysis of the simplest model incorporating Michaelis–Menten-type elimination—the one-compartment model with bolus intravenous input—were published in 1973 (3). For that model, $f(t, \theta)$ of Eq. 2 is zero; the model is expressed as:

$$\frac{dC(t)}{dt} = -VC(t)/[K + C(t)] \qquad \text{(Eq. 3)}$$

As Wagner (3) pointed out, for this model there is no solution that expresses $C(t)$ as an explicit function of $t$; thus, the solution is an implicit function. For more complex models, *i.e.*, a one-compartment model with first-order input, for which $f(t, \theta)$ in Eq. 2 is an exponential function, a solution in closed form does not exist.

It is possible, however, to fit these models to observed data by numerically integrating Eq. 2 to obtain points $[t, C(t)]$ predicted by the model. Many recent pharmacokinetic studies obtained parameter estimates by combining a nonlinear regression algorithm with numerical integration. Numerical integration requires more computation than fitting data to the solutions of the differential equations and can be expensive in terms of computer time. When combined with nonlinear regression algorithms that require many evaluations of the solution, the expense of fitting models in this way can be prohibitive. Furthermore, these methods may be unsatisfactory in terms of convergence and final fit.

These problems motivated a search for an approximate solution to Eq. 2 that might make estimation of the parameters with this model easier. During this search, mathematical properties of compartment models with Michaelis–Menten-type elimination were derived. The implications of these properties for computation and parameter estimation will be discussed. Finally, the results of computer simulation reveal the statistical properties of the parameter estimates obtained by fitting the two simplest Michaelis–Menten-type models to data.

## RESULTS

**Mathematical Development**—Tong and Metzler (4) derived the mathematical properties of solutions to Eq. 2. The mathematical details are given elsewhere (4), and only the two most important results for parameter estimation will be discussed here. The conditions on the model of Eq. 2 are that $f(t, \theta)$ be nonnegative and bounded, with $C(0) = 0$; *i.e.*, there must exist two positive constants, $C_0$ and $s$, such that:

$$0 \leq f(t, \theta) \leq C_0 \exp(-st) \qquad \text{for } t \geq 0 \qquad \text{(Eq. 4)}$$

Given these mild restrictions, the function $F(t, A)$ is a lower bound for $C(t)$ with $A = V/K$ and an upper bound for $C(t)$ with $A = V/(K + B)$, where $B$ is the maximum of $C(t)$, and was defined as (4):

$$F(t, A) = \exp(-At) \int_0^t f(\tau) \exp(A\tau)\, d\tau$$

$$= \begin{cases} \dfrac{C_0}{A - s}[\exp(-st) - \exp(-At)] & A \neq s \\ C_0 t \exp(-At) & A = s \end{cases} \qquad \text{(Eq. 5)}$$

With the assumed restrictions, Eq. 2 includes many compartment models with Michaelis–Menten-type elimination from one compartment. Equation 5 shows that the time–concentration curves of these models are bounded by functions of the same form as the model equations for a one-compartment model with first-order input and first-order output (5). This is in agreement with the statement by Wagner (3) and others (5) that, for the simplest model, the solution to Eq. 2 approaches the linear solution as the concentration increases. The distance between the bounds given by Eq. 5 depends on $V$, $K$, and the maximum of $C(t)$. As an example, the one-compartment model with first-order input (absorption rate = $K_A$) and Michaelis–Menten-type elimination will be considered. For this model, $f(t, \theta)$ is given by:

$$f(t, K_A, D) = K_a D \exp(-K_a t) \qquad \text{(Eq. 6)}$$

where $D$ is a dilution factor, roughly equal to the dose divided by a volume of distribution. By Eq. 5, the lower and upper bounds of the solution are:

$$\frac{K_A D}{K_A - V/K}[\exp(-Vt/K) - \exp(-K_A t)]$$

$$\frac{K_A D}{K_A - Q}[\exp(-Qt) - \exp(-K_A t)]$$

where $Q$ is the only solution of the equation:

$$Q + \frac{K_A D}{K}\left(\frac{Q}{K_A}\right)^{K_A/(K_A - Q)} - \frac{V}{K} = 0 \qquad \text{(Eq. 7)}$$

The bounds for the case in which $D = 3$, $K_A = 8$, $V = 0.418$, and $K = 0.182$ are shown in Fig. 1. For this case, the bounds are not restrictive. For the case in which $D = 3$, $K_A = 8$, $V = 1$, and $K = 2$, the bounds are shown in Fig. 2; for this case, the solution is bound rather closely by functions that are solutions to the linear compartment model. For larger $V$ and $K$ values, the bounds are so close together that the bounds and the solution appear as one line when plotted.

The other result of Tong and Metzler (4) is illustrated in Fig. 3. If $(K_0, V_0)$ is a point in the $(K, V)$ parameter space, then there is an infinite, open-ended wedge such that for any other $(K, V)$ in this wedge, the solution to Eq. 2 with parameters $V$ and $K$ lies within the bounds of the solution to Eq. 2 with parameters $V_0$ and $K_0$. Also, there is a line through $(K_0, V_0)$ within this wedge, such that any $(K, V)$ on this line determines a solution to Eq. 2 that is nearly identical to the solution of Eq. 2 with the parameters $(K_0, V_0)$. In other words, there is an infinite set of $(K, V)$ values that all generate the same time–concentration curve (to a finite accuracy). This observation will be illustrated further.

The parameters of Eq. 1 often are estimated by applying one of several linearizing transformations to the equation (1, 2). The parameters also may be estimated directly (and more correctly) from Eq. 1 by using a nonlinear estimation technique. In any case, the estimation of $v_{max}$ and $k_m$ will suffer from a high correlation of the estimates since the param-

**Table I—Specifications of Models and Simulations**

| Case | Model (Input) | Parameters | Parameter Values | Error Structure | $n$ | $N$ |
|---|---|---|---|---|---|---|
| 1 | Bolus intravenous | $C_0$, $V$, $K$ | 2.0, 0.22, 0.11 | Additive | 11 | 200 |
| 2 | Bolus intravenous | $C_0$, $V$, $K$ | 2.0, 0.22, 0.11 | Proportional | 11 | 200 |
| 3 | First order | $K_a$, $V$, $K$ | 1.5, 2.0, 5.0 | Additive | 11 | 200 |
| 4 | First order | $K_A$, $V$, $K$ | 1.5, 2.0, 5.0 | Proportional | 11 | 200 |
| 5 | First order | $K_A$, $V$, $K$, $D$ | 1.5, 2.0, 5.0, 10.0 | Additive | 11 | 200 |
| 6 | First order | $K_A$, $V$, $K$, $D$ | 1.5, 2.0, 5.0, 10.0 | Proportional | 11 | 200 |
| 7 | First order (three functions) | $K_A$, $V$, $K$, $D_1$, $D_2$, $D_3$ | 1.5, 2.0, 5.0, 10.0, 20.0, 40.0 | Proportional | 33 | 100 |
| 8 | First order | $K_A$, $V$, $K$, $D$ | 1.5, 2.0, 5.0, 10.0 | Proportional | 33 | 100 |
| 9 | First order | $K_A$, $V$, $K$, $D$ | 1.5, 2.0, 5.0, 40.0 | Proportional | 33 | 100 |

eters appear in a ratio in the equation and a change in the estimate of $v_{max}$ may be compensated for by a change in $k_m$. This problem is accentuated when, as in Eq. 2, the ratio of parameters does not appear in the function itself but rather in the derivative of the function being fit.

Previous work (4) showed that, for most ($K$, $V$) values, the solution to Eq. 2 is bounded by a function of two exponentials; in the previous example, these functions have one less parameter than the solution. (Approximately, $K_E$ is replaced by $V/K$.) Thus, if the data can be fit to Eq. 5, trying to fit the data to Eq. 2 by nonlinear regression methods will result in a situation analogous to singularity in the case of linear regression.

The result expressed in Fig. 3 implies that if ($V$, $K$) are estimated by least-squares techniques, the sum of squares surface will have a long valley with steep sides but little change along the floor. This situation results in difficult estimation problems (6). If an estimation algorithm can find a minimum along this narrow valley, the estimates of $V$ and $K$ will be highly correlated since they can move together along the valley floor without much change in the sum of squared residuals.

Thus, there are at least two sources of computational difficulties in fitting Eq. 2 to data:

1. Since there is no closed form solution, numerical integration must be used to obtain predicted values of $C(t)$ for a given model and $t$.
2. Parameter estimation is hampered by a high correlation between estimates of $V$ and $K$.

To understand the implications of the second difficulty, Monte Carlo simulations were performed.

**Computer Simulation**—The statistical properties of parameter estimates of nonlinear models are known only asymptotically, and it generally is not known how well these asymptotic properties approximate the results for small samples. Thus, Monte Carlo simulations were needed to determine the statistical characteristics of the estimates for a given model and experiment (7, 8). In view of the mathematical properties derived for Michaelis–Menten-type elimination models, a simulation study of the statistical properties for some simple models seemed necessary.

One shortcoming of simulation studies is that only a small part of the problem can be simulated. For this report, some representative cases (Table I) were chosen with the hope that they would yield insight into the general problem. All models were one-compartment ones with either bolus input or first-order absorption and Michaelis–Menten-type elimination. Two types of error structure were considered: (*a*) additive error in which each simulated "observation" was the model-predicted value plus a normal random number from the distribution $N(0, 0.09)$, and (*b*) proportional error in which each observation was the model-predicted value plus the product of the model value and an $N(0, 0.0025)$ random variable.

The proportional error structure is equivalent to a 5% error. This error structure violates one assumption of least-squares estimation, and either a transformation should be done or variable weights should be used. The usual least-squares estimation was carried out, however, in the belief that it reflects common practice where no error analysis is done and the error structure is not known.

The model values were obtained by numerically integrating either Eq. 3 or Eqs. 2 and 6 with the parameter values given in Table I. Each data set had $n$ observations. The values of $t$ were 0, 0.5, 1, 1.5, 2, 3, 4, 5, 6, 7, and 10 for the intravenous bolus model and 0.25, 0.5, 1, 1.5, 2, 3, 4, 6, 9, 12, and 18 for the first-order input models. Each model was simulated $N$ times; that is, $N$ sets of observations were generated; for each set of $n$ observations, the parameters were estimated by the computer program NONLIN (9), a nonlinear regression program. This program also estimated the standard deviation for each estimate and the correlation matrix of the estimates.

Table II summarizes the simulation results of Case 5 (Table I). Similar tables were prepared for all cases in Table I; for space reasons, only this table is presented in full. However, the conclusions and discussion are based on all of the tables[1].

In Table II, the first column identifies the parameters used to generate the $N = 200$ sets of observations, the standard deviations of the estimates, the largest eigenvalue ($E1$) of the estimated correlation matrix, and the correlations of the estimates. The second column gives either the values of the parameters or, in parentheses, the sample values of the 200 estimates. Thus, column 2 of the row labeled $s(V)$ contains the standard deviation of the 200 estimates of $V$; column 2 of the row labeled $C13$ contains the correlation of the 200 pairs of estimates of the first and third parameters ($K_A$ and $V$). The remaining columns of Table II give the sample statistics of the 200 estimates: minimum, maximum, 10th and 90th percentiles, mean, and median. Thus, in the row labeled $s(V)$, the first column gives the standard deviation of the 200 estimates of $V$; the following columns give the sample value followed by the statistics of the 200 estimates of $s(V)$ computed by the estimation algorithm from each

data set.

Table II displays a number of points important to understanding the deficiency of Michaelis–Menten-type models for pharmacokinetic analysis. The distributions of the $V$ and $K$ estimates are skewed strongly to the right with some very large estimates. This skewness inflates the means so that they are ~25–45 times larger than the parameter values used to generate the data. The medians also are shifted to the right, particularly the median of the $K$ estimates.

It may be thought that when extreme values are estimated for $V$ or $K$, the plots of the fitted curves indicate that something is wrong. However, Fig. 4 shows that very extreme values ($V$ = 1561 and $K$ = 5165) generate curves that are not much different from those generated when $V$ = 2 and $K$ = 5. Certainly, they could not be distinguished if each were represented by 11 observations containing 5% or more noise.

Table II also shows the high correlation between estimates of $V$ and $K$; for these 200 estimates, the correlation (Spearman) is 0.992. The estimate of the correlation computed by NONLIN for each data set indicates this finding; the mean estimated correlation is 0.988, the median is 0.993, and the minimum of the 200 is 0.940. The eigenvalues of the estimated correlation matrix sum to the number of parameters estimated (in this case, four) and the size of the largest eigenvalue ($E1$) indicate the dimensionality of the parameter estimation space. The average of the largest eigenvalue is ~3.5, indicating that some of the remaining three eigenvalues are close to zero. Thus, the dimensionality of the parameter space is less than four, a condition of singularity. Figure 5 is a plot of the estimates of $V$ and $K$. The top 10% was censored so that the other estimates can be shown in a reasonable scale. The estimates all lie close to a straight line.

Because the distributions of the $V$ and $K$ estimates are extremely skewed, the standard deviations are quite large [$s(V)$ = 201.6 and $s(K)$ = 803.1]. However, the 90th percentile indicates that, of the standard deviation estimates made with each data set, 90% of the $s(V)$ estimates are <114 and 90% of the $s(K)$ estimates are <557.

The main points made by Table II are:

1. Estimates of $V$ and $K$ are highly skewed to the right, with many of the estimates being many times larger than the true parameter values.
2. Estimates of $V$ and $K$ are very highly correlated so that the estimate of one almost determines the estimate of the other.
3. Estimates of $V$ and $K$ have very high variances, although the estimated variances as computed by NONLIN from individual data sets underestimate the variability.

Although not shown in Table II, the correlations of estimates of $V$ and $K$ with their respective standard deviation estimates also are high. For these 200 data sets, the correlation between estimates of $V$ and $s(V)$ is 0.977; the correlation between estimates of $K$ and $s(K)$ is 0.980.

Thus, the estimated variances of the $V$ and $K$ estimates, as computed by a nonlinear regression program, do not give a true picture of the uncertainty in the estimates.

As a related point, Table II shows that the linear parameters, $K_A$ and $D$, are estimated well in that the distributions of their estimates are symmetric with small bias and small standard deviations. The correlation of their estimates, while smaller than that of the $V$ and $K$ estimates, is still large (−0.762 for this set of 200 estimates).

The tables of the simulations of the other cases show similar results. Proportional error with a standard deviation of 5% gives much the same result as a constant error with a standard deviation of 0.05. For Cases 3 and 4 (Table I), it was assumed that $D$ = 10 was known; only three parameters were estimated. This procedure improved the estimation, but the distributions still were skewed to the right for Case 3, with means of 2.58 and 8.04 for $V$ and $K$, respectively, and 90th percentiles of 3.80 and 14.02. The correlation of the $V$ and $K$ estimates was 0.993.

Estimation was best for the simple model (Cases 1 and 2 of Table I). However, even for these cases, the distributions were skewed to the right with some very extreme values, and the correlations were high (0.934 for Case 1 and 0.974 for Case 2).

For all of these simulations, the initial estimates for the iterative nonlinear regression program were the true values of the parameters used to generate the data. A limited amount of simulation with other starting values indicated that, for a particular data set, the initial values affected the final estimates but, averaged over 200 simulations, initial estimates within 30% of the true values did not make much difference. Initial estimates that differ by more than 30% often converge to values far removed from the true parameters.

A Michaelis–Menten-type model may be well approximated by a linear model for a single drug exposure, but observations at more than one dose level will expose the nonlinearity of the system. Thus, an attempt to evaluate the effect of simultaneous fitting of observations at three dose levels was made (Case 7, Table I). For Case 7, it was assumed that $V$ and

**Table III—Summary of Parameter Estimates for Simultaneous Fitting, Case 7**

| Parameter | Parameter or Sample Value | Sample Statistics | | | | | |
|---|---|---|---|---|---|---|---|
| | | Minimum | $P_{10}$ | Mean | Median | $P_{90}$ | Maximum |
| $V$ | 2.00 | 1.68 | 1.81 | 2.00 | 2.00 | 2.18 | 2.39 |
| $K$ | 5.00 | 3.47 | 4.01 | 4.99 | 4.96 | 5.90 | 6.62 |
| $s(V)$ | (0.138) | 0.076 | 0.098 | 0.135 | 0.130 | 0.183 | 0.217 |
| $s(K)$ | (0.712) | 0.627 | 0.822 | 1.141 | 1.120 | 1.540 | 1.966 |

$K$ remained the same when $D$ = 10, 20, and 40. Data were simulated for three experiments ($D$ = 10, 20, and 40); these three observed curves, with a total of $n$ = 33 observations, were fit simultaneously to one set of $K_A$, $V$, and $K$ values and three $D$ values. This procedure gave much better parameter estimation. The distributions of the $V$ and $K$ estimates were symmetric about the true values with no extreme estimates. The results for $V$ and $K$ are shown in Table III. The correlation of the $V$ and $K$ estimates was reduced to 0.767.

When comparing Table III with Table II, it must be noted that the data sets of Table III had 33 observations while those of Table II had only 11. The improvement in estimation of $V$ and $K$ was not due only to the larger sample sizes. To confirm this fact, Cases 8 and 9 (Table I) also had 33 observations per data set but, in these cases, the observations consisted of three replications at each sampling time used in Cases 3–6. Although the variability was reduced markedly and there were no extreme estimates, the distributions were still skewed to the right and the correlations were still very high (0.991 for Case 8 and 0.983 for Case 9).

## DISCUSSION

The mathematical development and computer simulation indicate that it is not possible to estimate $V$ and $K$ of a Michaelis–Menten-type pharmacokinetic model with any precision from a single-dose experiment. Furthermore, the asymptotic theory standard deviations, as computed by a nonlinear regression program, are misleading in that they underestimate the uncertainty in the estimates. [Although the NONLIN program (9) was used in this study, this result would be true for any computer program that estimates the variance–covariance matrix of the estimates from the matrix of partial derivatives.] This observation may explain why in many studies the estimate of between-subject variability is so much larger than the estimate of within-subject variability of the estimates (10). It may be an artifact of estimation rather than a characteristic of the drug. These difficulties in estimating Michaelis–Menten parameters also make the comparison of algorithms for estimation less meaningful, as in Ref. 11.

In many situations, estimating $V$ and $K$ for the purpose of comparing values between studies (*i.e.*, in different disease states) is useless if the estimates are made from observations after only one dose of drug. However, the simulations indicate that if estimations can be made with observations obtained after two or more dose levels, then the estimations are much improved. To do this, it must be assumed that the biological system, like the computer system, can generate data with the same values of $K_A$, $V$, and $K$ at different doses and different times. It is not certain that this assumption is valid.

Although the Michaelis–Menten-type models are not useful for estimation of $V$ and $K$ with observations from only one dose, they may have other value. They may be useful to show that a system is better described by a nonlinear pharmacokinetic model than by a linear model, for describing data, and for prediction.

The size of these simulations ($N$ = 200 for most of them), while much larger than most computer simulations reported in the pharmaceutical sciences literature, is about minimum for validity. These simulations cover only a few points in the entire space of these models. Future research extending these simulations would be useful in evaluating these models. In particular, the errors assigned in these simulations were relatively small for pharmacokinetic data. Larger (and more realistic) errors could only make estimation more difficult. Development of other nonlinear models that avoid these computational problems also would be useful.

# Sorption Properties of Cross-Linked Insoluble Polyvinylpyrrolidone

**K. H. FRÖMMING *x, W. DITTER ‡, and D. HORN ‡**

Received June 10, 1980, from the **Institut für Pharmazie, Freie Universität Berlin, Königin-Luise-Str. 2f4, 1000 Berlin 33, West Germany*, and the ‡*Hauptlaboratorium, BASF Aktiengesellschaft, 6700 Ludwigshafen/Rhein, West Germany.* Accepted for publication December 2, 1980.

**Abstract** □ The interaction of 32 drugs of diverse chemical structure with cross-linked insoluble polyvinylpyrrolidone (crospovidone) was studied. By using a polymer to drug ratio of 10:1, the sorbed amount for 20 compounds was found to be <5%. After a 10-fold decrease of the polymer concentration, the sorbed amount of eight other compounds fell to or below the 5% level. Only tannic acid and hexylresorcinol exhibited a significantly stronger sorption tendency. The interaction appeared to be controlled by phenolic groups in the active ingredient. The binding can be quantified by an interaction constant, $K_s$, whose definition is based on a bulk phase model of interaction *via* independent binding sites. The exceptionally strong binding of hexylresorcinol, however, apparently was caused by cooperative interaction of the hexyl groups in the bound state. Desorption studies revealed that the binding was fully reversible in all cases. Therefore, the presence of cross-linked polyvinylpyrrolidone as a disintegrant in pharmaceutical preparations is not expected to interfere with GI drug absorption.

**Keyphrases** □ Polyvinylpyrrolidone—interaction with 32 pharmaceuticals of diverse chemical structure, sorption and desorption studies □ Sorption—interactions of 32 pharmaceuticals of diverse chemical structure with cross-linked insoluble polyvinylpyrrolidone □ Binding—interactions of 32 pharmaceuticals of diverse chemical structure with cross-linked insoluble polyvinylpyrrolidone, sorption and desorption studies

*N*-Vinylpyrrolidone can be polymerized to yield polyvinylpyrrolidone, a readily soluble polymer, or can be transformed into a cross-linked insoluble polyvinylpyrrolidone (crospovidone, I) by proliferous polymerization (1–3).

Compound I exhibits an exceptionally high swelling pressure (4), which apparently is connected with the increased hydration capacity of the polymer (5, 6). For that reason, I is particularly useful as a disintegrating agent in pharmaceutical formulations.

## BACKGROUND

Because of its disintegrating effect, I may enhance the release rate of drug from tablet formulations. With griseofulvin tablets containing a large amount of polyethylene glycol, I enhanced drug release at a significantly higher rate than when I was not present (7).

The same advantageous effect was observed in similar formulations with other drugs (8). The release of penicillins and cephalosporins from capsules was promoted by I (9). The dissolution rate of kavaine was increased after sorption onto I as a carrier (10).

Because of the dipolar character and the porous structure of I, specific interactions with solutes cannot be predicted. Only in a single case has a relatively strong binding of tannic acid and related compounds been reported (2). Other compounds such as acetaminophen, benzocaine, metamizole, and salicylamide exhibited no stronger interaction with I than with corn starch, carboxymethyl starch, and microcrystalline cellulose (11).

The present study investigated the possible interactions of I with numerous drugs of diverse chemical structure. Some compounds chosen were known for their binding tendency with polyvinylpyrrolidone (12). The experimental results are explained on the basis of models of noncooperative and cooperative interaction.

## EXPERIMENTAL

**Materials**—The following were obtained from commercial sources: acetaminophen[1], allopurinol[2], benzocaine[3], benzoic acid[4], *p-tert*-butylphenol[5], caffeine[6], chloramphenicol[2], cinnarizine[6], diphenhydramine[6], ethaverine[6], hexylresorcinol[7], *p*-hydroxybenzoic acid[7], isoniazid[6], menadione[4], methaqualone[4], nitrofurantoin[7], papaverine hydrochloride[4], phenazone[4] (antipyrine), procaine hydrochloride[4], promethazine hydrochloride[6], propylparaben[2], pyridoxine hydrochloride[4], reserpine[7], resorcinol[4], riboflavin[4], salicylic acid[4], sodium salicylate[4], sulfadiazine[6], sulfamidopyrine[6], tannic acid[4], tetracaine hydrochloride[3], and theophylline[6].

All materials were the highest available grade and were used without further purification.

The specific surface area of cross-linked polyvinylpyrrolidone[8] (I) was determined by nitrogen adsorption, according to the Brunauer, Emmett, and Teller method[9] (13), after the samples were dried carefully.

**Sorption Experiments**—For the easily soluble substances, 1000 mg was dissolved in 1000 ml of 0.01 *N* HCl, water, or artificial intestinal fluid (USP XIX) unless otherwise noted. Where the solubility was insufficient, the suspension was filtered after vibrational stirring for 0.5 hr. The filtrate was diluted until 200 ml contained 100 mg of solute. For even less soluble samples, saturated solutions at 25° were used.

The sorption experiments were performed in a thermostatted bath at 37 ± 0.5°. Compound I was added in amounts of 1000 or 100 mg/200 ml of solution, and the suspension was maintained under steady vibrational stirring at 150 rpm for 0.5 hr. Then the suspensions were filtered or centrifuged at 37°. The amount of unbound drug was determined spectrophotometrically, with the absorbance values of the polymer-free solutions of the drugs (which had gone through the same cycle of pretreatment) as a reference.

Determination of the residual drug concentrations was performed using appropriate calibration curves measured at the following characteristic wavelengths: acetaminophen, 243 nm; allopurinol, 251 nm; benzocaine, 226 nm; benzoic acid, 230 nm; *p-tert*-butylphenol, 274.5 nm; caffeine, 273 nm; chloramphenicol, 278 nm; cinnarizine, 253 nm; diphenhydramine, 258 nm; ethaverine, 252 nm; hexylresorcinol, 279 nm; *p*-hydroxybenzoic acid, 255 nm; isoniazid, 266 nm; menadione, 261 nm; methaqualone, 233.5 nm; nitrofurantoin, 366 nm; papaverine, 251 nm; phenazone, 239 nm; procaine hydrochloride, 290 nm; promethazine hydrochloride, 250 nm; propylparaben, 255 nm; pyridoxine hydrochloride, 290.5 nm; reserpine, 267 nm; resorcinol, 273 nm; riboflavin, 267 nm; salicylic acid, 237 nm; sodium salicylate, 236.5 nm; sulfadiazine, 243 nm; sulfamidopyrine, 258 nm; tannic acid, 275 nm; tetracaine hydrochloride, 228 nm; and theophylline, 271.5 nm.

**Desorption Experiments**—Drug-loaded samples of I were prepared by centrifuging the respective suspensions following sorption. After the sediments were isolated, the desorption of bound drug was studied at 25° by vigorously shaking the 1000-mg samples three or more times with 50 or 100 ml of the respective solvent for 15 min. The degree of desorption was determined by spectrophotometric analysis of the combined supernates after centrifuging the suspensions.

## RESULTS

Under the described experimental conditions, several drugs essentially did not interact with I: allopurinol[10], chloramphenicol, cinnarizine[10], caffeine, diphenhydramine hydrochloride, ethaverine hydrochloride,

isoniazid, menadione[10], methaqualone[10], nitrofurantoin[10], papaverine hydrochloride[10], phenazone, procaine hydrochloride, promethazine hydrochloride, pyridoxine hydrochloride, reserpine[10], riboflavin[10], sulfamidopyrine, tetracaine hydrochloride, and theophylline. In all cases, the amount of material bound onto I dispersed in 0.01 *N* HCl or water was <5%.

Table I lists all materials that exhibited a degree of sorption higher than 5% at high I concentrations (*i.e.*, 1000 mg/per 100 mg of drug). Decreasing the I concentrations by a factor of 10, however, decreased the amount bound (5% level and lower) in all cases.

The compounds listed in Table II were bound by I significantly even at low polymer concentrations. The strong binding of tannic acid in aqueous suspensions of I was reported previously (2).

The results of the binding studies of selected systems with artificial intestinal fluid are shown in Table III.

Except for tannic acid, hexylresorcinol displayed the strongest binding irrespective of the suspension medium pH (Tables II and III).

As to the desorption studies, characteristic results of a few selected compounds are shown in Table IV.

To determine whether the thermodynamics of the sorption process is influenced by surface phenomena, sorption studies were performed with two types of I, which differed by a factor of five in specific surface area. Typical data are shown in Fig. 1, where $[A_0]/[A]$, the ratio of the weighing-in concentration and the unbound amount of the drug, is plotted *versus* the polymer to drug ratio.

The close similarity of the sorption behavior of both I samples indicates that sorption thermodynamics is dominated by bulk phase properties of the polymer and that any possible influence of the extent of the specific surface area of the material can be neglected. Hence, the sorption data can be treated according to the mass law of chemical equilibrium of bulk phases. When considering only the polymer compartment, it may be assumed that binding of the drug, $A$, occurs on independent free binding sites, $F$, of the polymer. Then the sorption constant $K_s$ is defined as:

$$K_s = \frac{[FA]}{[A]([F_0] - [FA])} \qquad \text{(Eq. 1)}$$

The mass balance equation then is written as $[F_0] = [F] + [FA]$, where $[F_0]$ denotes the total concentration of binding sites, $[F]$ is the concentration of free bindings sites, and $[FA]$ is the concentration of occupied binding sites and is identical with the bound amount of drug.

**Table III—Data of Sorption Studies in Artificial Intestinal Fluid (USP XIX)**

[a] Amount of drug prior to sorption. [b] Initially sorbed amount of drug. [c] Experimental values too high; for further details, see text.

An alternative view of the system, based on the mass distribution of drug between the liquid and the (swollen) solid phase, is obtained by introducing the Nernst coefficient, $k$, of mass distribution of $A$:

$$k = \frac{[A]_s}{[A]} \qquad \text{(Eq. 2)}$$

where $[A]_s$ and $[A]$ denote the drug concentrations in the polymer and liquid phase, respectively.

With the assumption that $[A]$ is equilibrated with the portion of $[A]_s$ that remains unbound within the polymer phase, then:

$$k = \frac{[A] + [FA]}{[A]} \qquad \text{(Eq. 3)}$$

After introducing the phase ratio $\varphi = V_s/V_L$, in which $V_s$ and $V_L$ represent the volumes of the polymer[11] and liquid phase, respectively, the mass balance equation for the drug becomes:

$$[A_0] = [A] + \varphi[A] + \varphi[FA] \qquad \text{(Eq. 4)}$$

or, when rearranged, it becomes:

$$[FA] = \frac{1}{\varphi}([A_0] - [A]) - [A] \qquad \text{(Eq. 5)}$$

Substituting Eq. 5 into Eq. 3 gives:

$$\frac{[A_0]}{[A]} = 1 + k\varphi \qquad \text{(Eq. 6)}$$

As shown in Fig. 1, the experimental data are described by this equation, which supports the introduced model of binding. From the slope of the straight lines, the Nernst coefficient of interaction for both I samples is evaluated to be 84 and 79.

The coupling of $k$ with $K_s$ is performed by introducing Eqs. 5 and 6 into Eq. 1 to give:

$$K_s = \frac{k - 1}{[F_0] - [A](k - 1)} \qquad \text{(Eq. 7)}$$

or:

$$k = 1 + \frac{[F_0]K_s}{1 + [A]K_s} \qquad \text{(Eq. 8)}$$

This equation is closely related to an equation derived by Luck (14) to describe the Nernst partition equilibrium in certain textile dyeing processes.

From Eq. 8, it follows that for small values of the interaction constant $K_s$, the Nernst coefficient $k$ becomes independent of $[A]$ (Fig. 2). This condition holds for all compounds in Table I and those that were listed as not interacting with I. Therefore, the polymer to drug interaction may be characterized either by $k$ or $K_s$. However, to evaluate $K_s$ from experimental data according to Eqs. 6 and 7, a reasonable assumption has to be made concerning the value of $[F_0]$. If it is assumed that each monomeric subunit of the polymer may serve as a binding site, $[F_0]$ becomes equal to ~9 $M$. All $K_s$ values in Tables I–III were obtained using this assumption.

Because of the sensitive dependence of $K_s$ on experimental errors of the sorption data, the $K_s$ values in Table I obtained with $\varphi = 0.005$ and 0.0005 are in satisfactory agreement, with the exception of the propylparaben–water system; the reason for this discrepancy is unknown. In general, however, the results support the notion that sorption occurs according to a reversible equilibrium process in interacting systems.

For sodium salicylate, pronounced differences in $K_s$ were found in the

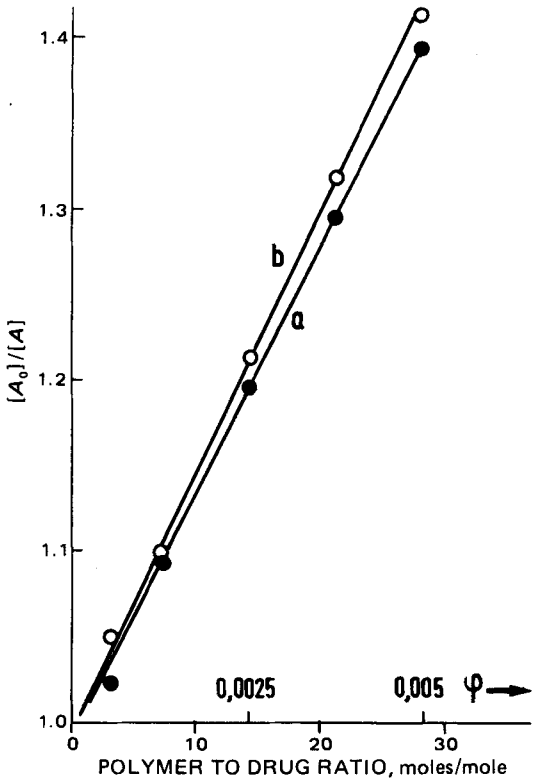

**Figure 1**—*Binding of propylparaben by I of different specific surface areas at 37°. The weighing-in concentration of the drug was 57 mg/200 ml. The specific surface areas of the I samples according to the Brunauer, Emmett, and Teller method were 5.42 (a) and 0.98 $m^2/g$ (b). The marking of the abscissa is defined by $\varphi = V_s/V_L$, where $V_s$ is the volume of the solid phase and $V_L$ is the volume of the liquid phase. Molar concentrations of the polymer refer to the molecular weight of the monomeric subunit.*

[11] For convenience, the volume of I in the dry state is considered.

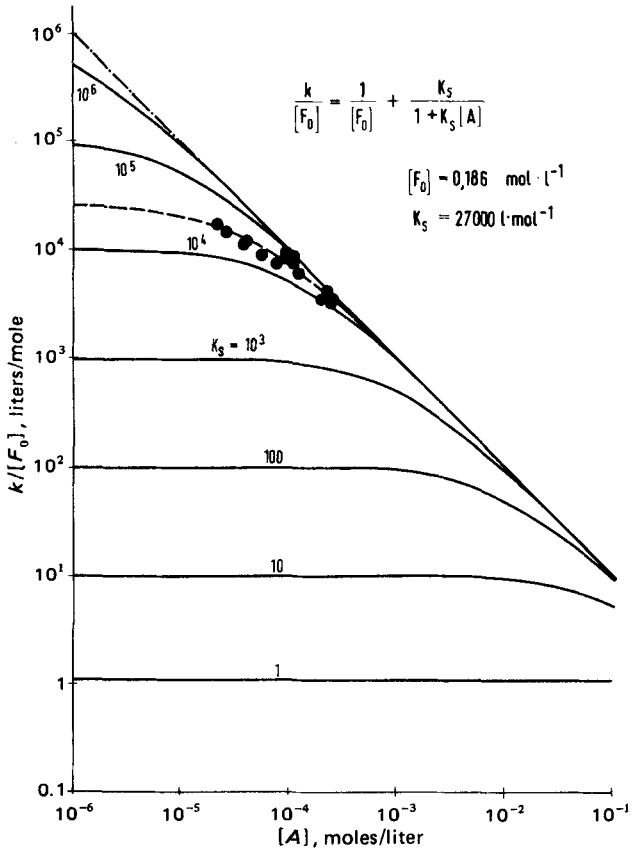

**Figure 2**—*Dependence of the Nernst coefficient on the equilibrium concentration of the interacting drug, [A], for various values of the binding constant, $K_s$. Key: —, theoretical curves according to Eq. 8; and ●– –, experimental values of tannic acid–I.*

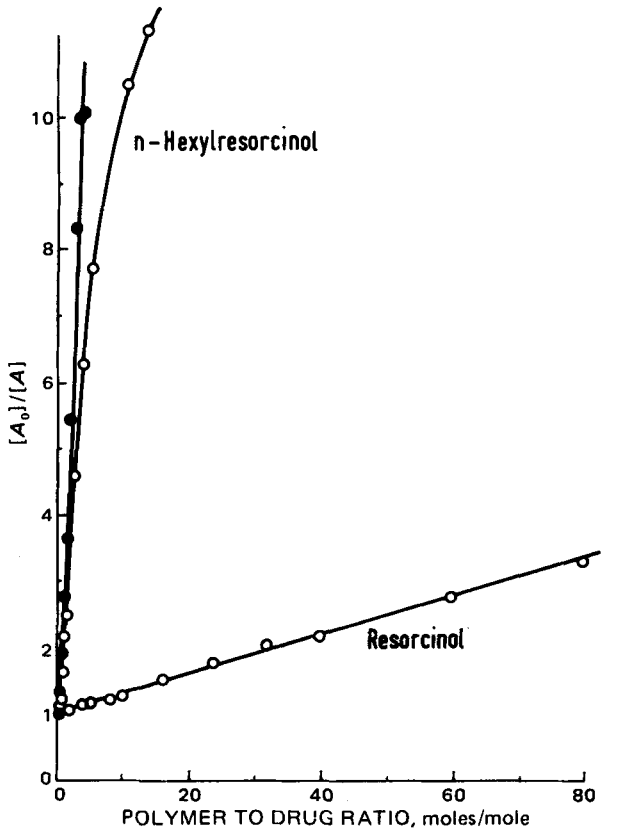

**Figure 3**—*Binding of resorcinol and of hexylresorcinol by I in 0.01* N *HCl at 37°. The weighing-in concentrations of the drug, [$A_0$], were 250 (○) and 500 (●) mg/liter.*

acidic system (0.01 *N* HCl) as compared to plain water; similar sorption experiments with salicylic acid did not show comparable differences. This difference can be explained by the fact that, at the end of the sorption experiments, pH values above 6.0 were observed in the former case while pH values always remained at ~3.1 in the latter case.

The $K_s$ values of the strongly interacting compounds are summarized in Table II. The exceptionally high $K_s$ values of tannic acid and hexylresorcinol deserve close scrutiny. In both cases, the Nernst coefficient is no longer independent of [*A*], although for different reasons.

The experimental results of a detailed investigation of the Nernst partition of the tannic acid–I system is shown in Fig. 2, where $\log(k/[F_0])$ is plotted against the logarithm of [*A*]. The experimental data are compared with theoretical curves as obtained from Eq. 8 for various $K_s$ values. For small $K_s$ values, where $[A]K_s \ll 1$ holds true, the Nernst coefficient $k$ becomes independent of [*A*]. This condition is satisfied by all compounds in Table I and by some compounds in Tables II and III.

The experimental data for tannic acid, however, closely approach the limiting straight line of slope −1 where $[A]K_s \gg 1$ and $\log k \sim \log[F_0] - \log[A]$. The concentration of effective binding sites, $[F_0]$, of the tannic acid interaction with I is, according to Eq. 8, 0.186 *M*. For the binding constant, $K_s$, a value of the order of $2.7 \times 10^4\ M^{-1}$ is estimated. These exceptional figures underline the special role tannic acid plays in the interaction behavior with I. Apparently, this interaction is related to the comparatively high molecular weight of tannic acid (mol. wt. ~1550) and its multifunctional chemical structure. In contrast to other compounds in this study, a single molecule of tannic acid covers many individual binding sites simultaneously, leading to extraordinarily strong binding.

Hexylresorcinol, on the other hand, is another example of a peculiar interaction mechanism with I. The experimental results of a detailed investigation of this system are shown in Fig. 3. With resorcinol, the plotting of $[A_0]/[A]$ *versus* $\varphi$ yields a perfect straight line; with hexylresorcinol, the situation is apparently changed. The steep slope of the curve indicates an extremely strong interaction. On the other hand, the marked deviation from linearity of the curve suggests that the introduced model of interaction no longer applies. However, the experimental results are readily explained in terms of a model of cooperative binding. A relevant plot of the data according to a theory of cooperative interaction (15) is shown in Fig. 4.

As depicted in Fig. 4, the hexylresorcinol data fit the concept of cooperative binding. Therefore, the $K_s$ values of hexylresorcinol in Table II, which were evaluated according to the model of noncooperative competitive binding, are valid only to a first approximation for the stated polymer to drug ratio. Of course, the extremely strong tendency of interaction, as documented in Figs. 3 and 4, is reflected nevertheless in the magnitude of the $K_s$ values.

The cooperative binding plot (Fig. 4) allows the maximum number of bound hexylresorcinol molecules per vinylpyrrolidone segment in the polymer to be determined. With increasing weighing-in concentrations of the drug, the binding curves approach a limiting straight line, which can be extrapolated to the polymer to drug ratio axis. The intercept yields $1/g$, where $g$ is the number of binding sites per polymer segment. An intercept value of 2 (Fig. 4) indicates that each hexylresorcinol molecule is bound by two vinylpyrrolidone residues.

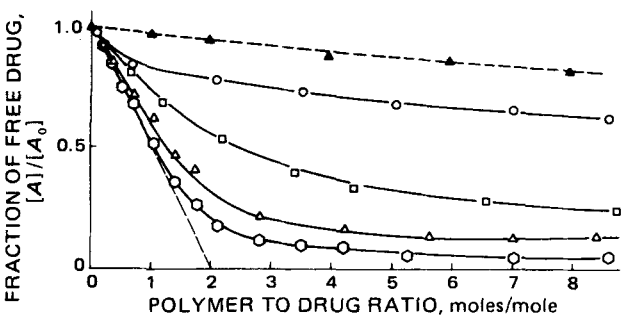

**Figure 4**—*Cooperative binding curves of hexylresorcinol–I in 0.01* N *HCl at 37°. For comparison, relevant data of the noncooperatively bound resorcinol are included. The polymer to drug ratio is expressed in moles of monomer segments per mole of drug. Key: —, hexylresorcinol at 25 (○), 80 (□), 250 (△), and 500 (○) mg/liter; and ---, resorcinol at 250 (▲) mg/liter.*

Finally, in the case of butylphenol, deviations from the expected constancy of the $K_s$ values with changing $\varphi$ are observed. There is no obvious explanation for this discrepancy. Perhaps a possible micellization reaction of the compound interferes with the polymer interaction in this case.

The results of the desorption studies also can be treated according to the introduced model of interaction. If the desorption experiment is started with an adsorbed concentration of drug of $[A]_{s,0}$, after the first desorption step the partition equilibrium can be described according to Eq. 2 as:

$$k = \frac{[A]_{s,1}}{[A]} = \frac{m_{s,1}/V_s}{m/V_L} \qquad \text{(Eq. 9)}$$

in which $m_{s,1}$ denotes the amount of the compound remaining in the polymer phase after the first desorption step and $m$ denotes the appropriate amount of desorbed material. Hence, the mass balance reads:

$$m_{s,0} = m + m_{s,1} \qquad \text{(Eq. 10)}$$

where $m_{s,0}$ represents the initially sorbed amount. From Eq. 9, it follows that:

$$k = \frac{1}{\varphi} \frac{m_{s,1}}{m_{s,0} - m_{s,1}} \qquad \text{(Eq. 11)}$$

which can be rearranged to yield for $n$ desorption steps:

$$m_{s,0} = \left(1 + \frac{1}{k\varphi}\right)^n m_{s,n} \qquad \text{(Eq. 12)}$$

The fraction, $\gamma_s$, of the initially sorbed amount $m_{s,0}$ remaining bound after $n$ desorption steps is $\gamma_s = m_{s,n}/m_{s,0}$:

$$\gamma_s = \left(1 + \frac{1}{k\varphi}\right)^{-n} \qquad \text{(Eq. 13)}$$

Experimental results of desorption studies with several substances with a pronounced sorption tendency are listed in Table IV. They are compared with theoretical values determined with Eq. 12 by considering the appropriate $k$ values as obtained from sorption studies. With 15-min equilibration times for each desorption step, generally the experimental and theoretical values are in satisfactory agreement, indicating that the molecules are reversibly bound even in cases of substantial interaction.

Again, hexylresorcinol and tannic acid play an exceptional role. With hexylresorcinol, the desorption process proceeds even faster than predicted theoretically due to the underlying cooperative mechanism of interaction, which is not accounted for in the derivation of Eq. 12. On the other hand, the discrepancies with tannic acid are explained partly by Fig. 2. As the desorption proceeds, the value of the Nernst coefficient increases, slowing down the efficiency of the stepwise desorption process. The theoretical values of Table IV, however, are based on the assumption of a constant value of $k$. The experimental verification of the degree of desorption is hampered further by the fact that tannic acid adheres to the surface of analytical glassware, disturbing a correct determination of the minute amounts desorbed in each single step.

## DISCUSSION

Thirty-two compounds of diverse chemical structure were studied with regard to their sorption tendencies toward I. Even with rather extreme polymer to drug ratios of 10:1 (never met in practice), the sorbed amount was <5% with 20 pharmaceuticals. None of the pharmaceuticals within this class carried phenolic functional groups.

Under the same experimental conditions, eight compounds showed sorption values between 5 and 33%. By decreasing the polymer concentration 10 times whereby a polymer to drug ratio of 1:1 was established, the sorbed amount fell to or below the 5% level in cases of readily soluble drugs. All compounds of this class were characterized by a simple aromatic structure, five of which (propylparaben, sodium salicylate, acetaminophen, resorcinol, and salicylic acid) carried hydroxyl groups.

Significant differences in binding between the water and 0.01 *N* HCl system were observed only with sodium salicylate; this result is explained readily by the change in pH.

In artificial intestinal fluid, the binding tendency of several pharmaceuticals (benzoic acid, *p*-hydroxybenzoic acid, and sulfadiazine) appeared to be less pronounced as compared to the sorption behavior in an acidic environment. No significant differences were found in this respect with benzocaine, *p-tert*-butylphenol, propylparaben, acetaminophen, and resorcinol. The same is true for hexylresorcinol and tannic acid, which exhibited the strongest binding tendency irrespective of the medium pH.

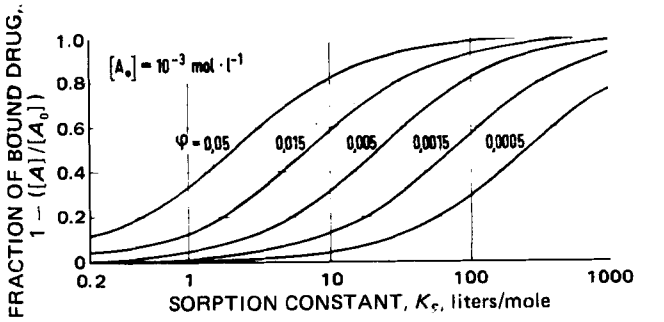

**Figure 5**—*Fraction of drug bound to I as a function of the binding constant,* $K_s$, *for various values of* $\varphi$.

As shown earlier, the degree of polymer to drug interaction is expressed by the value of the binding constant, $K_s$. Not unexpectedly, the results of binding studies with soluble polyvinylpyrrolidone (12) point out close similarities with the present findings. Higuchi and Kuramoto (16) found no complexing between soluble polyvinylpyrrolidone and citric acid, benzylpenicillin, cortisone, procaine hydrochloride, caffeine, and theophylline (16). The latter three compounds were investigated in the present study and were found to be noninteracting with I.

The affinity of other pharmaceuticals toward soluble polyvinylpyrrolidone decreased in the following order: sulfathiazole > *m*-hydroxybenzoic acid > *p*-hydroxybenzoic acid > *p*-aminobenzoic acid > salicylic acid > phenobarbital > benzoic acid > sodium salicylate > mandelic acid > chloramphenicol. These results again are in close agreement with the findings obtained with I.

Particularly interesting is the similarity of experimental results obtained with soluble polyvinylpyrrolidone and I with hexylresorcinol. Polli and Frost (17) reported particularly strong binding between polyvinylpyrrolidone and this resorcinol derivative. However, this conspicuous molecular interaction was explained vaguely as a possible change of the spatial orientation of the polymer during the interaction. The analysis of the experimental data presented here, which is also valid for the interaction of hexylresorcinol with soluble polyvinylpyrrolidone[12], clearly indicates the significance of a cooperative interaction mechanism in the sorption process (Fig. 4).

In the case of hexylresorcinol, binding to the polymer probably occurs not independently to single binding sites but preferably to the nearest neighbor binding sites, thereby inducing an aggregation of bound ligands. This peculiar mechanism of interaction (15) presumably is caused by hydrophobic interaction of the hexyl residues of nearest-neighbor ligands. In that way, the driving force of interaction, which is assumed to be dominated by hydrophilic hydrogen bonding in the case of resorcinol, is enhanced greatly.

Evidence for both hydrophilic and hydrophobic effects on the binding of benzene derivatives to polyvinylpyrrolidone also was found by Molyneux and Frank (18). In contrast to hexylresorcinol, however, the noncooperative character of interaction was basically not altered, and the interaction constants were only gradually changed. Usually, the strength of interaction increases with increasing numbers of polar functional groups and with the extent of the hydrophobic part of the molecules. The distinct complexing tendency of tannic acid with polyvinylpyrrolidone is readily explained in these terms.

The relevance of hydrogen bonding for the interaction with I is suggested by the well-known fact that phenolic compounds in general may form precipitates with soluble polyvinylpyrrolidone (19). Further evidence is offered by the observation that esterification of *p*-hydroxybenzoic acid leads to a decrease in binding strength with polyvinylpyrrolidone (20).

Of practical importance is the extent to which pharmaceuticals with a measurable binding tendency are released from the bound state during GI passage. This process may be considered as a series of desorption steps since, during the passage, intestinal absorption of the released drug takes place continuously. The release process generally relates only to the small fraction of drug staying in the bound state. The bound fraction, $\gamma_s$, can be estimated by means of Fig. 5, where $\gamma_s$ is plotted as a function of the interaction constant, $K_s$, for various solid to liquid ratios, $\varphi$. It follows that for the majority of pharmaceuticals investigated in the present study within wide limits of the polymer to drug ratio, the sorbed amount lies well below the 10% level.

[12] D. Horn and W. Ditter, to be published.

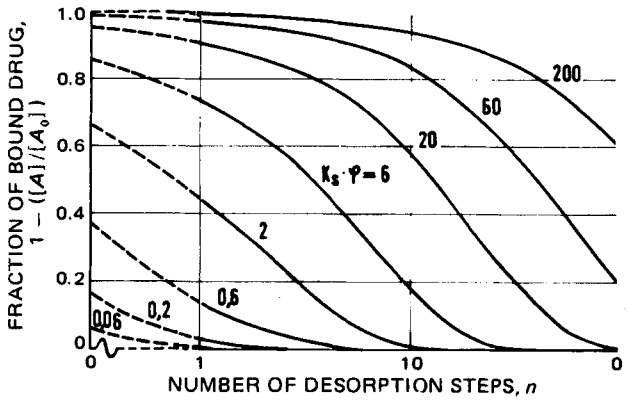

**Figure 6**—*Decrease of the initially sorbed amount of the drug as a function of the number of desorption steps,* n, *for various values of* $K_s\varphi$.

Finally, theoretical desorption curves are shown in Fig. 6 and were calculated according to Eq. 13. The graph depicts the decrease of the initially sorbed amount of the drug as a function of the number of desorption steps for increasing values of $K_s\varphi$. With regard to $K_s$ values on the order of 2–10 $M^{-1}$, indicating moderate binding (Table I) even when considering high values of $\varphi$ (*i.e.*, $\varphi = 0.02$), it follows from Fig. 6 that only a few desorption steps are necessary for complete release of the bound compound from the polymer.

Presumably, with the exception of tannic acid and closely related compounds, the presence of the disintegrant should not interfere with GI absorption of the pharmaceutical.

# Improved Delivery through Biological Membranes VIII: Design, Synthesis, and *In Vivo* Testing of True Prodrugs of Aspirin

**THORSTEINN LOFTSSON *, JAMES J. KAMINSKI ‡, and NICHOLAS BODOR §x**

Received August 25, 1980, from the **Department of Pharmaceutical Chemistry, School of Pharmacy, University of Kansas, Lawrence, KS 66045*, the ‡*Inter$_x$ Research Corporation, Lawrence, KS 66044*, and the §*Department of Medicinal Chemistry, College of Pharmacy, J. Hillis Miller Health Center, University of Florida, Gainesville, FL 32610.* Accepted for publication October 16, 1980.

**Abstract** □ Novel activated ester-type prodrugs of aspirin were designed and synthesized. The methylthiomethyl, methylsulfinylmethyl, and methylsulfonylmethyl esters of aspirin (acetylsalicylic acid) were cleaved *in vitro* in plasma to form aspirin rather than the corresponding salicylates. *In vivo* studies using dogs indicated that at least one aspirin derivative, methylsulfinylmethyl-2-acetoxybenzoate, is a true aspirin prodrug since aspirin was detected in the blood after prodrug administration.

**Keyphrases** □ Aspirin—activated ester-type prodrugs of aspirin synthesized and evaluated for analgesia, *in vivo* and *in vitro* studies □ Prodrugs, aspirin—activated ester-type prodrugs synthesized and evaluated for analgesic activity, *in vitro* and *in vivo* studies □ Analgesic activity—activated ester-type prodrugs of aspirin, synthesized and evaluated for analgesia, *in vitro* and *in vivo* studies

The GI side effects of aspirin (acetylsalicylic acid, I) are well known and documented (1). These side effects are associated with the free carboxylic group; thus, transient derivatives (prodrugs) and various formulations of I were prepared and tested in which the free carboxyl group was derivatized or bound. The results obtained were unsatisfactory due to the specific properties of I. The *o*-acetyloxyl group is rather labile. Extensive studies of the chemical hydrolysis (2–8) and *in vivo* hydrolysis (9) demonstrated the facile conversion of I to salicylic acid (II). Although II is also a potent anti-inflammatory agent, it was shown (10) that I is a far more potent analgesic and, thus, delivery to the bloodstream in the intact form is desirable. To achieve this, the carboxyl-protecting function must be cleaved

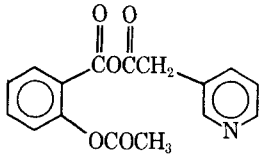
III

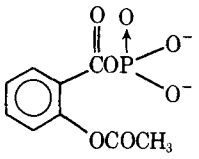


IV

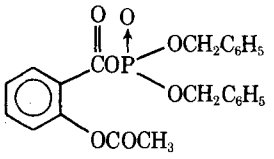
prior to the labile *o*-acetyl one, which is difficult since the prodrug must at the same time be stable enough in the neat form and in formulation.

## BACKGROUND

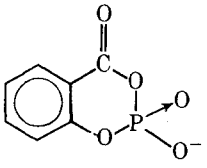
An early recommendation for an aspirin prodrug with decreased gastric irritation was aspirin anhydride (11). However, its low solubility in water, slow dissolution rate, and immunogenicity (12, 13) prevented further development. Attempts to increase the solubility were made by preparing mixed anhydrides[1] such as the pyridine-containing derivatives III and IV. However, these mixed anhydrides cannot be synthesized in a 100% pure form since some disproportionation always occurs and aspirin anhydride is formed as an impurity, even when using the clean acyl chloride–thallium carboxylate reaction (14). Mixed anhydrides probably also have immunogenic–allergenic properties similar to aspirin anhydride. A phosphoric acid mixed anhydride[2] (V) was considered, but all attempts at preparation failed, even when the stable ester (VI) was used, due to facile intramolecular reactions leading to the stable cyclic salicylphosphate (VII).



V



VI



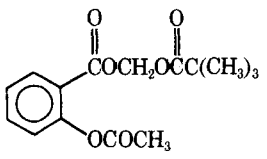
VII

Stable acyloxyalkyl derivatives of I such as the pivalyloxymethyl[1], benzoyloxymethyl, and analogous esters were synthesized, but they also showed low aqueous solubility and dissolution rates. More recently, the 4-acetamidophenyl ester (IX) (15, 16) and the triglycerides (X) (17, 18) were prepared.

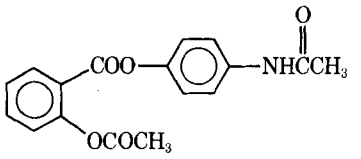
Although decreased GI irritation is claimed with both IX and X, there is no proof that these derivatives are true prodrugs of I and not of salicylic acid. Recent work (18) on X showed only the blood salicylate levels and the pharmacological testing involved only anti-inflammatory studies, but X still was indicated (without any proof) to be an aspirin prodrug.

Some aspirin salts, such as lysine acetylsalicylate (XI), were reported (19) to produce three times less GI bleeding than I.

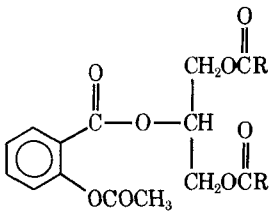
Other intended aspirin prodrugs include the 1′-ethoxyethyl ester (20), *N*-hydroxyethyl nicotinamide ester (21), and salicylamide ester (22). The patent literature also includes various derivatives but without much specific information.



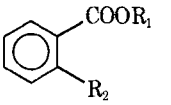
VIII



IX



X: R = $(CH_2)_nCH_3$



XI: $R_1 = CH_2SCH_3$, $R_2 = H$
XII: $R_1 = CH_2SOCH_3$, $R_2 = H$
XIII: $R_1 = CH_2SO_2CH_3$, $R_2 = H$
XIV: $R_1 = CH_2SCH_3$, $R_2 = OH$
XV: $R_1 = CH_2SOCH_3$, $R_2 = OH$
XVI: $R_1 = CH_2SO_2CH_3$, $R_2 = OH$
XVII: $R_1 = CH_2SCH_3$, $R_2 = OCOCH_3$
XVIII: $R_1 = CH_2SOCH_3$, $R_2 = OCOCH_3$
XIX: $R_1 = CH_2SO_2CH_3$, $R_2 = OCOCH_3$

None of the chemical derivatives of aspirin was reported to form aspirin in the body after oral or intravenous administration.

The present study reports novel derivatives of aspirin, at least one of which resulted in aspirin *in vivo*. These new prodrugs are activated esters that undergo further activation *in vivo*. The overall result is delivery of aspirin (I) rather than of salicylic acid.

Protective groups capable of being removed under mild conditions are of great value in peptide synthesis. Methylthiomethyl and β-ethylthiomethyl esters are used as protective groups for carboxylic acids for this purpose (23, 24). They are somewhat stable under normal conditions but can be made more labile by conversion into a sulfonium salt or by oxidation to the sulfone, which then is cleaved readily under neutral or mild alkaline conditions at room temperature to regenerate the acid. Therefore, similar groups might be suitable as temporary transport moieties for aspirin and other carboxylic acids.

Sulindac, a new anti-inflammatory agent containing a sulfinyl group, undergoes reversible reduction–oxidation biotransformation to the sulfide and an irreversible oxidation to the sulfone in several animal species including humans (25). The methylthiomethyl ester thus should be susceptible to enzymatic oxidation and subsequent cleavage in the body. Benzoic acid was used first as a model compound, and the corresponding methylthiomethyl (XI), methylsulfinylmethyl (XII), and methylsulfonylmethyl (XIII) esters were synthesized. Analogous derivatives of salicylic acid (XIV–XVI) and of aspirin (XVII–XIX) then were prepared.

Detailed studies as to the physicochemical properties and chemical and enzymic hydrolysis rates were carried out on XI–XIX. The results, including the complex hydrolysis characteristics of XVII–XIX, will be reported in separate papers. This report describes the enzymic hydrolysis studies on XIV–XIX; the data also show that at least one aspirin derivative is an effective true prodrug of I, resulting in aspirin *in vivo*.

## EXPERIMENTAL

**Methylthiomethyl Benzoate (XI)**—The compound was prepared by reacting benzoic acid with chloromethyl methyl sulfide in the presence of triethylamine as described earlier (23). The obtained ester was distilled under reduced pressure, bp 93–95°/0.3 mm [lit. (23) bp 106–108°/2 mm]; mol. wt. 182.24; IR (neat): 3060, 2920, 1710, 1595, 1450, 1330, 1310, 1250, 1100, 1070, 1025, 930, 750, and 710 $cm^{-1}$; NMR ($CDCl_3$): δ 7.2–8.2 (m, 5H), 5.4 (s, 2H), and 2.3 (s, 3H) ppm; mass spectrum (70 ev): *m/z* (relative intensity) 182 (9), 105 (100), and 77 (41).

**Methylsulfinylmethyl Benzoate (XII)**—To a chloroform solution containing 0.91 g (0.005 mole) of XI was added, in portions over 15 min with stirring, 1.0 g (0.005 mole) of *m*-chloroperbenzoic acid (85% solution). The resultant solution was stirred at room temperature overnight, washed twice with saturated aqueous sodium bicarbonate solution, and dried over anhydrous sodium sulfate. The reaction mixture was filtered, and the filtrate was evaporated under reduced pressure to afford a pale-yellow liquid, which crystallized on standing several hours at room temperature. Trituration of the residue in petroleum ether (bp 30–60°) gave 0.7 g (0.0035 mole) of the desired product (70% yield) as a white solid, mp 43–45°; IR (neat, melt): 3060, 3000, 2920, 1710, 1590, 1445, 1310, 1240, 1100, 1050, 800, and 710 $cm^{-1}$; NMR ($CDCl_3$): δ 7.3–8.3 (m, 5H), 5.2 (*AB*, 2H), and 2.7 (s, 3H) ppm; mass spectrum (70 ev): *m/z* (relative intensity) 168 (2), 135 (4), 105 (100), and 77 (42).

*Anal.*—Calc. for $C_9H_{10}O_3S$: C, 54.52; H, 5.08; S, 16.18. Found: C, 54.22; H, 5.22; S, 16.40.

**Methylsulfonylmethyl Benzoate (XIII)**—Use of the method described for XII, but with 2 equivalents of *m*-chloroperbenzoic acid, afforded the desired product, mp 116–118°; IR (KBr): 3060, 3000, 2920, 1730, 1590, 1545, 1420, 1300, 1250, 1095, 950, 800, and 720 $cm^{-1}$; NMR

[1] N. Bodor, unpublished work.

[2] N. Bodor, unpublished work. The pivalyloxymethyl ester (VIII) is a solid which has a low melting point (36–38°) and which is soluble to the extent of 25% in oil. The solution did not show any decomposition for 2 years at room temperature.

($CDCl_3$): δ 7.3–8.4 (m, 5H), 5.3 (s, 2H), and 3.0 (s, 3H) ppm; mass spectrum (70 ev): *m/z* (relative intensity) 184 (4), 135 (2), 105 (100), and 77 (36).

*Anal.*—Calc. for $C_9H_{10}O_4S$: C, 50.45; H, 4.71; S, 14.97. Found: C, 50.61; H, 5.00; S, 15.18.

**Methylthiomethyl 2-Hydroxybenzoate (XIV)**—To an acetonitrile solution containing 13.8 g (0.1 mole) of salicylic acid and 10.1 g (0.1 mole) of triethylamine at 0° was added dropwise, with stirring, 9.6 g (0.1 mole) of chloromethyl methyl sulfide. The solution was heated under reflux for 24 hr. The solvent was then removed under reduced pressure, and the residue was suspended in benzene. The formed triethylamine hydrochloride was removed by filtration, and the filtrate was washed twice with saturated aqueous sodium bicarbonate solution, dried over anhydrous sodium sulfate, and filtered. Removal of benzene by evaporation under reduced pressure afforded a liquid. Vacuum distillation gave 15.8 g (0.08 mole) of the desired product (80% yield) as a clear, colorless liquid, bp 107–109°/0.8 mm; IR (neat): 3200, 2920, 1670, 1600, 1580, 1480, 1415, 1350, 1280, 1200, 1170, 1140, 1080, 920, 840, 760, and 700 $cm^{-1}$; NMR ($CDCl_3$): δ 10.5 (broad s, 1H), 6.6–8.0 (m, 4H), 5.4 (s, 2H), and 2.3 (s, 3H) ppm; mass spectrum (70 ev): *m/z* (relative intensity) 198 (7), 121 (15), and 61 (100).

*Anal.*—Calc. for $C_9H_{10}O_3S$: C, 54.52; H, 5.08; S, 16.18. Found: C, 54.70; H, 5.26; S, 16.01.

**Methylsulfinylmethyl 2-Hydroxybenzoate (XV)**—Substitution of an equivalent quantity of XIV for the benzoic acid methylthiomethyl ester (XI) used for the synthesis of XII and repetition of the described procedure afforded the desired product, mp 110–112° (ethanol); IR (KBr): 3200, 3000, 1680, 1600, 1580, 1480, 1345, 1280, 1130, 1090, 940, and 770 $cm^{-1}$; NMR ($CDCl_3$): δ 10.2 (s, 1H), 6.7–8.1 (m, 4H), 5.3 (*AB*, 2H), and 2.8 (s, 3H) ppm; mass spectrum (70 ev): *m/z* (relative intensity) 214 (1), 121 (100), 93 (13), and 65 (10).

*Anal.*—Calc. for $C_9H_{10}O_4S \cdot 1/2H_2O$: C, 48.42; H, 4.97; S, 14.36. Found: C, 48.14; H, 4.51; S, 14.94.

**Methylsulfonymethyl 2-Hydroxybenzoate (XVI)**—By using the method described for the preparation of XIII, the ester XIV was transformed into the desired product in an 85% yield, mp 124–126° (ethanol); IR (KBr): 3200, 3000, 1680, 1600, 1580, 1480, 1420, 1345, 1320, 1280, 1240, 1190, 1130, 1090, 940, 770, and 710 $cm^{-1}$; NMR ($CDCl_3$): δ 10.0 (s, 1H), 6.8–8.1 (m, 4H), 5.3 (s, 2H), and 3.1 (s, 3H) ppm; mass spectrum (70 ev): *m/z* (relative intensity) 230 (10), 121 (100), 93 (10), and 65 (12).

*Anal.*—Calc. for $C_9H_{10}O_5S$: C, 46.95; H, 4.38; S, 13.93. Found: C, 47.14; H, 4.52; S, 14.52.

**Methylthiomethyl 2-Acetoxybenzoate (XVII)**—Substitution of an equivalent quantity of aspirin for the salicylic acid used in the preparation of XIV and repetition of that described procedure afforded the desired product, bp 148–150°/1 mm; IR (neat): 3060, 2920, 1755, 1715, 1600, 1480, 1450, 1365, 1280, 1200, 1060, 920, 750, and 705 $cm^{-1}$; NMR ($CDCl_3$): δ 6.9–8.2 (m, 4H), 5.3 (s, 2H), 2.3 (s, 3H), and 2.2 (s, 3H) ppm; mass spectrum (70 ev): *m/z* (relative intensity) 240 (2), 198 (10), 163 (9), 121 (41), and 61 (100).

*Anal.*—Calc. for $C_{11}H_{12}O_4S$: C, 54.98; H, 5.04; S, 13.35. Found: C, 55.17; H, 5.15; S, 13.69.

**Methylsulfinylmethyl 2-Acetoxybenzoate (XVIII)**—The method described for the synthesis of XV was used, starting with 7.2 g (0.03 mole) of the methylthiomethyl ester, XVII. Recrystallization from tetrahydrofuran of the crude product resulted in pure XVIII in an 80% yield (6.1 g), mp 118–122°; IR (KBr): 3000, 1750, 1720, 1600, 1480, 1370, 1300, 1180, 1080, 920, 830, 755, and 705 $cm^{-1}$; NMR ($CDCl_3$): δ 7.0–8.2 (m, 4H), 5.2 (*AB*, 2H), 2.6 (s, 3H), and 2.4 (s, 3H) ppm; mass spectrum (70 ev): *m/z* (relative intensity) 214 (2), 163 (23), 121 (100), 93 (7), 92 (7), and 65 (7).

*Anal.*—Calc. for $C_{11}H_{12}O_5S \cdot 1/2H_2O$: C, 49.80; H, 4.94; S, 12.09. Found: C, 49.49; H, 4.59; S, 12.69.

**Methylsulfonylmethyl 2-Acetoxybenzoate (XIX)**—To a stirred chloroform solution of 7.2 g (0.03 mole) of methylthiomethyl 2-acetoxybenzoate (XVII) at 0° was added 12.0 g (0.06 mole) of *m*-chloroperbenzoic acid. The reaction mixture was worked up as for XVI as a white crystalline product, mp 151–153°; IR (KBr): 3010, 1750, 1725, 1600, 1480, 1300, 1245, 1185, 1120, 1090, 1000, 920, 760, and 710 $cm^{-1}$; NMR ($CDCl_3$): δ 7.0–8.2 (m, 4H), 5.3 (s, 2H), 3.0 (s, 3H), and 2.4 (s, 3H) ppm; mass spectrum (70 ev): *m/z* (relative intensity) 272 (<1), 230 (21), 163 (11), 121 (100), 93 (10), 92 (10), and 65 (11).

*Anal.*—Calc. for $C_{11}H_{12}O_6S$: C, 48.52, H, 4.44; S, 11.78. Found: C, 48.48; H, 4.43; S, 11.76.

***In Vivo* Studies**—Four purebred female beagle dogs, 1.5 years old, were used to determine the blood levels of various metabolites after oral and intravenous administration of aspirin (I) and the three aspirin derivatives (XVII–XIX). For oral administration, the compounds were dissolved in polyethylene glycol 400 and placed in gelatin capsules. Dimethyl sulfoxide solutions were used for the intravenous dosing. The doses were adjusted so that the dogs received equimolar doses of aspirin and the aspirin derivatives, both intravenously and orally. Each experiment was repeated at least once. Each dog was allowed to rest for a minimum of 1 week before it was used again.

Blood (2 ml) was withdrawn from each dog and acidified immediately by mixing with 2 ml of chilled 10% aqueous potassium bisulfate and 1 drop of potassium fluoride (~25 mg) in a 15-ml centrifuge tube. This process lowers the sample pH to ~1 and quenches enzymatic ester hydrolysis. Ether (7.0 ml) was added to each tube, and the samples were mixed on a mechanical shaker for 30 min and then centrifuged. A 5.0-ml portion of the supernate was removed and evaporated to dryness, and the residue was dissolved in 1.0 ml of acetonitrile. This solution then was analyzed by high-pressure liquid chromatography (HPLC). The recoveries (±*SE*) of aspirin (I) and salicylic acid (II) from whole blood were 97.8 ± 3.2 and 98.3 ± 2.7%, respectively. Aspirin hydrolysis during the entire workup was 5.4 ± 0.5% (*SE*).

**Enzymatic Hydrolytic Cleavage of XIV–XIX and Aspirin in Human Plasma**—The plasma[3] was stored in a refrigerator and used within 1 week from the date it was collected. A portion of 100 μl of a standard solution of the compound in acetonitrile was added to 10 ml of plasma at 37°. The plasma samples were extracted according to a literature method (26). Thus, 0.50-ml samples of plasma were withdrawn from the test medium, placed in 15-ml stoppered centrifuge tubes, and acidified with 0.50 ml of 10% potassium bisulfate and 1 drop of potassium fluoride (~25 mg). Chloroform (3 ml) was added to each tube and mixed on a mechanical shaker for 15 min.

The resulting emulsions were centrifuged, and 2.0 ml of the chloroform solution was recovered. These extracts were evaporated to dryness under continuous nitrogen flow, and the residue was dissolved in 0.50 ml of methanol. The methanolic solution was analyzed by HPLC. Plasma samples were also analyzed separately by injecting 5–10 μl of plasma directly into the chromatograph. Both methods gave the same results. In the plasma studies, the substrate concentration was kept low ($<10^{-3}$ *M*), and the rate constants were calculated as first order by following the disappearance of the compound with time.

**Analytical Methods**—An HPLC method was developed for studies of the complex degradation of 2-acetoxybenzoates because hydrolysis of XVII–XIX can lead to at least three possible hydrolytic products for each compound. The chromatographic analysis was performed on a component system[4]. A 30-cm × 3.9-mm i.d. column[5], operated at ambient temperature, was used for all separations. The mobile phase used for the separation of methylthiomethyl 2-acetoxybenzoate (XVII) and its degradation products consisted of acetonitrile–acetic acid/sodium acetate–water (450:10:540). The pH was adjusted to 3.86 with 25% aqueous NaOH. At a flow rate of 2.0 ml/min, the retention times of XVII, XIV, aspirin (I), and salicylic acid (II) were 6.2, 9.2, 2.2, and 2.0 min, respectively.

The mobile phase used for separation of methylsulfinylmethyl (XVIII) and methylsulfonylmethyl (XIX) 2-acetoxybenzoates and their degradation products consisted of acetonitrile–methanol–acetic acid/sodium acetate–water (140:115:5:740). The pH was adjusted to 3.86 with 25% aqueous NaOH. At a flow rate of 2.0 ml/min, the retention times of XVIII, XIX, XV, XVI, I, and II were 6.9, 9.5, 7.1, 10.1, 5.2 and 3.6 min, respectively. For the separation of the benzoate derivatives, 70% methanol in water was used as the mobile phase. The plot of the peak heights *versus* the various amounts of each derivative studied was linear in the concentration range studied. In the reaction mixture, the concentration of the compounds was determined by comparison of the peak heights for the compounds to the corresponding standard curves. When the biological extracts or fluids were analyzed, the column was protected by a 5-cm × 2-mm i.d. precolumn packed with CO:Pell ODS[6].

## RESULTS AND DISCUSSION

The prodrugs of aspirin (XVII–XIX) and those of salicylic acid (XIV–XVI) were well-defined, stable compounds and are easy to synthesize. As expected, the melting point of the compounds increases in the

[3] The human plasma was obtained from the Community Blood Center of Greater Kansas City and contained ~80% plasma diluted with anticoagulant citrate phosphate dextrose solution USP.

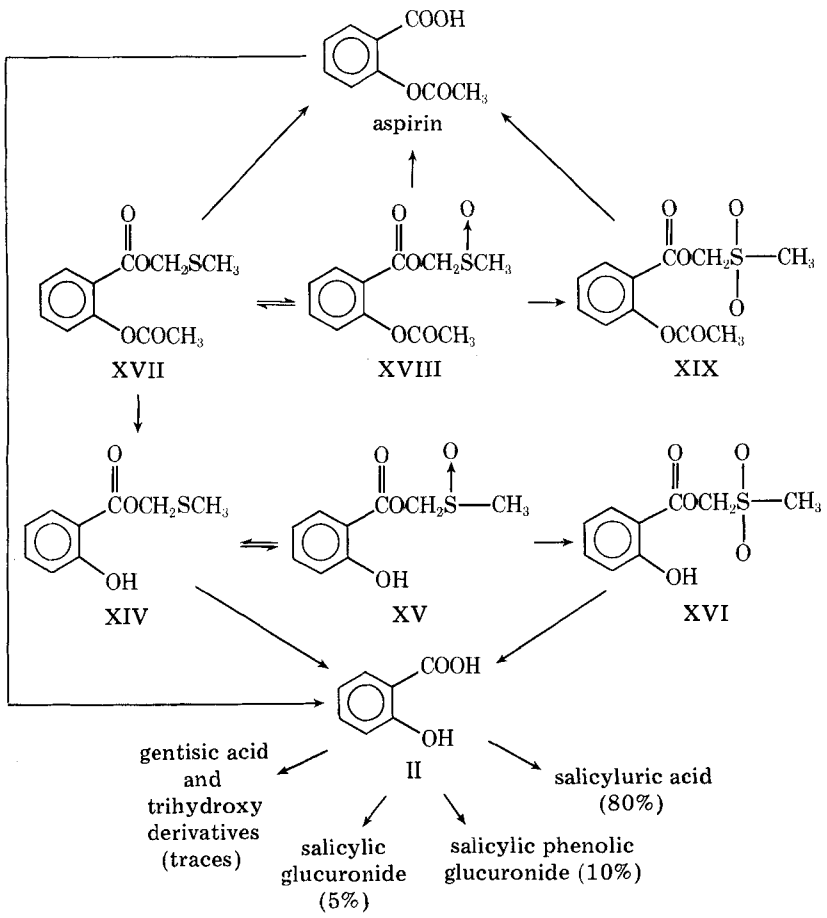

*Scheme I—Possible metabolic routes of methylthiomethyl (XVII), methylsulfinylmethyl (XVIII), and methylsulfonylmethyl (XIX) 2-acetoxybenzoates (based on Refs. 25, 27, and 28 and results obtained in this work).*

order of level of oxidation stage. Thus, while the methylthiomethyl derivative XVII is a liquid, XVIII has a melting point of 120° and XIX melts at 153°. The solubilities follow the reverse order since XVII is freely soluble in acetonitrile, methanol, and polyethylene glycol 400 (0.1 g/ml) while XIX is only sparingly soluble in methanol and acetonitrile and almost insoluble in polyethylene glycol.

Detailed physicochemical studies of the new esters, XII–XIX, were carried out after it was shown that enzymic cleavage of the aspirin prodrugs XVII–XIX results in significant amounts of aspirin.

The possible routes for the complex interconversion–metabolism of the prodrugs are shown in Scheme I. Thus, XVII, XVIII, and XIX theoretically could cleave to provide aspirin or the corresponding salicylates (XIV, XV, and XVI, respectively). Everything would finally result in salicylic acid, which undergoes the usual metabolism (25, 27, 28).

Alternatively, the thiomethyl ester(s) could undergo reversible oxidation to the sulfinyl and then to the corresponding sulfonyl esters.

Aspirin is hydrolyzed rapidly at 37° in human whole blood and plasma, with an average half-life of ~30 min and 1 hr, respectively (29). In the human body, aspirin is hydrolyzed even faster, with a half-life of 13–20 min (9) to form salicylic acid, which then is conjugated in part with glycine and glucuronic acid to form various acyl and phenolic conjugates (30). Several other minor metabolites also are formed. Free salicylic acid and its metabolites are eliminated from the body by renal excretion. For any derivative to be called a true aspirin prodrug, it has to be hydrolyzed enzymatically or nonenzymatically within the body to form aspirin. The rate of conversion must ensure buildup of the drug to a level capable of eliciting a pharmacological effect. Aspirin is much more active as an analgesic agent than salicylic acid, and aspirin formation in the body could be important for the analgesic activity of the compound (18).

Human plasma was used to determine the hydrolysis routes and rates of the compounds of main interest (XVII–XIX), as compared to the salicylates (XIV–XVI) and aspirin.

The hydrolysis rates in plasma of the 2-acetoxybenzoate esters (XVII–XIX) measured by following the disappearance of the compound with time and that of aspirin are listed in Table I. All three aryl esters have much shorter half-lives than that obtained for aspirin (~2 hr). Rowland *et al.* (9) studied aspirin hydrolysis in 90% volume fresh human blood and plasma at 37° and found the average half-life to be ~30 min in whole blood and slightly over 1 hr in plasma. In the present experiment,

80% volume plasma was used under different conditions and the aspirin half-life was somewhat longer. A wide variation in hydrolysis rates of aspirin was seen in plasma from different individuals (31). The hydrolysis rates of the 2-hydroxybenzoates (XIV–XVI) are compared to that of methyl salicylate (XX) in Table II. The ester, XX, was selected as a model

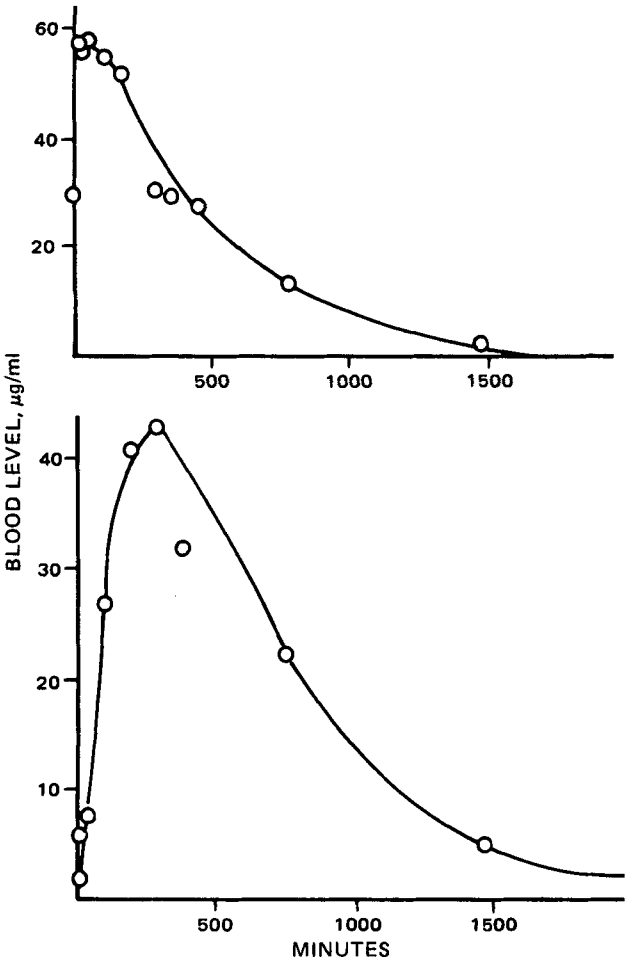

**Figure 5**—*Blood levels of salicylic acid (○) after administration of an intravenous dose of 302 mg of methylthiomethyl 2-acetoxybenzoate (XVII) to an 8.6-kg dog (top) and an oral dose of 570 mg of XVII to an 8.4-kg dog (bottom).*

for a salicylate. The $k_{obs}$ values were determined following the disappearance of the starting materials.

All sulfur-containing "activated" esters (XIV–XVI) are hydrolyzed faster in plasma than the methyl 2-hydroxybenzoate (XX). Thus, the methylsulfonylmethyl ester (XVI) is hydrolyzed 67 times faster than the methyl ester.

The disappearance of the aspirin prodrugs and appearance of aspirin, salicylic acid, and the corresponding salicylates are shown in Figs. 1–3. The prodrugs XVIII and XIX result in significant aspirin concentrations, while XVII cleaves according to both pathways, one leading to the salicylate (XIV) and the other to aspirin. These results imply that XVIII and XIX are promising true prodrugs of aspirin since no formation of the salicylates XV and XVI, respectively, was observed, and the main hydrolysis product was aspirin. The delivery characteristics of XVII–XIX thus were determined *in vivo* using beagle dogs.

After oral administration of XVII, XVIII, XIX, or aspirin equivalent to 50 mg of aspirin/kg and intravenous administration of XVII, XVIII, XIX, or aspirin equivalent to 25 mg of aspirin/kg to dogs, the appearance in the blood of the compound and its possible metabolites was followed as a function of time. With XIX, only 8 mg/kg was administered intravenously to the dog because of its low solubility in the vehicle dimethyl sulfoxide. The appearance and disappearance of salicylic acid in the blood were fitted to an exponential equation $C_p = Ne^{-k_a t} + Le^{-\alpha t} + Me^{-\beta t}$ (32, 33). The blood aspirin concentration after oral and intravenous administration of aspirin also was fit to the exponential equation, where $k_a$ was set equal to infinity after intravenous administration (34). The disappearance of XVIII in the blood after intravenous administration was fit to a simple first-order equation. The results are shown in Figs. 4–7.

The methylthiomethyl (XVII) and methylsulfonylmethyl (XIX) 2-acetoxybenzoates were metabolized rapidly in the body, resulting in peak blood salicylic acid levels within the first 10 min after an intravenous dose (Figs. 5 and 7). The first samples were withdrawn at 2 min after the intravenous injection. No aspirin, starting 2-acetoxybenzoate, or the possible intermediate 2-hydroxybenzoate esters was detected in these samples. After oral administration of XVII and XIX, only salicylic acid was detected. Methylsulfinylmethyl 2-acetoxybenzoate (XVIII) was metabolized more slowly, with a peak blood salicylic acid level at 30 min after an intravenous dose (Fig. 6), which is about the same time as obtained after intravenous aspirin (Fig. 5). Within 3–5 min after the intravenous administration, the aspirin formation rate was equal to the disappearance rate of XVII. However, after 7 min, no XVIII or aspirin was detected in the blood. After oral administration of XVIII, only salicylic acid was detected with a peak blood level at 300 min (Fig. 5).

All aspirin derivatives (XVII–XIX) apparently are metabolized mainly to salicylic acid.

Aspirin is hydrolyzed rapidly in the body to form salicylic acid. After intravenous aspirin, the plasma aspirin concentration *versus* time curve can be described by the biexponential equation $C_p = Ae^{-\alpha t} + Be^{-\beta t}$ (34). The half-life of the first exponent ($\alpha$) is 2–5 min and that of $\beta$ is 13–19 min. Therefore, aspirin disappears rapidly as it is formed from its prodrugs XVII–XIX and never reaches high blood levels. Salicylic acid was shown to be the only direct metabolite of aspirin (32). For the methylsulfinylmethyl 2-acetoxybenzoate (XVIII) to give such high aspirin levels in the body (Fig. 6), comparable to those obtained after an oral dose of aspirin (Fig. 4), a considerable fraction of the dose must be metabolized to form aspirin. Thus, at least XVIII is a true aspirin prodrug.

The analgesic efficacy of aspirin in the dog and the correlation between such analgesia and the plasma levels of aspirin and its primary metabolite, salicylic acid, were studied (35). It was concluded that the onset and duration of aspirin analgesia after oral and intravenous administration cannot be correlated with plasma aspirin levels and that, during analgesia, aspirin can only be detected in extremely low concentrations because of its rapid hydrolysis to salicylic acid. Therefore, although XVIII is the only

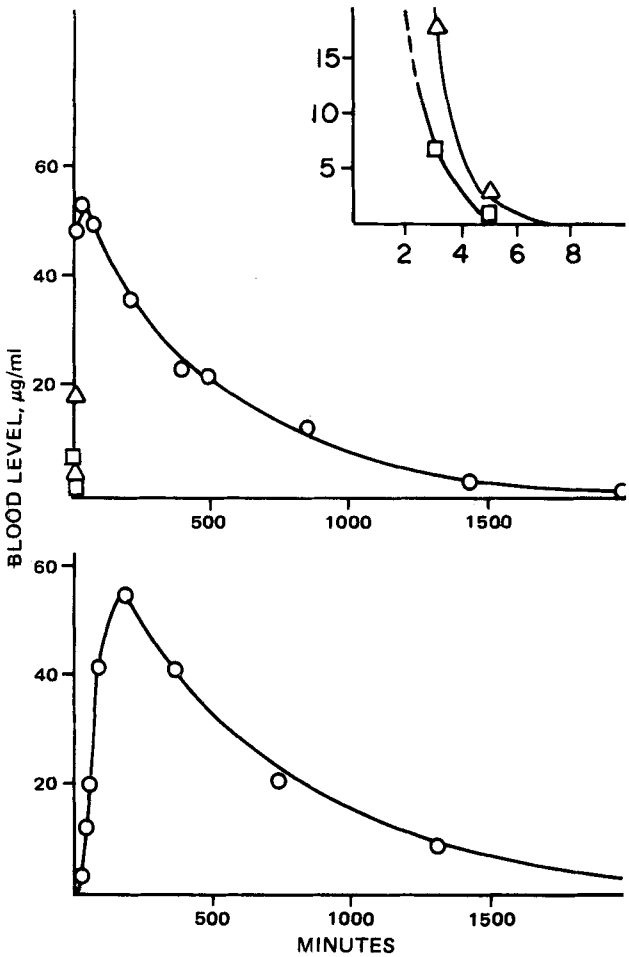

**Figure 6**—*Blood levels of methylsulfinylmethyl 2-acetoxybenzoate (XVIII) (△), aspirin (□), and salicylic acid (○) after administration of an intravenous dose of 370 mg of XVIII to a 9.2-kg dog (top) and an oral dose of 620 mg of XVIII to a 9.0-kg dog (bottom).*

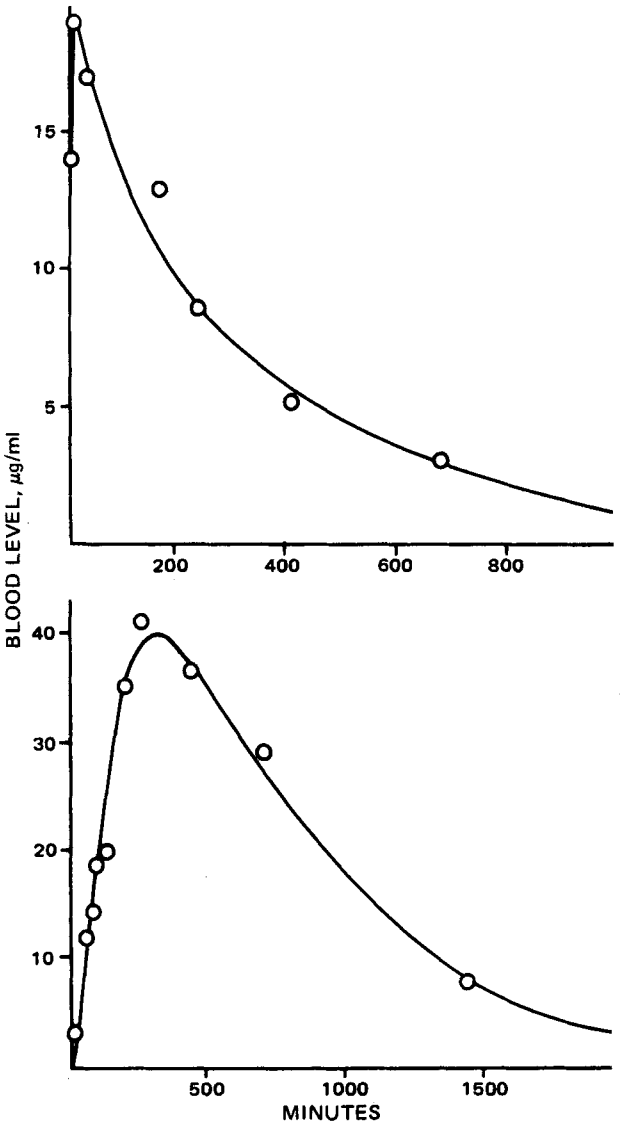

**Figure 7**—*Blood levels of salicylic acid (○) after administration of an intravenous dose of 115 mg of methylsulfonylmethyl 2-acetoxybenzoate (XIX) to a 9.2-kg dog (top) and an oral dose of 750 mg of XIX to a 9.2-kg dog (bottom).*

one of the three aspirin derivatives that gives detectable blood levels of aspirin in the dog, this finding does not necessarily mean that XVII and XIX are not useful prodrugs. This is particularly true since aspirin is metabolized about three times faster in dogs than in humans. Based on the human plasma cleavage data, XVII results mainly in the salicylate XIV. On the other hand, the methylsulfonylmethyl ester (XIX) has solubility problems. Thus, at least the methylsulfinylmethyl ester XVIII is a promising aspirin prodrug.

Similar prodrugs should be useful for improved delivery of a wide variety of acidic drugs, including the various known anti-inflammatory agents.

# Improved Delivery through Biological Membranes IX: Kinetics and Mechanism of Hydrolysis of Methylsulfinylmethyl 2-Acetoxybenzoate and Related Aspirin Prodrugs

**THORSTEINN LOFTSSON * and NICHOLAS BODOR ‡x**

Received August 25, 1980, from the **Department of Pharmaceutical Chemistry, School of Pharmacy, University of Kansas, Lawrence, KS 66045*, and the ‡*Department of Medicinal Chemistry, College of Pharmacy, J. Hillis Miller Health Center, University of Florida, Gainesville, FL 32610.* Accepted for publication November 24, 1980.

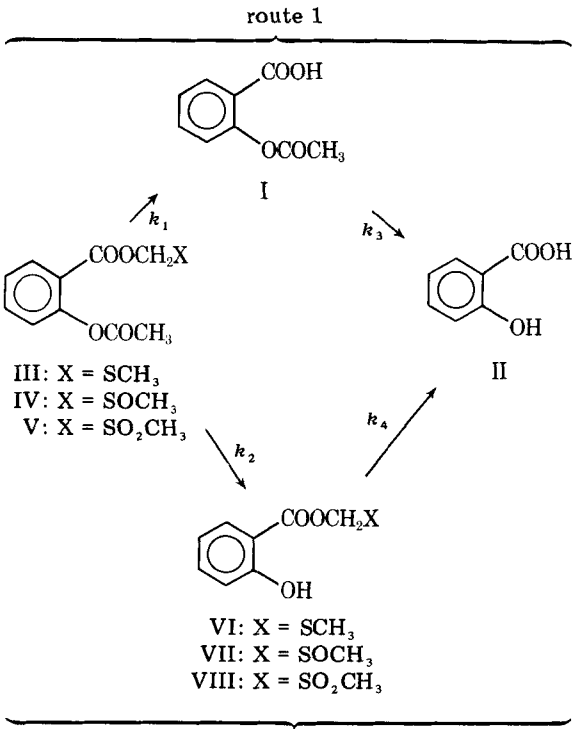
**Abstract** □ The complex kinetics and mechanism of the hydrolysis of the methylthiomethyl, methylsulfinylmethyl, and methylsulfonylmethyl 2-acetoxybenzoates, novel aspirin prodrugs, were studied. The pH profiles for the related salicylates and benzoates also were determined. Based on the activation parameters, isotope effects, and other data, it was established that the methylthiomethyl esters hydrolyze *via* a unimolecular alkyl–oxygen cleavage. The methylsulfinylmethyl and methylsulfonylmethyl 2-acetoxybenzoates undergo neutral hydrolysis of esters at pH > 4 to form aspirin, while water acts as a general base; but at lower pH, a different mechanism takes place and the *o*-acetyl group cleaves first, releasing the corresponding salicylates.

**Keyphrases** □ Methylsulfinylmethyl 2-acetoxybenzoate—kinetics and mechanism of hydrolysis □ Prodrugs, aspirin—methylsulfinylmethyl 2-acetoxybenzoate, kinetics and mechanism of hydrolysis □ Hydrolysis—kinetics and mechanism established for methylsulfinylmethyl 2-acetoxybenzoate and other related aspirin prodrugs

The results of the *in vitro* enzymic cleavage studies and the *in vivo* blood level data (1) indicate that the novel aspirin derivatives of the methylsulfinylmethyl and related ester type are promising, true aspirin prodrugs. These observations warranted a detailed study of the complex kinetics and mechanism of the chemical hydrolysis of these esters. Theoretically, the new prodrugs can hydrolyze in two steps *via* two routes (Scheme I).

Thus, the pH profiles for the hydrolysis of III–V and VI–VIII were determined and compared to that of aspirin and simple related benzoates [methylthiomethyl benzoate (IX), methylsulfinylmethyl benzoate (X), and methylsulfonylmethyl benzoate (XI)]. The various activated esters (methylthiomethyl, methylsulfinylmethyl, and methylsulfonylmethyl) and the *o*-phenolacetates may have different mechanisms of hydrolysis at the various pH values. The influence of ionic strength, dielectric constant, activation parameters, and solvent isotope effects also was studied to elucidate the mechanism of the hydrolysis and to explain the shapes of the pH profiles.

Comparison of the chemical and the enzymic hydrolysis revealed interesting differences.



*Scheme I*

## EXPERIMENTAL

**Instrumentation**—The high-pressure liquid chromatographic (HPLC) method (1) was used for the determination of aspirin (I), salicylic acid (II), the aspirin derivatives (III–V), and the salicylates (VI–VIII), except at pH > 9.55. At these pH values, the hydrolytic rate constants were determined directly spectrophotometrically at 349 nm using a spectrophotometer[1] equipped with a thermostated cell compartment maintained at 50.8° by a circulating water bath.

The phenolic pKa values of VI–VIII were determined[1] spectrophotometrically at room temperature. Four ovens were used in the determination of the activation parameters. A research pH meter[2] was equipped with a combination glass electrode standardized at the temperature at which the kinetic data were obtained.

**Materials**—All buffer solutions for kinetic studies were prepared from deionized water that was boiled for 5 min to liberate the dissolved gases and cooled under nitrogen. Sufficient water was added to weighed amounts of various buffer salts to yield a solution of the desired molarity and ionic strength. The buffer solutions were thermostated at 50.8° where the pH and volumes were adjusted. All buffer solutions were stored under nitrogen in a refrigerator and used within 1 week. Where the buffer capacity was questionable, the pH was checked following each kinetic run. All chemicals used were analytical grade.

**Determination of Hydrolytic Rate Constants**—For the determination of the hydrolysis rate constants of aspirin (I), its derivatives (III–V), and related compounds (VI–XI), 50 μl of a concentrated acetonitrile solution of each ester was added separately to 10 ml of buffer, previously equilibrated to the desired temperature in a water bath, and mixed thoroughly to give an initial concentration of $5 \times 10^{-4}$ mole/liter. All reactions were run under pseudo-first-order conditions. Aliquots (100 μl) were injected into the column at various intervals, and the pseudo-first-order rate constants were determined from the disappearance of the compound by linear regression of natural logarithm of the peak height *versus* time plots. The half-life, correlation coefficient, and standard error

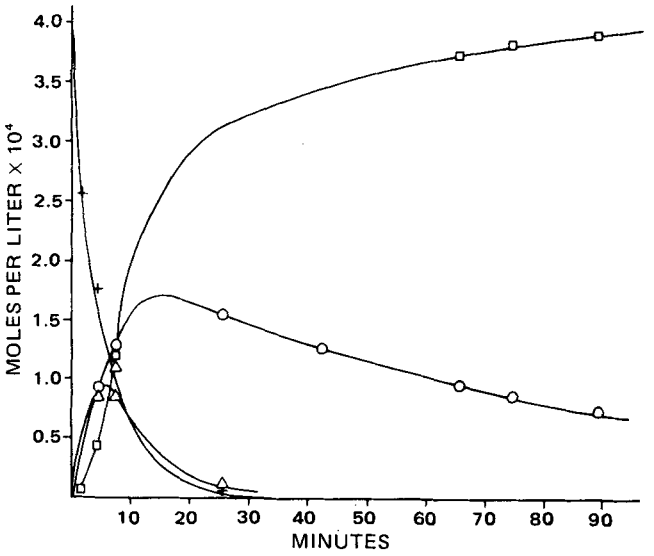

**Figure 1**—*Kinetics of hydrolysis of methylthiomethyl 2-acetoxybenzoate (III) (+) in 0.01* M *carbonate buffer (pH 9.55) at 50.8° and 0.1* M *ionic strength to form methylthiomethyl 2-hydroxybenzoate (VI) (△), aspirin (I) (○), and salicylic acid (II) (□).*

of the rate constant were calculated for each run (2).

At lower pH values, where hydrolysis was slow, the reaction mixture was introduced into ampuls of 1 or 2 ml, sealed under nitrogen, and immersed in a thermostated bath. Individual ampuls were withdrawn at various times, and the concentrations were determined using HPLC. At higher pH values, where the disappearance of absorbance at 349 nm was followed, 20 μl of a concentrated solution of the reactant in acetonitrile was added to 3 ml of buffer in a 1-cm quartz cell previously equilibrated to 50.8° in the cell compartment of the spectrophotometer. The cell was closed and shaken to ensure mixing. The pseudo-first-order rate constant was determined by linear regression of $\ln(A_t - A_\infty)$ *versus* time, where $A_\infty$ is the absorbance at 349 nm after 10 half-lives and $A_t$ is the absorbance at time $t$.

**Determination of Phenolic pKa Values of VI–VIII**—The pKa values for the 2-hydroxybenzoates (VI–VIII) were determined spectrophotometrically at room temperature (23°). Five tris(hydroxymethyl)-aminomethane and three carbonate buffers of ionic strength 0.1 *M* (using sodium chloride) were prepared at 23° in the pH 8.38–10.14 range. The UV absorption of the undissociated and dissociated forms was determined in 0.1 *N* HCl and 0.01 *M* $Na_2CO_3$ solutions. A solution (100 μl) of the compound in acetonitrile was added to 3.00 ml of buffer at time zero. Due to the rapid hydrolysis of the ester(s), the decrease in absorbance at 23° was followed at a given wavelength for a short time, and the absorbance at time zero was found by extrapolation. The pKa values were calculated using $pKa = pH - \log(a_{obs} - a_{HA})/(a_{A^-} - a_{obs})$, where $a_{obs}$ is the absorbance of the solution tested, $a_{HA}$ is absorbance of the unionized species, and $a_{A^-}$ is the absorbance of the ionized species. The pKa of methylthiomethyl 2-hydroxybenzoate (VI) was 9.60 ± 0.01; it was 9.00 ± 0.2 and 8.91 ± 0.02 for methylsulfinylmethyl 2-hydroxybenzoate (VII) and methylsulfonylmethyl 2-hydroxybenzoate (VIII), respectively.

**Determination of Activation Parameters for III and VI–VIII Hydrolysis**—The change in the reaction rates with temperature for the hydrolysis of VI–VIII in 0.1 *N* HCl (pH 1.1) and of III in unbuffered aqueous solution (pH 5) was studied. The ionic strength was maintained at 0.1 *M* with sodium chloride. Because of the slow reaction, the activation parameters for the hydrolysis of VII and VIII were determined using solutions of the compounds sealed in ampuls and stored at constant temperature for various intervals in four ovens maintained at 35.8, 44.0, 61.0, and 102.8°, respectively. The activation parameters for III and VI hydrolysis were determined by measuring the pseudo-first-order rate constants at 50–30°.

**Influence of Ionic Strength and Dielectric Constant**—The effect of the solvent ionic strength (0.05–0.5 *M* NaCl) on III hydrolysis in unbuffered aqueous solutions was studied at 50.8°. The effect of the solvent dielectric constant on the reaction rate also was investigated at 50.8° in an aqueous solution containing up to 30% dioxane. The dielectric constant of each water–dioxane mixture was calculated at 50.8° (3). The pseudo-first-order rate constants were determined using HPLC to follow the disappearance of III as a function of time.

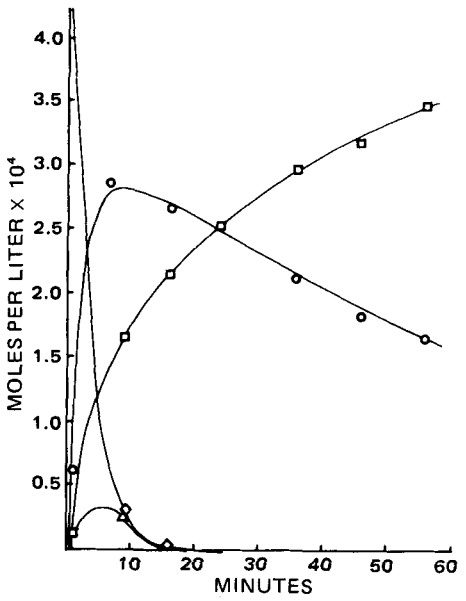

**Figure 2**—*Kinetics of hydrolysis of methylsulfinylmethyl 2-acetoxybenzoate (IV) in 0.01* M *carbonate buffer (pH 9.55) at 50.8° and 0.1* M *ionic strength to form methylsulfinylmethyl-2-hydroxybenzoate (VII) (△), aspirin (○), and salicylic acid (□).*

**Solvent Isotope Effect**—The deuterium solvent isotope effects on the hydrolysis rate of III, VII, and VIII were measured at 50.8° and ionic strength 0.1 *M*. The pseudo-first-order rate constants were determined as described. The hydrolysis rate constants for VII and VIII were determined in 0.1 *N* DCl solution in deuterium oxide (pD 0.9).

## RESULTS AND DISCUSSION

The hydrolysis rate constants were all first order for the 2-acetoxybenzoates (III–V). The pseudo-first-order rate constants ($k_{obs}$) for the three 2-acetoxybenzoates were determined by HPLC following the disappearance of the compound as a function of time at pH 1.13, 2.64, 4.00, 7.96, and 9.55 at four buffer concentrations at 50.8 ± 0.2° and ionic strength 0.1 *M*. The kinetics of the disappearance of III and the formation of the various hydrolysis products (I, II, and VI) are exemplified in Fig. 1 (pH 9.55 at 50.8°). Under the same conditions, IV gave only traces of the salicylate (VII) (Fig. 2) while the most reactive V hydrolyzed only to aspirin (Fig. 3).

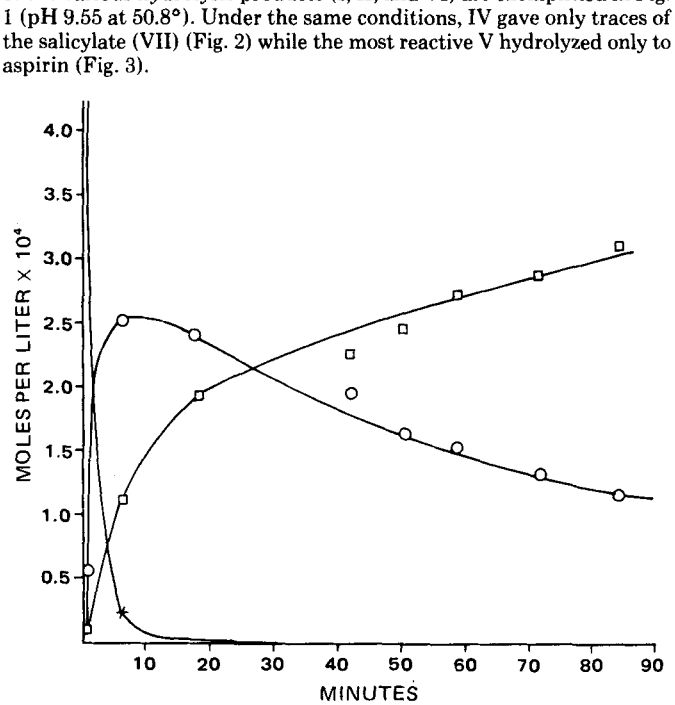

**Figure 3**—*Kinetics of hydrolysis of methylsulfonylmethyl 2-acetoxybenzoate (V) (+) in 0.01* M *carbonate buffer (pH 9.55) at 50.8° and 0.1* M *ionic strength to form aspirin (○) and salicylic acid (□).*

**Table II—Acid-Catalyzed, Base-Catalyzed, and Spontaneous Hydrolytic Rate Constants for Methylthiomethyl (III), Methylsulfinylmethyl (IV), and Methylsulfonylmethyl (V) 2-Acetoxybenzoates [a]**

| Rate Constant [b] | III | IV | V |
|---|---|---|---|
| $k_H$ | $2.97 \times 10^{-1}$ | $1.48 \times 10^{-2}$ | $1.42 \times 10^{-2}$ |
| $k_{H_2O}$ | $6.06 \times 10^{-2}$ | $2.35 \times 10^{-5}$ | $1.86 \times 10^{-5}$ |
| $k_{OH}$ | $5.61 \times 10^{2}$ | $1.75 \times 10^{3}$ | $2.50 \times 10^{3}$ |

[a] Conditions of 50.8 ± 0.2° and ionic strength 0.1 *M* (sodium chloride). [b] $k_H$ is the specific acid hydrolytic rate constant in liters per mole minute, $k_{H_2O}$ is the spontaneous hydrolytic rate constant in $minutes^{-1}$, and $k_{OH}$ is the specific base hydrolytic rate constant in liters per mole minute.

The $k_{obs}$ values were plotted against the buffer concentration, and the rate constants at zero buffer concentration ($k_0$) were obtained by linear regression (Table I). Only the carbonate buffer had any effect on the hydroxide-ion-catalyzed hydrolysis of III (slope = 2.50 ± 0.30) and IV (slope = 2.00 ± 0.01), but it had little effect on V hydrolysis. Tris(hydroxymethyl)aminomethane catalyzed the hydrolysis of IV (slope = 0.201 ± 0.007) and V (slope = 0.264 ± 0.009) but showed a very small effect on III (slope = 7.8 ± 0.4 × $10^{-2}$). Succinate buffer had a significant effect on the hydrolysis of V (slope = 3.15 ± 0.49 × $10^{-4}$) but little or no effect on the hydrolysis of the other two 2-acetoxybenzoate esters. The monochloroacetate buffer had a much smaller effect. The main degradation products at each pH were identified by HPLC to be the compounds according to Scheme I. At pH 4.00, 7.96, and 9.55, the main hydrolysis product was aspirin, which hydrolyzed further to salicylic acid (route 1, Scheme I); at pH 1.13, IV and V hydrolyzed to form only the corresponding 2-hydroxybenzoate esters (VII and VIII) (route 2), which are stable at low pH; no aspirin was formed. Compound III hydrolyzed mainly through route 1 at all pH values studied. The pH profiles for III–V, together with aspirin (I), are shown in Fig. 4. The curves for III–V can be described as a simple ester hydrolysis by:

$$k_0 = k_H a_{H^+} + k_{H_2O} + k_{OH} a_{OH^-} \qquad \text{(Eq. 1)}$$

where $k_{H_2O}$ is the rate constant for spontaneous water hydrolysis and $k_H$ and $k_{OH}$ are the rate constants for catalysis of the hydrolysis by hydronium and hydroxide ions, respectively.

The $k_H$, $k_{H_2O}$, and $k_{OH}$ values in Table II were calculated from the pseudo-first-order rate constants given in Table I using pKw = 13.26 at 50° (4). At pH 7.96, $k_1$ (Scheme I) was calculated by measuring the appearance of aspirin (Table III). In the hydrolysis of IV and V, tris(hydroxymethyl)aminomethane mainly affected $k_2$ but had little effect on $k_1$. At 0.04 *M* tris(hydroxymethyl)aminomethane concentration, ~50% of the hydrolysis went through route 1; but at zero buffer concentration, this route increased to ~90%. About 90% of the hydrolysis of III occurred *via* route 1 at all buffer concentrations; thus, its hydrolysis was catalyzed only very slightly by this buffer.

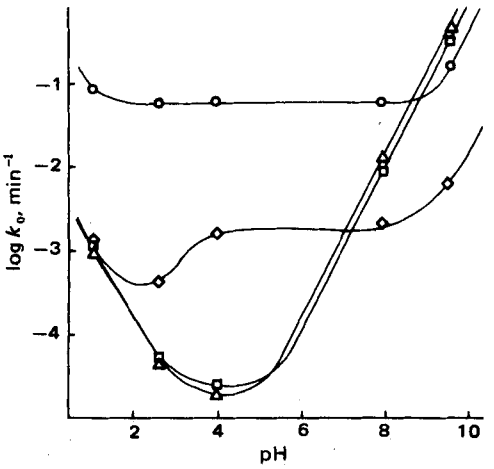

**Figure 4**—*Experimentally determined pH–rate profiles for hydrolysis of the methylthiomethyl (III) (○), methylsulfinylmethyl (IV) (□), and methylsulfonylmethyl (V) (△) 2-acetoxybenzoates at 50.8 ± 0.2° and 0.1 M ionic strength. The smooth curves from pH 0.5 to 10 were calculated using Eq. 1 and the constants given in Table II. The experimentally determined pH profile of aspirin (I) (◇) was included for comparison. The curve was calculated using Eq. 5.*

Hydrolysis of the possible intermediate salicylates (VI–VIII) also was studied. All the pseudo-first-order rate constants ($k_{obs}$) for the hydrolysis of the 2-hydroxybenzoates (VI–VIII) were determined at pH 1.13, 2.02, 2.64, 4.00, 5.97, 6.86, 7.96, 8.82, 9.55, 10.90, and 11.86 at four buffer concentrations at 50.8 ± 0.2° and ionic strength 0.1 *M*. The rate constants at zero buffer concentration ($k_0$) were obtained by extrapolation (Table IV).

Of the seven buffers, only the two trimethamine buffers had any significant effect on the hydrolysis rate. In the case of VI, this catalyzing effect was rather small at pH 7.96, and no effect was observed at pH 8.82. At pH 7.96, the slopes were 1.50 ± 0.06, 1.01 ± 0.08, and 2.23 ± 0.39 for VI, VII, and VIII, respectively. The pH rate profiles (Fig. 5) were fitted by computer to:

$$k_0 = f_{acid} k_{H_2O} + f_{base} k'_{H_2O} \qquad \text{(Eq. 2)}$$

where $k_{H_2O}$ and $k'_{H_2O}$ are the rate constants for the spontaneous water hydrolysis of the undissociated and dissociated reactant, respectively,

**Table III—Pseudo-First-Order Hydrolytic Rate Constants of Methylthiomethyl (III), Methylsulfinylmethyl (IV), and Methylsulfonylmethyl (V) 2-Acetoxybenzoates in Tris(hydroxymethyl)aminomethane Buffers at pH 7.96, 50.8 ± 0.1°, and 0.1 *M* Ionic Strength**

and $f_{acid}$ and $f_{base}$ are the fractions of the total reactant in acidic and basic form:

$$f_{acid} = \frac{a_{H^+}}{a_{H^+} + k_a} \quad \text{(Eq. 3)}$$

$$f_{base} = \frac{k_a}{a_{H^+} + k_a} \quad \text{(Eq. 4)}$$

where $k_a$ is the dissociation constant of the phenol group estimated from the pH hydrolytic rate profiles. By using the computer fitting, the pKa, $k_{H_2O}$, and $k'_{H_2O}$ values for VI–VIII were obtained (Table V).

The pKa values obtained from the pH–rate profiles at 50.8° were in reasonable agreement with the values obtained spectrophotometrically at 23° and pH 9.60, 9.00, and 8.91, respectively. The pKa values for phenols and the $pKa_2$ values for salicylic acid decrease somewhat with increasing temperature in this temperature range (5, 6).

To complete the hydrolytic sequence, the hydrolytic rate constants for aspirin were determined by HPLC at pH 1.13, 2.64, 4.00, 7.96, and 9.55 at 50.8 ± 0.2° and ionic strength 0.1 *M* (Table VI). Only the carbonate buffer significantly influenced the hydrolysis rate (slope = 0.34 ± 0.04). According to Edwards (7, 8), $k_0$ for aspirin hydrolysis may be expressed by:

$$k_0 = \frac{a_{H^+}}{a_{H^+} + k_a}(k_H a_{H^+} + k_{H_2O}) + \frac{k_a}{a_{H^+} + k_a}(k'_{H_2O} + k'_{OH} a_{OH^-}) \quad \text{(Eq. 5)}$$

where $k_a$ is the dissociation constant of aspirin and $k_H$, $k_{H_2O}$, $k'_{H_2O}$, and $k'_{OH}$ are the rate constants for the acid-catalyzed, spontaneous, and base-catalyzed hydrolysis of aspirin in acidic and basic forms, respectively. The $k_H$, $k_{H_2O}$, and $k'_{H_2O}$ values were calculated from the pseudo-first-order rate constants at pH 1.13, 2.64, and 4.00 using pKa = 3.5 and applying the method of determinants (9). The value of $k_{OH}$ was obtained at pH 9.55. The value obtained for $k_H$ was $1.32 \times 10^{-2}$ liter/mole/min; for $k_{H_2O}$, it was $1.92 \times 10^{-4}$ min$^{-1}$; for $k'_{H_2O}$, it was $2.11 \times 10^{-3}$ min$^{-1}$; and for $k'_{OH}$, it was 32.25 liters/mole/min. All of these values agree with the literature values (10).

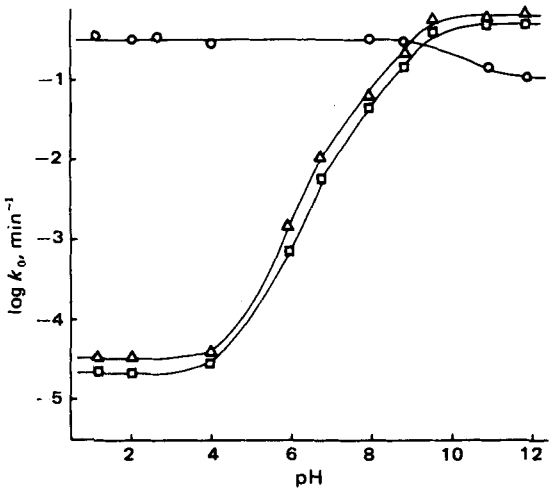

**Figure 5**—*The pH–rate profile for hydrolysis of methylthiomethyl 2-hydroxybenzoate (VI) (○), methylsulfinylmethyl 2-hydroxybenzoate (VII) (□), and methylsulfonylmethyl 2-hydroxybenzoate (VIII) (△) at 50.8 ± 0.2° and 0.1* M *ionic strength. The curves were calculated using Eqs. 1–4 based on the experimental data.*

To determine the hydrolysis mechanism of the various species (since the pH profile implies differences in the mechanism), additional investigations were conducted. Thus, the pseudo-first-order rate constants ($k_{obs}$) for the hydrolysis of IX–XI were determined by HPLC in 0.05 *M* buffers at pH 2.6, 4.0, 6.8, 7.9, and 9.2 at 25.5° (Table VII). The methylthiomethyl benzoate (IX) has a wide pH-independent region from pH 2.5 to 7, where $k_{obs}$ was ~$7.7 \times 10^{-4}$ min$^{-1}$. The methylsulfinylmethyl (X) and methylsulfonylmethyl (XI) benzoates hydrolyzed at much slower rates, the pseudo-first-order rate constants at pH 4.0 being only $1.6 \times 10^{-5}$ and $1.1 \times 10^{-5}$ min$^{-1}$, respectively. Next, the change in the reaction rates with temperature for the hydrolysis of the three 2-hydroxybenzoate derivatives (VI–VIII) in dilute hydrochloric acid and of the methylthiomethyl 2-acetoxybenzoate (III) in unbuffered aqueous solution was studied by following the disappearance of the compound (Tables VIII and IX).

The relatively high enthalpies ($\Delta H^{\ddagger}$) and small negative entropies ($\Delta S^{\ddagger}$) of activation of III and VI are typical for unimolecular ester hydrolysis following cleavage of the alkyl–oxygen bond (11). The values for VII and VIII fall into the range of neutral ester hydrolysis by general base catalysis (11) (Table X).

The effect of ionic strength on the spontaneous water hydrolysis of the

aspirin derivative III was investigated at 50.8 ± 0.1°. The small positive slope (0.202 ± 0.009) of the log $k_{obs}$ *versus* $\sqrt{I}$ plot indicates increased stability of the transition state with increasing ionic strength, or decreased stability of the reactant state, or both.

The effect of the solvent dielectric constant ($\epsilon$) on the rate constant of the spontaneous water hydrolysis of III to form aspirin also was studied using water–dioxane mixtures at 50.8°. The dielectric constant of each mixture at this temperature was calculated (3), and the measured $k_{obs}$ values were plotted *versus* $1/\epsilon$. The decrease in the solvent dielectric constant resulted in a decrease in the rate constant, which implies that the transition state is more polar than the reactant(s) (Table XI).

The deuterium solvent isotope effects on the hydrolysis rates of methylthiomethyl 2-acetoxybenzoate (III), methylsulfinylmethyl 2-hydroxybenzoate (VII), and methylsulfonylmethyl 2-hydroxybenzoate (VIII) were measured at 50.8° and 0.1 *M* ionic strength. The hydrolysis rate constant ($k_{D_2O}$) for III to form aspirin in unbuffered deuterium oxide solution was $5.06 \times 10^{-2}$ $min^{-1}$ compared to $6.06 \times 10^{-2}$ $min^{-1}$ in water, which results in an isotope effect ($k_{H_2O}/k_{D_2O}$) of 1.20. The hydrolysis rate constants for VII and VIII were measured in 0.1 *N* DCl solution in deuterium oxide (pD 0.9) and found to be $1.10 \times 10^{-5}$ and $1.68 \times 10^{-5}$ $min^{-1}$ compared to $2.23 \times 10^{-5}$ and $3.41 \times 10^{-5}$ $min^{-1}$ in water, respectively. The two 2-hydroxybenzoates showed the same solvent isotope effects, $k_{H_2O}/k_{D_2O} = 2.03$.

**Table IX—Observed Pseudo-First-Order Rate Constants ($k_{obs}$) for Hydrolysis of Methylthiomethyl 2-Acetoxybenzoate (III), Obtained by Following the Disappearance of III as a Function of Time in Aqueous Solution at 0.1 *M* Ionic Strength (Sodium Chloride) and Various Temperatures**

[a] The dielectric constant ($\epsilon$) of each mixture was calculated at 50.8° according to Ref. 3.

**Table XII—Relative Rates of Hydrolysis of Methylthiomethyl Benzoate (IX), Methylthiomethyl 2-Acetoxybenzoate (III), and Methylthiomethyl 2-Hydroxybenzoate (VI) at pH 4.00 at the Plateau and 25.5° [a]**

| Compound | $k_{obs}$, $min^{-1}$ | Relative Rate | pKa[b] |
|---|---|---|---|
| IX | $7.6 \times 10^{-4}$ | 1.0 | 4.2 |
| III | $3.45 \times 10^{-3}$ | 4.5 | 3.5 |
| VI | $1.90 \times 10^{-2}$ | 25 | 3.0 |

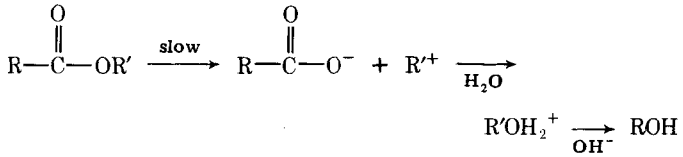
[a] The rate constant for IX was not extrapolated to zero buffer concentration. [b] The pKa of the carboxylic acid.

The pH–rate profiles of III and VI demonstrate large plateaus where the hydrolysis rates were pH independent. For III (Fig. 4), this plateau extended from about pH 2 to 8, with aspirin as the main hydrolytic product. Methylthiomethyl 2-hydroxybenzoate (VI) (Fig. 5) had an even wider plateau, showing no acid- or base-catalyzed regions on the pH profile from pH 1 to 12. The small decrease in the rate at ~pH 10 can be explained by the ionization of the 2-hydroxy group. Similar pH-independent hydrolysis behavior was shown by methylthiomethyl benzoate (IX) (Table VII).

The pH–rate profiles of VII and VIII show two plateaus with a large increase in the rate around the pKa of the 2-hydroxy group (Fig. 5). On the other hand, the pH–rate profiles for methylsulfinylmethyl (IV) and methylsulfonylmethyl (V) 2-acetoxybenzoates do not have these large plateaus but are V-shaped with a minimum at pH 4 (Fig. 4). The hydrolysis pathways, however, are changing with pH.

According to Fife (12), a plateau of the pH-independent rate, as for III, VI, and IX, could be due to: (*a*) attack of both hydronium ions and hydroxide ions, (*b*) water attack on the substrate, or (*c*) spontaneous, uncatalyzed decomposition of the substrate. The first possibility seems to be highly unlikely; if it occurred, the reaction would have a very large negative entropy of activation. Thus, the other two possibilities are left.

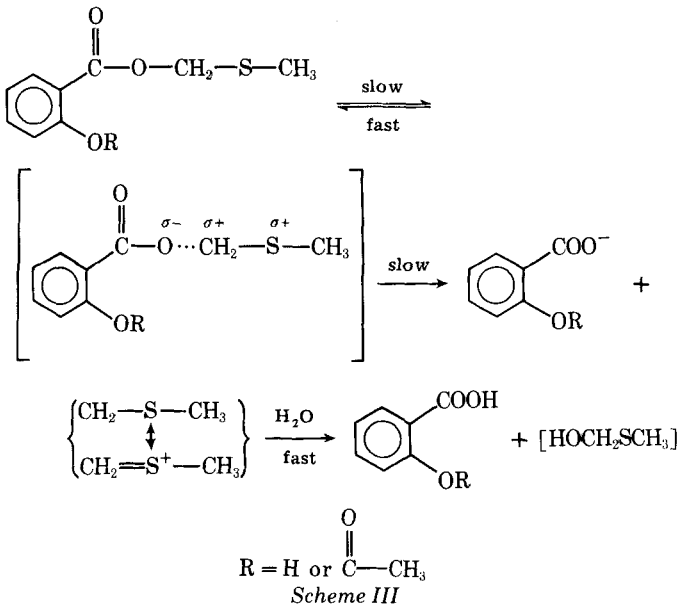
The pH–rate profiles for hydrolysis of both III and VI were obtained by following the disappearance of the compounds with time at various pH values. The main hydrolysis product of III in the plateau region is aspirin, which is hydrolyzed further to salicylic acid. Compounds III and VI have enthalpies of activation ($\Delta H^{\ddagger}$) of 21.2 and 21.1 kcal/mole and entropies of activation ($\Delta S^{\ddagger}$) of −7.12 and −4.04 e.u., respectively, in the pH-independent plateau region. These high enthalpies and low entropies of activation are characteristic for unimolecular reactions, which can be regarded as $S_N1$ reactions, where the leaving group is the carboxylate anion (11, 13) (Scheme II).



*Scheme II*

The enhanced solvation due to the charge separation in the transition state compared to the ground state results in a small negative entropy of activation but still is favorable compared to a bimolecular reaction involving water as a reactant ($S_N2$ reaction). Salomaa (14) studied the kinetics of uncatalyzed hydrolysis of some aliphatic acylals ($RCOOCHROCH_3$) in aqueous solutions and got similar values for the entropy of activation to those obtained in the present study. The hydrolysis rate of methylthiomethyl 2-acetoxybenzoate is highly dependent on the nature of the solvent, being ~14 times greater in water than in a 30% dioxane–water mixture, suggesting considerable charge development in the transition state. Change in ionic strength has a similar effect. Compound III is hydrolyzed with about the same rate in deuterium oxide as in water ($k_{D_2O}/k_{H_2O} = 1.2$). This small solvent isotope effect also is found in the hydrolysis of neutral ester molecules cleaved by alkyl–oxygen fission ($B_{AL}1$) (11, 13). The mechanism can be written as shown in Scheme III.

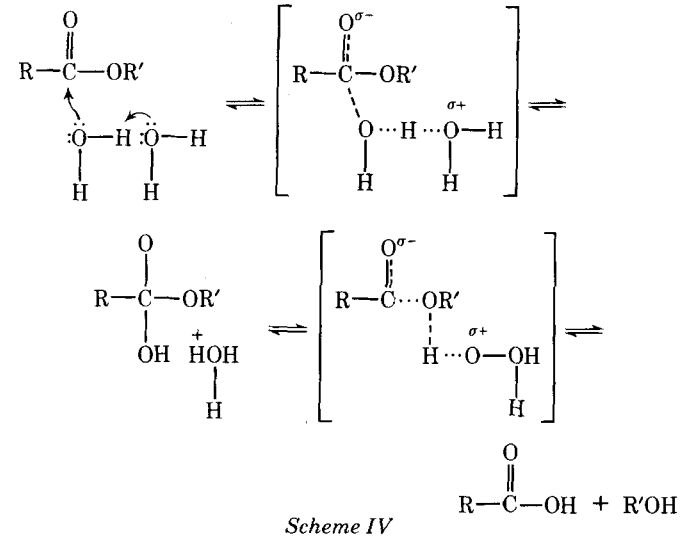
This mechanism would be facilitated by the fact that the carbonium ion formed is resonance stabilized by the neighboring sulfur group. In Table XII, the relative rates on the plateau for IX, III, and VI were listed at 25.5°. The increase in rate can be explained by the decreasing pKa or increased leaving group ability of the corresponding acid. The decrease



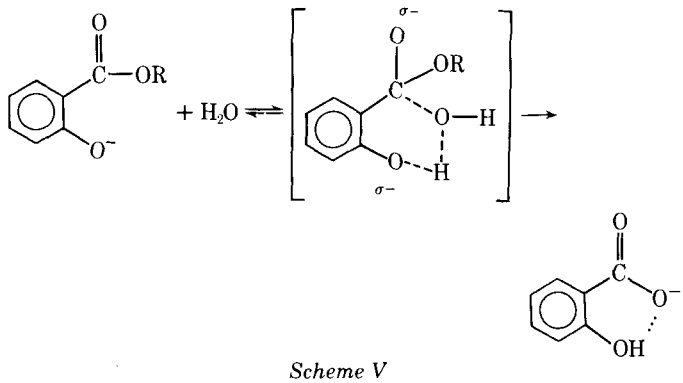
*Scheme III*

in the hydrolysis rate of VI at pH ~10 can be attributed to ionization of the 2-hydroxy group (pKa ~9.6 at 23°).

In the case of methylsulfinylmethyl (VII) and methylsulfonylmethyl (VIII) 2-hydroxybenzoates, the large negative entropy values and low enthalpies of activation are typical for neutral hydrolysis of esters, where water acts as a general base to assist the addition of a second water molecule to the ester carbonyl group (Scheme IV). The hydrolysis of both compounds show deuterium solvent isotope effect ($k_{H_2O}/k_{D_2O}$) of 2.03, which also is consistent with this mechanism. The significant rate increase at higher pH values can be explained by an intermolecular catalyzed attack by the ionized phenol group (Scheme V), as suggested by Bender *et al.* (15) in the case of *p*-nitrophenyl salicylate.



*Scheme IV*



*Scheme V*

The pH profiles for the aspirin derivatives IV and V (Fig. 4) show the common V-shape at a minimum of pH 4. The hydrolysis pathways, however, change with the pH. Thus, aspirin (I) is the main product at pH > 4, but the relatively stable 2-hydroxybenzoates (VII and VIII) form at lower pH values.

While the methylthiomethyl ester (III) of aspirin at pH 7.96 hydrolyzes almost exclusively (>90%) to aspirin, the same compound in human plasma clearly hydrolyzes *via* both routes; on the other hand, IV apparently goes to aspirin in plasma but follows this route to a significantly smaller proportion in chemical hydrolysis.

As expected, the enzymic hydrolysis is significantly faster in all cases. However, the overall picture underlines the fact that, due to binding, mechanistic, and other differences, the chemical cleavage studies of esters will not necessarily predict the relative rates, possible selectivity, product ratio, *etc.*, obtained in enzymatic conditions.

# Improved Delivery through Biological Membranes X: Percutaneous Absorption and Metabolism of Methylsulfinylmethyl 2-Acetoxybenzoate and Related Aspirin Prodrugs

**THORSTEINN LOFTSSON * and NICHOLAS BODOR ‡x**

Received August 25, 1980, from the *Department of Pharmaceutical Chemistry, School of Pharmacy, University of Kansas, Lawrence, KS 66045, and the ‡Department of Medicinal Chemistry, College of Pharmacy, J. Hillis Miller Health Center, University of Florida, Gainesville, FL 32610. Accepted for publication January 21, 1981.

**Abstract** □ Oxidative–reductive interconversion of the methylthiomethyl ester of aspirin and the corresponding sulfoxide and sulfone derivatives can be detected in rat liver homogenate, in addition to the extremely facile hydrolysis of these esters. The methylthiomethyl and methylsulfinylmethyl 2-acetoxybenzoates penetrate freshly excised hairless mice skin rather easily with the simultaneous hydrolysis of the two ester functions. Contrary to *in vivo* observations in dogs, where significant amounts of aspirin formed, the prodrugs cleave to salicylic acid and/or salicylate esters rather than aspirin.

**Keyphrases** □ Methylsulfinylmethyl 2-acetoxybenzoate—percutaneous absorption and metabolism, aspirin prodrugs □ Aspirin prodrugs—percutaneous absorption and metabolism □ Prodrugs—methylsulfinylmethyl 2-acetoxybenzoate and related aspirin agents, percutaneous absorption and metabolism

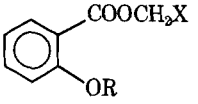
In the preceding papers of this series, novel prodrugs of aspirin (I) were described, together with the corresponding salicylic acid (II) derivatives as summarized by III–VIII. Although significant differences in the chemical and plasma hydrolyses of the double esters III–V were observed, *in vivo* studies clearly indicated that at least IV cleaves to aspirin; III and V might do so, but aspirin could not be detected in the dogs in these cases.

## BACKGROUND

In addition to the direct hydrolysis of the ester functions, oxidative interconversion of the sulfur-containing alkyl groups also is possible, which might alter the expected hydrolytic behavior. Thus, similarly to the case of sulindac (1), these esters can be expected to participate in the *in vivo* redox system shown in Scheme I. Other sulfides and sulfoxides undergo similar transformations (2), which most likely occur in the liver. Thus, one objective of the present studies was to determine whether the oxidized forms, IV and V, can be detected if III is incubated with liver homogenate.

The possible topical use of the aspirin prodrugs, III–V, or the salicylic acid derivatives, VI–VIII, also is of interest. The primary use of salicylic acid in topical medication, aside from its antiseptic and germicidal uses, has been as a keratolytic and anti-inflammatory agent. Keratolytic drugs act to damage the cornified layer of the skin, which is then sloughed off to whatever depth the agent has acted. The traditional keratolytic agent has been salicylic acid in concentrations up to 6% in various creams and ointments (3).

Steroids commonly are applied topically to alleviate inflammatory



III: R = $CH_3CO$, X = $CH_3S$–

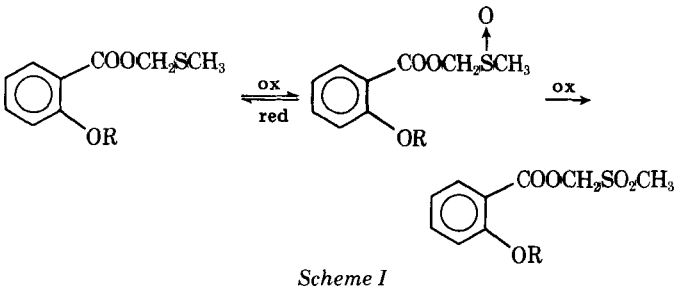

*Scheme I*

states such as some allergic skin conditions, but only one nonsteroidal anti-inflammatory agent, bufexamac, is marketed as a topical cream (4). In a recent study (5), the anti-inflammatory effects of several steroidal and nonsteroidal drugs were tested topically on guinea pig skins in which UV dermatitis was induced. Salicylic acid was just as good an anti-inflammatory agent as bufexamac, and aspirin was even more active and, in some cases, was superior to hydrocortisone (6).

In the present study, the apparent permeability of the potential prodrugs of aspirin, III and IV, through excised hairless mice skin was studied and compared to aspirin. Since the skin, as all other portals of entry into the body, possesses metabolic activity (7), simultaneous metabolism–absorption processes were considered.

## EXPERIMENTAL

**Metabolism Studies in Rat Liver Homogenate**—The liver homogenate was prepared following the method of Schneider (8). Two male Sprague–Dawley rats were killed by decapitation, and the livers were removed and chilled on an ice-cold glass plate. After cooling, the livers were weighed (total weight 28.4 g) and homogenized with a polytef pestle homogenizer in a glass mortar in 113.6 ml of 0.25 *M* sucrose (total volume 142 ml). The homogenate was centrifuged for 10 min at 600×*g*, and the supernate was decanted and centrifuged for 20 min at 24,000×*g*. The supernate, which was then 120 ml, was decanted and used undiluted for the oxidation–cleavage studies.

The supernate was stored in an ice bath and used within 5 hr after the killing of the animals. A 10-μl sample of a standard solution of the compound in acetonitrile was added to 3.0 ml of the supernate ($<10^{-3}$ *M*). Samples of 0.50 ml were removed, mixed with 0.50 ml of acetonitrile, and centrifuged for 20 min. The supernate was analyzed by high-pressure liquid chromatography (HPLC) as described previously (9).

**Permeability–Metabolism Studies Using Hairless Mice Skin**—Full-thickness dorsal skin of 12–14-week-old female hairless mice[1] was used. The mice were sacrificed by snapping of the spinal cord at the neck, and the whole dorsal skin then was removed. Adhering fat and other visceral debris were removed carefully from the undersurface. The excised skin was stretched gently over the lower opening of the plexiglass lid of a diffusion cell and secured with a rubber gasket, and excess skin was trimmed away.

The diffusion cells were manufactured[2] from plexiglass and consisted of a lower chamber (45 ml) with a side arm to allow sampling of the receptor phase, a lid, and a rubber gasket. A plastic-coated magnetic bar provided efficient mixing. The opening in the lid left exposed an 8.04-$cm^2$ area on the epidermis side through which penetration was measured. The

| IV | VII | $9.6 \pm 4.0 \times 10^{-3}$ | 1.18 |
| | II | $1.2 \pm 0.6 \times 10^{-2}$ | 0.33 |
| | Total | $2.2 \pm 1.0 \times 10^{-2}$ | 0.87 |

[a] The compounds detected in the receptor phase were aspirin (I), salicylic acid (II), and methylsulfinylmethyl 2-hydroxybenzoate (VII).

receptor was filled with pH 5.4 isotonic sodium acetate–boric acid buffer (60 mg and 1.84 g, respectively, in 100 ml of deionized water). As a preserving agent, 0.1% formaldehyde was added. All air bubbles were removed carefully from the dermal surface of the skin by tipping the cell.

A solution of the test compound was made in acetonitrile containing 10% polyethylene glycol 400. Then 200 μl of this solution was applied to the skin; and the acetonitrile was evaporated by blowing air on the surface, leaving a 2 *M* solution of the compound in polyethylene glycol 400 spread evenly on the skin. Each cell then was placed on a magnetic stirrer in a 31° incubator in which a high constant humidity was maintained. Samples of 1 ml were removed from the receptor phase *via* the side arm and replaced with fresh buffer. The samples were analyzed by HPLC.

## RESULTS AND DISCUSSION

The rat liver homogenate metabolism studies revealed that the various ester-type prodrugs of aspirin (III–V) and the corresponding salicylates (VI–VIII) were metabolized extremely fast. The disappearance rates of III and IV were 2.5 and 0.8 $min^{-1}$, corresponding to half-lives of 0.3 and 0.9 min, respectively. These values reflect significantly faster metabolism in the liver than in plasma. [The corresponding half-lives in human plasma at 37° were 1.2 (III) and 14 (IV) min, respectively.] The analysis of the liver homogenate mixtures indicated that III was hydrolyzed mainly to VI and then to salicylic acid. The main product from IV also was salicylic acid. However, despite the fast hydrolysis rates, small fractions of both IV and V could be detected after incubation of the homogenate with III. In the same way, small fractions of VII could be detected after incubation with VI, and small fractions of V could be detected after incubation of the homogenate with IV. This finding clearly indicates that some oxidative interconversion of the species occurs.

The skin permeability studies also indicated extensive metabolism of III and IV. This result is not surprising; although the stratum corneum is the main diffusion barrier (10), the conventional drug permeation mathematical models (11–13) had to be modified to account for simultaneous metabolism–permeation when prodrugs were used (14, 15). The whole skin, particularly the epidermis, contains many highly active enzyme systems (7), and some esterase activity has been found in the stratum corneum of pig skin (16).

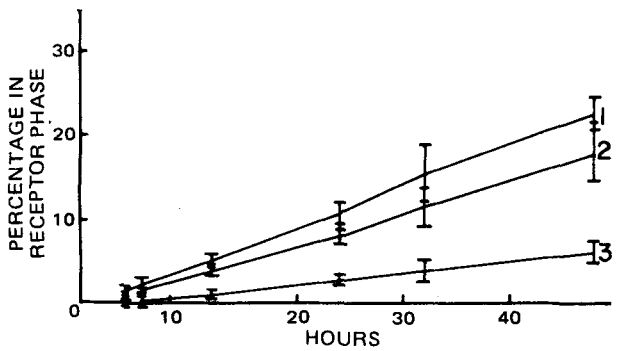

**Figure 1**—*Permeability of aspirin (I) through hairless mice skin as percentage of aspirin applied. Key: 1, total appearance in the receptor phase; 2, salicylic acid (II); and 3, aspirin.*

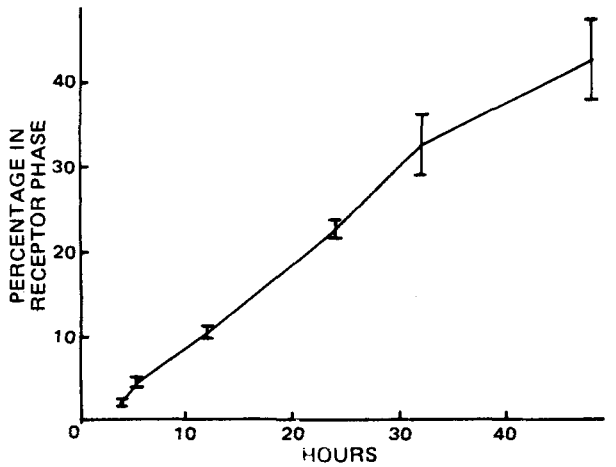

**Figure 2**—*Permeability of methylthiomethyl 2-acetoxybenzoate (III) through hairless mice skin as percentage of dose applied and appearance as salicylic acid (II) in the receptor phase.*

The main enzyme systems of interest in this study were the esterases, which can attack both the aromatic carboxyl esters and the acetyl ester in aspirin and its derivatives, and oxygenases, which could possibly oxidize the sulfur in the thiomethyl and sulfoxide derivatives.

The methylsulfonylmethyl 2-acetoxybenzoate (V) had low solubility in polyethylene glycol 400 and tended to precipitate after application to the skin. Therefore, it showed little permeability in the initial experiment and was not studied further. The obtained permeation profiles for I, III, and IV in terms of percentage in the receptor phase of the total amount applied to the skin as a function of time are displayed in Figs. 1–3. Permeability coefficients were calculated from the slopes of the amounts diffused *versus* time profile according to Eq. 1 in the time interval 5.5–24 hr:

$$P = \frac{V(dc/dt)}{AC_d} \qquad \text{(Eq. 1)}$$

where $P$ is the permeability coefficient, $V$ is the volume of the receptor phase, $A$ is the surface area of the exposed skin, and $C_d$ is the concentration of the solute in the donor phase.

The lag times were estimated graphically; they were quite sensitive to small differences in slopes, and slight experimental variability in slopes produced marked variability.

Each experiment was repeated five times, and the results given represent average values. The error bars in Figs. 1–3 represent the standard error of the mean. The permeability coefficients and lag times are listed in Table I.

The observed hydrolysis rate constant for aspirin in the receptor phase (pH 5.44) was measured separately at 31.0° and found to be $3.74 \pm 0.06 \times 10^{-4}$ $min^{-1}$ or a half-life of 31 hr. These results indicate that when aspirin is applied to the skin, ~30% penetrates the skin unmetabolized,

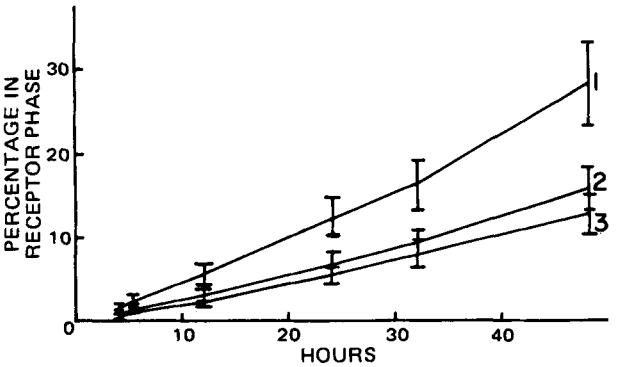

**Figure 3**—*Permeability of methylsulfinylmethyl 2-acetoxybenzoate (IV) through hairless mice skin as percentage methylsulfinylmethyl 2-hydroxybenzoate (VII) (curve 2), salicylic acid (curve 3), and total appearance (curve 1) in the receptor phase relative to the total amount applied to the skin.*

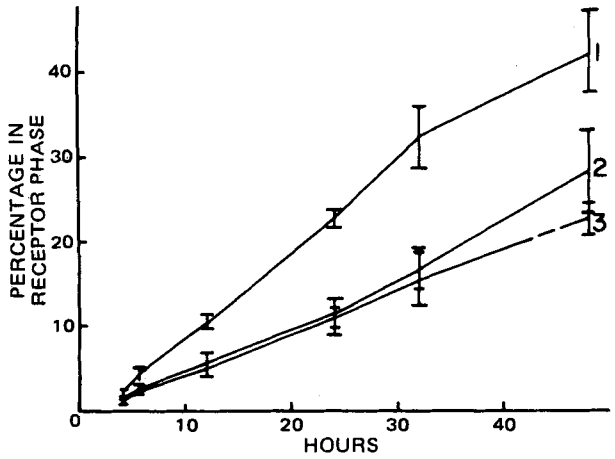

**Figure 4**—*Comparative permeability of aspirin (curve 3), methylthiomethyl 2-acetoxybenzoate (III) (curve 1), and methylsulfinylmethyl 2-acetoxybenzoate (IV) (curve 2) through hairless mice skin.*

while the major part, ~70% of the dose penetrating the skin, is hydrolyzed in the skin to salicylic acid during absorption (Fig. 1).

The hydrolysis half-life of the methylthiomethyl derivative (III) to aspirin was ~10 min and that of VI to salicylic acid, at 30° and pH 5.4, was ~9 min. If any significant amounts of aspirin are formed during passage through the skin or if III penetrates the skin without being metabolized, aspirin would be detected in the receptor phase. On the other hand, only salicylic acid was found when III was applied to the skin, which means that III is metabolized in the skin to VI or salicylic acid or both (Fig. 2).

The hydrolysis half-life of the methylsulfinylmethyl derivative (IV) to aspirin was ~10 days and that of VII to salicylic acid, at 30° and pH 5.4, was ~6 days. Thus, very little hydrolysis should occur in the receptor phase and almost all metabolites of IV detected in the receptor phase must be formed in the enzymatic cleavage in the skin. No aspirin was detected in the receptor phase after application of IV to the skin; only large amounts of VII and salicylic acid were found (Fig. 3). These results indicate that ~57% of IV penetrating the skin is metabolized to VII and that ~43% of IV is metabolized to salicylic acid.

The comparative cumulative penetration profiles for aspirin, III, and IV are shown in Fig. 4. The methylthiomethyl derivative (III) of aspirin is absorbed at a rate about two times faster than that of aspirin, while the methylsulfinylmethyl derivative (IV) is absorbed at the same rate as aspirin within experimental error.

It is clear that significant metabolism of all salicylic acid derivatives, including aspirin and its prodrugs, occur in the fresh mouse skin. The various ester functions hydrolyze with different rates and in a different order than what was shown to be their chemical hydrolysis or enzymatic cleavage in plasma or after the intravenous *in vivo* administration. The amounts penetrating the skin, however, are significant. It is possible to achieve therapeutic levels either as keratolytic or anti-inflammatory or analgesic agents. Further *in vivo* studies should be performed to answer these questions.

aluminum solutions has been studied extensively, and various aluminum species have been proposed. At high degrees of hydrolysis, which is suggested by the hydroxyl to aluminum ratio of 2.5 in the empirical formula, the proposed aluminum species include: $Al_6(OH)_{12}(H_2O)_{12}^{6+}$ (2), $Al_8(OH)_{20}^{4+}$ (3, 4), $Al_{13}O_4(OH)_{24}(H_2O)_{12}^{7+}$ (5–10), $Al_{14}(OH)_{34}^{8+}$ (11, 12), $Al_{10}(OH)_{22}(H_2O)_{16}^{8+}$ to $Al_{54}(OH)_{144}(H_2O)_{38}^{18+}$ (13), $Al_6(OH)_{16}(H_2O)_{4-5}^{2+}$ (14), $Al_6(OH)_{15}O^{1+}$ (14), and $Al_{20}$–$Al_{200}$ (15).

This study investigated the structure of aluminum chlorohydrate using X-ray diffraction and IR and $^{27}$Al-NMR spectroscopy.

## EXPERIMENTAL

**X-Ray Diffraction**—Commercial aluminum chlorohydrate[1] solutions [50% (w/w)] were air dried, and a powder was prepared by trituration in an agate mortar and pestle. Randomly oriented powder samples were prepared in McCreery mounts. Diffractograms were recorded[2] from 4 to 60° 2$\theta$ under the following conditions: Cu$K_\alpha$ radiation, 30 kv, 28 mamp, 1000 cps, and 2°/min.

The molecular dimension of aluminum chlorohydrate was determined by examining the increase in the interlayer spacing of montmorillonite as a result of intercalation of aluminum chlorohydrate. Approximately 50 ml of a 0.69% suspension of sodium-saturated montmorillonite was centrifuged at 5000 rpm for 5 min. The supernate was discarded, and the clay was resuspended in 50 ml of a 25% (w/w) aluminum chlorohydrate solution. The suspension was centrifuged as described, and the clay was resuspended in a second portion of aluminum chlorohydrate solution.

The process was repeated a total of four times to ensure complete saturation of the clay by aluminum chlorohydrate. The aluminum chlorohydrate-saturated montmorillonite was washed four times with double-distilled water by following the described procedure and then was air dried and stored in a vacuum desiccator. X-ray diffractograms were recorded while using special precautions to avoid the adsorption of water by the clay (16).

**IR Spectroscopy**—Air-dried aluminum chlorohydrate was incorporated into potassium bromide pellets, and the IR spectrum was recorded[3].

**NMR Spectroscopy**—Aluminum chlorohydrate solutions were diluted with deuterium oxide to produce solutions that were 1 *M* in aluminum. The $^{27}$Al-NMR spectrum was obtained at 20.723 MHz and 18.7 kg[4]. Potassium aluminum sulfate (0.1 *M*) in acidified deuterium oxide at pH 1 was the reference. The chemical shift of tetrahedral aluminum in aluminate, $Al(OH)_4^-$, was determined from a solution of aluminum chloride titrated with sodium deuteroxide to the soluble region above pH 10.

## RESULTS AND DISCUSSION

An X-ray diffractogram of aluminum chlorohydrate characteristic of all of the commercial samples is shown in Fig. 1. A broad peak occurred in the range of 4–10° 2$\theta$, indicating a *d*-spacing of 11.8 Å. The X-ray diffractogram indicated a poorly ordered material. The line broadening at 11.8 Å suggested a crystallite dimension that is normal to the reflecting planes *hkl* of ~50 Å. No well-crystallized forms of aluminum hydroxide such as gibbsite or bayerite were seen.

To estimate the size of the aluminum chlorohydrate complex, montmorillonite was used as a molecular caliper (17, 18). The X-ray diffractograms indicated that the interlayer spacing of montmorillonite increased by 8.9 Å as a result of aluminum chlorohydrate intercalation. Thus, the minimum dimension of aluminum chlorohydrate is believed to be 8.9 Å.

The proposed structures of highly hydrolyzed aluminum species were examined to determine if any species has a dimension of ~8.9 Å. The $Al_{13}O_4(OH)_{24}(H_2O)_{12}^{7+}$ complex is essentially spherical and is closest in size, 9 Å (6), to the experimentally determined size of aluminum chlorohydrate.

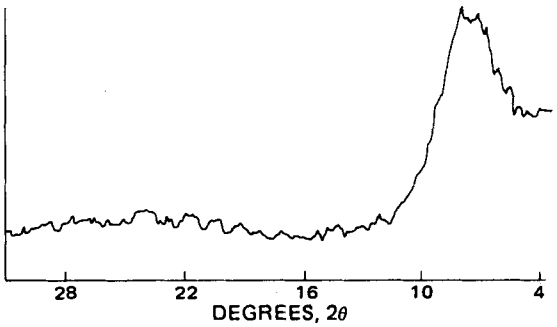

**Figure 1**—*X-ray diffractogram of aluminum chlorohydrate.*

The empirical formula for aluminum chlorohydrate, $Al_2(OH)_5Cl{\cdot}2H_2O$ (1), gives an aluminum to chloride ratio of 2:1, an aluminum to water ratio of 1:1, and an hydroxyl to aluminum ratio of 2.5:1 and compares well to the formula for the $Al_{13}O_4(OH)_{24}(H_2O)_{12}^{7+}$ complex if seven chloride anions are assumed to be present to neutralize the charge of the complex. The aluminum to chloride ratio of the proposed complex is 13:7 or ~2:1, and its aluminum to water ratio is 13:12 or approximately equal to the 1:1 ratio of the empirical formula. Its hydroxyl to aluminum ratio is 24:13. However, the four oxygen atoms in the proposed complex would appear as eight hydroxyl anions by the techniques commonly used to establish the stoichiometry of aluminum compounds (19). Therefore, the hydroxyl to aluminum ratio of the proposed complex would appear to be 32:13 or ~2.5:1, as for the empirical formula.

The excellent fit of the stoichiometry of the $Al_{13}O_4(OH)_{24}(H_2O)_{12}^{7+}$ complex to the empirical formula for commercial aluminum chlorohydrate further supports the hypothesis that the $Al_{13}O_4(OH)_{24}(H_2O)_{12}^{7+}$ complex is the structure of aluminum chlorohydrate. The small differences between the generally accepted empirical formula and the hypothesized structure may be due to the minor presence of other aluminum species in aluminum chlorohydrate and to the relatively nonspecific methods used for establishing the empirical formula.

The structure of the $Al_{13}O_4(OH)_{24}(H_2O)_{12}^{+7}$ complex is shown in Fig. 2. This structure is unusual since it contains a central aluminum atom

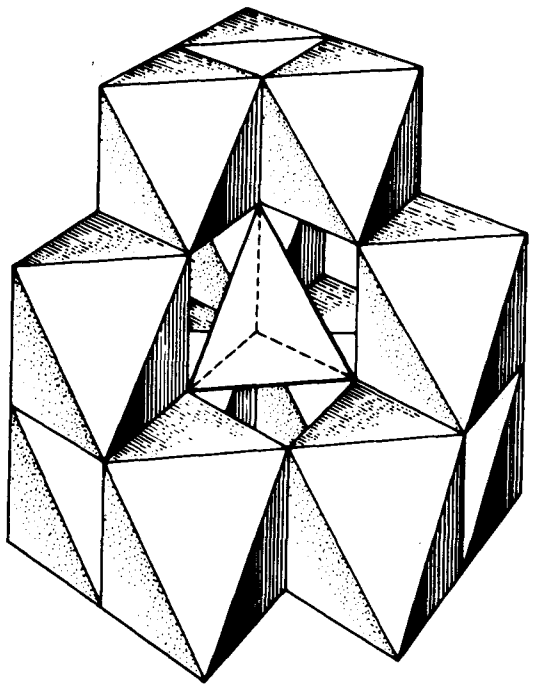

**Figure 2**—*Structure of the $Al_{13}O_4(OH)_{24}(H_2O)_{12}^{7+}$ complex showing the tetrahedral aluminum surrounded by 12 aluminums in octahedral configuration. (Reproduced, with permission, from Ref. 8.)*

in a tetrahedral environment surrounded by 12 aluminum atoms in octahedral environments. Aluminum in a tetrahedral environment is characterized by aluminate, $Al(OH)_4^-$, which only exists at high pH conditions. Aluminum in octahedral configuration occurs at neutral and acidic pH conditions and is the configuration of aluminum in aluminum hydroxide. Thus, aluminum chlorohydrate was examined by IR and $^{27}Al$-NMR spectroscopy to determine if aluminum was present in both octahedral and tetrahedral environments.

IR spectra have been published for aluminum chlorohydrate, aluminum hydroxide chloride, aluminum hydroxide, and hydrolyzed alumina (20–24). Based on these reports, the 3700–3400-$cm^{-1}$ region should show hydroxyl-stretching vibrations for ionic or surface hydroxyl anions. The hydroxyl-stretching vibrations of aluminum in octahedral configuration, $Al(H_2O)_6^{3+}$, should occur between 3100 and 2500 $cm^{-1}$. The region of 1200–800 $cm^{-1}$ should show absorption bands for the deformation of Al–O–H or Al–OH–Al. Absorption bands for the rocking of coordinated water and the vibrations of $AlO_6$ octahedra should occur below 800 $cm^{-1}$. IR absorption bands for aluminum in tetrahedral configuration were assigned as follows based on the IR spectrum of aluminate, $Al(OH)_4^-$: 725 $cm^{-1}$, $AlO_4$ antisymmetric stretching; 625 $cm^{-1}$, $AlO_4$ symmetric stretching; and 325 $cm^{-1}$, $AlO_4$ antisymmetric bending (25). The 800-$cm^{-1}$ band in synthetic trioctahedral analogs of kaolinite was assigned as Al–O tetrahedral vibrations (26).

Figure 3 shows the hydroxyl-stretching region of the IR spectrum of aluminum chlorohydrate. Riesgraf and May (20) assigned the 3400-$cm^{-1}$ band to the stretching of hydroxyl anions bound to aluminum. Bands between 3000 and 2500 $cm^{-1}$ were attributed to antisymmetric and symmetric stretching of water coordinated to aluminum. No changes were observed in this region of the IR spectrum during aging, as was observed for aluminum hydroxide (22, 23).

Figure 4 shows the IR spectrum of aluminum chlorohydrate for the 1200–300-$cm^{-1}$ region. The 1080-$cm^{-1}$ band was assigned as Al–O–H bending of bridge hydroxyl anions, and the 970-$cm^{-1}$ band was assigned as Al–OH deformation bending of Al–OH and $Al–OH_2$ (20). The bands at 780 and 640 $cm^{-1}$ were observed previously but not assigned (20). Based on the assignments of aluminum in a tetrahedral environment (25, 26), the bands at 780, 640, and 345 $cm^{-1}$ (Fig. 4) can be assigned as an $AlO_4$ antisymmetric stretch frequency, an $AlO_4$ symmetric stretch frequency, and an $AlO_4$ antisymmetric bending frequency, respectively. Both the $AlO_4$ antisymmetric stretching and $AlO_4$ symmetric stretching bands occurred at higher frequencies than were observed in aluminate, $Al(OH)_4^-$. This finding indicates that a slightly longer Al–O bond is present in the tetrahedral aluminum of aluminum chlorohydrate in comparison to aluminate. Thus, the IR spectrum of aluminum chlorohydrate clearly shows the presence of aluminum in both octahedral and tetrahedral configurations and suggests that the tetrahedral aluminum interacts with the octahedral aluminum atoms.

$^{27}Al$-NMR spectroscopy has been used to investigate aluminum complexes in solution (9, 25, 27–36). The $^{27}Al$-NMR spectrum of aluminum chlorohydrate at pH 4.8 (Fig. 5) consisted of three distinct signals: a sharp peak at 63.5 ppm and two broad peaks at ~1.7 and −0.4 ppm. The relative chemical shift differences were referenced to an external standard of $Al(H_2O)_6^{3+}$ at pH 1. The peak at 63.5 ppm is indicative of an Al–O bond

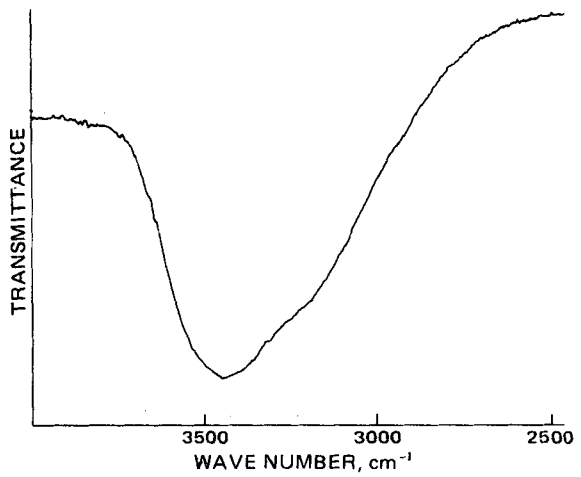

**Figure 3**—*IR spectrum of aluminum chlorohydrate in the 4000–2000-$cm^{-1}$ region.*

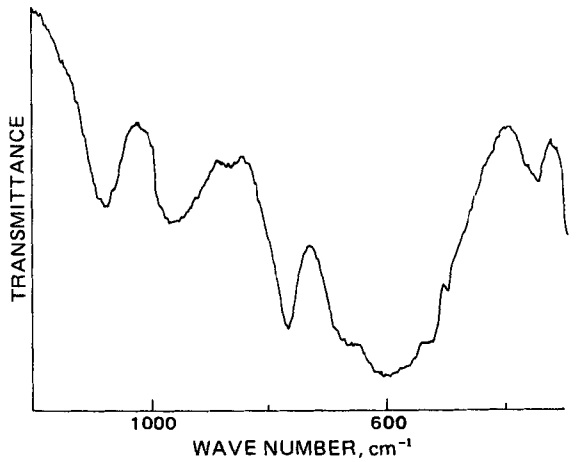

**Figure 4**—*IR spectrum of aluminum chlorohydrate in the 1200–200-$cm^{-1}$ region.*

in an $AlO_4$ tetrahedral configuration (9). The peak width of <40 Hz observed for this complex at pH 4.8 suggests that the tetrahedral aluminum is not in equilibrium with the aqueous environment since no line broadening was observed. Consequently, the tetrahedral $AlO_4$ group is thought to be bonded to other aluminum atoms. The broad resonances, *i.e.*, 150 and 400 Hz at −0.4 and 1.7 ppm, respectively, suggest the presence of aluminum atoms in octahedral environments, which are in rapid equilibrium with the aqueous solution.

The evidence is strong that aluminum chlorohydrate has a structure consisting of a central aluminum atom in a tetrahedral environment surrounded by 12 aluminum atoms in octahedral environments. Usually, tetrahedral aluminum is found only at high pH (pH >10), but the pH of aluminum chlorohydrate solutions is ~4.5. The question arises as to how this symmetrical complex forms with a tetrahedral aluminum in the center. The major synthetic procedure for preparing aluminum chlorohydrate involves the reaction of 5 moles of metallic aluminum with 1 mole of aluminum chloride (37). The pH of the reaction begins near 3 and ends near 4.5. Since the pH never rises above 4.5, it would be difficult for

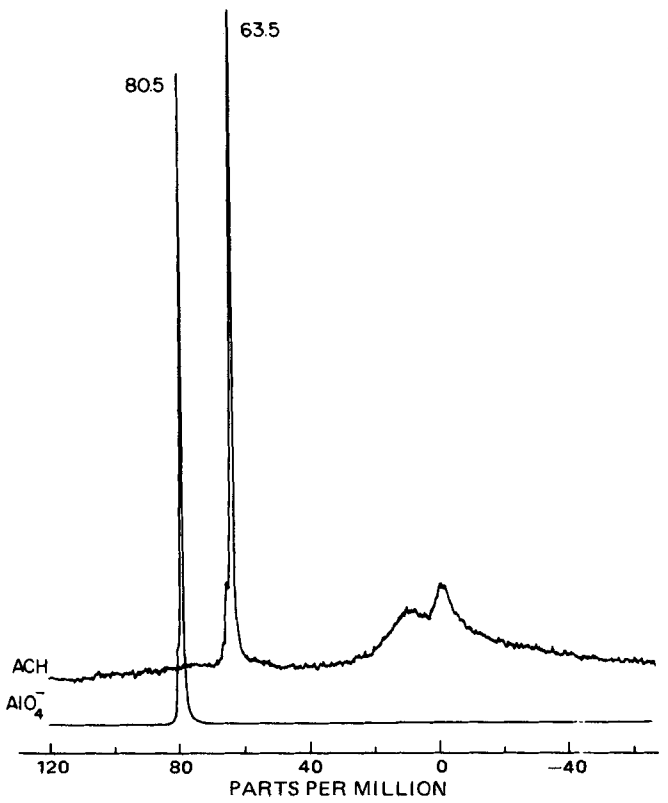

**Figure 5**—*$^{27}Al$-NMR spectrum of aluminum chlorohydrate (ACH) and sodium aluminate ($AlO_4^-$).*

a tetrahedral aluminum to form in solution. However, regions of high pH may occur during the reaction even though the bulk solution is at a much lower pH.

The main reactions that occur are the oxidation of metallic aluminum to aluminum ion ($Al^{3+}$) and the reduction of protons to produce hydrogen gas. These reactions occur only at the surface of metallic aluminum. The protons arise from water dissociation. Since the protons are quickly converted to hydrogen gas, a high hydroxyl concentration may be present at the aluminum surface, resulting in a pH gradient between the surface and the bulk. Therefore, aluminum can exist in a tetrahedral state in the system even though the apparent pH is 3–4.5.

As a cluster of tetrahedral aluminum diffuse away from the metallic aluminum surface, the pH gradient causes the tetrahedral configuration to convert to the octahedral configuration. However, the tetrahedral aluminum in the middle of the cluster is protected from the aqueous pH, and the $Al_{13}O_4(OH)_{24}(H_2O)_{12}^{7+}$ complex forms with a tetrahedral aluminum in the center and surrounded by 12 aluminum atoms in octahedral configuration. Seven chloride anions are associated with the complex as counterions to produce a neutral complex.

The structure of $Al_{13}O_4(OH)_{24}(H_2O)_{12}Cl_7$ is consistent with the current understanding of antiperspirant activity. Antiperspirant activity has been elicited primarily by the topical application of multivalent metals in ionic form (38). The exact mechanism of antiperspirant activity is controversial; several theories exist. However, most studies indicate that optimum activity is achieved when the metal is presented to the skin in ionic form. Regardless of whether the metal is acting directly as an antiperspirant and/or indirectly as a deodorant, a charged species is necessary. The $Al_{13}O_4(OH)_{24}(H_2O)_{12}^{7+}$ complex is small and compact with the charge well distributed. Therefore, its effective charge to radius ratio is high, and it will act as a highly charged form of aluminum. In addition, the pH of aluminum chlorohydrate solutions is ~4.5, which corresponds to the acid mantle of the skin. The hydroxyl groups present in the complex are responsible for the higher pH in comparison to aluminum chloride solutions. Therefore, little skin irritation is observed, and minimal clothing damage due to acid hydrolysis occurs.

# Aluminum Chlorohydrate II: Physicochemical Properties

**DIRK L. TEAGARDEN *, JOHN F. RADAVICH §, JOE L. WHITE ‡, and STANLEY L. HEM *x**

Received October 3, 1980, from the **Department of Industrial and Physical Pharmacy, the* ‡*Department of Agronomy, and the* §*School of Materials Engineering, Purdue University, West Lafayette, IN 47907.* Accepted for publication December 8, 1980.

**Abstract** □ Determination of the chloride content of aluminum chlorohydrate by a chloride-selective electrode indicated that $\gamma_{Cl^-} \rightarrow 1$. IR analysis demonstrated that chloride was exchanged readily by nitrate and that the IR bands of the anion were not perturbed significantly. Thus, chloride is believed to act as a counterion. A high positive charge is predicted based on the critical coagulation concentration of aluminum chlorohydrate and the stability of aluminum chlorohydrate to attack by protons, as demonstrated by pH-stat titration. Potentiometric titration with sodium hydroxide showed adsorption of hydroxyl anions initially, but a higher pH than expected was observed at the end-point. This behavior is consistent with the $Al_{13}O_4(OH)_{24}(H_2O)_{12}^{7+}$ complex, which would adsorb hydroxyl anions initially and in which the central tetrahedral aluminum is shielded from the added hydroxyl anions. The reaction rate with ferron (8-hydroxy-7-iodo-5-quinolinesulfonic acid) suggests that the major species in aluminum chlorohydrate is a large aluminum polycation. A platey morphology for lyophilized, air-dried, and spray-dried aluminum chlorohydrate was observed by scanning electron microscopy. The platey appearance is consistent with the structure of $Al_{13}O_4(OH)_{24}(H_2O)_{12}^{7+}$ since the spherical nature and high uneven charge of the complex make stacking difficult.

**Keyphrases** □ Aluminum chlorohydrate—physicochemical properties determined by IR spectroscopy and pH-stat and potentiometric titrations □ Spectroscopy, IR—analysis, aluminum chlorohydrate, physicochemical properties determined □ Potentiometric titration—aluminum chlorohydrate, physicochemical properties determined, IR spectroscopy and pH-stat titration □ Critical coagulation concentration—aluminum chlorohydrate, physicochemical properties determined using IR spectroscopy and pH-stat and potentiometric titrations

X-ray diffraction and IR and $^{27}$Al-NMR spectroscopy recently showed that aluminum chlorohydrate is composed of a central aluminum in tetrahedral configuration surrounded by 12 aluminum atoms, each in an octahedral configuration (1). The complex, $Al_{13}O_4(OH)_{24}(H_2O)_{12}^{7+}$, is essentially spherical with the +7 charge equally distributed on the surface. Seven chloride ions are believed to be associated with the complex as counterions. The objectives of this study were to examine the physicochemical properties of aluminum chlorohydrate and to determine if these properties are related to the recently proposed structure.

## EXPERIMENTAL

Aluminum chlorohydrate was obtained commercially as a 50% (w/w) solution[1].

Aluminum was quantified by a chelatometric titration procedure (2). The chloride content was determined by both the modified Volhard technique (3) and a chloride-selective electrode[2]. The aluminum chlorohydrate solutions were diluted with potassium nitrate solutions prior to measurement by the chloride-selective electrode to produce a solution having $1 \times 10^{-2}$–$1 \times 10^{-4}$ *M* chloride and an ionic strength of ~0.1. The chloride concentration of aluminum chlorohydrate solutions that had been hydrolyzed by nitric acid also was determined by the modified Volhard method and by the chloride-selective electrode. Hydrolysis was accomplished by adding the quantity of nitric acid indicated in Table I and heating to 70° for 1 hr.

Chloride in aluminum chlorohydrate was replaced by nitrate; after air drying, the IR spectrum was determined in potassium bromide pellets. One hundred milliliters of 0.308 *M* silver nitrate was placed in a 400-ml beaker, and 90 ml of a diluted aluminum chlorohydrate solution (0.308 *M* in chloride) was added slowly. Silver chloride precipitated throughout the addition. The mixture was stirred for 15 min and centrifuged at 2500 rpm for 10 min. The precipitate was discarded, and the supernate was prepared for IR spectroscopy[3].

**Table I—Chloride Content of Aluminum Chlorohydrate Determined by Volhard Method and Chloride-Selective Electrode**

| Nitrate Added, *M* | Volhard Method, *M* | Chloride-Selective Electrode, *M* |
|---|---|---|
| Potassium nitrate | | |
| $9.0 \times 10^{-2}$ | $2.3 \times 10^{-3}$ | $2.3 \times 10^{-3}$ |
| $9.9 \times 10^{-2}$ | $2.3 \times 10^{-4}$ | $2.3 \times 10^{-4}$ |
| Nitric acid | | |
| $9.0 \times 10^{-2}$ | $2.3 \times 10^{-3}$ | $2.1 \times 10^{-3}$ |
| $9.9 \times 10^{-2}$ | $2.3 \times 10^{-4}$ | $2.3 \times 10^{-4}$ |

The charge of the aluminum chlorohydrate complex was determined by the method of Matijevic *et al.* (4), except that 0.69% sodium montmorillonite was used as the lyophobic colloid rather than silver iodide. Potassium chloride, calcium chloride, aluminum nitrate, and thorium nitrate were used to prepare a standard curve of the valence of the coagulating cation *versus* the ratio of the critical coagulation concentration of the cation to the critical coagulation concentration of potassium.

The potentiometric titration curve of aluminum chlorohydrate or aluminum chloride with sodium hydroxide was determined with an automated titrator[4]. The aluminum chloride solution was brought to a ratio of 2.5 (hydroxyl to aluminum) with sodium hydroxide before the recorder was activated so that both aluminum samples were titrated from a hydroxyl to aluminum ratio of 2.5 to 3.0.

The rate and extent of acid neutralization by aluminum chlorohydrate was determined at pH 1, 2, and 3 at 25° with an automated titrator[4].

The distribution of aluminum in aluminum chlorohydrate (*i.e.*, monomers, small polycations, and large polycations) was determined by

the ferron (8-hydroxy-7-iodo-5-quinolinesulfonic acid) test (5).

**Scanning electron photomicrographs[5] of aluminum chlorohydrate** were taken following air drying, spray drying, or lyophilization.

## RESULTS AND DISCUSSION

Table I compares the chloride content of aluminum chlorohydrate solutions as determined by the Volhard titration and the chloride-selective electrode. The results by both methods were virtually identical. In addition, the chloride content was the same for intact and hydrolyzed aluminum chlorohydrate. Thus, the chloride activity coefficient of aluminum chlorohydrate must be close to 1, indicating that the chloride ion acts as a counterion. This finding is in contrast to the activity of chloride in chloride-containing aluminum hydroxide gel. The fact that the chloride content of chloride-containing aluminum hydroxide gel, as determined by a chloride-selective electrode, was less than that determined by the Volhard titration was attributed to the binding of the chloride ion to the aluminum hydroxy complex (6).

The degree of interaction of the anion with the $Al_{13}O_4(OH)_{24}(H_2O)_{12}^{7+}$ complex could be studied by IR spectroscopy if the anion was IR active. Thus, aluminum chlorohydrate was treated with silver nitrate to attempt to replace the IR inactive chloride with IR active nitrate. Nitrate anion was chosen because it is the same approximate size and charge as chloride, and it is symmetrical so that any perturbations due to interaction with the aluminum complex would cause a shift in the IR spectrum. The IR spectrum was not affected by the replacement of chloride by nitrate except for the appearance of bands at 1380 and 830 $cm^{-1}$. Both bands correspond to the bands for nitrate in sodium nitrate, indicating that the anion in aluminum chlorohydrate is readily exchangeable. Furthermore, the IR bands of sodium nitrate at 1358 and 836 $cm^{-1}$ show little interaction of the anion with the $Al_{13}O_4(OH)_{24}(H_2O)_{12}^{7+}$ complex (7). Thus, the activity of the chloride ion and the IR spectrum of aluminum nitrohydrate indicate that the anion is not part of the aluminum complex but rather functions as a counterion. This behavior is consistent with the structure of the $Al_{13}O_4(OH)_{24}(H_2O)_{12}^{7+}$ complex.

Table II shows that the critical coagulation concentration of aluminum chlorohydrate was less than thorium. The regression equation for the known cations (charge = 0.12 $CCC/CCC_{K+}$ + 0.97)[6] had a $R^2$ value of 0.990 and predicted a valence of 5.6 for aluminum chlorohydrate. This valence is the average of all species present in the aluminum chlorohydrate solution. In addition, the valence of highly charged cations may be greater than that determined by the critical coagulation concentration method because interionic distances increase rapidly with dilution (8). Therefore, the valence of aluminum chlorohydrate as determined by the critical coagulation concentration method is consistent with the high charge of the $Al_{13}O_4(OH)_{24}(H_2O)_{12}^{7+}$ complex.

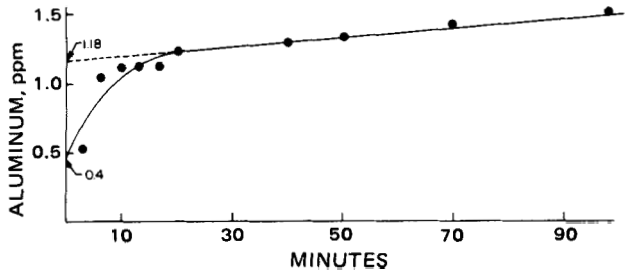

**Figure 3**—*Rate of reaction of a solution of aluminum chlorohydrate containing 9.87 ppm of aluminum with ferron.*

[5] Super III A, International Scientific Products, Mountain View, Calif.

[6] $CCC/CCC_{K+}$ is the ratio of the critical coagulation concentration of the cation to the critical coagulation concentration of potassium.

**Table II—Critical Coagulation Concentration (CCC) of Aluminum Chlorohydrate in Comparison to Known Cations**

| Ion | Charge | CCC, $N$ | $CCC/CCC_{K+}$ |
|---|---|---|---|
| Potassium | 1 | $6.25 \times 10^{-3}$ | 1.00 |
| Calcium | 2 | $8.73 \times 10^{-4}$ | 7.16 |
| Aluminum | 3 | $3.5 \times 10^{-4}$ | 17.85 |
| Thorium | 4 | $2.5 \times 10^{-4}$ | 25.00 |
| Aluminum chlorohydrate | Unknown | $1.62 \times 10^{-4}$ | 38.58 |

The titrigrams of aluminum chloride (following the addition of sodium hydroxide to produce a hydroxyl to aluminum ratio of 2.5) and of aluminum chlorohydrate are shown in Fig. 1. The pH of the aluminum chlorohydrate solution did not increase as rapidly as the aluminum chloride solution, indicating that the added hydroxyl concentration was being adsorbed by the aluminum chlorohydrate. The evenly distributed positive charge of the $Al_{13}O_4(OH)_{24}(H_2O)_{12}^{7+}$ complex would be expected to adsorb hydroxyl anions. Furthermore, the pH at the end-point (hydroxyl to aluminum ratio of 3) was higher for aluminum chlorohydrate. This finding suggests that more hydroxyl anions are in solution in the aluminum chlorohydrate solution, possibly because the tetrahedral aluminum in the center of the $Al_{13}O_4(OH)_{24}(H_2O)_{12}^{7+}$ complex is inaccessible to the added hydroxyl anions.

The reactivity of aluminum chlorohydrate to proton attack was investigated by pH-stat titration. Hydroxyl anions are released into solution if aluminum chlorohydrate breaks up under proton attack. As can be seen in Fig. 2, aluminum chlorohydrate is very stable to proton attack. Even at pH 1, only ~25% of the total hydroxyl anions in aluminum chlorohydrate were neutralized. The fact that protons do not readily attack the complex further indicates that aluminum chlorohydrate is positively charged. In addition, the charge is predicted to be high and evenly distributed to shield the hydroxyl anions of the complex from proton attack.

Based on the reaction rate with ferron, the distribution of aluminum species in aluminum chlorohydrate can be classified as 4% monomeric aluminum, 8% small polycations, and 88% large polycations (Fig. 3). The fact that the major species in aluminum chlorohydrate reacts slowly with ferron also is consistent with the structure of the $Al_{13}O_4(OH)_{24}(H_2O)_{12}^{7+}$ complex.

The morphology of aluminum chlorohydrate that had been air dried,

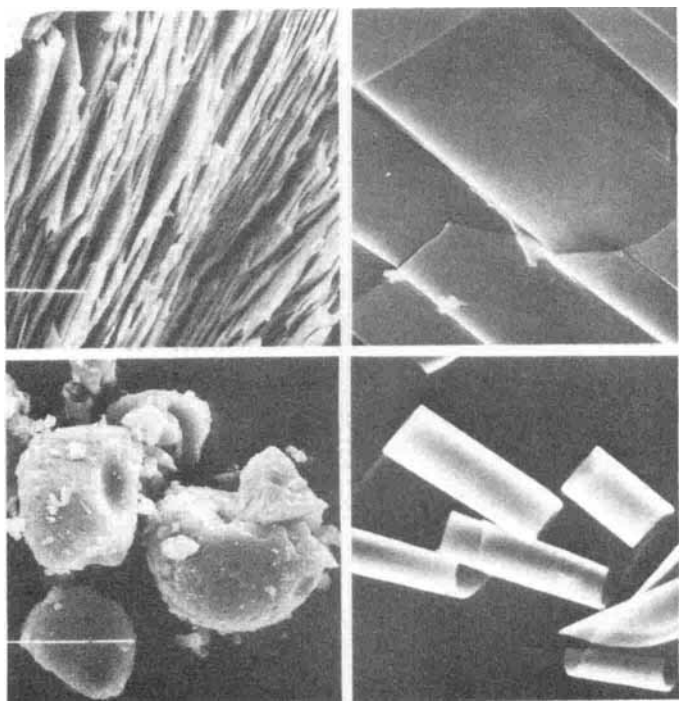

**Figure 4**—*Scanning electron photomicrographs of aluminum chlorohydrate. Key: upper left, lyophilized, 700×, line of 50 μm; upper right, lyophilized, 5000×; lower left, spray dried, 2000×, line of 5 μm; and lower right, air dried, 10,000×.*

lyophilized, or spray dried was examined by scanning electron microscopy (Fig. 4). All samples showed a platey structure, although it was most evident in the lyophilized sample. The spray-dried sample showed spherical particles that are inherent to spray drying. However, the spheres were made up of thin plates. The air-dried samples formed scroll-like sheets due to the more rapid rate of water loss from the top surface during drying. Johansson (9), in proposing the $Al_{13}O_4(OH)_{24}(H_2O)_{12}^{7+}$ complex, noted the formation of plate-like crystals during the study of a basic aluminum sulfate that was built up from the same kind of aluminum–oxygen complexes. It is suggested that the high uneven charge on the spherical units minimize contact with adjacent units so that a planar configuration provides the most favorable spatial and electrostatic arrangement.

# Automated Dissolution Testing of Combination Drug Product Using High-Pressure Liquid Chromatography

**DALE ERIC WURSTER ˣ, WILLIAM A. WARGIN, and MARTIN DeBERARDINIS, Jr.**

Received July 24, 1980, from the *School of Pharmacy, University of North Carolina, Chapel Hill, NC 27514.* Accepted for publication December 8, 1980.

**Abstract** □ An automated high-pressure liquid chromatographic (HPLC) system compatible with any standard tablet dissolution apparatus was developed. This system allowed the individual drug concentrations within a product to be determined simultaneously, even when the drugs had similar structures and UV spectra. This automated system permitted unattended sampling and concentration determination at predetermined time intervals. The dissolution medium was pumped continuously through a fixed-volume, microprocessor-controlled injector and returned to the USP rotating-basket dissolution apparatus. No corrections for the changing dissolution medium volume were necessary since each injection onto a reversed-phase HPLC column consumed just 10 μl of medium. Dissolution tests were performed on three brands of trisulfapyrimidines tablets. Sample injections were made automatically at 5.1-min intervals for ~2 hr. Dissolution profiles were determined for each drug in each product. Statistically significant differences were found in the mean concentration–time values between drugs within a drug product and between drug products.

**Keyphrases** □ High-pressure liquid chromatography—with automated dissolution testing of a combination drug product □ Dissolution—automated high-pressure liquid chromatography, combination drug product □ Combination drugs—dissolution testing using automated high-pressure liquid chromatography □ Trisulfapyrimidines—combination drug product, dissolution testing using automated high-pressure liquid chromatography

Automated procedures for dissolution testing of pharmaceuticals have been of interest since such procedures are labor saving and increase analytical reproducibility. These automated procedures usually involve pumping the dissolution medium directly through a flowcell mounted in a UV spectrophotometer (1–6). An inherent problem with such an arrangement is the lack of drug specificity. If two or more drugs in a drug product have similar UV spectra, this procedure is useless.

In view of the number of combination products on the market, an automated technique is needed that allows each drug in a product to be quantitated individually during a dissolution run.

## BACKGROUND

High-pressure liquid chromatography (HPLC) is a versatile analytical technique that combines the specificity of chromatography with the sensitivity of refractive index, UV, fluorescence, or electrochemical detection. Optimal retention times for the separation of active ingredients and dosage form excipients may be obtained by appropriately varying the mobile phase composition, pH, and/or flow rate. Changing the chromatographic temperature and utilization of gradient elution also are viable options. Other than filtration, aqueous samples require no special preparation prior to injection onto a reversed-phase HPLC column.

While various components of an HPLC system have been used to automate drug analysis procedures (3, 7) during dissolution, the actual chromatographic process has been included only in a manual (8) or semiautomated (7) procedure.

This report describes a totally automated HPLC method that has been used successfully to characterize the dissolution profile of each drug entity in a trisulfapyrimidines USP tablet. Completely unattended dissolution analysis is possible using this technique.

## EXPERIMENTAL

A USP rotating-basket dissolution apparatus, a dissolution stirrer drive[1], and a water bath[2] were used. The basket was rotated at 150 rpm, and the temperature of the dissolution medium (0.1 *N* HCl) was 37.0 ± 0.1°. A pump[3] circulated the dissolution medium through a fixed-volume (10-μl loop) microprocessor[4]-controlled injector[5] and returned the me-

dium to the dissolution flask. All dissolution medium was filtered through a 2-μm low-pressure solvent filter as it entered the external circulation system. Only 1.05 ml of dissolution medium was external to the bulk (900 ml) at any given moment, and the circulation rate was 2.25 ml/min. The time required for a sample of bulk dissolution medium to reach the injector loop was determined experimentally to be 0.3 min.

Another pump[6] delivered the mobile phase (180 ml of acetonitrile[7]–820 ml of 0.05 *M* sodium acetate[8] buffer, pH adjusted to 5.7 with acetic acid) through the injector and onto a 25-cm long × 4-mm i.d. reversed-phase[9] column at a flow rate of 1.50 ml/min. The chromatographic analysis was conducted at room temperature. The absorbance of the column effluent was measured[10] at 254 nm. Peak areas were integrated[11] automatically, and a recorder[12] was used to display chromatographic peaks (Scheme I).

Dissolution testing of three brands (six runs each) of trisulfapyrimidines tablets USP (500 mg) was performed according to USP XX guidelines to demonstrate the utility of the system. Each tablet consisted of 167 mg each of sulfadiazine (I), sulfamerazine (II), and sulfamethazine (III). Sample injections were made automatically at 5.1-min intervals for ~2 hr. Dissolution profiles were determined for each drug in each drug product. Six dissolution runs at 100 rpm also were performed on one formulation to assess the impact of the basket rotation rate on the dissolution profile. The dissolution medium and mobile phase (one batch each) were prepared in sufficient quantity for all runs.

A standard curve for each drug was constructed by making four solutions ranging from 0.045 to 0.185 mg/ml. Each standard solution was placed in the resin flask of the dissolution apparatus, and the apparatus was assembled in the same manner as if a dissolution test were to be conducted. When the standard solution reached 37°, solution circulation through the injector loop and basket rotation were initiated. Injections were controlled by the microprocessor, and the same injector loop was used as in the actual dissolution runs.

The standard curves were linear and exhibited coefficients of determination ($r^2$) of 0.998 for I and II and 0.997 for III. This excellent linearity allows single-point calibrations before each dissolution run to guard against changing detector response and column behavior. The coefficients of variation at each concentration were <2.0% for I and II and <2.7% for III.

## RESULTS AND DISCUSSION

Content uniformity tests were performed on each formulation according to USP XX guidelines (9). All products passed the specifications of 95.0–105.0% of the labeled amount of total sulfapyrimidines, with each drug providing not less than 31.5% nor greater than 35.0% of the total.

Figure 1 illustrates the typical chromatographic output of one dissolution run. The peaks (in the order shown) represent the amounts of I, II, and III present at a specific time. Machine integration (*Experimental*) yielded the area of each peak. Drug concentrations were determined from these integrated peak areas.

The dissolution data for each drug present in each run were fitted to:

$$C = C_{max}(1 - e^{-Kt}) \qquad \text{(Eq. 1)}$$

where $C$ is the experimentally determined sulfa drug concentration at time $t$, $C_{max}$ is the asymptote of the dissolution profile, and $K$ is the rate constant for the appearance of drug in solution, as opposed to a rate constant for dissolution, since it includes the process of disintegration.

A nonlinear least-squares regression analysis program[13] was used for fits. All coefficients of determination ($r^2$) fell in the 0.972–0.998 range, with most ≥0.990. Parameter estimates ($K$ and $C_{max}$) appear in Table I. The rate constant $K$ should be characteristic for a given drug in a particular formulation when evaluated by a specific dissolution testing procedure. The estimated rate constants presented in Table I indicate that this is the case.

Concentration values at 30.0 and 60.0 min were generated from the parameter estimates for each drug within each run (Table II). These times were chosen based on guidelines proposed by the Food and Drug Administration (10), which suggested that 50% (83.5 mg/900 ml) and 80%

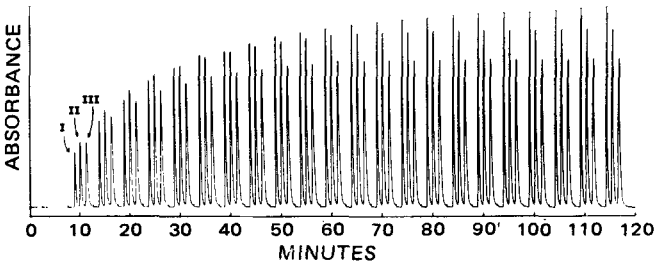

**Figure 1**—*Typical chromatographic output of one dissolution run. The time axis represents the summation of the dissolution time and the chromatographic time. The molar absorptivities of the three compounds are not equal in the present experimental conditions.*

[a] Results were analyzed for significance using an unpaired $t$ test ($\alpha = 0.05$); * = significant difference ($p < 0.001$), and ** = significant difference ($p < 0.05$).

(133.6 mg/900 ml) of the drug should be in solution after 30 and 60 min, respectively.

An analysis of variance[14] was performed on both the 30- and 60-min data for each drug entity to detect significant differences between formulations. When a significant difference was found, Tukey's critical difference ($\alpha = 0.05$) was used to identify the mean values responsible (Table III).

Ranking the formulations with respect to the amount of drug in solution at 30 and 60 min showed that Formulation C consistently exhibited lower levels. In all but one case, these levels were significantly lower than the formulation with the number one ranking and often were significantly lower than the second-ranked formulation. The predicted values of $C_{max}$ for Formulation C were not significantly different from those of Formulations A and B.

Figures 2–4 illustrate the product performances. In these figures, all of the concentration–time data for each drug entity within each drug product were fitted simultaneously to Eq. 1. The mean concentration points and standard deviations are superimposed on the fitted curves.

A comparison of the dissolution performance of Formulation A at basket rotation rates of 100 and 150 rpm is presented in Table IV. It has long been recognized that the dissolution rate of a drug may be greatly influenced by the degree of agitation present in the dissolution flask. Carstensen *et al.* (11) stated that rotation speeds of <150 rpm in USP Apparatus I may result in solution nonhomogeneity. For this reason, a basket rotation rate of 150 rpm was chosen for most determinations in this study.

[14] PROC ANOVA, Statistical Analysis System, Raleigh, NC 27605.

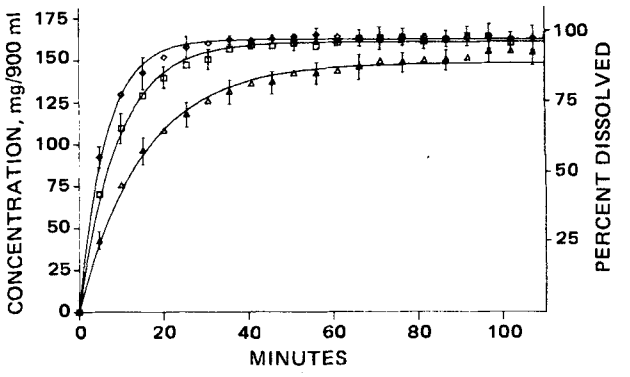

**Figure 2**—*Concentrations of drugs in solution* versus *time for Formulation A (average of six runs, basket rotation rate of 150 rpm). Standard deviations are superimposed on the plots. Key:* △, *I;* □, *II; and* ◇, *III.*

Figures 2 and 5 provide a visual comparison of the performance of Formulation A with basket rotation rates of 150 and 100 rpm, respectively. Although the rate constant for drug appearance in solution significantly increased with an increase in the basket rotation rate (Table IV), the predicted maximum concentration of drug in solution ($C_{max}$) was independent of the rotation rate.

As expected, it is possible for each active ingredient to have a unique dissolution rate (Tables I–III). Significant differences in the dissolved amounts were found between active drug entities and between manufacturers' formulations at both 30 and 60 min. Such differences necessitate the simultaneous determination of the dissolution profiles of each active component in a drug product. The typical automated dissolution apparatus, lacking the chromatographic procedure, can seldom accomplish such an analysis.

Although the system described was used with USP Apparatus I, USP Apparatus II or III can be employed equally well as long as the intake and outlet for the circulated dissolution medium are in the positions recommended by the USP. Since each injection consumes only 10 μl of dissolution medium, there is no need for volume replacement nor calculational compensation for decreasing dissolution medium volume. The 0.3 min required for a sample of bulk dissolution medium to reach the injector

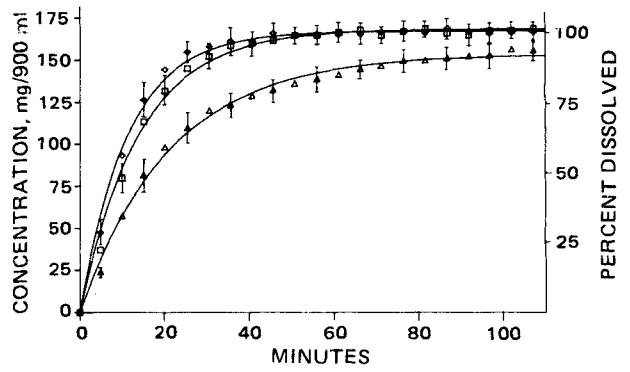

**Figure 3**—*Concentrations of drugs in solution* versus *time for Formulation B (average of six runs, basket rotation rate of 150 rpm). Standard deviations are superimposed on the plots. Key:* △, *I;* □, *II; and* ◇, *III.*

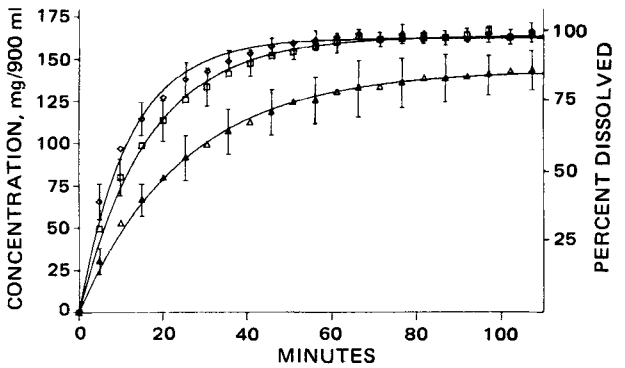

**Figure 4**—*Concentrations of drugs in solution* versus *time for Formulation C (average of six runs, basket rotation rate of 150 rpm). Standard deviations are superimposed on the plots. Key:* △, *I;* □, *II; and* ◇, *III.*

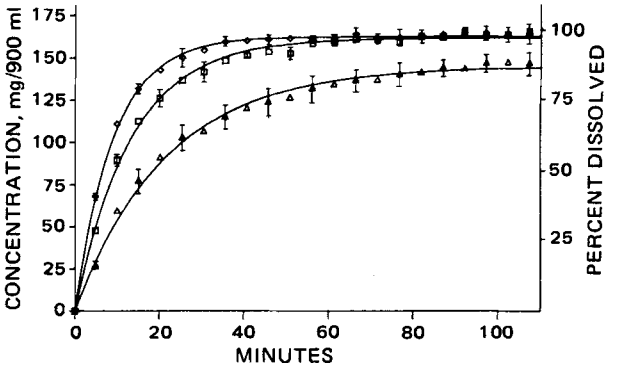

**Figure 5**—*Concentrations of drugs in solution* versus *time for Formulation A (average of six runs, basket rotation rate of 100 rpm). Standard deviations are superimposed on the plots. Key:* △, *I;* □, *II; and* ◇, *III.*

loop, while accounted for in the calculations, is actually insignificant if the dissolution time is in excess of 10 min. This rapid exchange of dissolution medium is accomplished with a relatively slow flow rate, and this slow flow rate is advantageous since it does not provide dissolution medium agitation in excess of that provided by the rotating basket. The 2-μm low-pressure solvent filter at the inlet port prevented particulate matter from scoring the injection valve and also prevented solid particulate buildup at the head of the column.

This system exhibits great flexibility for adaptation to the problems encountered with a particular product. Various drug and excipient entities can be accommodated by variations in the injection programming, the mobile phase composition, and pH and by gradient elution. Gradient elution is especially feasible in this system because it can be controlled by the same microprocessor that controls sample injections. No system is completely universal, however, and there are undoubtedly compound combinations for which adequate separations cannot be made with retention times short enough to allow injections at the intervals required by compendial specifications. The authors believe this latter case is relatively rare.

The HPLC system used in the present study is of the component or modular type. Substitution of a fluorescence, electrochemical, or refractive index detector in place of the UV detector would be a simple matter. The fluorescence detector could be especially useful for compounds present in very low concentrations. Additionally, the microprocessor can be programmed to change detector sensitivity during the chromatographic procedure, thereby furthering the ability to accommodate a drug product with widely varying concentrations of active ingredients.

After initial debugging, no reliability problems were encountered, and completely unattended dissolution testing was accomplished. Unattended testing is the ultimate aim of automation, and no method can be considered to be truly automated without this capability.

If the amount of drug dissolved from a dosage form need only be measured at widely spaced time intervals or at the end of the dissolution test, this system would be adaptable to monitoring six dissolution flasks. Such monitoring could be accomplished by the use of a multichannel pump and a switching valve to direct the flow from the appropriate dissolution flask to the injector loop. This switching valve would also have to permit return flow from the injector loop to the flask being sampled. If measurements were to be made on the contents of each dissolution flask at specific times (such as 30 and 60 min), initiation of the dissolution processes in the six flasks would need to be staggered.

The types of systems described readily lend themselves to computer interfacing. Such interfacing would mean that the operator's only contact with the dissolution test would be lowering the basket into the dissolution medium and collecting the completed dissolution profiles.

# Intestinal Absorption Mechanism of Amphoteric β-Lactam Antibiotics I: Comparative Absorption and Evidence for Saturable Transport of Amino-β-lactam Antibiotics by *In Situ* Rat Small Intestine

**AKIRA TSUJI *x, EMI NAKASHIMA *, IZUMI KAGAMI *, and TSUKINAKA YAMANA ‡**

Received August 13, 1980, from the **Faculty of Pharmaceutical Sciences and the* ‡*Hospital Pharmacy, Kanazawa University, Takara-machi, Kanazawa 920, Japan.* Accepted for publication December 11, 1980.

**Abstract** □ The disappearance of various β-lactam antibiotics from *in situ* rat small intestinal loops was studied at pH 7.4. For monobasic penicillins, despite the wide variety of apparent partition coefficients in isobutyl alcohol–water, the disappearance from the jejunal loops was almost 30% (±5% *SD*). On the other hand, the disappearance of amphoteric derivatives of penicillins and cephalosporins having very low lipid solubility varied widely between 12 and 80%. The peak blood levels after intraduodenal administration to the rats correlated well with the extent of disappearance of amphoteric penicillins from the intestinal loops. Absorption studies utilizing *in situ* intestinal loops were performed at variable dose ranges to yield a clear dose-dependent disappearance. It is suggested that certain carrier-mediated transport systems underlie the absorption mechanisms of amphoteric β-lactam antibiotics.

**Keyphrases** □ Aminopenicillins—intestinal absorption mechanism proposed, compared with monobasic penicillins, *in situ* rat intestinal loops □ Aminocephalosporins—intestinal absorption mechanism proposed, compared with monobasic penicillins, *in situ* rat intestinal loops □ Absorption, intestinal—mechanism proposed for saturable transport of amphoteric amino-β-lactam antibiotics, *in situ* rat intestinal loops □ Antibiotics, amino-β-lactam—compared with monobasic penicillins, intestinal absorption mechanism proposed, *in situ* rat intestinal loops

Aminopenicillins, such as ampicillin, amoxicillin, and cyclacillin, and aminocephalosporins, such as cephalexin and cephradine, are acid stable and are absorbed after oral administration (1, 2). Much interest has been focused on the mechanism of the GI absorption of these antibiotics.

## BACKGROUND

Many studies on the GI absorption of β-lactam antibiotics and their amino derivatives have been conducted to assess animal models (3, 4) or to compare their bioavailability (1, 5–7) rather than to elucidate the absorption mechanism. Recently, Tsuji *et al.* (8) reported that the GI absorption rates of monobasic penicillins in rats deviated significantly from the pH-partition hypothesis, and they explained this deviation on the basis of passive transport of the undissociated molecule through both the aqueous diffusion layer barrier adjacent to the GI membrane surface and the lipid barrier of the GI membrane. With the two-compartment diffusion mechanism, the structure–absorption rate relationship of this series of penicillins and cephalosporins, such as cephalothin and cefazolin, was established (9).

However, the GI absorption of aminopenicillins and aminocephalosporins cannot be predicted from this mechanism whereby the antibiotics are absorbed from the GI tract by passive diffusion of the unionized species. Amino-β-lactam antibiotics must have a zwitterionic structure to be ionized completely and to exhibit very low lipid solubility under GI conditions. Possible mechanisms were proposed for the membrane permeability of amphoteric penicillins and cephalosporins (10–21), but the mechanism by which amino-β-lactam antibiotics are absorbed is not clearly understood.

The present investigation was undertaken to determine the difference in absorption characteristics between monobasic and amphoteric β-lactam antibiotics. The comparative absorption of aminopenicillins, including ampicillin, amoxicillin, cyclacillin, and epicillin, and of three aminocephalosporins, cephalexin, cephradine, and cefadroxil, was studied in rats by the *in situ* GI loop method. Several monobasic penicillins also were included for comparison. The *in vitro* physicochemical properties, including comparative aqueous stabilities, solubilities, and dissolution rates, of the amphoteric β-lactam antibiotics (22, 23) as well as preliminary observations on the intestinal absorption were reported previously (15, 16, 21).

## EXPERIMENTAL

**Materials**—Ampicillin anhydrate[1] (1015 μg/mg), amoxicillin trihydrate[2] (850 μg/mg), cyclacillin anhydrate[1] (983 μg/mg), epicillin anhydrate[3] (pure powder), cephalexin monohydrate[4] (925 μg/mg), cephradine monohydrate[3] (952 μg/mg), and cefadroxil monohydrate[5] (947 μg/mg) were used as supplied. The monobasic penicillins were the same as those employed previously (8). The standard solution of the penicilloic acids of ampicillin, amoxicillin, and epicillin was prepared according to a reported procedure (24).

All other chemicals were reagent grade and were utilized without further purification, except for imidazole which was purified by double recrystallization from benzene followed by thorough washing with ether.

**Animals**—Male albino Wistar rats, 200 ± 25 g, were fasted for 20 hr prior to the experiment, but water was given freely. The rats were anesthetized with urethan (1.5 g/kg ip) ~1 hr prior to surgery.

***In Situ* Experiments on Absorption from Rat GI Loops**—*Disappearance from Small Intestinal Loops*—A midline incision was made to expose the small intestine, and the bile duct was ligated. The intestinal lumen was washed gently with 50 ml of pH 7.4 isotonic phosphate buffer[6] (25). Six milliliters of air was introduced to expel residual buffer and then was gently removed. In this experiment, two loops (each 5 cm long) were prepared by double ligation. The first loop was made 2 cm from the pylorus, and 1 cm of intestine separated the consecutive loop in the duodenum. For the study in the jejunum, the consecutive loops were prepared 15 cm from the pylorus. A dose of antibiotic was dissolved in pH 7.4 isotonic phosphate buffer, and 1 ml was injected into each intestinal loop. All studies lasted 1 hr.

At the end of the experiment, the remaining antibiotic solution was collected and the intestine was washed thoroughly with isotonic buffer. The solutions were combined to make up the desired volume. The samples were analyzed after filtration with a 0.45-μm membrane filter[7] to remove solid materials.

*Disappearance from Ligated Areas of Stomach, Small Intestine, and Large Intestine*—The rat alimentary tract was divided into four portions to locate the specific area for the absorption of amino-β-lactam antibiotics as follows: stomach, upper small intestine (20-cm length below the pylorus), lower small intestine (20-cm length above the ileum), and large intestine (10-cm length below the cecum). These regions were separated by ligation, and 2 mg of cyclacillin or cefadroxil in 1 ml was injected into each region. The drug was dissolved in pH 2.0 isotonic citrate buffer (25) or saline for the experiments in the stomach or intestinal regions, respectively. After 1 hr, the ligated GI segments were removed. Three rats were used. Other experimental procedures were the same as already described.

**Table I—Values for pKa, Apparent Partition Coefficient in Isobutyl Alcohol–Water at pH 7.4, and Disappearance from Rat Intestinal Loops 1 hr after Administration of Various β-Lactam Antibiotics**

| Antibiotic | Dissociation Constant | | Partition Coefficient in Isobutyl Alcohol–Water | Dose, mg/ml | Disappearance from *In Situ* Jejunal Loop, % ± *SD* | |
|---|---|---|---|---|---|---|
| | $pK_1$ | $pK_2$ | | | Upper | Lower |
| Penicillin V | 2.79[a] | — | 1.10[a] | 5 | 26.9 ± 4.0 (3)[b] | 27.4 ± 1.8 (3) |
| Phenethicillin | 2.80[a] | — | 1.55[a] | 5 | 37.9 ± 4.0 (3) | 33.8 ± 1.0 (3) |
| Propicillin | 2.76[a] | — | 3.02[a] | 5 | 30.9 ± 5.5 (4) | 32.5 ± 0.6 (3) |
| Oxacillin | 2.73[a] | — | 1.78[a] | 5 | 27.2 ± 3.0 (5) | 17.9 ± 1.7 (3) |
| Cloxacillin | 2.78[a] | — | 2.40[a] | 5 | 22.1 ± 1.4 (4) | 21.3 ± 1.5 (4) |
| Dicloxacillin | 2.76[a] | — | 4.07[a] | 5 | 28.9 ± 3.7 (4) | 29.9 ± 1.2 (3) |
| Floxacillin | 2.76[a] | — | 2.57[a] | 5 | 27.0 ± 0.8 (3) | 28.1 ± 2.4 (3) |
| Ampicillin | 2.67[a] | 6.95[a] | 0.373 | 2 | 12.9 ± 5.5 (4) | 11.8 ± 2.6 (4) |
| Amoxicillin | 2.67[a] | 7.11[a] | 0.130 | 2 | 19.7 ± 1.4 (4) | 17.0 ± 2.9 (5) |
| Cyclacillin | 2.64[a] | 7.18[a] | 0.866 | 2 | 79.5 ± 3.4 (4) | 79.7 ± 12.1 (5) |
| Epicillin | 2.77[c] | 7.17[c] | 0.438 | 2 | 21.2 ± 6.9 (4) | 20.8 ± 4.9 (5) |
| Cefadroxil | 2.70[d] | 7.22[d] | 0.0813 | 2 | 66.2 ± 9.1 (4) | 70.8 ± 3.2 (4) |
| Cephalexin | 2.67[e] | 6.96[e] | 0.193 | 2 | 40.2 ± 13.6 (4) | 36.9 ± 12.4 (4) |
| Cephradine | 2.63[e] | 7.35[e] | 0.268 | 2 | 55.4 ± 6.5 (3) | 52.0 ± 12.5 (3) |

[a] Data at 37° and $\mu = 0.5$ from Refs. 22 and 30. [b] The experimental number is given in parentheses. [c] Data at 35° and $\mu = 0.5$ from Ref. 22. [d] Unpublished results at 37° and $\mu = 0.5$ from this laboratory. [e] Data at 37° and $\mu = 0.5$ from Ref. 23.

*denal Administration*—Antibiotic solutions of ampicillin, amoxicillin, epicillin, and cyclacillin, prepared by dissolution in 1 ml of saline, were given to rats at a dose of 10 mg/kg. A stomach tube was employed for administration into the stomach in rats whose pylorus was ligated. For intraduodenal administration, the drug solution was injected into the proximal duodenum in rats whose pylorus was ligated.

To determine the amount of antibiotic absorbed, blood was taken from the jugular vein at appropriate time intervals and assayed by a microbiological method and/or fluorometry after being hemolyzed with an equivalent volume of distilled water.

The accumulation in the small intestinal tissue during the *in situ* absorption experiments was examined for cyclacillin. After the 1-hr experiments, part of the whole intestine was isolated, tearing off the mesentery, and the serosal surface then was blotted with filter paper. The intestine was cut into small slices and homogenized in a polytef homogenizer with saline to give a 10% (w/v, wet weight) homogenate. An aliquot of the homogenates then was analyzed.

**Analysis of Loop Samples**—The residual antibiotic and degradation product, the penicilloic acid, were assayed simultaneously by fluorometric determination for ampicillin and amoxicillin (26, 27) and also for epicillin. The fluorescence intensity was measured[8] with reference to that of quinine sulfate prepared with 0.1 *N* $H_2SO_4$. The assay for ampicillin was applied to epicillin, but the emission and excitation wavelengths were changed to 440 and 330 nm, respectively.

Aqueous mixtures of epicillin and its penicilloic acid in three proportions were analyzed, and the average recoveries were 106 ± 3 (*SD*)% for the intact drug and 103 ± 6% for the penicilloic acid. For cyclacillin, a spectrophotometric assay method (28) using imidazole mercuric chloride reagent was employed after acylation of the amino group with acetic anhydrate at pH 9.0. The compositions of the reagents were as described for ampicillin (28, 29). This method was employed only when the sample was diluted more than 25 times with the saline and in the concentration range of 15–80 μg/ml to prevent the influence of mucus and secretion products. The accuracy of this procedure was within 2% ($n = 5$).

High-performance liquid chromatography (HPLC) was utilized[9] for the determination of cephalexin, cephradine, cefadroxil, cyclacillin (only <10 μg/ml), and several monobasic penicillins. For the amino-β-lactam antibiotics, the carrier was 3–7% acetonitrile–0.01 *M* ammonium acetate, and the column was octadecylsilane chemically bonded on totally porous silica gel prepacked into a 4.0 × 300-mm[10] or a 4.6 × 250-mm[11] stainless steel column. For cyclacillin, the carrier was 0.1 *M* phosphate buffer of pH 4.0–4.2, and the column was strong cation-exchange resin[12] packed into a 4.6 × 500-mm stainless steel column. For the monobasic penicillins, the carrier was 0.02 *M* $KH_2PO_4$ and the column was anion-exchange resin[13] prepacked into a 2.1 × 500-mm stainless steel column. The detector was a UV spectrophotometer[14] set at 210 and 254 nm for the penicillins and cephalosporins, respectively.

An aliquot (50–100 μl) of the appropriately diluted solution was injected *via* a variable loop injector on flow, and the peak heights were measured. The calibration curves for the peak heights against the antibiotic concentration were satisfactorily linear and were prepared daily. The accuracy of the HPLC analysis from many trials was within 3%.

**Analysis of Blood Samples**—Fluorometric procedures (26, 27) were utilized for ampicillin and amoxicillin. Cyclacillin, epicillin, and amoxicillin were assayed by the microbiological paper disk diffusion method employing *Sartina lutea*[15] in the usual manner. Calculation of the penicillin concentration was made from the respective calibration curves prepared using pooled blood from control rats. The accuracies of the two analytical methods, *i.e.*, fluorometry and microbiological assay, were within 5%. The analytical data obtained by the methods agreed with each other within the limits of experimental error when a sample of amoxicillin was tested.

**Analysis of Cyclacillin from Tissue Homogenates**—The microbiological assay was employed, and the calibration curve was prepared using pooled 10% gut homogenates from control rats.

**Determination of Apparent Partition Coefficients**—For the study on the distribution of amphoteric β-lactam antibiotics in isobutyl alcohol–water, the aqueous phase was prepared to give a constant $Na^+$ concentration of 0.1 *M* using phosphate buffer for the reasons described previously (30). This buffer component was determined so as to maintain a constant ionic strength of 0.15 and a pH of 7.4. A $1 \times 10^{-3}$ *M* antibiotic solution was prepared with this solution. To minimize the volume exchange due to mutual miscibility, the aqueous and organic phases were saturated previously with each solvent.

Exactly 3–10 ml of each solution was transferred to a glass-stoppered flask and shaken for 2 hr to achieve complete equilibrium at 37 ± 0.1°. The two phases separated on standing for 1 hr, and the aqueous phase was centrifuged at 3000 rpm for 10 min. If necessary, after appropriate dilution with distilled water, the concentration in the aqueous phase was determined by HPLC. The apparent partition coefficient was calculated according to the equation described previously (30).

## RESULTS AND DISCUSSION

The pKa values and apparent partition coefficients of the β-lactam antibiotics at pH 7.4 in isobutyl alcohol–water are summarized in Table I.

**Disappearance of Various β-Lactam Antibiotics from *In Situ* Intestinal Loops**—Values for the percentage disappearance of various penicillins and cephalosporins during 1 hr are shown in Table I.

Despite the fact that the seven monobasic penicillins grouped by phenoxy and isoxazole derivatives exhibit a wide variety of apparent partition coefficients in isobutyl alcohol–water, their disappearance from both the upper and lower jejunums was almost 30% (±5% *SD*). Previous data concerning the rat *in situ* intestinal recirculating method demonstrated (9) that the intestinal absorption of ionized monobasic β-lactam

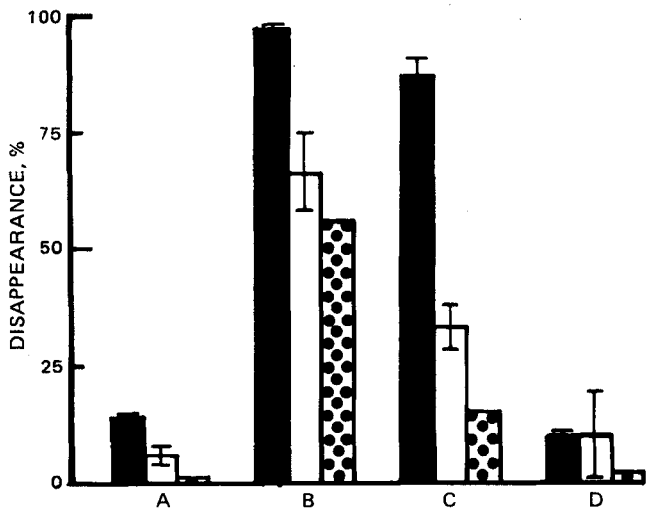

**Figure 1**—*Absorption of cyclacillin and cefadroxil from loops in the digestive tracts of rats. Key: closed columns, cyclacillin; open columns, cefadroxil; dotted columns, cephalexin; A, stomach; B, upper small intestine (20 cm below the pylorus); C, lower small intestine (20 cm above the ileocecum); and D, large intestine (10 cm below the cecum). The data for cephalexin are redrawn from Ref. 31.*

antibiotics followed apparent first-order kinetics with competing apparent first-order degradation to their β-lactam opening products. Between pH 6.5 and 9, absorption and the accompanying degradation were almost insensitive to changes in the intestinal lumen pH and initial drug concentration and to the lipophilicity of the molecules (9). The present results are consistent with those findings, suggesting that the disappearance of monobasic penicillins from the rat intestinal loops was entirely attributable to both absorption and degradation.

On the other hand, the percentage disappearance of amphoteric derivatives having rather low lipophilicity varied widely, between 12 and 80% during 1 hr at a 2-mg/ml dose (Table I). The degradation products (penicilloic acids) from aminopenicillins were determined at the end of the absorption experiment to be 1.6, 1.7, and 1.8% for ampicillin, amoxicillin, and epicillin, respectively. No detectable degradation products were observed with cyclacillin at this dose. The *in vitro* degradation of cephalexin, cephradine, and cefadroxil in the intestinal washings with isotonic phosphate buffer during 1 hr was 4.0, 4.7, and 2.1%, respectively. These findings of slight degradation of amophoteric β-lactam antibiotics strongly indicate that the high percentage disappearances of cyclacillin (80%), cephalexin (40%), cephradine (50%), and cefadroxil (70%) essentially were attributed to intestinal membrane transport resulting in accumulation by the gut tissue and/or transference into the vascular system.

These results suggest that some specialized transport mechanism may contribute to the absorption of zwitterionic antibiotics accompanying the simple diffusion transport (9) responsible in the absorption of ionized species of monobasic β-lactam antibiotics.

**Absorption and Tissue Accumulation of Cyclacillin and Cefadroxil from Different Areas of Rat Alimentary Tract and Comparative Blood Levels after Intraduodenal Administration of Aminopenicillins**—Figure 1 compares the percentage disappearances of cyclacillin and cefadroxil during 1 hr from four areas of the rat GI tract after injection into the ligated loop. The highest disappearance occurred from the small intestine, with almost all of the cyclacillin and 33–66% of the cefadroxil doses disappearing from the lumen. However, only ~10% of each dose disappeared from the stomach and large intestine. In a similar absorption study on cephalexin (redrawn in Fig. 1), Maekawa *et al.* (31) demonstrated that the total disappearance during 1 hr from the stomach, upper small intestine, lower small intestine, and large intestine of rats was 1.0, 56.2, 15.6, and 2.4%, respectively. These data are comparable with the present results for cyclacillin and cefadroxil. The accumulation of cyclacillin in the intestine was negligible (3%) during the *in situ* absorption experimental period.

Figure 2 shows the mean blood concentrations after intraduodenal administrations of aminopenicillins at a dose of 10 mg/kg. The peak blood concentrations for ampicillin, amoxicillin, and epicillin appeared after 1 hr, but cyclacillin was observed in the bloodstream within 0.5 hr after administration. The rank order of blood levels after intraduodenal administration was: cyclacillin > amoxicillin > epicillin ≥ ampicillin. The blood concentration of cyclacillin was far higher than the concentrations of the other penicillins ($p < 0.01$).

Ampicillin demonstrated a significantly lower blood level than amoxicillin ($p < 0.05$). The peak serum concentration after a single oral dose with sufficient water in humans was in the order (5, 6): cyclacillin > amoxicillin > ampicillin > epicillin, which is almost identical with that in rats. When the aminopenicillins were administered into the rat stomach, they were not detectable in the serum by microbiological assay, indicating that the aminopenicillins were scarcely absorbable from the stomach. The *in vitro* degradation of ampicillin, amoxicillin, epicillin, and cyclacillin after 1 hr at pH 2 and 35° was evaluated from the data of the degradation kinetics (22, 32) to be 5.8, 4.7, 2.9, and 7.2%, respectively. The disappearance of cyclacillin from the stomach (Fig. 1) thus may be due to its acid degradation. The present results support the claim of Lode (33) that absorption of ampicillin and cephalexin in humans occurred in the small intestine and not the stomach.

On this basis, the rat represents a suitable experimental animal for elucidation of the absorption mechanism of amino-β-lactam antibiotics in humans. Previous observations (31, 33) and the present results suggest that there is a specific area in the alimentary tract of mammals for the absorption of amino-β-lactam antibiotics. On the other hand, monobasic and lipophilic penicillins can be absorbed from both the stomach and small intestine below pH 6 (8, 9). The difference in permeability between amphoteric derivatives and monobasic ones may be attributed to a difference in the membrane transport mechanism. The latter types of β-lactam antibiotics may be absorbed by lipid membrane transport of the undissociated species through the barrier of the aqueous diffusion layer adjacent to the membrane surface (8, 9). The amino-β-lactam antibiotics, having very low lipid solubility (Table I) and being completely ionized in all alimentary tract areas, are unlikely to be absorbed by this mechanism.

**Effect of Dose on Absorption by *In Situ* Intestinal Loops**—To examine the mechanism responsible for absorption of amino-β-lactam antibiotics *in vivo*, the effect of the dose concentration on the percentage disappearance from the small intestinal lumen was investigated. If the percentage disappearance remains unaffected by the initial dose con-

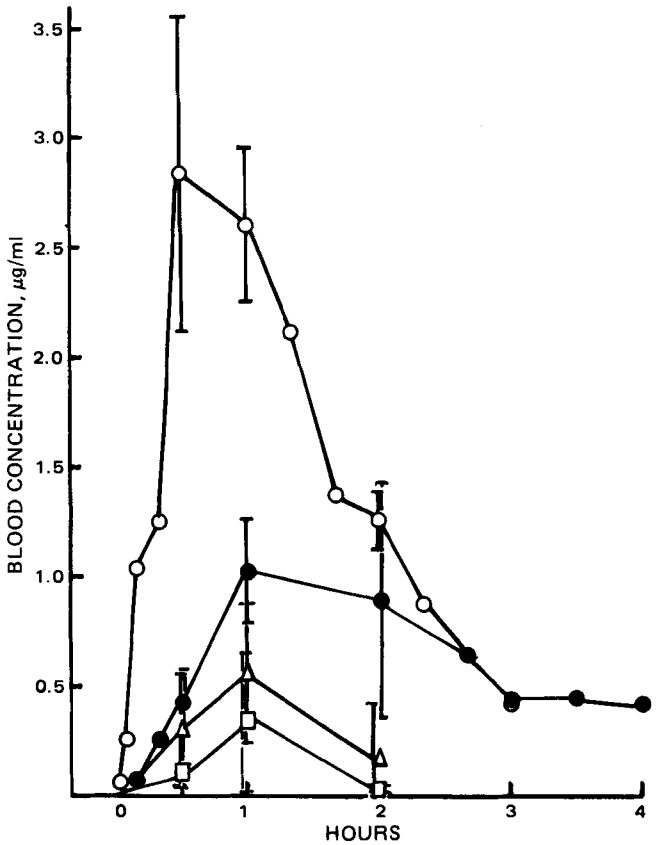

**Figure 2**—*Time courses of whole blood concentrations of aminopenicillins in rats after a 10-mg/kg dose in the duodenum. The mean levels and standard deviations (bars) for three animals are shown for 0.5, 1.0, and 2.0 hr. Key: □, ampicillin; ●, amoxicillin; ○, cyclacillin; and △, epicillin.*

[a] Upper duodenum, 2 cm from the pylorus. [b] The experimental number is given in parentheses. [c] Lower duodenum, with 1-cm separation from 1. [d] Upper jejunum, 15 cm from the pylorus. [e] Lower jejunum, with 1-cm separation from 3.

centration, then the apparent first-order absorption might proceed as observed previously (8, 9) for monobasic β-lactam antibiotics. However, if this value is affected, the contribution of some specialized mechanism would be strongly suggested.

Tables II and III show the percentages of total disappearance after 1 hr in the four small intestinal segments of each 5-cm loop and at various dose concentrations. The degradation products (penicilloic acids) remaining in the lumen also were determined for ampicillin, amoxicillin, and epicillin by fluorometric assay and for cyclacillin by HPLC. Small amounts of the degradation products of these four antibiotics were found (Tables II and III).

The percentage disappearance of amoxicillin, cyclacillin, cephalexin, cephradine, and cefadroxil depended remarkably on the initial dose concentrations. These dose dependencies revealed by their general pattern that the percentage disappearance at a low dose was extremely large while that at a high dose was markedly reduced. A similar phenomenon also was observed for epicillin, although the difference between the percentage disappearance at 20 μg/ml and that at 2 mg/ml was not statistically significant. Unfortunately, with our experimental system, it was difficult to detect saturation phenomena in the disappearance of ampicillin. However, after modification of our study, Shindo *et al.* (19) successfully demonstrated evidence for saturable absorption of ampicillin using an 8-cm long rat intestinal loop *in situ*. They found that the absorption of [$^{14}$C]ampicillin, labeled at the phenylglycyl moiety, showed an apparent tendency for saturation at a dose above 3 mg/loop, and the transference into the blood was marked in the upper and middle intestine. Absorption from limited parts also was observed with amoxicillin, cephalexin, and cefadroxil (Tables II and III), while cyclacillin and cephradine were absorbed from almost all parts of the intestine to the same extent.

Such remarkable dose-dependent absorption and the existence of specific areas of absorption suggest that the absorption of amino-β-lactam antibiotics may follow the same forms of specialized and saturable transport mechanisms since the competing degradation of β-lactam in the lumen solution is presumed to be small compared to the net absorption based on the facts discussed elsewhere.

Some investigators (10, 11, 13), using isolated rat gut, indicated the presence of an active transport mechanism of cephalexin and cyclacillin. Other studies (12, 14), however, showed by a similar *in vitro* technique that the β-lactam antibiotics, including cyclacillin (12), cephalexin (12), amoxicillin (14), and ampicillin (12, 14), were not transported by an active transport mechanism. Miyazaki *et al.* (14) demonstrated that, in both *in situ* and *in vitro* studies using rat small intestinal segments, the greater binding of amoxicillin than of ampicillin to the mucosa provided a possible explanation for the difference in body fluid concentration of these two drugs.

A recent report (20) indicated that cephradine, but not cephalexin and amoxicillin, was actively transported across the everted rat intestine. More recent findings clearly revealed that the absorption of amoxicillin (15, 17), cyclacillin (16, 17), cephalexin (21), and cephradine (21) from rat small intestinal perfusion solution was saturable. Kimura *et al.* (17) concluded that amoxicillin may be transported by a facilitated diffusion mechanism and that cyclacillin may be transported in part by active transport.

The present observations showing saturable absorption as a common phenomenon indicate that the same types of carrier-mediated transport mechanisms in the rat GI tract may underlie the absorption of amino-β-lactam antibiotics. Such a carrier system may be localized only in the small intestinal area and not in the stomach since no absorption was found in the latter part of the alimentary tract. Based on the present data for cyclacillin and cefadroxil and previous data (31, 33) for cephalexin, it is concluded that such a system is likely to make a small contribution in the large intestine.

Therefore, it is conceivable that carrier-mediated absorption is a common mechanism for the intestinal absorption of amino-β-lactam antibiotics, which are known to be effective *via* the oral route. The ki-

**Table III—Disappearance of Aminocephalosporins from Rat Intestinal Loops 1 hr after Administration**

# Intestinal Absorption Mechanism of Amphoteric β-Lactam Antibiotics II: Michaelis–Menten Kinetics of Cyclacillin Absorption and Its Pharmacokinetic Analysis in Rats

**AKIRA TSUJI *x, EMI NAKASHIMA *, IZUMI KAGAMI *, and TSUKINAKA YAMANA ‡**

Received August 13, 1980, from the **Faculty of Pharmaceutical Sciences and the ‡Hospital Pharmacy, Kanazawa University, Takara-machi, Kanazawa 920, Japan.* Accepted for publication December 11, 1980.

**Abstract** □ The absorption of cyclacillin at pH 7.0 by the rat small intestine was investigated using *in situ* perfusion. At the lowest dose of 95 μg/ml, the antibiotic disappearance was rapid and followed first-order kinetics, with the disappearance being 85% at 100 min. At the intermediate concentrations of 770 and 1200 μg/ml, the disappearance after 100 min was 69 and 54%, respectively, and semilogarithmic plots clearly showed convex curvatures. At the highest concentration of 30 mg/ml, cyclacillin disappeared slowly from the perfusate, in an apparent first-order fashion. The disappearence was 26% after 100 min of perfusion and was similar in extent at 5.2 mg/ml. This concentration–time profile was satisfactorily fitted to the simultaneous Michaelis–Menten and first-order kinetic equations. The area under the blood concentration *versus* time curve (*AUC*) after a single intraduodenal dose of cyclacillin was almost consistent with the *AUC* after the equivalent intravenous dose (10 mg/kg). Additional evidence from a pharmacokinetic analysis of steady-state blood concentrations after constant infusion of cyclacillin through the portal vein and the small intestinal lumen indicated that cyclacillin absorption by the rat intestinal tissue at relatively low concentrations (<1 mg/ml) followed solely Michaelis–Menten kinetics. Cyclacillin may be transported by certain types of carrier-mediated mechanisms.

**Keyphrases** □ Cyclacillin—intestinal absorption kinetics *in situ*, blood levels in rats after intravenous, intraportal, and intraduodenal administration □ Absorption kinetics—rat intestinal loops, blood cyclacillin levels after intravenous, intraportal, and intraduodenal administration □ Kinetics, absorption—blood cyclacillin levels after intravenous, intraportal, and intraduodenal administration, *in situ* rat intestinal loops □ Antibiotics, amino-β-lactam—cyclacillin, *in situ* intestinal absorption kinetics, blood levels after intravenous, intraportal, and intraduodenal administration to rats □ Pharmacokinetics—cyclacillin, intestinal absorption *in situ*, blood levels after intravenous, intraportal, and intraduodenal administration to rats

Previous *in situ* absorption studies (1–4) utilizing rat intestinal loops showed that the percentage disappearance of amino-β-lactam antibiotics, such as amoxicillin, cyclacillin, cephalexin, cephradine, and cefadroxil, was extremely large at a low dose but was markedly reduced at a high dose. Accumulated results from the past 10 years

# Intestinal Absorption Mechanism of Amphoteric β-Lactam Antibiotics II: Michaelis–Menten Kinetics of Cyclacillin Absorption and Its Pharmacokinetic Analysis in Rats

**AKIRA TSUJI *x, EMI NAKASHIMA *, IZUMI KAGAMI *, and TSUKINAKA YAMANA ‡**

Received August 13, 1980, from the **Faculty of Pharmaceutical Sciences and the ‡Hospital Pharmacy, Kanazawa University, Takara-machi, Kanazawa 920, Japan.* Accepted for publication December 11, 1980.

**Abstract** □ The absorption of cyclacillin at pH 7.0 by the rat small intestine was investigated using *in situ* perfusion. At the lowest dose of 95 μg/ml, the antibiotic disappearance was rapid and followed first-order kinetics, with the disappearance being 85% at 100 min. At the intermediate concentrations of 770 and 1200 μg/ml, the disappearance after 100 min was 69 and 54%, respectively, and semilogarithmic plots clearly showed convex curvatures. At the highest concentration of 30 mg/ml, cyclacillin disappeared slowly from the perfusate, in an apparent first-order fashion. The disappearence was 26% after 100 min of perfusion and was similar in extent at 5.2 mg/ml. This concentration–time profile was satisfactorily fitted to the simultaneous Michaelis–Menten and first-order kinetic equations. The area under the blood concentration *versus* time curve (*AUC*) after a single intraduodenal dose of cyclacillin was almost consistent with the *AUC* after the equivalent intravenous dose (10 mg/kg). Additional evidence from a pharmacokinetic analysis of steady-state blood concentrations after constant infusion of cyclacillin through the portal vein and the small intestinal lumen indicated that cyclacillin absorption by the rat intestinal tissue at relatively low concentrations (<1 mg/ml) followed solely Michaelis–Menten kinetics. Cyclacillin may be transported by certain types of carrier-mediated mechanisms.

**Keyphrases** □ Cyclacillin—intestinal absorption kinetics *in situ*, blood levels in rats after intravenous, intraportal, and intraduodenal administration □ Absorption kinetics—rat intestinal loops, blood cyclacillin levels after intravenous, intraportal, and intraduodenal administration □ Kinetics, absorption—blood cyclacillin levels after intravenous, intraportal, and intraduodenal administration, *in situ* rat intestinal loops □ Antibiotics, amino-β-lactam—cyclacillin, *in situ* intestinal absorption kinetics, blood levels after intravenous, intraportal, and intraduodenal administration to rats □ Pharmacokinetics—cyclacillin, intestinal absorption *in situ*, blood levels after intravenous, intraportal, and intraduodenal administration to rats

Previous *in situ* absorption studies (1–4) utilizing rat intestinal loops showed that the percentage disappearance of amino-β-lactam antibiotics, such as amoxicillin, cyclacillin, cephalexin, cephradine, and cefadroxil, was extremely large at a low dose but was markedly reduced at a high dose. Accumulated results from the past 10 years

(1–13) suggest that the GI absorption of amino-β-lactam antibiotics does not obey the so-called lipid theory but that certain carrier-mediated mechanisms underlie their absorption.

Among these classes of β-lactam antibiotics, cyclacillin revealed a remarkable dose-dependent disappearance from the rat gut lumen (2, 4). Recently, the presence of one or more carrier systems was proposed for the active transport of cyclacillin in the rat intestinal mucosa (8, 10). However, when various cyclacillin doses were administered orally to mice (14), rats (15), dogs (16), and humans (17), the peak blood levels were almost parallel to the dose. The question now arises as to whether the dose-dependent disappearance from the intestinal lumen solution is due to absorption into the bloodstream, to gut wall accumulation, or to both absorption and degradation in the gut lumen and at the mucosal surface.

The present study on cyclacillin absorption by the rat intestine was undertaken to elucidate: (*a*) the kinetics of disappearance from the recirculating intestinal perfusion solution, (*b*) the ratio of the area under the blood concentration–time curve (*AUC*) after the intraduodenal administration to that after an intravenous dose, and (*c*) the relationship between steady-state blood levels after constant infusion into the portal vein and those after single intestinal perfusion of cyclacillin at various doses.

## EXPERIMENTAL

**Materials**—Cyclacillin anhydrate (983 μg/mg) was used as received[1]. All other reagents and solvents were the best grade available.

**Animals**—Male albino Wistar rats weighing 220 ± 4 g and 214 ± 20 g were used in the measurement of *AUC* and the other experiments, respectively. They were fasted for 20 hr prior to the experiment, but water was given freely. The rats were anesthetized with urethan (1.5 g/kg ip) ~1 hr prior to surgery.

***In Situ* Recirculating Perfusion Method**—The procedure employed was essentially the same as that described previously (2). The bile duct was ligated in all recirculating perfusion experiments. The intestine was cannulated with a glass cannula at the pylorus and jejunum ends for ~30 cm and prewashed with 100 ml of pH 7.0 isotonic phosphate buffer. After washing with 20 ml of the pH 7.0 isotonic buffer containing cyclacillin, 6 ml of this antibiotic solution was recirculated continuously to produce a final volume of ~9 ml. The pH of the lumen solution was maintained at pH 7.0 by means of a pH-stat[2]. Samples withdrawn periodically from the perfusate were filtered to remove solid materials, diluted if necessary, and analyzed as described under *Analysis*. The total sampling volume was within 6% of the perfusion solution.

**Determination of *AUC* after Intravenous or Intraduodenal Administration**—A 30-cm intestinal loop was prepared by ligation between the pylorus and jejunum. Cyclacillin solution was prepared with physiological saline, and 10-mg/kg doses were given intravenously through the femoral vein (0.5 ml) or intraduodenally (1 ml). Aliquots (0.2 ml) of blood samples taken periodically from the jugular vein were assayed by the microbiological method after being hemolyzed with an equivalent volume of distilled water. The total weight of sampled blood was within 0.7% of the rat body weight.

**Tissue Accumulation after Intraduodenal Administration**—After completion of 1- or 5-hr experiments for *AUC* determination, the intestinal area of the 30-cm intestinal loop was isolated, tearing off the mesentery, and the serosal surface then was blotted with filter paper. The intestine was cut into small slices and homogenized in a polytef homogenizer with saline to give 10% (w/v, wet weight) homogenate. An aliquot of the homogenates then was analyzed.

**Constant Intraportal Infusion**—To obtain a steady-state blood level after constant infusion into the portal vein, antibiotic solutions of 5, 10, 15, and 20 mg/ml prepared with saline were infused at 0.003 ml/min into rats whose bile duct had been cannulated with a polyethylene tube to exclude bile. Aliquots (0.2 ml) of blood samples withdrawn periodically during 7-hr experiments were analyzed after being hemolyzed.

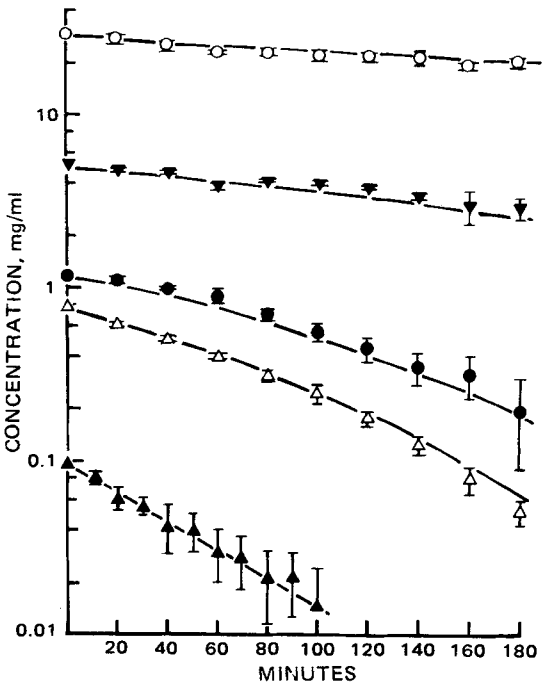

**Figure 1**—*Time courses for cyclacillin disappearance from isotonic phosphate buffer perfused through the rat small intestine as a function of dose. The points represent the mean concentration, and the vertical bars represent the standard deviations from three or six experiments. The curves are model-predicted concentrations based on nonlinear least-squares fitting of data to Eq. 1. Key: ▲, 95 μg/ml; △, 770 μg/ml; ●, 1200 μg/ml; ▼, 5200 μg/ml; and ○, 30 mg/ml.*

**Appearance in Blood after *In Situ* Single Intestinal Perfusion**—The rats were treated similarly as in the *in situ* recirculating perfusion experiments, but the bile duct was cannulated with a polyethylene tube to exclude bile. Cyclacillin solutions (0.1, 0.2, 0.5, and 1.0 mg/ml, prepared with pH 7.4 isotonic phosphate buffer) were perfused from the pylorus end at a flow rate of 2 ml/min and collected at the jejunum end. Aliquots (0.2 ml) of blood samples taken periodically during 7-hr absorption experiments were analyzed after being hemolyzed. The total weight of sampled blood was within 1% of the rat body weight.

**Analysis**—The residual cyclacillin in the recirculating perfusion solution was determined by both high-performance liquid chromatographic (HPLC) and microbiological assays.

The liquid chromatograph[3] was equipped with a UV detector[4] set at 210 nm. A strong cation-exchange resin[5] packed into a 4.6 × 500-mm stainless steel column was used as the stationary phase. The mobile phase was aqueous 0.1 *M* $KH_2PO_4$ adjusted to pH 4.0–4.2 with sodium hydroxide solution. Samples were eluted at a flow rate of 2 ml/min. The recirculating solution (10–50 μl) was withdrawn at suitable time intervals, injected *via* a variable-loop injector on flow after appropriate dilution, if necessary, and filtrated with a 0.45-μm filter[6]. The peak heights were measured, and the concentrations were calculated from calibration curves obtained daily.

The recirculating intestinal perfusion solution, intestinal tissue homogenates, and hemolyzed blood samples were analyzed by the microbiological paper disk method employing *Sartina lutea*[7]. For the latter two samples, standards were established by using fresh pooled 10% gut homogenates and fresh pooled blood, both from control rats.

The accuracies of the two analytical methods were as described previously (4).

## RESULTS AND DISCUSSION

**Concentration–Time Profile for *In Situ* Disappearance from Recirculating Perfusate**—Semilogarithmic plots of the disappearance of cyclacillin from the rat small intestinal lumen at pH 7.0 are given in Fig. 1. The analytical results determined by both HPLC and biological assay for samples of initial concentrations of 95, 1200, and 5200 μg/ml were in good agreement. The percentages of residual antibiotic at various doses as a function of time are summarized in Table I.

At the lowest concentration (95 μg/ml), cyclacillin disappearance was rapid and followed apparent first-order kinetics, with the disappearance being 85% at 100 min. At the intermediate concentrations of 770 and 1200 μg/ml, the disappearance after 100 min was 69 and 54%, respectively, and the semilogarithmic plots clearly showed convex curvatures. At the highest concentration (30 mg/ml), cyclacillin disappeared slowly from the perfusate in an apparent first-order fashion. The disappearance was 26% after 100 min of perfusion and was similar in extent at 5200 μg/ml. This concentration–time profile, showing a dramatic decrease in the disappearance rate with an increase in the initial cyclacillin concentration, indicates that the disappearance rate of this antibiotic from the rat intestinal perfusate can be described in the mixed kinetic terms of Michaelis–Menten and first order:

$$\frac{dC}{dt} = -\frac{V_{max}C}{K_m + C} - (k_1 + k_2)C \qquad \text{(Eq. 1)}$$

where $C$ is the cyclacillin concentration remaining in the perfusate at time $t$, $V_{max}$ is the maximum rate of disappearance, $K_m$ is the Michaelis–Menten constant, and $k_1$ and $k_2$ are the first-order rate constants of absorption and degradation, respectively, as defined previously (3).

Iterative nonlinear least-squares analysis of the data in Fig. 1 to be fitted to Eq. 1, using a NONLIN computer program (18), provided the following parameters[8,9]: $V_{max}$ = 502 ± 31 μg/ml/hr or 1.47 ± 0.09 m$M$ hr$^{-1}$, $K_m$ = 420 ± 27 μg/ml or 1.23 ± 0.08 m$M$, and $k_1 + k_2$ = 0.111 ± 0.014 hr$^{-1}$. During the fitting procedure, the concentration was weighted by the reciprocal of its square.

There were negligible concentrations of the penicilloic acid of cyclacillin on HPLC during the absorption experiments, which was consistent with previous observations using the *in situ* intestinal loop method (2, 4). The *in vitro* first-order degradation rate constant of this antibiotic was determined as 0.014 hr$^{-1}$ in the intestinal washing perfusate at 37°, indicating cumulative products of only 3% penicilloic acid from the initial dose after a 2-hr experiment. Subtraction of the first-order degradation rate constant ($k_2$) of 0.014 hr$^{-1}$ from the best fitting first-order rate constant of 0.111 hr$^{-1}$ yielded 0.097 hr$^{-1}$ as the net first-order absorption rate constant ($k_1$). This value was very close to values of other amino-β-lactam antibiotics, amoxicillin ($k_1$ = 0.062 hr$^{-1}$) (2) and cephradine ($k_1$ = 0.082 hr$^{-1}$) (3), as well as to the average first-order absorption rate constant for monobasic penicillins (0.076 hr$^{-1}$) (19) determined in similar experiments.

The solid lines in Fig. 1 were generated using Eq. 1 with the NONLIN-fitted parameters, indicating that Eq. 1 gives an excellent description of the experimental data for the cyclacillin disappearance from the rat *in situ* intestinal perfusate.

**Pharmacokinetic Evidence for Saturable Absorption by Blood Concentration Analysis**—In the disappearance of cyclacillin from the intestinal perfusate by Michaelis–Menten kinetics, it is important to distinguish between net transport across the GI tract into the bloodstream and competitive enzymatic degradation in the lumen and/or at the mucosal surface.

The contribution of each kinetic term in Eq. 1 to the total disappearance was calculated as a function of constant antibiotic concentration. At concentrations of >5 mg/ml, the first-order kinetic term, $k_1 + k_2$, may play the major role in the disappearance; with those of <1.0 mg/ml, the total disappearance is expected to be virtually due to Michaelis–Menten kinetics.

AUC *after Intraduodenal Dose Compared with Intravenous Dose*—Figure 2 shows the mean blood concentration–time profiles of cyclacillin

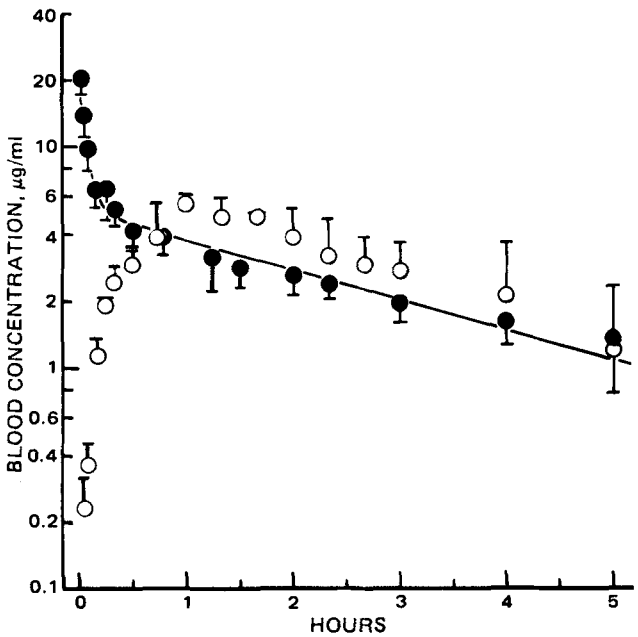

**Figure 2**—*Mean blood concentration of cyclacillin (10 mg/kg) following intravenous (●) or intraduodenal (○) administration in rats. The vertical bars represent the standard deviations from three experiments. The curve is the nonlinear least-squares line for the two-compartment open model.*

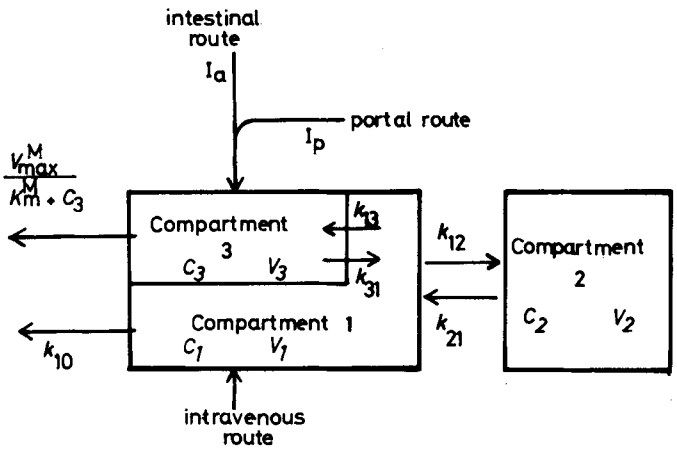
[8] Previously, we employed only the Michaelis–Menten kinetic term for the data fitting and reported $V_{max}$ = 842 ± 28 μg/ml/hr or 2.47 ± 0.08 m$M$ hr$^{-1}$ and $K_m$ = 654 ± 40 μg/ml or 1.91 ± 0.12 m$M$ (2). Additional experiments were conducted at the highest concentration of 30 mg/ml. Incorporation of a first-order kinetic term gave the best fit to all data of both the previous (2) and present studies.

[9] The computer analysis was performed with a FACOM M-160 digital computer at the Data Processing Center, Kanazawa University.



*Scheme I—Pharmacokinetic model for evaluation of the absorption rate of the drug.*

(10 mg/kg) after intravenous and intraduodenal administrations in rats whose intestine had been ligated 30 cm from the pylorus to prevent possible loss of the antibiotic into the feces. The results are summarized in Table II.

The blood concentration ($C_1$) following intravenous bolus injection declined biexponentially in accordance with:

$$C_1 = Ae^{-\alpha t} + Be^{-\beta t} \qquad \text{(Eq. 2)}$$

The data were fitted to a two-compartment open model. The values of $A$, $B$, $\alpha$, and $\beta$ were estimated to be 23.3 ± 2.4 μg/ml, 5.29 ± 0.29 μg/ml, 18.7 ± 2.2 $hr^{-1}$, and 0.326 ± 0.031 $hr^{-1}$, respectively, using the NONLIN computer program (18), where the blood concentration was weighted as its reciprocal[9]. The solid line in Fig. 2 represents the best fit of the data.

Evaluation of the data from the intraduodenal dose of cyclacillin revealed that the terminal phase of the blood level–time profile represented a function of the $\beta$ rate constant.

Both *AUC* values from the different administration routes were calculated according to the trapezoidal rule from time 0 to 5 hr, where pseudodistribution–equilibrium of cyclacillin might be attained. To each value was added the *AUC* value from 5 hr to time infinity, which was calculated using the terminal $\beta$ rate constant. The total blood areas after intravenous and intraduodenal dosing were 18.48 ± 2.28 and 18.46 ± 2.83 μg hr/ml, respectively, and thus were the same within the limits of experimental error.

These results indicate that cyclacillin was absorbed completely by the ligated intestine following intraduodenal administration and that there was no appreciable first-pass metabolism and degradation of cyclacillin in the intestine during absorption of the 10-mg/kg dose. In an absorption experiment after 1 hr, the dose of cyclacillin remaining in the intestinal lumen was determined to be 6.5%, and the accumulation in the tissue was 8.0%; the total absorption was 85.5% after 1 hr. After 5 hr, the percentages of the residual cyclacillin in the intestinal lumen and the accumulation in the tissue were 0.7 and 2.3%, respectively, indicating almost complete cyclacillin absorption in 5 hr.

*Absorption Kinetic Analysis of Steady-State Blood Concentration during Intraportal Vein Infusion and Single Intraduodenal Perfusion*—Although no significant first-pass effect was observed for cyclacillin at an intraduodenal dose of 10 mg/kg, Kind *et al.* (20) reported that penicillins were subject to significant inactivation by the isolated rat liver. Excretion of penicilloic acid after oral administration of cyclacillin in humans was reported to be 15–19% for a 0.250–1-g dose (16). Therefore, the possible consequences of metabolism in the gut or liver must be considered since such processes sometimes are saturable.

With the pharmacokinetic treatment of Gibaldi and Feldman (21), a three-compartment open model may be adequate for considering the saturable first-pass effect after intraduodenal or intraportal administration (Scheme I). The present model consists of a central compartment being sampled (Compartment 1), a rapid equilibrium hepatoportal system (Compartment 3), which is included in the central compartment, and a slow equilibrium peripheral compartment (Compartment 2). The model is based on observations of apparent biexponential pharmacokinetics following an intravenous bolus dose as described earlier. Compartment 3 includes drug metabolism in the liver during the first passage of the drug into the circulation after hepatic route administration. In this model, $C$ is the drug concentration in a given compartment and $V$ is the com-

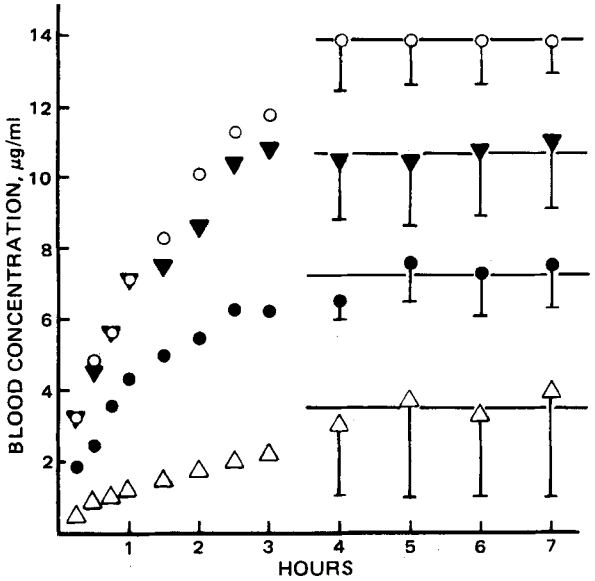

**Figure 3**—*Mean blood concentration of cyclacillin administered by constant portal vein infusion at a rate of 15.3 (△), 30.5 (●), 45.8 (▼), or 61.0 (○) μg/min. The vertical bars represent the standard deviations from three experiments.*

partment volume, $k_{10}$ represents the first-order rate constant for renal elimination, and $V^M_{max}$ and $K^M_m$ represent the maximal rate and Michaelis constant for hepatic metabolism, respectively.

From this model, the rates of drug amount in each compartment are given by:

$$V_1\frac{dC_1}{dt} = -(k_{12}+k_{13}+k_{10})V_1C_1 + k_{21}V_2C_2 + k_{31}V_3C_3 \quad \text{(Eq. 3)}$$

$$V_2\frac{dC_2}{dt} = k_{12}V_1C_1 - k_{21}V_2C_2 \quad \text{(Eq. 4)}$$

$$V_3\frac{dC_3}{dt} = k_{13}V_1C_1 - k_{31}V_3C_3 - \frac{V^M_{max}C_3}{K^M_m + C_3} + \text{input} \quad \text{(Eq. 5)}$$

$$\text{input} = I_p \text{ or } I_a \quad \text{(Eq. 6)}$$

where $I_a$ represents the absorption rate by the intestine and $I_p$ is the infusion rate through the portal vein.

At the steady state of drug distribution and elimination during a constant intestinal perfusion or constant portal vein infusion, Eqs. 7–9

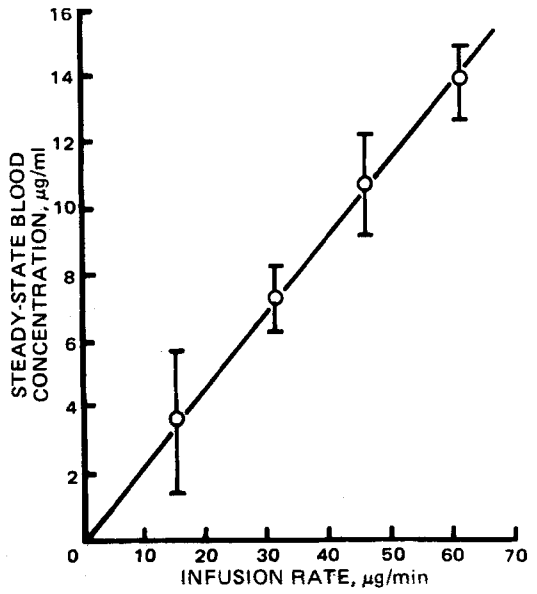

**Figure 4**—*Linear relationship between the steady-state blood concentration and portal vein infusion rate.*

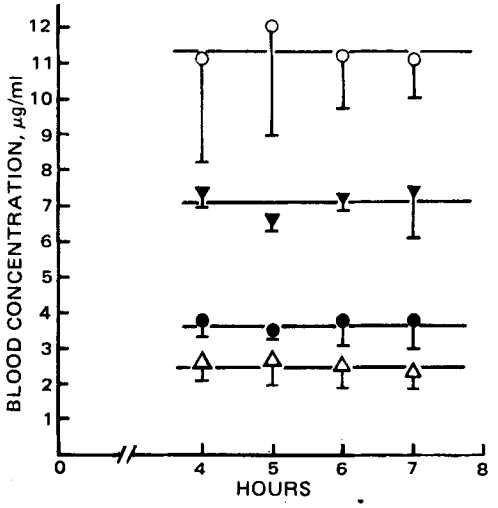

**Figure 5**—*Mean blood concentration of cyclacillin following single perfusion through the rat intestine at various drug concentrations. Key: △, 0.1 mg/ml; ●, 0.2 mg/ml; ▼, 0.5 mg/ml; and ○, 1.0 mg/ml. The vertical bars represent the standard deviation from three experiments.*

can be obtained by putting zero on the left side of Eqs. 3–6 and replacing $C_i$ by $C_i^{ss}$ (steady-state concentration) on the right sides of the equations:

$$-(k_{12}+k_{13}+k_{10})V_1C_1^{ss} + k_{21}V_2C_2^{ss} + k_{31}V_3C_3^{ss} = 0 \quad \text{(Eq. 7)}$$

$$k_{12}V_1C_1^{ss} - k_{21}V_2C_2^{ss} = 0 \quad \text{(Eq. 8)}$$

$$k_{13}V_1C_1^{ss} - k_{31}V_3C_3^{ss} - \frac{V^M_{max}C_3^{ss}}{K^M_m + C_3^{ss}} + \text{input} = 0 \quad \text{(Eq. 9)}$$

Rearrangement of Eqs. 7–9 gives:

$$\text{input} = k_{10}V_1C_1^{ss} + \frac{V^M_{max}C_3^{ss}}{K^M_m + C_3^{ss}} \quad \text{(Eq. 10)}$$

Combination of Eqs. 7 and 8 yields:

$$C_3^{ss} = \frac{(k_{13}+k_{10})V_1}{k_{31}V_3}C_1^{ss} \quad \text{(Eq. 11)}$$

where $C_3^{ss}$ is proportional to $C_1^{ss}$. If the proportionality constant is $K$, then $C_3^{ss}$ equals $KC_1^{ss}$.

When a steady-state blood concentration, $[C_1^{ss}]_{I_a}$, is achieved after constant intestinal perfusion of drug, the absorption rate, $I_a$, can be expressed as:

$$I_a = \left(k_{10}V_1 + \frac{V^M_{max}KV_3}{K^M_m + K[C_1^{ss}]_{I_a}}\right)[C_1^{ss}]_{I_a} \quad \text{(Eq. 12)}$$

Similarly, the portal vein infusion rate can be described as:

$$I_p = \left(k_{10}V_1 + \frac{V^M_{max}KV_3}{K^M_m + K[C_1^{ss}]_{I_p}}\right)[C_1^{ss}]_{I_p} \quad \text{(Eq. 13)}$$

From Eqs. 12 and 13, it can be seen that $I_a$ should be equal to $I_p$ when the steady-state levels of $[C_1^{ss}]_{I_a}$ and $[C_1^{ss}]_{I_p}$ are the same. This relationship predicts that the constant rate of intestinal absorption, $I_a$, can be determined without knowledge of any pharmacokinetic parameters such as the elimination rates from the liver and kidneys and the distribution volumes of the compartments.

As shown in Fig. 3, the steady-state blood cyclacillin concentrations during a constant rate of infusion through the portal vein in rats were 3.57 ± 2.18, 7.29 ± 1.01, 10.7 ± 1.5, and 13.9 ± 1.0 μg/ml (mean ± *SD*) between 4 and 7 hr at infusion rates of 15.3, 30.5, 45.8, and 61.0 μg/min, respectively. Plots of $[C_1^{ss}]_{I_p}$ *versus* the infusion rate, $I_p$, are given in Fig. 4. These plots apparently are linear, yielding the following regression equation:

$$I_p = 4.33[C_1^{ss}]_{I_p} \quad \text{(Eq. 14)}$$

The clearances of cyclacillin by both the renal and hepatic routes in rats appear to be linear within the range of experimental blood levels.

Figure 5 shows the blood concentration–time profiles of cyclacillin during a constant single perfusion of cyclacillin solution of $C_0$ (micrograms per milliliter) at a rate of 2 ml/min through the rat small intestine. A steady state was attained after 4 hr. The average steady-state blood levels, $[C_1^{ss}]_{I_a}$, between 4 and 7 hr were 2.50 ± 0.52, 3.67 ± 0.47, 7.11 ± 0.71, and 11.37 ± 2.09 μg/ml for intestinal cyclacillin concentrations of 0.1, 0.2, 0.5, and 1.0 mg/ml, respectively. The absorption rates, $I_a$, were calculated

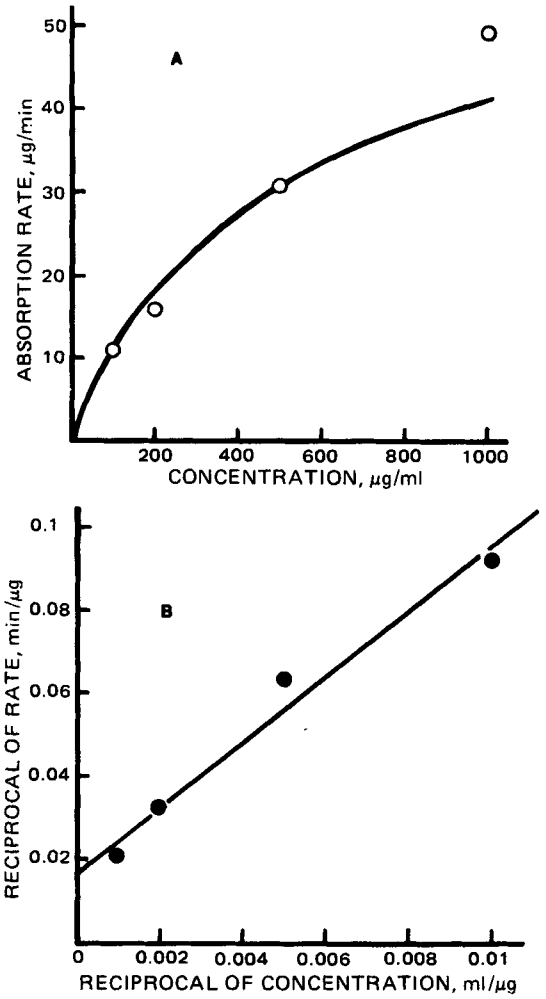

**Figure 6**—*A: Effect of drug concentration on the absorption rate of cyclacillin after rat intestinal single perfusion. B: Lineweaver–Burk plot of cyclacillin transport rate across the* in situ *rat intestinal wall to the bloodstream. The results are expressed as the means of three experiments;* $V'_{max}$ *= 3640 μg/hr and* $K_m$ *= 479 μg/ml.*

from Eq. 13 by substitution of $[C_1^{ss}]_{I_p}$ by $[C_1^{ss}]_{I_a}$ and are plotted *versus* $C_0$ in Fig. 6A. The relationship between the cyclacillin concentration perfused through the intestine, $C_0$, and the corresponding absorption rate $I_a$, demonstrated no proportionality but tended to be saturable. This finding is consistent with the fact that the disappearance of cyclacillin from the intestinal lumen in the *in situ* recirculating perfusion method followed Michaelis–Menten kinetics. If it is assumed that the net absorption of cyclacillin across the intestinal membrane is subject to a capacity-limited process at relatively low concentrations (<1.0 mg/ml), the steady-state absorption rate can be described solely by the Michaelis–Menten equation as follows:

$$I_a = \frac{V'_{max} C_0}{K_m + C_0} \qquad \text{(Eq. 15)}$$

where $V'_{max}$ is the maximal rate (micrograms per hour). A Lineweaver–Burk plot of the reciprocal of the absorption rate ($1/I_a$) *versus* the reciprocal of the cyclacillin concentration ($1/C_0$) is shown in Fig. 6B. Using the least-squares method for the plot, the calculated values of $V'_{max}$ and $K_m$ were 3640 μg/hr and 479 μg/ml, respectively, which are comparable to the values evaluated from the kinetics of disappearance from the recirculating perfusate at the same perfusion rate of 2 ml/min ($V'_{max}$ = 4520 ± 280 μg/hr[10] and $K_m$ = 420 ± 27 μg/ml).

[10] This value was estimated by multiplying $V_{max}$ by the intestinal recirculating perfusion volume of 9 ml.

## CONCLUSION

The criticism has been made that GI absorption studies of drugs based on the rate or extent of disappearance from the lumen solution utilizing proper experimental techniques *in vivo* may not necessarily reflect the net absorption into the bloodstream due to such factors as drug metabolism in the intestinal lumen and at the mocusal surface. Previous studies (2, 4) demonstrated that cyclacillin exhibited a strongly dose-dependent disappearance from rat intestinal loops, suggesting some specialized transport system. However, this finding does not exclude possible enzymatic metabolism during the absorption experiments.

The present study provided conclusive evidence that the disappearance of cyclacillin from the intestinal lumen followed simultaneous Michaelis–Menten and first-order kinetics and that cyclacillin absorption into the bloodstream was rapid and complete by comparison of both *AUC* values after intravenous and intraduodenal administration. At the dose used (10 mg/kg), the observed Michaelis–Menten kinetic term is expected to play a major role in the total disappearance from the GI lumen. Additional evidence from a pharmacokinetic analysis of the steady-state blood concentrations after constant infusion of cyclacillin into the portal vein and through the small intestinal lumen indicated that the uptake of cyclacillin by the rat intestinal tissue at relatively low concentrations of <1 mg/ml followed solely Michaelis–Menten kinetics. These results suggest that cyclacillin may be transported in the rat intestine by certain carrier systems and moved into the bloodstream without significant loss of antibiotic activity.

# Xilobam: Analysis, Determination of Decomposition Products, and Assessment of Stability

C. A. JANICKI ˣ, W. D. WALKLING, R. H. ERLICH *, and C. A. BAINBRIDGE

Received September 8, 1980, from *Pharmaceutical Development, McNeil Pharmaceuticals, Spring House, PA 19477.* Accepted for publication December 10, 1980. *Present address: Bristol Laboratories, Syracuse, NY 13201.

**Abstract** □ A stability-indicating UV assay was developed for xilobam, a member of a new class of CNS agents. The method was specific, precise, and accurate. TLC and high-pressure liquid chromatography were used to support method specificity. Xilobam is sensitive to heat, moisture, and basic conditions. The degradation products were identified as *N*-methylpyrrolidone, 2,6-dimethylaniline, and *N*,*N*′-bis(2,6-dimethylphenyl)urea. At high temperatures, the incorporation of molecular sieves into glass bottles of xilobam tablets was effective in preventing decomposition caused by moisture or volatile decomposition products.

**Keyphrases** □ Xilobam—analysis, determination of decomposition products, stability assessment □ CNS agents—xilobam, analysis, determination of decomposition products, stability assessment □ Decomposition products—xilobam, analysis, stability assessment □ Muscle relaxants—xilobam, analysis, determination of decomposition products, stability assessment

Xilobam, *N*-(2,6-dimethylphenyl)-*N*′-(1-methyl-2-pyrrolidinylidene)urea, a new class of central nervous system agents, is being evaluated clinically as a skeletal muscle relaxant (1, 2). Xilobam is a sparingly soluble base with a spectrophotometrically determined pKa of 6.1. A stability-indicating assay was required to evaluate drug safety supplies and clinical dosage forms. To develop the method, it was necessary to know the various degradation products of xilobam. The isolation and identification of these degradation products and the development of a rapid spectrophotometric assay for xilobam are described. Preliminary stability data and the identification of degradation products are given for a tablet dosage form.

## EXPERIMENTAL

**Apparatus**—UV spectra were obtained using 1-cm cells on a double-beam spectrophotometer[1]. TLC plates (5 × 20 cm) were silica gel[2]. The liquid chromatograph[3] was equipped with a UV detector (254 nm), a 6000-psi pump, and a loop injector. The column was 25 cm × 2 mm i.d. stainless steel, slurry-packed with a reversed-phase $C_{18}$ packing[4]. The mobile phase was 0.1% ammonium carbonate–acetonitrile (60:40) with a 1.0-ml/min flow rate.

**Chemicals**—Solvents were analytical reagent grade. Reference standards of the degradation products were obtained[5]. The acetonitrile[6] was distilled-in-glass quality. The molecular sieves were type 4A pellets[7] (a synthesized sodium alumino silicate).

**Xilobam Degradation**—Xilobam was dissolved or mixed separately in 1 *N* HCl, 1 *N* NaOH, and water at a concentration of 10 mg/ml. The samples were heated at 80 ± 2° for 24 hr.

The tablet degradation products were extracted with methanol, chromatographed on TLC plates, isolated, and identified by IR and NMR spectroscopy and mass spectrometry.

**Intermediate Identification**—A 12.5-mg/ml solution of xilobam in methanol was prepared. Aliquots (4 ml) of the solution were diluted separately to 50 ml with pH 4.0 and 7.0 citrate–phosphate buffers. The solutions were equilibrated with 50 ml of toluene at 80° for 4 hr. The toluene layers were separated and washed with 0.1 *N* HCl to remove residual xilobam and any 2,6-dimethylaniline.

The toluene layers were dried over magnesium sulfate and then analyzed by TLC and UV and IR spectroscopy. *m*-Chloroaniline was added to the toluene layers in excess, and the mixtures were allowed to stand for 2 days. The precipitate was filtered, dried, and assayed by electron-impact mass spectrometry. A control of 2,6-dimethylphenyl isocyanate in toluene was run simultaneously.

**TLC**—Xilobam was dissolved in methanol, and the degradation compounds were dissolved in methanol or methanol–chloroform (1:1). The TLC chambers were 2-liter, wide-mouth Mason jars fitted with standard lids. The developing solvent was 0.2 *M* sodium acetate buffer (adjusted to pH 4.7)–methanol–chloroform–ethyl acetate (2.5:17.5:53:27). Each plate was developed until the solvent front was ~2.5 cm from the top of the plate. The plates were air dried and viewed under short wavelength UV light or stained with iodine vapor.

**Stability-Indicating Assay**—A sample equivalent to 100 mg of xilobam was transferred to a 120-ml screw-capped bottle to which were added exactly 50 ml of chloroform and 25 ml of 0.1 *N* NaOH. The bottle was shaken mechanically for 30 min and centrifuged, and the aqueous layer was aspirated and discarded. The chloroform layer was transferred to a clean container. A 15-ml aliquot of the chloroform layer was pipetted to a 100-ml volumetric flask, diluted to volume with chloroform, and mixed.

A 5-ml aliquot of the diluted chloroform solution was pipetted into a 60-ml screw-capped bottle containing exactly 8 ml of cyclohexane. A 50-ml aliquot of 0.1 *N* HCl was pipetted into the bottle, and the bottle was capped, shaken mechanically for 30 min, and centrifuged. The acid layer was decanted to a clean container.

A 6-ml aliquot of the acid layer was pipetted into a 25-ml volumetric flask, diluted to volume with 0.1 *N* NaOH, and mixed. The UV absorbance of the sodium hydroxide solution was recorded in 1-cm cells *versus* a solvent blank of 0.1 *N* NaOH.

A 100-mg sample of xilobam reference standard was treated as were the test samples, and its spectrum was recorded at the same time as the test samples.

The calculation was:

$$\text{percent of label amount} = \frac{A_\mu C_s}{A_s C_\mu} \times 100 \qquad \text{(Eq. 1)}$$

where $A_\mu$ and $A_s$ are the absorbance of the sample and standard, respectively, at the maximum near 245 nm and $C_\mu$ and $C_s$ are the concentrations in milligrams per milliliter of the sample and standard, respectively. The molar absorptivity at the maximum is ~23,500. A minimum occurs at 225 nm with a molar absorptivity of ~9100.

**Specificity Study**—All possible degradation products (Table I) were taken through the UV assay at a molar concentration equivalent to 100 mg of xilobam. The various tablet excipients that might be present also were assayed.

**Precision, Accuracy, and Recovery**—A stock solution of xilobam (25.27 mg/ml in methanol) was prepared. A 5-ml aliquot was added to a 120-ml screw-capped bottle, evaporated to dryness under a nitrogen stream, and assayed.

While the test samples were being assayed, a 4-ml aliquot of the stock solution was diluted to the same final concentration and solvent composition as the test samples. To assess recovery, the absorbances of these solutions were recorded and compared to the test sample absorbances.

In addition, samples of 20 tablets, each containing 200 mg of xilobam, were ground to a fine powder. Triplicate samples were weighed and assayed, and the mean and standard deviation were calculated.

Liquid samples were diluted with methanol to a concentration of ~1 mg of xilobam/ml. A 5-ml aliquot was pipetted into a 10-ml volumetric flask, 4 ml of the internal standard solution was added, and methanol was added to volume. A 10-μl sample was injected into the chromatograph.

The internal standard was *N*-(3-chlorophenyl)-*N'*-(1-methyl-2-pyrrolidylidene)urea at a concentration of 2 mg/ml. Standard curves were obtained by plotting the peak height ratio *versus* concentration.

**pH Stability Profile**—A stock solution of xilobam (5 mg/ml in methanol) was prepared, and 4 ml was diluted to 0.1 mg/ml with buffers of varying pH. Potassium chloride–hydrochloric acid solutions were used for pH 1.0, citrate–phosphate buffers were used for pH 2.2–7.0, and glycine–sodium hydroxide buffers were used for pH 9.0–11.0. The solutions were stored at 60, 70, and 80° and were assayed for xilobam by the UV method.

## RESULTS AND DISCUSSION

**Solution Degradation Product Identification**—The acidic, basic, and aqueous hydrolysis solutions were assayed by HPLC, and assay values of 90, 0, and 0% of xilobam were obtained, respectively. By HPLC, the acidic solution gave a very large peak, which corresponded to 2,6-dimethylaniline, and two minor peaks close to the solvent peak. Sufficient solution was collected by semipreparative HPLC of the major peak, evaporated to dryness, and recrystallized; the residue was determined to be 2,6-dimethylaniline by its IR spectrum.

The basic and aqueous solutions both contained a precipitate. The precipitates were identified as *N,N'*-bis(2,6-dimethylphenyl)urea by IR and mass spectrometric analyses. The solution was chromatographed by HPLC, and the major peak was collected and purified as described. The material was identified as 2,6-dimethylaniline by IR spectrophotometry.

**Intermediate Identification**—The intermediate in xilobam decomposition was postulated to be 2,6-dimethylphenyl isocyanate. To prove this assumption, the intermediate was trapped by partitioning into toluene while xilobam was decomposed in the pH 4.0 and 7.0 solutions. The pH values represented hydrogen-ion concentrations on either side of the pKa of xilobam, which was determined spectrophotometrically to be 6.1. If different decomposition pathways occurred, it was anticipated that the different intermediates would be isolated.

The UV and IR spectra of the dried toluene layer were identical to those of 2,6-dimethylphenyl isocyanate treated similarly. TLC of the toluene layers, including the control, gave one spot each with an $R_f$ value of ~0.75, corresponding to the carbamate, formed by the *in situ* reaction with the alcohol in the mobile phase. Table I lists the $R_f$ values of the various degradation products separated from xilobam. The 2,6-dimethylphenyl isocyanate readily forms a methyl carbamate when treated with methanol. To test definitely for the isocyanate, 3-chloroaniline was added to the toluene layer. The precipitate was identified as 2,6-dimethylphenyl-3-chlorophenylurea. This compound could be formed only if the isocyanate was present in the toluene layer.

**UV Assay Specificity**—To verify assay specificity, each degradation product listed in Table I was assayed. There was no interference from any degradation product. Assay of the common tablet excipients also showed no UV interference.

**Precision, Accuracy, and Recovery**—Three analysts, to whom the stock solution concentration was unknown, assayed the solutions (Table II). The data show that the method is precise, since the standard deviation was ±1.48, and accurate, since the mean value was 97.5% of the theoretical value. A precision study also was conducted on a composite sample obtained by grinding 20 tablets. The mean from nine assays was 97.5% of the label amount with a standard deviation of 1.46.

The efficiency of the extraction was demonstrated by assaying portions of the stock solution and comparing the resulting absorbances to other portions simultaneously diluted to the same final concentration and solvent composition. The data are compared in Table III and indicate complete xilobam extraction.

**Drug Substance Stability**—Crystalline xilobam was stable for up to 3 months at 40, 60, and 40° at 80% relative humidity (RH) when stored in tight containers. Xilobam decomposed completely and rapidly at 80°. The major degradation product was identified as *N,N'*-bis(2,6-dimethylphenyl)urea.

**pH Stability Profile**—Decomposition of xilobam in solution followed first-order decomposition. The rate constants in reciprocal hours determined at 25, 60, 70, and 80° are given in Table IV. Higher pH values led to greater instability. The most stable pH range was 1–4. The calculated time in days for 10% decomposition at 25° is given in Table V.

**Dosage Form Stability**—Since xilobam hydrolyzes easily in aqueous solution, a tablet with minimum exposure to water was developed and

placed on stability. The tablets were stable at room temperature and 40° but decomposed at 40° and 80% RH and at 60° and decomposed rapidly at 80°. An odor of ammonia was noted from the decomposed samples. Tablets then were stored at 70° for 2 days in containers with and without closures. The tablets stored without closures were white and assayed satisfactorily. Tablets stored with closures were badly discolored, and

**Table VI—Xilobam Tablet Stability**

| | Percent of Label Amount (200 mg/tablet) | | | | |
|---|---|---|---|---|---|
| Days | 25° | 40° | 60° | 80° | With Molecular Sieves (80°) |
| Initial | 98.7 | 98.7 | 98.7 | 98.7 | 98.7 |
| 19 | — | — | — | — | 96.1 |
| 39 | 98.4 | 97.9 | 24.5 | 5.4 | — |
| 109 | 98.1 | 96.2 | — | — | 77.4 |

the assays showed extensive degradation. The experiment was repeated, and the headspace was analyzed by GLC–mass spectrometry. The mass spectroscopic data showed the presence of ammonia.

Molecular sieves that absorb both water and ammonia vapors were added to bottles of xilobam tablets. The tablets in amber glass bottles with standard closures were stored at 80° for 109 days. Tablets stored with molecular sieves were much more stable at 80° (Table VI). Without molecular sieves, complete degradation was observed.

The tablets that were degraded extensively were ground, extracted with methanol, and chromatographed by TLC. The separated spots were scraped from the plates; sufficient quantities were obtained to run IR, NMR, and mass spectrometric spectra. The degradation products were *N*-methylpyrrolidone, 2,6-dimethylaniline, and *N,N'*-bis(2,6-dimethylphenyl)urea. The proposed degradation pathway is given in Scheme I.

Xilobam tablets were studied for up to 2 years at 25° (room temperature) and 40° in amber glass containers. No differences were observed at these conditions for tablets stored without molecular sieves compared to those stored with molecular sieves. However, at higher temperatures, the tablets with molecular sieves were much more stable than those without them.

rutin

rutin and its metabolites were not present in human urine after oral administration. However, Booth *et al.* (7) identified 3-hydroxyphenylacetic acid (I), 3-methoxy-4-hydroxyphenylacetic acid (II), and 3,4-dihydroxyphenylacetic acid (III) as the urinary metabolites of rutin. The fundamental problem involved with using the method of Booth *et al.* (7) is that these compounds are excreted in the ordinary urine (8–13). Thus, an accurate determination of I–III derived from administered rutin is not possible.

A radioactive isotope tracer method is useful for metabolic studies. However, this method is inferior to a stable isotope tracer method in the structural elucidation of metabolites and in the safety in administration to humans.

This report identifies the urinary metabolites of rutin-2′,5′,6′-$d_3$ (rutin-*d*) (14) by GLC–mass spectrometry.

## EXPERIMENTAL

**Rutin and Authentic Compounds**—Rutin[1] was purified by column chromatography using cross-linked dextran gel[2] with methanol and then was recrystallized from methanol–water (1:1). Quercetin[1], 3-hydroxyphenylacetic acid[1] (I), 3-methoxy-4-hydroxyphenylacetic acid[1] (II), 3,4-dihydroxyphenylacetic acid[1] (III), 3,4-dihydroxytoluene[3] (IV), 3-(3,4-dihydroxyphenyl)propionic acid[4], and α-*p*-hydroxyphenyllactic acid[5] were obtained commercially.

β-*m*-Hydroxyphenylhydracrylic acid (V) was synthesized from β-*m*-benzyloxyphenylhydracrylic acid (mp 95°) by reductive debenzylation under hydrogen gas on 5% palladium-on-charcoal and then was recrystallized from ethyl acetate, mp 158° dec. [lit. (15) mp 159°].

*Anal.*—Calc. for $C_9H_{10}O_4$: C, 59.34; H, 5.53. Found: C, 59.38; H, 5.43.

Rutin-*d* was prepared by hydrogen exchange according to the procedure of Hiraoka *et al.* (14). PMR spectra showed the isotopic ratio of $d_1$-, $d_2$-, and $d_3$-forms in deuterium-labeled rutin prepared in these laboratories was approximately 1:6:3.

**GLC–Mass Spectrometry**—A GLC–mass spectrometer[6] and a data processing system[7] connected to a minicomputer[8] were used. The GLC system employed a 2-m × 3-mm i.d. glass column packed with 2% OV-105 on 60–80-mesh Chromosorb W; it was packed with 1.5% OV-1 on 80–100-mesh Shimalite for quercetin analysis. The column, flash heater, and separator temperatures were 160, 180, and 280°, respectively, and the helium flow rate was 20 ml/min. The mass spectrometer employed an ionization-source temperature of 310° and ionization energy of 20 ev.

One minute following injection of the sample, automatic magnet scanning was initiated, covering an *m/z* range of 50–500 every 8 sec. All scanning data were stored in the data processing system. Mass chromatograms were obtained on a digital plotter for selected mass numbers.

**Drug Administration**—Two of four healthy male volunteers received 10 mg of rutin-*d*/kg po, and the other two subjects received 50 mg of nonlabeled rutin/kg po. The test subjects were not allowed fruit and vegetables for 4 days prior to and 2 days after drug administration.

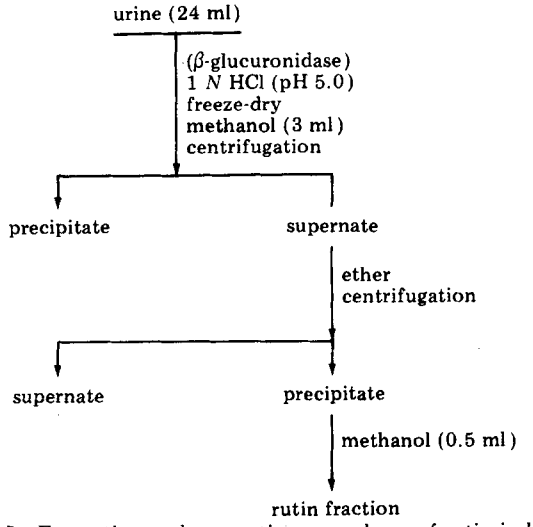
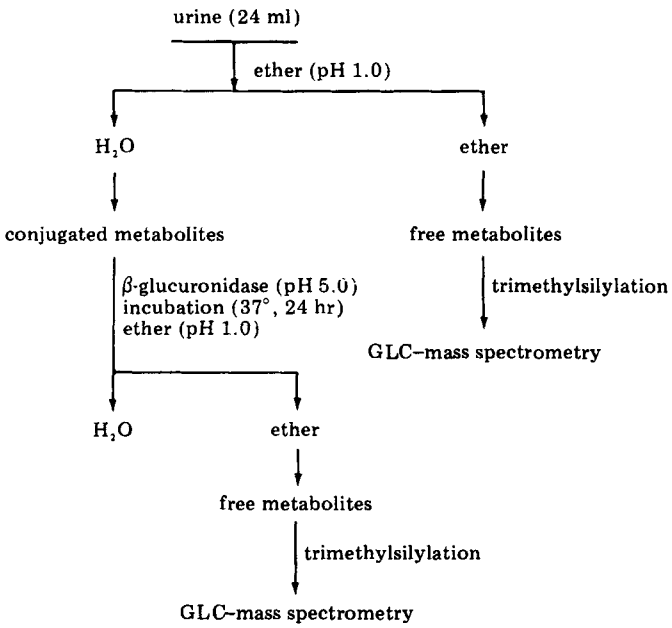


*Scheme I—Extraction and separation procedures of rutin in human urine prior to and after oral administration of rutin for TLC analysis.*

**TLC Analysis of Rutin**—Urine collections were made at 0–24 hr prior to and at 0–48 hr after administration of nonlabeled rutin. The fractionation procedure of urine samples for TLC[9] is shown in Scheme I. Conjugated metabolites were hydrolyzed by incubation with β-glucuronidase[10] (30,000 units/24 ml of urine) at 37° for 24 hr. Each ether layer thus fractionated was concentrated to dryness under reduced pressure and then was dissolved in 5 ml of methanol. An aliquot (0.1 ml) of this solution was subjected to TLC. The solvent system was *n*-butyl alcohol–acetic acid–water (4:1:2). The spots were visualized by aluminum chloride (16); rutin had an $R_f$ value of 0.45.

**Identification of Metabolites by GLC–Mass Spectrometry**—Urine was collected for 24 hr prior to and after administration of rutin-*d*. The fractionation procedure of urine samples is shown in Scheme II. The ether layer was concentrated to dryness under reduced pressure. The residue was dissolved in dry pyridine (0.1 ml) and trimethylsilylated with *N,O*-bis(trimethylsilyl)acetamide (0.05 ml) and then was subjected to the GLC–mass spectrometric computer system.



*Scheme II—Extraction and separation procedures of metabolites in human urine prior to and after oral administration of rutin-d for GLC–mass spectrometric analysis.*

## RESULTS AND DISCUSSION

**TLC Analysis of Rutin**—The rutin analysis was not performed successfully by GLC under the various conditions tested with methyl and cyanoethyl silicone phase columns. The urine samples collected prior to and after rutin administration were subjected to TLC after the extraction and separation procedures shown in Scheme I. The TLC results revealed that rutin was not detected in the urine with or without β-glucuronidase treatment. To another urine sample collected prior to rutin administration was added rutin in an amount to give a concentration of 20 μg/ml, and this sample also was subjected to TLC. In this case, rutin was detected. Therefore, excretion of rutin into the urine after rutin administration is negligible or, at least, <20 μg/ml. These findings suggest that orally administered rutin might be metabolized completely.

**Determination of Metabolites by GLC–Mass Spectrometry**—The isotopic ratio of $d_1$-, $d_2$-, and $d_3$-forms in deuterium-labeled rutin (rutin-*d*) was 1:6:3. Particular attention was paid to the $d_2$-form to determine rutin metabolites by GLC–mass spectrometry. The masses of the molecular ions of the deuterated and nondeuterated trimethylsilylated derivatives of the metabolites derived from rutin are shown in Fig. 1.

The urine samples collected prior to and after administration of rutin-*d* were subjected to trimethylsilylation with *N,O*-bis(trimethylsilyl)-acetamide and analyzed by the GLC–mass spectrometric computer system. Mass chromatograms were obtained by monitoring the molecular ions of the $d_0$- ($M^+$) and $d_2$- [$(M + 2)^+$] forms of the trimethylsilylated derivatives of possible metabolites derived from rutin. A metabolite was identified by examining the presence of duplicate peaks at the same retention time in the mass chromatogram.

Typical mass chromatograms obtained from the urine without β-glucuronidase hydrolysis are shown in Figs. 1A (prior to) and 1B (after rutin-*d* administration). The ratio of peak intensities [$(M + 2)^+$:$M^+$] shown in Fig. 1A was practically the same as that estimated from the natural abundance. On the other hand, in peaks a, b, c, and d shown in Fig. 1B, the ratios of the peak intensities [$(M + 2)^+$:$M^+$] became larger than those shown in Fig. 1A, indicating the increment of the peak intensity in the respective $(M + 2)^+$ peaks. In addition, the comparison of the peak intensity ratios of $M^+$ and $(M + 2)^+$ in the mass chromatogram peak e (Figs. 1A and 1B) indicated a clear increment of the $(M + 2)^+$ peak in Fig. 1B. These findings make it clear that orally administered rutin-*d* was metabolized to five metabolites, which also were present in the urine as endogenous metabolites.

The mass spectra corresponding to the mass chromatogram peaks a, b, and c were the trimethylsilylated derivatives of 3-hydroxyphenylacetic acid (I), 3-methoxy-4-hydroxyphenylacetic acid (II), and 3,4-dihydroxyphenylacetic acid (III), respectively. Identification was made by comparing the mass spectra and the GLC retention times of the respective mass chromatogram peaks with those of the trimethylsilylated authentic compounds.

In the mass spectrum of the mass chromatogram peak d, the ion at *m/z* 268 appeared to be the molecular ion corresponding to the trimethylsilylated derivative of 3,4-dihydroxytoluene (IV) because it was 116 mass units [$COOSi(CH_3)_3 - H$] lower than the molecular ion of the trimethylsilylated derivative of III (*m/z* 384). The GLC retention time and mass spectrum of trimethylsilylated authentic IV confirmed the structure of Metabolite d as IV. The *m/z* values of the molecular ion and fragment ion in the mass spectrum of peak d after rutin-*d* administration were 2 mass units higher than those in the mass spectrum prior to rutin-*d* administration and thus were in mass spectra a, b, and c. These findings clearly indicated that these metabolites were derived from rutin-*d*.

In the mass spectrum of the mass chromatogram peak e after rutin-*d* administration, peak intensities at *m/z* 269, 282, and 400 were larger than those estimated from the natural abundance. The metabolite, although excreted in only a small amount, should originate from rutin-*d*. This metabolite was assigned as β-*m*-hydroxyphenylhydracrylic acid (V) and was identified by comparing the GLC retention time and mass spectrum of the trimethylsilylated authentic compound. The optical rotation and the absolute configuration of this metabolite could not be determined.

These five metabolites identified in urine without β-glucuronidase hydrolysis also were found in the urine treated with β-glucuronidase.

Recently, much attention has been directed toward organic acids in human urine by the GLC–mass spectrometric computer system called "metabolic profiling" (9–13, 17). Rutin was metabolized to give four phenolic acids in human urine. The observation showed that flavonoids in plants as a diet also must be metabolized to give these types of phenolic acids in the urine.

Other possible metabolites derived from rutin-*d*, such as 3,4-dihydroxyphenylpropionic acid, α-*p*- or α-*m*-hydroxyphenyllactic acid, and β-*p*-hydroxyphenylhydracrylic acid, were excluded by the mass spectra in one investigation (18). Quercetin, an aglycone of rutin, was not found in urine. It was impossible to follow the metabolic change occurring in the A ring on which no deuterium atoms are labeled.

In this study, five metabolites (I–V) derived from orally administered rutin-*d* were differentiated from these compounds endogenously present and were successfully identified by the mass chromatographic method. These metabolites occur in urine *via* the reduction of the double bond of the γ-pyron ring (I–V) and the dehydroxylation at the 4′-position of the B ring (I and V). A study concerning the reduction in this metabolism is now in progress.

# Simultaneous High-Performance Liquid Chromatographic Determination of Theophylline, Ephedrine Hydrochloride, and Phenobarbital in Tablets

**HENRY S. I. TAN ˣ, PRAKONGSIRI C. BOONCONG, and SHARON L. FINE ***

Received June 13, 1980, from the *College of Pharmacy, University of Cincinnati–Medical Center, Cincinnati, OH 45267.* Accepted for publication December 8, 1980. *Present address: George Washington University Hospital, Washington, DC 20037.

**Abstract** □ A rapid reversed-phase high-performance liquid chromatographic (HPLC) method was developed for the simultaneous assay of theophylline, ephedrine hydrochloride, and phenobarbital in a tablet matrix. A methanolic extract of the powdered sample containing salicylamide as the internal standard was injected into the chromatograph. The HPLC system used methanol–0.007 *M* monobasic potassium phosphate (37:63, pH 2.3) as the mobile phase. Detection was at 254 nm, and quantitation was based on the drug–internal standard peak area ratio. This ratio was linear over a concentration range of 20.9–83.5 μg of theophylline, 4–15.9 μg of ephedrine hydrochloride, and 1.3–5.1 μg of phenobarbital. Overall recoveries (±*SD*) from three synthetic tablets were: theophylline, 99.8 ± 1.3%; ephedrine hydrochloride, 100.2 ± 0.6%; and phenobarbital, 99.4 ± 0.7%. The method was compared to the compendial method and also was applied to the assay of commercial tablets containing these three active ingredients. The proposed method is applicable to the assay of individual tablets.

**Keyphrases** □ High-performance liquid chromatography—simultaneous assay of theophylline, ephedrine hydrochloride, and phenobarbital □ Sedatives—simultaneous high-performance liquid chromatographic assay of theophylline, ephedrine hydrochloride, and phenobarbital □ Bronchodilators—simultaneous high-performance liquid chromatographic assay of theophylline, ephedrine hydrochloride, and phenobarbital

Tablets containing a mixture of theophylline, ephedrine hydrochloride, and phenobarbital are used as bronchodilators and sedatives. This dosage form was official in NF XIV and then was admitted to USP XX. No changes were made in the assay upon admission to USP XX, except that ephedrine sulfate instead of the hydrochloride now is used as the standard (1).

## BACKGROUND

The compendial method is laborious and time consuming (~10 hr), involving the passage of the sample solution through two liquid chromatographic columns followed by partial or complete evaporation of the several liquid fractions obtained. The method also involves solvent extraction of one of the eluates, resulting in separation of the mixture into three fractions, each containing a single drug. The fractions are measured by UV spectroscopy.

Lach *et al.* (2) analyzed these tablets by UV spectroscopy, but a separate tablet sample was required for the assay of each drug. Measurement was made after each drug was isolated from the tablet matrix by a different solvent extraction.

GLC methods for the analysis of mixtures of these three drugs in tablets or suspensions were previously reported (3, 4). In these reports, ephedrine generally was assayed separately, and the phenobarbital and theophylline were chromatographed directly after solvent extraction. Ephedrine was converted to benzaldehyde prior to chromatography by treating a second sample with periodate (3). The suspensions were assayed by separating the sample into two fractions, one containing ephedrine and the other containing theophylline and phenobarbital, which then were gas chromatographed (4).

Quantitative determinations of single entities of theophylline or phenobarbital in various dosage forms and biological samples based on reversed-phase high-performance liquid chromatography (HPLC) were published previously and reviewed (5, 6). Some reversed-phase HPLC assays for ephedrine hydrochloride also were reported (7, 8).

This paper presents the simultaneous assay of theophylline, ephedrine hydrochloride, and phenobarbital in tablet mixtures by reversed-phase HPLC with salicylamide as the internal standard. The HPLC method is simple and rapid and is also more accurate and reproducible than the compendial method.

## EXPERIMENTAL

**Apparatus**—The high-performance liquid chromatograph[1] was equipped with a constant-flow pump[2], a valve-type injector[3], a fixed-wavelength (254-nm) UV detector[4], and a strip-chart recorder[5].

**Reagents and Materials**—*l*-Ephedrine hydrochloride[6], theophylline[7], salicylamide[7], phenobarbital[8], 0.007 *M* $KH_2PO_4$ in water (adjusted to pH 2.3 with 85% aqueous phosphoric acid), and methanol[9] were used. Other chemicals used were analytical grade.

**Chromatographic Conditions**—A 25-cm × 4.5-mm i.d. 10-μm Partisil ODS II ITP column[10] was used at ambient temperature. The mobile phase was methanol–0.007 *M* $KH_2PO_4$ (pH 2.3, 37:63). This solution was filtered through a 5-μm membrane filter[11], degassed, and then pumped through the HPLC system at a rate of 1.2 ml/min. The detector was attenuated to 2.0 aufs for theophylline and salicylamide and to 0.05 aufs for ephedrine hydrochloride and phenobarbital.

**Internal Standard Solution**—The internal standard was salicylamide prepared as a 12-mg/ml solution in methanol.

**Preparation and Assay of Standard Solution**—Approximately 260 mg of theophylline, 50 mg of ephedrine hydrochloride, and 16 mg of phenobarbital were weighed accurately into a 100-ml volumetric flask. After ~25 ml of methanol was added, the mixture was placed in an ultrasonic bath for 5 min and the resulting solution was diluted to volume with methanol. Twenty milliliters of this solution was pipetted into a 25-ml volumetric flask. After addition of 1.0 ml of the internal standard solution, the solution was diluted to the mark with methanol and filtered through a 5-μm membrane filter[11]. By using a 25-μl syringe[12], three 20-μl portions of the filtrate were chromatographed under the described HPLC conditions and the average drug–salicylamide peak area ratio was determined.

**Assay of Theophylline, Ephedrine Hydrochloride, and Phenobarbital Tablets**—Twenty tablets were weighed and finely powdered. A portion of the powder equivalent to 8 mg of phenobarbital was weighed accurately and transferred to a 50-ml volumetric flask. Approximately 20 ml of methanol was added, and the mixture was placed in an ultrasonic bath for 5 min and then diluted to volume with methanol. Twenty milliliters of this mixture was pipetted into a 25-ml volumetric flask and treated as already described.

## RESULTS AND DISCUSSION

A study of theophylline, ephedrine hydrochloride, and phenobarbital tablets from 13 manufacturers revealed that 45% of the tablet lots were not chemically equivalent, indicating a need for improvement in manufacturing and quality control (2). An assay for quality control use, par-

ticularly for content uniformity and dissolution tests, should be simple, convenient, rapid, and accurate.

Theophylline, ephedrine hydrochloride, and phenobarbital vary greatly in acidity and polarity. In addition, the polar, strongly basic amine ephedrine has low molar absorptivity at its wavelengths of maximum absorption of 252, 257, and 263 nm. In the mobile phases that gave good symmetrical peaks for weakly acidic theophylline and phenobarbital and good separation between the three drugs at various pH values, ephedrine showed small, broad, and unsymmetrical peaks. However, the mobile phase of methanol–0.007 $M$ $KH_2PO_4$ (pH 2.3, 37:63) produced a sharp and symmetrical ephedrine peak.

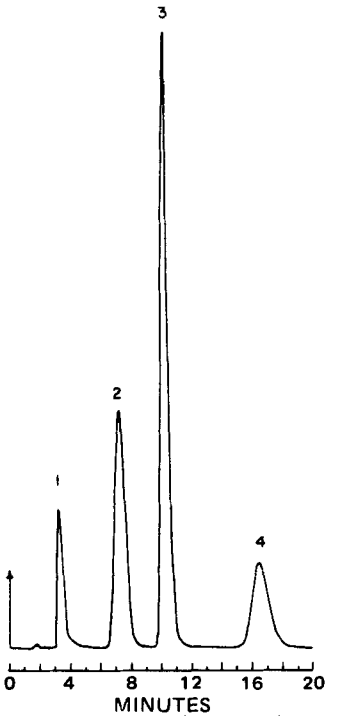

**Figure 1**—*Chromatogram of a mixture of ephedrine hydrochloride (1), theophylline (2), salicylamide (3), and phenobarbital (4) in methanol at 2.0 aufs.*

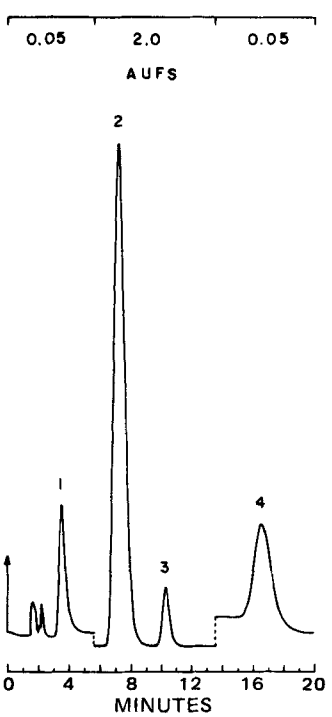

**Figure 2**—*Chromatogram of a commercial tablet. Key: 1, ephedrine hydrochloride; 2, theophylline; 3, salicylamide (internal standard); and 4, phenobarbital.*

The proposed HPLC method simultaneously assays the three drugs; the tablet sample is dissolved in methanol, and this solution is injected into the chromatograph in the presence of salicylamide as the internal standard. The peaks of the four compounds were well resolved (Fig. 1), although it was necessary to change the attenuation of the detector during the run due to the relatively lower ephedrine hydrochloride and phenobarbital concentrations. Under the experimental conditions, the retention times were: ephedrine hydrochloride, ~3.3 min; theophylline, ~7.5 min; salicylamide, ~10.5 min; and phenobarbital, ~17 min. The average height equivalent to a theoretical plate ($\pm SD$) of the column ranged from 1.47 ± 0.05 mm for ephedrine hydrochloride, to 0.80 ± 0.03 mm for theophylline, to 0.34 ± 0.02 mm for phenobarbital ($n$ = 10).

Quantitation was based on the drug–internal standard peak area ratio. With these ratios, the linearity between the detector response at 254 nm and amount of drug injected was established for the three drugs. Linearity was obtained between 20.9 and 83.5 μg of theophylline, 4 and 15.9 μg of ephedrine hydrochloride, and 1.3 and 5.1 μg of phenobarbital. The working amount was 41.6 μg of theophylline, 7.7 μg of ephedrine hydrochloride, and 2.6 μg of phenobarbital. The regression equations ($\pm SD$, $n$ = 3) for the drug–internal standard peak area ratio ($A$) and amount of drug injected ($B$, expressed in milligrams) were $A = (221.29 \pm 2.09)B + (0.90 \pm 0.11)$ for theophylline, $A = (5.24 \pm 0.13)B + (0.003 \pm 0.001)$ for ephedrine hydrochloride, and $A = (29.29 \pm 0.54)B - (0.000 \pm 0.002)$ for phenobarbital. The correlation coefficients ($\pm SD$, $n$ = 3) were 0.9987 ± 0.0009, 0.9997 ± 0.0004, and 0.9997 ± 0.0001 for theophylline, ephedrine hydrochloride, and phenobarbital, respectively.

A tablet mixture containing the same amounts of theophylline, ephedrine hydrochloride, and phenobarbital as in the commercial tablet was prepared. When the tablet placebo[13] was subjected to the assay, a small peak appeared on the chromatogram (retention time of ~2 min), which could be attributed to one or more ingredients in the placebo. No peaks were observed in the region of the peaks of salicylamide and the three active ingredients. The recovery data from the synthetic tablets are presented in Table I. The overall recoveries ($\pm SD$) from three synthetic tablet mixtures were 99.8 ± 1.3% for theophylline, 100.2 ± 0.6% for ephedrine hydrochloride, and 99.4 ± 0.7% for phenobarbital.

For comparison, the synthetic tablets also were analyzed by the compendial method. Except for theophylline, the recoveries for ephedrine hydrochloride and phenobarbital were consistently higher (Table I). The compendial overall recoveries ($\pm SD$, $n$ = 3) were 100.8 ± 0.7%, 107.8 ±

[13] The composition of the tablet placebo was: cornstarch, 52.66%; confectioners sugar, 38.89%; dextrose, 6.78%; sodium bisulfite, 0.15%; and magnesium stearate, 1.52%.

0.7%, and 108.6 ± 2.2% for theophylline, ephedrine hydrochloride, and phenobarbital, respectively.

The HPLC method was applied to the assay of commercial tablets (Table II). Again, the compendial results for ephedrine hydrochloride and phenobarbital were higher than those obtained by the proposed HPLC method. By coincidence, the theophylline content in the three commercial tablet samples investigated was low; the values were around the minimum limit of the compendial potency requirement range of 90.0–110.0% of the label claim. Figure 2 shows a typical chromatogram of the assay solution from commercial tablets.

The HPLC method is more accurate and precise and considerably less time consuming than the compendial method. The wide detector response range between theophylline and phenobarbital was due to the large difference in concentration and posed no problems. The change in the detector attenuation during the chromatographic run did not affect the results. The wide variation in polarity, which necessitated the prior separation of ephedrine in the GLC methods (4, 5), presented no problems under the proposed experimental conditions. The method also is applicable to the assay of individual tablets since the procedure is based on the quantities of drugs present in one tablet.

# Immunological Studies of Poisonous Anacardiaceae: Production of Tolerance in Guinea Pigs Using 3-*n*-Pentadecylcatechol-"Modified" Autologous Blood Cells

**EDNA S. WATSON ˣ, JAMES C. MURPHY, PHILIP W. WIRTH, MAHMOUD A. ElSOHLY, and PAUL SKIERKOWSKI**

Received July 7, 1980, from the *Research Institute of Pharmaceutical Sciences, School of Pharmacy, University of Mississippi, University, MS 38677.* Accepted for publication December 15, 1980.

**Abstract** □ The development of contact sensitivity to poison ivy urushiol in guinea pigs was prevented by intravenous injection of 3-*n*-pentadecylcatechol (I) coupled to autologous blood cells. Hartley, linebred, guinea pigs were treated with pentadecylcatechol-"modified" blood cells or sham-treated blood cells 2 weeks prior to attempted topical sensitization with I. Skin testing of all guinea pigs with 3-, 1-, and 0.3-μg doses of I applied in 5 μl of acetone to abdominal skin sites was begun 2 weeks after attempted sensitization and repeated at 2- or 4-week intervals thereafter for 6 months or until study termination. Profound tolerance to I was observed at all skin testing intervals in the group receiving haptenated red cells and did not weaken substantially with time. Contact sensitivity to I in control animals, however, waned with time; the study was terminated at 6 months because of the low sensitivity level of the control animals at that period. Complete or partial tolerance was induced in ~80% of the treated animals. The immune tolerance obtained by the single injection of pentadecylcatechol-associated red blood cells was of long duration and urushiol specific. This treatment also conferred tolerance to three unsaturated congeners of I. The allergenic potencies of the pentadecylcatechols declined with increasing saturation of the alkyl side chain. Binding studies using tritiated pentadecylcatechol showed that 81% of the activity incorporated into the red cell was membrane associated and that 19% was cell sap associated.

**Keyphrases** □ Urushiol—production of tolerance using 3-*n*-pentadecylcatechol with autologous blood cells, guinea pigs □ Poison ivy—production of tolerance to urushiol using 3-*n*-pentadecylcatechol with autologous blood cells, guinea pigs □ 3-*n*-Pentadecylcatechol—production of tolerance to urushiol, guinea pigs □ Immunology—production of tolerance to urushiol using 3-*n*-pentadecylcatechol, guinea pigs

Poison ivy (*Toxicodendron radicans*), poison oak (*T. diversilobum* and *T. quercifolium*), and poison sumac (*T. vernix*) are the main causes of contact dermatitis in the United States. One or more of these species is present in almost every state in the continental United States. These plants are so prevalent and insidious that ~80% of the U.S. population is allergic to them and 50% are clinically sensitive, *i.e.*, react to 2 μg of urushiol or less (1).

## BACKGROUND

The dermatitogenic principles contained in the resin of these plants are a group of chemically related catechols, commonly referred to as urushiols, differing mainly in the length and degree of unsaturation of the 3-*n*-alk(en)yl side chain. Poison ivy urushiol was shown to be mainly (>95%) a mixture of 3-*n*-pentadec(en)ylcatechols with zero, one, two, or three double bonds in the $C_{15}$ side chain (2–7). Poison oak urushiol, however, consists mainly (>98%) of the $C_{17}$ homologs (2, 3, 6). A small percentage of the $C_{15}$ congeners was found in poison oak urushiol, and a small percentage of the $C_{17}$ homologs was found in poison ivy components (2, 3, 6). The analysis and identification of poison sumac urushiol are incomplete.

Contact of these catechols with the skin of susceptible individuals results in sensitization to all urushiols of the plant family Anacardiaceae (8–10). Once sensitivity is developed, it is difficult, if not impossible, to eliminate. Hyposensitization by administration of plant extracts is not regularly obtained. It requires large doses and months or years to be produced, and sensitivity is rapidly regained upon cessation of treatment (10, 11). The albino guinea pig is the animal of choice for studying sensitivity to these allergens (12). Tolerance to poison ivy was reported to be produced in guinea pigs by subcutaneous injection of pentadecylcatechol (I) in mineral oil or by oral administration of large doses of I prior to attempted sensitization (13). However, since urushiols and I itself are potent primary irritants and skin sensitizers, their use for producing tolerance in nonsensitive humans is heavily compromised.

Recently, a series of ring-substituted derivatives of I was studied for potential use in the production of immune tolerance to contact sensitivity in guinea pigs (14, 15). Some 6-substituted derivatives were reported to

produce tolerance to I and to have low sensitizing and skin irritation potential (14).

Recent studies showed that sensitization to contact sensitizers by the cutaneous route requires presentation of the contact allergen to the immune system by Langerhans cells present in the skin (16). When initial exposure is oral or parenteral by routes other than topical, immune tolerance to the sensitizer usually develops (14, 17, 18).

The discovery that intravenous injection of some skin sensitizers or closely related chemicals would prevent subsequent sensitization to the sensitizer suggested that the resulting tolerance may be mediated by coupling of the hapten with some blood components (19). Subsequent studies showed that membrane-coupled antigen (haptenated spleen, red, lymph node, thymic, or peritoneal exudate cells) is the tolerogenic form (20, 21).

The present report describes the induction of tolerance to poison ivy urushiol by intravenous injection of pentadecylcatechol-associated autologous red blood cells 2 weeks prior to attempted contact sensitization with I. Tolerance to the mono-, di-, and triolefinic congeners of I also was produced by this treatment. Tolerance induced by pentadecylcatechol-associated red cells was specific for poison ivy urushiol and not due to a general lack of immunocompetence of the tolerized animals. Radioisotopic studies using tritiated pentadecylcatechol as tracer showed that the majority of cell-bound pentadecylcatechol (81%) was associated with the red cell membrane and that the remainder was associated with the soluble cell sap.

## EXPERIMENTAL

**Animals**—Female, Camm-Hartley[1], line-bred guinea pigs, 450–500 g, were used. Guinea pig food[2] and water supplemented with ascorbic acid were provided *ad libitum*.

**Preparation of Pentadecylcatechol**—Poison ivy urushiol purified as in a previous study (3) was reduced by catalytic hydrogenation, and the resulting pentadecylcatechol was purified by passage over a dry silica gel 60 (2) column with chloroform as the eluting solvent. Fractions were collected and tested for I using 1% alcoholic ferric chloride. Fractions containing I were combined, and the solvent was evaporated. The resulting residue was chromatographed on a MN-polyamide SC 6[3] column (particle size <0.07 mm) with 90% ethanol–water as the eluting solvent. Fractions containing I were combined. The solvent was evaporated, and the residue was crystallized from hexane to give colorless needle crystals of I, mp 58–59°. The identity of I was determined by GLC and GC–mass spectrometry.

**Preparation of Poison Ivy Urushiol Congeners**—The mono-, di-, and triolefinic components of poison ivy urushiol were isolated from purified poison ivy extract by converting the urushiol to its acetate derivative with acetic anhydride and pyridine. Urushiol acetate was passed over a silica gel G column impregnated with 5% $AgNO_3$, using 1% methanol in chloroform as the solvent system. The polarity of the eluting solvent was increased gradually to 4% methanol in chloroform; fractions containing the mono-, di-, or triolefinic congener acetates were pooled based on their TLC similarities in silver nitrate-impregnated silica gel plates. Each olefinic acetate was converted to the corresponding allergenically active congener by hydrolysis with sodium carbonate in dioxane–water solution (4:1). The reaction mixture was neutralized, and the free catechols were ether extracted. The identity and purity of the olefinic congeners were determined by GLC and GC–mass spectral analysis of the trimethylsilyl derivatives (22).

**Table II—Method for Calculation of Degree of Delayed-Type Hypersensitivity**

| | Erythema and Edema Scores | | | | | |
|---|---|---|---|---|---|---|
| | 24 hr | | 48 hr | | 72 hr | |

| 01 | 0 | 0 | 2 | 1 | 2 | 0 |
| 02 | 1 | 0 | 3 | 2 | 3 | 1 |
| 03 | 0 | 0 | 0 | 0 | 0 | 0 |
| 04 | 2 | 2 | 4 | 4 | 4 | 3 |
| Average (number of responders = 3) | 1.0 | 0.6 | 3 | 2.3 | 3 | 1.3 |
| Erythema and edema sum | 1.6 | | 5.3 | | 4.3 | |
| *Degree of delayed-type hypersensitivity = 4.4* | | | | | | |

**Tritiated Pentadecylcatechol**—Fifty milligrams of I containing 50 μg of the triolefinic congener, 3-*n*-pentadeca-8,11,14-trienylcatechol, was tritium reduced[4]. The specific activity was 10.6 mCi/mg.

**Pentadecylcatechol Solutions**—Solutions used for red cell modification consisted of 2 mg of I/ml of propylene glycol. Sensitizing solutions of I were prepared in acetone at a concentration of 1 mg/0.15 ml. All skin test solutions were prepared in acetone to contain 3, 1, or 0.3 μg of I/5 μl, except for the olefinic congeners which were prepared in acetone at 3 μg/5 μl. All solutions were analyzed for purity prior to use.

**Preparation and Injection of Pentadecylcatechol-"Modified" and Sham-Treated Red Blood Cells**—Guinea pigs were anesthetized with ether, and a 3-ml blood sample was withdrawn from each animal by cardiac puncture into heparinized syringes. To remove serum proteins, the blood cells were washed three successive times with 10-ml volumes of normal saline followed by 600×*g* centrifugation. The washed, packed red cells were resuspended in 40 ml of normal saline. Propylene glycol (0.5 ml) was added to the control cell suspensions, and 1 mg of I in 0.5 ml of propylene glycol was added to the I-treated cell suspensions.

The cell suspensions were mixed by inversion and incubated 1 hr at 37°. Cells were removed from suspension by centrifugation and washed three times with normal saline to remove unbound I. After washing, the hapten-modified or sham-treated red cells were resuspended to 3 ml with saline and injected into the marginal ear vein of the animal of cell origin. Guinea pigs were anesthetized intramuscularly with 50 mg of ketamine[5]/kg and 0.5 mg of chlorpromazine[6]/kg prior to injection.

**Sensitization**—Sensitization of all animals to I was attempted 2 weeks after haptenated or sham-treated red cell injection by topical application of 1 mg of I to the dorsal neck skin of ~5 $cm^2$. Animals were sensitized to dinitrochlorobenzene[7] by applying 2 μl of a 50% acetone solution of dinitrochlorobenzene to the dorsal surface of the left ear.

**Skin Testing**—Hair was removed from the abdominal skin with small animal clippers[8]. Test sites, ~1.5 × 1.5 cm, were delineated with a felt-tip pen[9], and 5 μl of a test solution or vehicle was dropped from a syringe[10] onto the skin within the sites. Sites not visibly healed from previous testing were not used for retesting. The test sites were observed and scored for presence and intensity of erythema and edema at 24, 48, and 72 hr after testing, using the scoring system of Draize *et al.* (23) (Table I). To compare the intensity of the inflammation of the responding sites of treated and control animals, the degree of delayed-type hypersensitivity for each group to the individual test doses was calculated. The erythema scores of the responding animals in each group were summed and divided by the number of animals in the group responding at 24, 48, and 72 hr. The edema scores of each group were averaged similarly. The averaged erythema and edema scores were added to obtain a 24-, 48-, and 72-hr value. The final degree of delayed-type hypersensitivity for each group was obtained by averaging the 24-, 48-, and 72-hr summed values as in Table II. The score of 8 is the maximal degree of delayed-type hy-

persensitivity attainable. To skin test for dinitrochlorobenzene sensitivity, a drop of 0.5% dinitrochlorobenzene in olive oil was inuncted into the flank with a glass rod; the sites were observed for presence of erythema at 24 hr after testing.

**Data Analysis**—Differences in the number of experimental and control animals presenting erythema responses to pentadecylcatechol were analyzed using $\chi^2$ statistics. The data for each test period were arranged in a 2 × 2, treatment by response, contingency table. A null hypothesis of equal proportionality was tested using one degree of freedom.

## RESULTS AND DISCUSSION

Red blood cells were either pentadecylcatechol modified or sham treated *in vitro* as described and injected intravenously into the guinea pig of cell origin 2 weeks prior to attempted sensitization with I. Groups of animals given haptenated or sham-treated red cells received identical treatment throughout the study. Pentadecylcatechol-modified red cell-induced tolerance was duplicated in five separate experiments, using a total of 55 treated and 40 control animals, with similar results. Data from two of these experiments were selected for this paper.

**Induction of Tolerance to I with Pentadecylcatechol-Modified Red Cells**—Twenty-four naive guinea pigs were injected with autologous pentadecylcatechol-modified red cells, and a similar control group was given autologous sham-treated red cells intravenously. Sensitization of both groups to I was attempted 2 weeks after treatment. A third group of 10 guinea pigs (negative controls) was not pretreated or sensitized. Two weeks after attempted sensitization and at 2- or 4-week intervals thereafter until the conclusion of the study, all animals were skin tested simultaneously with 3, 1, and 0.3 μg of I and with acetone. Test sites not visibly healed were not used. Since no erythema or edema was observed on any acetone test site, the vehicle control data were omitted.

To represent the skin test responses of each group concisely, the percentage of the animals in each group presenting erythema on one or more of the three observation periods (24, 48, and 72 hr) to the three test doses is shown in Table III. Injection of hapten–red cell conjugates 2 weeks prior to attempted sensitization to I produced a high level of tolerance to skin test doses of I that persisted for 20 weeks. The frequency of reactivity of the control group to the 3 μg of I ranged from 70 to 100% throughout the study, while the percentage responding in the haptenated red cell-treated group ranged from 21 to 33%. The reactivity of the control group to 1 μg of I ranged from 63 to 83%, whereas 0–17% of the group treated with haptenated red cells were sensitive to this test dose. None of the treated animals ever reacted to 0.3 μg of I at any time during the study, while the sensitivity of the control group to this dose ranged from 4 to 46%. Tolerance to I did not appear to wane with time but was partially broken by the second attempt at sensitization after the 20th week. However, the sensitivity of the controls tended to decrease slowly after the 8-week test period and was not strengthened by the second sensitizing dose.

The sensitivity of the pentadecylcatechol-modified red cell-treated animals ranged from complete tolerance to moderate sensitivity, whereas the control group responses were moderate to extreme. The tolerance of seven of the treated animals was complete in that they never responded to any test dose of I during the entire study. Six of the treated animals responded only once during the study, and these responses were +1 erythema to 3 μg of I. Four treated animals responded on two skin test periods to 3 μg of I; these responses were mainly +1 erythema, but an occasional +2 erythema was observed. Two additional treated animals responded to 3 μg of I on four or five of the nine test periods; most of these responses were +2 erythema with rarely a +1 edema. The remaining five treated animals (20%) were not perceivably tolerant and responded to 3 μg of I on nearly every occasion. These animals also responded occasionally to 1 μg of I.

Overall, the data indicate that 80% of the treated group was tolerant to I from the 20 weeks following attempted sensitization to I. Testing of 10 naive guinea pigs with the three test solutions resulted in primary irritancy responses in two out of the 10 animals to 3 μg of I. Since this dose was found by others to be irritating in ~50% of naive animals tested, the occasional responses to this dose in the treated animals may represent false positive responses. Only two animals in the control group failed to respond to doses of <3 μg.

To compare the differences in sensitivity of the treated and control animals, the degree of delayed-type hypersensitivity for each group was calculated (Table IV). The sensitivity of the responding animals in the control group gradually declined after the 6-week test and was not increased by a second sensitizing dose at Week 20. The sensitivity of the responding animals in the treated group, on the other hand, gradually increased until the 14th week, and a second attempt at sensitization did not increase their sensitivity.

Statistical analysis of the data showed that at the 3-μg test level, significant differences existed between the treated and control groups

[a] Weeks after attempted sensitization. [b] Not tested.

throughout the entire 24 weeks. At the 1-μg dose level, significant differences were observed over the first 14 weeks. Loss of significance at the 20 and 24th weeks to the 1-μg test level apparently resulted from a loss of sensitivity in the control group rather than from a loss of tolerance in the experimental group. At the 0.3-μg dose level, the differences in tolerant and control groups were not consistently significant due to the paucity of responses in the control group.

To show that tolerance to I was caused by haptenated red cell treatment and not by lack of immunocompetence, all treated animals were given sensitizing doses of dinitrochlorobenzene after the initial skin test with I. The control guinea pigs were not given sensitizing doses and served as negative dinitrochlorobenzene controls. None of the control group responded to dinitrochlorobenzene whereas all of the treated tolerant animals developed sensitivity to it. Therefore, tolerance induced by pentadecylcatechol-modified red cell injection was immunologically specific.

**Specificity of Pentadecylcatechol-Induced Sensitivity and Pentadecylcatechol-Modified Red Cell-Induced Tolerance**—A group of 11 guinea pigs was given tolerizing injections of haptenated red cells, and a control group of eight was given sham-treated red cells. Sensitization of both groups to I was attempted 2 weeks later. Both groups were skin tested with 3-, 1-, and 0.3-μg doses of I and with vehicle at 2 and 4 weeks after attempted sensitization. At 6 and 8 weeks after attempted sensitization, each group was tested with 3 μg each of I and its mono-, di-, and triolefinic congeners. The frequency of erythema responses of these animals to the skin test doses are shown in Table V. Animals were scored as reactive if erythema was observed at least once during the 72-hr observation period after test substance application.

The degree of delayed-type hypersensitivity of treated and control groups to I and its congeners was calculated as previously described and is shown in Table VI. All control animals developed sensitivity to I and its three congeners, but the skin reactions to the different congeners were not of equal severity. The degree of delayed-type hypersensitivity produced by triolefin was two to three times that produced by I. The degree of delayed-type hypersensitivity decreased with increased saturation of the side chain. The order of allergenic potency was triolefin > diolefin > monoolefin > I. The haptenated red cell-treated pigs were highly tolerant to I and its congeners throughout the 8 weeks of study. The differences in sensitivity of the treated and control groups were highly significant ($p < 0.01$ or $<0.001$) at the 3-μg level of I and its congeners throughout the 8 weeks. Differences were not significant at the 1- and 0.3-μg doses of I because of lack of a high degree of sensitivity of control animals. Over 80% of the treated animals in this experiment were tolerant, which confirms the results of the previous study. Again, two animals in the treated group (15%) did not develop tolerance.

**Table VII—Determination of Radioactivity Associated with Intact Tritiated Pentadecylcatechol Red Cell Conjugates, Red Cell Membrane Ghosts, and Red Cell Sap[a]**

| | Tritium, μCi | | Percent of Total Activity | | Percent of Incorporated Activity | |
|---|---|---|---|---|---|---|
| Unincorporated (incubation supernate) | 3.29 | | 47.0 | | | |
| First wash (supernate) | 0.28 | | 4.0 | | | |
| Second wash (supernate) | 0.15 | | 2.5 | | | |
| Third wash (supernate) | 0.09 | | 1.9 | | | |
| Total unincorporated | | 3.81 | | 55.4 | | |
| Incorporated | | | | | | |
| Lysate of whole cells | 0.24 | | 3.4 | | 12.7 | |
| Wash of ghosts | 0.12 | | 1.7 | | 6.3 | |
| Total cell sap | | 0.36 | | 5.1 | | 19.0 |
| Red cell ghost | | 1.53 | | 21.95 | | 80.9 |
| Total recovered activity | | 5.70 | | 82.45 | | 99.9 |

[a] Total activity added to suspension was 7 μCi.

**Determination of Membrane-Associated Pentadecylcatechol**—Tritium-labeled pentadecylcatechol red cell conjugates were prepared to determine the percentage of I that became bound to the red cell and the localization of I (membrane associated or cell sap associated). Cell suspensions were incubated with 1 mg of I (7 μCi of tritiated pentadecylcatechol). After removal of the incubation supernate (unincorporated activity) followed by three successive washes, aliquots of the conjugates were used to determine the radioactivity incorporated into the intact cells or they were lysed with hypotonic solution, and the activity associated with the red cell membrane ghosts and cell sap was determined.

The determinations were made on four separate cell suspensions with essentially the same results. The results of a typical assay are shown in Table VII. Twenty-seven percent of the activity (equivalent to 270 μg of I) became associated with the red cell. Fifty-five percent of the activity was in the incubation mixture, and the remaining 17.5% was believed to have been retained in the incubation vessel. Approximately 81% of the red cell-incorporated activity (equivalent to 219 μg of I) was associated

with the red cell membrane. The remaining 19% was associated with the red cell sap and represented ~51 μg of I.

It was reported that membrane-associated urushiol or I (red blood cell or lymphocyte membrane associated) will induce blastogenesis of peripheral blood lymphocytes *in vitro* (24). Urushiol was shown to be highly soluble in, but not covalently bound to, the cell membrane since the urushiol was not removed from the membrane with aqueous washes but was removable with dimethyl sulfoxide. Haptenated membranes were shown to induce contact sensitivity to picryl chloride *in vitro* when administered subcutaneously (25), while intravenous administration of the haptenated membranes induced specific immunological tolerance. Thus, the administration route of the membrane-associated hapten appears to be important in determining whether contact sensitivity or tolerance will result.

Since haptenated membranes can induce hapten-specific tolerance as well as contact sensitivity, it is unlikely that the haptenated membrane is the tolerogen and sensitizer. The membrane probably serves as a physiological vehicle that carries the lipophilic substance until the immune system intercepts the hapten. Whether contact sensitivity or tolerance results probably depends on the prevalence of the interceptor cell type (macrophage, Langerhans cell, T-lymphocyte, B-lymphocyte) that initially reacts with the hapten. The route of hapten administration likely would favor a higher incidence of interaction of the hapten with one of these cell types.

# Laser Raman Investigation of Pharmaceutical Solids: Griseofulvin and Its Solvates

**BARBARA A. BOLTON and PARAS N. PRASAD** ˣ

Received July 24, 1980, from the *Department of Chemistry, State University of New York at Buffalo, Buffalo, NY 14214.* Accepted for publication December 16, 1980.

**Abstract** □ Laser Raman spectroscopy is convenient for characterizing griseofulvin solvates and investigating solute–solvent interactions and desolvation. The spectra of both lattice and intramolecular vibrations were monitored. A new solvate of griseofulvin with bromoform was characterized by Raman spectroscopy. A temperature-dependence study of the solvates of griseofulvin with chloroform, bromoform, and benzene revealed no phase transformation or chemical change. In the benzene solvate, only weak Van der Waals interactions existed between the solute and solvent. However, in solvates with chloroform and bromoform, a weak hydrogen bonding existed between the proton of the solvent and the C=O group of the benzofuran ring in griseofulvin. Examination of desolvation in these solvates revealed that the crystal did not go through any intermediate structure during desolvation. As the solvent molecule escaped, the lattice reverted to the structure of unsolvated griseofulvin.

**Keyphrases** □ Griseofulvin—unsolvated and solvate forms, laser Raman spectroscopy, physicochemical stability, desolvation □ Spectroscopy, laser Raman—investigation of griseofulvin and its solvates, physicochemical stability, desolvation □ Pharmaceutical solids, polymorphic—griseofulvin and its solvates, investigation using laser Raman spectroscopy, physicochemical stability, desolvation □ Antifungal agents—griseofulvin and its solvates, investigation with laser Raman spectroscopy, physicochemical stability, desolvation

Many drugs in the solid state exhibit polymorphism, in which the same compound exists in several crystalline modifications at the same temperature (1, 2). Interest in polymorphism stems from the fact that different crystalline modifications of the same drug have different physical and, in some cases, chemical properties that may be a serious consideration in the manufacture of the dosage form (1, 2). For example, differences in the solubility of polymorphic forms can cause serious bioavailability problems.

with the red cell membrane. The remaining 19% was associated with the red cell sap and represented ~51 μg of I.

It was reported that membrane-associated urushiol or I (red blood cell or lymphocyte membrane associated) will induce blastogenesis of peripheral blood lymphocytes *in vitro* (24). Urushiol was shown to be highly soluble in, but not covalently bound to, the cell membrane since the urushiol was not removed from the membrane with aqueous washes but was removable with dimethyl sulfoxide. Haptenated membranes were shown to induce contact sensitivity to picryl chloride *in vitro* when administered subcutaneously (25), while intravenous administration of the haptenated membranes induced specific immunological tolerance. Thus, the administration route of the membrane-associated hapten appears to be important in determining whether contact sensitivity or tolerance will result.

Since haptenated membranes can induce hapten-specific tolerance as well as contact sensitivity, it is unlikely that the haptenated membrane is the tolerogen and sensitizer. The membrane probably serves as a physiological vehicle that carries the lipophilic substance until the immune system intercepts the hapten. Whether contact sensitivity or tolerance results probably depends on the prevalence of the interceptor cell type (macrophage, Langerhans cell, T-lymphocyte, B-lymphocyte) that initially reacts with the hapten. The route of hapten administration likely would favor a higher incidence of interaction of the hapten with one of these cell types.

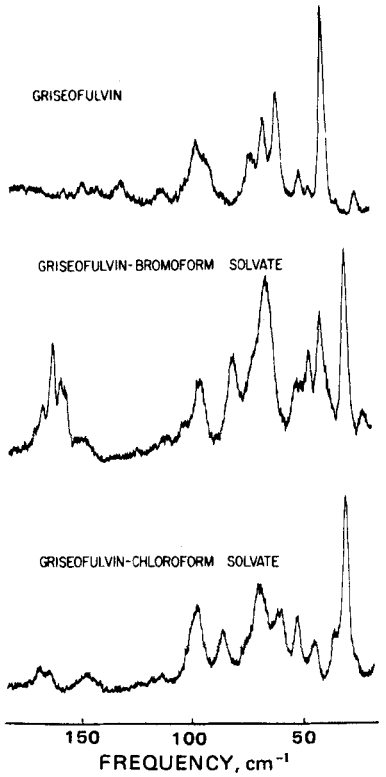

**Figure 1**—*Raman spectra of the lattice vibrations of the unsolvated griseofulvin and the griseofulvin solvates with chloroform and bromoform at 135°K.*

## BACKGROUND

The present study examined polymorphism exhibited by griseofulvin, which is used in the treatment of fungus infection (3). This compound in the solid state exists in the unsolvated form, and its solvates with chloroform (4, 5) and benzene (6) have been studied by various techniques. Reducing the particle size of griseofulvin enhances its GI tract absorption (3, 4). Particle-size reduction can be obtained by desolvating the solvates of griseofulvin. Thus, study of the stability of the solvates, the solute–solvent interaction, and the desolvation process is of great importance.

Normally, the methods used to characterize polymorphs are X-ray diffraction, optical and electron microscopy, thermal methods (differential thermal analysis, differential scanning calorimetry, and thermal gravimetric analysis), and IR spectroscopy of the internal vibrations (1, 2). Recently, Raman spectroscopy of lattice vibrations was introduced to study the polymorphism of pharmaceutical solids (7). The lattice vibrations (also called phonons) correspond to librations and translations of the entire molecule in the lattice. These vibrations are of low frequency (10–150 $cm^{-1}$) and are easily observed in the Raman spectra. The lattice vibrations are characteristic of the crystal structure and interactions. Thus, the Raman spectra of the lattice vibrations can be used to characterize the solid states of a drug and to study the stabilities of various crystalline modifications (8–10).

The Raman spectra of intramolecular vibrations also can be obtained in the same experimental arrangement. Intramolecular vibrations can be used to study both the specific nature of the solute–solvent interaction and the chemical stability of the various forms. The present study was based on the principle that a physical transformation in the solid state shows a dominant effect on the phonon spectra but only a small effect on intramolecular vibrations. On the other hand, a chemical change leads to a large change in both the phonon spectra and the spectra of intramolecular vibrations.

Laser Raman spectroscopy was used for the following investigations on griseofulvin: (*a*) the characterization and identification of unsolvated griseofulvin and its various solvates, (*b*) the physical and chemical stability of these solvates with changes of external conditions such as temperature, (*c*) the effect of chemical perturbation (*e.g.*, change of a substituent group) on the crystal structure, (*d*) the nature of solute–solvent interactions in a solvate, and (*e*) the process of solvate desolvation.

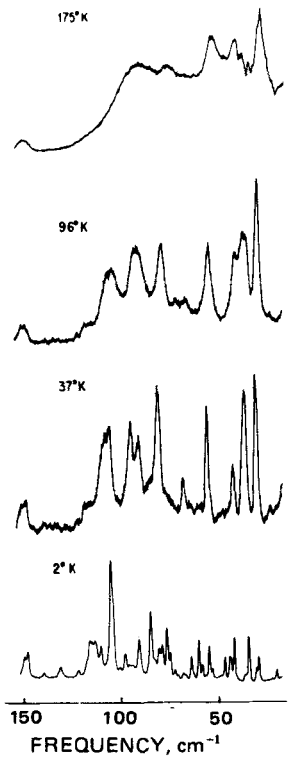

**Figure 2**—*Lattice vibration Raman spectra of the benzene solvate at several temperatures.*

## EXPERIMENTAL

The griseofulvin[1] solvates were grown from benzene (protonated and deuterated), chloroform (protonated and deuterated), and bromoform[2]. The chloroform and bromoform solvates were readily formed by slow solvent evaporation and were air stable for days. To obtain the benzene solvates, between 0.06 and 0.08 g of griseofulvin was added to 5 ml (±5%) of benzene. While the 5-ml volume was maintained, the solution was heated to boiling (~75°). When all of the griseofulvin was dissolved, the solution was transferred to a warmed beaker and checked for any visible matter. This hot solution was cooled rapidly in an ice bath to 10–15°. When this temperature was maintained for 24 hr, only the benzene solvate of griseofulvin was formed. This solvate was stable in air for only a few hours.

Raman spectra were obtained using a double monochromator[3] and the 5145-Å line of a coherent radiation argon-ion laser. Most samples were studied below room temperature because of the improved spectral resolution. Spectra were taken with the sample in liquid nitrogen or by cooling the sample with a flow of nitrogen vapor that provided an effective bath of ~125°K or higher. To obtain spectra below the liquid nitrogen temperature, crystals were cooled in a cryostat[4] using a flow of helium vapor. The spectra of the benzene solvates were taken at 2°K. To obtain this temperature, a vacuum was pulled on liquid helium, forming a superfluid state. The temperature was measured with a chromel-constantan thermocouple referenced at an ice bath. Direct-current detection was used. The band positions were measured relative to the laser line and were accurate to ±1.0 $cm^{-1}$.

## RESULTS AND DISCUSSION

The following discussion emphasizes the aspects rather than the specific system investigated.

**Characterization of Various Solvates**—Raman spectra of the phonon region provide unambiguous characterization of the various crystalline modifications of a given substance. For this purpose, the observed phonon spectral patterns were used. The spectral pattern is defined by the number of peaks observed and their frequencies and relative intensities. Although relative intensities may show some variations de-

[1] McNeil Laboratories.
[2] Aldrich Chemical Co.
[3] Spex model 14018.
[4] 10 DT Janis Research Supervaritemp.

pendent on crystal orientation, use of a polycrystalline or powdered sample helps minimize this problem and provides reproducible spectral patterns that can identify and distinguish between various polymorphs. On the other hand, the internal vibration region (which also can be investigated using IR techniques) generally shows only small shifts in frequencies and only in selected regions.

The results of phonon spectral studies to characterize griseofulvin and its chloroform and benzene solvates were reported previously (7); the present study investigated other solvates. Griseofulvin also was reported to form a solvate with dioxane (6); however, the phonon spectra obtained on crystals grown from dioxane solution were identical to those of unsolvated griseofulvin. Thus, no evidence of solvate formation with dioxane was found.

An attempt was made to form a solvate with bromoform. As shown in Fig. 1, the Raman phonon spectra of the samples obtained from chloroform and bromoform solutions clearly are different from those of the unsolvated griseofulvin. Again, the low temperature (135°K) spectra provided improved resolution of peaks (Fig. 1) and assisted in the comparison. Thus, the crystalline modification obtained from bromoform was different from that of the unsolvated griseofulvin. The presence of the solvent (bromoform) internal vibration in the internal vibration region also confirmed the formation of a solvate between bromoform and griseofulvin. This solvate was never reported previously.

**Temperature Study of Crystalline Forms**—The phonon spectra of griseofulvin and its solvates were studied from room temperature down to liquid helium temperature (2°K). As the temperature was lowered, more structures became resolved due to the reduced linewidth of the peaks, and the phonon frequencies shifted to higher values. Figure 2 shows the spectra at several temperatures for the benzene solvate in the 10–150-$cm^{-1}$ spectral region. In this region the benzene solvate showed nine resolved peaks at 96°K and 33 resolved peaks at 2°K. On the other hand, 12 peaks were observed for the chloroform solvates at 136°K, but only 31 peaks were observed for the same solvate at liquid helium temperature.

Except for the increased number of peaks due to improved resolution, the number of spectral features of each crystalline form remained the same as the temperature was varied; *i.e.*, there was no spectra discontinuity. This result clearly indicates absence of any structural phase transitions or any chemical change for either griseofulvin or any of the solvates studied. A phase transition or a chemical change will clearly reveal itself by a change in the spectral pattern of the phonon region (9, 10).

The reduction in linewidths of the peaks and the shift of frequencies with temperature are general phenomena that arise primarily from the anharmonicity of the lattice (11, 12). The temperature dependence of the phonon frequencies is derived mainly from thermal expansion of the lattice which, in turn, is a consequence of lattice anharmonicity (11). The observed effect clearly indicates a considerable degree of lattice anharmonicity for these crystals. The linewidths of the peaks reflect the contribution from disorders in the lattice as well as from anharmonic phonon–phonon interactions (12). The line broadening derived from disorder can be assumed to be temperature independent, but the broadening due to anharmonic phonon–phonon interactions is highly temperature dependent. Thus, a temperature-dependence study of the linewidth can be used to investigate the presence of disorder in the lattice (12). For griseofulvin and its solvates, the linewidths were highly dependent on temperature. At 2°K, the lines were narrow, indicating highly-ordered lattices.

**Chemical Perturbation of Crystal Structure**—It often becomes necessary to improve a drug by changing a substituent group in the molecular structure. However, since bioavailability is dependent on the crystal structure of the compound, it is helpful to know how the parent compound's crystal structure is affected by chemical substitution. A previous investigation on organic solids suggested that Raman spectroscopy can provide useful information in this area (13, 14). If a small chemical perturbation (changing only a small substituent group in the parent structure) yields a crystal structure that is identical (in space group) to the parent crystal structure, the phonon spectral pattern bears a close correspondence with that of the parent material.

For griseofulvin, this criterion was used to obtain information regarding the crystal structure of the new bromoform solvate. The bromoform solvate can be visualized as being derived from the chloroform solvate by chemical substitution of the chloroform. The phonon spectra of these two solvates at 135°K are compared in Fig. 1. Except for the shifts in phonon frequencies, there appeared to be close correspondence between the phonon peaks in the spectra of the two solvates, suggesting that they have the same crystal structures. The phonon frequencies in the bromoform solvate were lower than those for the chloroform solvate. This shift to lower frequencies was perhaps a result of a larger unit cell required by a larger solvent molecule (bromoform compared to chloroform).

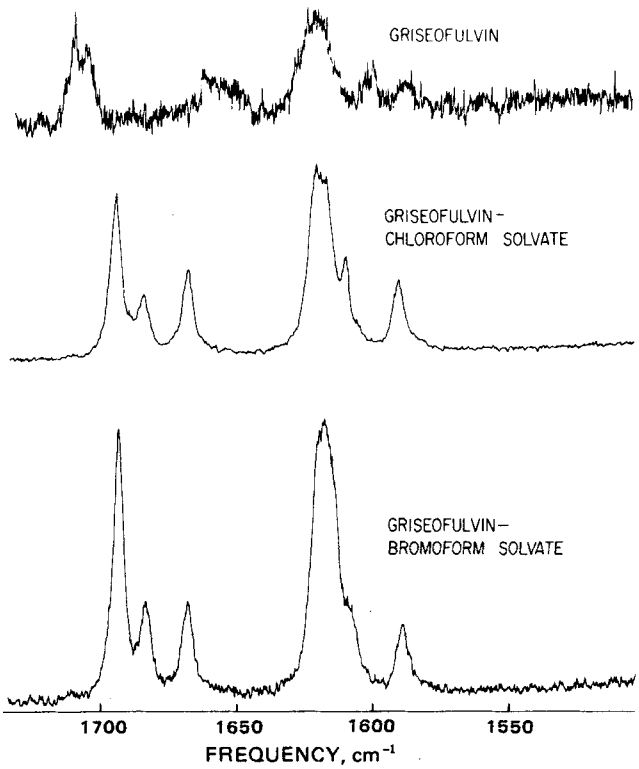

**Figure 3**—*Raman spectra of the chloroform and bromoform solvates obtained for the 1550–1800-$cm^{-1}$ spectral region.*

**Solute–Solvent Interactions**—To investigate the interaction between the griseofulvin molecule and the solvents involved in solvate formation, a comparative study of the internal vibrational frequencies of various functional groups of the drug and the solvent molecule was needed in the solvate as well as in the pure states.

The internal vibrational spectra of the benzene solvate appeared to be essentially a superposition of the spectra of pure griseofulvin and benzene. The frequency shifts of the vibrations of both components were <3 $cm^{-1}$. The solvate spectra contained no additional bands other than those observed for the pure components. Since these shifts were small, the interaction between griseofulvin and benzene was weak and of a Van der Waals type. A manifestation of this weak interaction was the loss of benzene when the griseofulvin–benzene solvate was exposed to the atmosphere. After 24 hr, an unsealed sample exhibited a spectrum identical to that of the unsolvated griseofulvin.

In the 200–1550-$cm^{-1}$ region, the chloroform and bromoform solvates exhibited a behavior similar to that of the benzene solvate. The spectra were essentially a superposition of those of the pure components. Two spectral regions showed changes: 1550–1800 and 2800–3200 $cm^{-1}$. Figure 3 shows that the 1703.5- and 1708.5-$cm^{-1}$ bands of pure griseofulvin shifted to 1684.0 and 1694.5 $cm^{-1}$ in the chloroform solvate. A similar observation was noted for the bromoform solvate where a slightly larger shift occurred. These vibrational frequencies correspond to the C=O stretching modes of the benzofuran ring of griseofulvin.

Table I shows the analysis of the C–H stretching region (2800–3200 $cm^{-1}$) of the bromoform solvate and the chloroform (deuterated and protonated) solvates. Except for the transitions at 2998 $cm^{-1}$, there was a 1:1 correlation between the three solvates. The pure chloroform-*h* solvent transition at 3011.0 $cm^{-1}$ shifted by 13 $cm^{-1}$ to 2998.0 $cm^{-1}$ in the solvate. Pure bromoform solvent transition at 3023.0 $cm^{-1}$ shifted by 24 $cm^{-1}$ to 2999.5 $cm^{-1}$. In both cases, there was a shift of the C–H stretching mode of the solvent in the solvate.

These results indicate a specific interaction between the C–H group of the solvents and the C=O group of griseofulvin and, possibly, a weak hydrogen bonding between H– –O. This result is consistent with the X-ray diffraction work of Cheng and Shefter (15) who also found a short H– –O distance.

This additional interaction tends to make these solvates more stable than the benzene solvate. When exposed to air for several days, the

[a] The following abbreviations are used: s = strong, m = medium, w = weak, vw = very weak, and Br = broad.

griseofulvin–chloroform or bromoform solvate showed no degradation.

**Desolvation**—As a crystalline solvate undergoes desolvation, the solvent molecule makes an exit due to an external perturbation (*e.g.*, rise in temperature) and the lattice can suffer several consequences. Three possibilities define the modes of desolvation:

1. The lattice still exists in the same crystalline form even in the absence of the solvent molecule.
2. Desolvation produces an intermediate structure, which eventually reverts to that of the unsolvated griseofulvin.
3. As the solvent molecule escapes, the lattice immediately (or in an extremely short period) reverts to the structure of the unsolvated griseofulvin.

Phonon spectra were used to investigate desolvation in the chloroform and benzene solvates. A crystal of the stable, deuterated chloroform solvate was washed with ethanol, air dried, and ground to a powder. A small sample of this crystal was heated uniformly with a flow of warm nitrogen vapor at 60°. After each 15-min interval, the sample was removed and cooled to 135°K, and a spectrum of the phonon region was obtained. After 1 hr, the phonon spectra (Fig. 4) appeared to be the superimposed spectra of the chloroform solvate and unsolvated griseofulvin. Additional solvate heating showed that only unsolvated griseofulvin was present. As the solvent diffused out, the solvate lattice collapsed. Since the crystal structure returned to that of unsolvated griseofulvin, the structures of these solvates were not stable without the solvent.

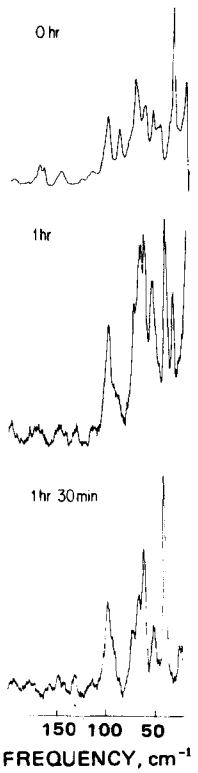

**Figure 4**—*Raman spectra of the lattice vibrations of the deuterated chloroform solvate obtained as a function of the desolvation process.*

Sekiguchi *et al.* (6) studied the desolvation mechanism of the benzene solvate by periodically measuring X-ray powder diffraction patterns. They observed a peak that was not present in the benzene solvate spectrum or in the pure griseofulvin spectrum and concluded that an intermediate structure was formed during desolvation. The benzene solvate desolvation was monitored by placing a single crystal in a focused laser beam, which allowed the monitoring of the phase boundary by periodically obtaining the phonon spectra. As Fig. 4 shows, the desolvation exhibited the appearance of an unsolvated griseofulvin peak (59 $cm^{-1}$), which grew in intensity upon further desolvation. No new peak was observed during desolvation. While the data show no intermediate structure, additional work with single-crystal X-ray crystallography may be necessary to establish unequivocally the presence or absence of an intermediate structure during desolvation.

Laser Raman spectroscopy has a number of advantages and disadvantages. It is convenient and versatile for investigating pharmaceutical solids, and spectra of both lattice vibrations and intramolecular vibrations in the same arrangement can be obtained. The spectra of lattice vibrations provide valuable information on crystalline interactions and can be used to characterize crystalline modifications, the effect of various perturbations on crystal structures, and the desolvation process. The study of intramolecular vibrations is used to study both the specific nature of the solute–solvent interaction and the chemical stability of the various forms.

From an experimental point of view, Raman spectroscopy offers several advantages over other techniques used to study drugs:

1. No special sample preparation is required, so the grinding required for X-ray powder diffraction or the pressing for IR absorption is eliminated.
2. Because the incident laser radiation can be focused into a very small spot, extremely small amounts of material can be used.
3. Raman spectra of lattice vibrations can be obtained easily in a short time.
4. The internal vibration region is examined easily in the same experiment.
5. The temperature of the sample can be controlled accurately during the experiment, allowing thermal studies of the various forms.
6. The use of a coherent, tunable, and monochromatic dye laser permits tuning of the exciting radiation to some electronic transitions. This resonance Raman technique permits work with very low laser light levels and highly colored materials.

On the other hand, Raman spectroscopy has some disadvantages. The Raman effect is highly inefficient and, thus, is more suitable for the study of concentrated species than for a small amount of impurity. In general, only relative intensities of various Raman peaks are measured, and even then the relative intensities do not easily provide quantitative information on the concentrations of various species. Moreover, with colored samples, the excitation wavelength of the laser and the power levels must be chosen carefully so that the sample does not undergo thermal or photochemical decomposition.

In view of these limitations, Raman spectroscopy cannot be used as a substitute for all other techniques. However, when used with discretion, it can be a powerful technique for the investigation of pharmaceutical solids.
