# High-Performance Liquid Chromatographic Analysis of Clorazepate Dipotassium and Monopotassium in Solid Dosage Forms

**L. ELROD, Jr., D. M. SHADA, and V. E. TAYLOR ˣ**

Received October 14, 1980, from the *Analytical Research Department, Abbott Laboratories, North Chicago, IL 60064.* Accepted for publication December 16, 1980.

**Abstract** □ Methodology for the quantitative determination of clorazepate dipotassium and monopotassium in solid dosage forms was developed. Clorazepate was resolved from its degradation products, making the analysis specific and stability indicating. Analytical separation was performed on a octadecylsilylated silica column. Clorazepate was extracted from the dosage forms with 0.04% NaOH and chromatographed with aqueous 0.005 *M* tetra-*n*-butylammonium ion (pH 7.5)–acetonitrile (70:30) as the eluent. The analysis was completed in ~20 min with a precision of <2.4% *RSD*.

**Keyphrases** □ High-performance liquid chromatography—analysis of clorazepate dipotassium and monopotassium in solid dosage forms □ Clorazepate, dipotassium and monopotassium—high-performance liquid chromatographic analysis, solid dosage forms □ Tranquilizers—clorazepate dipotassium and monopotassium, high-performance liquid chromatographic analysis, solid dosage forms

In the past, clorazepate (I) primarily was determined chromatographically as its primary degradation product and major metabolite nordiazepam (II). Clorazepate decarboxylates to give nordiazepam; in aqueous systems (pH 2–11), the transformation is unimolecular with respect to clorazepate. Nordiazepam can undergo further metabolic transformations to oxazepam and the glucuronide in urine (1).

GLC has been used extensively (2–6) for the analysis of clorazepate as nordiazepam in biological fluids. Similarly, nordiazepam has been determined in plasma and urine by high-performance liquid chromatography (HPLC) in both reversed-phase (7–11) and normal-phase (12, 13) chromatographic modes.

Recently, a reversed-phase HPLC system for the qualitative identification of clorazepate in oral dosage forms was reported (14). With aqueous phosphate buffer (pH 8) and methanol (1:2 and 3:4) as the eluent, clorazepate was chromatographed intact on an octadecylsilylated column both with and without tetra-*n*-butylammonium ion (0.005 *M*) as an ion-pairing counterion. This paper reports the quantitation of clorazepate in its dosage forms by a similar procedure used in these laboratories for several years. The procedure has been applied to eight formulations of clorazepate (monopotassium and dipotassium), both capsules and tablets, and is specific and stability indicating.

## EXPERIMENTAL

**Reagents and Chemicals**—Acetonitrile[1], tetra-*n*-butylammonium hydroxide[2], phosphoric acid[3], and sodium hydroxide[4] were used as received. 2,6-Dimethylaniline[5] was converted to the hydrochloride by acidification of a hexane[4] solution of the amine (10% v/v) with concentrated hydrochloric acid[6]. The precipitated amine salt was filtered, washed with hexane, and dried for use as the internal standard. Distilled water was used for all aqueous reagent and mobile phase preparations.

**Apparatus**—The liquid chromatograph consisted of a pump[7], a loop-type injector[8], a variable-wavelength UV detector[9], and a recorder/data handling system[10] for quantitative work. The 30-cm × 4-mm i.d. column contained an octadecylsilylated silica material[11].

**Mobile Phase**—A 0.005 *M* aqueous solution of tetra-*n*-butylammonium ion was prepared from 5.0 ml of tetra-*n*-butylammonium hydroxide in 1 liter of water, and the pH was adjusted[12] to 7.5 with phosphoric acid. The mobile phase was prepared by diluting 300 ml of acetonitrile to 1 liter with 0.005 *M* tetra-*n*-butylammonium-ion solution. The eluent was filtered[13] through a 0.45-μm membrane filter[14], stirred magnetically, and degassed under vacuum.

**Chromatographic Conditions**—The temperature was ambient, and the flow rate was ~1.8 ml/min. The detector sensitivity was set at 0.2 au (230 nm). The injector loop size was 20 μl, and the chart speed was 0.2 cm/min.

**Sample Solvent**—Sodium hydroxide (0.04% w/v) was filtered[13] through a 0.45-μm membrane filter[14].

**Internal Standard**—2,6-Dimethylaniline hydrochloride (30 mg) was dissolved in, and diluted to 100.0 ml with, the sample solvent.

**Reference Standard**—A solution containing 50–60 μg of clorazepate reference standard[15]/ml was prepared by dissolving it in, and diluting appropriately with, the sample solvent. An ultrasonic water bath[16] was employed to aid dissolution. A 5.0-ml portion of this solution and 2.0 ml of the internal standard solution were diluted to 10.0 ml with the sample

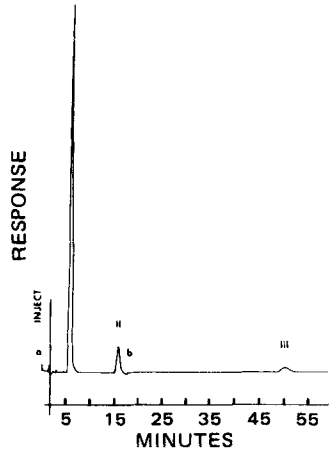

**Figure 1**—*Chromatogram of a mixture of 49.8 μg of clorazepate (I)/ml, 2.25 μg of nordiazepam (II)/ml, and 2.16 μg of 2-amino-5-chlorobenzophenone (III)/ml (a at 2.0 ml/min and b at 3.0 ml/min).*

solvent, giving 25–30 μg of clorazepate/ml and 60 μg of internal standard/ml in the final solution.

**Sample Preparation**—Sample preparations were similar for all dosage forms but varied slightly between capsule and tablet formulations.

**Clorazepate Capsules**—The average capsule fill weight was determined by weighing 20 filled capsules, emptying the contents as completely as possible, and reweighing the emptied shells.

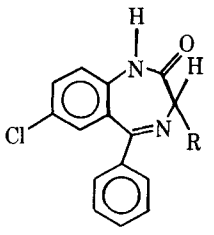
Four capsules then were weighed, the contents were transferred to a 250-ml volumetric flask, and the emptied shells were reweighed to obtain the sample weight. Approximately 200 ml of the sample solvent was added, and the flask was placed in an ultrasonic bath[16] for 5 min. The sample was diluted to volume with the sample solvent and mixed. A portion of the sample then was filtered[17] through a 0.4–0.5-μm membrane filter[18] and diluted according to dose strength with the sample solvent as follows: 3.0–3.75 mg, no dilution; 6.5–7.5 mg, 25.0 ml to 50.0 ml; and 13–15 mg, 25.0 ml to 100.0 ml. A 5.0-ml portion of the last solution and 2.0 ml of the internal standard solution were diluted with the sample solvent to 10.0 ml.

**Clorazepate Tablets**—The number of tablets equivalent to 112.5 mg (for 11.25- and 22.5-mg tablets) or 75 mg (for 3.75-, 7.5-, and 15.0-mg tablets) of clorazepate dipotassium were placed in a 500-ml tall form beaker, and 200.0 ml of the sample solvent was added. The sample then was homogenized[19] at ~6000 rpm for 3.0 min. A portion of the blended solution was filtered[17] through a 0.4–0.5-μm membrane filter[18] and diluted according to dose strength with the sample solvent as follows: 11.25 and 22.5 mg, 5.0 ml to 50.0 ml; and 3.75, 7.5, and 15.0 mg, 15.0 ml to 100.0 ml. A 5.0-ml portion of the last solution and 2.0 ml of the internal standard solution were diluted with the sample solvent to 10.0 ml.

**Analysis and Calculation**—Twenty microliters of both the standard and sample preparations were injected. Normal run time was ~20 min since nordiazepam sometimes can be observed at 14–16 min. Multiple standard preparations were analyzed, and their response ($R_s$) was averaged for calculation purposes:

$$R_s = \left(\frac{A_2}{A_1}\right)_{std}(C) \qquad \text{(Eq. 1)}$$

where $A_1$ is the peak area of clorazepate, $A_2$ is the peak area of the internal standard, and $C$ is the concentration of clorazepate in the standard



I: R = COOK (monopotassium)
I·KOH: R = COOK·KOH (dipotassium)
II: R = H

[19] Polytron homogenizer, Brinkmann Instruments, Westbury, N.Y.

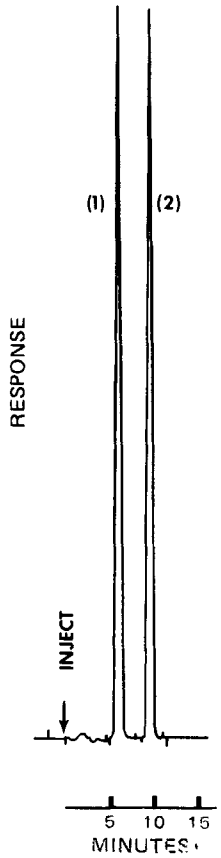

**Figure 2**—*Typical chromatogram of a sample preparation. Key: 1, clorazepate and 2, internal standard.*

(milligrams per milliliter).

For capsules:

$$\frac{\text{mg of clorazepate}}{\text{capsule}} = \left(\frac{A_1}{A_2}\right)_{spl} \times R_s \times 500 \times DF \times \frac{W_1}{W_2} \qquad \text{(Eq. 2)}$$

where $DF$ is the appropriate dilution factor from the procedure and $W_1$ and $W_2$ are the average capsule fill weight and individual sample weight, respectively, in milligrams.

For tablets:

$$\frac{\text{mg of clorazepate}}{\text{tablet}} = \left(\frac{A_1}{A_2}\right)_{spl} \times R_s \times 400 \times \frac{DF}{N} \qquad \text{(Eq. 3)}$$

where $N$ is the number of tablets used in the sample preparation.

## RESULTS AND DISCUSSION

Clorazepate (I) decarboxylates readily to give nordiazepam (II) as the primary degradation product. Further acidic hydrolysis produces 2-amino-5-chlorobenzophenone (III). Other minor degradation products have been observed but at such low levels as to not be of concern in this assay.

HPLC provided the technique by which clorazepate could be separated from its degradation products for quantitation. With an octadecylsilylated stationary phase and methanol–water mixtures, poor peak shapes and retention were obtained for clorazepate. However, clorazepate chromatographed well when an eluent containing aqueous tetra-*n*-butylammonium ion (pH 7.5) and acetonitrile was employed. The use of tetra-*n*-butylammonium ion in the HPLC of weakly acidic species was previously reviewed (15, 16).

Figure 1 shows a chromatogram of clorazepate, nordiazepam, and 2-amino-5-chlorobenzophenone mixture under chromatographic conditions similar to those described here. Clorazepate was resolved from its degradation products, making the assay both specific and stability indicating.

The sample solvent (0.04% NaOH) was chosen to improve the stability of the clorazepate solutions during the time required to perform the analysis. At the pH of this solvent (~11.3), clorazepate was stable for at least 3–4 hr, after which time a gradual decline in the assay value was observed. Samples for analysis were prepared and analyzed within a few hours.

**Table I—Clorazepate Analysis in Dosage Forms**

| Formulation | Dose, mg | Standard Addition Recovery, %[a] | Precision mg ± *SD* | Precision *RSD*, % |
|---|---|---|---|---|
| Clorazepate monopotassium capsules | 3.25 | | 3.38 ± 0.05 | 1.52 |
| | 6.25 | 97.9–100.2 | 6.49 ± 0.07 | 1.09 |
| | 13.0 | | 12.82 ± 0.18 | 1.42 |
| Clorazepate dipotassium capsules | | | | |
| A | 3.0 | 97.9–101.5 | 2.95 ± 0.07 | 2.36 |
| B | 3.75 | | | |
| | 7.5 | 96.3–100.5 | 7.56 ± 0.12 | 1.64 |
| | 15.0 | | 14.78 ± 0.25 | 1.71 |
| C | 3.75 | | | |
| | 7.5 | 98.8–102.1 | 7.19 ± 0.09 | 1.32 |
| | 15.0 | | | |
| D | 7.5 | 98.9–101.0 | 7.49 ± 0.09 | 1.18 |
| E | 7.5 | 100.7–101.2 | 7.30 ± 0.11 | 1.50 |
| Clorazepate dipotassium tablets | 11.25 | 99.7–100.4 | 10.98 ± 0.09 | 0.84 |
| | 22.5 | | 22.01 ± 0.27 | 1.25 |
| | 3.75 | | 3.68 ± 0.02 | 0.51 |
| | 7.5 | 98.7–102.1 | 7.67 ± 0.05 | 0.68 |
| | 15.0 | | 15.06 ± 0.18 | 1.21 |

[a] Clorazepate reference standard.

All samples analyzed in this work were routine research and quality assurance samples from in-house sources. A typical chromatogram for the analysis of a formulation is presented in Fig. 2. Nordiazepam sometimes was observed as a very small peak at ~14–16 min, in which case the total analysis time was ~20 min. The long retention time of nordiazepam prevented its quantitation under these conditions at the normally low levels (<1%) encountered in the formulations. 2-Amino-5-chlorobenzophenone and other related impurities were present at such low levels as not to be observed at all.

Figure 3 is a chromatogram of a sample that had been intentionally degraded at elevated temperature. The intact clorazepate assay was 15.5%. A large peak also was observed for nordiazepam, indicating that this procedure detects decomposition and is stability indicating.

**Linearity**—A plot of the ratio of the clorazepate peak area to the internal standard peak area *versus* the clorazepate concentration in the solution was linear to at least 0.3 mg/ml and passed essentially through the origin ($r > 0.999$). The analytical concentration of clorazepate was 0.025–0.030 mg/ml.

**Recovery**—A known amount of clorazepate was added to the various formulations to check the recovery of standard additions. Additions at 50, 100, and 150% of label claim were added to at least one dose strength within each formulation. Weighed amounts of clorazepate standard were added to either placebo formulations or previously assayed dosages containing the active ingredient. The preparations then were analyzed as described (Table I). Recoveries ranged from 96.3 to 102.1%.

**Precision**—Analytical precision for clorazepate was determined by replicate analysis of 10 individual sample preparations on two separate days (Table I). Different analysts also were involved in some cases. The relative standard deviations ranged from ±0.51 to ±2.36%.

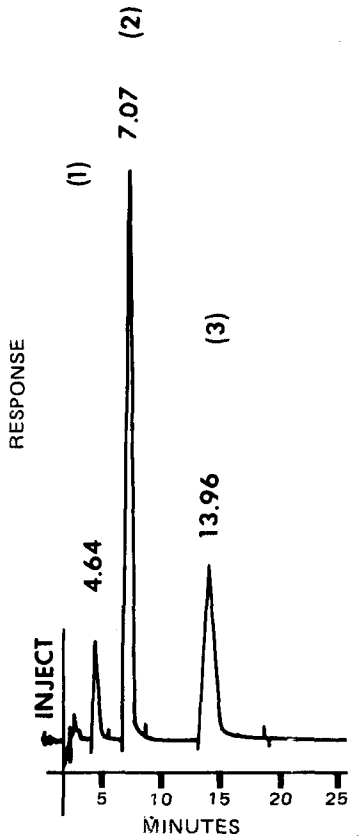

**Figure 3**—*Chromatogram for the analysis of a sample artificially degraded under accelerated conditions. Key: 1, clorazepate; 2, internal standard; and 3, nordiazepam.*

# Dissolution Profiles and Specifications for Dihydroergotoxine Sublingual Tablets Using a New *In Vitro* Method

JOHN P. HUNT, VINOD P. SHAH, VADLAMANI K. PRASAD ˣ, DONALD J. SCHUIRMANN, and BERNARD E. CABANA

Received February 28, 1980, from the *Biopharmaceutics Laboratory, Food and Drug Administration, Washington, DC 20204.* Accepted for publication December 29, 1980.

**Abstract** □ A dissolution method (paddle method) for determining the dissolution rate profile for 0.5- and 1.0-mg dihydroergotoxine methanesulfonate sublingual tablets was developed. A fluorometric method was used for measuring drug concentration in the dissolution medium, distilled water. It was essential to filter the dissolution sample to avoid interference from undissolved excipients. When different kinds of filters were used with the dissolution samples and standards, different degrees of apparent drug binding to the filter occurred. The dissolution rate profiles for several different products were compared to the innovator's product. The *in vitro* method and data obtained were used to propose dissolution specifications for these sublingual products.

**Keyphrases** □ Dihydroergotoxine—*in vitro* dissolution method for sublingual tablets, dissolution profiles □ Dissolution—dihydroergotoxine sublingual tablets, *in vitro* method □ Psychotherapeutic agents—dihydroergotoxine, *in vitro* dissolution method for sublingual tablets

Dihydroergotoxine is a psychotherapeutic agent used in the treatment of mood depression, confusion, and unsociability in elderly patients. Dihydroergotoxine sublingual tablets contain equal amounts of the mesylate forms of the dihydrogenated ergot alkaloids dihydroergocristine, dihydroergocornine, and dihydroergokryptine (*i.e.*, sum total of dihydro-α-ergokryptine and dihydro-β-ergokryptine) (1).

This drug is not in the official compendia, but the number of applications received by the Food and Drug Administration (FDA) for marketing approval for these products[1] has increased. Since there is no published method for *in vivo* bioavailability determination of dihydroergotoxine, firms seeking FDA approval were required to meet an *in vitro* dissolution specification as an interim minimum (2). This paper describes the development of a discriminatory *in vitro* dissolution method.

## EXPERIMENTAL

**Apparatus**—A dissolution apparatus described in USP XX Method II was used to establish dissolution specifications. The apparatus was equipped with a transparent constant-temperature water bath, which held six dissolution assemblies so that six dissolution tests could be run simultaneously. The water bath was connected to a free-standing water bath pump[2]. Each stirring shaft[3] of each dissolution assembly and its attached paddle[4] were positioned so that the bottom edge of the paddle was 4.5 ± 0.2 cm from the lowest inner surface of the dissolution vessel[5]. The dissolution profile of dihydroergotoxine tablets was determined in 500 ml of distilled water at 37° and 50 rpm. A volume of 500 ml of dissolution medium was selected due to the size of the dosage strengths tested (0.5 and 1.0 mg) and the assay sensitivity limit.

**Sampling**—A sampling system was designed with a proportioning pump[6] so that filtered dissolution test specimens from six dissolution assemblies could be collected simultaneously. The pumping system had an on-line filter adapter[7], which contained a disposable filter (glass fiber[8], polytef[9], cellulose[10], or nylon[11]) for each dissolution assembly. Filters were replaced for each dissolution test.

Dissolution specimens (2–3 ml) were collected at each time, and an equivalent volume of dissolution medium was replaced immediately. Collected specimens were allowed to equilibrate to room temperature (25°) in a water bath before being read directly in a spectrophotofluorometer[12]. Prior to reading the filtered standard solutions and collected dissolution specimens, the spectrophotofluorometer was set for an emission intensity reading of 100 for a 1.0-μg/ml unfiltered standard solution.

Standard curves were linear over a concentration range of 0.05–4.0 μg/ml for both filtered and unfiltered standard solutions. A typical equation for an unfiltered standard curve was $y = 97.9x + 1.64$ ($r = 0.9980$); for a filtered standard curve using glass-fiber filters, it was $y = 91.3x + 0.450$ ($r = 0.9993$).

**Table I—Influence of Filter Composition on Dihydroergotoxine Binding [a]**

| | Polytef | Glass Fiber | Cellulose | Nylon |
|---|---|---|---|---|
| $N$[b] | 22 | 55 | 20 | 6 |
| Mean percent unbound | 93.2 | 92.2 | 74.0 | 44.3 |
| Range | 85–98.5 | 84–100 | 58–93.5 | 25–70 |
| $SD$ | 4.0 | 4.3 | 10.1 | 15.7 |
| $SE$ | 0.9 | 0.6 | 2.3 | 6.41 |
| $CV$[c] | 4.3 | 4.6 | 13.6 | 35.5 |

[a] Percent of apparent drug filter binding was determined using an aqueous 1.0-μg of dihydroergotoxine/ml standard solution. The standard's filtered fluorescence reading for each filter was compared to the standard's unfiltered fluorescence reading of 100. Binding = 100 − observed reading. [b] Number of filters tested. [c] Coefficient of variation.

## RESULTS AND DISCUSSION

Spectrophotofluorometric scans demonstrated that an aqueous solution of dihydroergotoxine methanesulfonate[13] (with the assumption that all three drug moieties have the same dissolution characteristics) had maximum excitation and emission wavelengths of 283 and 353 nm, respectively.

Initial studies revealed that dihydroergotoxine standard solutions gave lower relative emission intensity readings when filtered with cellulose filters than when read as unfiltered solutions. Further investigations were conducted using standard solutions to determine the effects other filters had on fluorescence readings. Study results indicated an apparent drug filter binding effect, which was dependent on the type of filter used (Table I). For cellulose and nylon filters, there appeared to be significant binding (~25 and 55%, respectively). For polytef and glass-fiber filters, slight binding seemed possible when the small assay variability (coefficient of variation of 4.3 and 4.6%, respectively) and the differences between unfiltered and filtered fluorescence readings for those filters (~7 and 8%, respectively) were considered.

Sublingual tablets, 0.5 and 1.0 mg, from several manufacturers were

[a] S5 (lot 040X6375), S6 (lot 039Y6389), S7 (lot 035X6265), and S8 (lot 038Y6389) represent four lots of the innovator Sandoz Pharmaceuticals; B2 (lot 116581) was from Bolar; and M3 (lot 3MMJ082) and M4 (lot 3MF0081) were from Mead Johnson. Six tablets of each product were used except that 12 tablets of S7 were tested. [b] Mean of 12 tablets. [c] See Footnote 14.

tested. Glass-fiber filters were used because of their low apparent drug binding effect. Dissolution profiles from 2 min to infinity[14] were determined. For each dissolution run, at least six tablets were tested and a filtered standard curve was prepared.

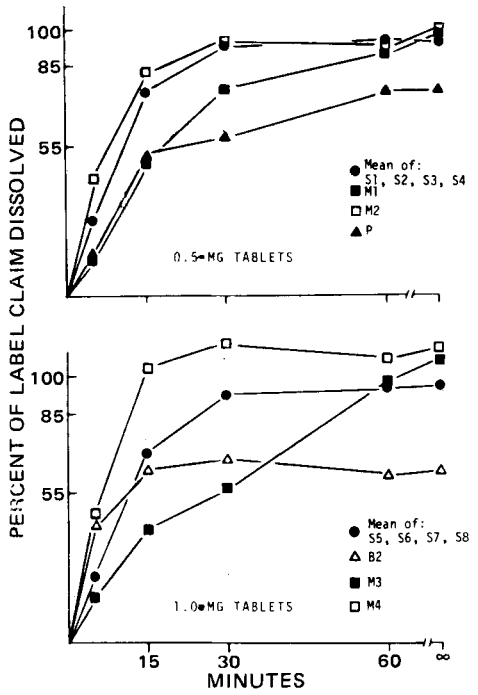

**Figure 1**—*Dissolution profiles for 0.5- and 1.0-mg dihydroergotoxine mesylate tablets in distilled water at 37° by the 50-rpm paddle method. The data points represent a mean of 48 tablets representing four batches for 0.5-mg tablets and a mean of 30 tablets representing four batches for 1.0-mg tablets for Product S. For all other brands, the values represent a mean of six or 12 tablet determinations.*

[14] Infinity dissolution was determined after stirring the dissolution medium for an additional 30 min at 200 rpm following 60 min of specimen collection.

**Table IV—*p* Values for the Significance Tests Associated with Analysis of Variance of Percent Dihydroergotoxine Dissolved**

| Effect | 0.5-mg Tablet 15 min | 0.5-mg Tablet 30 min | 1.0-mg Tablet 15 min | 1.0-mg Tablet 30 min |
|---|---|---|---|---|
| Brands | 0.602 | 0.020 | 0.989 | 0.469 |
| Lots within brands | 0.001 | 0.086 | 0.005 | 0.001 |

The dissolution test results for 0.5- (Table II) and 1.0- (Table III) mg tablets demonstrated that there were brand-to-brand and lot-to-lot dissolution differences (Fig. 1). To establish differences between brands and between lots within a brand, analyses of variance were carried out on the percent of drug dissolved for 0.5- and 1.0-mg tablets at 15 and 30 min using the NESTED procedure previously described (3). The $p$ values for the associated significance tests are summarized in Table IV. There were significant differences ($p \leq 0.005$) between lots within brands for 0.5-mg tablets at 15 min and for 1-mg tablets at 15 and 30 min. In addition, there were significant differences among brands for 0.5-mg tablets at 15 min ($p = 0.02$).

The differences observed under these test conditions were attributed to drug product manufacturing differences, excipients, and other tablet

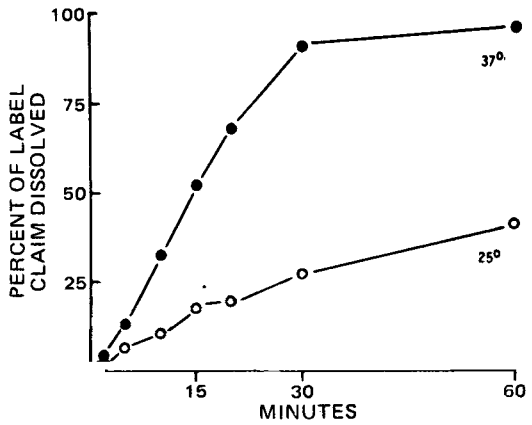

**Figure 2**—*Effect of temperature on the dissolution rate of innovator's product (S1; lot 720X5534) of 0.5-mg sublingual tablets. Dissolution values represent the average of two tablets.*

| Minutes | 0.5 mg | | | | | 1.0 mg, |
|---|---|---|---|---|---|---|
| | Product M2[a] | Product P | Product B1 | Product R | Product S1 | Product M4 |
| 2 | 2.5, 5.5[b] | 0.0, 2.0 | 2.0, 0.6 | 27.3, 38.8 | 0.6, 3.0 | 8.7, 8.3 |
| 5 | 11.0, 13.0 | 4.0, 7.5 | 9.5, 5.8 | 66.8, 67.8 | 6.3, 6.0 | 20.2, 20.3 |
| 10 | 23.5, 25.5 | 16.0, 13.5 | 22.0, 23.3 | 75.3, 84.8 | 8.3, 10.6 | 37.2, 39.8 |
| 15 | 29.5, 39.0 | 22.0, 37.5 | 30.5, 37.8 | 79.8, 87.8 | 16.3, 16.0 | 48.7, 60.8 |
| 20 | 45.5, 56.0 | 33.5, 57.0 | 50.5, 59.8 | 85.3, 82.8 | 19.3, 16.5 | 73.2, 73.3 |
| 30 | 74.5, 81.2 | 41.5, 54.5 | 71.5, 70.3 | 75.8, 87.8 | 27.3, 23.0 | 94.2, 97.8 |
| 60 | 89.0, 90.5 | 61.0, 55.5 | 75.0, 75.3 | 82.8, 84.3 | 34.8, 42.0 | 106, 101 |

[a] Letter represents manufacturer, and number represents a different production lot. Refer to Tables II and III for explanation of symbols. [b] Values for two tablets.

variations. Other studies, under slightly modified test conditions, also helped to establish that dissolution differences may be due to formulation differences. Two brands, P and B2, failed to achieve total dissolution (Fig. 1). With both preparations, insoluble material in the dissolution medium and a film on the stirring shafts and paddles indicated the possibility of an insoluble complex formation. Total dissolution could be achieved only by further dilution to 900 ml of medium.

The extent of dissolution as a function of temperature was not clear cut and predictable because of the differences in formulations (Table V). For example, Products M2, P, B1, and M4 initially dissolved slowly at 25°; however, after 60 min, the extent of dissolution was comparable to that at 37°. On the other hand, temperature had no influence on Product R (the dissolution profiles at 25 and 37° were identical). However, the rate and extent of dissolution of Product S1 were decreased significantly at 25° when compared to the results obtained at 37° (Fig. 2).

Based on the *in vitro* dissolution results, the FDA implemented a dissolution specification for 0.5- and 1.0-mg sublingual tablets using the paddle method (4) where the dissolution medium is 500 ml of distilled water at 37°. The paddle height is 4.5 cm, and the stirring speed is 50 rpm. The dissolution specimens are filtered with either glass or polytef filters prior to drug content analysis.

*In vivo* bioavailability data for *in vitro–in vivo* correlations are lacking. Therefore, based on the *in vitro* performance of eight batches representing 0.5- and 1.0-mg tablets of the innovator product[15], a dissolution specification was set. For tablets to be considered acceptable, they must dissolve not less than 55% in 15 min and not less than 85% in 30 min for a mean of 12 tablets. However, no tablet should fall below 45 and 75% at those respective times.

The described *in vitro* dissolution method and its specifications should help ensure both product-to-product and lot-to-lot uniformity and consistency for dihydroergotoxine sublingual tablet dosage forms.

# NOTES

# Loss of Nitroglycerin from Solutions to Intravenous Plastic Containers: A Theoretical Treatment

**A. WASEEM MALICK ˣ, ANTON H. AMANN, DAVID M. BAASKE, and ROGER G. STOLL**

Received June 3, 1980, from *American Critical Care, McGaw Park, IL 60085.* Accepted for publication September 10, 1980.

**Abstract** □ The physical instability of nitroglycerin solutions in plastic containers has been reported extensively. A systematic study of potency loss in plastic infusion bags was reported recently. This paper presents a theoretical treatment of the data and a proposed model consisting of adsorption onto the surface followed by partitioning into the plastic.

**Keyphrases** □ Nitroglycerin—loss from solution to plastic intravenous containers, a theoretical treatment □ Plastic containers—loss of nitroglycerin from intravenous plastic containers, a theoretical treatment □ Adsorption, potential—nitroglycerin loss from solution in plastic intravenous containers, a theoretical treatment

Numerous studies (1–10) have reported stability problems associated with nitroglycerin solutions in plastic containers meant for intravenous infusions. Adsorption of the drug by plastic containers and infusion sets was suggested as the cause. Yuen *et al.* (8) studied the loss of nitroglycerin from aqueous solutions in immersed strips of plastic. Based on equilibrium and kinetic studies, these workers proposed an adsorption–absorption mechanism in which adsorption plays a minor role. Although their report provided some insight into the phenomenon, it did not deal with the system as a whole, *i.e.*, nitroglycerin solutions contained in intravenous bags.

The loss of nitroglycerin from solutions stored in commercial plastic intravenous bags was reported recently (10). Immediate significant losses were followed by a gradual decrease in concentration. No chemical degradation was observed. In this report, a theoretical treatment of the data and a proposed model are presented.

## EXPERIMENTAL

The applicability of the proposed model was tested using recently reported data of nitroglycerin compatibility with intravenous admixture aids (10). In brief, the procedures for obtaining the kinetic data entailed: (*a*) the addition by syringe of an aqueous nitroglycerin preparation to

# Loss of Nitroglycerin from Solutions to Intravenous Plastic Containers: A Theoretical Treatment

**A. WASEEM MALICK ˣ, ANTON H. AMANN, DAVID M. BAASKE, and ROGER G. STOLL**

Received June 3, 1980, from *American Critical Care, McGaw Park, IL 60085.* Accepted for publication September 10, 1980.

**Abstract** □ The physical instability of nitroglycerin solutions in plastic containers has been reported extensively. A systematic study of potency loss in plastic infusion bags was reported recently. This paper presents a theoretical treatment of the data and a proposed model consisting of adsorption onto the surface followed by partitioning into the plastic.

**Keyphrases** □ Nitroglycerin—loss from solution to plastic intravenous containers, a theoretical treatment □ Plastic containers—loss of nitroglycerin from intravenous plastic containers, a theoretical treatment □ Adsorption, potential—nitroglycerin loss from solution in plastic intravenous containers, a theoretical treatment

Numerous studies (1–10) have reported stability problems associated with nitroglycerin solutions in plastic containers meant for intravenous infusions. Adsorption of the drug by plastic containers and infusion sets was suggested as the cause. Yuen *et al.* (8) studied the loss of nitroglycerin from aqueous solutions in immersed strips of plastic. Based on equilibrium and kinetic studies, these workers proposed an adsorption–absorption mechanism in which adsorption plays a minor role. Although their report provided some insight into the phenomenon, it did not deal with the system as a whole, *i.e.*, nitroglycerin solutions contained in intravenous bags.

The loss of nitroglycerin from solutions stored in commercial plastic intravenous bags was reported recently (10). Immediate significant losses were followed by a gradual decrease in concentration. No chemical degradation was observed. In this report, a theoretical treatment of the data and a proposed model are presented.

## EXPERIMENTAL

The applicability of the proposed model was tested using recently reported data of nitroglycerin compatibility with intravenous admixture aids (10). In brief, the procedures for obtaining the kinetic data entailed: (*a*) the addition by syringe of an aqueous nitroglycerin preparation to

*0022-3549/81/0700-0798$01.00/0*

*© 1981, American Pharmaceutical Association*

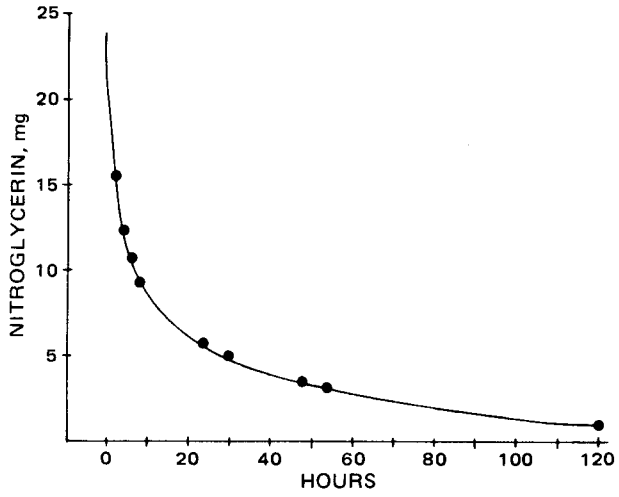

**Figure 1**—*Amount of nitroglycerin in a plastic bag as a function of time. The symbols (●) are experimental points. The solid line is the theoretically computed curve according to Eq. 10.*

a 100-ml polyvinyl chloride[1] plastic bag to yield a final nominal concentration of 50 μg/ml, and (*b*) mixing the solution and sampling at given intervals for potency determination by high-performance liquid chromatography (HPLC). Nitroglycerin potency assays were performed according to the method of Baaske *et al.* (10). Figure 1 summarizes the results.

## THEORETICAL

The loss of nitroglycerin from solution in plastic bags can be described by two processes: rapid adsorption of nitroglycerin by the surface of the plastic bag, followed by dissolution of nitroglycerin into the plastic. This loss can be represented diagramatically as in Scheme I.

$$\text{nitroglycerin in aqueous solution} \underset{k_2}{\overset{k_1}{\rightleftarrows}} \text{adsorbed nitroglycerin on plastic surface} \xrightarrow{k_3} \text{nitroglycerin dissolved in plastic matrix}$$

*Scheme I*

The process may be considered to be dependent on the following factors: (*a*) the amount of nitroglycerin in solution, (*b*) the ratio of nitroglycerin solution volume to the area of the plastic surface in contact with the solution, (*c*) the rate at which fresh nitroglycerin molecules from the solution are adsorbed at the plastic surface following the sorption of nitroglycerin by the plastic matrix, and (*d*) the solubility of nitroglycerin in the plastic matrix and the partition coefficient of nitroglycerin between plastic and the aqueous phase.

Scheme I can be expressed in terms of the instantaneous amounts of nitroglycerin in solution ($A$), nitroglycerin adsorbed to the plastic surface ($B$), and nitroglycerin dissolved in the plastic matrix ($C$) (Scheme II).

$$A \underset{k_2}{\overset{k_1}{\rightleftarrows}} B \xrightarrow{k_3} C$$

*Scheme II*

The differential equations describing the rate of change of $A$, $B$, and $C$ are:

$$\frac{dA}{dt} = -k_1A + k_2B \qquad \text{(Eq. 1)}$$

$$\frac{dB}{dt} = k_1A - k_2B - k_3B \qquad \text{(Eq. 2)}$$

$$\frac{dC}{dt} = k_3B \qquad \text{(Eq. 3)}$$

Experimental data show a rapid initial drop of nitroglycerin in solution followed by a relatively slower rate of loss. This finding suggests that the rate of nitroglycerin adsorption to the surface is much greater than the rate of sorption by the plastic matrix. The adsorbed layer of nitroglycerin onto the plastic surface can be pictured as a few molecules thick at most.

[1] Viaflex container, Travenol Laboratories, Morton Grove, IL 60053.

The molecules of the adsorbed layer of nitroglycerin that are removed by sorption into the plastic are expected to be replaced rapidly by fresh molecules from the solution. Since nitroglycerin is being adsorbed continually at the surface and removed by dissolution into the matrix, $B$ should approach steady state:

$$\frac{dB}{dt} = 0 = k_1A - k_2B - k_3B \qquad \text{(Eq. 4)}$$

By introducing the steady-state approximation and the initial conditions (at $t = 0$, $A = A_0$, $B = 0$, and $C = 0$), the following solution for $A$ is obtained:

$$A = \alpha e^{-[k_1k_3/(k_2+k_3)]t} + \beta e^{-(k_2+k_3)t} - \alpha e^{-k_1t} - \beta e^{-k_1t} + A_0e^{-k_1t} \qquad \text{(Eq. 5)}$$

where $\alpha$ and $\beta$ are constants.

A comparison of the processes controlled by $k_2$ and $k_3$ in the scheme suggests that the magnitude of $k_2$ is smaller than $k_3$. The loss of nitroglycerin from the adsorbed layer to the relatively polar aqueous phase is described by $k_2$, whereas $k_3$ describes the sorption of the adsorbed nitroglycerin molecules by the nonpolar plastic matrix. Since the affinity of nitroglycerin is expected to be much greater for the nonpolar plastic matrix than the aqueous phase, it is expected that $k_3 \gg k_2$.

Following this assumption, Eq. 5 reduces to:

$$A = \beta e^{-k_3t} + (A_0 - \beta)e^{-k_1t} \qquad \text{(Eq. 6)}$$

where:

$$\beta = \frac{A_0}{\frac{k_3^2}{k_1k_2} + \frac{k_1^2}{k_2} - \frac{2k_3}{k_2}} \qquad \text{(Eq. 7)}$$

and $k_1$ is a function of the amount of drug in solution, the surface area available for adsorption, and the formulation differences between solutions and plastic matrixes, and $k_3$ is a function of the volume of the plastic matrix and the solubility of nitroglycerin in the plastic matrix.

The $k_3/k_2$ ratio describes the overall partitioning behavior of nitroglycerin between the plastic and the aqueous phase. The relationship of the true partition coefficient ($PC$) and $k_3/k_2$ can be described by:

$$\frac{k_3}{k_2} = aPC \qquad \text{(Eq. 8)}$$

where $a$ is a proportionality constant related to, among other factors, the mass of the plastic, the volume of aqueous nitroglycerin solution, and the formulation differences between the solution and the plastic bag.

Similarly, the $k_1/k_2$ ratio can be related to the affinity constant ($k_{Lang}$) in a Langmuir type of adsorption (11):

$$\frac{k_1}{k_2} = \rho k_{Lang} \qquad \text{(Eq. 9)}$$

where $\rho$ is a proportionality constant that is also related to the surface area of the plastic, the volume of the aqueous nitroglycerin solution, and the formulation differences between the solution and the plastic bag.

Langmuir adsorption treatment cannot be applied rigorously to this model since an equilibrium situation between the adsorbate (nitroglycerin) and the adsorbent (plastic) does not exist during the experiment. The adsorbed molecules, instead of reaching an equilibrium with the nonadsorbed molecules in the aqueous solution, are removed continually from the surface by the plastic matrix.

## RESULTS AND DISCUSSION

Figure 1 shows a plot (at room temperature) of the amount of nitroglycerin remaining in the plastic bag as a function of time. As predicted by the model, a biexponential loss of nitroglycerin with time is seen. The rate constants for adsorption ($k_1$) and sorption by the plastic matrix ($k_3$), together with the constants $\beta$ and $A_0 - \beta$, were obtained by using a back-projection (stripping) technique (12). Figure 1 shows the actual data points and the curve obtained by theoretical computation. The solid theoretical curve was generated by using the equation derived for the proposed model (Eq. 6) and substituting the values of the constants obtained from the experimental data. The final form of the equation is:

$$A = 8.957e^{-0.028t} + 14.943e^{-0.235t} \qquad \text{(Eq. 10)}$$

The experimental data points show an excellent fit with the solid theoretical line. Thus, the proposed model describing (*a*) the loss of nitroglycerin from the solution in the plastic bags as a rapid adsorption to the

plastic surface, (*b*) followed by sorption of nitroglycerin to the plastic matrix by dissolution is in good agreement with the actual data. The model presented here should be useful for future investigations.

# High-Performance Liquid Chromatographic Determination of Verapamil in Plasma by Fluorescence Detection

**ERIC WATSON * and PATRICIA A. KAPUR ˣ**

Received September 5, 1980, from the *Department of Anesthesiology, School of Medicine, Center for the Health Sciences, University of California, Los Angeles, CA 90024.* Accepted for publication October 17, 1980. *Present address: School of Pharmacy, University of Southern California, Los Angeles, CA 90033.

**Abstract** □ A rapid and highly sensitive method is reported for the quantitative determination of verapamil in plasma. Verapamil and its internal standard are extracted from alkalinized plasma with heptane and then back-extracted into dilute sulfuric acid. An aliquot is injected directly into a high-performance liquid chromatograph, separated by reversed-phase chromatography, and quantified by a fluorescence detector. The procedure is suitable for the routine determination of verapamil in plasma in concentrations as low as 1 ng/ml.

**Keyphrases** □ Verapamil—high-performance liquid chromatography, fluorescence detection, canine plasma □ High-performance liquid chromatography—verapamil, canine plasma, fluorescence detection □ Antiarrhythmic agents—high-performance liquid chromatography, verapamil, canine plasma, fluorescence detection

Verapamil, 5-[(3,4-dimethoxyphenethyl)methylamino]-2-(3,4-dimethoxyphenyl)-2-isopropylvaleronitrile (I), has been used for several years in Europe as an effective antiarrhythmic drug and is now undergoing clinical evaluation in the United States. Studies are underway in this laboratory to show the efficacy of verapamil in suppressing halothane–epinephrine arrhythmias (1).

Several analytical procedures have been reported for determining verapamil in plasma, including spectrophotometry (2), GLC with mass fragmentography (3), GLC (4), and high-performance liquid chromatography (HPLC) (5). None of these methods was considered completely satisfactory for reasons of simplicity, speed, and the ability to determine metabolites quantitatively. Therefore, an HPLC procedure was developed, and its application for the determination of verapamil in canine plasma following intravenous injection is reported here.

## EXPERIMENTAL

**Chemicals and Reagents**—Verapamil[1] (I) and its internal standard, 4-[(3,4-dimethoxyphenethyl)methylamino] -2- (3,4-dimethoxyphenyl)-2-isopropylbutyronitrile[2] (II), were obtained as hydrochloride salts. Glass-distilled heptane[3] and HPLC grade acetonitrile[4] were used. Sodium hydroxide (2 *N*), sulfuric acid (0.2 *N*), and pH 3.0 phosphate buffer (1 *M*) were prepared with deionized water.

**HPLC**—A liquid chromatograph[5] was used with a fluorescence detector[6]. The column[7] was $C_{18}$ reversed phase, and the eluting solvent was 45% acetonitrile–55% pH 3.0 potassium phosphate (0.1 *M*). The solvent was degassed prior to use by applying a vacuum. The flow rate was set at 1 ml/min. The detector settings were 203 nm for excitation with a 320-nm emission filter.

**Procedure**—To 0.5 ml of plasma were added 50 ng of II, 0.25 ml of 2 *N* NaOH, and 3 ml of heptane. The mixture was shaken mechanically for 15 min and then centrifuged. The organic layer was transferred to a 5-ml conical tube, and 50 μl of 0.2 *N* $H_2SO_4$ was added. The contents were mixed in a vortex mixer for 1 min and centrifuged, and a 10-μl sample was injected into the chromatograph.

## RESULTS AND DISCUSSION

Standard curves were prepared routinely from spiked plasma samples containing 40, 100, and 250 ng of verapamil/ml. Peak height ratios were plotted as a function of the verapamil concentration added and were linear within this range. Intercepts usually passed through the origin. The lower limit of sensitivity of the assay was ~1 ng/ml, and this level was completely adequate for analyzing the samples in this study. Assay reproducibility and precision were evaluated by the repeated analyses of spiked plasma samples containing 100 ng of verapamil/ml. The coefficient of variation at this level was 4.6% ($n$ = 12). The slopes of the standard curves from water or biological fluids were similar, indicating insignificant

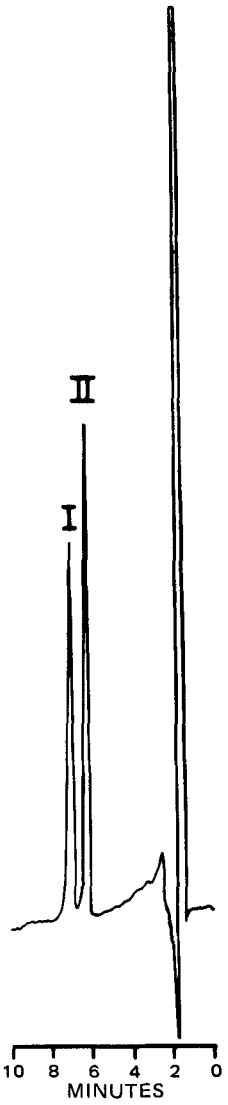

**Figure 1**—*Chromatogram of the extract of a 0.5-ml plasma sample taken 8 min after the intravenous injection of 0.2 mg of verapamil/kg. Key: I, verapamil; and II, internal standard.*

differences in the extractability of the compounds from aqueous solutions of different compositions.

A chromatogram of an extracted plasma sample from a dog that had received 0.2 mg of verapamil/kg iv 8 min previously is shown in Fig. 1. The verapamil concentration was 95 ng/ml.

Figure 2 shows a semilog plot of the concentration–time curve obtained after intravenous injection of 0.1 mg of verapamil/kg in a dog. The levels declined exponentially as fitted by the regression analysis program AUTOAN to a three-compartment open model according to:

$$C_x = Ae^{-\alpha t} + Be^{-\beta t} + Pe^{-\pi t} \qquad \text{(Eq. 1)}$$

where $C_x$ is the plasma verapamil concentration; $A$, $B$, and $P$ are the coefficients of the three compartments; and $\alpha$, $\beta$, and $\pi$ are the decay constants from these compartments. The terminal half-lives were 0.25, 6.5, and 129 hr, respectively. However, although the data from this experiment were compatible with a three-compartment model, it is not possible to state that three compartments exist for verapamil. Additional experiments of longer duration are required to reach statistically valid conclusions. The half-lives of the initial distribution phase ($t_{1/2\alpha}$, 0.25 hr) and for the apparent terminal phase ($t_{1/2\beta}$, 6.5 hr) were in agreement with previously reported values (6, 7).

The retention times of verapamil and II were 7 and 6 min, respectively. No endogenous compounds were present in plasma with the same elution times and fluorescence spectra.

A high first-pass effect was reported for patients receiving oral verapamil (6). In the study reported here, verapamil was administered intravenously only; therefore, the presence of substantial amounts of metabolic products would not be expected. Throughout the study, no evidence of metabolic products was observed. Since these products would be more polar, their elution times would be expected to be less than the elution time of verapamil. Therefore, the use of heptane as the extracting solvent is extremely advantageous since there are no major peaks eluting prior to verapamil that may possibly obscure the presence of metabolic products. While authentic metabolites have not been tested in this chromatographic system, it is reasonable to expect that they would elute ahead of verapamil.

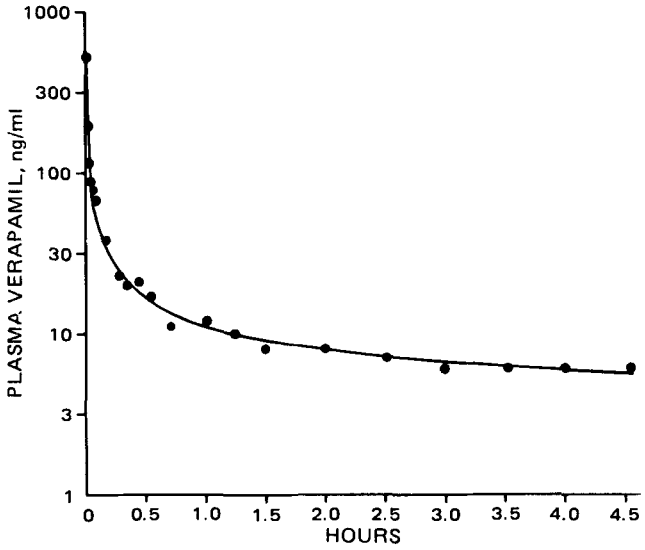

**Figure 2**—*Change in plasma verapamil concentration with time after the intravenous injection of 0.1 mg/kg at time zero.*

Other studies are being planned to evaluate the pharmacokinetics of verapamil and the individual metabolic products following oral administration. A discrepancy exists between the duration of the electrophysiological and hemodynamic effects of verapamil and its concentration in plasma. The possibility that this discrepancy may be related to the concentration of metabolites has been proposed (8), and the method described here may be of value in resolving this problem.

The ultimate objectives in undertaking pharmacokinetic metabolic and disposition studies are to predict disposition in individual patients and to optimize doses and schedules rapidly. The development of a highly sensitive and specific analytical procedure for measuring verapamil in plasma should enable more detailed and longer term clinical disposition studies than have been reported previously.

# Parabolic Equation Relating Free and Total Drug Concentrations in Cases of Nonlinear Plasma Protein Binding

**HARRIET L. BEHM** * **and JOHN G. WAGNER** ˣ

Received September 10, 1980, from the *College of Pharmacy and the Upjohn Center for Clinical Pharmacology, University of Michigan, Ann Arbor, MI 48109.* Accepted for publication December 10, 1980. *Present address: Pharmaceutical R & D, Squibb Institute for Medical Research, New Brunswick, NJ 08903.

**Abstract** □ In many cases of nonlinear drug–protein binding, investigators have fitted data to the classical Langmuir model with two classes of binding sites involving four parameters. For human serum albumin binding of tolmetin and salicylate, a simple two-parameter parabolic equation relating free to total concentrations fitted the binding data better. Thus, the free fraction corresponding to the serum or plasma drug concentration in the blood sample taken from a subject can be estimated directly from the parabolic model. This is not the case when the Langmuir model is used to describe nonlinear binding data since the positive root of a cubic equation must be obtained to estimate the free from the total concentration. The direct relationship between free and total drug concentrations would be useful in many clinical situations.

**Keyphrases** □ Drug–protein binding—Langmuir and parabolic models compared, parameter estimation, equilibrium dialysis of salicylic acid and tolmetin with human serum albumin □ Equilibrium dialysis—drug–protein binding, Langmuir and parabolic models compared for free drug concentration estimation □ Models, mathematical—Langmuir and parabolic models compared for free drug concentration estimation, equilibrium dialysis

When equilibrium dialysis is used to measure nonlinear drug–protein binding, the free fraction of drug obtained from the equilibrium concentrations in the buffer and plasma compartments of the dialysis apparatus is always less than that in the original plasma or serum sample. The free fraction corresponding to the initial total drug concentration must be estimated from a function describing the binding over a range of equilibrium drug concentrations. If only one serum or plasma sample containing drug is available, one cannot calculate the correct free and bound drug concentrations in the original plasma or serum sample (1).

## BACKGROUND

Free fractions corresponding to the initial plasma or serum total drug concentrations can be estimated by solving a quadratic ($k = 1$) or cubic ($k = 2$) equation (1) when nonlinear drug–protein binding data, obtained using equilibrium dialysis, are fitted to the classical Langmuir model (2):

$$C_b = \sum_{i=1}^{k} \frac{n_i C_p C_f}{Kd_i + C_f} \qquad \text{(Eq. 1)}$$

where $C_b$ is the protein-bound drug concentration at equilibrium, $C_p$ is the protein concentration, $C_f$ is the free (unbound) drug concentration at equilibrium, $Kd_i$ is the dissociation constant for the $i$th class of binding sites, $n_i$ is the number of identical independent binding sites in a class, and $k$ is the number of classes. The disadvantage of this technique is that the free drug concentration corresponding to a total drug concentration cannot be estimated directly.

With tolmetin–human serum albumin ($k = 2$ or 3) (3) or salicylate–human serum albumin ($k = 2$) (4) binding data from equilibrium dialysis experiments, it was found empirically that a plot of the free fraction *versus* total equilibrium drug concentration was linear:

$$\frac{C_f}{C_t} = a + bC_t \qquad \text{(Eq. 2)}$$

where $C_t$ is the total drug concentration and $a$ and $b$ are the intercept and slope of the straight line, respectively. The constant $a$ is dimensionless, while $b$ has dimensions of $\mu M^{-1}$. This equation can be rearranged to give a simple parabolic relationship that passes through the origin and predicts zero drug bound at zero total drug concentration:

$$C_f = aC_t + bC_t^2 \qquad \text{(Eq. 3)}$$

In many cases, the binding data were fitted much better to Eq. 3 than to the classical Langmuir model (Eq. 1 with $k = 2$). This parabolic relationship is useful in many clinical situations since $C_f$ can be estimated directly for a given $C_t$ value. The concentration range was 0–1200 $\mu M$ for tolmetin and 0–2400 $\mu M$ for salicylic acid, and the parameters of Eq. 3 (Tables I and II) are valid only in these ranges.

## EXPERIMENTAL

All drug–protein binding assays were performed using equilibrium dialysis as described previously (5). Equilibration was attained when samples were placed in an oscillating water bath (at 37°) for 18 hr. Drug concentrations were estimated by methods published previously (2). The unlabeled[1] and [$^{14}$C]salicylic acid[2] were obtained commercially. Human serum albumin[3] solution (25%) was diluted with water to 4% and used in the binding studies with various buffers, while fatty acid-free human serum albumin[4] was used for the binding studies at various temperatures. The program NONLIN (6) was used for fitting the binding data to Eq. 1 ($k = 2$) or 3.

## RESULTS

The estimated parameters and their coefficients of variation for the two models (Eqs. 1 and 3) for salicylic acid–human serum albumin binding data are shown in Table I; coefficients of variation were obtained as indicated. For the Langmuir model, the estimated parameters, $P(i)$, in terms of previously defined constants were $P(1) = n_1C_p$, $P(2) = Kd_1$, $P(3) = n_2C_p$, and $P(4) = Kd_2$. Here, $n_1C_p$ and $n_2C_p$ are the binding capacities at 4% human serum albumin. With salicylic acid, fits to the parabolic relationship were much better than to the Langmuir model with two classes of binding sites ($k = 2$), as reflected by the much smaller coefficients of variation for the parabolic model than for the Langmuir model. However, fits to both models were excellent. Measures of fit[5], corr and $r^2$, for fitting of data to the parabolic model ranged from both being 0.997 to both being 1.00. The corr and $r^2$ values ranged from 0.998 and 0.999, respectively, in 0.05 $M$ $KH_2PO_4$ buffer to 0.995 and 0.996, respectively, in triethanolamine buffer when data were fitted to the Langmuir model with $k = 2$.

The estimated parameters and their coefficients of variation for the two models (Eqs. 1 and 3) for the tolmetin–human serum albumin binding data are shown in Table II. The computer fitting of data obtained using imidazole buffer provided no standard deviations for two of the estimated parameters. Again, fits to the parabolic model (as reflected by the lower coefficients of variation) were better than to the Langmuir model but were not as dramatically different as the fits with the salicylic acid data. However, fits to both models were extremely good. Measures of fit, corr and $r^2$, for the parabolic model fitting ranged from 0.992 and

0.990, respectively, in 0.1 *M* $KH_2PO_4$ to both being 0.999 in imidazole. The corr and $r^2$ values for fittings to the Langmuir model ranged from 0.993 and 0.992, respectively, in tromethamine to 0.999 and 1.00, respectively, in imidazole.

The binding of salicylic acid to two types of albumin was investigated at six temperatures, from 4 to 58 or 59°, with the higher temperature being different for the two types of albumin. These data were computer fitted to Eq. 3. With the salicylic acid–human serum albumin binding data, parameter $b$ of Eq. 3 remained constant with a change in temperature when the highest temperature was excluded. The means and standard deviations of $b$ were 1.06 (0.026) and 0.895 (0.047) for 4% albumin and 4% fatty acid-free albumin, respectively. The parameter $a$ increased with an increase in temperature, and plots of $a$ *versus* temperature exhibited convex curvature (not shown).

To compare estimated parameters obtained by the Langmuir and parabolic models, the models were manipulated to obtain limiting values for the ratios of bound to free drug concentrations as the total or free drug concentration approached zero (infinite dilution). The Langmuir model can be manipulated to obtain the limiting relationship (7):

$$\frac{C_b}{C_f} = \frac{P(1)}{P(2)} + \frac{P(3)}{P(4)} \qquad \text{(Eq. 4)}$$

For the parabolic model, the limiting relationship is:

$$\frac{C_b}{C_f} = \frac{1 - a}{a} \qquad \text{(Eq. 5)}$$

The limiting values of $C_b/C_f$ obtained from Eqs. 4 and 5 for the Langmuir and parabolic models, respectively, and for the binding of salicylic acid to human serum albumin using eight buffers are listed in Table III. The limiting values for the Langmuir and parabolic models were comparable in each case. Limiting values for the tolmetin–human serum albumin binding data (not shown) also were similar.

**Table III—Limiting Values of Ratio of Bound to Free Drug Concentrations for Salicylic Acid**

[a] See Eq. 4. [b] See Eq. 5. [c] See footnote to Table I.

## DISCUSSION

Many factors can cause variability in drug–protein binding from subject to subject or patient to patient. Variables include age (8, 9), drug therapy (10, 11), prolonged bedrest (12), cigarette smoking (13), and disease (14, 15). Circadian fluctuations in drug–protein binding also can occur (16). Because of the individual differences in drug–protein binding, the binding characteristics for each subject or patient undergoing pharmacokinetic evaluation should be determined rather than using pooled plasma or serum (17).

# High-Pressure Liquid Chromatographic Assay of Theophylline, Ephedrine Hydrochloride, and Phenobarbital Tablets

**TSUN-MING CHEN ˣ and LESTER CHAFETZ**

Received October 6, 1980, from the *Analytical Research Laboratories, Warner-Lambert Pharmaceutical Research, Morris Plains, NJ 07950.* Accepted for publication December 1, 1980.

**Abstract** □ An innovative high-pressure liquid chromatographic method is described in which theophylline, ephedrine hydrochloride (measured as benzaldehyde), and phenobarbital are determined simultaneously with butabarbital as the internal standard. Chromatographic conditions were selected to afford a pH sufficient for rapid oxidation of ephedrine and relatively high UV absorbance for the barbiturates and a detection wavelength near the maximum for benzaldehyde and the barbiturates and the minimum for theophylline. Chromatograms show peaks from iodate, theophylline, phenobarbital, butabarbital, and benzaldehyde, in order of increasing retention time, all within the dynamic range of a conventional recorder. Procedures are provided for the assay of conventional and sustained-action tablet formulations.

**Keyphrases** □ High-pressure liquid chromatography—simultaneous determination of theophylline, ephedrine hydrochloride, and phenobarbital, conventional and sustained-action tablet formulations □ Theophylline—simultaneous determination with ephedrine hydrochloride and phenobarbital by high-pressure liquid chromatography, conventional and sustained-action tablet formulations □ Ephedrine hydrochloride—simultaneous determination with theophylline and phenobarbital by high-pressure liquid chromatography, conventional and sustained-action tablet formulations □ Phenobarbital—simultaneous determination with theophylline and ephedrine hydrochloride by high-pressure liquid chromatography, conventional and sustained-action tablet formulations

The theophylline, ephedrine hydrochloride, and phenobarbital tablet is recognized in USP XX (1), which provides a laborious assay in which the drug components are separated by chromatography on two partition columns and solvent extraction and then determined by UV spectrometry. Elefant *et al.* (2) described a GLC assay for this formulation, and Schultz and Paveenbampen (3) reported one for a similar suspension dosage form. Both methods require derivative formation, and neither has proved satisfactory in speed and convenience.

High-pressure liquid chromatography (HPLC) affords easy separation of the three active components of the formulations; however, the enormous differences in their relative amounts and in their UV absorption maxima and absorptivities make their simultaneous determination by HPLC with UV detection a challenging analytical problem. This report describes an innovative solution to this problem, affording peaks within one dynamic range span of a recorder.

## BACKGROUND

Conventional tablets, the USP formulation, declare 130 mg of hydrous theophylline, 24 mg of ephedrine hydrochloride, and 8 mg of phenobarbital; similar proportions are in sustained-action tablets. Hydrous theophylline shows a UV maximum at ~271 nm with an absorptivity (liters per gram centimeter) of ~48. Its UV spectrum is not affected greatly by pH. In acidic solution, ephedrine and phenobarbital have weak UV spectra due to their benzene ring structure, with maxima at ~256 nm and absorptivities of ~1.

Penner[1] developed a normal-phase HPLC method using detection at 254 nm and an attenuation change between elution of the phenobarbital and theophylline peaks to keep the latter on the recorder scale. Suraski and DiPede[2] developed this method further, using a separate injection of greater dilution to keep the theophylline peak within the recorder dynamic range. They suggested that use of a computing integrator could allow for one injection of all three drug components. In this method, ephedrine and phenobarbital are determined simultaneously and theophylline is determined separately, using the same chromatographic system. It is also possible to determine phenobarbital and theophylline together and ephedrine separately. The UV maximum of phenobarbital can be shifted to ~240 nm with an absorptivity of ~43 by raising the pH to 9–11, where the predominant UV chromophore is the monoanion of the ureide ring; however, a high pH is incompatible with HPLC column

stability. The UV spectrum of ephedrine is not affected significantly by changes in pH.

One solution to the problems of simultaneous determination of all three drugs in conventional and sustained-action tablets is described here. A reversed-phase HPLC method was developed with butabarbital as the internal standard. The internal standard solution contains periodate, which oxidizes ephedrine to benzaldehyde without affecting theophylline or the barbiturates. UV detection is at 241 nm, at the maximum for the barbiturates and benzaldehyde and near the absorption minimum for theophylline, thus minimizing the concentration difference. All three drug components and the internal standard are on scale so the method can be employed using peak responses from a recorded chromatogram as well as from computerized data reduction systems.

## EXPERIMENTAL

**Apparatus**—The HPLC instrument included a solvent delivery system[3], a microparticulate reversed-phase column of octadecylsilane bonded on silica[4], and a UV detector[5] set at 241 nm. An automatic sampler[6] and a computing integrator[7] were used.

**Mobile Phase**—Acetonitrile (240 ml) was mixed with pH 7.8, 0.01 *M* phosphate buffer (760 ml).

**Internal Standard**—Butabarbital sodium (25 mg) was dissolved in 1.7% (w/v) dibasic potassium phosphate solution (50 ml). Then 40 ml of this solution was mixed with 10 ml of 1% (w/v) sodium metaperiodate solution.

**Standard Preparation**—*Tablets*—About 120 mg of theophylline USP reference standard, 8 mg of phenobarbital USP reference standard, and 25 mg of ephedrine sulfate USP reference standard were weighed accurately and transferred to a 200-ml volumetric flask. The standards were dissolved in 10 ml of methanol and ~100 ml of chloroform and diluted to the mark with chloroform. Then 15.0 ml of this solution was pipetted into a 50-ml volumetric flask and diluted to volume with chloroform.

*Sustained-Action Tablets*—About 204 mg of theophylline USP reference standard, 25 mg of phenobarbital USP reference standard, and 53 mg of ephedrine sulfate USP reference standard were weighed accurately into a 200-ml volumetric flask. This mixture was dissolved in 10 ml of methanol and ~100 ml of chloroform and diluted to volume with chloroform. Then 20.0 ml of this solution was pipetted into a 100-ml volumetric flask and diluted to volume with chloroform.

**Assay Preparation**—*Tablets*—Not less than 20 tablets were weighed and finely powdered. A portion of the powdered tablets equivalent to about one average tablet weight was weighed accurately, transferred to a 200-ml volumetric flask, and shaken mechanically for 20 min with 10 ml of methanol and 100 ml of chloroform. Chloroform was added to the mark, the solution was mixed and filtered, and exactly 15.0 ml of the filtrate was diluted to 50 ml in a volumetric flask with chloroform.

*Sustained-Action Tablets*—Not less than 20 tablets were weighed and finely powdered. An amount of powder equivalent to about one average tablet weight was weighed accurately, transferred to a 200-ml volumetric flask, and shaken mechanically for 20 min with 10 ml of methanol and 100 ml of chloroform. Chloroform was added to the mark, and the solution was mixed and filtered. Then 20.0 ml of the filtrate was pipetted into a 100-ml volumetric flask and diluted to volume with chloroform.

*Procedure*—The assay preparation (10.0 ml) and standard preparation (10.0 ml) were pipetted into 25-ml glass-stoppered conical flasks and evaporated to dryness in a warm water bath with the aid of a stream of air. The residues were dissolved in 4.0 ml of the internal standard solution, and the flasks were stoppered and mixed. Then they were permitted to stand at room temperature for 30 min. Then 1.0 ml of 1% (v/v) aqueous propylene glycol solution was added to each flask, and the flasks were stoppered and mixed.

**System Suitability**—*Resolution*—A flow rate of 1.0 ml/min for the mobile phase was set, and the system was allowed to equilibrate until a stable baseline was obtained on the recorder. Then 10 μl of the standard preparation solution was injected into the chromatograph at 0.24-aufs detection sensitivity when the recorder was used or at a suitable attenuation when a computing integrator was used. (An attenuation setting of 16 was used for the instrument employed in these studies[7].)

In order of increasing elution time, the five peaks are iodate (from the reagent), theophylline, phenobarbital, butabarbital, and benzaldehyde (from ephedrine). They should be completely resolved, with resolution factors between each pair of neighboring peaks of not less than 1.5. The resolution factor, $R$, is calculated from $2(tr_y - tr_x)/(W_y + W_x)$, where $tr_y$ and $tr_x$ are the retention times for neighboring peaks $x$ and $y$, the latter having the longer retention time, and $W_x$ and $W_y$ are the peak widths at the baseline for the respective peaks.

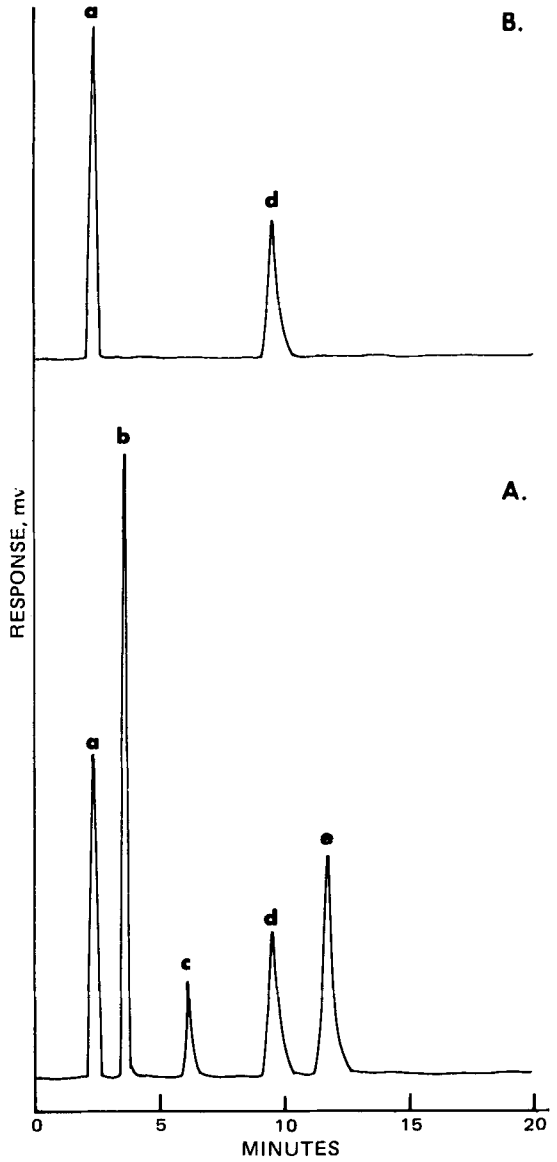

**Figure 1**—*Chromatograms of internal standard (B) and standard preparation (A). Key: a, iodate; b, theophylline; c, phenobarbital; d, butabarbital; and e, ephedrine as benzaldehyde.*

*Linearity*—Solutions at concentration levels of about 80, 90, 100, 110, and 120% of the appropriate standard preparation were prepared. Then each solution (10 μl) was injected into the liquid chromatograph. The concentrations of each active component were plotted against the respective ratios of its peak response to that of the internal standard. A straight line should be obtained in each instance.

*Assay*—Alternately 10 μl of the solutions from the standard preparation and the assay preparation was injected by means of a fixed-volume loop, and the peak responses were determined. The ratios of the peak responses were determined for theophylline, ephedrine hydrochloride as benzaldehyde, and phenobarbital to the internal standard in the chromatograms from the standard preparation and the assay preparation. The amount of each active ingredient, in milligrams per tablet, was calculated from $FC(R_U/R_S)(T/S)$, where $C$ is the exact concentration, in milligrams per milliliter, of the assayed component in the standard preparation; $R_U$ and $R_S$ are the response ratios for each to the internal standard for the chromatograms from the assay preparation and the

**Table I—Dilution Factors [a]**

| Drug | Conventional Tablets | Sustained-Action Tablets |
|---|---|---|
| Theophylline | 733.3 | 1000 |
| Ephedrine hydrochloride | 627.3 | 941 |
| Phenobarbital | 667 | 1000 |

[a] The theophylline factor includes 1.100, the ratio of the molecular weights of hydrous and anhydrous theophylline. The ephedrine hydrochloride factor includes 0.941, the ratio of the equivalent weights of the hydrochloride and sulfate salts.

standard preparation, respectively; $T$ and $S$ are the weights, in milligrams, of the average tablet and of the portion of the tablet taken for assay, respectively; and $F$ represents the factors from dilutions (Table I).

## RESULTS AND DISCUSSION

Figure 1 shows typical chromatograms for a conventional tablet formulation and a placebo mixture in which a reagent peak appears at ~2.3 min due to iodate, at ~3.5 min due to theophylline, at ~6.0 min due to phenobarbital, and at ~9.4 min due to butabarbital; benzaldehyde, from ephedrine, has a retention time of ~11.7 min. The chromatograms show no interference from the excipients and the oxidation products of propylene glycol, formaldehyde, and acetaldehyde.

**Table III—Recovery Data at 80 and 120% Label Claim**

| Drug | Percent Found: 80 | 120 |
|---|---|---|
| | Conventional Tablets | |
| Theophylline | 82.2, 81.9 | 117.8, 119.5 |
| Ephedrine hydrochloride | 82.4, 82.6 | 120.3, 123.1 |
| Phenobarbital | 79.7, 79.0 | 121.4, 118.8 |
| | Sustained-Action Tablets | |
| Theophylline | 80.7, 80.7 | 117.9, 118.8 |
| Ephedrine hydrochloride | 79.4, 79.4 | 118.4, 118.6 |
| Phenobarbital | 79.1, 79.7 | 119.5, 120.3 |

The determination of ephedrine as benzaldehyde after periodate oxidation was shown to be stability indicating by Chafetz (4). Omission of periodate from the system had no effect on the retention times or response of theophylline, phenobarbital, or butabarbital. Ephedrine was moved to a retention time of ~20 min; however, its response was decreased by a factor of >200. Ephedrine can be visualized only by changing the detector to ~260 nm and using an increased concentration or lower attenuation.

The UV detection of phenobarbital and butabarbital at 241 nm is due to the monoanion form of the ureide ring, the unionized form having little absorbance in the near UV; hence, the incorporation of pH 7.8 buffer in the mobile phase. This mobile phase provides sufficient alkalinity to be in the $pKa_1$ range for the barbiturates and for a rapid reaction rate of periodate with ephedrine. (The apparent pH of the mobile phase is 8.3.)

Precision and recovery data for conventional and sustained-action theophylline, ephedrine hydrochloride, and phenobarbital tablets are shown in Tables II and III. Calculation of resolution factors between adjacent peaks provides values greater than 5. Peak response ratios *versus* concentrations for each component to the internal standard were rectilinear. Recovery was determined by adding known amounts of the drugs to the excipients, which included starch, lactose, stearic acid, and polyethylene glycol 6000 for conventional tablets and starch USP, lactose USP, stearic acid powder, polyethylene glycol 6000, guar gum, methylcellulose USP, sugar powder, ethylcellulose NF, magnesium stearate USP, carnauba wax, D&C Red No. 30 lake, and D&C Yellow No. 10 lake for sustained-action tablets.

activity studies among catecholamine analogs, with emphasis on the P-388 leukemia activity of phenethylamine and benzylamine compounds. In that study, the benzylamine analog (I) of dopamine (II) was active against P-388 leukemia. The trihydroxy compound, 5-hydroxydopamine (III), also was active. The current study extended this work to additional benzylamine derivatives including two trihydroxy analogs.

## RESULTS AND DISCUSSION

3,4,5-Trimethoxybenzylamine (IV) was prepared by two routes to determine the advantages of catalytic *versus* chemical reduction as synthetic procedures in the benzylamine series (Scheme I). Reduction of the amide with sodium acetoxyborohydride (6) produced IV in a 50% yield. Catalytic reduction of the nitrile in chloroform by the method of Secrist and Logue (7) gave a somewhat better yield of IV (75%) and is the method of choice. Cleavage of the methoxyl groups with hydroiodic acid (8) yielded the target compound 3,4,5-trihydroxybenzylamine as the hydroiodide (V). Several isomeric di- and trihydroxybenzylamines were prepared previously as either free bases or hydrochloride salts (9). The synthesis of 2,3,4-trihydroxybenzylamine hydroiodide (VII) was accomplished by the borohydride method, while 2,3-dihydroxybenzylamine hydroiodide (XI) was prepared in good yield by catalytic reduction of the nitrile followed by hydroiodic acid treatment.

The antitumor results are shown in Table I. The compounds (I–III) on which the present study is based were previously shown to be active against P-388 leukemia (4). The target compounds, V and XI, were determined to be active, but VII gave T/C values[1] of only 123 and 121%. The corresponding acetophenone (VIII), however, was active, and the activity of 3,4-dihydroxybenzaldehyde (XIII) was confirmed.

The generalized structure–activity relationships described previously for the catecholamines (4) continue to apply in the benzylamine series. Positioning of vicinal hydroxyl groups in the benzylamine series such that oxidation to *ortho*-derivatives might occur provides active materials (I, V, VIII, XI, and XIII). Dihydroxy compounds that cannot be oxidized to a quinoid form (XIV) or can be oxidized only to a *p*-quinone (XV) are inactive. As noted previously (4), dihydroxybenzoic acid (XII) analogs are not active. The addition of an apparent excess of lipophilic character converts an active compound (VIII) to an inactive one (IX).

2,3,4-Trihydroxybenzylamine (VII) was expected to be active against P-388 leukemia but was not. Two good P-388 dose–response experiments employing five doses each (range 600–50 mg/kg) gave values that approached but did not exceed a T/C value of 125%. Compound VII showed more toxicity than the other analogs, with the doses at 600, 400, and 200 mg/kg being toxic in each experiment.

[1] Percent T/C = (treated survival to control survival) × 100%.

**Table I—P-388 Lymphocytic Leukemia Antitumor Activity [a]**

| Compound | Optimum Dose, mg/kg/day | T/C, % | T − C, g |
|---|---|---|---|

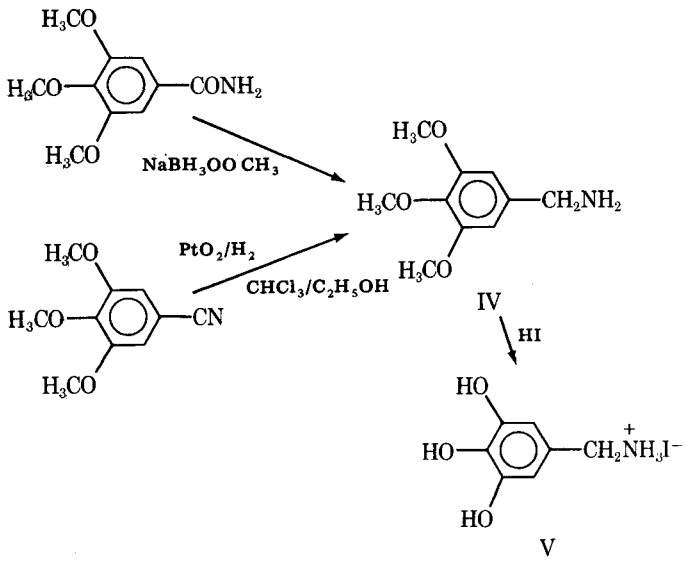
## EXPERIMENTAL[2]

**3,4,5-Trimethoxybenzylamine (IV)**—*Method A*—3,4,5-Trimethoxybenzamide (3.6 g, 18 mmoles) and sodium borohydride (3.1 g, 82 mmoles) were suspended in 40 ml of dried *p*-dioxane. To the suspension was added acetic acid (4.8 g, 80 mmoles) in 20 ml of dried *p*-dioxane over 20 min at 10°. The resulting mixture was refluxed for 3 hr. After cooling, water was added to decompose the excess borohydride, and the mixture was evaporated to dryness under reduced pressure. The residue was stirred in 100 ml of chloroform and filtered, and the filtrate was saturated with hydrogen chloride gas. A white hydrochloride was produced after evaporation, and it was dissolved in a minimum amount of water and extracted once with ethyl acetate.

The aqueous layer was made basic with 10% NaOH and saturated with sodium chloride. The mixture was extracted twice with ether. The ether extracts were combined, dried over sodium sulfate, and evaporated to dryness to give 1.8 g (50%) of an oil. The NMR spectrum indicated that IV was pure; NMR (deuterochloroform): 1.68 (s, 2H, $NH_2$), 3.9 (m, 11H, $CH_3$ and $CH_2$), and 6.65 (s, 2H, aromatic). This product was used without further purification for the next step.

*Method B*—3,4,5-Trimethoxybenzonitrile (7.5 g, 39 mmoles) was dissolved in 250 ml of absolute ethanol and 10 ml of chloroform and was



*Scheme I*

[2] All melting points are uncorrected and were recorded on a Thomas–Hoover capillary apparatus. Elemental analyses were performed by Galbraith Laboratories, Knoxville, Tenn. NMR data are delta values relative to tetramethylsilane in deuterochloroform or 3-(trimethylsilyl)propionic acid sodium salt in deuterium oxide. Starting materials and compounds not described under *Experimental* were obtained from Aldrich Chemical Co.

hydrogenated over platinum oxide (0.5 g) at 45 psi for 5 hr. The catalyst was filtered, and the filtrate was evaporated to dryness under reduced pressure to give a white powder. The hydrochloride salt thus obtained was dissolved in 30 ml of water and extracted twice with ether. The aqueous layer was made basic with 10% NaOH, saturated with sodium chloride, and extracted three times with ether. The ether extracts were combined, dried over sodium sulfate, and evaporated to dryness to give 5.6 g (75%) of pale-yellow oil with an NMR spectrum identical to that described for the product from Method A.

**3,4,5-Trihydroxybenzylamine Hydroiodide (V)**—To a magnetically stirred solution of IV (7.5 g, 38 mmoles) in 47% hydroiodic acid (75 ml, 470 mmoles) under nitrogen was added, by syringe, 43.5 ml (460 mmoles) of acetic anhydride through a septum. The reaction mixture was refluxed for 4 hr and evaporated to dryness *in vacuo*. Ethanol (100 ml) was added to the residue, and the solvent was evaporated again to yield a pale-yellow powder (5.0 g, 46%). Recrystallization from ethanol plus ether gave fine crystals, mp 196–198° dec.; NMR (deuterium oxide): 4.00 (s, 2H, $CH_2$) and 6.55 (s, 2H, aromatic).

*Anal.*—Calc. for $C_7H_9NO_3$·HI: C, 29.68; H, 3.53; N, 4.96. Found: C, 29.66; H, 3.52; N, 4.81.

**2,3,4-Trimethoxybenzylamine (VI)**—Compound VI was prepared as an oil in a 73% yield on a 5-g scale from the amide, using borohydride reduction as described for IV. It was used without further purification; NMR (deuterochloroform): 1.95 (s, 2H, $NH_2$), 3.70 (s, 2H, $CH_2$), 3.79–3.83 (m, 9H, $CH_3$), 6.50 (d, 1H, $J$ = 4.5 Hz, aromatic), and 6.85 (d, 1H, $J$ = 4.5 Hz, aromatic).

**2,3,4-Trihydroxybenzylamine Hydroiodide (VII)**—Compound VII, mp 178–181° dec., was prepared on a 7-g scale (89%) from VI by the procedure used for V; NMR (deuterium oxide): 4.15 (s, 2H, $CH_2$), 6.50 (d, 1H, $J$ = 4.5 Hz, aromatic), and 6.81 (d, 1H, $J$ = 4.5 Hz, aromatic).

*Anal.*—Calc. for $C_7H_9NO_3$·HI: C, 29.68; H, 3.53; N, 4.96. Found: C, 29.81; H, 3.70; N, 4.87.

**2,3-Dimethoxybenzylamine (X)**—2,3-Dimethoxybenzonitrile (3.29 g, 20 mmoles) was dissolved in 200 ml of absolute ethanol, and 10 ml of chloroform and 0.5 g of platinum oxide were added to this solution. The mixture was hydrogenated for 3 hr at 40 psi, the catalyst was filtered, and the solvent was evaporated. Then the residue was dissolved in a minimum amount of water and made basic with 10% NaOH. The mixture was saturated with sodium chloride and extracted three times with ether. The ether extracts were combined, dried over sodium sulfate, and evaporated to dryness to give 2.9 g (90%) of a yellow oil. The oil was used without further purification; NMR (deuterochloroform): 2.25 (s, 2H, $NH_2$), 3.8 (m, 8H, $CH_2$ and $CH_3$), and 6.81 (m, 3H, aromatic).

**2,3-Dihydroxybenzylamine Hydroiodide (XI)**—Compound XI, mp 157–158° dec., was prepared from X on a 5-g scale (60%) by the procedure used for V; NMR (deuterium oxide): 4.20 (s, 2H, $CH_2$) and 6.95 (m, 3H, aromatic).

*Anal.*—Calc. for $C_7H_9NO_2$·HI: C, 31.46; H, 3.75; N, 5.24. Found: C, 31.59; H, 3.96; N, 5.26.

**Antitumor Testing**—Antitumor activity was determined as percent T/C values, with T/C ≥ 125% defined as statistically significant (Table I). Dose–response studies were carried out for each compound according to published National Cancer Institute protocols (10). Six mice per dose were inoculated intraperitoneally with $10^6$ P-388 leukemia cells on Day 0. Control (untreated) mice usually died on about Day 11. Mice receiving drug were treated on Days 1–9 with intraperitoneal doses of the compound under investigation. Physiological saline (0.9%) was the vehicle. The mice (average weight 20 g) were weighed on Day 5; the weight difference between treated and control mice (T − C) was an indication of dose toxicity. Weight losses greater than 4 g were considered excessive.

# Aluminum Chlorohydrate III: Conversion to Aluminum Hydroxide

**DIRK L. TEAGARDEN *, JOE L. WHITE ‡, and STANLEY L. HEM *x**

Received October 3, 1980, from the **Department of Industrial and Physical Pharmacy and the* ‡*Department of Agronomy, Purdue University, West Lafayette, IN 47907.* Accepted for publication December 8, 1980.

**Abstract** □ Bayerite, an aluminum hydroxide polymorph, readily forms when the hydroxyl to aluminum ratio of aluminum chlorohydrate is raised to 3 by titration with sodium hydroxide. Dilution of aluminum chlorohydrate solutions with water leads to the formation of gibbsite, another aluminum hydroxide polymorph. The mechanism of conversion in each instance is related to the structure of the $Al_{13}O_4(OH)_{24}(H_2O)_{12}^{7+}$ complex.

**Keyphrases** □ Aluminum chlorohydrate—conversion to aluminum hydroxide □ Aluminum hydroxide—conversion from aluminum chlorohydrate □ Antiperspirant activity—conversion of aluminum chlorohydrate to aluminum hydroxide

Aluminum chlorohydrate recently was shown (1) to be the $Al_{13}O_4(OH)_{24}(H_2O)_{12}^{7+}$ (I) complex described by Johansson *et al.* (2). This structure is unusual in that it is composed of a central aluminum atom in tetrahedral configuration surrounded by 12 octahedral aluminum atoms. The charge is neutralized by chloride ions. In contrast, aluminum hydroxide is composed exclusively of aluminum in octahedral configuration. The basic unit of aluminum hydroxide is a six-member ring composed of aluminum in octahedral configuration formed by a dehydration–deprotonation reaction (3). The relationship between aluminum chlorohydrate and aluminum hydroxide was demonstrated by examining the effect of neutralizing aluminum chlorohydrate by the addition of sodium hydroxide and the effect of diluting with water.

## EXPERIMENTAL

Aluminum chlorohydrate was obtained commercially as a 50% (w/w) solution[1]. The effect of increasing the hydroxyl to aluminum ratio of aluminum chlorohydrate to 3 was studied by adding 500 ml of 0.394 *N* NaOH at a rate[2] of 10 ml/min to 500 ml of an aluminum chlorohydrate

hydrogenated over platinum oxide (0.5 g) at 45 psi for 5 hr. The catalyst was filtered, and the filtrate was evaporated to dryness under reduced pressure to give a white powder. The hydrochloride salt thus obtained was dissolved in 30 ml of water and extracted twice with ether. The aqueous layer was made basic with 10% NaOH, saturated with sodium chloride, and extracted three times with ether. The ether extracts were combined, dried over sodium sulfate, and evaporated to dryness to give 5.6 g (75%) of pale-yellow oil with an NMR spectrum identical to that described for the product from Method A.

**3,4,5-Trihydroxybenzylamine Hydroiodide (V)**—To a magnetically stirred solution of IV (7.5 g, 38 mmoles) in 47% hydroiodic acid (75 ml, 470 mmoles) under nitrogen was added, by syringe, 43.5 ml (460 mmoles) of acetic anhydride through a septum. The reaction mixture was refluxed for 4 hr and evaporated to dryness *in vacuo*. Ethanol (100 ml) was added to the residue, and the solvent was evaporated again to yield a pale-yellow powder (5.0 g, 46%). Recrystallization from ethanol plus ether gave fine crystals, mp 196–198° dec.; NMR (deuterium oxide): 4.00 (s, 2H, $CH_2$) and 6.55 (s, 2H, aromatic).

*Anal.*—Calc. for $C_7H_9NO_3$·HI: C, 29.68; H, 3.53; N, 4.96. Found: C, 29.66; H, 3.52; N, 4.81.

**2,3,4-Trimethoxybenzylamine (VI)**—Compound VI was prepared as an oil in a 73% yield on a 5-g scale from the amide, using borohydride reduction as described for IV. It was used without further purification; NMR (deuterochloroform): 1.95 (s, 2H, $NH_2$), 3.70 (s, 2H, $CH_2$), 3.79–3.83 (m, 9H, $CH_3$), 6.50 (d, 1H, $J$ = 4.5 Hz, aromatic), and 6.85 (d, 1H, $J$ = 4.5 Hz, aromatic).

**2,3,4-Trihydroxybenzylamine Hydroiodide (VII)**—Compound VII, mp 178–181° dec., was prepared on a 7-g scale (89%) from VI by the procedure used for V; NMR (deuterium oxide): 4.15 (s, 2H, $CH_2$), 6.50 (d, 1H, $J$ = 4.5 Hz, aromatic), and 6.81 (d, 1H, $J$ = 4.5 Hz, aromatic).

*Anal.*—Calc. for $C_7H_9NO_3$·HI: C, 29.68; H, 3.53; N, 4.96. Found: C, 29.81; H, 3.70; N, 4.87.

**2,3-Dimethoxybenzylamine (X)**—2,3-Dimethoxybenzonitrile (3.29 g, 20 mmoles) was dissolved in 200 ml of absolute ethanol, and 10 ml of chloroform and 0.5 g of platinum oxide were added to this solution. The mixture was hydrogenated for 3 hr at 40 psi, the catalyst was filtered, and the solvent was evaporated. Then the residue was dissolved in a minimum amount of water and made basic with 10% NaOH. The mixture was saturated with sodium chloride and extracted three times with ether. The ether extracts were combined, dried over sodium sulfate, and evaporated to dryness to give 2.9 g (90%) of a yellow oil. The oil was used without further purification; NMR (deuterochloroform): 2.25 (s, 2H, $NH_2$), 3.8 (m, 8H, $CH_2$ and $CH_3$), and 6.81 (m, 3H, aromatic).

**2,3-Dihydroxybenzylamine Hydroiodide (XI)**—Compound XI, mp 157–158° dec., was prepared from X on a 5-g scale (60%) by the procedure used for V; NMR (deuterium oxide): 4.20 (s, 2H, $CH_2$) and 6.95 (m, 3H, aromatic).

*Anal.*—Calc. for $C_7H_9NO_2$·HI: C, 31.46; H, 3.75; N, 5.24. Found: C, 31.59; H, 3.96; N, 5.26.

**Antitumor Testing**—Antitumor activity was determined as percent T/C values, with T/C ≥ 125% defined as statistically significant (Table I). Dose–response studies were carried out for each compound according to published National Cancer Institute protocols (10). Six mice per dose were inoculated intraperitoneally with $10^6$ P-388 leukemia cells on Day 0. Control (untreated) mice usually died on about Day 11. Mice receiving drug were treated on Days 1–9 with intraperitoneal doses of the compound under investigation. Physiological saline (0.9%) was the vehicle. The mice (average weight 20 g) were weighed on Day 5; the weight difference between treated and control mice (T − C) was an indication of dose toxicity. Weight losses greater than 4 g were considered excessive.

# Aluminum Chlorohydrate III: Conversion to Aluminum Hydroxide

**DIRK L. TEAGARDEN *, JOE L. WHITE ‡, and STANLEY L. HEM *x**

Received October 3, 1980, from the **Department of Industrial and Physical Pharmacy and the* ‡*Department of Agronomy, Purdue University, West Lafayette, IN 47907.* Accepted for publication December 8, 1980.

**Abstract** □ Bayerite, an aluminum hydroxide polymorph, readily forms when the hydroxyl to aluminum ratio of aluminum chlorohydrate is raised to 3 by titration with sodium hydroxide. Dilution of aluminum chlorohydrate solutions with water leads to the formation of gibbsite, another aluminum hydroxide polymorph. The mechanism of conversion in each instance is related to the structure of the $Al_{13}O_4(OH)_{24}(H_2O)_{12}^{7+}$ complex.

**Keyphrases** □ Aluminum chlorohydrate—conversion to aluminum hydroxide □ Aluminum hydroxide—conversion from aluminum chlorohydrate □ Antiperspirant activity—conversion of aluminum chlorohydrate to aluminum hydroxide

Aluminum chlorohydrate recently was shown (1) to be the $Al_{13}O_4(OH)_{24}(H_2O)_{12}^{7+}$ (I) complex described by Johansson *et al.* (2). This structure is unusual in that it is composed of a central aluminum atom in tetrahedral configuration surrounded by 12 octahedral aluminum atoms. The charge is neutralized by chloride ions. In contrast, aluminum hydroxide is composed exclusively of aluminum in octahedral configuration. The basic unit of aluminum hydroxide is a six-member ring composed of aluminum in octahedral configuration formed by a dehydration–deprotonation reaction (3). The relationship between aluminum chlorohydrate and aluminum hydroxide was demonstrated by examining the effect of neutralizing aluminum chlorohydrate by the addition of sodium hydroxide and the effect of diluting with water.

## EXPERIMENTAL

Aluminum chlorohydrate was obtained commercially as a 50% (w/w) solution[1]. The effect of increasing the hydroxyl to aluminum ratio of aluminum chlorohydrate to 3 was studied by adding 500 ml of 0.394 *N* NaOH at a rate[2] of 10 ml/min to 500 ml of an aluminum chlorohydrate

solution, which was 0.788 *M* in aluminum. Upon completion of the titration, stirring was continued for 10 min; the solid phase that formed was washed with distilled water. After air drying, the solid phase was examined by X-ray diffraction[3] and IR spectroscopy[4].

The effect of dilution with deionized water was studied by adding enough distilled water to the commercial 50% (w/w) aluminum chlorohydrate solution (6.2 *M* in aluminum) to produce solutions ranging from $1.39 \times 10^{-3}$ to 2.5 *M* in aluminum. The solutions were aged at 25° in plastic bottles. Turbidity was monitored by measuring the absorbance at 400 nm. The white precipitate that formed in some solutions was collected by filtration through a 100-Å filter[5]. The solid phase was washed with distilled water and lyophilized. A sample of the filtrate also was lyophilized. Both lyophilized samples were examined by IR spectroscopy as potassium bromide pellets.

## RESULTS AND DISCUSSION

The relationship between aluminum chlorohydrate and aluminum hydroxide was investigated by titrating an aluminum chlorohydrate solution with sodium hydroxide until the hydroxyl to aluminum ratio was 3. Figure 1 shows the hydroxyl-stretching region of the IR spectrum before and after titration. After 10 days, this region was much sharper, and indications of distinct absorption bands had developed. After 111 days,

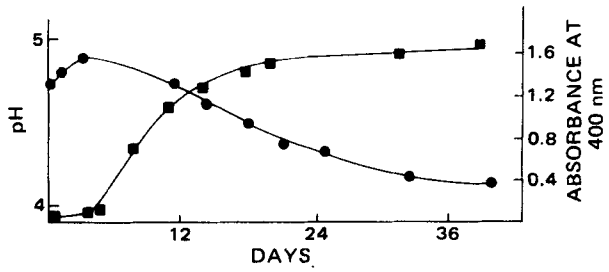

**Figure 2**—*Change in pH (●) and turbidity (■) following dilution of aluminum chlorohydrate to $2.5 \times 10^{-2}$ M in aluminum during aging at 25°.*

sharp bands occurred at 3650, 3540, and 3460 $cm^{-1}$. These hydroxyl-stretching bands correspond to the hydroxyl-stretching vibrations of bayerite (4). The X-ray diffractogram of the 111-day sample had sharp peaks at 4.72, 4.35, 3.20, 2.22, and 1.72 Å. The position of these peaks also correspond to those of bayerite (4).

The conversion of aluminum chlorohydrate to bayerite can be rationalized based on the structure of the I complex. The added hydroxyl

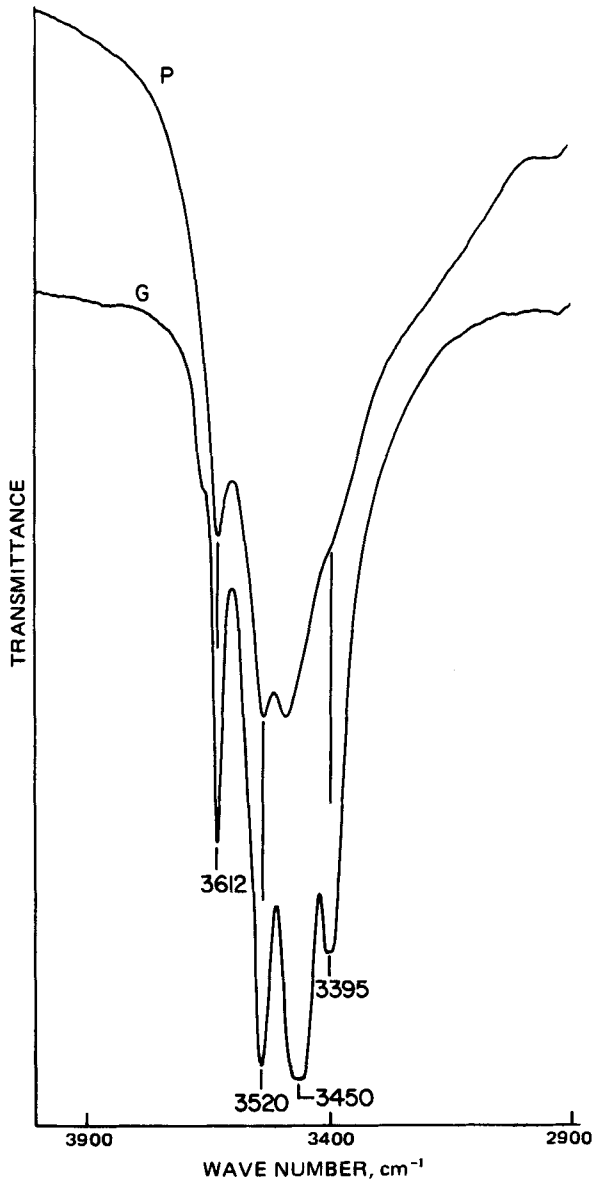

**Figure 3**—*Hydroxyl-stretching frequency region of IR spectrum of solid phase that formed following dilution of aluminum chlorohydrate to $2.5 \times 10^{-2}$ M in aluminum (P) compared to natural gibbsite (G).*

anions are strongly attracted to the highly charged aluminum polynuclear cation. As the charge is neutralized, the complex disassociates and aluminum hydroxide forms. Because the solution pH was raised to 8 by the addition of sodium hydroxide, bayerite, the aluminum hydroxide polymorph that forms under basic conditions, was produced.

Aluminum chlorohydrate also is unstable if it is diluted with water (5, 6). Figure 2 shows that when aluminum chlorohydrate was diluted to $2.5 \times 10^{-2}$ *M* in aluminum, the pH first increased and then decreased. Earlier reports only noted a decrease in pH following dilution. However, the initial increase in pH is important and is consistent with the recently proposed structure of aluminum chlorohydrate (1). The central tetrahedral aluminum in the I complex is surrounded by 12 aluminum atoms in octahedral configuration. In dilute aqueous solution, the highly charged aluminum polycations are widely separated, and the stabilizing effect of the chloride counterions and other aluminum chlorohydrate complexes is reduced. As the I complex disassociates, the tetrahedral aluminum is exposed to the aqueous environment. Since the octahedral configuration is the stable form of aluminum below pH 8 (7–10), the tetrahedral aluminum converts to an octahedral configuration. Exposure of the four negatively charged oxygens, which form the outer shell of the aluminum tetrahedral, to the aqueous environment results in the attraction of protons and water to complete the octahedral configuration. The adsorption of protons is reflected in the initial increase in pH. However, the overall trend is a decrease in pH, which is consistent with the formation of octahedral aluminum into aluminum hydroxy polymers by the deprotonation–dehydroxylation mechanism (3).

The stability of aluminum chlorohydrate is concentration dependent since very little change in pH was observed unless the solution was <0.1 *M* in aluminum. At high concentration, the positively charged I spherical complexes are tightly packed and surrounded by stabilizing chloride counterions. Thus, aluminum chlorohydrate complex is self-stabilizing at high concentration.

Turbidity measurements of the diluted aluminum chlorohydrate solutions also showed that the stability of the complex was concentration dependent. Turbidity was not observed during this study unless the concentration was ~0.1 *M* or lower in terms of aluminum. Figure 2 also shows the development of turbidity following dilution to $2.5 \times 10^{-2}$ *M* in aluminum.

The insoluble degradation product resulting from the dilution of aluminum chlorohydrate was collected by filtration and examined by IR spectroscopy. The hydroxyl-stretching bands coincide with the hydroxyl-stretching bands of gibbsite (Fig. 3). The IR spectrum of the lyophilized filtrate was identical to the reference spectrum for aluminum chlorohydrate (11). Thus, it is believed that the I complex disassociates in dilute solution. The tetrahedral aluminum converts to an octahedral configuration due to the pH, and the octahedral aluminum species form aluminum hydroxide by deprotonation–dehydration. Gibbsite is the end-product of dilution since it is the stable polymorph of aluminum hydroxide in the acidic region. Therefore, the conversion of aluminum chlorohydrate to aluminum hydroxide upon complete neutralization or following dilution with water is consistent with the structure of the I complex that was proposed recently to be aluminum chlorohydrate.

# Modified Colorimetric Method for Plasma Prednisolone

**A. N. NARURKAR and C. I. JAROWSKI** ˣ

Received October 27, 1980, from the *College of Pharmacy and Allied Health Professions, St. John's University, Jamaica, NY 11439.* Accepted for publication January 30, 1981.

**Abstract** □ A simple, precise, rapid, and sensitive colorimetric method was adapted for the quantitative analysis of prednisolone in dog plasma. A paper chromatographic procedure was modified by the use of thin-layer plates coated with microcrystalline cellulose. Heparinized blood samples were separated from the cellular elements and extracted with methylene chloride. After washing with acid and alkali, the extract was evaporated to dryness. The residue was dissolved in methanol and streaked on the TLC plate. After development, the band that was detected by UV light was scraped off and extracted with methanol. The methanol extract was treated with the Porter–Silber reagent (phenylhydrazine). Absorbance was measured at 410 nm. Replicate assays indicated a mean recovery of 97.5% and a coefficient of variation of 5.13%.

**Keyphrases** □ Prednisolone—modified method for colorimetric determination in dog plasma □ Colorimetry—modified method for determination of plasma prednisolone □ Glucocorticoids—prednisolone, colorimetric determination in plasma

The various methods used for the determination of prednisolone in plasma all have one or more shortcomings. Jenkins and Sampson (1) used a paper chromatographic procedure for the isolation of prednisolone after preliminary extraction with methylene chloride. Their procedure was modified by replacing the paper chromatographic procedure with thin-layer plates coated with microcrystalline cellulose. Microcrystalline cellulose was tried after preliminary screening revealed that inefficient separation occurred on the silica gel-coated plates recommended in the USP XX procedure (2).

The modified procedure decreased the time required for separation and also increased assay sensitivity. As a consequence, a simple, direct, and rapid analytical method for prednisolone in plasma was developed independently.

## EXPERIMENTAL

## EXPERIMENTAL

**Materials**—Anhydrous prednisolone USP[1], methanol[2] (HPLC grade),

[1] Merck & Co., Rahway, N.J.
[2] Fisher Scientific Co., Fair Lawn, N.J.

*0022-3549/81/0700-0810$01.00/0*

*© 1981, American Pharmaceutical Association*

toluene[3], methylene chloride[4], sodium hydroxide pellets[2] (analytical reagent grade), acetic acid[2], nitrogen[4], sulfuric acid[2] (analytical reagent grade), and phenylhydrazine hydrochloride[5] were obtained commercially.

**Equipment**—A spectrophotometer[6], a centrifuge[7], an analytical balance[8], a multiple developing tank[9], TLC glass plates[10] precoated with Avicel F (250-$\mu$m thickness), a micropipet[11], a camera with photo-UV system[12], a minerlight lamp, a multiband UV detector[13] (254/366 nm), and a water bath[14] were used.

**Preparation of Prednisolone Standard Solution in Methanol**—A stock solution of prednisolone was prepared by dissolving 100 mg of anhydrous prednisolone USP in 1000 ml of methanol. The stock solution then was diluted serially with methanol to give standard solutions containing 0.5, 1.0, 5.0, 10.0, 20.0, 25.0, and 50.0 $\mu$g of prednisolone/ml.

**Preparation of Reagents**—Dilute sulfuric acid solution (1.63:1) was prepared by adding 190 ml of water to 310 ml of concentrated sulfuric acid. Phenylhydrazine hydrochloride solution (Porter–Silber reagent) was prepared by dissolving 65 mg of phenylhydrazine hydrochloride in 100 ml of the dilute sulfuric acid (3).

**Quantitative Color Reaction for Prednisolone**—Eight milliliters of the phenylhydrazine reagent solution was added to a prednisolone sample in 1 ml of methanol (*i.e.*, various standard solutions of prednisolone in methanol), and the solution was heated to 60 ± 1° for 20 min. The resultant yellow solution was cooled to 25° in a running cold water bath. The methanol–phenylhydrazine–sulfuric acid blank was treated similarly. With a 5-cm cell, the absorbance of the standard solution was measured against a methanol–sulfuric acid–phenylhydrazine reagent blank at 410 nm. Spectrophotometric readings usually were taken within 5 min after color formation. The standard curve then was constructed by plotting the absorbance values *versus* the corresponding prednisolone concentrations.

**Preparation of Plasma Samples**—Blood samples collected from fasted beagle dogs were placed in heparinized tubes and centrifuged at 2300 rpm for 15 min to harvest the clear plasma.

**Preparation of Plasma Standards**—A series of standards was prepared by spiking 4 ml of clear plasma samples with 5.0, 10.0, 15.0, and 20.0 $\mu$g of prednisolone.

**Extraction**—Four milliliters of the plasma standard was extracted with 25 ml of methylene chloride, and the extract was washed with 2 ml of 0.1 *N* NaOH followed by 2 ml of 0.1 *N* acetic acid and then with 2 ml of distilled water. The extract was evaporated to dryness and redissolved in 200 $\mu$l of methanol by agitating on a vortex mixer.

**TLC**—Glass plates (20 × 20 cm) precoated with microcrystalline cellulose to a thickness of 250 $\mu$m were used. The solvent system was toluene–methanol–distilled water (84.8:14.6:0.6).

The chromatographic plate was divided into three equal sections. The left section was used for spotting the prednisolone standard solution in methanol, the right section was used for spotting prednisolone solution extracted from plasma, and the center section was used for the plasma blank. The solutions were applied as streaks 2.5 cm from the bottom of the plate. The solution was dried during application with the aid of a nitrogen stream.

With the described solvent system, the chromatogram was developed in a multiple development tank, previously equilibrated and lined with absorbent paper. The solvent then was allowed to move until it reached 15 cm above the baseline. The plate was removed, dried at room temperature, and visualized under shortwave UV light. The prednisolone standard band and the corresponding bands in the spiked plasma samples and the blank solutions were marked. The $R_f$ value for prednisolone was 0.3. The bands corresponding to this $R_f$ value were removed by scraping the microcrystalline cellulose onto a glazed weighing paper, and the scrapings were pulverized and transferred to 25-ml centrifuge tubes. Methanol (10 ml) was added, and the samples were agitated on a vortex mixer for 5 min and centrifuged at 2300 rpm for 5 min.

The clear methanol layers were decanted, and the residue was treated similarly with 5 ml of methanol three times. The pooled methanolic extracts then were evaporated to a 1-ml volume. These methanolic extracts of prednisolone from plasma were analyzed according to the method described previously. The standard curve of prednisolone in plasma then was constructed by plotting the absorbance values *versus* various prednisolone concentrations.

**Table I—Estimation of Prednisolone (20 $\mu$g/4 ml) in Plasma [a]**

| Sample Replicate Number | Estimated, $\mu$g/4 ml | Recovery, % |
|---|---|---|
| 1 | 19.25 | 96.25 |
| 2 | 19.50 | 97.50 |
| 3 | 20.25 | 101.25 |
| 4 | 21.00 | 105.00 |
| 5 | 18.25 | 91.25 |
| 6 | 18.75 | 93.75 |
| Mean | | 97.50 |

[a] Coefficient of variation = (standard deviation × 100)/mean = (1 × 100)/19.50 = 5.13%.

## RESULTS AND DISCUSSION

**Variation of Absorbance with Prednisolone in Methanolic Phenylhydrazine Acid Solution**—With 0.5–50 $\mu$g of prednisolone, the absorbance varied linearly with the amount of prednisolone. Under the experimental conditions, the Porter–Silber colorimetric method was sensitive to 1 $\mu$g of prednisolone. The regression equation obtained was $y = 0.023x + 0.0062$, and the correlation coefficient was 0.9998.

**Standard Curve of Prednisolone in Plasma**—Plots of absorbance *versus* 5–20 $\mu$g of prednisolone/4 ml of plasma were linear, passing through the origin with a slope of 0.023. The extraction caused a prednisolone loss of ~10%. The regression equation obtained was $y = 0.023x + 0.0068$, and the correlation coefficient was 0.9997.

**Method Accuracy and Precision**—Table I lists the results obtained from the analysis of a number of spiked plasma samples (20 $\mu$g/4 ml). These data reflect the accuracy and precision of the method. The mean recovery and the coefficient of variation were 97.5 and 5.13%, respectively.

In summary, TLC separation of microgram quantities of prednisolone extracted from dog plasma were assayed efficiently by a simple colorimetric procedure. This procedure should be considered when more sophisticated equipment or procedures are not available.

# Identification of 2-Chlorothioxanthen-9-one in Gastric Aspirate in a Case of Chlorprothixene Poisoning

**JON ELLING PETTERSEN** *§x, **GERD TEIEN** ‡, and **GUNNAR ARNFINN ULSAKER** ‡

Received November 10, 1980, from the *Institute of Clinical Biochemistry, University of Oslo, Rikshospitalet, Oslo, Norway, and the ‡National Centre for Medicinal Products Control, Oslo, Norway. Accepted for publication December 2, 1980. §Present address: Department of Clinical Chemistry, Institute of Medical Biology, University of Tromsø, N-9001 Tromsø, Norway.

**Abstract** □ In gastric aspirate from a case of severe chlorprothixene poisoning, large amounts (~30% of the chlorprothixene) of a previously unrecognized compound were found and identified tentatively as 2-chlorothioxanthen-9-one by combined GLC–low-resolution mass spectrometry and high-resolution mass spectrometry. The identity of the unknown compound was verified after synthesis of 2-chlorothioxanthen-9-one by two procedures. Only negligible amounts of 2-chlorothioxanthen-9-one were formed when chlorprothixene, dissolved in acids, bases, chloroform–isopropanol, methanol, or gastric fluid, was stored in the dark. However, large amounts of the drug were converted to 2-chlorothioxanthen-9-one upon exposure to UV light. Moreover, considerable quantities of unidentified degradation products were formed when chlorprothixene was exposed to lamp light as well as to UV light. Therefore, samples from cases of acute drug poisoning should be protected from light until analysis.

**Keyphrases** □ Chlorprothixene—degradation product identification, GLC–mass spectrometry, gastric aspirate □ GLC–mass spectrometry—analysis, chlorprothixene and degradation product, gastric aspirate □ Thioxanthene derivatives—chlorprothixene and degradation product, GLC–mass spectrometric analysis, gastric aspirate □ Tranquilizers—chlorprothixene, GLC–mass spectrometric analysis, gastric aspirate, degradation product

In our hospital, gastric lavage is performed routinely in all patients with suspected intoxication, and it is useful to analyze gastric aspirate (and unknown tablets) by combined GLC–mass spectrometry for the primary detection of the intoxicants in cases of acute drug poisoning (1). An advantage of using gastric aspirate samples is that nonmetabolized drugs may be demonstrated. This task is much simpler than identifying drug metabolites, which may be found in the urine, for example.

Seven thioxanthene derivatives have been described in humans after chlorprothixene ingestion. They all are probably true metabolites of the drug and not postmortem degradation products (2, 3). In the present work, an additional thioxanthene derivative, 2-chorothioxanthen-9-one, was identified in the gastric aspirate from a case of severe chlorprothixene poisoning.

## EXPERIMENTAL

Chlorprothixene[1] [3-(2-chloro-9*H*-thioxanthen-9-ylidene)-*N*,*N*-dimethyl-1-propanamine, I] was purchased. 2-Chlorothioxanthen-9-one was synthesized by a convenient new method—*viz.*, oxidation of chlorprothixene by potassium permanganate in benzene using 1,4,7,10,13,16-hexaoxacyclooctadecane (18-crown-6) as a catalyst. The structure also was verified by a patented two-step synthesis (4). In the first step, 2-carboxy-4′-chlorophenylsulfide was made from 4-chlorothiophenol and 2-iodobenzoic acid. In the second step, the ring system was formed by dehydration in hot concentrated sulfuric acid.

Gastric aspirate was obtained from a case of severe chlorprothixene poisoning. The pH was adjusted to 9.5 prior to extraction of the neutral and basic compounds with chloroform–isopropanol (95:5 v/v). The extract was received by this laboratory for analysis after ~3 months. It was not possible to obtain reliable data on the storage conditions.

I II

*Scheme I—Structural formulas of chlorprothixene (I) and its degradation product, 2-chlorothioxanthen-9-one (II).*

Combined GLC–low-resolution mass spectrometry was performed using a gas chromatograph[2], a molecular separator of the glass frit type, and a single-focusing low-resolution mass spectrometer[3] operated with an ionizing energy of 70 ev. The gas chromatograph was equipped with a silanized glass column (2.5 m × 2 mm i.d.) packed with 3% QF-1 on Supelcoport, 80–100 mesh. The column was maintained isothermally at 210°, and helium was used as the carrier gas with a flow rate of 30 ml/min. The instrument was connected on-line to a computer system[4].

High-resolution mass spectrometry was performed with a double-focusing instrument[5] (source temperature, 220°; ionizing energy, 70 ev; ionization current, 100 μamps). The samples were introduced by the heated direct-insertion probe. Peak-matching measurements using heptacosafluorotributylamine as a standard were performed with a resolving power of 1:15,000.

## RESULTS AND DISCUSSION

GLC of the neutral and basic compounds in gastric aspirate from a case of severe chlorprothixene poisoning showed, in addition to chlorprothixene, a large peak (30% of the chlorprothixene peak area) with a relative retention volume of 0.55 compared to chlorprothixene.

The mass spectrum of the unknown compound (Fig. 1) showed prominent peaks in the high mass range and almost no fragment ions in the lower mass range, thus indicating a stable molecular structure, probably a ring structure. The peaks at *m/z* 246/248 and 218/220 indicated a chlorine atom in the compound. The direct formation of the ion at *m/z* 218 from the ion at *m/z* 246 and of the ion at *m/z* 220 from that at *m/z* 248 was shown by metastable peaks at 193.2 and 195.2, respectively.

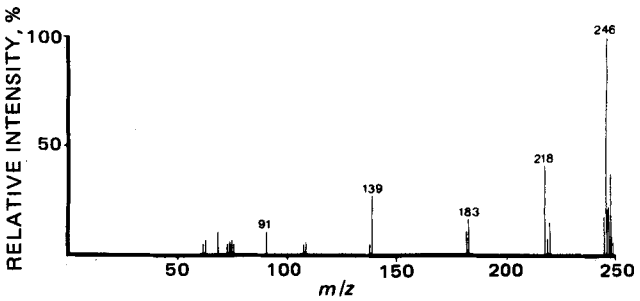

**Figure 1**—*Low-resolution mass spectrum of a previously unrecognized compound in gastric aspirate from a case of severe chlorprothixene poisoning. This mass spectrum was identical to that of authentic 2-chlorothioxanthen-9-one (not shown).*

Table I—Formation of 2-Chlorothioxanthen-9-one (II) from Chlorprothixene (I) under Various Conditions

| Exposure to Light | Solvent | Temperature | Days | Amount of II Formed[a], % |
|---|---|---|---|---|
| Darkness | 2 *M* HCl | 80° | 9 | ND |
| | 2 *M* KOH | 80° | 9 | ND |
| | 1 *M* NaOH | 22° | 18 | ND |
| | 5 *M* NaOH | 22° | 18 | 0.2 |
| | Gastric fluid, simulated[b] | 80° | 1 | ND |
| | Gastric fluid I (pH 2.4)[c] | 37° | 31 | 0.6 |
| | Gastric fluid II (pH 1.5)[c] | 37° | 38 | 1.5 |
| | Gastric fluid III (pH 6.5)[c] | 37° | 31 | 0.6 |
| | Chloroform–isopropanol (95:5 v/v) | 4° | 32 | ND |
| | Chloroform–isopropanol (95:5 v/v) | 4° | 580 | 0.5 |
| | Chloroform–isopropanol (95:5 v/v) | 22° | 32 | ND |
| | Chloroform–isopropanol (95:5 v/v) | 22° | 580 | 3.5 |
| Lamp light | Methanol | 22° | 34 | ND[d] |
| | Chloroform–isopropanol (95:5 v/v) | 22° | 34 | ND[d] |
| UV light (254 nm) + lamp light | Methanol | 22° | 4 + 16 | 32[d] |
| | Chloroform–isopropanol (95:5 v/v) | 22° | 4 + 16 | 31[d] |

[a] The formation of II was measured by GLC; see *Experimental*. ND = not detectable (<0.2%). [b] Prepared according to the USP method (5). [c] Obtained by gastric aspiration in three healthy adults. [d] Considerable quantities (5–40%) of degradation products of I other than II.

Exact mass measurements in a high-resolution mass spectrometer showed that the empirical formula of the ion at *m/z* 246 was $C_{13}H_7ClOS$ (theoretical mass, 245.9906; observed mass, 245.9906). Similarly, the ions at *m/z* 218 and 183 were shown to be $C_{12}H_7ClS$ (theoretical mass, 217.9957; observed mass, 217.9959) and $C_{12}H_7S$ (theoretical mass, 183.0268; observed mass, 183.0264), respectively.

From these data, the unknown compound was identified tentatively as 2-chlorothioxanthen-9-one (II). This compound was synthesized by two methods. The synthetic compounds cochromatographed with the unknown in GLC, and their mass spectra were identical. Thus, the identity of the unknown compound was established as II.

Table I shows the formation of II from chlorprothixene (I) under various storage conditions. Only negligible amounts were formed when the drug was stored in the dark or in lamp light. However, when I was treated with UV light for 4 days followed by storage in lamp light for 16 days, ~30% of I was converted to II. Moreover, considerable quantities of unidentified degradation products of I were formed when I was exposed to lamp light and UV light. These findings are in accordance with unpublished data (6). Therefore, samples from cases of acute drug poisoning should be stored in the dark.

# GLC Analysis of Phenylalkyl Primary Amines Using Nitrogen Detector

**J. I. JAVAID** ˣ **and J. M. DAVIS**

Received August 21, 1980, from the *Illinois State Psychiatric Institute, 1601 West Taylor Street, Chicago, IL 60612.* Accepted for publication December 2, 1980.

**Abstract** □ A comprehensive method for the analysis of several phenylalkyl primary amines of biological interest was developed. The amines were derivatized with perfluoro acid anhydrides or carbon disulfide in ethyl acetate, and the respective acyl derivatives or isothiocyanate derivatives were analyzed by GLC using nitrogen-specific detection. The described procedure was used to measure the amphetamine concentrations in rat serum, brain, and liver after intraperitoneal injection (5 mg/kg).

**Keyphrases** □ Phenylalkyl primary amines—GLC analysis using nitrogen detection, rat serum, brain, and liver □ Amphetamines—phenylalkyl primary amines, GLC analysis using nitrogen detection, rat serum, brain, and liver □ GLC—nitrogen detection, analysis, phenylalkyl primary amines in rat serum, brain, and liver

The use of nitrogen–phosphorus detection in GLC has many applications in biomedicine for the trace analyses of nitrogen-containing compounds. The nitrogen–phosphorus detector is generally 10–100 times more sensitive than the flame-ionization detector and has very little response to organic compounds that do not contain phosphorus or nitrogen atoms. Thus, therapeutic levels of many drugs containing a secondary or tertiary nitrogen, *e.g.*, anticonvulsants (1, 2), analgesics (3), tricyclic antidepressants (4–6), antipsychotics (7, 8), and drugs of abuse (9–11), can be measured. However, this approach has not yet been exploited for the analysis of primary amines. The use of GLC with nitrogen detection was suggested for the identification of amphetamine in forensic toxicology (9).

In this report, a comprehensive method for the analysis of several phenylalkyl primary amines is described. The amines were derivatized with acid anhydrides or carbon disulfide, and the *N*-acyl and isothiocyanate derivatives were analyzed by GLC with nitrogen detection.

## EXPERIMENTAL

commercially[1]. Glass-distilled[2] methanol, ethyl acetate, and hexane were used. Trifluoroacetic anhydride, pentafluoropropionic anhydride, and heptafluorobutyric anhydride were used as received[3]. Carbon disulfide and acetic anhydride were analytical grade.

The gas chromatograph[4] was equipped with a dual nitrogen–phosphorus detector. The instrument was set according to the instruction manual provided by the manufacturer, except that the offset current applied to the alkali metal bead was adjusted to give a recorder deflection of 20% of the full scale at a range of 1 and an attenuation of 32. The voltage input can be increased further to improve sensitivity to a point when the detector response to baseline noise ratio is optimum.

The 0.9-m coiled glass (2-mm i.d.) column was packed with 3% OV-17 on 80–100-mesh WHP Supelcoport. The gas flow rates were as follows: hydrogen, 3 ml/min; air, 50 ml/min; and helium (carrier gas), 30 ml/min. Oven temperature of 130° isothermal and injection port and detector temperatures of 200 and 300°, respectively, were used when trifluoroacetic anhydride was the derivatizing reagent.

**Procedures**—The stock solutions of standard reference compounds were made in methanol to give 1-mg (as free base) concentrations. The salts were extracted from 1 ml of 1 *N* NaOH solutions with 0.5 ml of hexane or ethyl acetate. Primary amines without derivatization eluted as broad peaks because of the polar amino group. Several derivatizing reagents were tried to find optimum conditions. Amphetamine, β-phenethylamine, and tyramine were used as prototype amines for determining these conditions. These primary amines, when underivatized, eluted immediately as broad peaks from 3% OV-17 at 130°.

**Derivatization with Carbon Disulfide**—Isothiocyanate derivatives were prepared according to a previously published method (12). Extracted solutions of amphetamine, phenethylamine, and tyramine were transferred to a reaction vial, and 0.5 ml of carbon disulfide was added. The mixture was shaken for 15 min, dried under nitrogen, redissolved in ethyl acetate, and injected into the chromatograph. Under these conditions, the derivatized amphetamine and phenethylamine eluted as symmetrical peaks with retention times of ~4.6 and 4.8 min, respectively, relative to the injection time.

**Derivatization with Acid Anhydrides**—To the amine solutions in the reaction vial was added 0.5 ml of the acid anhydride, and the mixture was shaken and left at room temperature for 1 hr. Then, the vials were either dried under nitrogen and redissolved in hexane for chromatographic analysis or washed with water and ammonium hydroxide as follows. For this purpose, the reaction was carried out in glass centrifuge tubes. After the reaction, 1 ml of distilled water was added carefully with constant mixing, the tubes were shaken for ~30 sec, and the water was discarded. Then 1 ml of 2 *N* $NH_4OH$ was added, the tubes were shaken for 5 min, and the hexane layer was separated and injected into the chromatograph.

**Amphetamine Levels in Biological Tissues**—The applicability of the method to biological fluids was determined by measuring amphetamine levels in rat serum, brain, and liver after amphetamine administration. The rats were injected intraperitoneally with amphetamine sulfate (5 mg/kg) and sacrificed 30 min later. Blood was collected, and the serum was separated by centrifugation. The brain and liver were removed and homogenized in 0.4 *N* HCl (1:10 w/v). The homogenate was centrifuged, and the amphetamine concentration was measured in the acidic layer after extraction.

To 1 ml of the serum and the brain and liver acid extracts was added 500 ng of benzylamine as the internal standard. The pH was adjusted to 10 by the addition of 0.1 ml of 5 *N* NaOH, and the mixture was extracted with 1 ml of ethyl acetate. Trifluoroacetic anhydride (0.5 ml) was added directly to this extract, and the mixture was left at room temperature for 1 hr. Then it was dried under a nitrogen stream, redissolved in 1 ml of hexane, and injected into the chromatograph.

## RESULTS AND DISCUSSION

Without derivatization, the phenylalkyl primary amines were eluted from the 3% OV-17 column at low temperatures as broad tailing peaks. However, after derivatization, the peaks were symmetrical. Figure 1 shows a representative chromatogram of six amines when analyzed after derivatization with trifluoroacetic anhydride. Since the GLC separation of free amines generally results in peak tailing due to spurious adsorption onto the column, several approaches were used for derivatization of the

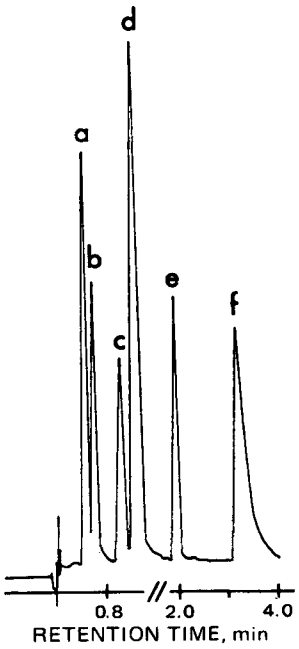

**Figure 1**—*Representative chromatogram showing the separation of six phenylalkyl primary amines as their trifluoroacyl derivatives. Key: a, α-phenethylamine; b, benzylamine; c, amphetamine; d, β-phenethylamine; e, p-methylamphetamine; and f, tyramine.*

amino groups (13, 14). The isothiocyanate derivatives of phenethylamine and amphetamine resulted in symmetrical peaks, whereas that of tyramine was not eluted. This result was probably due to the presence of the underivatized hydroxyl group in tyramine because Narasimhachari and Vouros (12) were able to analyze the isothiocyanate derivative of tyramine after silylation.

Acyl derivatives of amines, because of their ease of preparation, have been used successfully for GLC analysis. In this study, the trifluoroacetyl and heptafluorobutyryl derivatives of phenylalkyl primary amines were evaluated for GLC analysis with nitrogen detection. The best results were obtained when these amines were derivatized with trifluoroacetic anhydride. All of the primary amines, including tyramine, eluted as sym-

Table I—Retention Times and Detector Response for Trifluoroacetyl and Isothiocyanate Derivatives of Phenylalkyl Primary Amines

| Amine | Nanomoles Injected | Retention Time, min | | Detector Response | |
|---|---|---|---|---|---|
| | | Trifluoroacetyl Derivative | Isothiocyanate Derivative | Trifluoroacetyl Derivative | Isothiocyanate Derivative |
| α-Phenethylamine | 0.165 | 0.80 | 2.56 | 96 | 34 |
| Benzylamine | 0.187 | 0.96 | 2.56 | 32 | 17 |
| Amphetamine | 0.148 | 1.44 | 4.64 | 212 | 31 |
| β-Phenethylamine | 0.165 | 1.60 | 4.80 | 88 | 60 |
| Tyramine | 0.146 | 4.16 | No peak | 40 | — |

metrical peaks under the described conditions. Unlike the isothiocyanate derivative, a second reaction was not needed to derivatize the phenolic hydroxyl group in tyramine. The stereoisomers of trifluoroacetyl derivatives of primary amines did not separate under the described conditions since *d*- and *l*-amphetamines eluted with the same retention times, as did the *d*- and *l*-α-phenethylamines.

The nitrogen detector response to the trifluoroacetyl derivatives was generally better than that to the corresponding isothiocyanate derivatives. Table I gives the comparison of trifluoroacetyl and isothiocyanate derivatives of some primary amines and also shows that the nitrogen detector response varied with different compounds and was not related to the amount of nitrogen present in the compound. For example, on a mole per mole basis, amphetamine has less nitrogen than benzylamine, but amphetamine as the trifluoroacetyl derivative had a 6.5 times better response than did benzylamine. This differential response probably depends on the formation of cyanide radicals after pyrolysis. Although the exact mechanism of the nitrogen detector response is not known, it was suggested (15) that the organic molecules containing nitrogen are pyrolyzed to form cyano radicals, which then remove an electron from the atomized alkali metal bead. These cyanide ions then can combine at the collector to form hydrogen cyanide, thus generating an output signal. Hence, the differential response of nitrogen-containing compounds may be due to their characteristics for producing cyanide radicals after pyrolysis.

The linearity of the nitrogen detector response was determined by derivatizing various concentrations of amphetamine (0.5–2.0 μg/ml), phenethylamine (0.5–2.0 μg/ml), and tyramine (1–10 μg/ml) in duplicate and injecting into the chromatograph. There was a linear response with all three primary amines. The regression equations by the least-squares method were: amphetamine, $y = 16.8x + 0$, $r = 0.990$; phenethylamine, $y = 27.8x - 3.25$, $r = 0.997$; and tyramine, $y = 5.76x + 1.5$, $r = 0.988$.

The excess derivatizing reagent was removed either by drying under nitrogen or by washing as described. When washing was used, the average coefficient of variation for amphetamine analysis of duplicate samples over the 0.5–2.0-μg/ml range was 4.1%, compared to an average coefficient of variation of 14.1% when the reacted samples were dried under nitrogen. However, the hydroxylated phenylalkyl primary amine (tyramine) peak disappeared if the reaction mixture was washed to remove excess trifluoroacetic anhydride. This finding suggests that *N*-acyl derivatives are more stable than *O*-acyl derivatives. This fact could be used to improve the chromatogram and reduce the analysis time by reducing the number of peaks if only a quantitation of nonhydroxylated primary amines in biological fluids is needed. The variability in the analysis of duplicate samples due to the loss during drying could be minimized by using the internal standard method.

Table II—Amphetamine Concentrations in Different Rat Tissues 30 min after Intraperitoneal Injection (5 mg/kg) [a]

| Tissue [b] | Amphetamine, ng/ml or g | *SEM* |
|---|---|---|
| Serum | 512 | ±81 |
| Brain | 4484 | ±885 |
| Liver | 5267 | ±299 |

[a] For details, see the procedures. [b] Three rats.

The amphetamine concentrations in rat serum, brain, and liver were determined (Table II). Thus, the method can be used to determine the phenylalkyl primary amines in biological fluids. However, the extraction procedure, specificity, and sensitivity of each compound must be established experimentally for each tissue.

# Behavioral and Neurochemical Interactions of Dextroamphetamine and Methylphenidate in Rats

**T. G. REIGLE *x, W. L. ISAAC ‡, and W. ISAAC ‡**

Received November 10, 1980, from the *Department of Pharmacology, School of Pharmacy, and the ‡Department of Psychology, University of Georgia, Athens, GA 30602. Accepted for publication December 4, 1980.

**Abstract** □ The effects of dextroamphetamine and methylphenidate on locomotor activity and brain levels of norepinephrine and dopamine were compared in male Sprague–Dawley rats. Both drugs produced a dose-related increase in locomotor activity during the hour immediately following intraperitoneal administration. However, combined administration of the drugs elicited only the effect of dextroamphetamine. Brain levels of norepinephrine and dopamine also increased 1 hr after dextroamphetamine dosing. Methylphenidate did not exhibit these effects and antagonized the neurochemical changes produced by dextroamphetamine. Although both drugs are considered to exert their effects by indirect activation of brain catecholamine systems, differences in their mechanism of action appear to result in a lack of additive or antagonistic effects when dextroamphetamine and methylphenidate are coadministered. These findings may have clinical significance with respect to the use of such agents in minimal brain dysfunction.

**Keyphrases** □ Stimulants—dextroamphetamine and methylphenidate, effects on behavior and neurochemistry, rats □ Dextroamphetamine—effects on behavior and neurochemistry, rats, coadministration with methylphenidate □ Methylphenidate—effects on behavior and neurochemistry, rats, coadministration with dextroamphetamine □ CNS agents—dextroamphetamine and methylphenidate, effects on behavior and neurochemistry, rats

Both dextroamphetamine and methylphenidate have been employed successfully in the treatment of hyperkinesis or minimal brain dysfunction (1, 2). In experimental animals, these drugs exhibit the characteristic actions of central nervous system (CNS) stimulants by producing dose-dependent increases in locomotor activity and stereotyped behaviors (3, 4). Both the clinical and behavioral stimulant actions of these agents have been attributed to activation of brain catecholamine systems (5, 6). However, the mechanisms by which these drugs enhance brain catecholamine activity apparently are different.

## BACKGROUND

Reserpine, which depletes catecholamines by interfering with presynaptic granular storage, antagonizes the stimulant effects of methylphenidate but not those of dextroamphetamine (7). α-Methyl-*p*-tyrosine, an inhibitor of catecholamine synthesis, antagonizes the effects of dextroamphetamine but leaves the actions of methylphenidate relatively intact (8). These findings led to the proposal that methylphenidate facilitates the impulse-mediated release of catecholamines from reserpine-sensitive granular storage pools whereas dextroamphetamine acts primarily by increasing the release of a reserpine-resistant pool of newly synthesized cytoplasmic amines. Other investigators (9, 10) suggested that methylphenidate acts by blocking the presynaptic uptake of catecholamines released by nerve activity and that dextroamphetamine acts primarily by enhancing catecholamine release in the absence of neuronal stimulation.

Since both drugs are individually effective in ameliorating hyperkinetic symptoms, produce similar behavioral effects in animals, and indirectly activate brain catecholamine systems by different mechanisms, it was felt that coadministration of these agents might potentiate their separate effects and have possible clinical significance. This hypothesis was tested by evaluating the effects of moderate doses of dextroamphetamine and methylphenidate, individually and in combination, on the locomotor activity and brain catecholamine content of rats. The dose levels of both drugs were shown to have submaximal effects (3, 11, 12) and, thus, permitted the appearance of behavioral or neurochemical changes in either direction upon combination.

## EXPERIMENTAL

**Animals**—Sprague–Dawley male albino rats[1] were 20 days old when received and were adapted to the laboratory and daily handling for 7 days. For an additional 15 days, they were adapted to the apparatus and handling and injection procedures (13). Food and water were available at all times, and a 12-hr light–dark cycle was maintained.

**Apparatus**—The rats were housed in clear plastic mouse-breeding cages (45 × 24 × 25 cm) with a hardware cloth cover during activity measurements. Each plastic container was housed in a separate sound-treated cubicle, open at one end; it was 85 × 56 × 56 cm and individually lighted with a 20-w fluorescent bulb mounted 29 cm above the floor of the activity chamber. Twelve such cubicles were housed in a sound-treated room.

A single IR light beam bisected the length of each plastic container ~2 cm above the floor and fell upon a photocell. An IR filter covered the photocell, making it insensitive to ambient illumination. When the subjects broke the beam in their chambers, counts were recorded on individual counters in a separate room.

**Procedure**—Two dose levels of methylphenidate hydrochloride (1.6 and 3.2 mg/kg) and dextroamphetamine sulfate (0.4 and 0.8 mg/kg) and a combination of dextroamphetamine sulfate (0.4 mg/kg) and of methylphenidate hydrochloride (1.6 mg/kg) were studied. Placebo injections of the drug vehicle (bacteriostatic water) were included to give a total of six experimental conditions. All injections were administered intraperitoneally in an equal volume (1 ml/kg) 5–10 min before the subjects were placed in the activity measurement apparatus. When placed in the cubicle, all equipment was turned on and 5 min was allowed for adaptation. Activity measures were obtained for the next 60 min. Activity scores were transformed by a $\sqrt{x+1}$ transformation, as recommended for frequency scores (14).

Six separate orders of daily drug administrations were utilized, producing a 6 × 6 Latin square with two subjects within each order. All subjects were run through their orders three times. The first replication was for adaptation to the drug injections, and only scores from the last two replications were compared and evaluated by analysis of variance and Duncan's multiple range test (14).

Age-matched rats subjected to adaptation and handling procedures identical to those already described (13) were used for brain catecholamine analysis. Groups of animals (eight to 10 rats/group) received the same drug treatments utilized in the locomotor activity study and were sacrificed 30 min after intraperitoneal injection. Whole brains were removed rapidly, rinsed with tap water, and homogenized[2] in 12 ml of cold 0.4 *N* $HClO_4$. Homogenates were centrifuged at 30,000×*g* for 30 min, and the supernate was frozen immediately and stored for 1–2 days prior to chemical assay. Norepinephrine and dopamine were assayed by the fluorometric methods of Anton and Sayre (15) and Carlsson and Waldeck (16), respectively. Catecholamine concentrations were expressed as nanograms per gram of brain (wet weight) and were compared across treatments by analysis of variance and Duncan's multiple range test (14).

## RESULTS AND DISCUSSION

The locomotor activity data are presented in Fig. 1. Analysis of variance revealed that the difference between replications was not significant [$F(1,11) = 3.94$, $p > 0.05$], nor was the interaction between drug conditions and replications [$F(5,55) = 1.25$, $p > 0.05$]. The activity levels observed under the drug conditions, however, did differ significantly

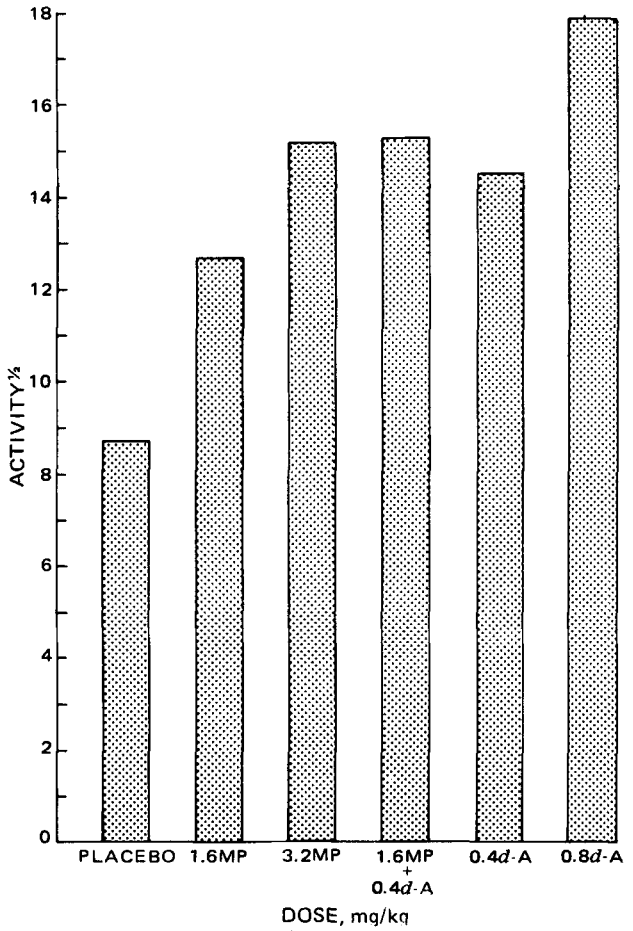

**Figure 1**—*Effects of dextroamphetamine (d-A), methylphenidate (MP), and their combination on square root-transformed locomotor activity scores in the rat.*

[$F(5,55) = 55.82$, $p < 0.01$]. Further analysis of the differences among drug treatments using the multiple range test ($\alpha = 0.01$) indicated that the placebo condition produced the lowest amount of locomotor activity and that the low dose of methylphenidate produced a significant increase. Administration of 0.4 mg of dextroamphetamine/kg, 3.2 mg of methylphenidate/kg, and the combined dose of 0.4 mg of dextroamphetamine/kg and 1.6 mg of methylphenidate/kg produced increases in locomotor activity that were significantly greater than the lower dose of methylphenidate, but the effects of these treatments did not differ significantly among themselves. The highest dose of dextroamphetamine produced a higher level of activity than the other drug conditions.

Thus, both drugs produced dose-related increases in locomotor activity and, as demonstrated previously (3), dextroamphetamine was more potent than methylphenidate. However, the drug combination was no more effective than dextroamphetamine alone. Intermediate dose levels of both drugs (3) were chosen so that changes in activity in either direction, as a consequence of the drug combination, could be detected. Since the higher dose of dextroamphetamine produced a greater increase in activity than the other treatments, the effects of the dextroamphetamine–methylphenidate combination were not limited by an activity ceiling. Also, since both the placebo and low dose of methylphenidate produced less activity than the drug combination, the results were not limited in the opposite direction. With these doses, methylphenidate neither enhanced nor suppressed the effects of dextroamphetamine on locomotor activity.

The effects of the various drug treatments on brain catecholamine levels are presented in Table I. Analysis of variance revealed significant differences among treatments on the brain levels of both norepinephrine [$F(5,51) = 5.14$, $p < 0.01$] and dopamine [$F(5,46) = 12.53$, $p < 0.01$]. Further analysis of these differences (Duncan's multiple range test; $\alpha = 0.05$) indicated that both doses of dextroamphetamine produced significant increases in brain dopamine, although the effects of these treatments were not different from each other. Brain dopamine levels following either methylphenidate or the dextroamphetamine–methylphenidate combination were not significantly different from those observed in the placebo-treated animals. Similar findings were obtained with respect to brain norepinephrine. The increase produced by 0.8 mg of dextroamphetamine/kg did not quite achieve statistical significance ($0.05 < p < 0.10$). However, the 0.4-mg/kg dose significantly increased brain norepinephrine, and the effects of the two amphetamine doses did not differ from each other. Once again, the effects of all other treatments were not significantly different from those of the placebo.

**Table I—Effects of Dextroamphetamine, Methylphenidate, and Their Combination on Rat Brain Catecholamines**

| Treatment (Dose, mg/kg) | Dopamine | | Norepinephrine | |
|---|---|---|---|---|
| | Nanograms per Gram[a] | Percent Placebo | Nanograms per Gram[a] | Percent Placebo |
| Placebo | 760 ± 14 | — | 287 ± 10 | — |
| Dextroamphetamine (0.4) | 894 ± 23[b] | 118[b] | 325 ± 12[c] | 113[c] |
| Dextroamphetamine (0.8) | 924 ± 29[b] | 122[b] | 320 ± 12[d] | 111[d] |
| Methylphenidate (1.6) | 771 ± 13 | 101 | 287 ± 10 | 100 |
| Methylphenidate (3.2) | 788 ± 24 | 104 | 257 ± 13 | 90 |
| Dextroamphetamine (0.4) + methylphenidate (1.6) | 769 ± 19 | 101 | 272 ± 13 | 95 |

[a] Data expressed as mean ± *SEM* of eight to 10 animals/group. [b] $p < 0.01$ *versus* placebo. [c] $p < 0.05$ *versus* placebo. [d] $p < 0.10$ *versus* placebo.

Thus, with respect to these neurochemical measures, not only were the effects of dextroamphetamine not enhanced by methylphenidate, they were significantly antagonized. The effects of amphetamine on brain catecholamine systems are complex. However, in agreement with the present findings, most previous reports indicated that low amphetamine doses capable of increasing locomotor activity produced increases in brain norepinephrine and dopamine while higher doses tended to cause a depletion (11, 12). In contrast, doses of methylphenidate that produced comparable increases in locomotor activity had no effect on brain catecholamines, indicating a difference in the mechanism of action of these two drugs. The doses of amphetamine employed could increase brain catecholamine levels by stimulating synthesis, inhibiting metabolism, or decreasing neuronal firing. The ability of amphetamine to inhibit monoamine oxidase has been demonstrated *in vitro*; however, rather large concentrations were required, and enzyme inhibition was difficult to observe following *in vivo* drug administration (17). Impulse flow in catecholamine neurons is inhibited by amphetamine (18), but this action also is produced by several other drugs, including methylphenidate, that have no appreciable effect on brain catecholamine levels (8).

Thus, the most plausible explanation for increases in brain catecholamines following amphetamine appears to be synthesis enhancement. The increased release elicited by amphetamine of newly synthesized catecholamines from nongranular cytoplasmic pools could reduce end-product inhibition of cytoplasmic tyrosine hydroxylase in presynaptic neurons (19). This would result in the increased formation and, hence, elevated levels of brain catecholamines observed in the present study. The greater release produced by larger amphetamine doses could exceed the synthetic capacity of the affected neurons, resulting in the net catecholamine depletion observed previously (11, 12).

The observed antagonism of amphetamine-induced increases in brain catecholamines by methylphenidate could be explained similarly. By facilitating the efflux of catecholamines from granular storage, methylphenidate would provide a source of replacement for the amines released from cytoplasmic pools by amphetamine such that synthesis could not be activated by a reduced catecholamine level in the cytoplasmic compartment. Behaviorally, this would not prevent stimulant effects due to the release of newly synthesized catecholamines by amphetamine but could prevent an additive action by methylphenidate since the amines displaced from the granules might replenish the cytoplasmic pool rather than act as a source for the activation of postsynaptic events.

Although amphetamine and methylphenidate individually exert behavioral stimulant effects and enhance the activity of brain catecholamine systems, differences in their mechanism of action can prevent additive or potentiating effects when these drugs are coadministered. These findings suggest that a therapeutic advantage may not be gained by combining amphetamine and methylphenidate in the treatment of hyperkinetic disorders.

# Plasma Protein Binding of Zomepirac Sodium

**PATRICK J. O'NEILL**

Received July 14, 1980, from the *Department of Drug Metabolism, McNeil Pharmaceutical, Spring House, PA 19477.* Accepted for publication December 19, 1980.

**Abstract** □ The plasma protein binding of zomepirac, a new nonnarcotic analgesic, was studied using equilibrium dialysis. Experiments were performed using human plasma and plasma from mice, rats, and rhesus monkeys, all species of pharmacological or toxicological interest. At concentrations approximating those achieved *in vivo*, the binding was fairly constant at 98–99% in all species except the rhesus monkey, where binding was decreased from 98 to ~96% at higher concentrations (>50 μg/ml). Zomepirac (10 μg/ml) did not appear to displace or to be displaced by warfarin (10 μg/ml) in human plasma. However, salicylate (5–200 μg/ml) caused a concentration-dependent decrease in zomepirac (10 μg/ml) binding. Zomepirac did not affect salicylate binding.

**Keyphrases** □ Zomepirac sodium—plasma protein binding studies in plasma from humans, rats, mice, and rhesus monkeys, interaction studies with warfarin and salicylic acid □ Plasma protein binding—zomepirac sodium in plasma from humans, rats, mice, and rhesus monkeys □ Warfarin—interaction studies with zomepirac sodium, effect on plasma protein binding □ Salicylic acid—interaction studies with zomepirac sodium, effect on plasma protein binding □ Analgesics, nonnarcotic—zomepirac sodium, plasma protein binding studies in humans, rats, mice, and rhesus monkeys, interaction studies with warfarin and salicylic acid

Plasma protein binding of drugs is an important factor in drug disposition (1–3). This report describes the interaction of zomepirac sodium, a new nonnarcotic analgesic agent (4–6), with plasma proteins from several species. Some preliminary binding interaction studies in human plasma are also reported.

## EXPERIMENTAL

**Materials**—Zomepirac sodium [sodium 5-(4-chlorobenzoyl)-1,4-dimethyl-1*H*-pyrrole-2-acetate dihydrate] was labeled with carbon 14 at a specific activity of 10.18 μCi/mg[1]. The drug was 96–98% radiochemically pure by TLC at the time of use. [$^{14}$C]Salicylic acid[2] and [$^{14}$C]warfarin[2] were used at specific activities of 421 and 164 μCi/mg, respectively. Both drugs were 99% radiochemically pure by TLC.

Heparinized plasma was harvested from blood collected from Wistar rats[3], CD-1 Swiss mice[3], and rhesus monkeys[4]. Citrated human plasma was purchased locally. Sorensen's buffer (0.067 *M* phosphate, pH 7.4) was prepared by dissolving 1.72 g of monobasic potassium phosphate and 7.70 g of dibasic sodium phosphate in 1 liter of distilled water.

**Methods**—Binding experiments were performed on an equilibrium dialysis system[5]. Regenerated cellulose dialysis membranes (mol. wt. cutoff of 5000) were prepared by three rinses in distilled water and three rinses in buffer. The membranes were placed between two-piece polytef dialysis cells (1-ml volume per side) mounted in a spring-loaded rack, and each half-cell was filled. One side of the cell was filled with plasma, and the other side was filled with the drug in buffer.

The cells were rotated at 12 rpm for 2 hr at room temperature, and then the half-cells were emptied and assayed for total carbon 14 as a measure of zomepirac. These dialysis conditions were selected since preliminary experiments in the absence of plasma (*i.e.*, zomepirac dialyzed against buffer) showed that equilibrium was reached in 2 hr and that plasma binding was not different at room temperature or 37°. Furthermore, TLC analysis of selected samples showed that no degradation of zomepirac occurred under these conditions.

**Interaction Studies**—[$^{14}$C]Zomepirac was dialyzed against undiluted rat, mouse, monkey, and human plasma at concentrations ranging from 0.1 to 250 μg/ml, depending on the species. These concentrations were in the ranges of those observed after pharmacological doses of zomepirac sodium (7–10).

To assess the potential for displacement of zomepirac by other agents, experiments were performed with warfarin[6] and salicylic acid[7] using human plasma. The [$^{14}$C]zomepirac concentration was 10 μg/ml. Warfarin was tested at 10 μg/ml, and salicylic acid was tested from 5 to 200 μg/ml. When the effect of zomepirac on the binding of these agents was evaluated, a tracer of [$^{14}$C]warfarin (~10,000 dpm/ml, 0.03 μg/ml) or salicylate (~10,000 dpm/ml, 0.01 μg/ml) was added, and nonradioactive zomepirac was used.

**Sample Analysis**—Total radioactivity was determined by adding aliquots of both plasma and buffer solutions (after dialysis) to 10 ml of scintillation cocktail[8]. Samples were counted in a refrigerated liquid scintillation spectrometer and were corrected for quenching using the external standard method.

Selected samples were analyzed for drug decomposition during dialysis. Zomepirac was assayed by applying aliquots of the postdialysis plasma and buffer samples to silica gel TLC plates[9] developed in chloroform–methanol–acetic acid (94:5:1 v/v/v). Analysis was by either segmentation and liquid scintillation counting or radioscan. No decomposition was observed.

# Plasma Protein Binding of Zomepirac Sodium

**PATRICK J. O'NEILL**

Received July 14, 1980, from the *Department of Drug Metabolism, McNeil Pharmaceutical, Spring House, PA 19477.* Accepted for publication December 19, 1980.

**Abstract** □ The plasma protein binding of zomepirac, a new nonnarcotic analgesic, was studied using equilibrium dialysis. Experiments were performed using human plasma and plasma from mice, rats, and rhesus monkeys, all species of pharmacological or toxicological interest. At concentrations approximating those achieved *in vivo*, the binding was fairly constant at 98–99% in all species except the rhesus monkey, where binding was decreased from 98 to ~96% at higher concentrations (>50 μg/ml). Zomepirac (10 μg/ml) did not appear to displace or to be displaced by warfarin (10 μg/ml) in human plasma. However, salicylate (5–200 μg/ml) caused a concentration-dependent decrease in zomepirac (10 μg/ml) binding. Zomepirac did not affect salicylate binding.

**Keyphrases** □ Zomepirac sodium—plasma protein binding studies in plasma from humans, rats, mice, and rhesus monkeys, interaction studies with warfarin and salicylic acid □ Plasma protein binding—zomepirac sodium in plasma from humans, rats, mice, and rhesus monkeys □ Warfarin—interaction studies with zomepirac sodium, effect on plasma protein binding □ Salicylic acid—interaction studies with zomepirac sodium, effect on plasma protein binding □ Analgesics, nonnarcotic—zomepirac sodium, plasma protein binding studies in humans, rats, mice, and rhesus monkeys, interaction studies with warfarin and salicylic acid

Plasma protein binding of drugs is an important factor in drug disposition (1–3). This report describes the interaction of zomepirac sodium, a new nonnarcotic analgesic agent (4–6), with plasma proteins from several species. Some preliminary binding interaction studies in human plasma are also reported.

## EXPERIMENTAL

**Materials**—Zomepirac sodium [sodium 5-(4-chlorobenzoyl)-1,4-dimethyl-1*H*-pyrrole-2-acetate dihydrate] was labeled with carbon 14 at a specific activity of 10.18 μCi/mg[1]. The drug was 96–98% radiochemically pure by TLC at the time of use. [$^{14}$C]Salicylic acid[2] and [$^{14}$C]warfarin[2] were used at specific activities of 421 and 164 μCi/mg, respectively. Both drugs were 99% radiochemically pure by TLC.

Heparinized plasma was harvested from blood collected from Wistar rats[3], CD-1 Swiss mice[3], and rhesus monkeys[4]. Citrated human plasma was purchased locally. Sorensen's buffer (0.067 *M* phosphate, pH 7.4) was prepared by dissolving 1.72 g of monobasic potassium phosphate and 7.70 g of dibasic sodium phosphate in 1 liter of distilled water.

**Methods**—Binding experiments were performed on an equilibrium dialysis system[5]. Regenerated cellulose dialysis membranes (mol. wt. cutoff of 5000) were prepared by three rinses in distilled water and three rinses in buffer. The membranes were placed between two-piece polytef dialysis cells (1-ml volume per side) mounted in a spring-loaded rack, and each half-cell was filled. One side of the cell was filled with plasma, and the other side was filled with the drug in buffer.

The cells were rotated at 12 rpm for 2 hr at room temperature, and then the half-cells were emptied and assayed for total carbon 14 as a measure of zomepirac. These dialysis conditions were selected since preliminary experiments in the absence of plasma (*i.e.*, zomepirac dialyzed against buffer) showed that equilibrium was reached in 2 hr and that plasma binding was not different at room temperature or 37°. Furthermore, TLC analysis of selected samples showed that no degradation of zomepirac occurred under these conditions.

**Interaction Studies**—[$^{14}$C]Zomepirac was dialyzed against undiluted rat, mouse, monkey, and human plasma at concentrations ranging from 0.1 to 250 μg/ml, depending on the species. These concentrations were in the ranges of those observed after pharmacological doses of zomepirac sodium (7–10).

To assess the potential for displacement of zomepirac by other agents, experiments were performed with warfarin[6] and salicylic acid[7] using human plasma. The [$^{14}$C]zomepirac concentration was 10 μg/ml. Warfarin was tested at 10 μg/ml, and salicylic acid was tested from 5 to 200 μg/ml. When the effect of zomepirac on the binding of these agents was evaluated, a tracer of [$^{14}$C]warfarin (~10,000 dpm/ml, 0.03 μg/ml) or salicylate (~10,000 dpm/ml, 0.01 μg/ml) was added, and nonradioactive zomepirac was used.

**Sample Analysis**—Total radioactivity was determined by adding aliquots of both plasma and buffer solutions (after dialysis) to 10 ml of scintillation cocktail[8]. Samples were counted in a refrigerated liquid scintillation spectrometer and were corrected for quenching using the external standard method.

Selected samples were analyzed for drug decomposition during dialysis. Zomepirac was assayed by applying aliquots of the postdialysis plasma and buffer samples to silica gel TLC plates[9] developed in chloroform–methanol–acetic acid (94:5:1 v/v/v). Analysis was by either segmentation and liquid scintillation counting or radioscan. No decomposition was observed.

| 10 | 92.8 ± 0.6 | 200 | — |

[a] Mean ± *SD* of five determinations.

Salicylic acid was assayed by pooling plasma or buffer samples (~2 ml), adjusting to pH 1–2 with 0.5 ml of 6 *N* $H_2SO_4$, and extracting with 10 ml of ether. After shaking for 15 min and centrifuging for 5 min, an aliquot of the ether layer was counted for carbon 14 and the remainder was evaporated to dryness under nitrogen. More than 95% of the radioactivity was extracted. The residue was dissolved in a small amount of methanol and spotted on a TLC plate. The plate was developed in toluene–dioxane–acetic acid (90:24:4 v/v/v) and analyzed as described earlier. No salicylic acid degradation was observed.

Warfarin samples were pooled as described for salicylate and extracted with 10 ml of ethylene dichloride (15 min of shaking and 10 min of centrifugation). An aliquot of the organic layer was counted for carbon 14, and the remainder was evaporated to near dryness. Approximately 80% of the radioactivity was extracted. The extract was spotted on a TLC plate, and the plate was developed in toluene–ethyl formate–formic acid (5:4:1 v/v/v). Only 59% of the radioactivity in the dialysate corresponded to [$^{14}$C]warfarin, while essentially all of the carbon 14 in the plasma was unchanged warfarin. Therefore, the buffer was corrected for the presence of degradation products prior to calculating the extent of binding.

Percent bound values were calculated as follows:

$$\text{percent bound} = \frac{C_{b+f} - C_f}{C_{b+f}} \times 100 \qquad \text{(Eq. 1)}$$

where $C_{b+f}$ is the drug concentration on the plasma side of the membrane (bound plus free drug) and $C_f$ is the drug concentration on the buffer side (free drug).

## RESULTS AND DISCUSSION

Results of experiments evaluating the relationship between zomepirac concentration and extent of binding are shown in Table I. The mean percent bound to human plasma was essentially constant from 0.1 to 10 μg/ml, ranging from 98.4 to 98.9%. Similar findings were observed in the other species, although binding to monkey plasma was reduced slightly with higher zomepirac concentrations (≥50 μg/ml).

The results of the binding interaction studies in human plasma are shown in Table II. Warfarin (10 μg/ml) had no effect on zomepirac (10 μg/ml) binding, even though both drugs were tested at high concentrations relative to the those achieved after therapeutic doses of the drug (10, 11). Similarly, zomepirac did not alter warfarin binding. The effect of salicylic acid on zomepirac plasma binding is shown in Table II. At all concentrations tested, salicylate caused a statistically significant reduction in zomepirac binding, thus resulting in higher free drug concentrations. At 200 μg of salicylate/ml, this effect would result in a change in free fraction from 0.014 to 0.072, a fivefold increase. Zomepirac had no effect on salicylate binding.

Thus, similar to other acidic compounds (12, 13), zomepirac was highly bound to plasma proteins. Based on these preliminary studies, *in vivo* interactions of zomepirac and warfarin resulting from protein binding effects apparently are unlikely. While the potential for interactions with salicylate (*i.e.*, aspirin) exists, the *in vivo* importance cannot be predicted (14). Furthermore, these studies do not rule out drug interactions due to metabolic effects, additive pharmacological effects, or effects of drug metabolites.

# High-Pressure Liquid Chromatographic Determination of Methscopolamine Nitrate, Phenylpropanolamine Hydrochloride, Pyrilamine Maleate, and Pheniramine Maleate in Tablets

D. R. HEIDEMANN

Received August 8, 1980, from the *Analytical Research Department, Dorsey Laboratories (Division of Sandoz, Inc.), Lincoln, NE 68501.* Accepted for publication December 18, 1980.

**Abstract** □ Methscopolamine nitrate, phenylpropanolamine hydrochloride, pyrilamine maleate, and pheniramine maleate were determined in a multilayer film-sealed tablet with an enteric-coated core by reversed-phase high-pressure liquid chromatography without interference from active components and/or matrix decomposition.

**Keyphrases** □ Methscopolamine nitrate—high-pressure liquid chromatographic analysis, tablets □ Phenylpropanolamine hydrochloride—high-pressure liquid chromatographic analysis, tablets □ Pyrilamine maleate—high-pressure liquid chromatographic analysis, tablets □ Pheniramine maleate—high-pressure liquid chromatographic analysis, tablets □ High-pressure liquid chromatography—simultaneous determination of methscopolamine nitrate, phenylpropanolamine hydrochloride, pyrilamine maleate, and pheniramine maleate in tablets

Phenylpropanolamine, pyrilamine, pheniramine, and tropane alkaloids are active components employed in cold preparations. Simultaneous analysis of these compounds is complicated by the low concentration of tropane alkaloids in relationship to the other three amines and by the weak UV absorbance of the tropane alkaloid molecule.

## BACKGROUND

Various spectrophotometric methods have been employed for the analysis of phenylpropanolamine, pheniramine, and pyrilamine; however, extensive sample cleanup and separation are involved prior to the UV finishes (1, 2). Colorimetric methods and other indirect UV methods employed for the determination of methscopolamine and other tropane alkaloids are tedious and nonspecific (3–5).

Various stability-indicating high-pressure liquid chromatographic (HPLC) and GLC methods were reported for the determination of products containing one or more tropane alkaloids (6–12). The problem of simultaneously determining scopolamine and atropine with a preponderant concentration of phenylpropanolamine and chlorpheniramine was addressed by Santoro *et al.* (13) using GLC. However, this method also involved tedious sample preparation prior to injection.

The procedure described in the present study for the simultaneous determination of methscopolamine nitrate, phenylpropanolamine hydrochloride, pyrilamine maleate, and pheniramine maleate is rapid and stability indicating.

## EXPERIMENTAL

**Reagents**—Phenylpropanolamine hydrochloride[1], pyrilamine maleate[2], pheniramine maleate[3], methscopolamine nitrate[4], tropic acid[5], and acetonitrile[6] were used as obtained. Ethylenediamine sulfate was prepared by precipitating the salt from an aqueous solution of ethylenediamine[5] and sulfuric acid with methanol. All other chemicals were reagent grade and were used without further purification.

**Apparatus**—A constant-flow high-pressure liquid chromatograph[7] was used in conjunction with a variable-wavelength detector[8]. Effluents were monitored at 216.5 nm. Peak areas were determined using an electronic digital integrator[9]. The stainless steel column (25 cm × 4.6 mm i.d.) was obtained prepacked with 10-μm reversed-phase material[10]. An automatic injection system was used to introduce the sample onto the column inlet[11].

The mobile phase was $2.85 \times 10^{-3}$ *M* ethylenediamine sulfate buffer adjusted to pH 7.44 ± 0.02 with 1 *M* ammonium hydroxide–acetonitrile (1:1 v/v). The mobile phase was prepared fresh daily, and the flow rate was 3.8 ml/min.

**Sample**—The formulation investigated was a film-sealed tablet with an outer layer and an enteric-coated core[12]. The samples were assayed initially and after extended storage at elevated temperatures.

Ten tablets were crushed between paper and transferred to a 500-ml volumetric flask. Then 250 ml of 0.05 *N* hydrochloric acid in 50% alcohol was added. The preparation was heated for 15 min on a steam bath and shaken automatically for 2 hr. The sample was diluted to volume with water and filtered through glass microfiber[13]. The standard was prepared

**Table I—Recovery of Active Ingredients**

| Active Ingredient | Label, mg/tablet | Assay, mg/tablet | $CV^a$ |
|---|---|---|---|
| Phenylpropanolamine hydrochloride | 50 | 49.9 | 0.57 |
| Methscopolamine nitrate | 4 | 3.95 | 1.35 |
| Pyrilamine maleate | 25 | 24.8 | 1.14 |
| Pheniramine maleate | 25 | 25.4 | 0.63 |

[a] Standard deviation from the mean of 10 determinations divided by the mean expressed as a percent.

simultaneously in the same manner. The resulting theoretical concentrations of active components in the preparation were 1.0 mg of phenylpropanolamine hydrochloride, 0.5 mg of pyrilamine maleate, 0.5 mg of pheniramine maleate, and 0.08 mg of methscopolamine nitrate.

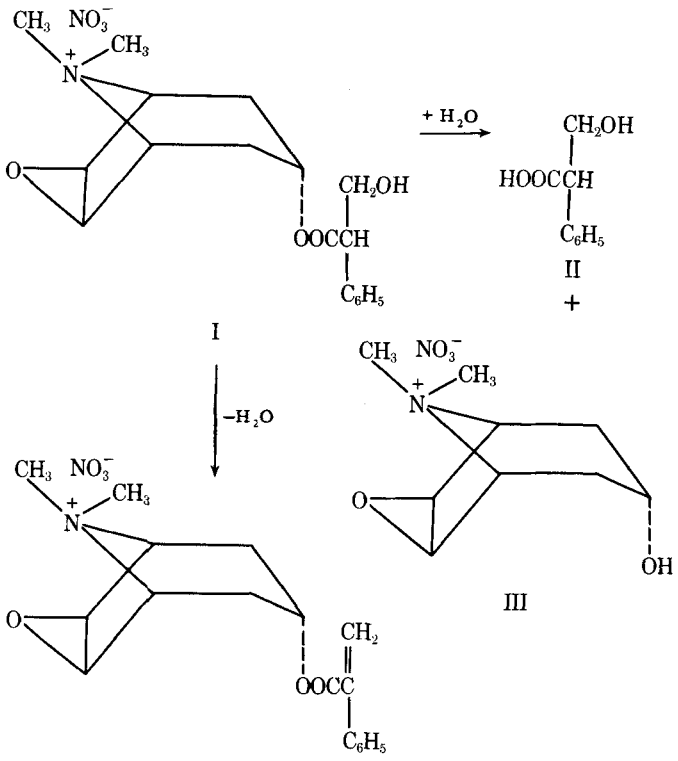
**Assay**—Thirty microliters of standard and sample preparations was injected into the chromatograph, and the peak areas were determined. The quantity of active components was determined by comparing the peak area of the sample to the respective peak area of the standard of known concentration.

## RESULTS AND DISCUSSION

The recovery and coefficient of variation for each active component are shown in Table I. The standard demonstrated linearity for the four active ingredients over a region of ±20% of the theoretical product content. The addition of a sample blank to the standard resulted in less than a ±1% effect for all active components. Figure 1 represents a typical chromatogram.

Tropane alkaloids are subject to degradation by both hydrolysis and dehydration. The degradation pathway of methscopolamine is shown in Scheme I (6–8). Tropic acid, methscopine, and aposcopolamine were resolved from all peaks. Tropic acid eluted at the void volume, and aposcopolamine eluted after methscopolamine (Fig. 2). Methscopine has little UV absorbance at this wavelength and concentration and was not detected. Figure 3 represents a sample spiked with tropic acid and aposcopolamine bromide.

The degradation pathway of phenylpropanolamine is not established. However, stability-indicating spectrophotometric methods such as



*Scheme I—Degradation pathway of methscopolamine nitrate (I) to tropic acid (II), methscopine nitrate (III), and aposcopolamine methylnitrate (IV).*

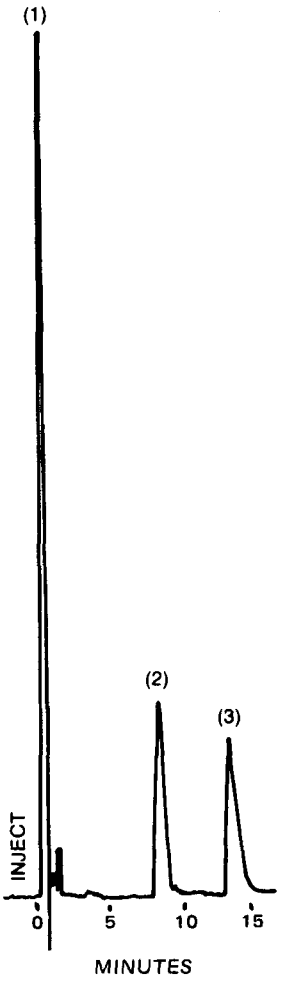


**Figure 2**—*Chromatogram of methscopolamine and its UV-active degradation products. Key: 1, tropic acid; 2, methscopolamine; and 3, aposcopolamine.*

periodate oxidation of phenylpropanolamine to benzaldehyde followed by extraction into hexane (1) indicate that the molecule is subject to decomposition in pharmaceutical preparations with time at normal and

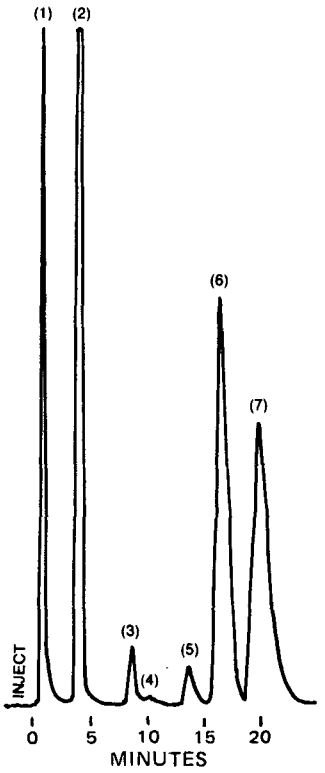

**Figure 3**—*Representative chromatogram of sample spiked with tropic acid and aposcopolamine bromide. Key: 1, tropic acid and excipients; 2, phenylpropanolamine; 3, methscopolamine; 4, excipient; 5, aposcopolamine; 6, pyrilamine; and 7, pheniramine.*

elevated temperatures. While the degradation products of phenylpropanolamine cannot be quantified by this method, a significant decrease in phenylpropanolamine was observed in stressed samples. Assay results for fresh and stressed samples by periodate oxidation correlated well with this assay, thus supporting the stability-indicating properties of this assay for phenylpropanolamine.

The recovery of the antihistamines, pyrilamine maleate[5] and pheniramine maleate, from a tablet matrix containing resinous material became increasingly difficult as the tablet was subjected to stress. Consequently, the acidic–alcoholic sample solution was exposed to heat to free the remaining antihistamines from the matrix.

In general, the chromatograms of stressed samples showed a decrease in phenylpropanolamine and methscopolamine but no loss in the pheniramine or pyrilamine content. There was no indication that excipients or degradation products interfered with the four peaks.

Careful control of buffer pH was necessary to obtain adequate separation of the pyrilamine and pheniramine peaks. The monitoring wavelength of 216.5 nm was selected as the optimum response *versus* baseline noise for the four species. At this wavelength, trace amounts of $\alpha$-aminopropiophenone, a precursor and possible trace contaminant in phenylpropanolamine, do not absorb to a significant amount.

# Antiparasitic Structure–Activity Relationships of Congocidine Derivatives

**MEIR BIALER *[x], JOSEPH EL-ON [‡], BORIS YAGEN [§], and RAPHAEL MECHOULAM [§]**

Received October 23, 1980, from the **Department of Pharmacy, School of Pharmacy, the* [‡]*Department of Parasitology, Hadassah Medical School, and the* [§]*Department of Natural Products, School of Pharmacy, Hebrew University of Jerusalem, Jerusalem, Israel.* Accepted for publication December 17, 1980.

**Abstract** □ Several congocidine analogs were synthesized and tested for *in vivo* activity against *Trypanosoma congolense* and *in vitro* activity against amastigotes of *Leishmania tropica*. The tripyrrole derivative, β-{[*N*-methyl-4-[*N*-methyl-4-(guanidinoacetamido)pyrrole -2- carboxamido]pyrrole-2-carboxamido]pyrrole-2-carboxamido}butyroamidine dihydrochloride, was less toxic and more active than congocidine. The guanidinoacetyl moiety appears to be a structural requirement for antiparasitic activity in the congocidine series.

**Keyphrases** □ Congocidine derivatives—tri- and monopyrrole analogs, synthesized and evaluated for antiparasitic activity in mice, *in vivo* and *in vitro* studies □ Structure–activity relationships—tripyrrole derivatives of congocidine synthesized and evaluated for antiparasitic activity in mice, *in vivo* and *in vitro* studies □ Antiparasitic activity—tripyrrole derivatives of congocidine synthesized and evaluated for activity in mice, *in vitro* and *in vivo* studies

Congocidine (I) and distamycin A (II) are basic oligopeptide antiviral antibiotics isolated from the medium of *Streptomyces* sp. (1–3). The structure of congocidine was established by a series of degradations and a total synthesis (4, 5) and was shown to be identical to that of netropsin, which was isolated from a medium of *Streptomyces netropsis* (6, 7).

## BACKGROUND

Congocidine (I) and distamycin A (II) are the major components of a group of pyrrole amidine antiviral antibiotics. Unlike distamycin A and in addition to its antiviral and antibacterial activities (8, 9), congocidine also shows antiparasitic activity against *Trypanosoma congolense* (the source of its name) and other parasites (1, 2, 7). Little information is available on the structural requirements for the antiparasitic activity of congocidine. The only reported study (10) demonstrated that replacement of the *N*-methylpyrrole ring in congocidine by thiophene, pyridine, or benzene led to the loss of its trypanocidal activity.

Several studies on the distamycin series showed that when distamycin A (a tripeptide) was converted to its tetra- or pentapeptide analogs, the antiviral and antibacterial activities against some viruses and bacteria increased (11–14). At the same time, cytotoxicity was somewhat reduced, indicating that the biological and cytotoxic activities were separable.

A similar observation was made in the congocidine series. Several tripyrrole derivatives of congocidine were less cytotoxic and more active than the parent drug in three tests against Herpes simplex virus (15). The present study evaluated the antiparasitic activity of different tri- and monopyrrole derivatives of congocidine to establish some structural requirements in the congocidine molecule. Congocidine and its derivatives were tested against *Leishmania tropica*[1] *in vitro* in mouse peritoneal exudate cells and against *T. congolense*[2] *in vivo*.

## EXPERIMENTAL

**Chemistry**—The syntheses of the compounds were described previously (15, 16).

**Parasitology**[3]—*Animals*—Male mice of the inbred strains $C_3H$ and

[1] The *L. tropica* LRC-L137 strain was obtained from the strain collection of the World Health Organization's International Reference Center for Leishmaniasis (WHO-LRC) at the Department of Protozoology, Hadassah Medical School, Jerusalem, Israel.

[2] The *T. congolense* TREU 1183 strain was kindly supplied by Professor Curtis L. Patton, Department of Epidemiology and Public Health, Yale University, New Haven, Conn.

[3] Some of the parasitological work was presented at the annual meeting of the Israeli Society of Protozoologists (April 1980) and will appear as the following abstracts: J. El-On, C. L. Greenblat, D. T. Spira, R. Mechoulam, and M. Bialer, "The Effect of Congocidine Derivatives on *Leishmania tropica* and *Trypanosoma congolense*," in *J. Protozoology Supplement* (1981).

elevated temperatures. While the degradation products of phenylpropanolamine cannot be quantified by this method, a significant decrease in phenylpropanolamine was observed in stressed samples. Assay results for fresh and stressed samples by periodate oxidation correlated well with this assay, thus supporting the stability-indicating properties of this assay for phenylpropanolamine.

The recovery of the antihistamines, pyrilamine maleate[5] and pheniramine maleate, from a tablet matrix containing resinous material became increasingly difficult as the tablet was subjected to stress. Consequently, the acidic–alcoholic sample solution was exposed to heat to free the remaining antihistamines from the matrix.

In general, the chromatograms of stressed samples showed a decrease in phenylpropanolamine and methscopolamine but no loss in the pheniramine or pyrilamine content. There was no indication that excipients or degradation products interfered with the four peaks.

Careful control of buffer pH was necessary to obtain adequate separation of the pyrilamine and pheniramine peaks. The monitoring wavelength of 216.5 nm was selected as the optimum response *versus* baseline noise for the four species. At this wavelength, trace amounts of $\alpha$-aminopropiophenone, a precursor and possible trace contaminant in phenylpropanolamine, do not absorb to a significant amount.

# Antiparasitic Structure–Activity Relationships of Congocidine Derivatives

**MEIR BIALER *[x], JOSEPH EL-ON [‡], BORIS YAGEN [§], and RAPHAEL MECHOULAM [§]**

Received October 23, 1980, from the **Department of Pharmacy, School of Pharmacy, the* [‡]*Department of Parasitology, Hadassah Medical School, and the* [§]*Department of Natural Products, School of Pharmacy, Hebrew University of Jerusalem, Jerusalem, Israel.* Accepted for publication December 17, 1980.

**Abstract** □ Several congocidine analogs were synthesized and tested for *in vivo* activity against *Trypanosoma congolense* and *in vitro* activity against amastigotes of *Leishmania tropica*. The tripyrrole derivative, β-{[*N*-methyl-4-[*N*-methyl-4-(guanidinoacetamido)pyrrole -2- carboxamido]pyrrole-2-carboxamido]pyrrole-2-carboxamido}butyroamidine dihydrochloride, was less toxic and more active than congocidine. The guanidinoacetyl moiety appears to be a structural requirement for antiparasitic activity in the congocidine series.

**Keyphrases** □ Congocidine derivatives—tri- and monopyrrole analogs, synthesized and evaluated for antiparasitic activity in mice, *in vivo* and *in vitro* studies □ Structure–activity relationships—tripyrrole derivatives of congocidine synthesized and evaluated for antiparasitic activity in mice, *in vivo* and *in vitro* studies □ Antiparasitic activity—tripyrrole derivatives of congocidine synthesized and evaluated for activity in mice, *in vitro* and *in vivo* studies

Congocidine (I) and distamycin A (II) are basic oligopeptide antiviral antibiotics isolated from the medium of *Streptomyces* sp. (1–3). The structure of congocidine was established by a series of degradations and a total synthesis (4, 5) and was shown to be identical to that of netropsin, which was isolated from a medium of *Streptomyces netropsis* (6, 7).

## BACKGROUND

Congocidine (I) and distamycin A (II) are the major components of a group of pyrrole amidine antiviral antibiotics. Unlike distamycin A and in addition to its antiviral and antibacterial activities (8, 9), congocidine also shows antiparasitic activity against *Trypanosoma congolense* (the source of its name) and other parasites (1, 2, 7). Little information is available on the structural requirements for the antiparasitic activity of congocidine. The only reported study (10) demonstrated that replacement of the *N*-methylpyrrole ring in congocidine by thiophene, pyridine, or benzene led to the loss of its trypanocidal activity.

Several studies on the distamycin series showed that when distamycin A (a tripeptide) was converted to its tetra- or pentapeptide analogs, the antiviral and antibacterial activities against some viruses and bacteria increased (11–14). At the same time, cytotoxicity was somewhat reduced, indicating that the biological and cytotoxic activities were separable.

A similar observation was made in the congocidine series. Several tripyrrole derivatives of congocidine were less cytotoxic and more active than the parent drug in three tests against Herpes simplex virus (15). The present study evaluated the antiparasitic activity of different tri- and monopyrrole derivatives of congocidine to establish some structural requirements in the congocidine molecule. Congocidine and its derivatives were tested against *Leishmania tropica*[1] *in vitro* in mouse peritoneal exudate cells and against *T. congolense*[2] *in vivo*.

## EXPERIMENTAL

**Chemistry**—The syntheses of the compounds were described previously (15, 16).

**Parasitology**[3]—*Animals*—Male mice of the inbred strains $C_3H$ and

[1] The *L. tropica* LRC-L137 strain was obtained from the strain collection of the World Health Organization's International Reference Center for Leishmaniasis (WHO-LRC) at the Department of Protozoology, Hadassah Medical School, Jerusalem, Israel.

[2] The *T. congolense* TREU 1183 strain was kindly supplied by Professor Curtis L. Patton, Department of Epidemiology and Public Health, Yale University, New Haven, Conn.

[3] Some of the parasitological work was presented at the annual meeting of the Israeli Society of Protozoologists (April 1980) and will appear as the following abstracts: J. El-On, C. L. Greenblat, D. T. Spira, R. Mechoulam, and M. Bialer, "The Effect of Congocidine Derivatives on *Leishmania tropica* and *Trypanosoma congolense*," in *J. Protozoology Supplement* (1981).

Balb/c (25–35 g, 8–12 weeks old) were used. The $C_3H$ mice were the source of peritoneal exudate cells, while the Balb/c mice were used for *in vivo* studies of *T. congolense*.

*Cutaneous Leishmaniasis*—Mice peritoneal exudate cells were prepared from thioglycolate-stimulated mice as described by Handman *et al.* (17). The cells were cultivated in 24-well microplates at 37° and were infected 2 hr after cultivation with promastigotes prepared from a stabilate held at liquid nitrogen. The drug was introduced 24 hr after the transformation into intracellular amastigotes. The development of the parasites was checked daily, and the parasite survival index was determined. This index is the mean number of intracellular parasites multiplied by the percent of infection, as compared with the untreated infected control.

*Trypanosomiasis*—Balb/c mice were inoculated intraperitoneally with $5 \times 10^5$ trypanosomes. Drug treatment was begun 2–3 days after infection

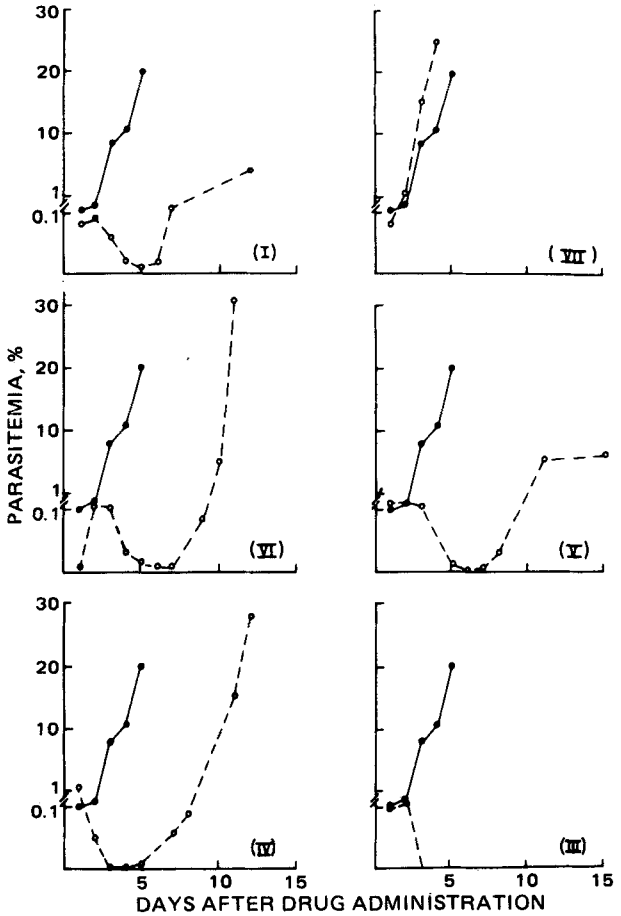

**Figure 1**—*Effect of congocidine derivatives on the growth of* T. congolense *in Balb/c mice. Day 1 is the 1st day of drug administration (40 mg/kg). The full-line (●) drawing indicates the results in mice receiving no drug.*

when parasites were detected in the blood. The parasites were counted daily in blood smears prepared from the mouse tail.

## RESULTS

The tripyrrole analog of congocidine (III) showed the greatest growth inhibition of *T. congolense* in mice. Two injections (40 mg/kg ip) given

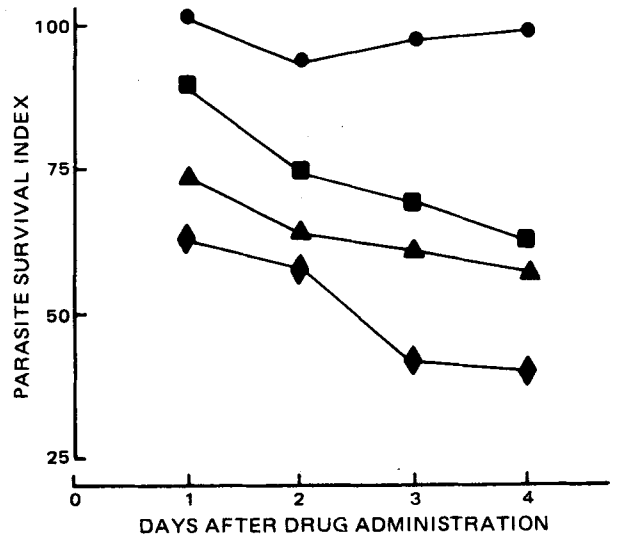

**Figure 2**—*Effect of distamycin A and congocidine derivatives on the growth of* L. tropica *amastigotes in peritoneal exudate cells from $C_3H$ mice at 37°. Key: ●, 10 μg of I/ml; ▲, 100 μg of II/ml; ♦, 10 μg of III/ml; and ■, 25 μg of IV/ml.*

on the 5th and 6th days of infection (when the parasitemia was >0.01%) were trypanocidal to such an extent that no parasites were detected over 90 days. The mice were tested every 15 days (Fig. 1). The other drugs, including the parent drugs (I and II), were less effective; they lowered parasitemias significantly but did not eliminate the parasites totally. Mice administered congocidine (I) or IV (40 mg/kg) three or more times died either from high parasitemia or from the toxic effect of the drug. Compound II was less toxic but also less effective against the parasite as compared with I. Six doses of II (40 mg/kg) did not affect the growth of the parasites, while five doses of 80 mg/kg inhibited the growth only partially.

*In vitro* studies indicated that III was also the most effective compound against *L. tropica* amastigotes in $C_3H$ mouse mononuclear phagocytes (Fig. 2). In cultures treated with 10 μg of III/ml, the parasite survival index indicated 50% survival on the 2nd day and 20% by the 4th day. Compounds IV (25 μg/ml) and II (100 μg/ml) also reduced growth but were not as effective as III. Cytotoxicity to host cells was observed at 25, 50, 50, and 200 μg/ml of I, III, IV, and II, respectively.

The doses used were the minimal effective nontoxic ones. Thus, no inhibitory effects on the growth of *L. tropica* were seen when II and IV were given in a concentration of <100 and 25 μg/ml, respectively. The monopyrrole analog of congocidine (VI) had the same effect against *T. congolense* as the parent drug. Its position isomer (VII) was completely inactive.

## DISCUSSION

In two antiparasitic tests, the tripyrrole derivative of congocidine (III) was more potent and less toxic than congocidine and more potent than its analog (IV). Although less toxic than congocidine, IV demonstrated the same inhibitory activity as the parent drug in the two systems tested. These results showed that there are considerable structural requirements in the congocidine series for their antiparasitic activity.

It was reported previously (15) that the tripeptide (IV) is more active in some antiviral tests than the dipeptide congocidine (I). However, this modification alone did not improve the antiparasitic activity, although it improved the therapeutic index. Surprisingly, the addition of a methyl group to the β-aminopropionamidine moiety in IV, leading to III, increased the antiparasitic activity and further improved the therapeutic index. The fact that distamycin A was totally inactive in the two antiparasitic tests demonstrated that the guanidinoacetyl moiety in the congocidine molecule cannot be replaced by a formamido moiety, contrary to observations in the antiviral field.

# High-Performance Liquid Chromatographic Analysis of Carbenicillin and Its Degradation Products

**PHILIP A. TWOMEY**

Received November 19, 1980, from the *Penicillin Recovery Department, Pfizer Inc., Groton, CT 06340.* Accepted for publication December 22, 1980.

**Abstract** □ An ion-pair reversed-phase high-performance liquid chromatographic system is used to separate carbenicillin from carbenicillin penicilloic acid, carbenicillin penilloic acid, penicillin G, penicillin G penicilloic acid, and penicillin G penilloic acid. Conditions are provided for resolution of the carbenicillin diastereomer pair and for elution as a single peak, facilitating quantitation.

**Keyphrases** □ Carbenicillin—degradation products, high-performance liquid chromatographic analysis, mobile phase modifications □ High-performance liquid chromatography—analysis, carbenicillin, resolution of diastereomer pair or single-peak elution by mobile phase modifications □ Antibiotics—carbenicillin, high-performance liquid chromatographic analysis, mobile phase modifications □ Degradation—carbenicillin, high-performance liquid chromatographic analysis

Carbenicillin, a broad-spectrum semisynthetic penicillin-type antibiotic, is important because of its antipseudomonal and antiproteus effect. Most classical analytical methods available for penicillin purity or potency determinations are applicable to carbenicillin; the iodometric and hydroxylamine methods and the microbiological agar diffusion assay are the most widely used. The latter method is the one specified by the Antibiotic Regulations of the Food and Drug Administration (1). Carbenicillin monosodium monohydrate is used as a reference standard for this assay (2).

## BACKGROUND

Recent literature (3–6) indicated that high-performance liquid chromatography (HPLC), especially reversed-phase or ion-pair reversed-phase HPLC on microparticulate (≤10 μm) bonded packing materials, is amenable to the analysis of penicillins. In many penicillin analyses,

*0022-3549/81/0700-0824$01.00/0*

# High-Performance Liquid Chromatographic Analysis of Carbenicillin and Its Degradation Products

**PHILIP A. TWOMEY**

Received November 19, 1980, from the *Penicillin Recovery Department, Pfizer Inc., Groton, CT 06340.* Accepted for publication December 22, 1980.

**Abstract** □ An ion-pair reversed-phase high-performance liquid chromatographic system is used to separate carbenicillin from carbenicillin penicilloic acid, carbenicillin penilloic acid, penicillin G, penicillin G penicilloic acid, and penicillin G penilloic acid. Conditions are provided for resolution of the carbenicillin diastereomer pair and for elution as a single peak, facilitating quantitation.

**Keyphrases** □ Carbenicillin—degradation products, high-performance liquid chromatographic analysis, mobile phase modifications □ High-performance liquid chromatography—analysis, carbenicillin, resolution of diastereomer pair or single-peak elution by mobile phase modifications □ Antibiotics—carbenicillin, high-performance liquid chromatographic analysis, mobile phase modifications □ Degradation—carbenicillin, high-performance liquid chromatographic analysis

Carbenicillin, a broad-spectrum semisynthetic penicillin-type antibiotic, is important because of its antipseudomonal and antiproteus effect. Most classical analytical methods available for penicillin purity or potency determinations are applicable to carbenicillin; the iodometric and hydroxylamine methods and the microbiological agar diffusion assay are the most widely used. The latter method is the one specified by the Antibiotic Regulations of the Food and Drug Administration (1). Carbenicillin monosodium monohydrate is used as a reference standard for this assay (2).

## BACKGROUND

Recent literature (3–6) indicated that high-performance liquid chromatography (HPLC), especially reversed-phase or ion-pair reversed-phase HPLC on microparticulate (≤10 μm) bonded packing materials, is amenable to the analysis of penicillins. In many penicillin analyses,

*0022-3549/81/0700-0824$01.00/0*

*© 1981, American Pharmaceutical Association*

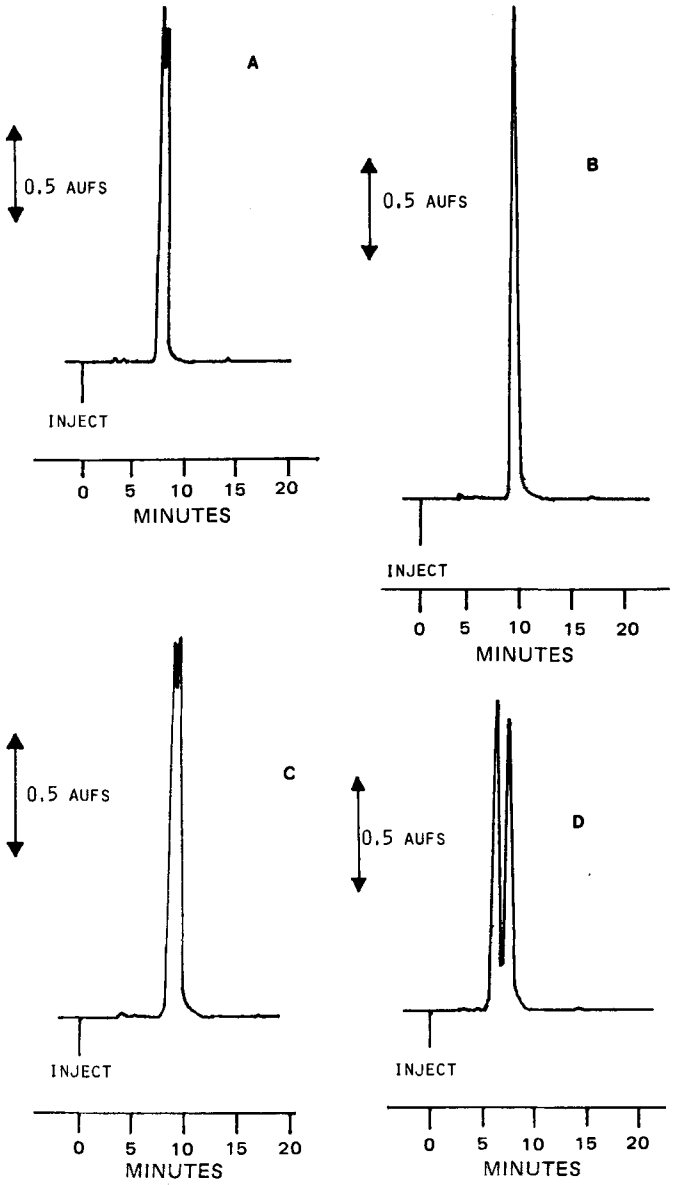

**Figure 1**—*Chromatograms of carbenicillin (0.850 mg/ml) with a mobile phase of 37% methanol at 1.2 ml/min and the detector wavelength at 220 nm. Key (pH of mobile phase): A, 3.00; B, 3.35; C, 3.70; and D, 4.35.*

HPLC procedures are the methods of choice because of demonstrated precision, accuracy, speed, and ability to provide ancillary information relative to the nature and identity of purity-depressing substances such as reaction by-products or natural degradation products present in the sample. In addition, the analyses often can be accomplished when the drug is part of a complex mixture such as a biological fluid or blend formulation.

Carbenicillin is a somewhat unique semisynthetic penicillin in that the normal synthesis routes produce a diastereomer mixture. This mixture complicates quantitative analysis by HPLC since reversed-phase microparticulate column packings generally are selected for their ability to separate the components of a mixture. Thus, the same criterion used to select HPLC as an analytical method for carbenicillin can negate its quantitation since the carbenicillin diastereomers tend to elute as two peaks, except when the chromatographic conditions are closely controlled. This tendency is especially true when methanolic mobile phases and high efficiency columns are used.

This report describes the mobile phase modifications used with a 5-$\mu$m octadecylsilyl-bonded silica-based column to provide either separation of the carbenicillin diastereomers or elution as one peak, depending on the desires of the analyst. In addition, separation of carbenicillin from some of its possible degradation products is demonstrated.

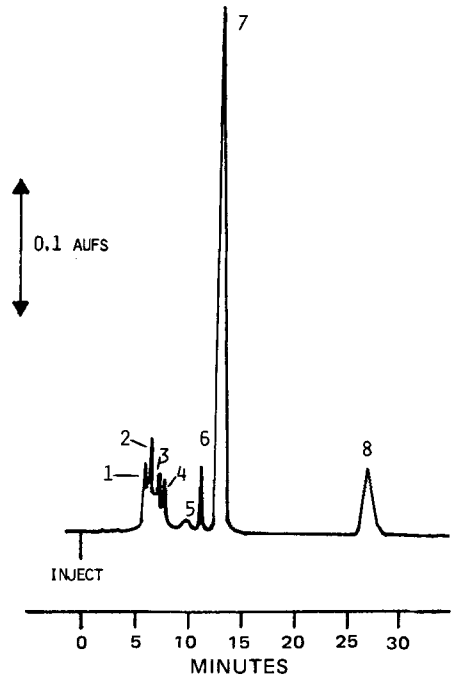

**Figure 2**—*Chromatograms of carbenicillin (1.944 mg/ml) spiked with 5–8% degradation products. The mobile phase was 35% methanol (pH 3.35) at 1.3 ml/min, and the detector was at 254 nm. Key: 1, carbenicillin penilloic acid; 2, carbenicillin penicilloic acid; 3, penicillin G penilloic acid epimer; 4, penicillin G penilloic acid epimer; 5, penicillin G penicilloic acid epimer; 6, penicillin G penicilloic acid epimer; 7, carbenicillin; and 8, penicillin G.*

## EXPERIMENTAL

**Apparatus**—The liquid chromatograph system consisted of a constant-flow pump[1], a fixed-volume loop injection valve[2], a 150 × 4.6-mm i.d. column packed in this laboratory by the method of Broquaire (7) with 5-$\mu$m Spherisorb ODS[3], a variable-wavelength UV detector[4], an electronic integrator[5], and a potentiometric recorder[6].

**Reagents**—Distilled water and distilled-in-glass methanol[7] were used. Production lots[8] of carbenicillin and penicillin G were used in the preparation of the degradation products by published methods (8). The remaining chemicals were reagent grade.

**Mobile Phase**—The mobile phases consisted of 35 or 37% methanol with the balance being 0.05 *M* $KH_2PO_4$ (v/v). Tetrabutylammonium bromide[9] (0.1%, w/v) was added as the ion-pair reagent. The pH was adjusted with 10% $H_3PO_4$, and the solution was degassed (laboratory vacuum) for 5 min prior to the initial use. Flow rates between 1.0 and 1.5 ml/min were employed.

**Carbenicillin Solutions**—A laboratory working standard of carbenicillin monosodium monohydrate dissolved in 0.02 *M* phosphate buffer (pH 7.0) was used for the liquid chromatographic work.

## RESULTS AND DISCUSSION

The HPLC resolution of the carbenicillin diastereomer pair and the subsequent quantitation problem were discussed previously (6). Diastereomers of other penicillins and cephalosporins were separated by HPLC (9), and the relationship of the mobile phase composition and pH on the degree of resolution was shown. The HPLC resolution of the carbenicillin diastereomers with a reversed-phase system and a micropar-

ticulate column[10] first was observed in this laboratory in 1974[11], but the mobile phase pH effects were not understood fully at that time.

It was determined in the present study that the carbenicillin diastereomers can be either resolved or eluted as a single peak, depending on the mobile phase pH (Figs. 1A–1D). The conditions used to produce the chromatogram of Fig. 1B are more conducive to quantitation, either by manual or electronic methods. For example, Yamaoka *et al.* (6) were required to use a gravimetric method (cutting and weighing the HPLC recorder tracing) to obtain quantitative results.

Carbenicillin degrades *via* hydrolytic or decarboxylative routes. Penicillin G, which results from the carbenicillin side-chain decarboxylation, was present at a low level in the working standard of carbenicillin monosodium monohydrate, as evidenced by the peak near 17 min in Fig. 1B. Some carbenicillin samples were found to contain penicillin G sodium in amounts between 3.5 and 4.9% (10). The working standard also contained other process-related substances at low levels which eluted between 3 and 7 min.

To demonstrate assay noninterference, carbenicillin and penicillin G degradation products were synthesized by the methods reported previously (8), with one anomaly; the yield of penicillin G penicilloic acid as its monosodium salt monohydrate was significantly less than was reported, and this substance crystallized only with great difficulty. In addition, the conditions stated for the preparation of carbenicillin penicilloic acid apparently provide a mixture of epimers in an approximate 60:40 ratio, as evidenced by HPLC. Only one epimer crystallized.

The carbenicillin degradation products were essentially pure by HPLC[12]. The physical data obtained[13] were consistent with those reported (8, 11). A synthetically prepared mixture of carbenicillin, carbenicillin penicilloic acid, carbenicillin penilloic acid, penicillin G, penicillin G penicilloic acid, and penicillin G penilloic acid was subjected to chromatographic analysis. The chromatogram of Fig. 2 shows that carbenicillin was separated adequately from the degradation products used and that the carbenicillin peak could be quantitated easily.

A detector linearity study for carbenicillin concentrations, as its monosodium salt monohydrate, between 0.25 and 4.05 mg/ml in pH 7.0 phosphate buffer, showed an origin-oriented linear response at 254 nm. The calibration curve at 254 nm was characterized with a regression coefficient of 0.9998.

Reproducibility was demonstrated with 10 replicate analyses of the same solution (1.634 mg/ml) at 15-min intervals. The carbenicillin peaks were quantitated electronically by area, and the relative standard deviation was 0.79%.

Dissolving the carbenicillin working standard in the mobile phase adjusted to pH 7.0 caused a slow but steady degradation of carbenicillin. However, solutions of carbenicillin in 0.02 *M* phosphate buffer (pH 7.0) were stable for at least 5 hr.

This HPLC procedure is readily adaptable to the determination of penicillin G in carbenicillin samples and, with appropriate mobile phase modifications, has utility for the analysis of other penicillins.

# Enzymatic Assays for 2,4-Diamino-5-methyl-6-[(3,4,5-trimethoxyanilino)methyl]quinazoline, a Promising New "Nonclassical" Antifolate

**J. J. HEUSNER * and J. J. McCORMACK *‡x**

Received November 19, 1979, from the **Vermont Regional Cancer Center and Pharmacology Department, College of Medicine, University of Vermont, Burlington, VT 05405,* and the ‡*Laboratory of Medicinal Chemistry and Biology, Division of Cancer Treatment, National Cancer Institute, National Institutes of Health, Bethesda, MD 20205.* Accepted for publication January 7, 1981. (Inquiries should be directed to the University of Vermont.)

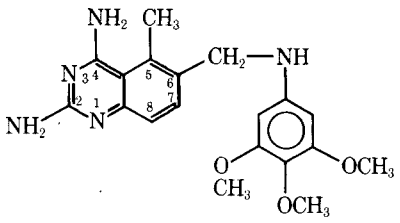
**Abstract** □ 2,4-Diamino-5-methyl-6-[(3,4,5-trimethoxyanilino)-methyl]quinazoline (I) is a promising new "nonclassical" antifolate. Inhibition of dihydrofolate reductase from bacterial (*Lactobacillus casei*) and mammalian (beef liver) sources was employed to develop useful enzymatic assays for this compound. A linear relationship was obtained by plotting the I concentration *versus* $1/V$. The resultant standard curves maintained linearity particularly well between the 30 and 70% control range, with a correlation coefficient of 0.99 for both enzyme systems. The two enzyme systems are characterized by differences in sensitivity, stability, and day-to-day variation. The $ID_{50}$ for the beef liver reductase system was $1.6 \times 10^{-9}$ *M* (±0.3); for the *L. casei* system, it was $1.35 \times 10^{-8}$ *M* (±0.2). The apparent advantage for the beef liver enzyme was offset somewhat by its relative instability and its higher day-to-day variability. Studies in mice demonstrated that these assays are suitable for pharmacokinetic studies *in vivo*. Such studies indicated that I has a serum $t_{1/2}$ of 45 min in mice; a similar serum $t_{1/2}$ (50 min) was estimated in studies with $^{14}C$-labeled I in position 6.

**Keyphrases** □ 2,4-Diamino-5-methyl-6-[(3,4,5-trimethoxyanilino)-methyl]quinazoline—two enzyme assays using beef liver reductase and *Lactobacillus casei* □ Enzymatic analyses—2,4-diamino-5-methyl-6-[(3,4,5-trimethoxyanilino)methyl]quinazoline using beef liver reductase and *Lactobacillus casei* □ Antifolates—2,4-diamino-5-methyl-6-[(3,4,5-trimethoxyanilino)methyl]quinazoline enzymatic analyses using beef liver reductase and *Lactobacillus casei*

2, 4-Diamino-5-methyl-6-[(3, 4, 5-trimethoxyanilino)-methyl]quinazoline (I) is a potent inhibitor of dihydrofolate reductase [5,6,7,8-tetrahydrofolate:$NADP^+$ oxidoreductase (EC 1.5.1.3)]. Compound I was originally synthesized by Elslager and colleagues as part of an effort to develop quinazoline antifolates with useful antiprotozoal activity (1). Interest in possible antineoplastic applications of I was stimulated when the agent was reported (2) to be a potent inhibitor of the enzyme from several sources, including the L-1210 murine leukemia line.

In comparison to methotrexate, I offers several qualities that may prove advantageous clinically. Since it is a much more lipophilic derivative than is methotrexate, it may penetrate the central nervous system (CNS) more readily and thus be more effective than methotrexate against CNS neoplasms.

Bertino (3) commented upon the increased uptake of I into neoplastic cells compared to methotrexate, and he and his colleagues (4) reported also that I is effective against a wider range of transplantable murine tumors than is methotrexate. Methotrexate, a weak dicarboxylic acid (pKa 4.7), can be metabolized to a 7-hydroxy metabolite, which may contribute to its nephrotoxicity (5). High-dose methotrexate therapy is associated with significant clinical nephrotoxicity in patients, despite vigorous hydration and alkalinization of the urine (6). It is possible that I may offer an advantage as a substitute for methotrexate in high-dose antifolate regimens.



I

Studies are underway to determine the pharmacokinetic and pharmacodynamic properties of I relative to those of methotrexate. This article reports two enzymatic assays for this "nonclassical" antifolate.

## EXPERIMENTAL

Beef liver dihydrofolate reductase is available commercially[1] in 5-unit vials. The enzyme was prepared just prior to use by diluting 3 μl of the commercial suspension in 2 ml of chilled 0.1 *M* phosphate buffer at pH 7.0. *Lactobacillus casei* dihydrofolate reductase was obtained[2] in 20-unit vials. This stock enzyme solution was prepared by dissolving 1 mg of powder in 4 ml of 0.1 *M* phosphate buffer at pH 7.0.

The assay system employed was a slight modification of that described by Burchall and Hitchings (7), involving measurement of the decrease in absorbance at 340 nm, catalyzed by dihydrofolate in a 1-ml system. The system was composed of NADPH[3] ($1 \times 10^{-4}$ *M*), 2-mercaptoethanol ($1 \times 10^{-2}$ *M*), and dihydrofolate [$6.6 \times 10^{-5}$ *M*, prepared according to Futterman (8)] in 0.1 *M* phosphate buffer at pH 7.0. The quantity of enzyme solution used for each assay was sufficient to produce an absorbance decrease of 0.17 unit for the beef liver and of 0.2 unit for the *L. casei* systems over a 10.5-min assay period. The enzyme assays were performed[4] at a chamber temperature of 37°. A reference blank containing buffer, enzyme, and 2-mercaptoethanol was employed during each run.

Compound I was dissolved in dimethyl sulfoxide at $1.1 \times 10^{-3}$ *M* and then serially diluted in 0.1 *M* phosphate buffer at pH 7.0 to give a suitable range of concentrations. After a 5-min preincubation at 37°, first NADPH and then dihydrofolate (as a 1:3 dilution in 0.1 *M* phosphate buffer at pH 7.0) were added to the cells to initiate the enzymatic reaction. Controls without inhibitor were run with each assay. A NADPH control (reaction mixture minus dihydrofolate) was run daily to assess absorbance changes due to NADPH oxidation. This value was subtracted from each value determined to give a more accurate control and inhibitor value. Absorbance changes were measured every 90 sec for 10.5 min, and $ID_{50}$ values were obtained by a least-squares regression analysis of the lines determined by plotting the enzyme activity *versus* the inhibitor concentration.

Compound I was formulated for intravenous administration to mice by solubilizing 10 mg in 0.4 ml of propylene glycol with stirring. After solubilization, the addition of 0.6 ml of normal saline produced a solution suitable for injection. Injections were made into the tail vein of female

**Table I—Levels of I in Mouse Serum after Intravenous Administration**

| Minutes | Concentration, $M \times 10^{-6}$ | |
|---|---|---|
| | Enzymatic Assay[a] | Isotopic Assay[b] |
| 15 | 20.7 (±0.3) | 2.3 (±0.1) |
| 30 | 16.5 (±0.5) | 1.8 (±0.1) |
| 60 | 9.5 (±1.3) | 1.25 (±0.1) |
| 90 | 6.1 (±1.3) | 0.73 (±0.06) |
| 120 | 4.3 (±1.1) | 0.59 (±0.07) |
| 180 | 1.7 (±0.2) | — |

[a] *L. casei* enzyme; I was administered at 10 mg/kg. Estimated serum elimination $t_{1/2}$ was 45 min. Data are from six separate experiments (one mouse for each time point). Figures in parentheses are the standard errors of the mean. [b] Data from four experiments; I was administered at 1 mg/kg. Estimated serum elimination $t_{1/2}$ was 50 min.

mice (Swiss-Webster, 20–22 g), and blood samples were collected by retro-orbital puncture. Compound I labeled in position 6 with carbon 14 (specific activity of 21 μCi/mg) was used[5]. For the isotopic studies, 10 μl of serum was placed in 10 ml of scintillation fluid[6] and radioactivity was measured by liquid scintillation spectrometry[7].

## RESULTS AND DISCUSSION

In anticipation of pharmacokinetic studies of I, two assay procedures were developed based on the inhibitory activity of I on dihydrofolate reductase from bacterial and mammalian sources. A linear relationship was obtained by plotting the I concentration *versus* $1/V$[8]. This linearity held well for I concentrations producing 30–70% inhibition of dihydrofolate reductase. The correlation coefficient for such lines was 0.99 for both enzyme systems. The standard curves obtained by linear or semilog plots of the I concentration *versus* the percent control are suitable for pharmacokinetic studies.

By using this enzymatic approach to drug assay, studies in mice indicated a serum elimination half-time of ~45 min (Table I). Sigel and colleagues[9], using a different assay, found a similar serum elimination half-time for I in the dog. A small amount of $^{14}$C-labeled I was obtained for exploratory pharmacokinetic studies in our laboratories. As shown in Table I, the elimination profile determined by the isotopic method was similar to that observed with the enzymatic method. The I levels were lower in the isotopic studies because a lower dose of I was employed (1 mg/kg).

Both enzyme assays are advantageous in that they are highly sensitive with a lower limit of sensitivity of $5 \times 10^{-10}$ *M* for the beef system and of $5 \times 10^{-9}$ *M* for the *L. casei* system (Table II). The sensitivity of both assays can be increased by lowering the amount of dihydrofolate present and/or reducing the amount of enzyme used per assay.

The two enzyme systems differ in sensitivity, stability, and accuracy. The $ID_{50}$ was $1.6 \times 10^{-9}$ *M* (±0.3) for the beef system and $1.35 \times 10^{-8}$ *M* (±0.2) for the *L. casei* system. Under the experimental conditions employed, the beef liver enzyme was about one order of magnitude more sensitive to I than was the bacterial enzyme; however, the instability of the beef preparation was reported previously (9). On the other hand, the *L. casei* enzyme was considerably more stable and easier to work with. For example, the beef enzyme began to lose activity after several hours in solution, while the bacterial enzyme solution was essentially stable throughout the day. In addition, the latter solution may be refrozen with a large measure of its activity retained upon subsequent thawing.

A disadvantage of both enzyme assays is relatively high day-to-day variability: 20% for the beef liver assay and 15% for the *L. casei* assay. Other investigators (10, 11) automated the methotrexate enzymatic assay to improve these figures. In our studies, a standard curve was generated daily. Another disadvantage of both enzyme assays is the relatively narrow range of linearity of the concentration–inhibition curve (30–70% control values have the highest reliability). However, reasonable estimates of required dilutions can be made, which will reduce assay time.

**Table II—Relationship between Inhibition of Dihydrofolate Reductase and I Concentration**

| Concentration, $M \times 10^{-9}$ | Percent Control[a] | |
|---|---|---|
| | *L. casei* | Beef Liver |
| 44 | 28 (±1.0) | — |
| 33 | 33.5 (±1.0) | — |
| 22 | 41.3 (±1.7) | — |
| 16.5 | 46.7 (±2.3) | — |
| 11 | 53.7 (±2.3) | — |
| 8.8 | 58.3 (±3.7) | — |
| 6.6 | 63 (±5.0) | — |
| 5.5 | 67.3 (±4.3) | 27.7 (±1.7) |
| 4.4 | 70.7 (±5.3) | 32 (±2.0) |
| 3.3 | 75.5 (±5.5) | 37 (±3.0) |
| 2.2 | 83.3 (±6.7) | 44.3 (±3.3) |
| 1.1 | — | 57 (±5.0) |
| 0.88 | — | 61.3 (±5.7) |
| 0.66 | — | 66.7 (±6.0) |
| 0.55 | — | 70 (±7.0) |

[a] Each value is the mean of three separate determinations of the standard curve. Figures in parentheses are the standard errors of the mean.

The described methods for determining I levels are sensitive, relatively specific, and accurate. These enzyme assays employ common laboratory equipment and readily available reagents and should prove applicable in various preclinical and clinical research situations. Measuring levels of I in biological material will be of added importance in preclinical and clinical studies in view of observations by Duch *et al.* (12) that I and related compounds can produce substantial concentration-dependent inhibition of histamine metabolism and consequent elevation of histamine levels in experimental animals.

# Immunological Studies of Poisonous Anacardiaceae: Effect of Vehicle on Absorption of 3-*n*-Pentadecylcatechol and Its Diacetate Ester Derivative after Oral Feeding in Rats

PAUL SKIERKOWSKI *x, MAHMOUD A. ElSOHLY ‡, ERNEST C. HARLAND ‡, BARBARA S. KING ‡, JAMES C. MURPHY ‡, and E. S. WATSON ‡

Received September 15, 1980, from the *Department of Pharmaceutics and the ‡Research Institute of Pharmaceutical Sciences, School of Pharmacy, University of Mississippi, University, MS 38677. Accepted for publication December 22, 1980.

**Abstract** □ Tritium-labeled 3-*n*-pentadecylcatechol and its diacetate ester were fed to Sprague–Dawley rats. Both compounds were dissolved in ethanol and in corn oil vehicles and administered by gavage. The rats were placed in metabolic cages, and the urine and feces were collected. The radioactivity excreted in the urine and feces was determined by liquid scintillation counting, and the percentage of the administered dose was utilized as a measure of absorption. While there was no difference between the absorption of either compound, absorption was affected by the vehicle. Approximately 30% of the administered radioactivity appeared in the urine when ethanol was the vehicle, but about half that amount (14%) was excreted in the urine when the compounds were dissolved in corn oil. A subsequent bile cannulation study showed that the balance of the radioactivity found in the feces was not a result of biliary excretion. The majority of the activity recovered from urine and feces was eliminated within 48 hr after dosing. These data indicate that oil is a poor vehicle for GI absorption of urushiol components.

**Keyphrases** □ Absorption, GI—3-*n*-pentadecylcatechol and its diacetate derivative, effect of vehicle, rats □ 3-*n*-Pentadecylcatechol—poison ivy component, effect of vehicle on GI absorption, rats □ Urushiol—poison ivy component of 3-*n*-pentadecylcatechol, effect of vehicle on GI absorption, rats □ Poison ivy—3-*n*-pentadecylcatechol component of urushiol, effect of vehicle on GI absorption, rats

Three poisonous species of the family Anacardiaceae [*viz.*, *Toxicodendron radicans* (poison ivy), *T. diversilobum* (poison oak), and *T. vernix* (poison sumac)] are collectively responsible for most allergic contact dermatitis in the United States. Because of the ubiquity of these plants, ~80% of the U.S. population exhibit some allergic response to them, and 50% of the population is clinically allergic (sensitivity to 2 μg of urushiol or less) (1).

## BACKGROUND

The allergenic constituents of these species commonly are referred to as urushiols and consist of dihydric phenols with either a 15- or 17-carbon side chain in the third ring position, which may or may not contain 1–3 double bonds (2, 3). The administration of plant extracts to desensitize humans has been practiced clinically since the 1920's. Urushiols are insoluble in water and usually are dissolved in corn, olive, or almond oil (4). Urushiols are extreme irritants, and injection or oral administration of these substances to sensitive humans in doses sufficient to produce prophylaxis requires extreme care (5, 6).

Toxicity can be eliminated by methylation of the ring hydroxyl groups (7, 8). Experiments in this laboratory showed that esterification of the urushiol hydroxyl groups markedly reduced their toxicity. However, these ester derivatives desensitize sensitive guinea pigs and produce immunological tolerance in naive guinea pigs when administered orally or intravenously (8).

The toxicities of the free *versus* esterified urushiols were compared in this laboratory. In mice, the $LD_{50}$ of free poison oak urushiol *via* the intraperitoneal route was 73.75 mg/kg while that of the esterified urushiol was 324.70 mg/kg. Oral doses of the free urushiol in corn oil required to produce lethality were >600 mg/kg, while oral doses of 1600 mg/kg of the esterified urushiol in corn oil produced no lethality. From these studies, it appeared that corn oil prevented urushiol absorption and protected mice from its toxic effects. This study was undertaken to determine the effect of the vehicle on the absorption of the urushiol component, 3-*n*-pentadecylcatechol (I), and its diacetate derivative (II) after oral administration to rats.

## EXPERIMENTAL

**3-*n*-Pentadecylcatechol (I)**—Poison ivy urushiol was isolated by ethanolic extraction of fresh leaves, berries, and green stems of *T. radicans*[1] using a reported extraction procedure (2). The urushiol extract was partially purified (60% pure) as previously described (3). Aliquots of the purified urushiol oil were reduced to I by catalytic hydrogenation, using 5% palladium-on-carbon, and the mixture containing I was purified further by passage over a dry silica gel 60 column with chloroform as the eluting solvent.

The eluting fractions were tested for I using 1% ethanolic ferric chloride; fractions containing I were combined, and the solvent was evaporated *in vacuo*. The residue containing I was purified further by passage over a polyamide column[2] with 90% ethanol in water as the eluting solvent. Fractions containing I were combined, and the solvent was evaporated. Further purification of I was accomplished by repeated crystallization of the residue in hexane. Colorless needle crystals of I resulted, mp 58–59°. The identity of I was confirmed by GLC and GLC–mass spectral analysis using previously described procedures (2, 9).

**Pentadecylcatechol Acetate (II)**—Crystalline I was dissolved in acetic anhydride and pyridine and was stirred at room temperature overnight. The reaction mixture then was poured over crushed ice and extracted with chloroform. The chloroform extract was washed successively with chilled dilute sulfuric acid, water, saturated sodium bicarbonate, and again with water. The chloroform solution was dried (sodium sulfate), and the solvent was evaporated, yielding II. GLC–mass spectral analysis showed quantitative conversion to the diacetate derivative.

**3-*n*-Pentadeca-8,11,14-trienylcatechol (Triolefinic Congener)**—The triolefinic congener of I was isolated from purified poison ivy urushiol extract. Urushiol (>60% pure) was converted to its diacetate derivative with acetic anhydride and pyridine. The urushiol acetate was passed over a dry silica gel[3] column impregnated with silver nitrate with 1% methanol in chloroform as the eluting solvent. The polarity of the eluting solvent was increased gradually to 4% methanol in chloroform, and fractions containing the mono-, di-, or triolefinic congener acetates were pooled separately based on their TLC similarities on silver nitrate-impregnated silica gel plates. The solvent was evaporated from the pool containing the triolefinic congener acetate, and the allergenically active triolefinic congener was regenerated by basic hydrolysis using 10% sodium carbonate in dioxane–water (4:1). The reaction mixture then was acidified, and the free congener was determined by GLC and GLC–mass spectral analysis of the trimethylsilyl derivative (9).

**Radiolabeled Material**—Fifty milligrams of I containing 50 μg of the triolefinic congener was tritium reduced[4]. The specific activity was 10.6 mCi/mg of I.

[1] *T. radicans* (L.) Kuntze (Anacardiaceae) was collected near the University of Mississippi campus in Oxford, Miss., by M. A. ElSohly in 1975. The plant samples were authenticated by Dr. M. W. Quimby. Voucher species are stored in the drug plant herbarium at the School of Pharmacy, University of Mississippi, University, MS 38677.

Table I—Cumulative Percentage of Orally Administered Tritiated Pentadecylcatechol (I) or Its Diacetate Derivative (II) Excreted in Urine

| Hours Postdose | Tritiated I in Ethanol | Tritiated I in Oil | Tritiated II in Ethanol | Tritiated II in Oil |
|---|---|---|---|---|
| 6 | 7.35 ± 2.84 | 4.41 ± 1.13 | 8.27 ± 3.57 | 3.63 ± 2.21 |
| 24 | 21.53 ± 5.65 | 11.49 ± 1.32 | 24.41 ± 2.06 | 11.90 ± 3.57 |
| 48 | 25.02 ± 7.04 | 13.07 ± 0.90 | 28.40 ± 1.66 | 13.17 ± 3.84 |
| 72 | 25.82 ± 7.33 | 13.55 ± 0.91 | 29.92 ± 1.87 | 13.71 ± 3.97 |
| 96 | 26.55 ± 7.71 | 13.97 ± 0.99 | 30.74 ± 1.94 | 14.11 ± 4.09 |
| 120 | 28.33 ± 7.37 | 14.22 ± 1.02 | 31.50 ± 1.84 | 14.40 ± 4.16 |

To prepare the labeled acetate derivative, the tritium-labeled I was converted to the acetate derivative using the procedure described earlier. Labeled materials were purified by preparative silica gel TLC to a purity of >90% prior to use.

**Ethanol and Corn Oil Solutions of I and II**—Aliquots of tritiated I or tritiated II in benzene were evaporated to dryness, and unlabeled I and II crystals were added as carrier. Ethanol and corn oil were the vehicles used to prepare solutions containing 2 mg of I/ml or the equivalent of 2 mg of I as the acetate per milliliter. Specific activities of prepared solutions were determined by liquid scintillation counting using internal standardization.

**Animals**—Female Sprague–Dawley rats, 250–300 g, were obtained from an in-house breeding colony. They were fasted 12 hr prior to intragastric administration of the radiolabeled solutions.

**Urine and Fecal Excretion**—Four animals each were administered 1-mg po doses of tritiated I or tritiated II in either corn oil or ethanol. After dosing, animals were housed in individual metabolism cages, and urine and feces were collected at 6, 24, 48, 72, 96, and 120 hr. The urine volumes were measured, and aliquots were mixed with 15 ml of scintillation cocktail[5]. After drying in a desiccator, the feces were weighed, frozen in liquid nitrogen, pulverized, and uniformly mixed. Aliquots of 80–120 mg were weighed accurately and then combusted in a sample oxidizer[6]; the resulting tritiated water was incorporated into 15 ml of liquid scintillation cocktail[7].

All samples were dark-adapted overnight and then counted for 10 min or 1% ($2\sigma$) error in a liquid scintillation counter[8]. Absolute activity was calculated by the use of an external standard channel ratio quench correction curve. The radioactivity in both urine and feces was expressed as the percentage of the activity of the dose excreted for the sampling period and the cumulative percent of dose amounts. Average excretion values for each collection interval then were calculated for each group.

**Biliary Excretion**—When results of the oral dosing study indicated that most of the administered dose was excreted in the feces, another study was conducted to see if this result was due to biliary excretion of the labeled material or to a lack of absorption of the compound from the GI tract.

The bile ducts of four rats were cannulated. Animals were dosed orally with a freshly prepared solution containing the equivalent of 1 mg of I in the form of tritiated II in ethanol. The bile was collected, and the volume was measured at 6, 12, 24, and 30 hr. Aliquots of bile were mixed with scintillation cocktail[5] and measured for radioactivity.

## RESULTS AND DISCUSSION

**Urine and Fecal Excretion**—Tritium-labeled I and II were dissolved in corn oil and in ethanol, and the percentage of the orally administered radioactivity appearing in the urine was taken as a measure of absorption in rats. The radioactivity appearing in the urine at 6, 24, 48, 72, 96, and 120 hr after oral dosing was determined and expressed as the cumulative percent excreted (Table I). Approximately 30% of the administered radioactivity appeared within 120 hr in the urine of rats dosed with the ethanol solutions. Only half that amount (14%) of the activity was excreted in the urine when these compounds were given in oil. In this study, the absorption patterns of the two compounds were similar in both vehicles. Seventy-five percent or more of the total activity excreted in the urine appeared within the first 24 hr regardless of the vehicle or compound. The rapid absorption of I also was noted by Godfrey *et al.* (10) from an orally administered glycerol–95% ethanol solution.

Table II—Cumulative Percentage of Orally Administered Tritiated Pentadecylcatechol (I) or Its Diacetate Derivative (II) Excreted in Feces

| Hours Postdose | Tritiated I in Ethanol | Tritiated I in Oil | Tritiated II in Ethanol | Tritiated II in Oil |
|---|---|---|---|---|
| 24 | 35.04 ± 8.94 | 61.31 ± 4.22 | 36.26 ± 8.08 | 74.65 ± 12.71 |
| 48 | 49.94 ± 1.74 | 69.42 ± 4.10 | 52.04 ± 5.10 | 79.33 ± 11.48 |
| 72 | 51.99 ± 2.18 | 70.45 ± 4.06 | 54.91 ± 5.73 | 81.51 ± 10.62 |
| 96 | 52.73 ± 2.41 | 70.83 ± 4.09 | 55.55 ± 5.75 | 81.78 ± 10.53 |
| 120 | 52.98 ± 2.46 | 71.03 ± 4.12 | 55.90 ± 5.77 | 81.91 ± 10.50 |

The radioactivity excreted in the feces at 24, 48, 72, 96, and 120 hr after oral dosing is expressed as cumulative percent excreted (Table II). The majority of the administered radioactivity of both compounds was eliminated in the feces. There was a greater percentage of tritiated I and II excreted in the feces of rats dosed with oil solution (71 and 82%, respectively) than in the feces of rats receiving the ethanol solution, apparently due to reduced absorption of these compounds from corn oil. As with the urinary excretion patterns, most of the activity eliminated in the feces (≥64%) appeared within the first 24 hr after dosing, and the bulk of the remaining material appeared during the second 24-hr period. The total recovery of the administered radioactivity within 120 hr ranged from 81 to 96%.

**Biliary Excretion**—Studies by Godfrey *et al.* (10) showed a persistence of I in the bile, liver, spleen, appendix, and body fluids, which was taken as evidence for enterohepatic circulation of I and its metabolites. Since the majority of administered radioactivity in the present study was eliminated in the feces within the first 24–48 hr, it was of interest to determine if some activity recovered in the feces might have been due to absorption followed by excretion into the feces. Thus, the bile ducts of rats were cannulated, and the animals were dosed with tritiated II in ethanol. The bile was collected at 6, 12, 24, and 30 hr, until negligible amounts of activity appeared in the bile.

Approximately 2% of the administered activity appeared in the bile every 6 hr for the first 24 hr for a cumulative total of 8.85%. After 30 hr, negligible amounts were observed in the bile. Since 8.85% of the administered radioactivity was excreted in the bile within the first 24 hr, it can be assumed from the previous experiment that a maximum of 15% of the activity appearing in the feces (64% of the administered doses) represents biliary-excreted activity.

The results of the present study indicate that oils are poor vehicles for administering urushiols or their water-insoluble derivatives. The investigation of other vehicles to improve the absorption of these compounds is in progress. Additional studies also are being conducted to determine the urinary and biliary metabolites of these compounds. Optimal absorption may significantly alter the cost of prophylaxis since less drug will be required to obtain therapeutic tissue levels. In addition, decreasing the amount of material eliminated in the feces might significantly reduce the toxic side effects, particularly perianal dermatitis.

# Approximation in Point–Area Deconvolution Algorithm as Mathematical Basis of Empirical Instantaneous Midpoint–Input Deconvolution Method

**Keyphrases** □ Point–area deconvolution algorithm—compared with instantaneous midpoint–input deconvolution method, drug absorption, calculation for *in vivo* drug input functions □ Drug absorption—point–area deconvolution algorithm compared with instantaneous midpoint–input deconvolution method □ Pharmacokinetics—point–area deconvolution algorithm compared with instantaneous midpoint–input deconvolution method, calculation for *in vivo* drug input functions

*To the Editor:*

Recently, Chiou (1) presented an empirically based deconvolution method for the determination of *in vivo* drug absorption, without reference to the point–area deconvolution algorithm (2). However, this empirical algorithm is equivalent to the point–area method when the analytical integration of the characteristic response is approximated by a rectangular function. Such an approximation to a defined integral can result in an unstable algorithm.

In the present communication, the relationship between the empirical method of Chiou (1) and the point–area deconvolution method (2) is derived, and the instability of the former method is demonstrated.

Define the plasma drug concentration–time function, $G(t)$, obtained after a unit drug impulse input (*e.g.*, intravenous bolus or oral solution) as the characteristic response of the body. Assume the body acts as a time-invariant linear system to drug input. Under the latter assumption, the plasma drug concentration–time function, $R(t)$, obtained after some arbitrary drug input, $In(t)$, into the body is defined by the convolution of the input function and the characteristic response. Thus, given $R(t)$ and $G(t)$, the input function, $In(t)$, can be defined by deconvolution of:

$$R(t) = \int_0^t In(t-\tau)G(t)\,d\tau \qquad \text{(Eq. 1)}$$

However, if $R(t)$ is sampled only at a set of time points $p_i (i \in 0, 1, 2, \ldots, p_0 = 0, p_{i+1} > p_i, p_i \geq 0)$, the analytical function $R(t)$ is not defined. The deconvolution of $R(p_i)$ and $G(t)$ to obtain $In(t)$ is an ill-defined problem since the convolution of a number of input functions with $G(t)$ will generate the observed responses, $R(p_i)$. Consequently, deconvolution must be based on some logical algorithm that assumes some functional form for either $R(t)$ or the input function (2–5). In particular, a staircase input function can always be derived such that the convolution of this function with $G(t)$ generates the observed responses, $R(p_i)$. The latter is the point–area deconvolution method (2).

For a staircase input function into a time-invariant linear system, the responses, $R(p_i)$, are given by:

$$R(p_i) = \sum_{j=1}^{i}\left[K_j \int_{p_i-p_j}^{p_i-p_{j-1}} G(t)\,dt\right] \qquad i \in 0, 1, 2, \ldots \qquad \text{(Eq. 2)}$$

where $R(p_0) = 0$, $K_0 = 0$, and $K_i$ $(i \in 1, 2, \ldots)$ is the magnitude of a step of duration $(p_i - p_{i-1})$ in the staircase input function. The cumulative input in any interval, $(p_i - p_{i-1})$, is $K_i(p_i - p_{i-1})$, which is given by Eq. 2 as:

$$K_i(p_i - p_{i-1}) = \frac{\left[R(p_i) - \sum_{j=1}^{i-1}\left(K_j \int_{p_i-p_j}^{p_i-p_{j-1}} G(t)\,dt\right)\right](p_i - p_{i-1})}{\int_0^{p_i-p_{i-1}} G(t)\,dt} \qquad \text{(Eq. 3)}$$

If the integrals of $G(t)$ are approximated by rectangular functions centered about the midpoint of the integration interval, then:

$$\int_{p_i-p_j}^{p_i-p_{j-1}} G(t)\,dt \simeq (p_j - p_{j-1})G\left(p_i - \frac{p_j}{2} - \frac{p_{j-1}}{2}\right) \qquad \text{(Eq. 4)}$$

Using the approximations of Eq. 4 in Eq. 3 gives:

$$K_i(p_i - p_{i-1}) = \frac{R(p_i) - \sum_{j=1}^{i-1} K_j(p_j - p_{j-1})G\left(p_i - \frac{p_j}{2} - \frac{p_{j-1}}{2}\right)}{G\left(\frac{p_i - p_{i-1}}{2}\right)} \qquad \text{(Eq. 5)}$$

Substituting $f_j = K_j(p_j - p_{j-1})$ into Eq. 5 gives:

$$f_j = \frac{R(p_i) - \sum_{j=1}^{i-1} f_i G\left(p_i - \frac{p_j}{2} - \frac{p_{j-1}}{2}\right)}{G\left(\frac{p_i - p_{i-1}}{2}\right)} \qquad \text{(Eq. 6)}$$

where $f_i (i \in 1, 2, \ldots)$ is the fraction of the dose absorbed in the time interval $(p_i - p_{i-1})$, and $\Sigma_{j=1}^{i} f_j$ is the cumulative drug input at time point $p_i$.

The deconvolution algorithm specified by Eq. 6 is equivalent to the empirical algorithm specified by Chiou (1) and is simply an approximation to the point–area method (2). The point–area deconvolution method is a correction and rationalization of a convolution method described by Resigno and Segre (6). In the latter algorithm, the integrals of $G(t)$ are approximated by rectangular functions centered about the midpoint of integration. Consequently, the new algorithm of Chiou (instantaneous midpoint–input method) is a restatement of a previously known algorithm.

Provided the approximations specified by Eq. 4 are reasonable, Eqs. 3 and 6 should give essentially similar results when applied to the determination of *in vivo* drug

**Table I—Comparison of the Theoretical and Calculated Cumulative Drug Input for a Zero-Order Lidocaine Infusion**

| Hours | $R(t)$, μg/ml | Cumulative Drug Input, mg: Theoretical | Cumulative Drug Input, mg: Calculated by Instantaneous Midpoint–Input Method |
|---|---|---|---|
| 0.5 | 0.8314 | 55.8 | 69.54 (24.62)[a] |
| 1.0 | 1.1884 | 111.6 | 132.22 (18.48) |
| 1.5 | 1.4720 | 167.4 | 192.74 (15.14) |
| 2.0 | 1.7037 | 223.2 | 252.58 (13.16) |
| 2.5 | 1.8929 | 279.0 | 312.21 (11.90) |

input. This is true for the examples involving exponential drug input functions cited by Chiou (Tables I–IV in Ref. 1). Since the point–area method defines a staircase input function, the method gives exact results for zero-order absorption rates. Consequently, the examples cited by Chiou for zero-order absorption (Tables VI and VII in Ref. 1) simply reflect the degree of accuracy of the approximations, specified by Eq. 4, for the particular characteristic responses used in the examples. When the approximations of Eq. 4 are invalid, the instantaneous midpoint–input method gives erroneous cumulative drug input functions. As an example, consider the plasma concentrations (micrograms per milliliter) of lidocaine after a 1-mg iv bolus as the characteristic response, where $G(t) = 0.0276e^{-0.123t} + 0.0084e^{-0.00673t}$ and the units of $t$ are minutes.

Apply the instantaneous midpoint–input deconvolution method to the plasma drug concentrations that would result from a 1.86-mg/min constant intravenous infusion of lidocaine. The results of applying this method are given in Table I. This example illustrates the large errors that can result by approximating integrals by rectangular functions. The point–area method gives exact results for this example (Table I).

In conclusion, the instantaneous midpoint–input method is an approximation of the point–area method. The use of approximations in the latter method can result in large errors in the cumulative drug input functions, and such unnecessary approximations should be avoided.

## Stability of Nitroglycerin Ointment

**Keyphrases** □ Nitroglycerin—stability of ointment at elevated temperatures □ Vasodilators—stability of nitroglycerin ointment at elevated temperatures □ Stability—nitroglycerin ointment at elevated temperatures

*To the Editor:*

Topical nitroglycerin therapy offers a longer duration of action than sublingual administration and thus is popular as a prophylactic treatment for angina pectoris (1, 2). Previous studies indicated that the potency of nitroglycerin tablets may be affected by the environment in which the tablets are stored (3, 4). It also was demonstrated that nitroglycerin in solutions for intravenous use interacts with plastic infusion bags and intravenous giving sets (5, 6), resulting in decreased availability of nitroglycerin. Since we are unaware of any report on the stability of nitroglycerin ointment during storage, we evaluated the stability of nitroglycerin ointment capsules stored at elevated temperatures for extended periods.

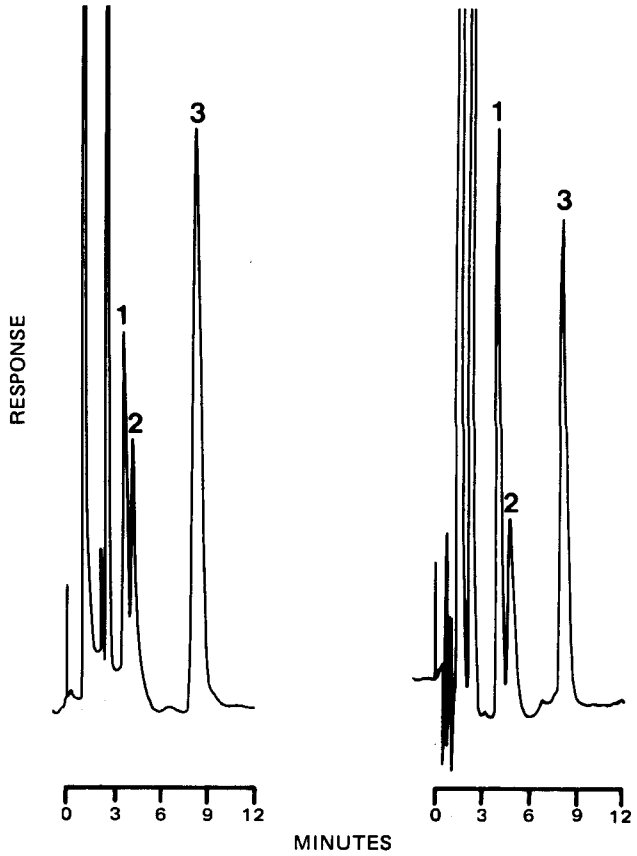

**Figure 1**—*(Left) Chromatogram of an aqueous solution of nitroglycerin and the two dinitroglycerins. Key: 1, 1,3-dinitroglycerin; 2, 1,2-dinitroglycerin; and 3, nitroglycerin. (Right) Chromatogram of an octanol extract of nitroglycerin ointment. Key: 1, unknown interfering peak; 2, unknown interfering peak; and 3, nitroglycerin.*

Capsules from unopened bottles of nitroglycerin (3% w/w) ointment capsules[1] were stored on individual glass dishes in an oven at 37 ± 1° and in the original glass bottle at room temperature (20–24°) in the dark. Capsules were removed from storage after 5, 10, and 18 weeks and were assayed for nitroglycerin content as follows. Each capsule was cut open, the ointment was removed completely, and its weight was recorded. The nitroglycerin then was extracted from the ointment by vortexing with 5 ml of octanol for 10 min and centrifuging at 3000 rpm for 10 min. This method achieved >96% extraction of nitroglycerin.

The extract then was diluted with methanol before assay using kinetic (7) and high-performance liquid chromatographic (HPLC) methods (8). Standard curves for the two methods were constructed by adding known amounts of nitroglycerin, standardized by the method of Dean and Baun (9), to octanol, which then was diluted in methanol to give appropriate concentrations for analysis. In four determinations of six different nitroglycerin concentra-

**Table I—Percentage of Nitroglycerin in Ointment Capsules Stored at 37° for 18 Weeks**

| Weeks | Percent Content (Mean ± *SE*, $n = 5$) Kinetic Assay | HPLC Assay |
|---|---|---|
| 0 | 3.24 ± 0.06 | 3.19 ± 0.11 |
| 5 | 3.18 ± 0.10 | 3.23 ± 0.08 |
| 10 | 3.17 ± 0.12 | 3.20 ± 0.10 |
| 18 | 3.22 ± 0.05 | 3.19 ± 0.09 |

tions, the correlation coefficient of results obtained by the two methods was 0.988.

Unfortunately, the HPLC method and the other previously reported high-pressure liquid chromatographic method (10) were not specific for glyceryl dinitrates due to the presence of unknown interfering peaks from the ointment extract (Fig. 1). No reduction in size of the interfering peaks was achieved by using other organic solvents (hexane, ether, and methanol) to extract the ointment. The relative height of these peaks did not change over time. It was established by TLC separation (11) prior to HPLC analysis that the amount of glyceryl dinitrates present in the ointment was negligible. Triacetin, which is used as a solvent for nitroglycerin in some preparations, cochromatographed with glyceryl 1,2-dinitrate using the method of Crouthamel and Dorsch (8).

No loss of nitroglycerin was found after storage of individual capsules for 18 weeks at 37° (Table I). The amount of the dinitrates present in the ointment was negligible throughout the study.

The good stability of nitroglycerin in the ointment formulation tested is consistent with a high affinity of nitroglycerin for the lipophilic ointment base and a low affinity for the gelatin capsule in which the ointment is presented. In contrast, the availability of nitroglycerin from aqueous solutions infused from plastic infusion bags through giving sets is reduced due to the high affinity of nitroglycerin for the plastic (12).

## Comparison of Plasma and Urine Analyses for Thiazides in Bioavailability/Bioequivalence Study

**Keyphrases** □ Thiazides—plasma *versus* urine analysis in bioavailability/bioequivalence study □ Bioavailability—thiazides, plasma *versus* urine analysis □ Bioequivalence—thiazides, plasma *versus* urine analysis □ Diuretics—thiazides, plasma *versus* urine analysis in bioavailability/bioequivalence study

*To the Editor:*

Thiazides are widely used as diuretics in the treatment of hypertension. In the recent proposal (1) for bioavailability/bioequivalence requirements, the thiazides were identified as having potential bioequivalence problems. To ensure bioequivalence of thiazide products, both *in vitro* dissolution and *in vivo* bioavailability requirements were proposed. The *in vivo* requirements call for bioavailability studies in humans and comparison of blood level and/or urinary excretion profiles of the drug with a standard reference product. It is generally assumed that blood (or plasma or serum) level measurements give a better assessment of bioavailability and bioequivalence than urinary measurements because of complicated pharmacokinetic considerations such as drug metabolism and urine collection problems.

It is sometimes argued that the presence of drug in the blood is not a real estimate of the drug availability at the site of action but only an estimate of drug bioavailability. It is preferable to determine the amount of drug at the site of action or to measure therapeutic effect, but these two procedures are generally not feasible. Thiazide diuretics are weak carbonic anhydrase inhibitors that enhance the renal excretion of sodium and chloride ions and an accompanying volume of water, thereby causing diuresis. This therapeutic effect is due to inhibition of ion reabsorption in the distal tubule. Thiazides are primarily excreted unchanged in urine by active secretion in the proximal tubule (2). Thus, from a pharmacological and a therapeutic viewpoint, measurement of the urinary excretion of the drug appears to be a logical choice in lieu of measurement in blood for the assessment of bioavailability of a diuretic dosage form.

Previous work on chlorothiazide and hydrochlorothiazide suggested that urinary level measurements give adequate information for bioavailability/bioequivalence assessment (3, 4). Figure 1 shows the amount of drug eliminated in the urine ($AE$) and the area under the curve ($AUC$) in the same subjects for various thiazides. For hydrochlorothiazide, ~34% of the administered drug was recovered in 0–12-hr urine samples at all dose levels (100, 50, and 25 mg), thus suggesting a dose–response relationship. As expected, the amount of drug in urine decreased with a decrease in hydrochlorothiazide administration, but the $AUC$ did not correspond and correlate with the $AE$ values (Subjects 2 and 3, Fig. 1A). Earlier data (5) for hydrochlorothiazide showed no relationship between the $AUC$ and $AE$ (Fig. 1B), between the $AUC$ and product bioavailability, or between $C_{max}$ and dose administered or bioavailability.

A preliminary study using chlorothiazide products showed that, although approximately the same amount of drug was excreted in 48 hr from subjects administered 250-

**Table I—Percentage of Nitroglycerin in Ointment Capsules Stored at 37° for 18 Weeks**

| Weeks | Percent Content (Mean ± *SE*, $n = 5$) Kinetic Assay | HPLC Assay |
|---|---|---|
| 0 | 3.24 ± 0.06 | 3.19 ± 0.11 |
| 5 | 3.18 ± 0.10 | 3.23 ± 0.08 |
| 10 | 3.17 ± 0.12 | 3.20 ± 0.10 |
| 18 | 3.22 ± 0.05 | 3.19 ± 0.09 |

tions, the correlation coefficient of results obtained by the two methods was 0.988.

Unfortunately, the HPLC method and the other previously reported high-pressure liquid chromatographic method (10) were not specific for glyceryl dinitrates due to the presence of unknown interfering peaks from the ointment extract (Fig. 1). No reduction in size of the interfering peaks was achieved by using other organic solvents (hexane, ether, and methanol) to extract the ointment. The relative height of these peaks did not change over time. It was established by TLC separation (11) prior to HPLC analysis that the amount of glyceryl dinitrates present in the ointment was negligible. Triacetin, which is used as a solvent for nitroglycerin in some preparations, cochromatographed with glyceryl 1,2-dinitrate using the method of Crouthamel and Dorsch (8).

No loss of nitroglycerin was found after storage of individual capsules for 18 weeks at 37° (Table I). The amount of the dinitrates present in the ointment was negligible throughout the study.

The good stability of nitroglycerin in the ointment formulation tested is consistent with a high affinity of nitroglycerin for the lipophilic ointment base and a low affinity for the gelatin capsule in which the ointment is presented. In contrast, the availability of nitroglycerin from aqueous solutions infused from plastic infusion bags through giving sets is reduced due to the high affinity of nitroglycerin for the plastic (12).

## Comparison of Plasma and Urine Analyses for Thiazides in Bioavailability/Bioequivalence Study

**Keyphrases** □ Thiazides—plasma *versus* urine analysis in bioavailability/bioequivalence study □ Bioavailability—thiazides, plasma *versus* urine analysis □ Bioequivalence—thiazides, plasma *versus* urine analysis □ Diuretics—thiazides, plasma *versus* urine analysis in bioavailability/bioequivalence study

*To the Editor:*

Thiazides are widely used as diuretics in the treatment of hypertension. In the recent proposal (1) for bioavailability/bioequivalence requirements, the thiazides were identified as having potential bioequivalence problems. To ensure bioequivalence of thiazide products, both *in vitro* dissolution and *in vivo* bioavailability requirements were proposed. The *in vivo* requirements call for bioavailability studies in humans and comparison of blood level and/or urinary excretion profiles of the drug with a standard reference product. It is generally assumed that blood (or plasma or serum) level measurements give a better assessment of bioavailability and bioequivalence than urinary measurements because of complicated pharmacokinetic considerations such as drug metabolism and urine collection problems.

It is sometimes argued that the presence of drug in the blood is not a real estimate of the drug availability at the site of action but only an estimate of drug bioavailability. It is preferable to determine the amount of drug at the site of action or to measure therapeutic effect, but these two procedures are generally not feasible. Thiazide diuretics are weak carbonic anhydrase inhibitors that enhance the renal excretion of sodium and chloride ions and an accompanying volume of water, thereby causing diuresis. This therapeutic effect is due to inhibition of ion reabsorption in the distal tubule. Thiazides are primarily excreted unchanged in urine by active secretion in the proximal tubule (2). Thus, from a pharmacological and a therapeutic viewpoint, measurement of the urinary excretion of the drug appears to be a logical choice in lieu of measurement in blood for the assessment of bioavailability of a diuretic dosage form.

Previous work on chlorothiazide and hydrochlorothiazide suggested that urinary level measurements give adequate information for bioavailability/bioequivalence assessment (3, 4). Figure 1 shows the amount of drug eliminated in the urine ($AE$) and the area under the curve ($AUC$) in the same subjects for various thiazides. For hydrochlorothiazide, ~34% of the administered drug was recovered in 0–12-hr urine samples at all dose levels (100, 50, and 25 mg), thus suggesting a dose–response relationship. As expected, the amount of drug in urine decreased with a decrease in hydrochlorothiazide administration, but the $AUC$ did not correspond and correlate with the $AE$ values (Subjects 2 and 3, Fig. 1A). Earlier data (5) for hydrochlorothiazide showed no relationship between the $AUC$ and $AE$ (Fig. 1B), between the $AUC$ and product bioavailability, or between $C_{max}$ and dose administered or bioavailability.

A preliminary study using chlorothiazide products showed that, although approximately the same amount of drug was excreted in 48 hr from subjects administered 250-

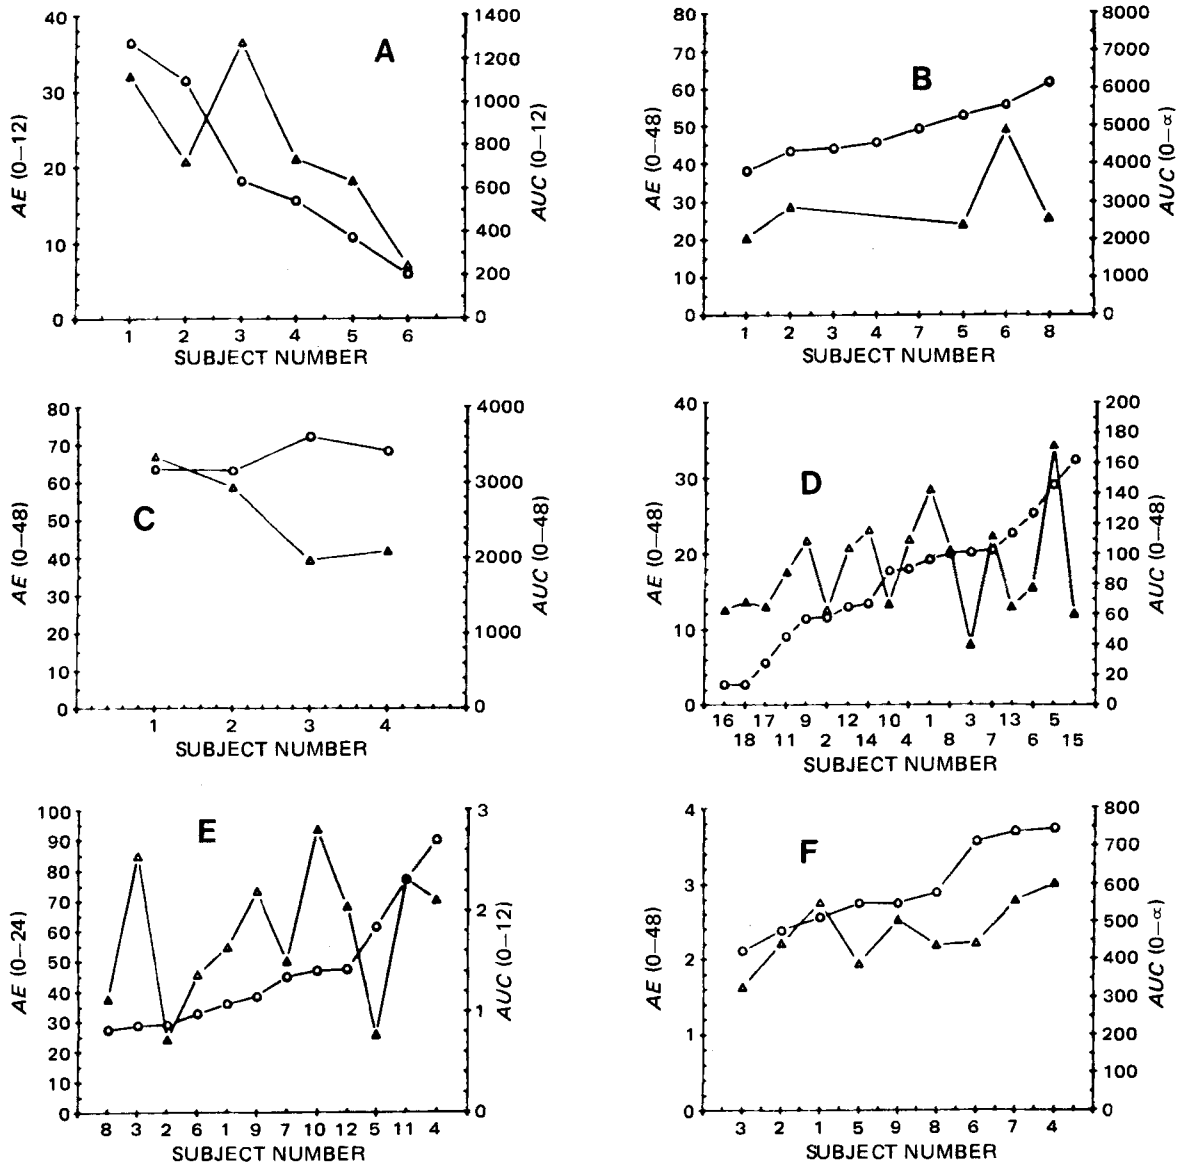

**Figure 1**—*Comparison of* AUC (△) *and* AE (○) *values for thiazides in the same subjects. Key: A, hydrochlorothiazide—Subjects 1 and 2 received a 100-mg dose, Subjects 3 and 4 received a 50-mg dose, and Subjects 5 and 6 received a 25-mg dose; B, hydrochlorothiazide—all subjects received a 75-mg dose; C, chlorothiazide—Subjects 1 and 2 received a 250-mg dose and Subjects 3 and 4 received a 500-mg dose; D, polythiazide—all subjects received a 1-mg dose; E, hydroflumethiazide—all subjects received a 100-mg dose; and F, bendroflumethiazide—all subjects received a 10-mg dose.*

and 500-mg doses, there was an approximate twofold difference in *AUC* (3), thus suggesting a lack of correlation between *AE* and *AUC* values (Fig. 1C).

Previous bioavailability studies involving plasma levels and urinary excretion measurements on polythiazide [Fig. 1D (6)], hydroflumethiazide [Fig. 1E (7)], and bendroflumethiazide [Fig. 1F (8)] were analyzed to determine the correlation between *AE* and *AUC* values. (The *AUC* values were calculated using the trapezoidal rule from the data provided.) Analysis of the data for the same panel of subjects shows wide variation in the *AUC* with nearly the same *AE*, suggesting a lack of correlation.

The lack of correlation observed between the plasma *AUC* and *AE* values is puzzling. One explanation may be the possible interaction of the thiazide with red blood cells. All thiazides have a sulfonamide group, and compounds with such groups have been shown to interact and bind with red blood cells (9). One hydrochlorothiazide study (10) also postulated an interaction between red blood cells and hydrochlorothiazide. The equilibrium drug concentration in plasma, which is most frequently measured for *AUC* determinations, is directly influenced by the interaction between the thiazide and red blood cells.

The reported plasma *AUC* measurements are more variable than the *AE* measurements, making it difficult to assess the amount of drug absorbed. On the other hand, the results of urinary excretion show comparatively less variation, making it easier for estimation of bioavailability/bioequivalence for thiazides. Thus, comparison of *AUC* and *AE* results indicate that urinary measurement from carefully planned and executed bioavailability studies are adequate to establish bioequivalence of thiazide diuretics.

## Technique for Preparing Appendage-Free Skin (Scar) on Hairless Mouse

**Keyphrases** □ Scar tissue—technique for preparing appendage-free skin on the hairless mouse □ Burns—examination of scar tissue, technique for preparing appendage-free skin on the hairless mouse □ Skin—technique for preparing appendage-free skin on the hairless mouse, examination of scar tissue

*To the Editor:*

Scar formation is, minimally, a reconstruction of skin that has undergone total destruction of its epidermal elements through disease or physical trauma (1). Since epidermal elements such as hair follicles often penetrate deeply into and beyond the dermal structure, significant repair of dermal and subdermal damage also is associated with the appearance and function of the scarred surface. When cells of epidermal origin are obliterated within the surface, including those deep within the follicular invaginations, the epidermis of a small wound is repaired by lateral migration of cells from its periphery. Based on histological examination of actual injuries, an epidermal structure is formed, which, as a minimally functional renewed surface, is without normal skin lines and is devoid of pilosebaceous and eccrine appendages. It has a flattened interface with the dermis. The dermis is repaired by fibroblasts that appear in large numbers in the wound. Depending on the nature and extent of the damage, the scar may be raised or depressed and is usually schlerotic (hard) due to the synthesis of new collagen.

An appendage-free structure such as scar tissue should be useful for sorting out transfollicular and transepidermal contributions to percutaneous absorption by studying it side by side with normal skin. To do this study with the least possible complications, experimental wounds need to be developed that result in scarring but that also represent minimal damage and restructuring of the dermal matrix.

Many researchers have developed methods to produce experimental wounds in laboratory animals. These procedures include excision of surface tissues (2–7), branding (8–10), severe chemical burning (11), thermal burning (12), and X-ray and UV irradiation (13, 14). The major emphasis of these investigations has been to study the healing process; the end result, the scarred surface, has been of only incidental concern. Where scar tissue has been purposefully studied histologically and otherwise, tissue samples normally have been of etiological rather than of experimental origin (15, 16). Therefore, we attempted to develop a simple reliable technique to produce scars with minimal dermal involvement in small laboratory animals for the purpose of studying the physicochemical (barrier) properties of scar tissue itself.

Male hairless mice[1], 60–80 days old, were anesthetized with methoxyflurane[2], and their dorsal surfaces were scalded using a previously reported technique (17). Essentially, the dorsal surface of an animal was immersed for 30 sec in water maintained at 60°. These conditions were chosen because they produce a borderline full-thickness burn on hairless mouse skin (17) and are routinely used to separate epidermis from dermis in preparing epidermal membranes for mass transfer studies (18). At the outset, the conditions appeared to be at or near the threshold to accomplish the stated goal.

The scalded mice were placed on a table with the burned surfaces exposed. An area was marked on the traumatized dorsal surface roughly approximating 6–8 $cm^2$ of the body surface area. With the blade of a spatula, the epidermis was scraped off the surface. Occasionally, the epidermal layer was separated as a single piece, but it usually came off in fragments. The blade was moved back and forth on the exposed skin several times, exposing the outlines of superficial blood vessels. The skin was uniformly erythematous. The animals then were returned to individual

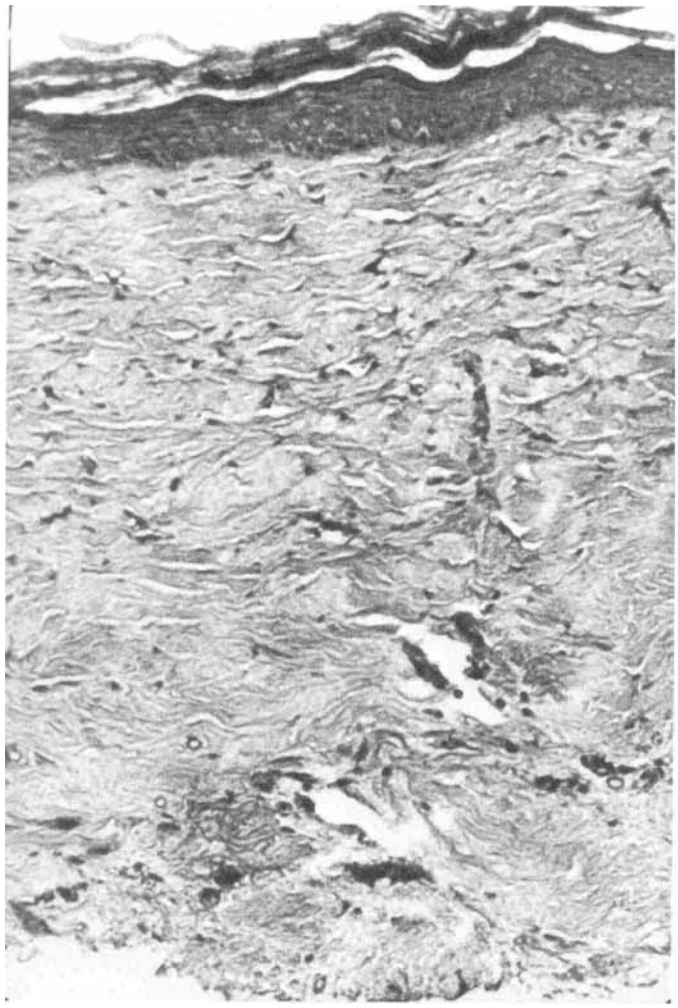

**Figure 2**—*Histological appearance of scar tissue obtained ~3 months postburn.*

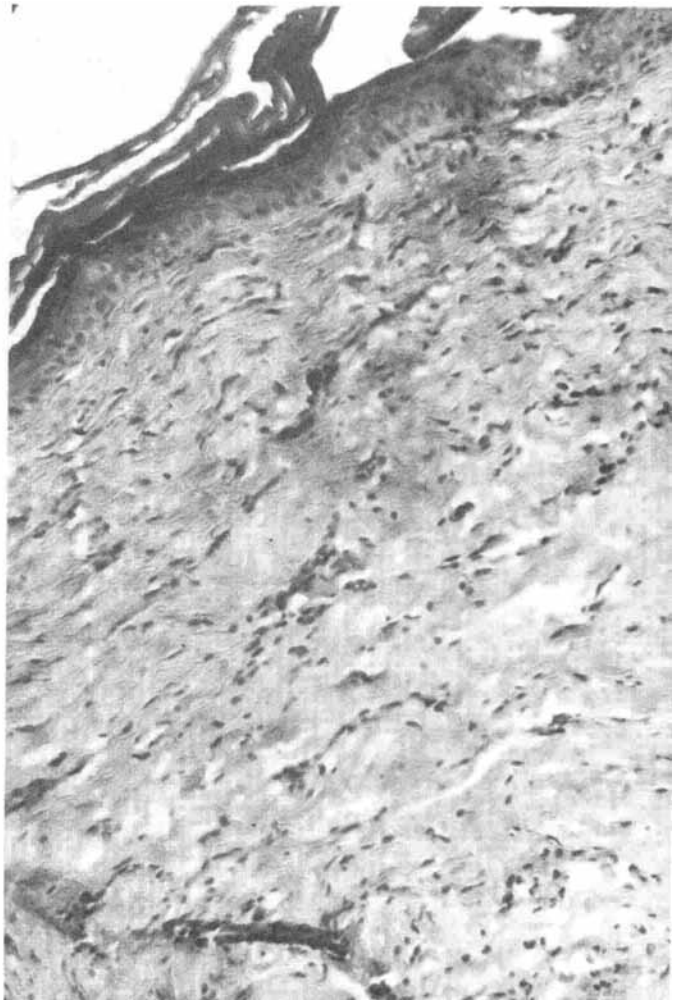

**Figure 3**—*Histological appearance of scar tissue obtained ~4 months postburn.*

cages and were supplied food and water *ad libitum*.

The traumatized animals were examined daily. A clearly defined wound was evident on the 1st day after inflicting the burn. In 1 week, a thick eschar covered the affected area. This eschar desiccated gradually and finally sloughed by about the 4th week postburn. The newly exposed surface appeared smooth and pinkish and refracted light in a manner typical of scarred surface. The scarred area was substantially contracted relative to the initial area from which the epidermis was removed. The wounds appeared to heal inward from thin margins, a process typical of full-thickness wound reepithelialization.

For purposes of histological examination, mice were sacrificed by spinal cord dislocation. Small scar biopsies were taken, and microscopic slides were prepared using standard hematoxylin and eosin staining techniques. Figure 1 represents the normal skin of the hairless mouse, and Figs. 2 and 3 represent the scar tissues obtained ~3 and 4 months, respectively, after inflicting the wound. The normal skin has a distinct epidermis and dermis containing loosely arranged connective tissue and numerous cystic pilosebaceous glands extending through the epidermis. The epidermal–dermal junction is convoluted. This normal slide can be contrasted to the 3-month-old burn scar (Fig. 2), which evidences a somewhat thickened epidermis and a more compact dermis (greater cellulosity and deposited collagen). The absence of the cystic pilosebaceous glands is notable, as is the flatness of the epidermal–dermal interface. Both features are typical of a scarred surface. The 4-month-old scar (Fig. 3) is less cellular with compact dermal collagen, a more developed stratum corneum, and a thinner viable epidermis, all features normally associated with a mature scar.

In separate experiments, attempts were made to produce scarring on the Swiss mouse and the rat. A similar procedure was employed with one minor variation. Before burning the skin for 30 sec at 60°, the anesthetized animal's dorsal surfaces were scalded briefly (60°) for ~ 5 sec, and all hair was plucked by hand. However, in these animals, the surface healed without scarring and with only a slight decrease in the density of hair. The necrotizing conditions apparently were not sufficient to destroy epidermal cells seated deeply on the follicular islands upon burning of these pellaged species. Rather, their more prominent, more deeply anchored hair follicles provided for survival of cells capable of regenerating a normal-appearing integument.

The methodology described produces the desired result in the hairless mouse[1]. A scar tissue is obtained that is being used to study permeation and other properties of skin devoid of its usual appendages. These studies should

reveal the impact of scar formation on the bioavailability of drugs and irritants applied topically over the scarred surface.

# BOOKS

## REVIEWS

**Controlled Release of Bioactive Materials.** Edited by RICHARD BAKER. Academic, 111 Fifth Ave., New York, NY 10003. 1980. 473 pp. 15 × 23 cm. Price $34.50.

This book constitutes a collection of 27 papers delivered at the sixth International Symposium on Controlled-Release Materials in New Orleans in 1979. The first 12 papers deal with various aspects of controlled drug delivery systems.

In the first paper, Heller and Baker review the theory and practice of controlled drug delivery from biodegradable polymers. The mechanisms of drug release from these polymers are discussed in depth, and several illustrative examples are presented. Applications of biodegradable polymers are discussed further in the ensuing two papers by Pitt *et al.* and Petersen *et al.*

In the fourth paper, Theeuwes and Echenhoff present the applications of osmotic drug delivery systems. The design and experimental performance of two osmotic devices are described. The generic osmotic pump (Alzet) is designed to deliver the contents of 170 μl at the rate of either 1 μl/hr over a 1-week period or 0.5 μl/hr over 2 weeks. The other device is the elementary osmotic pump, which is generally fabricated in the shape of a tablet, with a single-delivery orifice. A paper by Chandrasekaran and Shaw is concerned with controlled, transdermal drug delivery.

Other papers of pharmaceutical interest deal with polymers that include poly(lactic acid) and the hydrogels. Rhine and coworkers present a new approach to achieve zero-order release kinetics from diffusion-controlled polymer matrix systems. The theoretical basis for these kinetics is presented as is a comparison of kinetics from matrix devices of other geometries.

The second half of the book is concerned essentially with topics not directly related to drug delivery systems. Controlled-release systems containing insecticides, molluscicides, and plant growth regulators are discussed and described. Implantable systems for the delivery of insect growth regulators to livestock are evaluated by Jaffe and coworkers. The basic technology used to design several of these systems is very similar to drug-containing devices.

This book is a collection of high quality research papers, prepared by scientists in widely different fields. As such, the book is highly recommended for both academic and industrial pharmaceutical scientists, chemists, biologists, and chemical engineers who have an interest in controlled-release technology.

**British National Formulary 1981: Number 1.** The Pharmaceutical Press, 1 Lambert St., London, SE1 7JN, England. 1981. 387 pp. 12 × 23 cm. Price £3.80

*The British National Formulary* is designed for use by doctors, pharmacists, and nurses in the National Health Service in the United Kingdom. Unlike earlier editions that were published every 2 or 3 years and contained only those drugs and preparations having the confidence of the Joint Formulary Committee, the 1981 edition is an outgrowth of the Committee's response to requests for a wider coverage of drugs available in the United Kingdom and more detailed guidance in prescribing and dispensing.

This new edition provides more descriptive information to assist the prescriber in selecting the appropriate treatment for a particular patient. A double-column format was followed to accommodate the increased volume of information and to allow the book to "still fit into the doctor's pocket."

The BNF begins with sections on Guidance on Prescribing and Emergency Treatment on Poisoning. The main text consists of classified notes divided into 15 chapters: Gastro-intestinal System; Cardiovascular System; Respiratory System; Central Nervous System; Infections; Endocrine System; Obstetrics and Gynaecology; Malignant Disease and Immunosuppression; Nutrition and Blood; Musculoskeletal and Joint Diseases; Eye; Ear, Nose, and Oropharynx; Skin; Immunological Products and Vaccines; and Anaesthesia. Each chapter begins with appropriate notes for prescribers to facilitate selection of suitable treatment followed by detailed monographs of the relevant drugs and preparations (indications, contraindications, cautions, side-effects, doses, dosage forms, routes of administration, and relative prices). Drugs appear under their pharmacopoeial titles or British Approved Names and are listed alpha-

reveal the impact of scar formation on the bioavailability of drugs and irritants applied topically over the scarred surface.

## REVIEWS

**Controlled Release of Bioactive Materials.** Edited by RICHARD BAKER. Academic, 111 Fifth Ave., New York, NY 10003. 1980. 473 pp. 15 × 23 cm. Price $34.50.

This book constitutes a collection of 27 papers delivered at the sixth International Symposium on Controlled-Release Materials in New Orleans in 1979. The first 12 papers deal with various aspects of controlled drug delivery systems.

In the first paper, Heller and Baker review the theory and practice of controlled drug delivery from biodegradable polymers. The mechanisms of drug release from these polymers are discussed in depth, and several illustrative examples are presented. Applications of biodegradable polymers are discussed further in the ensuing two papers by Pitt *et al.* and Petersen *et al.*

In the fourth paper, Theeuwes and Echenhoff present the applications of osmotic drug delivery systems. The design and experimental performance of two osmotic devices are described. The generic osmotic pump (Alzet) is designed to deliver the contents of 170 μl at the rate of either 1 μl/hr over a 1-week period or 0.5 μl/hr over 2 weeks. The other device is the elementary osmotic pump, which is generally fabricated in the shape of a tablet, with a single-delivery orifice. A paper by Chandrasekaran and Shaw is concerned with controlled, transdermal drug delivery.

Other papers of pharmaceutical interest deal with polymers that include poly(lactic acid) and the hydrogels. Rhine and coworkers present a new approach to achieve zero-order release kinetics from diffusion-controlled polymer matrix systems. The theoretical basis for these kinetics is presented as is a comparison of kinetics from matrix devices of other geometries.

The second half of the book is concerned essentially with topics not directly related to drug delivery systems. Controlled-release systems containing insecticides, molluscicides, and plant growth regulators are discussed and described. Implantable systems for the delivery of insect growth regulators to livestock are evaluated by Jaffe and coworkers. The basic technology used to design several of these systems is very similar to drug-containing devices.

This book is a collection of high quality research papers, prepared by scientists in widely different fields. As such, the book is highly recommended for both academic and industrial pharmaceutical scientists, chemists, biologists, and chemical engineers who have an interest in controlled-release technology.

**British National Formulary 1981: Number 1.** The Pharmaceutical Press, 1 Lambert St., London, SE1 7JN, England. 1981. 387 pp. 12 × 23 cm. Price £3.80

*The British National Formulary* is designed for use by doctors, pharmacists, and nurses in the National Health Service in the United Kingdom. Unlike earlier editions that were published every 2 or 3 years and contained only those drugs and preparations having the confidence of the Joint Formulary Committee, the 1981 edition is an outgrowth of the Committee's response to requests for a wider coverage of drugs available in the United Kingdom and more detailed guidance in prescribing and dispensing.

This new edition provides more descriptive information to assist the prescriber in selecting the appropriate treatment for a particular patient. A double-column format was followed to accommodate the increased volume of information and to allow the book to "still fit into the doctor's pocket."

The BNF begins with sections on Guidance on Prescribing and Emergency Treatment on Poisoning. The main text consists of classified notes divided into 15 chapters: Gastro-intestinal System; Cardiovascular System; Respiratory System; Central Nervous System; Infections; Endocrine System; Obstetrics and Gynaecology; Malignant Disease and Immunosuppression; Nutrition and Blood; Musculoskeletal and Joint Diseases; Eye; Ear, Nose, and Oropharynx; Skin; Immunological Products and Vaccines; and Anaesthesia. Each chapter begins with appropriate notes for prescribers to facilitate selection of suitable treatment followed by detailed monographs of the relevant drugs and preparations (indications, contraindications, cautions, side-effects, doses, dosage forms, routes of administration, and relative prices). Drugs appear under their pharmacopoeial titles or British Approved Names and are listed alpha-

**British National Formulary 1981: Number 1.** The Pharmaceutical Press, 1 Lambert St., London, SE1 7JN, England. 1981. 387 pp. 12 × 23 cm. Price £3.80

*The British National Formulary* is designed for use by doctors, pharmacists, and nurses in the National Health Service in the United Kingdom. Unlike earlier editions that were published every 2 or 3 years and contained only those drugs and preparations having the confidence of the Joint Formulary Committee, the 1981 edition is an outgrowth of the Committee's response to requests for a wider coverage of drugs available in the United Kingdom and more detailed guidance in prescribing and dispensing.

This new edition provides more descriptive information to assist the prescriber in selecting the appropriate treatment for a particular patient. A double-column format was followed to accommodate the increased volume of information and to allow the book to "still fit into the doctor's pocket."

The BNF begins with sections on Guidance on Prescribing and Emergency Treatment on Poisoning. The main text consists of classified notes divided into 15 chapters: Gastro-intestinal System; Cardiovascular System; Respiratory System; Central Nervous System; Infections; Endocrine System; Obstetrics and Gynaecology; Malignant Disease and Immunosuppression; Nutrition and Blood; Musculoskeletal and Joint Diseases; Eye; Ear, Nose, and Oropharynx; Skin; Immunological Products and Vaccines; and Anaesthesia. Each chapter begins with appropriate notes for prescribers to facilitate selection of suitable treatment followed by detailed monographs of the relevant drugs and preparations (indications, contraindications, cautions, side-effects, doses, dosage forms, routes of administration, and relative prices). Drugs appear under their pharmacopoeial titles or British Approved Names and are listed alpha-

betically unless there is a drug of choice, which then is listed first. Preparations are listed immediately following the drug that is their main ingredient.

Appendixes 1–3 contain pertinent information on drug interactions, intravenous additives, and borderline substances. A small formulary section also is included for dispensing those preparations commonly prepared extemporaneously, as are a dental formulary, an index of manufacturers, and an extensive subject index.

The BNF is a pocket book for easy referral, and thus cannot contain all the information necessary for prescribing and dispensing, but should be supplemented by manufacturer's data sheets and specialized texts as needed.

Future editions will be published twice a year to maintain current information on the drugs and preparations.

**The Use of Alternatives in Drug Research.** Edited by ANDREW N. ROWAN and CARL J. STRATMANN. University Park Press, 233 E. Redwood St., Baltimore, MD 21202. 1980. 190 pp. 15 × 23 cm. Price $24.50.

The advent of the National Toxicology Program has caused a rethinking of the procedures available for economical toxicological assessment of the thousands of chemicals to which people are exposed and the means whereby such exposure can be limited or prevented. This volume follows the pathway of chemical evaluation by *in vitro* systems designed to reduce, but not eliminate, the use of animals in pharmacological and toxicological research. As the various contributors state, there comes a time when only the whole animal will provide the final answer.

Hansch's contribution points out a logical manner in which modern drug modifications can be carried out *in vitro* utilizing computer techniques that allow rational changes in basic molecules to increase potency and decrease possible side effects, utilizing partition coefficients and binding to receptor sites. Many contributors point out that *in vitro* use of bacteria and cultured cells and tissues can indicate binding sites that cannot be determined by *in vivo* studies. Thus, the techniques that have been used to develop treatments for polio, mumps, and measles now can be used to screen antiviral chemicals to determine their antiviral potency and the maximum concentrations at which no toxic effects are caused to tissue culture cells.

Macrophages can be grown in culture, and *in vitro* studies of cellular immunity can be undertaken prior to whole animal testing. Micropharmacokinetics of various agents can be undertaken with this system. Protozoan diseases now can be studied with culture systems, and the various diseases afflicting humans and animals, such as trypanosomiasis, leishmaniasis, trichomoniasis, and amoebiasis, in either vector or vertebrate forms, can be evaluated for chemical susceptibility.

Pharmacologists have utilized both tissue slices and cell-free systems to study chemical biotransformations, enabling the evaluation of metabolic processes prior to introduction into whole animals, but the conjugation processes are not usually included in such studies and overall excretion may result in damage to such organs as the kidneys. However, tissue perfusion can eliminate this drawback partially. The mechanisms whereby both inorganic and organic chemicals exert their toxic effects on cell membranes and constituents can be studied with such models as amoeba proteus and isolated rat hepatocytes. Immunological preparations have been prepared by *in vitro* methods, but numerous biologicals have caused disease in humans because they contained live viruses; either the viruses were not killed during processing or they were not susceptible to the antiviral agent used. Thus, whole animal testing must be conducted.

By far, the greatest application of *in vitro* tests is the microbiological assessment of mutagenic and possible carcinogenic potentials of chemicals. Such methods are discussed by Rosenkrantz *et al.*, who point out the various modifications of microbial assays, the activation by S-9 fractions from various tissues, and the pitfalls encountered. However, such tests coupled with various cultured animal and human cell lines greatly assist in showing cell transformations and their possible link to the mutagenic and carcinogenic processes.

Of all *in vivo* tests used for the determination of skin and eye irritation, the Draize test has had the greatest application and has caused the most emotional impact. This eye test does not differentiate intermediate irritants and has a great degree of subjectivity. Recently, a cytotoxicity test was proposed based on the *in vitro* effects of irritants on I-929 mouse embryo cells. The results obtained compare favorably with eye irritation obtained in the Draize test. However, more work must be done to establish it as the method of choice.

In general, this symposium volume should indicate to pharmacologists and toxicologists that *in vitro* procedures should be applied to drug development and chemical evaluation during preliminary research. The succinct nature of the material presented and the extensive bibliography recommend this volume, and it should be in the library of all researchers and students in these fields.

Pharmacologists have utilized both tissue slices and cell-free systems to study chemical biotransformations, enabling the evaluation of metabolic processes prior to introduction into whole animals, but the conjugation processes are not usually included in such studies and overall excretion may result in damage to such organs as the kidneys. However, tissue perfusion can eliminate this drawback partially. The mechanisms whereby both inorganic and organic chemicals exert their toxic effects on cell membranes and constituents can be studied with such models as amoeba proteus and isolated rat hepatocytes. Immunological preparations have been prepared by *in vitro* methods, but numerous biologicals have caused disease in humans because they contained live viruses; either the viruses were not killed during processing or they were not susceptible to the antiviral agent used. Thus, whole animal testing must be conducted.

By far, the greatest application of *in vitro* tests is the microbiological assessment of mutagenic and possible carcinogenic potentials of chemicals. Such methods are discussed by Rosenkrantz *et al.*, who point out the various modifications of microbial assays, the activation by S-9 fractions from various tissues, and the pitfalls encountered. However, such tests coupled with various cultured animal and human cell lines greatly assist in showing cell transformations and their possible link to the mutagenic and carcinogenic processes.

Of all *in vivo* tests used for the determination of skin and eye irritation, the Draize test has had the greatest application and has caused the most emotional impact. This eye test does not differentiate intermediate irritants and has a great degree of subjectivity. Recently, a cytotoxicity test was proposed based on the *in vitro* effects of irritants on I-929 mouse embryo cells. The results obtained compare favorably with eye irritation obtained in the Draize test. However, more work must be done to establish it as the method of choice.

In general, this symposium volume should indicate to pharmacologists and toxicologists that *in vitro* procedures should be applied to drug development and chemical evaluation during preliminary research. The succinct nature of the material presented and the extensive bibliography recommend this volume, and it should be in the library of all researchers and students in these fields.

# Structure–Activity Relationships of Phenethylamine Hallucinogens

**DAVID E. NICHOLS**

Received from the *Department of Medicinal Chemistry and Pharmacognosy, School of Pharmacy and Pharmacal Sciences, Purdue University, West Lafayette, IN 47907.*

**Keyphrases** □ Phenethylamines—structure–activity relationships, compared with other hallucinogens, animal, human, and *in vitro* studies reviewed, literature survey □ Structure–activity relationships—phenethylamines, compared with other hallucinogens, animal, human, and *in vitro* studies reviewed, literature survey □ Hallucinogens—phenethylamines, structure–activity relationships, compared with other hallucinogens, animal, human, and *in vitro* studies reviewed, literature survey

The phenethylamine hallucinogens are simple 2-phenylethylamine derivatives of the general formula I, the majority of which are substituted with methoxy and alkyl or halogen groups. Where R is a methyl group, the compounds have been referred to as hallucinogenic "amphetamines." Although not strictly correct, this nomenclature is used throughout this discussion.

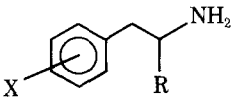
Although these drugs are not widely abused at present, several were prevalent on the illicit drug market during the 1960's. The more common ones were 1-(2,5-dimethoxy-4-methylphenyl)-2-aminopropane ("STP," II) (1), 1-(3,4-methylenedioxyphenyl)-2-aminopropane (III) (2), and 1-(4-methoxyphenyl)-2-aminopropane (IV) (3). The latter two were responsible for several deaths. Their popularity was due to their relatively high potency, coupled with the economic attractiveness of starting materials such as anisaldehyde, piperonal, and methylhydroquinone. With the exception of lysergide (LSD), the "classical" hallucinogens psilocin or psilocybin and mescaline were seldom available (4). Thus, the amphetamines served as convenient substitutes.

Structure–activity studies have been carried out with several classes of hallucinogens. However, lysergamides, related to lysergide and the most potent series, have received only limited attention, chiefly due to the molecular complexity of lysergic acid and the problems inherent in modification of such a structure. The simple tryptamines have been investigated somewhat more extensively, but few novel compounds have emerged. In addition, many of the indoles necessary as starting materials are tedious to synthesize. Therefore, the tryptamines have probably not received the attention they deserve.

In contrast, the phenethylamines have been studied extensively. The commercial availability or ease of synthesis of numerous substituted benzaldehydes has led to the synthesis and evaluation of literally hundreds of analogs. Because the mechanism of action for phenethylamine hallucinogens appears to be identical or similar to that for lysergide and the tryptamines (5–10), studies with phenethylamines could be used to infer information about the action and binding features of indoles.

This class of agents was reviewed by Nieforth (11) in 1971 as "psychotomimetic" phenethylamines. It is not the intent of this author to delve into the significance and comparisons of such terms as psychotomimetic, hallucinogenic, and psychedelic. The controversy over appropriate terminology has been considered in the literature. Within this discussion, the terms hallucinogenic and psychotomimetic are used interchangeably. Psychedelic is another term that has been used to describe this class of compounds.

A word of caution about biological data is in order. Activity is discussed for several animal and *in vitro* models, as well as for humans, where available. However, the use of *in vitro* and animal data can be misleading. For example, compounds have been compared in rats for their ability to disrupt a conditioned avoidance response. In clinical terms, this approach is meaningless. In rabbits, many compounds have been compared for their ability to elicit hyperthermia.



I: R = H or $CH_3$, X = OR, alkyl, halogen
II: R = $CH_3$, X = 2,5-$(OCH_3)_2$-4-$CH_3$
III: R = $CH_3$, X = 3,4-$OCH_2O$
IV: R = $CH_3$, X = 4-$OCH_3$

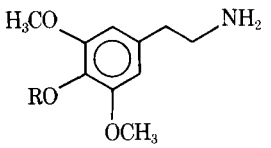
Again, these data have little clinical relevance. In general, however, such tests have been correlated with potency of the compounds in humans. Many of the animal tests were found to allow predictions, albeit approximate, of human potency. Thus, in cases where animal data are cited, some effective central component of action is indicated. Nevertheless, the reader should be aware that only those compounds that were assayed in humans can be truly categorized as hallucinogenic.

There is a good deal of flexibility in interpretation even in this situation, and much of this should be attributed to the multiplicity of actions possessed by the phenethylamines. These simple structures have direct actions on serotonin receptors, both as agonists (12–14) and as antagonists (15), are capable of releasing serotonin (16), norepinephrine, and dopamine (17), have direct actions at dopamine receptors, or can be metabolized to species that further influence qualitative mechanisms of action (18), all depending on the particular structure studied. The effect on monoamine oxidase for most structures also is unknown. These and other factors combine to varying degrees for each agent. Hence, a particular compound could be said to possess a unique profile of action all its own. That is, each substitution pattern could be expected to present a slightly different qualitative pattern of clinical activity that will be revealed only by tests in humans. Therefore, when one speaks of hallucinogenic activity, it is uncertain just exactly what is meant. Most often, in humans at least, the term refers to a subjective similarity to a standard agent such as lysergide or mescaline. In this light, one can see how inadequate any animal testing will be. Fortunately, Shulgin and his coworkers provided a wealth of quantitative human data for correlation and analysis.

Although elucidation of subtle qualitative structure–activity relationships must await more structured and well-designed clinical assays, legal strictures and public sentiment presently oppose such research. One is forced to rely largely on animal assays. Ignoring the work that has used animals and *in vitro* models leaves a serious gap in an understanding of structure–activity relationships. Such studies should be considered, but with the caveats discussed always in mind.

This paper briefly, but critically, reviews the advances made in understanding the structure–activity relationships of phenethylamine hallucinogens. It is hoped that a clearer picture will emerge of the probable requirements for receptor binding and some of the essential conformational and stereochemical features. Where possible, these requirements are related to human clinical activity.

Comprehensive reviews of hallucinogens were presented by Brawley and Duffield (6) and subsequently by Shulgin (19–21). Jacobs and Trulson (22) also recently presented a brief review of the mechanism of action for hallucinogens. However, none of these reports dealt in sufficient depth with the structure–activity requirements for the most widely studied class of hallucinogens, the phenethylamines. The excellent and comprehensive reviews by Shulgin come closest to this goal but tend to focus on active compounds and a description of structure–activity relationships as they apply to human clinical studies. These reviews understandably omit several studies where activity in animal models has not been confirmed by human testing.



V: R = $CH_3$
VI: R = $CH_2CH_3$

The present discussion attempts to pull together findings from many approaches, both *in vivo* and *in vitro*. The treatment begins with aromatic substitution patterns and proceeds to brief highlighting of what is known about the molecular mechanism of action. It is hoped that the reader will gain a better understanding of the structural features necessary for activity and, where possible, insight into the possible reasons for their importance.

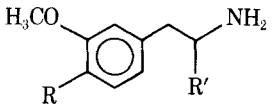
## AROMATIC SUBSTITUENTS

**Orientation**—It has been concluded that a 2,4,5-trisubstitution pattern yields optimally active compounds (19, 23). Although this statement generally remains true, some interesting exceptions exist. For example, replacement of the 4-methoxy group in mescaline (V) with an ethoxy group gives escaline (VI), which is about six times more active than mescaline (24).

Within the 3,4,5-trisubstituted series, replacement of the 4-methoxy with a bromine, alkyl, or alkylthio group leads to compounds with high activity (24). Acute dosages in humans were reported to be in the 10–20-mg range (21). In an *in vitro* assay, several 3,4,5-trisubstituted compounds showed potency comparable to similarly substituted 2,4,5-substitution patterns (25). This point is important. Attention has been called to the possibility of quinone generation from 2,5-dimethoxy-substituted compounds as an explanation for their high potency (19, 21, 23, 26). Although di-*O*-demethylation and consequent oxidation to quinones were observed in liver microsomes, no such reactions were detected *in vivo* (27). However, the potential neurotoxicity of such reactive metabolites (28), even if produced only in miniscule amounts, should give cause for concern in the unlikely event that these drugs might be used on a chronic high dosage basis.

In general, the most active compounds studied to date possess 4,5-disubstitution with a methoxy group at either the 2-position (2,4,5-substitution) or the 3-position (3,4,5-substitution). However, 2,4,6-trimethoxyamphetamine possesses about 10 times the activity of mescaline in humans (21). Since little work has been reported with 2,4,6-substituted compounds, it is impossible to assess whether further substituent modification will give more potent compounds in this series.

**Nature of Substituents**—In any substitution series, the 4-substituent has been of unique importance. Although it probably contributes a general lipophilic effect that favors more effective central nervous system (CNS) penetration (29), it also may serve in at least two other specific roles. First, the most active compounds possess *para*-substituents that are resistant to oxidative metabolism. Increasing potency generally parallels increasing stability of this group. Second, a recent *in vitro* quantitative study indicated that serotonin receptors may possess a specific hydrophobic site that accommodates the *para*-substituent,



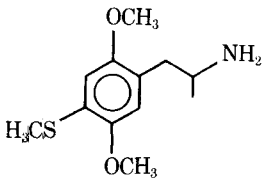
VII: R = $OCH_3$, R′ = H
VIII: R = $OCH_2CH_3$, R′ = H
IX: R = $CH_3$, R′ = H
X: R = Br, R′ = $CH_3$

providing it is <5–6 Å in length (30). These conclusions were supported by studies of molecular connectivity (31). Green *et al.* (32) also proposed a specific hydrophobic site approximately at this region of the serotonin receptor.

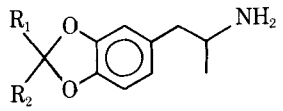
The unique importance of the *para*-substituent can be best illustrated with several examples. Anderson *et al.* (33, 34) evaluated a series of isomeric 2,4,5-trisubstituted dimethoxymethylamphetamines. Substantial activity in the rabbit hyperthermia model was observed only when the substituents were in the 2,5-dimethoxy-4-methyl configuration. A similar finding occurred for a series of 2,4,5-substituted dimethoxymethylthioamphetamines. Significant activity occurred only with the 2,5-dimethoxy-4-methylthio orientation (35).

The *para*-substituent is even more critical for compounds lacking an *o*-methoxy group. For example, 3,4-dimethoxyamphetamine (VII) may be orally active in humans but only at acute doses of >1 g (36). However, simple replacement of the 4-methoxy in VII with an ethoxy group gives VIII, leading to some retention of central activity. In humans, VIII possessed mood-elevating properties in the 0.1–0.2-g range (36). In an assay in mice, 3-methoxy-4-methylamphetamine (IX) was just as potent and long lasting as 2,5-dimethoxy-4-methylamphetamine (II) (37). In a series of bromomethoxyamphetamines, the 3-methoxy-4-bromo group (X), but not the isomeric 3-bromo-4-methoxy group, elicited a mescaline-like effect in rats (38). Thus, for hallucinogen-like activity in rodent models, the *o*-methoxy group may not be required. However, it was found that IX, despite its reported activity in mice, is totally inactive in humans at doses 10-fold greater than the threshold for II (36).

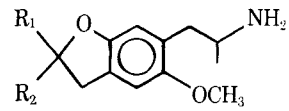
An interesting variation in activity is encountered where the *para*-substituent is an alkylthio group. It was speculated initially that the metabolic lability of sulfur might provide interesting biological properties, in contrast to more oxidation-resistant groups (39). Clinical studies of the first compound in this series, 1-(2,5-dimethoxy-4-methylthiophenyl)-2-aminopropane (XI), proved it to be highly active (26). Its duration of action was reduced somewhat from that observed with more metabolically stable compounds. However, this drug appears to produce a unique enhancement of intellectual function while lacking other features of the hallucinogens such as severe visual sensory distortion. Shulgin and his colleagues (21, 40) described this "aleph" effect and expanded on this lead. Alkylthio-substituted compounds in both the 2,4,5- and 3,4,5-series have been examined for activity. Several



XI



XII: $R_1 = R_2 = H$
XIII: $R_1 = H$, $R_2 = CH_3$
XIV: $R_1 = R_2 = CH_3$



XV: $R_1 = R_2 = H$
XVI: $R_1 = H$, $R_2 = CH_3$
XVII: $R_1 = R_2 = CH_3$

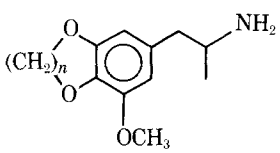
are quite potent and retain the specific intellectual-enhancing properties of XI. The more interesting of these compounds contain the alkylthio group in an orientation *para* to the side chain.

Replacement of a 2-, 3-, or 5-methoxy with a larger alkoxy, methyl, or halogen usually resulted in inactive compounds (34, 41, 42), although some activity was retained in a few cases. Within the 2,5-dimethoxy series, replacement of one methoxy with a hydroxy group increased *in vitro* serotonin receptor affinity (43, 44). Substitution at the 5-position with hydroxy had a greater enhancing effect on affinity than at the 2-position.

**Steric Effects**—Recent studies are beginning to answer questions about the bulk properties of the aromatic ring substituents. Although there may be a hydrophobic region on the receptor that accommodates the *para*-substituent, bulky hydrocarbon groups are not tolerated, as illustrated by the series of 2,5-dimethoxy-4-alkyl-substituted amphetamines. Activity can be ordered in the following sequence for the 4-alkyl group: propyl > ethyl > methyl and also propyl > isopropyl > *tert*-butyl (45–47). The clinical activity of the *p*-isopropyl and *p*-*tert*-butyl homologs has not been established, and potencies are based on animal studies (46, 48). However, the *tert*-butyl homolog was inactive in humans at acute dosages up to 10 mg, far above the effective amount for a *p*-methyl group (20).

It has been proposed that the receptor that interacts with hallucinogens can be modeled as a planar surface which can tolerate little, if any, steric bulk projecting from the binding face of the hallucinogen molecule (49, 50). Nonbonded interactions between the 4-alkyl and an adjacent methoxy group certainly play a role in the allowed conformational states of the alkyl group. One can envision the type of steric profile presented to the receptor by an isopropyl or *tert*-butyl group. In the latter case, it would be impossible to rotate the *tert*-butyl group to remove bulk completely from one face of the molecule. With an isopropyl group, this would not be so severe.

Evidence to support the idea of a deleterious effect of bulky substituents comes from studies on two series of homologs. Structures XII, XIII, XV, and XVI were shown to possess clinical activity (36, 51). Compound XIV has not been tested in humans, but was inactive in animal models (52). The *gem*-dimethyl compound (XVII) is inactive in humans (20). This pattern of activity is in agreement with the suggestion that one face of the molecule must remain unhindered. This explanation may apply to the inactivity of the ethylenedioxy (XVIII*a*) and trimethylenedioxy (XVIII*b*) compounds (53).



XVIII*a*: $n = 2$
XVIII*b*: $n = 3$

In addition to interactions between substituents and the receptor, interaction between the substituents themselves probably plays an important role in determining activity. X-ray crystallographic studies established that the 4-methoxy group of mescaline is twisted nearly perpendicular to the ring plane (54). It is unlikely that a more bulky group such as ethoxy can rotate from a perpendicular conformation. In view of the substantial potency, not only of escaline (VI) but of its 4-isopropoxy homolog, isoproscaline (36), it seems doubtful that the 4-oxygen plays any crucial role with respect to resonance overlap of its $n$ electrons with the $\pi$ system of the aromatic ring. This concept is reinforced by the fact that the 4-substituent can be replaced by alkyl or halogen with an increase in activity.

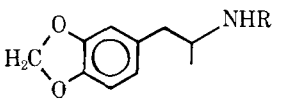
On the other hand, twisting of the 2- or 5-methoxy functions seems to abolish activity. Such twisting has been invoked to explain the inactivity of certain 2,3-dimethoxy-substituted compounds (55) since a 2,3-methylenedioxy group usually gives active compounds (23). One may speculate that the 2- and 5- or the 3- and 5-methoxy groups, depending on the substitution pattern, must lie coplanar with the aromatic ring. One obvious effect of this arrangement is to maximize overlap between the oxygen $n$ electrons and the ring $\pi$ system. However, this explanation seems weakened by the observation that 2,3,5- and 2,3,6-trimethoxyamphetamines are clinically active as hallucinogens (19). The picture here is not very clear, and one wonders to what extent qualitative differences in mechanism of action may be responsible.

Snyder and Richelson (56) suggested that intramolecular hydrogen bonding between the $o$-methoxy and side-chain amino groups could be important for activity. However, no evidence for such hydrogen bonding has been obtained from X-ray crystallographic studies (57, 58).

Although theoretical (59) and experimental gas-phase (60) studies indicated a noncoplanarity when two methoxy groups are adjacent, NMR solution studies found such methoxy groups to be equivalent (61). Furthermore, the high activity of the dihydrobenzofuran derivative (XV) suggests that the orientation of the 5-methoxy group is not critical if it remains coplanar with the ring. Steric effects seem to indicate that a 5-methoxy group should be directed away from the 4-alkyl group. In XV, the alkoxy function is directed toward the 4-alkyl group.

## SIDE-CHAIN MODIFICATION

**$N$-Substitution**—It has been demonstrated with several compounds that $N$-alkylation abolishes or dramatically attenuates *in vivo* activity (26, 47, 62–64) and *in vitro* receptor affinity (65). Only in the case of 3,4-methylenedioxy ring substitution has $N$-alkylation afforded active compounds, the $N$-methyl (XIX) and $N$-ethyl (XX) analogs. These analogs retain potency comparable to the primary amine (III), although qualitative aspects of the intoxication are altered (66). In III, the ($R$)-enantiomer possesses activity; upon $N$-methylation, the isomer with the ($S$)-configuration has proven to be active.



XIX: R = $CH_3$
XX: R = $CH_2CH_3$

These results have been interpreted to mean that the actions of ($R$)-III and $N$-methyl-($S$)-III are mediated by different mechanisms. This idea is reinforced by the finding that there is no cross-tolerance between III and XIX (62). This result is not too surprising since III was shown to possess both a lysergide-like and an amphetamine-like component of action (67–70). Thus, it was speculated that III exerts its effects by direct action on serotonin receptors, similar to explanations for the action of ($R$)-II. By contrast, $N$-methyl-($S$)-III was suggested to work by release of endogenous transmitter (62). Unfortunately, studies of III and its derivatives are complicated by its multiplicity of actions on various monoaminergic systems.

Although it has been concluded that $N$-methylation generally destroys activity, this conclusion may be premature since few $N$-methylated amphetamines have been examined. Cheng *et al.* (17) studied a series of substituted amphetamines and found that substitution patterns other than 2,5-dimethoxy have a significant indirect component of action. If the arguments relating to III are valid, many of these derivatives may retain or possess enhanced activity upon methylation. Furthermore, as with amphetamine, the ($S$)-isomer is expected to be the more potent releaser and thus possess activity.

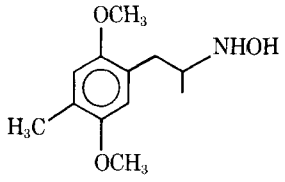
Further extension of the $N$-alkyl group to higher homologs generally abolishes activity (66). $N,N$-Dialkylation does not give active compounds, even with the 3,4-methylenedioxy substitution (36).

In an analogy to the opiate antagonists, DeSantis and Nieforth (71) prepared the $N$-propyl, $N$-cyclopropylmethyl, and $N$-allyl derivatives of mescaline. In mice, the propyl and allyl derivatives produced a slight antagonism of mescaline-induced disruption of swimming behavior.

One other active substitution on nitrogen is the $N$-hydroxy group. $N$-Hydroxylation of III gives a compound possessing clinical activity (66). Coutts and Malicky (72) evaluated several congeners of II. One, the $N$-hydroxy derivative (XXI), elicited behavioral effects in rats but at about six times the dosage required for II.

**Side-Chain Alkylation**—The addition of a methyl group to the $\alpha$-side-chain position dramatically enhances the *in vivo* activity of 2,4,5-trisubstituted compounds. For example, 2,4,5-trimethoxy-$\beta$-phenethylamine is inactive (73), but addition of an $\alpha$-methyl group gives the corresponding amphetamine, which is 17 times more potent than mescaline (23). This potency increase also is observed in compounds with a hydrophobic *para*-substituent such as methyl or bromine but is less dramatic. 2,5-Dimethoxy-4-methylphenethylamine is clinically active at doses of ~15–20 mg (74); addition of an $\alpha$-methyl group to give II increases potency about fourfold.

The potency increase with $\alpha$-methylation is very small in 3,4,5-substituted compounds. Addition of an $\alpha$-methyl group to mescaline gives 3,4,5-trimethoxyamphetamine, a compound only about twice as active as mescaline (23). This slight increase is maintained in this series where the 4-substituent is a hydrophobic group. This finding probably reflects an effect on metabolism since addition of the $\alpha$-methyl group has little effect on *in vitro* receptor affinity in either series (30, 65). Thus, it is tempting to speculate



XXI

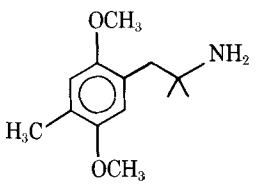
that 2,4,5-substituted compounds are more susceptible to amine oxidation than are 3,4,5-substituted analogs. However, Clark *et al.* (75) reported that 2,4,5-trimethoxyphenethylamine is deaminated less extensively than mescaline by a soluble rabbit liver amine oxidase preparation. In any case, with either substitution pattern, the simple addition of the $\alpha$-methyl group increases hydrophobicity and at least facilitates passive diffusion into the CNS.

Extension of the $\alpha$-methyl group to ethyl or higher homologs abolishes activity (76). This result was observed in 3,4,5-trimethoxy compounds and in several 2,5-dimethoxy-4-substituted analogs (77). The addition of an $\alpha$-ethyl group, while abolishing hallucinogenic action, leads to potential antidepressant compounds (77–80). At present, there is no explanation as to why this occurs.

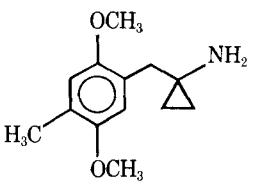
*In vitro*, the $\alpha$-ethyl group shows mixed agonist–antagonist action at the serotonin receptor whereas the $\alpha$-methyl group is a pure agonist (81). The conformational properties, as determined by solution NMR studies, for $\alpha$-methyl and $\alpha$-ethyl compounds do not differ significantly (82). Their dynamic behavior appears comparable, and it is difficult to ascribe the difference in action to a conformational effect. Theoretical calculations using empirical potential functions likewise have failed to reveal a conformational explanation for the difference (83). Some undefined steric effect seems the most plausible answer.

Dialkyl substitution on the $\alpha$-carbon also destroys activity. This effect is evident as a loss of *in vitro* activity and a lack of behavioral effect in cats for XXII (84). Surprisingly, linking these two methyl groups in the form of a cyclopropyl ring (XXIII) restores some activity. The original report suggested that this result might be due to enhanced distribution into lipid for the cyclopropyl group but not the *gem*-dimethyl group. More recently, the difference in activity was attributed to the lack of conformational flexibility for the dimethyl compound and its inability to assume the active conformation (85). These conclusions were supported by theoretical calculations and carbon 13 spin-lattice relaxation times from solution NMR studies. The data support the idea that the active conformation is one where the side chain must be in an antiperiplanar arrangement with the aromatic ring.

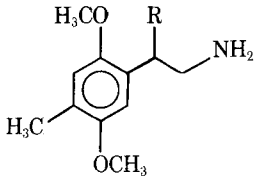
On the other hand, adding a second $\alpha$-methyl group to III to give the $\alpha,\alpha$-dimethylphenethylamine led to an active compound (36). Again, the 3,4-methylenedioxy substitution presents an anomalous case. This analog can be



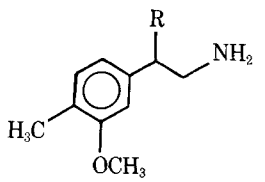
XXII



XXIII



XXIV: R = H
XXV: R = $CH_3$



XXVI: R = H
XXVII: R = $CH_3$

viewed as a substituted phentermine derivative, and its activity also may prove to be due to the release of endogenous neurotransmitter.

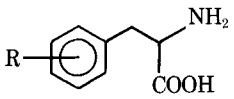
The addition of a $\beta$-methyl group to the side chain dramatically attenuates *in vivo* activity in animals (47). This effect also was observed for $\beta$-hydroxy or $\beta$-keto analogs in an *in vitro* receptor affinity assay (55). In the latter instance, the beta substituent was most deleterious when an *o*-methoxy group also was present. This may be due to an unfavorable steric interaction between the beta and *ortho*-substituents. However, in the ear-scratch response in mice (48) for XXIV–XXVII, only XXV retained any activity, and it was very weak (86). This finding again emphasizes the importance of the $\alpha$-methyl and *o*-methoxy groups for optimal activity.

The $\alpha,\beta$- or $\beta,\beta$-dimethyl side-chain substitution abolishes hallucinogen-like activity in animal models (47). None of these substitutions has been tested yet in humans.

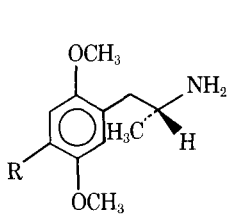
There are two reports of phenylalanine analogs of hallucinogens. The 2,5-dimethoxy-4-methyl analog (XXVIII*a*) and the mescaline congener [3-(3,4,5-trimethoxyphenyl)alanine (XXVIII*b*)] were examined for activity, although neither is expected to be a substrate for brain decarboxylases according to Ferrini and Glasser (87). Neither of these substituted phenylalanines showed biological activity (88–90).

**Stereochemistry**—It has been known for several years that in the substituted hallucinogenic amphetamines, the (*R*)-enantiomer is the most active (91–93). Although the (*S*)-enantiomers generally have not been studied at high dosage levels, the (*R*)-enantiomer subjectively and quantitatively reproduces the effect of twice its weight of racemate in humans. Both *in vitro* and animal models demonstrate stereoselectivity, with about a four- to 10-fold difference in potency between the (*R*)- and (*S*)-enantiomers (94–98). The classical approach to this observation has related the (*R*)-configuration of the amphetamines, shown in binding orientation A, to the (*R*)-configuration at C-5 of lysergide. With this view, the methyl group of the amphetamines corresponds to the C-4 methylene group of lysergide. However, the relatively small effect (30, 96) on receptor affinity in $\alpha$-methyl compounds with the (*R*)-configuration, as compared with the $\alpha$-unsubstituted phenethylamines, seems inconsistent with any interaction of the $\alpha$-methyl group with the receptor.

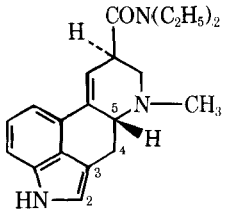
A newer hypothesis from these laboratories related this stereoselectivity to binding orientation B, where the



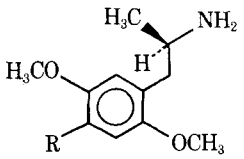
XXVIII*a*: R = 2,5-$(OCH_3)_2$-4-$CH_3$
XXVIII*b*: R = 3,4,5-$(OCH_3)_3$



binding orientation A



lysergide



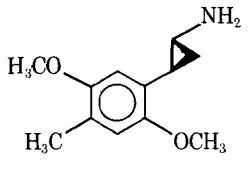
binding orientation B

$\alpha$-methyl group is allowed to project away from the binding surface (49, 50). With either hypothesis, it was assumed that the receptor binds to the alpha face of the lysergide molecule since this surface presents the most unhindered access to the N-6 unshared electrons (58, 98). The phenethylamines were assumed to bind in a conformation where the side chain is relatively coplanar with the aromatic ring in an extended, or antiperiplanar, arrangement. This arrangement would give the closest similarity to lysergide. In conformation B, the $\alpha$-methyl group is directed away from the binding surface. In this view, $\alpha$-methylation has little effect on receptor binding when the configuration is *R*. In contrast, and consistent with experimental findings (14, 96), the methyl group of the (*S*)-enantiomer has a deleterious effect on affinity.

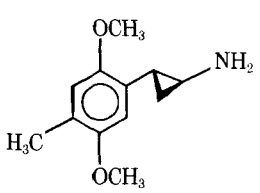
Of the two isomers of the 2-phenylcyclopropylamine analog of II, the (1*R*,2*S*)-enantiomer (XXIX*a*) is more active (99). The (1*S*,2*R*)-isomer (XXIX*b*) showed no activity at any dose tested. If the argument is valid that the steric bulk of the C-3 methylene must project away from the receptor, then activity for the (1*R*,2*S*)-isomer is only consistent with a binding conformation for flexible analogs similar to that shown for XXIX*a*. If strict structural congruences can be invoked, this hypothesis would correlate the 5-methoxy group of the phenethylamines with the 5-hydroxy group of serotonin. This is borne out by the greater enhancement of *in vitro* receptor affinity when the 5-methoxy group of the phenethylamines is replaced by hydroxy than when the 2-methoxy group is replaced by hydroxy (43).

Problems arise in considering stereochemistry for other substituted amphetamines. As discussed in the section on *N*-substitution, methylation of III reverses the stereoselectivity of activity and it is the (*S*)-enantiomer of *N*-methyl-III that is active. However, this latter derivative may possess different mechanisms of action (62).

Both the (*R*)- and (*S*)-enantiomers of 3,4-dimethoxyamphetamine were required to elicit a mescaline-like behavioral profile in rats (100). Furthermore, coadministration of the (*R*)-enantiomer of 3,4-dimethoxyamphetamine with (*S*)-amphetamine gave a response identical to that obtained with racemic 3,4-dimethoxyamphetamine. Cheng *et al.* (17) demonstrated that this compound possessed an indirect releasing component of action in an *in vitro* smooth muscle assay. Therefore, it is possible that the *in vivo* effects of racemic 3,4-dimethoxyamphetamine also may be partially ascribed to the releasing effects of the (*S*)-enantiomer.



XXIX*a*
(1*R*,2*S*)



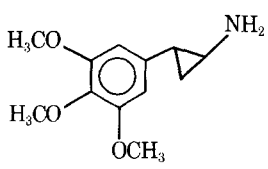
XXIX*b*
(1*S*,2*R*)

Although many additional studies are needed to elucidate such mechanisms definitively, the following conclusions would be generally consistent with previous work (17, 94, 96). For compounds possessing 2,5-dimethoxy substituents, the (*R*)-enantiomer has stereoselective *in vivo* activity. This action is correlated with *in vitro* direct agonist effects at serotonin receptors. For any other substitution patterns, a possible indirect component of action, such as a releaser of serotonin or catecholamines, must be considered. In this latter case, the (*S*)-enantiomer may contribute a significant component to *in vivo* activity. One may speculate that *N*-methylation allows retention of activity with these substitutions (62). For the 3,4,5-trisubstitution pattern of mescaline itself, *in vivo* activity appears to correlate with a direct effect at the serotonin receptor (30, 55).

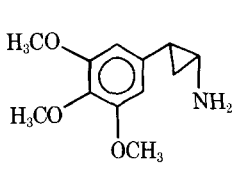
**Rigid Analogs**—Several rigid analogs of phenethylamine hallucinogens have been evaluated to elucidate the binding conformation of the side chain. To date, none has been particularly revealing, although some interesting findings have emerged. The simplest rigid analogs are the substituted 2-phenylcyclopropylamines. The 3,4,5-trimethoxy compounds (XXX and XXXI) first were prepared as mescaline analogs (101). Inactivity for the *cis*-isomer (XXXI) seems to establish conclusively the side-chain binding conformation as *trans* in the flexible phenethylamines. As discussed previously, the 2,5-dimethoxy-4-methyl-substituted analog (XXXIX) has been resolved into its enantiomers. Activity only for the (1*R*,2*S*)-enantiomer has provided evidence of the binding conformation for the (*R*)-enantiomer of the amphetamines.

Recently, Law and Borne (102) reported the synthesis and preliminary pharmacology for the substituted *exo*- and *endo*-2-azabicyclo[2.2.2]octanes (XXXII and XXXIII, respectively). Examination of spontaneous activity in mice indicated that the *endo*-isomer (XXXIII) was about two times more active than the *exo*-isomer. This finding provides further evidence for an antiperiplanar side-chain conformation as important for activity.

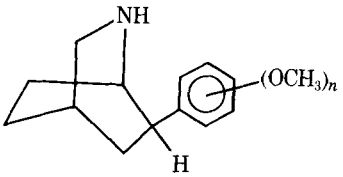
Additional studies of the side-chain conformation and stereochemistry have been carried out utilizing rigid analogs. In particular, 2-amino-1,2,3,4-tetrahydronaphthalenes (2-aminotetralins) have received attention. Kang and Green (103) pointed out the possibility that these compounds could be compared to lysergide. The unsub-



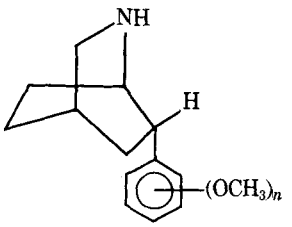
XXX



XXXI



XXXII



XXXIII

$n$ = 2 (3,4-substituted)
$n$ = 3 (3,4,5-substituted)

stituted parent (XXXIV), as the racemate, shows some similarity to the hallucinogens in rat models (104). The (*S*)-(−)-enantiomer seems to possess biological activity (105). This stereochemistry is inverted from that observed for lysergide. This observation was used in arguments presented earlier against orientation A as the active binding orientation for the phenethylamines (49).

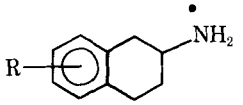
Green *et al.* (106) also examined a series of methoxy- and hydroxy-substituted 2-aminotetralins. They reported that XXXV possessed electroencephalographic effects in rats that were similar to those evoked by mescaline.

In a series more closely approximating active hallucinogens, the dimethoxymethyl-substituted compounds (XXXVI–XXXVIII) were examined. Although *in vivo* activity was indicated for the aminoindan (XXXVIII) at high doses (107), other studies proved that XXXVIII was much less active than the tetralin (XXXVII) both *in vivo* (108) and *in vitro* (109). Neither compound produced a mescaline-like response in the conditioned avoidance response in rats. The dimethoxy compound (XXXVI) possessed a sedative effect in mice (104). Although none of the tetralins had clearcut hallucinogen-like action in any animal models, XXXVII produces hyperthermia in rabbits and evokes a rage response in cats (49).

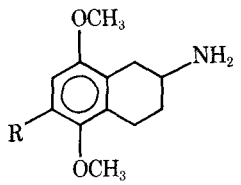
Violland *et al.* (110) also examined several methoxy-substituted 2-aminotetralins as analogs of hallucinogens. In mice and dogs, these compounds possessed pharmacological activity characterized by ataxia, sedation and, in some cases, analgesia. *N*-Alkylated derivatives of 2-amino-2,3-dihydrophenalene also were prepared. Although possessing pharmacology similar to the aminotetralins, they were much more potent. Again, no clinical studies have been carried out with any of the aminotetralins or phenalenes, and there is no evidence to suggest that they possess hallucinogenic action in humans.

Numerous other investigators have explored the 2-aminotetralins as congeners of lysergic acid, with particular reference to identification of the oxytocic pharmacophore of the ergot alkaloids. Such studies are not reviewed here.

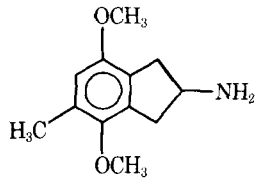
Additional rigid analogs have been prepared where the phenethylamine side chain is incorporated into a heterocyclic ring (XXXIX–XLII). Compound XXXIX could be viewed as possessing the structural features of both mescaline and methylphenidate (111), although it possessed no mescaline-like action in animal models. The morpholino



XXXIV: R = H
XXXV: R = 7-OH



XXXVI: R = H
XXXVII: R = $CH_3$



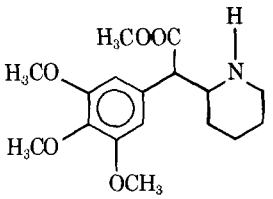
XXXVIII

analog (XL) was reported to possess more mescaline-like tendency in animals than XLI or XLII (112). It is unknown whether any of these compounds possess hallucinogenic action in humans. However, none had appreciable potency in animal models.

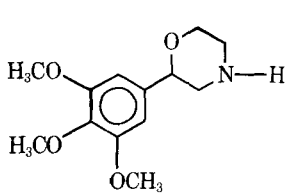
## EFFECTS OF DISTRIBUTION AND METABOLISM

The ability of the compounds to penetrate the CNS is a requisite for activity. As pointed out by Vogel and Evans (113), when one considers the actual levels of drug detected in the brain rather than the systemically administered dose, dramatic differences in structure–activity relationships may appear. That is, some compounds that appear to possess little activity upon peripheral adminstration are highly potent if actually administered into the CNS. For compounds with a more favorable distribution, only small doses may be needed to achieve the same brain levels. These distribution differences are independent of actual efficacy at the receptor(s). Vogel and Evans (113) argued further that structure–activity relationships should be based on minimal effective brain levels rather than on dosage measures that reflect a quantity necessary for peripheral administration. Although this approach has merit, most investigators probably will not carry out the additional studies required to establish minimal effective brain level values.

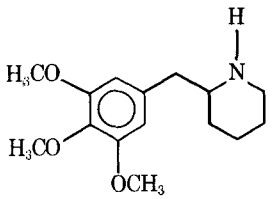
The importance of passive partitioning was noted in a study where 1-octanol–water partition coefficients were measured and correlated with human clinical activity (29). As expected, the regression obtained was parabolic, with an optimum log $P$ value of 3.14. Although $R^2$ for the regression was only 0.62, there was large variability in the human data. Furthermore, the study included numerous compounds that undoubtedly possess several components of action, as is the case for III. Coincidentally, the optimum log $P$ value from this study was nearly identical, within statistical limits, to the optimum determined in an *in vitro*



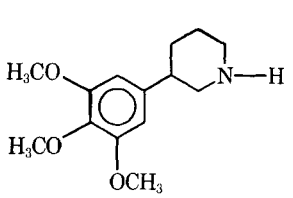
XXXIX



XL



XLI



XLII

assay (30). In the latter study, this value reflected, in part, a specific hydrophobic interaction with the receptor.

The CNS distribution of [$^3$H]mescaline and the isomeric 2,3,4-trimethoxyphenethylamine was studied using autoradiography (114). The latter compound is inactive and gave weak and homogeneous labeling in the brain. By contrast, mescaline was selectively accumulated in the hippocampus and amygdala. The findings of this study are in agreement with similar results obtained for the distribution of $^3$H-labeled II (115). However, the 2,3,4-trimethoxy isomer also is metabolized more rapidly than mescaline (116). Mitoma (117) compared 2,4,5-trimethoxyamphetamine with the isomeric 2,3,4-substitution. The latter is inactive clinically while 2,4,5-trimethoxyamphetamine is 17–20 times more active than mescaline. Surprisingly, the brain levels of the inactive 2,3,4-isomer were higher than those attained with the active 2,4,5-substitution pattern in rats.

No studies of differential brain distribution for enantiomers of active amphetamines have been published. However, the (*S*)-(+)-enantiomer of II is metabolized more rapidly than the (*R*)-(−)-isomer when the drug is administered as the racemate (118, 119).

Some distinction should be made between metabolic processes that essentially "detoxify" the hallucinogenic phenethylamines and those that may be involved in the mechanism of action, *i.e.*, may be responsible for generating active species. For a discussion of the former processes, the review by Castagnoli (120) is excellent. The latter type of metabolism is of major interest here. Also of interest are processes that metabolize compounds possessing high *in vitro* potency but that lack whole animal or clinical activity.

It was once believed that phenethylamines, particularly mescaline, might be active due to the formation of a metabolite (121). A recent study (122) indicated that this is not the case, at least for mescaline. Zweig and Castagnoli (27, 123) also suggested that di-*O*-demethylation of II may generate an active metabolite that contributes to activity. The inability to generate significant amounts of these metabolites, coupled with the high observed *in vitro* activity for II, argues against this possibility. Furthermore, Ho *et al.* (124, 125) showed that II is oxidized primarily at the methyl group in the *para* position, leading to the *p*-hydroxymethyl and *p*-carboxy species. Weinkam *et al.* (126) confirmed that the *p*-hydroxymethyl derivative is the major metabolite in rabbit liver microsome preparations. Thus, if *O*-demethylation does occur, it is very minor. Unfortunately, no definitive experiments have been carried out that would settle the issue. It is this reviewer's opinion, however, that this process is not important in the intoxication mechanism. This seems to be the only instance where controversy presently exists regarding the role of an active metabolite in the activity of the phenethylamines.

There are examples to suggest that some compounds possessing high affinity for *in vitro* receptors may lack *in vivo* activity due to rapid metabolic inactivation. Such effects must be considered when developing receptor structure–activity relationships. Lack of *in vivo* or clinical activity may camouflage the fact that a particular compound actually possesses high intrinsic activity at a receptor site.

Charalampous *et al.* (127) showed that the half-life of mescaline in humans is ~6 hr. By contrast, the inactive 3,4-dimethoxyphenethylamine is metabolized extensively, with a half-life of <1 hr (128). This result is consistent with the other findings (75) that phenethylamines with more than three methoxy groups are not deaminated *in vivo*.

As was mentioned under *Aromatic Substituents*, functions in the *para* position that are resistant to metabolism give more potent compounds. Since deamination is a minor metabolic pathway in humans, increased resistance of the aromatic ring and its substituents to metabolism will certainly affect activity. The most obvious result will be an increased biological half-life and consequent duration of action.

In 3,4-dimethoxyamphetamine, the 4-methoxy group is about 15 times more extensively *O*-demethylated than the 3-methoxy group (129). Likewise, in 2,4,5-trimethoxyamphetamine, *O*-demethylation at the 4-position is about twice that at the 5-position and nearly three times that of the 2-methoxy group (130). With a *p*-alkyl, Ho *et al.* (125) found that the *p*-methyl group of II is oxidized progressively to the carboxy group. Tansey *et al.* (131) studied the metabolism of the *p*-ethyl homolog of II and reported that the benzylic carbon of the *p*-ethyl group was hydroxylated but much more slowly than the methyl of II. Finally, with a halogen in the *para* position, such as in the bromine homolog of II, no organic bromide was detectable in the urine following administration to humans (132). The stability of the *p*-halogen group, either as bromine or iodine, led to investigation of the utility of these compounds as brain-imaging radiopharmaceuticals (133).

## ACTION AT MOLECULAR LEVEL

Little is known of the mechanism of receptor interaction for hallucinogenic phenethylamines. However, circumstantial evidence indicates that one event that occurs may be electron donation to the receptor to form a charge transfer complex. This initially was suggested by Karreman *et al.* (134) in 1959, based on extended Hückel molecular orbital calculations for lysergide. Subsequent quantum chemical studies by several groups led to development of correlations between activity and energy of the highest occupied molecular orbital (135, 136).

Experimentally, the possible requirement for a high energy aromatic system was indicated by correlations between activity and: (*a*) the degree of native fluorescence (137), (*b*) the excitation wavelength and molar absorptivity (138), and (*c*) the strength of the charge transfer complex between substituted phenethylamines and 1,4-dinitrobenzene (139). Furthermore, Domelsmith and Houk (140) observed good correlation between human activity and experimentally measured energy of the first aromatic ionization potential in the gas phase. Ionization potentials are well correlated with the highest occupied molecular orbital.

Dipaolo *et al.* (141) carried out model interaction calculations for phenethylamines using 3-methylindole as the interacting species. Using CNDO calculations, they reported a correlation between human activity and interaction energy. However, this study only included interactions between the aromatic ring of the phenethylamines and the six-membered ring of indole.

Green *et al.* (142), using a more rigorous theoretical approach, calculated several electronic parameters for tryptamines. High frontier electron density at the 4- and 5-positions of the tryptamines appears to be well correlated with activity. Assuming that tryptamines and phenethylamines possess a similar mechanism of action implies that charge transfer complexation may be a possible receptor interaction for hallucinogens in general.

The biological activities for XII–XVII were discussed under *Steric Effects*. Decreased activity (or inactivity) of compounds with steric bulk protruding toward both faces of the molecule also is consistent with the formation of an electron donor–acceptor complex as a component of the molecular mechanism of action. Charton (143) pointed out the importance of such effects in model systems where bulky groups were attached to the donor molecule.

However, Glennon *et al.* (44) recently suggested that, depending on the aromatic substitution pattern, phenethylamines may orient differently upon binding to the receptor. That is, depending on the particular substituents possessed by the phenethylamine, it may bind in either binding orientation A or binding orientation B. If so, interpretation of structure–activity relationships at the molecular level may be very difficult.

Although all of the hallucinogens possess a basic nitrogen atom, there is little apparent dependence on basicity. Whereas lysergide or substituted phenylcyclopropylamines have pKa values of ~8–8.3, the phenethylamines or substituted amphetamines have higher pKa values, at ~9.4–9.8. Weinstein *et al.* (144) suggested that the amine undergoes deprotonation upon binding and that quantum chemical calculations of the bound species are carried out more properly when the amino is considered to be nonprotonated. Although this concept has not been verified experimentally, lower pKa values would facilitate deprotonation. Of course, one should also be aware that less basic amines also are less highly ionized at physiological pH. This fact normally will lead to brain levels that are higher than for a more basic amine.

At present, little else in the way of a molecular mechanism of action can be safely concluded. This situation is certainly not unique to the hallucinogens. Nevertheless, the multiplicity of pharmacological actions and the subjective nature of the effects they produce make studies difficult at the molecular level. Experiments aimed at defining these receptor interactions must be carefully designed and cautiously interpreted.

## CONCLUSIONS

The preceding sections dealt with various aspects of the nature and conformation of aromatic ring substituents and the side chain in the hallucinogenic phenethylamines. Although these empirical structure–activity relationships can be described, there is at present no clear rationale for many of them. Certainly the mechanisms at the receptor level are unknown. The multiplicity of actions these compounds have on monoaminergic systems have made their study very difficult. Furthermore, structure–activity relationships that define these multiple actions have not been approached.

Some may question whether it is realistic to expect any structural congruence between phenethylamines and tryptamines to emerge. However, this hypothesis has been the guiding principle of much of the recent work with phenethylamines. If a clear structural–functional relationship between the phenethylamines and the tryptamines could be identified, one would have the molecular pharmacology equivalent of a series of simultaneous equations. Reactive and functional sites in the two series could be studied in parallel. Quantum chemical comparisons would be most interesting. It may be justified to speculate that such findings would lead to important insights into fundamental receptor activation mechanisms.

The reality is that we are still some distance from such a unified theory. Nevertheless, significant progress has been made in the past 10 years in defining the importance to activity of various structural and physicochemical parameters within the phenethylamines. It is perhaps unfortunate that research interest in this fascinating class of compounds is limited to so few laboratories.

## ACKNOWLEDGMENTS

The author is most appreciative of research support provided over the last few years in the form of U.S. Public Health Service Grants DA-01916 and DA-02189 from the National Institute on Drug Abuse.

A warm thanks is extended to Dr. Alexander T. Shulgin for reading early drafts of the manuscript and providing many helpful comments, as well as for providing several relevant but previously unpublished values for biological activity.

# N-Hydroxymethyl Derivatives of Nitrogen Heterocycles as Possible Prodrugs I: N-Hydroxymethylation of Uracils

PADAM C. BANSAL *, IAN H. PITMAN ‡x, JOSIAH N. S. TAM *, MATHIAS MERTES *, and JAMES J. KAMINSKI *

Received October 21, 1980, from the *School of Pharmacy, University of Kansas, Lawrence, KS 66045, and the ‡Victorian College of Pharmacy Ltd., 381 Royal Parade, Parkville, Victoria, Australia. Accepted for publication January 7, 1981.

**Abstract** □ Solid samples of 1,3-dihydroxymethyluracil, 3-hydroxymethyl-1-methyluracil, and 1-hydroxymethyl-3-methyluracil were prepared, and their structures were confirmed by spectroscopic analysis. The thermodynamics and kinetics of the formation of N-hydroxymethylated uracils in aqueous formaldehyde solutions also were studied. The equilibrium constants for formation of N-1-hydroxymethyl derivatives were approximately twice those for formation of N-3-hydroxymethyl derivatives, and they were formed more rapidly throughout the pH 3–8 range. Substituents at C-5 of uracil had little effect on the thermodynamics of N-hydroxymethylation. The potential usefulness of N-hydroxymethyl compounds as prodrugs is discussed.

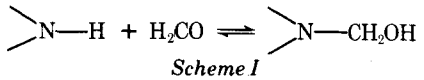
**Keyphrases** □ Uracil—N-hydroxymethyl derivatives synthesized, structures confirmed by NMR and elemental analyses, potential prodrugs □ N-Hydroxymethyl derivatives—of uracil, synthesis, structures confirmed by NMR and elemental analyses, potential prodrugs □ Prodrugs, potential—N-hydroxymethyl derivatives of uracil synthesized, structures confirmed by NMR and elemental analyses

The reversible reactions of formaldehyde with amines (1–7), amides (8, 9), and imides (10–15) in aqueous solution to form the corresponding N-hydroxymethyl derivatives have been studied extensively, and numerous rate and equilibrium constants have been reported. An N-hydroxymethylation reaction is represented in Scheme I. Reactions of this type are important in biological systems (16–19) and, because they can alter hydrogen-bonding possibilities in a molecule, they have been employed (20–22) to modify the secondary structure of nucleic acids in solutions. This paper is concerned with the kinetics and thermodynamics of N-hydroxymethylation of uracil (I) and several substituted uracils.

## BACKGROUND

Uracil is not a drug, but its structure is representative of many molecules that are drugs. It is a heterocyclic molecule that contains both an amide and an imide group. Molecules that contain these groups frequently are very insoluble in water and organic solvents because of large crystal lattice energies due to intermolecular hydrogen bonds. There are two acidic protons in uracil, each of which can form a hydrogen bond with a carbonyl group in another molecule. Evidence that such bonds contribute to the stability of uracil crystals comes from comparison of the melting point and the solubility of uracil with those of N-alkyl uracils (Table I). The melting point of uracil is decreased and the solubility is increased when the N-1 and/or N-3 protons are replaced by a methyl group. IR and X-ray structure studies of uracil support the conclusion that, in the uracil crystals, molecules are linked by intermolecular hydrogen bonds (23–25).

The replacement of the N–H proton by a methyl group is not normally an allowable substitution in drug molecules, because it is a permanent change and can significantly change the pharmacological properties of the drugs. A better approach toward reducing the extent of intermolecular hydrogen bonds in a molecule like uracil would be the synthesis of transient chemical derivatives, *i.e.*, prodrugs. In prodrug molecules, the N–H protons could be replaced by groups such as the hydroxymethyl, which would be removed rapidly in water.



*Scheme I*

When the prodrug reverts to the parent drug, formaldehyde is released. Formaldehyde toxicity does not appear to be of great concern since pivampicillin and methenamine, which are marketed as safe drugs, also release formaldehyde in the body upon administration (26–29). However, formaldehyde toxicity may depend on the frequency of dose and the duration that the drug has to be taken.

This approach should be applicable to other heterocyclic drug molecules that are poorly soluble in water and other solvents by virtue of intermolecular hydrogen bonds in their crystalline phase. The application of some of these concepts to drug molecules recently was reported (30, 31).

## RESULTS AND DISCUSSION

**Structure of Hydroxymethyl Derivatives of Uracil (I), 3-Methyluracil (III), and 1-Methyluracil (V)**—Elemental analysis of the crystalline compound that precipitated from uracil solution in aqueous formaldehyde was consistent with the composition of 1 equivalent of uracil and 2 equivalents of formaldehyde. Evidence that the compound had Structure II rather than Structure VIII came from IR analysis (potassium bromide disks) and NMR spectra. The IR spectrum exhibited a strong peak at 1720 $cm^{-1}$, indicating the molecule contained at least one carbonyl group. The two doublets at 7.70 and 5.72 ppm in the NMR spectrum of the compound in dimethyl sulfoxide-$d_6$ (Table II), which were assigned (32) to the C-6 and C-5 protons, are much closer in chemical shift to those of the same protons of 1,3-dimethyluracil (VII, a model for Structure II, 7.68 and 5.67 ppm in dimethyl sulfoxide-$d_6$) than they are to those of 2,4-dimethoxypyrimidine (IX, a model for Structure VIII, 8.31 and 6.53 ppm).

Assignment of the other signals in the NMR spectrum of 1,3-dihydroxymethyluracil (II) was achieved by comparison with the spectra of 1-hydroxymethyl-3-methyluracil (IV) and 3-hydroxymethyl-1-methyluracil (VI) in dimethyl sulfoxide-$d_6$. The latter compounds were prepared from III and V.

Features of the NMR spectrum of a 50-mg/ml solution of IV in dimethyl sulfoxide-$d_6$ are described in Table II. The broad singlet at 6.62 ppm disappeared when water was added to the solution and can be assigned to the OH proton. The broad singlet at 5.10 ppm enclosed an area that was double that of the OH proton, and it sharpened when either deuterium oxide or trifluoroacetic acid was added (to increase exchange

**Table I—Solubility and Melting Point of Uracil and N-Alkylated Uracils**

[a] Solvent A was dimethyl sulfoxide-$d_6$, and Solvent B was deuterochloroform. [b] Symbols are: d, doublet; bs, broad singlet; t, triplet; and dt, diffuse triplet.

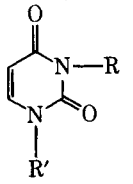
rates) or when the OH proton was irradiated. These results indicate that the signal at 5.10 ppm can be assigned to the N-1 $CH_2O$ protons in IV and that, in this relatively concentrated solution, they are only weakly coupled to the OH proton.

The multiplicity of the signals at 6.62 and 5.10 ppm was different in less concentrated solutions. When the concentration of IV in dimethyl sulfoxide-$d_6$ was 10 mg/ml, the OH proton was a diffuse triplet at 6.66 ppm and the N-1 $CH_2O$ protons were a doublet centered at 5.13 ppm. Similar changes in multiplicity with change in concentration were observed for spectra in deuterochloroform (Table II). These results suggest that the OH proton is more strongly coupled to the N-1 $CH_2O$ protons in dilute rather than in concentrated solutions. The OH proton probably participates in intermolecular hydrogen-bonding reactions with other IV molecules in concentrated solutions.

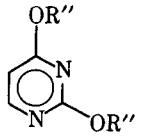
The spectra of VI solutions in dimethyl sulfoxide-$d_6$ are described in Table II. One difference between VI and IV is that its spectra in dimethyl sulfoxide-$d_6$ and in deuterochloroform were insensitive to concentration changes between 50 and 6.25 mg/ml. The OH resonance was a triplet centered at 6.12 ppm and was strongly coupled with the N-3 $CH_2O$ protons that appeared as a sharp doublet centered at 5.26 ppm. The N-3 $CH_2OH$ proton appears to have a much smaller tendency than the N-1 $CH_2OH$ proton to participate in intermolecular hydrogen bond formation.

Comparison of the NMR spectral characteristics of II with those of IV and VI enabled the following peak assignments to be made: C-6 H, 7.70 ppm; N-1 $CH_2OH$, 6.72 ppm; N-3 $CH_2OH$, 6.20 ppm; C-5 H, 5.72 ppm; N-3 $CH_2OH$, 5.25 ppm; and N-1 $CH_2OH$, 5.13 ppm.

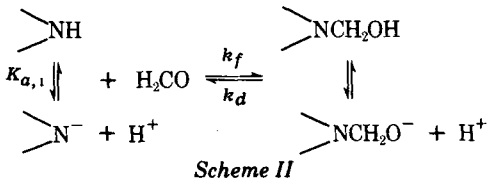
**Thermodynamics and Kinetics of *N*-Hydroxymethylation of III and V in Water**—The addition of 2.5 *M* formaldehyde to solutions of III or V (pH 4–10) produced changes in UV and NMR spectra that were complete within 4 hr at pH 4 and in <30 min at pH >7. The resulting spectra did not change during 7 days at 25°. UV spectral characteristics of reactants and products are in Table III, and NMR data (in deuterium oxide) are in Table IV.



I: R = R′ = H
II: R = R′ = $CH_2OH$
III: R = $CH_3$, R′ = H
IV: R = $CH_3$, R′ = $CH_2OH$
V: R = H, R′ = $CH_3$
VI: R = $CH_2OH$, R′ = $CH_3$
VII: R = R′ = $CH_3$



VIII: R″ = $CH_2OH$
IX: R″ = $CH_3$



*Scheme II*

Confirmation that the products were IV and VI, respectively, came from the fact that the final solutions had identical spectra to solutions of authentic material in the same solvents.

Rate and equilibrium constants were calculated from UV changes. A pseudo-first-order rate constant, $k_{obs}$, was calculated from plots of log $(A - A_\infty)$ *versus* time for reactions in solutions containing excess formaldehyde. Values of $k_{obs}$ were related linearly to the initial formaldehyde concentration, $[H_2CO]_0$, and the line had a positive intercept on the $y$ axis when $[H_2CO]_0 = 0$. Thus, it was concluded that $k_{obs}$ values were related to values of $[H_2CO]_0$:

$$k_{obs} = k_f[H_2CO]_0 + k_d \qquad \text{(Eq. 1)}$$

where $k_f$ and $k_d$ are the second- and first-order rate constants, respectively, for the reaction depicted in Scheme II. Values of $k_f$ and $k_d$ calculated from plots of $k_{obs}$ against $[H_2CO]_0$ are in Table V.

The pH dependence of $k_f$ and $k_d$ is consistent with the conclusion that the rate-determining step in the forward reaction involves the uracil anion and formaldehyde and that for the reverse reaction involves the anion of the *N*-hydroxymethyl derivative. The mechanism proposed for the reverse reaction is identical to the one that was suggested (31, 32) to account for the decomposition of *N*-hydroxymethyl derivatives of other amides and imides.

According to the model, the rate law for the rate-determining step in the reactions would be:

$$k_{obs} = \frac{k_f' K_a^u}{K_a^u + [H^+]}[H_2CO]_0 + \frac{k_d' K_a^{HU}}{K_a^{HU} + [H^+]} \qquad \text{(Eq. 2)}$$

where $K_a^u$ and $K_a^{HU}$ are the acid dissociation constants of the uracil and the *N*-hydroxymethyl derivative (*i.e.*, to yield $>NCH_2O^-$), respectively, and $k_f'$ and $k_d'$ are the rate constants for reactions of the anionic species. The values of $K_a^u$ for III and V are $1 \times 10^{-10}$ and $2 \times 10^{-10}$, respectively (33). The $K_a^{HU}$ values are not known, but they are expected to be larger than the $K_a^u$ values because the negative charge would be localized on the oxygen atoms in the *N*-hydroxymethyl anions whereas it would be delocalized in the uracil anions. Hence, under the experimental conditions, both $K_a^{HU}$ and $K_a^u$ are less than $[H^+]$ and can be neglected from the de-

**Table IV—NMR Data for Uracil and Substituted Uracils in Deuterium Oxide**

| Compound | Solvent[a] | Chemical Shifts, ppm[b] C-6 H | C-5 H | N-1 $CH_2OD$ | N-3 $CH_2OD$ |
|---|---|---|---|---|---|
| I | A | 7.55 d | 5.83 d | — | — |
| | B | 7.68 d | 5.88 d | 5.23 s | 5.33 s |
| III | A | 7.50 d | 5.86 d | — | — |
| | B | 7.68 d | 5.89 d | 5.24 s | — |
| V | A | 7.63 d | 5.80 d | — | — |
| | B | 7.57 d | 5.82 d | — | 5.39 d |

[a] Solvent A was deuterium oxide, and Solvent B was 2.5 *M* $H_2CO$ in deuterium oxide. [b] Symbols are: d, doublet; and s, singlet.

nominators in Eq. 2, which becomes:

$$k_{obs} = \frac{k_f' K_a^u}{[H^+]}[H_2CO]_0 + \frac{k_d' K_a^{HU}}{[H^+]} \quad \text{(Eq. 3)}$$

By definition:

$$k_f' = \frac{k_f[H^+]}{K_a^u} \quad \text{(Eq. 4)}$$

$$k_d' = \frac{k_d[H^+]}{K_a^{HU}} \quad \text{(Eq. 5)}$$

Confirmation that the model is consistent with the data comes from the fact that values of $k_f[H^+]/K_a^u$ (*i.e.*, $k_f'$) and $k_d[H^+]$ (*i.e.*, $k_d' K_a^{HU}$) were essentially constant between pH 3 and 6.

The anion of III is a stronger base than that of V, and it reacts ~40 times more rapidly with formaldehyde. Both properties are likely to arise because the anion of V is stabilized by delocalization of its electrons among the adjacent oxygen atoms.

Equilibrium constants for the *N*-hydroxymethylation reactions of III and V were calculated both from values of the quotient $k_f/k_r$ and from the slopes of plots of $(A_0 - A)/[H_2CO]_0$ *versus* $A$, where $A_0$ is the initial absorbance of uracil solution and formaldehyde and $A$ is the absorbance of a similar solution in which hydroxymethylation has reached equilibrium. Values of the equilibrium constants for III and V are in Table VI.

The results indicate that the magnitude of the equilibrium constant for formation of the >N-1 $CH_2OH$ derivative is double that for formation of the >N-3 $CH_2OH$ derivative. Thus, IV is formed more rapidly and to a greater extent than VI.

No *N*-hydroxymethylation of III and V was observed to occur at pH values two or more units above their pKa values.

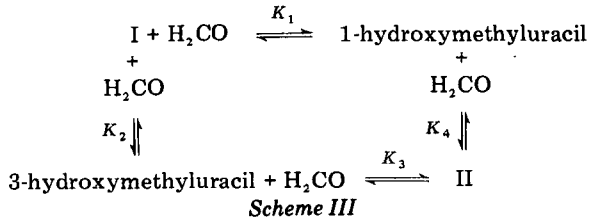
**Thermodynamics of Uracil *N*-Hydroxymethylation**—Addition of 2.5 *M* $H_2CO$ to uracil solutions in water (or deuterium oxide) caused the UV and NMR spectra to change to those produced by equimolar solutions of II. Relevant data are shown in Tables III and IV.

Knowledge of the reactions of III and V in aqueous formaldehyde, together with the knowledge that II also is formed, leads to the conclusion that the relevant reactions of uracil are those shown in Scheme III. The magnitudes of the equilibrium constants in Scheme III were evaluated both from changes in UV absorbance and from phase solubility diagrams. All experiments were carried out at pH 3–7, a range in which the reactants and products were not appreciably ionized.

The absorbance of an equilibrated solution of uracil in aqueous formaldehyde, $A$, can be related to the initial absorbance of the solution, $A_0$:

$$\frac{A}{A_0} = \frac{1 + K_1[H_2CO]_0\epsilon_1 + K_2[H_2CO]_0\epsilon_2 + K_1K_4[H_2CO]^2\epsilon_3}{1 + K_2[H_2CO]_0 + K_2[H_2CO]_0 + K_1K_4[H_2CO]^2} \quad \text{(Eq. 6)}$$

where $\epsilon_1$ is the ratio of molar extinction coefficients for 1-hydroxymethyluracil and uracil, $\epsilon_2$ is the ratio for 3-hydroxymethyluracil and uracil, and $\epsilon_3$ is the ratio for II and uracil. An iterative procedure that utilized Eq. 6 and experimental data yielded values of $K_1 + K_2$ and $K_1K_4$.



*Scheme III*

By definition:

$$K_1/K_2 = K_3/K_4 \quad \text{(Eq. 7a)}$$

The value of $K_1/K_2$ was evaluated using Eq. 7a on the basis that the value of $K_3/K_4$ would be the same as that for the ratio of equilibrium constants for *N*-hydroxymethylation of III and for V. In other words:

$$\frac{K_1}{K_2} = 2.26 \quad \text{(Eq. 7b)}$$

When this assumption had been made, values of $K_1$, $K_2$, $K_3$, and $K_4$ were computed from the values of $K_1 + K_2$, $K_1K_4$, and $K_3/K_4$ (Table VI).

The second method of calculating equilibrium constants was based on phase solubility analysis. Experiments involved measuring the total amount of uracil that dissolved $[I]_T$ in solutions containing different amounts of formaldehyde. The solubility of uracil in solutions that did not contain formaldehyde was $[I]_0$. Equilibrium constants were calculated by:

$$\frac{[I]_T - [I]_0}{[I]_0([I]_T - [I]_0 - [H_2CO]_0/2)} = \frac{4K_1K_4([I]_T - [I]_0 - [H_2CO]_0/2)}{\{(K_1 + K_2)[I]_0 - 1\}^2} + \frac{2(K_1 + K_2)}{(K_1 + K_2)[I]_0 - 1} \quad \text{(Eq. 8)}$$

Figure 1 shows a plot of $[I]_T$ *versus* $[H_2CO]_0$. The plot is an Ap type (34) of phase solubility diagram, which indicates a 1:1 interaction of ligand (formaldehyde) with the substrate (I). Figure 2 shows a linear plot of $([I]_T - [I]_0)/\{[I]_0([I]_T - [I]_0 - [H_2CO]_0/2)\}$ *versus* $([I]_T - [I]_0 - [H_2CO]_0/2)$. Values of $K_1K_4$ and $(K_1 + K_2)$ were calculated from the slope of this plot and the intercept at $[H_2CO]_0 = 0$, respectively. The magnitudes of the individual equilibrium constants were calculated by utilizing the relationship $K_3/K_4 = K_1/K_2$ and making the approximation that $K_3/K_4 = 2.26$ (Table VI).

The similarity between $K$ values calculated from both UV spectrophotometric methods and phase solubility studies adds support to the validity of the model.

Lewin (11) studied the interaction of uracil with aqueous formaldehyde by measuring changes that occur in pH when formaldehyde is added to partially neutralized uracil solutions. The pH changes occur because each *N*-hydroxymethylation reaction removes one acidic hydrogen atom from the uracil molecule. Lewin (11) interpreted his results as indicating that only IV was formed to any appreciable extent. The appropriate equilibrium constant was evaluated using:

$$\text{antilog } \Delta pH = 1 + K_2[H_2CO]_0 \quad \text{(Eq. 9)}$$

The model used in the present study requires that:

$$\text{antilog } \Delta pH = \frac{1 + (K_1 + K_2)[H_2CO]_0 + K_1K_4[H_2CO]_0^2}{1 + 0.32K_2[H_2CO]_0 + 0.63K_1[H_2CO]_0} \quad \text{(Eq. 10)}$$

where 0.63 is the ratio of acid dissociation constants for 3-hydroxymethyluracil and uracil and 0.32 is the ratio for 1-hydroxymethyluracil and uracil. These ratios were evaluated by assuming that the pKa values

**Table V—Rate Constants for *N*-Hydroxymethylation of III and V at 25°**

| Compound | pH | $10^4 k_{obs}$[a], $min^{-1}$ | $10^2 k_f$, $M^{-1}\,min^{-1}$ | $10^{-5} k_f'$, $M^{-1}\,min^{-1}$ | $10^2 k_d$, $min^{-1}$ | $10^6 k_d' K_a^{HU}$, $min^{-1}\,M$ |

[a] Values of $k_{obs}$ were calculated at $[H_2CO]_0 = 1$ *M*.

Table VI—Equilibrium Constants for *N*-Hydroxymethylation of Uracil and Uracil Derivatives at 25° and $\mu$ = 0.1 *M*

| Compound | pH Range | Method | $K, M^{-1}$ | $K_1, M^{-1}$ | $K_2, M^{-1}$ | $K_3, M^{-1}$ | $K_4, M^{-1}$ |
|---|---|---|---|---|---|---|---|
| V | 4–7 | UV | 1.5 | | | | |
| | 4–6 | Kinetic | 1.3 | | | | |
| III | 4–7 | UV | 3.4 | | | | |
| | 4–6 | Kinetic | 2.2 | | | | |
| I | 5–7 | Phase solubility | | 5.2 | 2.3 | 2.2 | 1.2 |
| | 5–7 | UV | | 5.3 | 2.3 | 4.0 | 1.8 |
| 5-Methyluracil | 4–6 | UV | | 3.1 | 1.4 | 5.8 | 2.5 |
| 5-Fluorouracil | 4 | UV | | 4.2 | 1.9 | 4.4 | 1.9 |
| 5-Chlorouracil | 4 | UV | | 4.1 | 1.8 | 6.4 | 2.8 |
| 5-Bromouracil | 4 | UV | | 4.8 | 2.1 | 5.5 | 2.4 |
| 5-Iodouracil | 4 | UV | | 4.2 | 1.9 | 6.7 | 2.9 |

of the *N*-hydroxymethyluracil derivatives were equal to those of the respective *N*-methyluracils.

If $[H_2CO]_0$ is in excess and the values $K_1 = K_2 = K_3 = K_4 = L$, Eq. 10 reduces to:

$$\text{antilog } \Delta pH = \frac{(1 + L[H_2CO]_0)^2}{1 + 0.95L[H_2CO]_0} \simeq 1 + L[H_2CO]_0 \quad \text{(Eq. 11)}$$

Hence, Lewin's method was not sensitive enough to distinguish between the various *N*-hydroxymethyl derivatives of uracil.

Inspection of the *K* values in Table VI reveals that *N*-hydroxymethylation of N-1 of uracil is the most favored reaction whether or not an *N*-hydroxymethyl group is present on N-3.

The strength of the *N*-hydroxymethylation reactions is greater than would be immediately concluded from the magnitude of the constants in Table VI. Formaldehyde exists in water as an equilibrium mixture of anhydrous and hydrated formaldehyde. The equilibrium constant for the hydration reaction (35) is 41 $M^{-1}$ at 25°. Hence, if the concentration of water is taken to be 55.5 *M*, the equilibrium constants for reaction of the uracils with anhydrous formaldehyde are the values in Table VI multiplied by the factor of 2277, which takes into account the relative concentration of anhydrous formaldehyde. Consequently, *N*-hydroxymethylation is a strong reaction as are the addition reactions of other amines to formaldehyde (36).

**Thermodynamics of *N*-Hydroxymethylation of 5-Substituted Uracils**—UV spectrophotometric measurements, identical to those described in the previous section, were used to calculate the *K* values for *N*-hydroxymethylation of the 5-substituted uracils (Table VI).

Although there is about a 200-fold difference in the acidity of the N–H functions of these compounds (pKa 7.7–9.9), the affinity of formaldehyde for 5-substituted uracils is essentially independent of their acidities, and substitution at the 5-position does not influence the magnitude of equilibrium constants in a systematic way. These results are consistent with reports that the equilibrium constants for the addition to formaldehyde of simple primary amines (1) are not much larger than those for addition of urea and amides (8), although the difference in the pKa of amine and amide groups is large.

**Melting Point, Solubility, and Dissolution Rate of II**—Comparison of uracil (I) and II indicated that II had a lower melting point (101° compared to 340°), higher water solubility (500 mg/ml compared to 2.8 mg/ml)[1], and higher water dissolution rate ($82 \times 10^{-5}$ *M*/min compared to 1.6 *M*/min)[1]. This behavior was predicted on the basis that *N*-hydroxymethylation changes intermolecular hydrogen-bonding possibilities in the solid phase. It supports the contention that such derivatives are potentially useful prodrugs.

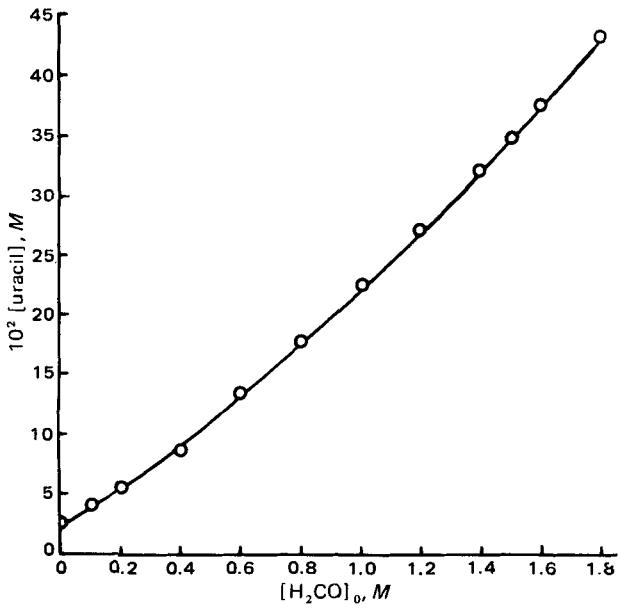

**Figure 1**—*Phase solubility diagram of uracil in aqueous formaldehyde at 25°, 0.1 M I.*

## EXPERIMENTAL

Uracil[2], 5-fluorouracil[2], 5-bromouracil[2], 5-iodouracil[2], 5-methyluracil[2], 1-methyluracil[3], and 3-methyluracil[3] were used without further purification. 5-Chlorouracil[4] was recrystallized from aqueous ethanol. Formaldehyde (37% aqueous solution) was used without further purification, and its concentration was calculated using the USP method (38). Formaldehyde used in the NMR studies was obtained by dissolving paraformaldehyde in deuterium oxide. Buffer solutions at $\mu$ = 0.1 *M* were prepared as described previously (39).

Tetramethylsilane or sodium 4,4-dimethyl-4-silapentanesulfonate was used as the reference in NMR spectral measurements.

**Preparation of *N*-Hydroxymethyl Derivatives**—*1,3-Dihydroxymethyluracil (II)*—Uracil (I) (4.75 g) was dissolved in 10 ml of 37% (w/w) formaldehyde (pH adjusted to 7 with sodium hydroxide) at 25°. Refrigeration of this solution resulted in a white crystalline precipitate which, following recrystallization from acetonitrile and drying over calcium chloride, melted at 101° (melting point of uracil was 338°). The mass spectrum (*m/z* 172) and elemental analysis of the solid were consistent with the conclusion that the compound was II.

*Anal.*—Calc. for $C_6H_8N_2O_4$: C, 41.84; H, 4.65; N, 16.28. Found: C, 41.62; H, 4.63; N, 16.38.

*3-Hydroxymethyl-1-methyluracil (VI)*—1-Methyluracil (V) (600 mg) was dissolved in 1 ml of 37% formaldehyde. Refrigeration of this solution resulted in a white crystalline precipitate which, on drying over calcium

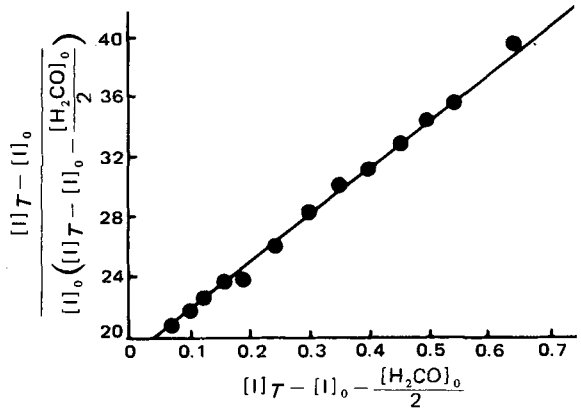

**Figure 2**—*Plot of* $([I]_T - [I]_0)/[I]_0([I]_T - [I]_0 - [H_2CO]_0/2)$ *versus* $[I]_T - [I]_0 - ([H_2CO]_0/2)$ *for the reaction of uracil and formaldehyde at 25°, 0.1 M I.*

[1] The methods of calculating these values were identical to those described in Ref. 37.

[3] Cyclo Chemical Co.

[4] K & K Laboratories.

chloride, melted at 110° (melting point of V was 232°). The mass spectrum (*m/z* 156) and elemental analysis of the solid were consistent with the conclusion that the compound was VI.

*Anal.*—Calc. for $C_6H_8N_2O_3$: C, 46.15; H, 5.13; N, 17.95. Found: C, 46.28; H, 5.10; N, 18.15.

*1-Hydroxymethyl-3-methyluracil (IV)*—3-Methyluracil (III) (1 g) was dissolved in 1 ml of 37% formaldehyde. The crystals of IV were obtained as described for II and VI and, on drying over calcium chloride, melted at 92° (melting point of III was 178°). The mass spectrum (*m/z* 156) and elemental analysis of the solid were consistent with the conclusion that the compound was VI.

*Anal.*—Calc. for $C_6H_8N_2O_3$: C, 46.15; H, 5.13; N, 17.95. Found: C, 46.04; H, 5.22; N, 17.77.

**Kinetic Measurements**—The rates of formation of hydroxymethyl derivatives of III and V were monitored spectrophotometrically by following the change in UV absorbance that occurred when 0.1 ml of a 0.003 *M* solution of III or V was added to a 1-cm stoppered UV cell containing 3 ml of formaldehyde solution in buffer equilibrated at 25° and $\mu = 0.1$ *M*. The rates of the forward and reverse reactions and the equilibrium constants were determined as already described. All kinetic runs were conducted under pseudo-first-order conditions in which formaldehyde was used in large excess.

**Determination of Equilibrium Constants by Spectrophotometry**—Solutions of uracil and 5-substituted uracils (0.0001 *M*) were prepared in buffered formaldehyde solutions. The solutions were equilibrated in a thermostated bath at 25°. The UV absorbance of equilibrated solutions at a fixed wavelength was recorded at several pH values (pH 4–7), and equilibrium constants were calculated as described.

**Phase Solubility Studies**—Uracil (500 mg) was weighed in a series of 25-ml polyseal-lined screw-capped vials to which was added exactly 5 ml of formaldehyde of increasing concentrations (0–2 *M*) in buffer ($\mu = 0.1$ *M*). The vials were sealed, placed in a constant-temperature water bath at 25.00 ± 0.02°, and agitated with a rotating-action shaker until equilibrium was achieved (usually within 5 days). The total amount of uracil in solution in each vial was determined spectrophotometrically at $\lambda_{max}$ 257 nm by diluting aliquots of filtered equilibrated solutions in the buffer.

# *N*-Hydroxymethyl Derivatives of Nitrogen Heterocycles as Possible Prodrugs II: Possible Prodrugs of Allopurinol, Glutethimide, and Phenobarbital

**PADAM C. BANSAL *, IAN H. PITMAN ‡x, and TAKERU HIGUCHI ***

Received October 21, 1980, from the **School of Pharmacy, University of Kansas, Lawrence, KS 66045*, and the ‡*Victorian College of Pharmacy Ltd., 381 Royal Parade, Parkville, Victoria, Australia.* Accepted for publication January 7, 1981.

**Abstract** □ Solid samples of 1-hydroxymethyl- and 1,5-dihydroxymethylallopurinol, 1-hydroxymethylglutethimide, and 1-hydroxymethylphenobarbital were prepared, and equilibrium constants for their formation from formaldehyde and allopurinol, glutethimide, or phenobarbital were calculated. The *N*-hydroxymethyl derivatives had higher water solubilities and faster dissolution rates than the parent drugs, and they appear to be potentially useful as prodrugs.

**Keyphrases** □ Allopurinol—*N*-hydroxymethyl derivative synthesized, structure confirmed by NMR and elemental analyses, potential prodrug □ Glutethimide—*N*-hydroxymethyl derivative synthesized, structure confirmed by NMR and elemental analyses, potential prodrug □ Phenobarbital—*N*-hydroxymethyl derivative synthesized, structure confirmed by NMR and elemental analyses, potential prodrug □ Prodrugs, potential—*N*-hydroxymethyl derivatives of allopurinol, glutethimide, and phenobarbital synthesized, structures confirmed by NMR and elemental analyses

The potential usefulness of *N*-hydroxymethyl derivatives of heterocyclic amides and imides as prodrugs was discussed in a previous paper (1). This work was consistent with studies on the *N*-hydroxymethyl derivatives of hydantoins (2) and other amides and imides (3).

The present paper is concerned with the synthesis and properties of *N*-hydroxymethyl derivatives of allopurinol (I), glutethimide (II), and phenobarbital (III). These drugs have low water solubility and dissolve slowly. Hence, it is likely that their bioavailability and delivery (4) would be improved if appropriate prodrug forms could be developed.

## RESULTS AND DISCUSSION

The interaction of formaldehyde with allopurinol (I), glutethimide (II), and phenobarbital (III) at 25° was studied by analyzing phase solubility diagrams (Figs. 1–3). These diagrams were constructed by plotting the total substrate concentration in solution $[S]_T$ *versus* the added formaldehyde concentration $[H_2CO]_T$. At least one solid phase was present in all solutions.

***N*-Hydroxymethylation of I**—Analysis, using arguments set out by Higuchi and Connors (5) of the double Bs-type phase solubility diagram for I (Fig. 1), led to the conclusion that the reactions shown in Scheme I took place. The A–E portion of the diagram is consistent with the formation of 1-hydroxymethylallopurinol (1-hydroxymethyl-4,5-dihydropyrazolo[3,4-*d*]pyrimidin-4-one, I*a*), and the E–I portion is consistent with the formation of 1,5-dihydroxymethylallopurinol {1,5-bis(hydroxymethyl)-4,5-dihydropyrazolo[3,4-*d*]pyrimidin-4-one, I*b*}. The B–C portion is believed to be caused by saturation of the solution with respect to I*a*.

Confirmation of these postulates comes from elemental analysis and NMR spectra (in dimethyl sulfoxide-$d_6$) of the solid phase at point E and in the portion H–I (Table I), from calculation of the stoichiometry of the reactions using portions B–D and F–G, and from equilibrium constants calculated from the slopes of the lines AB ($K_{Ia}$) and EF ($K_{Ib}$).

The NMR peak at 5.63 ppm in the spectrum of the solid isolated at point E and those at 5.40 and 5.63 ppm in the spectrum of the solid isolated in the portion H–I had similar chemical shifts to the N–$CH_2$–O protons in the *N*-hydroxymethyluracils (1). The stoichiometry of the solid isolated at point E calculated from the phase solubility diagram was 1 part of I to 1.03 parts of formaldehyde, and that of the compound isolated in the region H–I was 1 part of I to 2.06 parts of formaldehyde. The elemental analyses of the compounds were as expected for I*a* and I*b*.

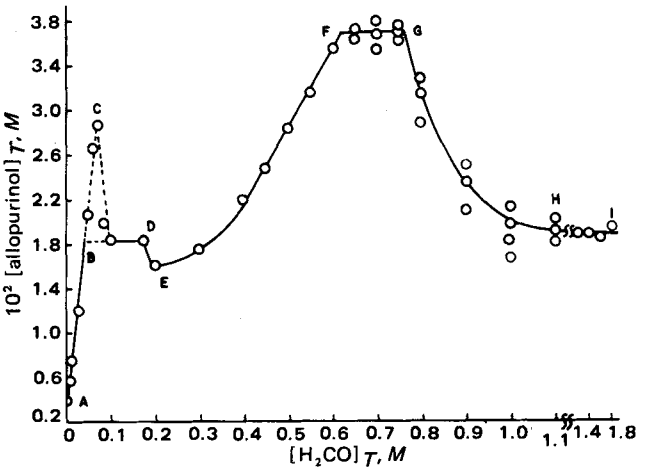

**Figure 1**—*Plot of I solubility as a function of formaldehyde concentration in aqueous buffer at pH 4.9, μ = 0.1* M, *and 25°.*

The equilibrium constants calculated from the phase solubility diagram were 120 $M^{-1}$ for formation of I*a* ($K_{Ia}$) and 4 $M^{-1}$ for the formation of I*b* ($K_{Ib}$). This value of $K_{Ia}$ is similar to values reported (6) for the addition of secondary amines to formaldehyde (40–800 $M^{-1}$). The value of $K_{Ib}$ is similar to that calculated for the addition of amino and imino groups in uracils to formaldehyde (1).

***N*-Hydroxymethylation of II**—The Bs-type phase solubility diagram in Fig. 2 was analyzed similarly to the one for *N*-hydroxymethylation of I. Elemental analysis and NMR spectral data (Table I) of the solid phase obtained at point D (from deuterium oxide solutions) indicated that it was 1-hydroxymethylglutethimide (1-hydroxymethyl-3-phenyl-2,6-piperidinedione, II*a*). Confirmation of the reactions shown in Scheme II was obtained from the facts that the phase solubility diagram indicated that the stoichiometry of the complex was 1 equivalent of II to 1.02 equivalents of formaldehyde and that the equilibrium constant for its formation, $K_{IIa}$, was 3.4 $M^{-1}$.

**Table II—Amounts of Substrate and Ligand Used in Phase Solubility Studies**

| Substrate | Ligand | Total Volume, ml | Equilibrium Time, days |
|---|---|---|---|
| I, 0.1 g | Formaldehyde, 0–2 *M* | 5 | 15 |
| II, 0.4 g | Formaldehyde, 0–2 *M* | 5 | 10 |
| III, 0.4 g | Formaldehyde, 0–2 *M* | 20 | 10 |

**Table III—Melting Points, Solubilities, and Initial Dissolution Rates[a] of Drugs and Their Prodrugs**

| Compound | Melting Point | Solubility[b], *M* | Initial Dissolution Rate, *M*/min × $10^5$ |
|---|---|---|---|
| I | 360° | 0.004 | 0.2 |
| Ib | 350° | 0.019 | 1.2 |
| II | 85° | 0.005 | 1.3 |
| IIa | 82° | 0.022 | 2.2 |
| III | 178° | 0.004 | 0.9 |
| IIIa | 99° | 0.025 | 2.8 |

[a] Dissolution rates were obtained in pH 7 buffer at 25° and $\mu$ = 0.1 *M*. [b] Solubilities were obtained from phase solubility diagrams (Figs. 1–3).

Formaldehyde concentrations of >2 *M* caused the total amount of II in solution to increase, resulting in the separation of an oil (Table II). The reactions occurring in this region of the phase solubility diagram were not investigated further, but they probably are caused by addition of the >N–$CH_2OH$ group to additional formaldehyde molecules to form polymers such as >N–$[CH_2O]_n$–. There is evidence (7) that formaldehyde polymerizes in concentrated aqueous solutions.

***N*-Hydroxymethylation of III**—The complex Bs-type phase solubility diagram for this system is shown in Fig. 3.

Based on the *N*-hydroxymethylation of uracil (1) and II, the reactions shown in Scheme III were expected. However, only one compound was

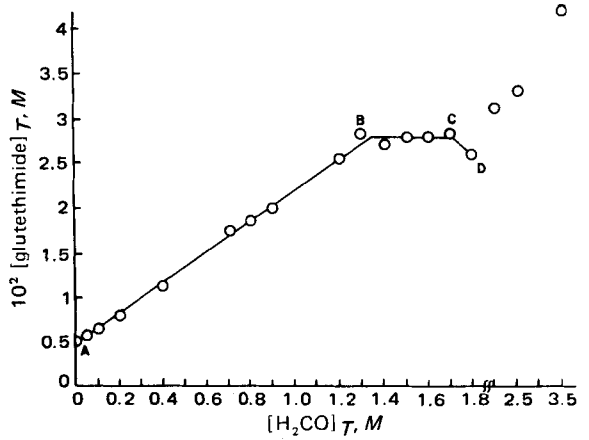

**Figure 2**—*Plot of II solubility as a function of formaldehyde concentration in aqueous buffer at pH 5.1, $\mu$ = 0.1 M, and 25°.*

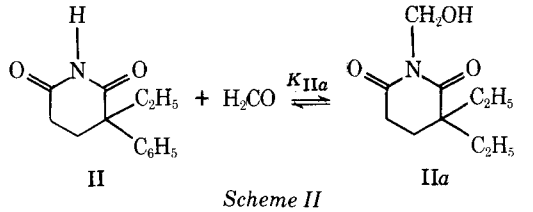


*Scheme II*

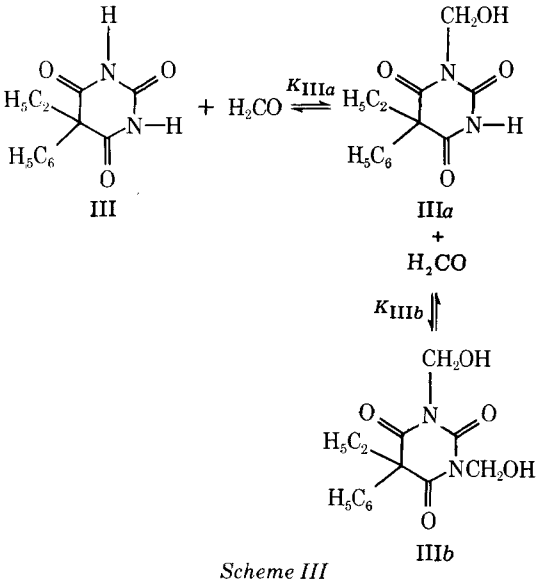
isolated from the system. The solid phase at point D had an elemental analysis and NMR spectrum consistent with it being 1-hydroxymethylphenobarbital (IIIa). Analysis of the portion B–C of the phase solubility diagram indicated that the compound had the required stoichiometric composition. Isolation of 1,3-dihydroxymethylphenobarbital was complicated by the fact that a viscous oil phase again separated out at formaldehyde concentrations of >1.6 *M*.

The shape and slope of the portion A–B of the phase solubility diagram would be a function of the equilibrium constants $K_{IIIa}$ and $K_{IIIb}$. At low formaldehyde concentrations, the curve would have a limiting slope that would be related directly (5) to $K_{IIIa}$. The $K_{IIIa}$ value was estimated to be 9 $M^{-1}$. Hence, equilibrium data are consistent with the proposed reaction scheme.

**Aqueous Solubility and Dissolution Rates**—Aqueous solubilities and relative dissolution rates in water of I, Ib, II, IIa, III, and IIIa are listed in Table III. The solubilities were obtained from the phase solubility diagrams (5), and dissolution rates were calculated as described under *Experimental*.

As expected (1), the change in intermolecular hydrogen-bonding possibilities in the solid state produced by *N*-hydroxymethylation of amines or imides increased the water solubilities of I–III. The increase in water solubility was reflected by an increase in the dissolution rate as required by the Noyes–Whitney model for dissolution (8, 9).

The *N*-hydroxymethyl derivatives were converted rapidly to the parent



*Scheme III*

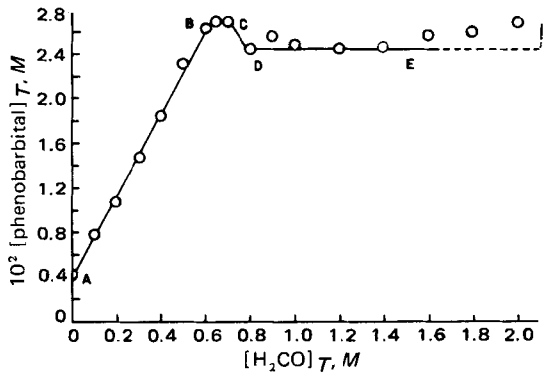


**Figure 3**—*Plot of III solubility as a function of formaldehyde concentration in aqueous buffer at pH 4.9, $\mu$ = 0.1 M, and 25°.*

drug. This result was indicated by the fact that the solid phase in a suspension of the *N*-hydroxymethyl derivatives (500 mg in 25 ml of pH 7 buffer) that had been shaken for 10 min had the same melting point and NMR spectrum in dimethyl sulfoxide as the parent drug. UV spectra of dilute solutions of the *N*-hydroxymethyl derivatives in pH 7 buffer were superimposable on those of the parent drug after the solutions had been shaken for 10 min.

All of these observations support the contention that *N*-hydroxymethyl derivatives of poorly soluble amides, imides, and amines are potentially useful prodrugs.

## EXPERIMENTAL

**Chemicals and Equipment**—Allopurinol[1] (I), phenobarbital[1] (III), and glutethimide[2] (II) were used without further purification, as was formaldehyde[3] (37% aqueous solution).

Solutions containing formaldehyde were prepared fresh by appropriate dilution of the 37% formaldehyde solution. The succinic acid–sodium borate buffers (pH 3.69–6.9, $\mu$ = 0.1 *M*) and monobasic potassium phosphate–sodium borate buffers (pH 6.3–9.25, $\mu$ = 0.1 *M*) were prepared by the method described by Pitman (10). Sodium chloride was used to adjust the ionic strength ($\mu$ = 0.1 *M*).

3-(Trimethylsilyl)propanesulfonic acid was used as an internal reference in the NMR measurements.

**Phase Solubility**—A fixed quantity of substrate, in excess of its aqueous solubility, was weighed in a series of 25-ml polyseal-lined screw-capped vials to which were added fixed volumes of formaldehyde solutions of increasing concentration in the buffer (Table II). Vials were sealed, placed in a constant-temperature water bath at 25.0 ± 0.2°, and agitated with a rotating-action shaker until equilibrium was achieved. Aliquots of the supernatant liquid were removed using a pipet (whose tip had been wrapped with glass wool) or solutions were filtered using a sintered-glass funnel of medium porosity and analyzed spectrophotometrically.

**Isolation of *N*-Hydroxymethyl Derivatives**—*1,5-Dihydroxymethylallopurinol (Ib)*—One gram of allopurinol was dissolved in 50 ml of 2 *M* formaldehyde at pH 7. Agitation of this solution for 24 hr resulted in a white crystalline precipitate. The elemental analysis (Table I) and NMR spectrum of the solid (dried over calcium chloride) were consistent with the conclusion that the compound was *Ib*.

*1-Hydroxymethylallopurinol (Ia)*—Compound I*a* was isolated in a similar manner to I*b*, except 0.2 *M* formaldehyde was used in this case. The elemental analysis (Table I) and NMR spectrum of the dry solid were consistent with it being I*a*.

*1-Hydroxymethylglutethimide (IIa)*—Compound II*a* was prepared by agitating 1 g of glutethimide in 100 ml of 1.5 *M* formaldehyde in a pH 7 buffer for 24 hr. The NMR spectrum and elemental analysis of the resultant solid (dried over calcium chloride) were consistent with it being II*a* (Table I). However, at high concentrations of formaldehyde (10 *M*), a viscous oil was isolated. This oil was believed to be II*a* and the corresponding diformyl compound, which would be formed by a dimer of formaldehyde.

*1-Hydroxymethylphenobarbital (IIIa)*—Compound III*a* was prepared by agitating 1 g of phenobarbital in 20 ml of 1 *M* formaldehyde in a pH 5 buffer for 24 hr. The resultant white crystalline precipitate melted at 99° when drying over calcium chloride. The elemental analysis (Table I) and NMR spectrum of the solid were consistent with it being III*a* (Table I). However, at high concentrations of formaldehyde (10 *M*), a viscous oil was isolated.

**Dissolution Rate**—All dissolution studies were performed according to the USP dissolution test (11).

The solid whose dissolution rate was to be measured was reduced to a uniform particle size by sifting it through a 40-mesh sieve and collecting it in a 60-mesh sieve. Approximately 250 mg of this material then was compressed into a tablet in an evacuable potassium bromide die at 10,000 psi for 30 sec using a laboratory press. The dissolution medium (500 ml, pH 7 buffer solution) was placed in a 1-liter beaker immersed in a constant-temperature bath at 25°. One tablet was placed in a basket, and the basket was rotated at 100 rpm. The samples (5 ml) were withdrawn at appropriate times and analyzed spectrophotometrically.

# Determination of Oxfendazole in Cow Milk by Reversed-Phase High-Performance Liquid Chromatography

**I. W. TSINA** ˣ **and S. B. MATIN**

Received August 18, 1980, from the *Department of Analytical and Metabolic Chemistry, Syntex Research, Palo Alto, CA 94304.*
Accepted for publication January 6, 1981.

**Abstract** □ A specific and sensitive high-performance liquid chromatographic method for the analysis of oxfendazole in cow milk is described. Oxfendazole was extracted from milk using a mixture of acetone and chloroform under alkaline conditions. The solvents were evaporated, and the oily residue was purified by hexane–acetonitrile partition and acid–base extraction. The residue obtained after cleanup was redissolved in methanol for chromatographic analysis. Chromatography was performed on a reversed-phase column with acetonitrile–water as the mobile phase. As low as 0.005 μg of oxfendazole/g can be measured by this method using 50 g of milk. The method was applied to measure oxfendazole in the milk of a cow given an oral 5-mg/kg dose.

**Keyphrases** □ Oxfendazole—high-performance liquid chromatographic analysis of cow milk □ High-performance liquid chromatography—analysis of oxfendazole in cow milk □ Anthelmintics—oxfendazole, high-performance liquid chromatographic analysis in cow milk

Oxfendazole, [5-(phenylsulfinyl)-1*H*-benzimidazol-2-yl]carbamate (I), is a new orally effective anthelmintic agent for the control of GI and lung parasites in cattle and sheep (1). The use of oxfendazole as an anthelmintic in dairy cattle may result in its presence in milk at low levels. To protect the general public from exposure to drug residue in milk, a government guideline for the safe use of animal drugs requires a sensitive analytical method for drug level monitoring in marketed milk (2).

## BACKGROUND

Oxfendazole belongs to the benzimidazole class of anthelmintics. The analysis of benzimidazole compounds in animal tissues and biological fluids by colorimetric (3), fluorometric (3–5), high-performance liquid chromatographic (HPLC) (6, 7), and radioimmunoassay (8) methods has been described. The colorimetric and fluorometric methods lack the specificity and sensitivity needed for assay from milk. HPLC and radioimmunoassay are intended for use in plasma, utilizing minimum sample cleanup. Because of the high fat content of raw milk, these methods are not applicable to the analysis of trace drug levels in milk.

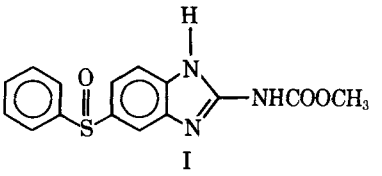
An HPLC method for the analysis of benzimidazole compound in animal tissues and milk based on ion-exchange chromatography also was reported (9). The sensitivity achieved was 0.05 μg/g in cow milk and 0.1 μg/g in cattle tissues. To ascertain the safe use of oxfendazole in food-producing animals, an analytical method capable of measuring the drug level at 0.005 μg/g in milk is required.

This paper describes an analytical method using HPLC and UV detection. The nanogram per gram level of measurement was achieved by a highly efficient extraction and cleanup procedure. The method was used to establish the depletion profile of oxfendazole in milk of a dairy cow following a single oral dose of 5 mg of oxfendazole/kg.

## EXPERIMENTAL

**Reagents and Chemicals**—All solvents were distilled-in-glass grade[1]. Other reagents and chemicals were reagent grade. Phosphate saline buffer (pH 8) was 0.05 *M*, containing 9 g of sodium chloride in 1 liter of buffer. Oxfendazole and the internal standard, [5-(4-methylsulfinylphenoxy)-1*H*-benzimidazol-2-yl]carbamate (II), were obtained in-house[2].

**Apparatus**—Analyses were performed on a high-performance liquid chromatograph[3] equipped with a UV detector set at 254 nm and a 10-mv recorder. A 4-mm × 30-cm reversed-phase column[4] coupled with a precolumn[5] was used for chromatographic separation.



I

**Chromatographic Conditions**—The mobile phase was 24.5% acetonitrile in water at a flow rate of 2 ml/min. The columns were operated at ambient temperature, and column pressure was maintained between 1000 and 2000 psi.

**Extraction**—Raw milk (50 g) was weighed into a 250-ml polypropylene bottle, and a solution of internal standard (1 ml of a 1-μg/ml solution in 0.1 *N* HCl) was added. The bottle contents were swirled, and 150 ml of acetone was added. The bottle was capped and mechanically shaken for 10 min.

After centrifugation, the acetone extract was poured into a 500-ml separator. Then 10 ml of pH 8 phosphate buffer and 300 ml of chloroform were added to the acetone extract. The mixture was shaken for 10 min, and the layers were allowed to separate over 10 min. The lower organic layer was drained into a 500-ml erlenmeyer flask containing 80 g of granular anhydrous sodium sulfate, and the flask was stoppered and shaken briefly. The mixture was filtered through a 80-mm i.d. polypropylene powder funnel fitted with a glass wool plug.

The filtrate was collected into a 1-liter round-bottom evaporation flask. The erlenmeyer flask was rinsed with 50 ml of chloroform–acetone (2:1), and the rinse solvent was filtered through the same funnel and combined with the first extract in the 1-liter flask. The organic extract was evaporated to an oily residue, using a vacuum rotary evaporator with the water bath set at 37°. The residue obtained was transferred to a 125-ml separator with the aid of 50 ml of hexane and 50 ml of acetonitrile, and the separator was capped and shaken for 5 min. The separated acetonitrile layer then was drained into another separator and washed twice with 25 ml of hexane.

The final acetonitrile extract was drained into a 250-ml round-bottom flask and evaporated to a residue on a rotary evaporator. The residue obtained was transferred quantitatively to a 125-ml separator with the aid of 50 ml of ethyl acetate. The ethyl acetate was extracted with 0.2 *N* HCl (3 × 10 ml). The acid was combined in another 125-ml separator and washed with hexane (2 × 10 ml). All ethyl acetate and hexane layers were discarded. Then 6 ml of 1 *N* NaOH was added to the acid extract, and the solution pH was adjusted to 8 by the addition of 300 mg of sodium bicarbonate.

The basic solution was extracted with ethyl acetate (2 × 25 ml). The ethyl acetate extract was dried over a bed of anhydrous sodium sulfate (5 g) and evaporated to a residue. The residue was redissolved in 10 ml of ethyl acetate and filtered through a 0.5-μm filter[6] into a 15-ml conical test tube. The filtrate was evaporated to dryness and redissolved in 200

**Table I—Percent of Radioactivity Present at Each Step of Extraction**

| Extraction Step | Recovery[a], % |
|---|---|
| Acetone extract | 93.21 |
| Chloroform–acetone (2:1) extract | 92.12 |
| Aqueous layer | 1.27 |
| Hexane | 1.02 |
| Ethyl acetate after 0.2 *N* HCl extraction | 4.84 |
| Hexane wash of 0.2 *N* HCl | NM[b] |
| Base after ethyl acetate extraction | 0.57 |
| Final extract for HPLC | 79.23[c] |
| HPLC assay (μg/g) | 0.01 |

[a] From raw milk spiked with 0.01 μg of [$^{14}$C]oxfendazole/g. [b] Not measurable. [c] About 6% of the radioactivity was not accounted for, probably due to adsorption onto glassware.

μl of methanol. An aliquot (25 μl) was injected onto the chromatograph for analysis.

**Extraction Efficiency and Total Recovery**—A known amount of $^{14}$C-labeled oxfendazole was spiked into drug-free raw milk. Extraction efficiency and total recovery of oxfendazole were established by monitoring the radioactivity present in every fraction at each step.

**Calibration Curve Preparation**—Oxfendazole levels in unknown samples were determined with a calibration curve prepared in the following manner. Known amounts of oxfendazole and the internal standard were spiked into drug-free raw milk in the range of 0.005–0.05 μg of oxfendazole/g and 0.02 μg of the internal standard/g. The samples were processed as described and subjected to HPLC analysis. The calibration curve was constructed by plotting the ratio of the chromatographic peak heights of oxfendazole and the internal standard *versus* micrograms of oxfendazole spiked per gram.

Spiking solutions of oxfendazole, 0.25, 0.5, 1, 1.5, 1, and 2.5 μg/ml, were prepared by diluting the stock solution of oxfendazole with 0.1 *N* HCl. Oxfendazole stock solution was prepared by dissolving 10 mg of oxfendazole in 100 ml of methanol–0.1 *N* HCl (1:1). The internal standard spiking solution (1 μg/ml in 0.1 *N* HCl) was prepared by the dilution of a stock internal standard solution of 50 μg/ml with 0.1 *N* HCl. One milliliter of each oxfendazole spiking solution was added to 50 g of raw milk to yield spiking levels of 0.005, 0.01, 0.02, 0.03, 0.04, and 0.05 μg of oxfendazole/g. One milliliter of the spiking internal standard solution then was added to the raw milk (50 g) already fortified with oxfendazole to obtain 0.02 μg of the internal standard/g.

**Analysis of Milk Samples Containing Oxfendazole Levels of >0.05 μg/g**—Milk samples containing oxfendazole levels higher than the calibration curve range were diluted with appropriate amounts of blank milk obtained from an untreated animal. The samples after dilution were treated in the same manner as described under *Extraction*. A dilution factor then was included in the final calculation against the calibration curve.

**Table II—Statistical Parameters of Milk Calibration Curves**

| Curve Number | Correlation Coefficient | Linear Regression Intercept, μg/g | Linear Regression Slope[a] |
|---|---|---|---|
| I | 0.9995 | 0.0003 | 51.16 |
| II | 0.9997 | 0.0004 | 49.17 |
| III | 0.9993 | 0.0007 | 49.84 |
| IV | 0.9998 | 0.0002 | 50.06 |

[a] The mean was 50.06 ± 0.83 (*SD*).

## RESULTS AND DISCUSSION

Oxfendazole, a benzimidazole carbamate, was chromatographed using a reversed-phase microparticulate column and a mobile phase of 24.5% acetonitrile in water. Baseline resolution of oxfendazole and its structural analog used as an internal standard was achieved. The UV spectrum of oxfendazole in methanol indicated that its $\lambda_{max}$ was at 228 nm with a molar extinction coefficient of 45,565. Due to the ready availability of a 254-nm fixed-wavelength UV detector, detection at 254 nm was preferred. The molar extinction coefficient at 254 nm was 11,025 and was adequate for the sensitivity requirement of this assay.

Oxfendazole extraction from milk using various solvents was investigated. The extraction of milk directly with ethyl acetate caused an unbreakable emulsion. Emulsion formation also was observed when chloroform was used. To eliminate this problem, acetone was added to milk to precipitate the milk protein and also to act as an extracting solvent. The acetone extract then was partitioned with chloroform to remove water. The organic layer obtained was cleaned up further *via* hexane–acetonitrile partitioning and acid–base extraction. Until the acetone–chloroform extraction step, ~92% of the spiked [$^{14}$C]oxfendazole was extracted. The overall recovery of [$^{14}$C]oxfendazole spiked in milk that went through the entire extraction procedure was 79%. A step-by-step account of loss and recovery throughout the assay is summarized in Table I.

The chromatograms of control milk and milk spiked with oxfendazole

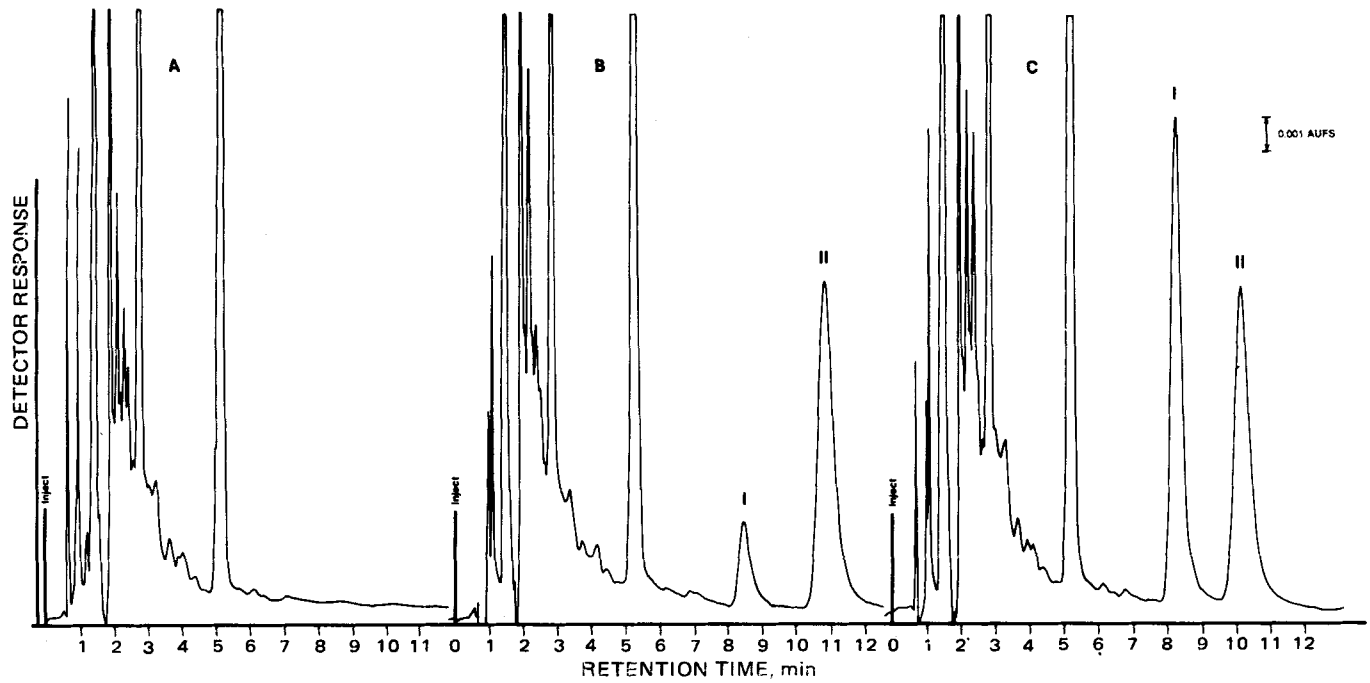

**Figure 1**—*A, high-performance liquid chromatogram obtained from the analysis of control milk processed through the procedure; B, control milk spiked with 0.005 μg of oxfendazole/g and 0.02 μg of internal standard/g; and C, control milk spiked with 0.03 μg of oxfendazole/g and 0.02 μg of internal standard/g. Chromatographic conditions were: mobile phase, 24.5% acetonitrile in water; flow rate, 2 ml/min; temperature, ambient; and detection, 254 nm at 0.01 aufs. Key: I, oxfendazole; and II, internal standard.*

and the internal standard are shown in Fig. 1. The chromatogram obtained from the analysis of drug-free milk showed no interference peak at the retention time of oxfendazole and the internal standard. Chromatograms from milk spiked with 0.005 or 0.03 μg of oxfendazole/g along with 0.02 μg of the internal standard/g indicated adequate peak response for both compounds at these concentrations.

The calibration curve obtained from the analysis of blank milk spiked with oxfendazole in the 0.005–0.05-μg/g concentration range was linear. The statistical parameters showing linear regression fits of four calibration curves are given in Table II. Table III summarizes the data obtained from the repeat analysis of milk samples spiked with oxfendazole.

Coefficient of variance (standard deviation per mean) was calculated to assess assay variability. The coefficients of variance for the analysis at 0.005, 0.01, 0.02, 0.03, 0.04, and 0.05 μg/g ($n = 4$) were 1.95, 4.84, 2.94, 0.66, 1.98, and 1.99%, respectively.

Oxfendazole levels in the milk of a cow following the administration of 5 mg of oxfendazole/kg were determined by the described method. The cow was milked at 0 (predose), 4, 8, 12, and 24 hr after dose on the 1st day. For the next 6 days, milking was carried out every 12 hr. The oxfendazole levels in milk 4, 8, 12, 24, 36, 48, 60, and 72 hr following dose administration were 0.097, 0.212, 0.334, 0.460, 0.325, 0.173, 0.058, and 0.009 μg/g, respectively. Oxfendazole was not detected beyond 72 hr after dose.

# GLC Determination of Itanoxone in Biological Fluids

**HENRI COUSSE ˣ, JEAN-PAUL RIBET, and JEAN-CLAUDE VEZIN**

Received August 11, 1980, from the *P. Fabre S.A. Research Center, 17 Avenue Jean Moulin, 81106 Castres, France.* Accepted for publication January 6, 1981.

**Abstract** □ A sensitive and reliable method for the quantitative determination of itanoxone, 4-[4′-(2-chlorophenyl)phenyl]-4-oxo-2-methylenebutanoic acid, in biological fluids is described. A quantitative ethyl acetate extraction of the plasma samples is followed by reduction and methylation of itanoxone. Quantification is achieved by GLC using electron-capture detection and an internal standard. The minimum concentration of itanoxone detected in plasma is 0.1 μg/ml. Recovery of the titrated compound added to human plasma averaged 100.9 ± 2.92% (*RSD*).

**Keyphrases** □ Itanoxone—GLC determination in biological fluids □ GLC determination, electron-capture detection—analysis, itanoxone, biological fluids □ 4-[4′-(2-Chlorophenyl)phenyl]-4-oxo-2-methylenebutanoic acid—itanoxone, GLC determination in biological fluids

Itanoxone (1), 4-[4′-(2-chlorophenyl)phenyl]-4-oxo-2-methylenebutanoic acid (I), is used in the treatment of metabolic disorders (2–10). The impurities likely to be found in this raw material were studied (11), as was a purification process (12). The present study perfected a sensitive and reliable method for studying the absorption, metabolism, and excretion of I in animals and humans at relatively low doses.

TLC methods were described for the determination of I in pharmaceutical formulations[1] (13). Quantitation was achieved using the UV-absorbing properties of I. The method described in this paper used GLC followed by electron-capture detection for the determination of small quantities of I in biological fluids and pharmaceutical formulations.

## EXPERIMENTAL

**Reagents and Materials**—Itanoxone[2] (I) and internal standard (II) were obtained by a Friedel–Crafts reaction between itaconic anhydride and the corresponding aromatic derivative (14). The standard solutions

| | 0.050 | | |

and the internal standard are shown in Fig. 1. The chromatogram obtained from the analysis of drug-free milk showed no interference peak at the retention time of oxfendazole and the internal standard. Chromatograms from milk spiked with 0.005 or 0.03 μg of oxfendazole/g along with 0.02 μg of the internal standard/g indicated adequate peak response for both compounds at these concentrations.

The calibration curve obtained from the analysis of blank milk spiked with oxfendazole in the 0.005–0.05-μg/g concentration range was linear. The statistical parameters showing linear regression fits of four calibration curves are given in Table II. Table III summarizes the data obtained from the repeat analysis of milk samples spiked with oxfendazole.

Coefficient of variance (standard deviation per mean) was calculated to assess assay variability. The coefficients of variance for the analysis at 0.005, 0.01, 0.02, 0.03, 0.04, and 0.05 μg/g ($n = 4$) were 1.95, 4.84, 2.94, 0.66, 1.98, and 1.99%, respectively.

Oxfendazole levels in the milk of a cow following the administration of 5 mg of oxfendazole/kg were determined by the described method. The cow was milked at 0 (predose), 4, 8, 12, and 24 hr after dose on the 1st day. For the next 6 days, milking was carried out every 12 hr. The oxfendazole levels in milk 4, 8, 12, 24, 36, 48, 60, and 72 hr following dose administration were 0.097, 0.212, 0.334, 0.460, 0.325, 0.173, 0.058, and 0.009 μg/g, respectively. Oxfendazole was not detected beyond 72 hr after dose.

III

of the products to be analyzed were stored in glass containers at 5°. All solvents were analytical reagent grade, and the reducing catalyst was 10% palladium-on-charcoal[3].

Diazomethane (15, 16), used as the methylating agent, was obtained from *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide[4] as follows. A 250-ml distilling flask was fitted with a condenser for distillation and with a funnel. The condenser was connected to two 50-ml receiver tubes immersed in ice water. Ether (10 ml) was placed in the first receiver, and 35 ml of ether was placed in the second. The outlet tube passed above the surface of the acetic acid solution in an erlenmeyer flask.

In the distilling flask was introduced 5 ml of 60% (w/w) potassium hydroxide aqueous solution, and then 5 ml of 2-ethoxyethanol and 3 ml of ether were added. In the dropping funnel was placed 20 ml of 10% (w/w) *N*-methyl-*N*-nitroso-*p*-toluenesulfonamide in ether. The flask was heated in a water bath at 70°, and the ethereal solution was transferred gently into the flask at a regular rate during 15–20 min. The diazomethane that formed was driven off by ether and collected in the two receivers.

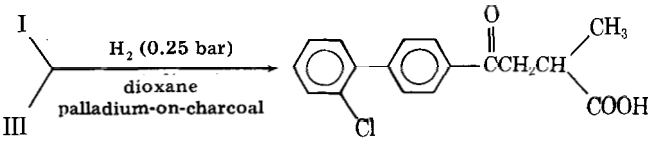
This semimicromethod does not present any serious danger of explosion or toxicity if handled carefully under a well-ventilated hood. To avoid accidental exposure to diazomethane, work was performed in a saturated acetic acid atmosphere under a hood. The ethereal solution of diazomethane should be kept in hermetically stoppered glass tubes and stored at 5° for up to 1 week.

In compliance with these safety rules, the diazomethane solution can be titrated at 0° with an excess of accurately titrated benzoic acid solution. The benzoic acid must be in excess as evidenced by the complete decolorization of the diazomethane solution. The unreacted benzoic acid is determined using 0.2 *N* alcoholic potassium hydroxide in the presence of phenolphthalein. Any diazomethane accidentally given off is neutralized immediately by acetic acid into atoxic methyl acetate.

**Instrumentation**—A gas chromatograph[5] was fitted with a nickel 63 electron-capture detector, an integrator[6], and a recorder[7]. A densitometer[8] and a reciprocating shaker[9] also were used.

**TLC**—The products obtained by synthesis or contained in pharmaceutical formulations were evaluated on thin layers (250 μm) of silica gel 60 $F_{254}$[3], ascendingly developed with methanol–chloroform (15:85) in a saturated atmosphere (13). Each sample was taken up in 0.1% (w/w) ethanol, and 5-μl aliquots were spotted. After development to within 10 cm of the solvent front, the plates were dried and the spots were visualized by irradiation of the plates under a UV lamp (254 nm). Under these conditions, I, II, III, and IV had $R_f$ values of 0.42, 0.35, 0.29, and 0.47, respectively.

This technique also was used to analyze IV by fluorescence inhibition (13). Quantitative determination was carried out by comparison with a range of standards chromatographed under the same conditions as the samples. Aliquots equivalent to 1.5, 3.5, 7.5, and 12.5 μg of IV standard ethanolic solution likewise were spotted on the plate. A calibration curve



IV

*Scheme I*

was obtained by plotting the percentage of fluorescence inhibition *versus* known concentrations of IV in ethanol. Values for unknown concentrations of IV in samples were calculated from the standard curve.

**GLC Conditions**—Analyses were performed using a glass column, 1.1 m × 2 mm i.d., packed with 3% OV-225 (phenylcyanopropyl) on Chromosorb W.A.W. (80–100 mesh). The column was conditioned for 24 hr at 260° with a nitrogen flow of 10 ml/min. Gases (nitrogen, compressed air, and hydrogen) used for chromatography were purified with filters containing 4-Å molecular sieves. The detector and injector temperatures were 290 and 250°, respectively. The column was maintained isothermally at 230°. Nitrogen was the carrier gas. The flow rates for nitrogen, hydrogen, and compressed air were maintained at 50, 20, and 400 ml/min, respectively. The pulse interval for the electron-capture detector was 20 μsec. Because of the elevated temperature of the injector, high temperature septa[10] were used.

**Assay**—Itanoxone is a polar molecule that cannot be analyzed directly by GLC with specific columns generally used for organic acids. Compounds I and II were determined by GLC after two derivatizations, including reduction of the ethylenic bond followed by esterification of the acid group (17). Reduction was used to obtain a single compound from I and its isomer (III) which might form during extraction and chromatography at high temperature (Scheme I). Reduction also avoids the formation of a cyclopropane derivative (VI) by the addition of diazomethane to the ethylenic bond (Scheme II). Quantitation by TLC has been used at this step for I in pharmaceutical formulations and synthesis products.

Chromatography at low concentrations, such as those found in blood and urine, required an electron-capture detector for good sensitivity. By derivatizing the acid group, polarity was decreased and volatility was increased, thus providing increased sensitivity with a shorter analysis time. Methyl esters were formed quantitatively and rapidly with the diazomethane reagent.

**Sample Preparation**—Blood samples were collected routinely in heparinized tubes, and plasma was separated by centrifugation. Exactly 1 ml of plasma was pipetted into a 25-ml glass-stoppered extraction tube.

Plasma samples (1 ml) were spiked with 0.5 ml of the internal standard solution (10 μg). Then 1 ml of the buffer solution[11] (pH 2.2) and 10 ml of ethyl acetate were added. The preparation was shaken vigorously for 1–2 hr, and the layers were separated by centrifugation for 10 min at 3000 rpm. Ethyl acetate was transferred quantitatively to another 25-ml extraction tube and was evaporated to dryness with a gentle nitrogen stream. The residue then was dissolved in 2 ml of dioxane, and the reduction of I was performed as follows.

To the 2 ml of dioxane solution of the residue were added 0.1 ml of acetic acid in dioxane (10% w/w) and 2 mg of palladium-on-charcoal (10%). Then the solution was mixed with a magnetic stirrer; each cen-

trifuge tube was stoppered and purged with nitrogen, and hydrogen was passed through it. Hydrogenation was conducted for 1 hr at 0.25 bar. After centrifugation for 10 min at 3000 rpm, the residue was extracted with 2 ml of dioxane and centrifuged. Dioxane fractions were collected in 10-ml conical glass vials, and the solvent was removed under reduced pressure (15 mm) at 60°. The residue then was dissolved in an ethereal solution of diazomethane until nitrogen bubbles disappeared. This mixture was allowed to react completely at room temperature for 1 hr. After evaporation[12], the residue was dissolved in 2 ml of hexane. Volumes of 1 μl were injected into the gas chromatograph.

**Calculations**—An integrator was employed for measurement of retention times and peak areas. Values for unknown concentrations of I in plasma were calculated from the internal standard (II) introduced before treatment.

## RESULTS AND DISCUSSION

The TLC method was used for the quantitative determination of the reduced compound. TLC does not require expensive instrumentation, and the time required to determine the concentration of itanoxone (I) in pharmaceutical formulations varies according to the number of samples, *i.e.*, ~4 hr for six samples. Under these conditions, the minimal detectable amount is 0.5 mg/ml. A linear relationship between fluorescence inhibition and concentration is obtained for IV over the 0–15-mg/ml range. Quantification from a standard curve was adequate. To increase precision, the results are expressed on the basis of an average of three spots; reproducibility is limited to ±1%.

GLC has an advantage over previously reported methods because of its great sensitivity for I. The samples were esterified for GLC measurements. Under the assay conditions, IV and V methyl esters had retention times of 4 and 6 min, respectively (Fig. 1). The lower limit of detection sensitivity of I in human plasma extracts is 0.1 μg/ml. This value is based on a sample signal equivalent to 10% of the full-scale response. A linear relationship between detector response and concentration was obtained for I over the 0–20-μg/ml range.

Compound I was isomerized to III during GLC. The high working temperatures favor isomerization. The olefin was reduced to IV to avoid differentiation of the two isomers I and III and the side reaction with diazomethane to form a cyclopropane derivative. A series of samples containing known amounts of I was prepared to determine optimal reaction times for the formation of IV.

The results indicated that reduction of I was completed within 60 min, using palladium-on-charcoal in dioxane media (Fig. 2). Figure 3 illustrates a chromatogram of placebo human plasma extracts.

Reduction with platinum oxide as a catalyst gave small amounts of the

Beyond 100% reduction, the ketonic group is reduced to a secondary alcohol.*

side-products VII and VIII. Reduction of the ketonic group occurred mainly with other catalysts such as platinum oxide, with a relative excess of catalyst and/or a high hydrogen pressure (Scheme III). Acetic acid was necessary, and up to 30% (w/w) water did not interfere with reduction.

The derivatives were stable for at least 3 weeks. The choice of II as the internal standard in the estimation of I was based on similar physicochemical characteristics. Compound II, the chemical isomer of I, was added prior to extraction. Partition coefficients of I and II were log $P$ = 7.65 and 7.77, respectively, indicating equal extraction of both compounds.

For recovery experiments, known amounts of I and II in ethyl acetate were evaporated to dryness in glass-stoppered extraction tubes, and plasma was added. The samples were mixed thoroughly and extracted. The materials were derivatized and analyzed by GLC.

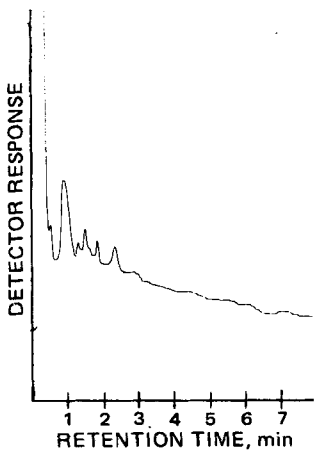

**Figure 3**—*Gas–liquid chromatogram (electron-capture detector) of placebo human plasma extracts.*

**Table I—Accuracy and Reproducibility of GLC Analysis of I Added to Human Plasma**

| Added, μg/ml | Mean Recovered Amount (Range) | Recovery, %[a] |
|---|---|---|
| 0.1 | 0.101 (0.097–0.103) | 101 |
| 0.5 | 0.49 (0.480–0.51) | 98 |
| 1 | 1.03 (0.95–1.31) | 103 |
| 5 | 4.81 (4.74–5.33) | 96.2 |
| 10 | 10.35 (9.84–10.72) | 103.5 |
| 15 | 15.50 (14.68–15.96) | 104 |

[a] Mean ± *SD* = 100.95 ± 2.92; number of analyses = 4.

The results (Table I) show the accuracy and reproducibility of the GLC analysis of I in clinical samples. The response factor was calculated using the ratio of peak areas for similar concentrations of I and II (1.22 ± 0.12). The method has been used in laboratories to determine the amount of I in rat blood compared with radioisotopic methods (18, 19). It also has been used for the determination of I in plasma and urine of humans and in pharmacokinetic studies (18).

Recently, a simple and fast high-performance liquid chromatographic method (20) was developed in which derivatization was not necessary. However, the sensitivity was not as good as that using GLC electron-capture detection.

# Synthesis, Structure, and Features of Anilinium Anilinomethanesulfonates

**MIGUEL G. NEUMANN and ROBERT A. M. C. DE GROOTE** ˣ

Received September 11, 1980, from the *Instituto de Física e Química de São Carlos, USP, C.P. 369, 13560 São Carlos, SP, Brazil.* Accepted for publication January 6, 1981.

**Abstract** □ Two series of anilinomethanesulfonate derivatives, the anilinium and *p*-toluidinium anilinomethanesulfonates, were synthesized. They present interesting spectroscopic features and can be used as characteristic derivatives of the parent compounds. These series allow the easy study of the N–H stretching frequencies of the secondary amine whereas difficulties are encountered with the parent compounds due to the occurrence of O–H stretching bands in the same frequency range. All three compounds present a common fragmentation pattern in mass spectral analysis. Through these analyses, the salt structure of the anilinium anilinomethanesulfonates is demonstrated in opposition to a sulfonamide structure, giving further support to the salt structure of other series previously reported.

**Keyphrases** □ Anilinomethanesulfonates, derivatives—synthesis and structure elucidation by elemental, IR, and mass spectral analyses □ Mass spectrometry—analysis, anilinomethanesulfonate derivatives, synthesis and structure elucidation □ IR spectroscopy—analysis, anilinomethanesulfonate derivatives, synthesis and structure elucidation

Methanesulfonation of the amine groups of pharmacologically active drugs is used to increase their solubility (1) and to control their hydrolysis in biological media (2). Some common examples are *p*-phenetidinomethanesulfonate[1], dihydroergotamine[2], and dipyrone[3]. On the other hand, some researchers have studied aminomethanesulfonic compounds as potential antiviral (3) or carcinogenic agents (4, 5) since their structures are analogous to the carboxylic amino acids. As part of research into the properties of aminomethanesulfonates, the kinetics of formation of substituted anilinomethanesulfonates were studied recently (6). The inherent difficulties of analyzing IR spectra of substituted aromatic aminomethanesulfonates with regard to the O–H stretching bands also were discussed (7).

Little work has been reported concerning the analysis of the anilinomethanesulfonates, their chemical structure, and the different products that form, depending on the synthetic method. To find appropriate methods of analysis and identification of these products, a new series of derivatives was prepared by the reaction of equimolar

# Synthesis, Structure, and Features of Anilinium Anilinomethanesulfonates

**MIGUEL G. NEUMANN and ROBERT A. M. C. DE GROOTE** ˣ

Received September 11, 1980, from the *Instituto de Física e Química de São Carlos, USP, C.P. 369, 13560 São Carlos, SP, Brazil.* Accepted for publication January 6, 1981.

**Abstract** □ Two series of anilinomethanesulfonate derivatives, the anilinium and *p*-toluidinium anilinomethanesulfonates, were synthesized. They present interesting spectroscopic features and can be used as characteristic derivatives of the parent compounds. These series allow the easy study of the N–H stretching frequencies of the secondary amine whereas difficulties are encountered with the parent compounds due to the occurrence of O–H stretching bands in the same frequency range. All three compounds present a common fragmentation pattern in mass spectral analysis. Through these analyses, the salt structure of the anilinium anilinomethanesulfonates is demonstrated in opposition to a sulfonamide structure, giving further support to the salt structure of other series previously reported.

**Keyphrases** □ Anilinomethanesulfonates, derivatives—synthesis and structure elucidation by elemental, IR, and mass spectral analyses □ Mass spectrometry—analysis, anilinomethanesulfonate derivatives, synthesis and structure elucidation □ IR spectroscopy—analysis, anilinomethanesulfonate derivatives, synthesis and structure elucidation

Methanesulfonation of the amine groups of pharmacologically active drugs is used to increase their solubility (1) and to control their hydrolysis in biological media (2). Some common examples are *p*-phenetidinomethanesulfonate[1], dihydroergotamine[2], and dipyrone[3]. On the other hand, some researchers have studied aminomethanesulfonic compounds as potential antiviral (3) or carcinogenic agents (4, 5) since their structures are analogous to the carboxylic amino acids. As part of research into the properties of aminomethanesulfonates, the kinetics of formation of substituted anilinomethanesulfonates were studied recently (6). The inherent difficulties of analyzing IR spectra of substituted aromatic aminomethanesulfonates with regard to the O–H stretching bands also were discussed (7).

Little work has been reported concerning the analysis of the anilinomethanesulfonates, their chemical structure, and the different products that form, depending on the synthetic method. To find appropriate methods of analysis and identification of these products, a new series of derivatives was prepared by the reaction of equimolar

amounts of the anilinomethanesulfonate (I) with anilinium or *p*-toluidinium chloride in water at room temperature to form the anilinium or *p*-toluidinium anilinomethanesulfonates (II) (Scheme I).

## EXPERIMENTAL

**Anilinomethanesulfonate Sodium Salts**—All anilinomethanesulfonates were synthesized from the corresponding anilines and sodium hydroxymethanesulfonate and were purified by previously described methods (6).

**Anilinium and *p*-Toluidinium Anilinomethanesulfonates**—These compounds were prepared by mixing equimolar amounts of the parent anilinomethanesulfonate with anilinium or *p*-toluidinium chloride at room temperature in a minimal amount of water under strong agitation. After precipitation, which was almost instantaneous, the compound was filtered, washed with cold ethanol and ether, and dried under vacuum at room temperature.

Recrystallization was performed using 50% ethanol–water. Special care was required because the anilinium compounds may be affected by light.

Elemental analysis values for all compounds were within 0.5% of those calculated from the theoretical structure of II.

The melting points for the anilinium- and *p*-toluidinium-substituted anilinomethanesulfonates, respectively, were: R = H, 118–120 and 123–124°; R = *m*-Cl, 119–120 and 123–124°; R = *p*-Cl, 129–134 and 139–142°; R = *p*-$CH_3$, 122–124 and 131°; and R = *p*-$OCH_3$, 121–123 and 134–136°. All compounds melted with decomposition.

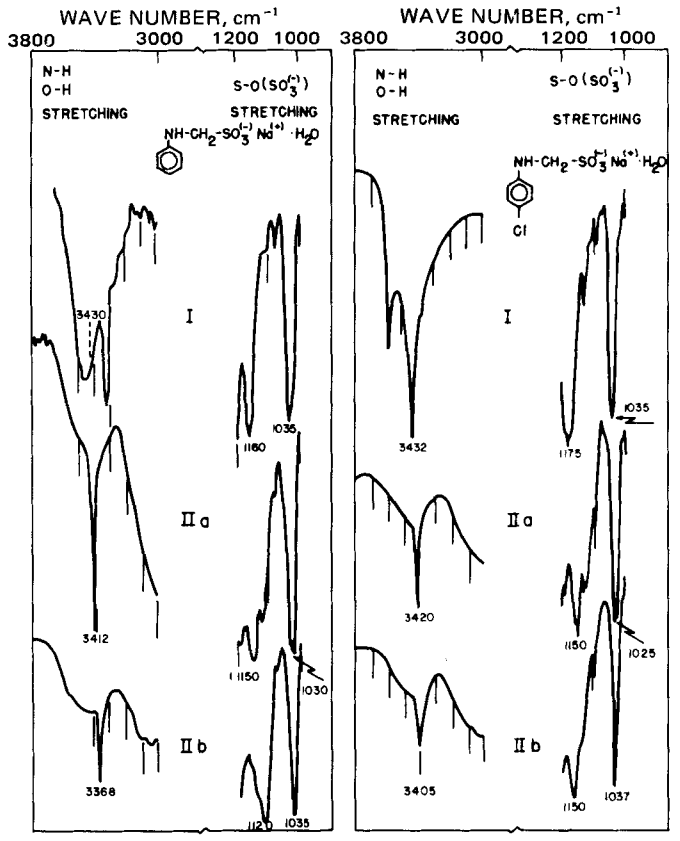

**Figure 1**—*IR spectra of sodium anilinomethanesulfonate (I), anilinium anilinomethanesulfonate (IIa), and* p*-toluidinium anilinomethanesulfonate (IIb) and its* p*-chloro-substituted derivatives.*

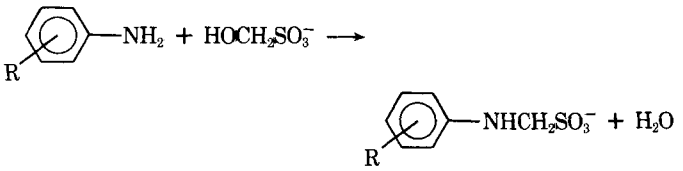
**Instrumentation**—IR spectra were measured on a high-resolution double-beam spectrophotometer[4]. All spectra were taken from solid pellets with 0.5% of the product in potassium bromide.

Mass spectra were taken at various temperatures with a quadrapole spectrometric system[5].

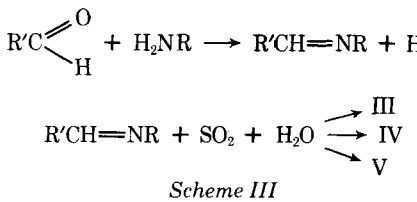
## RESULTS AND DISCUSSION

The classic synthesis of substituted anilinomethanesulfonates (I) involves the reaction of equimolar amounts of the substituted aniline hydroxymethanesulfonate in a suitable solvent (6) (Scheme II).



*Scheme II*

Another common method for aliphatic and, in particular, C-substituted compounds is based on the addition of sulfur dioxide to the corresponding Schiff base dissolved or suspended with enough water to form the hydrogen sulfate ion ($HSO_3^-$). Depending on the aldehyde and the amine, three products (III–V or a mixture of them) might be formed when using the Schiff base method (8) (Scheme III).



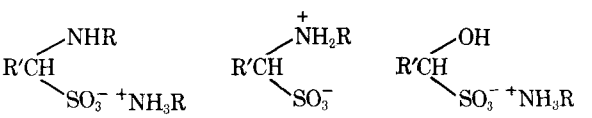
*Scheme III*

Structure III is obtained with aromatic amines, IV is obtained with aliphatic amines, and V is obtained when either the starting amine is very bulky (steric hindrance) or the aromatic aldehyde is substituted with strong withdrawing groups. In both cases for V, hydrolysis of the Schiff base is faster than the reaction with the bisulfite reagent. Considering the experimental procedure, it might be assumed that the proportion in which III and IV are formed is a function of the difference of the pKa values between aliphatic and aromatic amines.

This method cannot be used for formaldehyde derivatives (R′ = H) since a mixture of bis(phenylamino)methane and resinous material is formed (9).

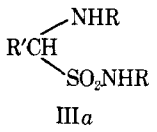
**IR Spectral Analysis**—The anilinium salt structure of V was confirmed by its IR spectra. The characteristic derivatives, IIa and IIb, present very characteristic N–H and S–O ($SO_3^-$) stretching bands (10). The N–H stretching frequencies for these compounds were presented elsewhere (7). If the structure of V is sulfonamide-like, as was suggested (11), the N–H stretching frequency for the *sec*-amine group and for the sulfonamide group should be different. Therefore, two narrow stretching bands around 3400 $cm^{-1}$ should be expected for a IIIa (R′ = H) structure.

As can be seen from Fig. 1, only one sharp N–H stretching band appeared at this frequency range, well separated from the characteristic N–H ($NH_3^+$) broad band at 3200–2600 $cm^{-1}$. However, the sulfonamide S–O ($SO_2$) stretching bands appear around 1335 (asymmetric) and 1175 (symmetric) $cm^{-1}$. The main absorptions in this region for I, IIa, and IIb



III: R′ = aryl  IV: R′ = alkyl  V: R′ = $C_6H_4NO_2$, R = alkyl, aryl; R′ = alkyl, aryl, R = *tert*-butyl

[4] Perkin-Elmer model 180.
[5] Finnigan model 1015.



IIIa

were at 1175 (asymmetric) and 1050 (symmetric) $cm^{-1}$, which are typical of sulfonic acid salts.

**Mass Spectral Analysis**—The mass spectra of the sodium anilinomethanesulfonates (I) and their anilinium (IIa) and *p*-toluidinium (IIb) derivatives (Tables I–III) are consistent with the fragmentation pattern shown in Scheme IV. This pattern provides additional support for the anilinium salts *versus* the sulfonamide structure for two reasons: (*a*) the fragments found in the mass spectra of the anilinium (IIa) and *p*-toluidinium (IIb) derivatives were similar to those found in the mass spectra of the parent anilinomethanesulfonates; and (*b*) no fragments corresponding to the mass of the sulfonamides were apparent.

Some characteristics of these mass spectra should be mentioned.

1. The similarity of the mass spectra of I and II together with the lack of the parent peak, as would be expected for any salt (12), justifies a common fragmentation pattern for all three types of compounds.

2. The abundance of the Schiff base peaks (A and B), the cationic aniline peaks (E), and the characteristic $SO_2$ and SO peaks suggest successive or alternative fragmentations through C–S and N–C cleavages, followed by hydrogen losses.

3. The substituted phenyl fragments (C) may rearrange to other structures in accordance with the patterns for substituted aromatic compounds (13), as in the case of *p*-toluidinomethanesulfonate where peaks corresponding to the tropylium and cyclopentadienyl cations appear with 100 and 34% frequency, respectively.

4. For the halogen-substituted compounds, important fragments arise from the cleavage of the halogen atom from the aromatic ring, followed by decomposition of the latter. This pattern can be seen in Table II for the anilinium *p*-bromoanilinomethanesulfonate, for which the base peak corresponds to the cyclopentadienyl cation.

5. For the methoxy-substituted compounds, important fragments are found corresponding to $CH_3$–O cleavage, typical of aromatic ethers (14). That is, the base peak for the *p*-methoxyanilinomethanesulfonate is the $O\text{-}C_6H_5\text{-}N{=}CH_2$ fragment.

The mass spectra of the characteristic derivatives taken at tempera-

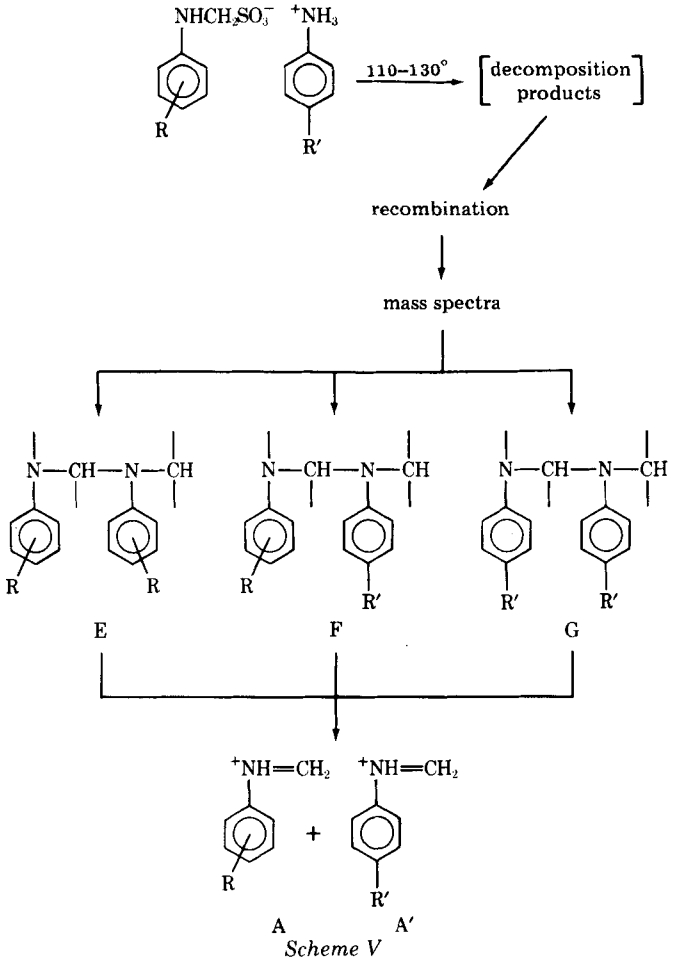

*Scheme V*

tures near their melting points (110–130°) showed significant amounts of higher molecular weight fragments. These fragments arise from dimers formed by recombination of the decomposition products of the initial compounds. The corresponding data are shown in Table IV, and the probable products are shown in Scheme V.

## CONCLUSIONS

The formation of the characteristic anilinium and *p*-toluidinium derivatives from the parent anilinomethanesulfonates displaces the water molecule of crystallization of the latter, as may be seen from elemental and IR analyses. This displacement is due to the exchange of sodium by the anilinium or *p*-toluidinium counterion. These derivatives are studied more easily than the parent compounds by mass spectra due to their lower melting points. Thus, the mass spectra must be monitored at low temperatures since polymerization occurs in the melting range of these derivatives, leading to the detection of dimer fractions and unexpected Schiff bases. This polymerization did not occur in the ionization chamber since there was no significant difference in the relative intensity of the dimer fragments when the initial compounds were monitored at different temperatures above the melting points.

The experimental method used in the present study together with the elemental, IR, and mass spectral analyses demonstrate the salt structure of V and furnishes new arguments for the salt structure of these compounds as opposed to the sulfonamide structure suggested previously (11).

The easy synthesis, low melting point, and unambiguous IR spectra suggest that these compounds can be used advantageously as characteristic derivatives for anilinomethanesulfonates.

Preliminary data[6] obtained by X-ray crystallography show that the distance between O–N ($SO_3^-H_3N^+$) is ~2.8 Å, which indicates that no covalent bonds are present in the characteristic derivatives II*a* and II*b*.

# Urinary Excretion of Meperidine and Its Metabolites

S. Y. YEH [x], H. A. KREBS [*], and A. CHANGCHIT [‡]

Received November 3, 1980, from the *National Institute on Drug Abuse, Division of Research, Addiction Research Center, Lexington, KY 40583.* Accepted for publication January 6, 1981. *Present address: Analytical Chemistry Branch, Environmental Protection Agency, Research Triangle Park, NC 27711. ‡Graduate Center for Toxicology, University of Kentucky, Lexington, KY 40506.

**Abstract** □ The urine of male and female mice, rats, guinea pigs, rabbits, cats, and dogs, given meperidine hydrochloride, 20–40 mg/kg ip, was analyzed by GLC for meperidine, normeperidine, *p*-hydroxymeperidine, and total (free and conjugated) meperidinic and normeperidinic acids. More than 90% of the excreted drugs was found in the 24-hr urine. Meperidine was observed in the urine of mice, rats, guinea pigs, and cats, but only a trace amount was observed in the urine of rabbits and dogs. Normeperidine, *p*-hydroxymeperidine (except in the mice), and total meperidinic and normeperidinic acids were observed in all species. All of the species studied have the capacity to *N*-demethylate meperidine to normeperidine and to hydrolyze meperidine and normeperidine to their respective acids. The male has a higher *N*-demethylating activity than the female with the exception of mice. Ester hydrolysis is a major metabolic pathway for meperidine metabolism.

**Keyphrases** □ Meperidine—metabolism, urinary excretion in mice, rats, guinea pigs, rabbits, cats, and dogs □ Metabolites—of meperidine, urinary excretion in mice, rats, guinea pigs, rabbits, cats, and dogs □ Metabolism—of meperidine in mice, rats, guinea pigs, rabbits, cats, and dogs □ Excretion, urinary—meperidine and its metabolites in mice, rats, guinea pigs, rabbits, cats, and dogs □ Analgesics—meperidine and its metabolites, urinary excretion in mice, rats, guinea pigs, rabbits, cats, and dogs

Urinary disposition of meperidine and its metabolite, normeperidine, has been determined in humans (1–9) and monkeys (10), but little information is available for other laboratory species. In two rats, 50% of the injected *N*-$^{14}$C-labeled meperidine could be accounted for in the urine as radioactive material within 24 hr after subcutaneous administration (11). After administration of meperidine (125 mg/kg sc or 25 mg/kg iv) to rats, 3.7% of the dose was accounted for in the 24-hr urine as meperidine, 17% as normeperidine, and 11% as meperidinic acid (11). The major metabolites of meperidine are normeperidine and free and conjugated meperidinic and normeperidinic acids. Small amounts of other metabolites have been identified, including meperidine *N*-oxide (12), *p*-hydroxymeperidine (13), *N*-hydroxynormeperidine (14), and *p*-hydroxynormeperidine[1]. The known metabolic pathways of meperidine are shown in Scheme I.

The analgesic effect of meperidine appears to differ among species, a phenomenon that may be due to differences in meperidine metabolism. Meperidine induces analgesia in mice (15–18), rats (19, 20), guinea pigs (21), cats (22), and humans (23) but not in dogs (24, 25). The present study was undertaken to investigate the differences in meperidine metabolism among species.

## EXPERIMENTAL

**Chemicals**—Meperidine hydrochloride[2], normeperidine hydrochloride[2], *p*-hydroxymeperidine[3], and lidocaine hydrochloride[4] were used as received. Meperidinic and normeperidinic acids were obtained by alkaline hydrolysis of their respective esters. Other chemicals and solvents were analytical grade.

**Animals**—Animals were housed in air-conditioned quarters (23°) with 12-hr light and dark cycles. Food and water were given *ad libitum*. A dose of meperidine hydrochloride dissolved in 0.9% NaCl was administered intraperitonally to 28 male and 21 female Swiss Webster [Lai: Cox (Wi)] mice[5], five male and five female Wistar [Lai: Cox (XW)] rats[5], five male and four female Hartley albino guinea pigs[6], two male and two female New Zealand rabbits[6], two male and two female cats, and one male and one female beagle dogs. These animals were chosen because they are commonly used in biological research.

After drug administration, all animals except the mice were caged individually in stainless steel metabolic cages. The mice were housed in groups of seven to 10 animals per cage. The mice, rats, guinea pigs, and

[a] Measures of variance where shown are ± $SE$. [b] Twenty-eight male mice were divided into three groups of 10, 10, and eight. [c] Significantly different from the females at $p < 0.05$ level. [d] Dashes indicate amounts below detectable limits. [e] Twenty-one female mice were divided into three groups of seven each. [f] The urine of the third group was insufficient for determination.

rabbits were deprived of food for 24 hr following drug administration, but water was given *ad libitum*. Urine was collected 24 hr prior to drug administration (control) and 0–24 and 24–48 hr after drug administration. After the pH and volume were measured, all urine was frozen until drug analysis.

**Determination of Meperidine and Its Metabolites**—Meperidine, $p$-hydroxymeperidine, normeperidine, and meperidinic and normeperidinic acids were determined with a GLC procedure previously described (26). With lidocaine as the internal standard, free drugs were extracted with ether from the urine adjusted to pH 10. Upon evaporation of the extract to dryness, the residues were derivatized with trifluoroacetic anhydride. After removal of the excess derivatizing agent, the residue was dissolved in 50 μl of ethyl acetate (dried over calcium hydride), and 1 μl was injected into a gas–liquid chromatograph equipped with a Poly I-110 (1.8 m × 2 mm) column and flame-ionization detector.

Total (free and conjugated) meperidinic and normeperidinic acids were determined as meperidine and normeperidine, respectively, after the sample was treated with ethanol–sulfuric acid. Meperidine and its metabolites were extracted from the urine as the free base but were converted to the percent equivalent of administered dose.

## RESULTS AND DISCUSSION

Urinary excretion of meperidine and its metabolites in mice, rats, guinea pigs, rabbits, cats, and dogs is presented in Table I. The amount of meperidine (Fig. 1) observed in the urine of mice, rats, guinea pigs, and cats was significantly higher than that in the urine of rabbits and dogs. The amount of meperidine in the urine of mice, rats, guinea pigs, and cats was comparable to that of humans (1–9) and monkeys (10). This observation appears to correlate well with meperidine analgesia reported between species. Normeperidine, $p$-hydroxymeperidine (except in the mice), and total meperidinic and normeperidinic acids were observed in all species studied; these metabolites also were reported in humans (7, 13).

Urinary pH affects excretion of meperidine and its metabolites in humans (6, 7). Urine acidification increases the excretion of meperidine

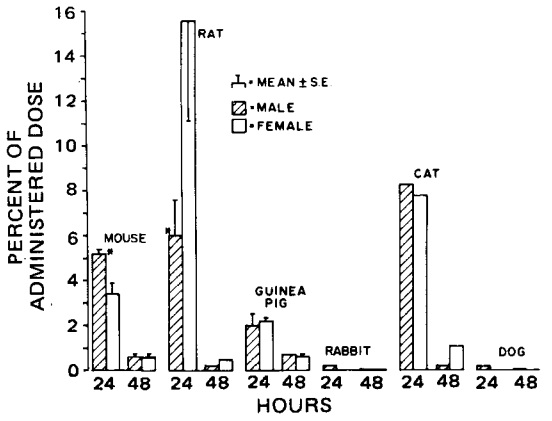

**Figure 1**—*Urinary excretion of meperidine in the mouse, rat, guinea pig, rabbit, cat, and dog after intraperitoneal administration of meperidine. The asterisk (*) indicates significantly different from the female at* $p < 0.05$ *level.*

and normeperidine, whereas very little of these compounds is excreted in alkaline urine. The recovery of meperidine and its metabolite, normeperidine, from 10 patients whose urinary pH was maintained at 4.8–5.25 varied between 10 and 50 and 2 and 20%, respectively, of the administered dose. However, 1% of the administered dose was excreted in subjects whose urinary pH was maintained at >7.0. In the present study, the urinary pH of animals was not controlled. The physiological urinary pH of dogs and rabbits appeared in the same range as the other species studied. Therefore, the small amount of meperidine and normeperidine found in the dog and rabbit urine appears to be a metabolic effect and not due to urinary pH.

The results indicate that all species studied have the capacity to *N*-demethylate meperidine to normeperidine (Fig. 2) and to hydrolyze meperidine and normeperidine to their respective acids (Figs. 3 and 4). With the exception of mice, meperidine excretion tended to be less in males than in females, and normeperidine and the sum of normeperidine and normeperidinic acids excretion tended to be greater. These data are consistent with the male having a higher *N*-demethylating activity than the female, with the exception of mice (27, 28). The present data on *in vivo* meperidine metabolism between male and female rats also correlate well with those obtained in *in vitro* studies (29).

The higher amount of normeperidine in the urine of mice, rats, and guinea pigs than in the urine of rabbits, cats, and dogs may reflect the further metabolism of normeperidine in the latter species.

Although conjugated *N*-hydroxynormeperidine was identified in the urine of rats and guinea pigs (14), *N*-hydroxynormeperidine was not determined in the present study because the pure standard was not available. Under the conditions for the determination of conjugated meperidinic and normeperidinic acids, *N*-hydroxynormeperidine probably was converted to normeperidine and measured as such or it decomposed.

The amount of meperidinic acid excreted in the urine of both sexes of the mouse, rat, guinea pig, cat, rabbit, and dog did not appear to be significantly different, suggesting that the esterase activity in both sexes may be equal. The ratios of meperidine to normeperidine excreted in 48

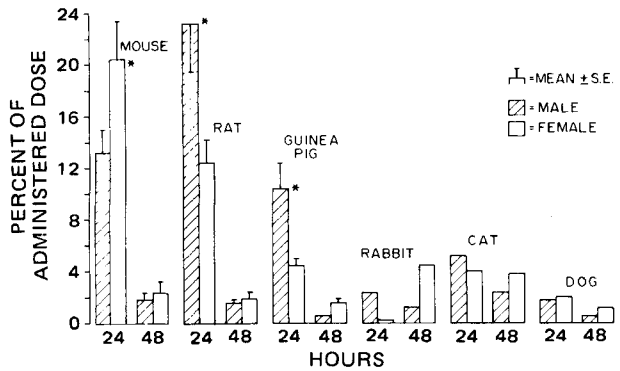

**Figure 2**—*Urinary excretion of normeperidine in the mouse, rat, guinea pig, rabbit, cat, and dog after intraperitoneal administration of meperidine. The asterisk (*) indicates significantly different from the female at* $p < 0.05$ *level.*

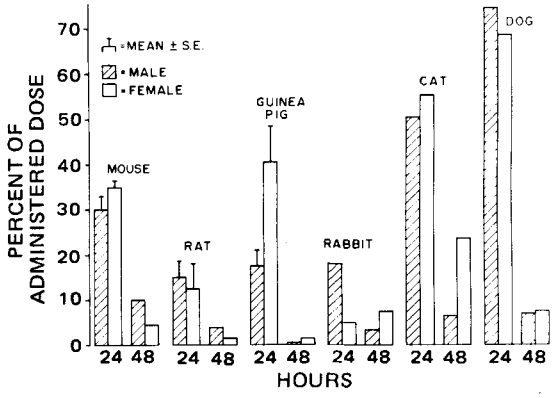

**Figure 3**—*Urinary excretion of total meperidinic acid in the mouse, rat, guinea pig, rabbit, cat, and dog after intraperitoneal administration of meperidine.*

hr in both sexes were less than one, whereas the ratios of total meperidinic acid to total normeperidinic acid ranged from 10 to 65. These data suggest that meperidine may be metabolized more extensively than its metabolite, normeperidine. The normeperidinic acid ought to be derived from normeperidine since meperidinic acid does not undergo *N*-demethylation to normeperidinic acid (4). Similarly, it was observed that morphine was metabolized more extensively than normorphine in dogs (30).

*p*-Hydroxymeperidine, a metabolite with mild analgesic effects, was observed in the urine of all species studied except mice (Table I). Free *p*-hydroxymeperidine varied among species and between sexes and accounted for 0.1–4% of the administered dose (Fig. 5). Conjugated *p*-hydroxymeperidine was not determined because the procedure is not optimal for its determination.

In one study in male guinea pigs, the dose of meperidine in one group of animals was twice that in the other. The urinary excretion profile between the two groups did not appear different.

The dogs and cats excreted 80–100% of the administered dose as total drug in the 48-hr urine; the other species excreted 16–60% of the dose. From 80 to 90% of the excreted drug was found in the 24-hr urine. This finding confirms the observation of Way *et al.* (3) that after meperidine administration to rats three times daily for several days, virtually no drug could be recovered from the animals 24 hr later. The amount unaccounted for could be due to *N*-hydroxy- and *p*-hydroxynormeperidine and metabolites excreted in the feces. Significant amounts of radioactivity have been found in the large intestine and feces of rats administered *N*-$^{14}$C-labeled meperidine (11). Gastric and biliary excretion of meperidine in humans also was observed (31).

Meperidine induces analgesia in mice (15–18), rats (19, 20), guinea pigs (21), cats[7] (22), and humans (23), and some intact meperidine was observed in the urine of these species. In the dog, a large dose (which produces toxic effects) is needed to induce mild analgesic effects (24, 25). Very little meperidine was observed in the dog urine. Meperidine could be substituted for morphine in the morphine-dependent monkey[8] and humans (23) but not in dogs (24, 25).

The small amount of meperidine and normeperidine observed in the

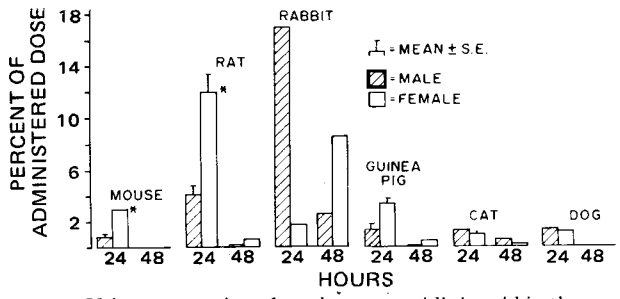

**Figure 4**—*Urinary excretion of total normeperidinic acid in the mouse, rat, guinea pig, rabbit, cat, and dog after intraperitoneal administration of meperidine. The asterisk (*) indicates significantly different from the male at* $p < 0.05$ *level.*

[8] G. Deneau, D. McCarthy, and M. H. Seevers, reported to the Committee on Drug Addiction and Narcotics, 1959, p. 2057.

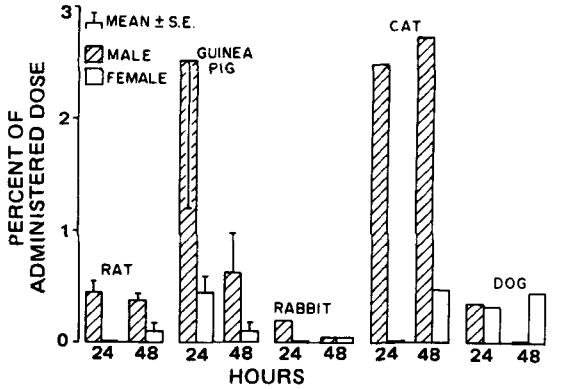

**Figure 5**—*Urinary excretion of* p*-hydroxymeperidine in the rat, guinea pig, rabbit, cat, and dog after intraperitoneal administration of meperidine.*

urine of rabbits and dogs is consistent with the mild analgesic effects of the drug in dogs. This finding suggests that these two species metabolize meperidine faster than other species, which is supported by the work of Peters *et al.* (10) on the hypothermic effect and urinary excretion of meperidine among strains of monkeys and the plasma half-life of meperidine in dogs, humans, and monkeys. These researchers reported that the median analgesic dose of meperidine in the squirrel monkey (8.0 mg/kg) was ~2.3 times that in the rhesus monkey (3.5 mg/kg) (10). Rhesus monkeys excreted substantially higher fractions of the dose as meperidine than did squirrel monkeys. On the other hand, squirrel monkeys excreted a threefold higher fraction of the dose as normeperidine than did the rhesus monkeys. This result indicates that the squirrel monkey metabolizes meperidine faster than the rhesus monkey. The plasma half-lives of meperidine in humans and monkeys are 3.0 and 1.8 hr, respectively[9] (32–34), significantly longer than the plasma half-life (0.5 hr) in the dog (4, 35).

Among the metabolites, normeperidine and *p*-hydroxymeperidine were reported to have analgesic effects with low potency (15, 16, 19), whereas meperidinic and normeperidinic acids had no analgesic effects (4). The potency ratio between meperidine and normeperidine in mice was 1:0.7 (15, 16), whereas the ratio between meperidine, normeperidine, and *p*-hydroxymeperidine in rats on a molar basis was 1:0.33:0.07 (19). If the amount of meperidine and normeperidine excreted in the urine reflects the relative amount of meperidine and normeperidine present in the body and brain, it is possible that normeperidine plays a role in the analgesic effect of meperidine because of its relatively high analgesic potency and high percentage excretion. The relationship between meperidine analgesia and the brain concentration of meperidine and normeperidine in different species administered varying doses of the drug by different routes requires further study.

In summary, after intraperitoneal administration of 20–40 mg of meperidine hydrochloride/kg to mice, rats, guinea pigs, cats, and dogs, >90% of the excreted drugs was found in the 24-hr urine. The amounts of meperidine observed in the urine of mice, rats, guinea pigs, and cats were significantly higher than those observed in the rabbits and dogs. This observation appears to correlate well with the meperidine analgesia reported in these species. Normeperidine, *p*-hydroxymeperidine (except in the mice), and total meperidinic and normeperidinic acids were observed in all species. All species studied have the capacity to *N*-demethylate meperidine to normeperidine and to hydrolyze meperidine and normeperidine to their respective acids. The male has a higher *N*-demethylating activity than the female, with the exception of mice. Ester hydrolysis is a major metabolic pathway for metabolism of meperidine.

# GLC–Mass Fragmentographic Determination of Saccharin in Biological Fluids

C. PANTAROTTO ˣ, M. SALMONA, R. FANELLI, M. BIANCHI, and K. SZCZAWINSKA

Received April 30, 1980, from the *Instituto di Ricerche Farmacologiche "Mario Negri," Via Eritrea, 62–20157 Milan, Italy.* Accepted for publication January 7, 1981.

**Abstract** □ A specific and sensitive method is described for the determination of saccharin in biological fluids. The compound is extracted as its methyl derivative following a salt–solvent pair procedure and assayed by GLC with either flame-ionization or mass fragmentographic detection using ethylated or trideuteromethylated saccharin, respectively, as the internal standard for quantitation. Detector response was linear over concentrations of 50 ng/ml–10 μg/ml with multiple-ion detection mass fragmentography and from 2 μg/ml up to milligram levels with flame-ionization detection. Interference from endogenous substrates was never observed. Plasma kinetics and urinary elimination of saccharin in healthy human volunteers given the sweetener orally, acutely (50 mg/60 kg of body weight) or for 5 days (130 mg/60 kg of body weight/day divided over the three main meals), also are reported.

**Keyphrases** □ Saccharin—GLC–mass fragmentographic determination in human biological fluids, plasma kinetics and urinary excretion □ GLC—determination of saccharin in human biological fluids, plasma kinetics and urinary excretion □ Mass fragmentography—determination of saccharin in human biological fluids, plasma kinetics and urinary excretion □ Sweeteners, artificial—saccharin, GLC and mass fragmentographic determination of saccharin in biological fluids, humans

Saccharin, 1,2-benzisothiazol-3(2*H*)-one 1,1-dioxide (I), is an artificial sweetener used in soft drinks, slimming diets, and diabetic foods. Recent toxicological studies (1) with this compound showed a higher incidence of bladder cancer in male rats fed during two-generation studies with a diet containing 5% I. Kinetic and distribution studies may be useful for investigating the causes of toxicity induced by exogenous compounds. However, the assay methods described in the literature for I determination are not suitable for studies in humans because of poor sensitivity or the use of labeled substrates (2, 3). Therefore, a specific and sensitive GLC–mass fragmentographic procedure was developed for the measurement of nanogram concentrations of I in biological fluids.

## EXPERIMENTAL

**Chemicals**—Saccharin[1] (I) was used as the dihydrated sodium salt. Methyl iodide[2], ethyl iodide[2], trideuteromethyl iodide[3], and tetrahexylammonium hydrogen sulfate[4] also were used. All solvents were analytical reagent grade.

**GLC**—The chromatograph[5] was equipped with a flame-ionization detector[6]. The column was a glass tube, 2 m × 4 mm i.d., packed with 100–120-mesh Gas Chrom Q coated with 3% OV-17[7]. All newly prepared columns were conditioned at 280° for 1 hr without carrier gas flow and then for 24 hr with a carrier gas flow rate of 15 ml/min. During analysis, nitrogen was used as the carrier gas at a flow rate of 30 ml/min. Air and hydrogen flow rates were adjusted to give maximum detector response. The operating conditions were: column oven temperature, 210°; injection port heater temperature, 250°; and flame-ionization detector temperature, 250°.

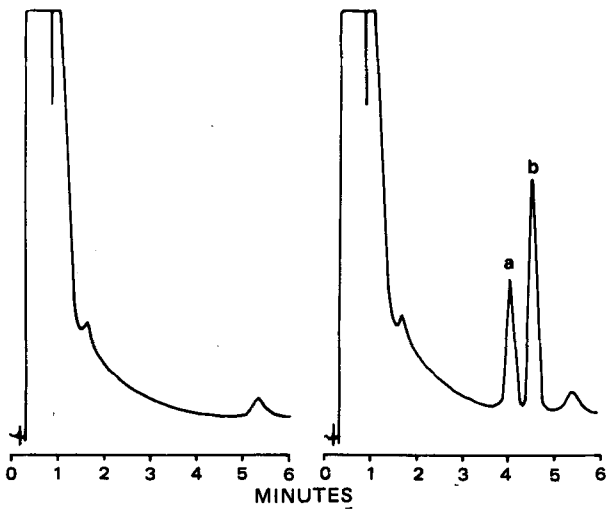

**Figure 1**—*Chromatograms obtained from control urine (left) and urine of a volunteer after I intake (right). Key: peak a, methylated I; and peak b, ethylated I (internal standard).*

**Mass Spectrometry**—Mass spectra were recorded on an instrument coupled with a gas chromatograph[8] and used under the following conditions: energy of the ionization beam, 70 ev; ion source temperature, 290°; accelerating voltage, 3.5 kv; and trap current, 60 μamp. Mass fragmentography was carried out at 70 ev by focusing the mass spectrometer[9] on the ions at *m/z* 197 and 133 for methylated I and at *m/z* 200 and 136, characteristic of the spectrum of trideuteromethylated I. In both

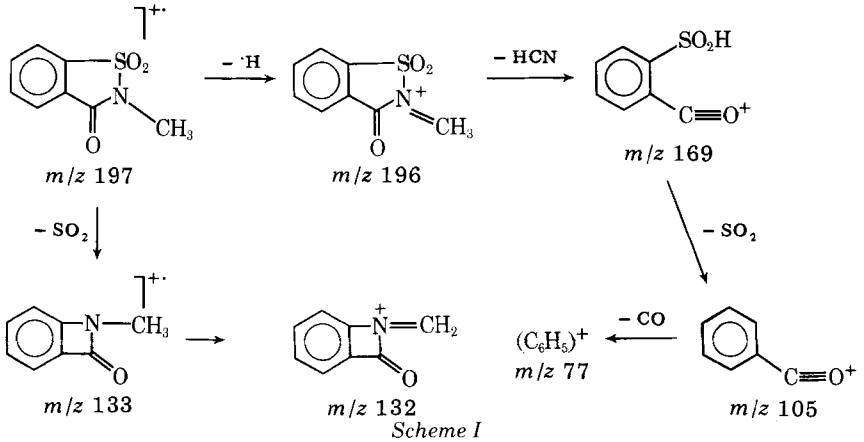

*Scheme I*

cases, the GLC conditions were as described, except that helium was the carrier gas.

**Extraction and Derivative Formation**—To 1 ml of plasma or urine, either 20 μg of ethylated I or 500 ng of trideuteromethylated I as the internal standard was added, depending on the expected concentration range and the type of detector used (flame ionization or mass fragmentography). The samples were deproteinized by the addition of 100 μl of trichloroacetic acid and then centrifuged at 4000×*g* for 20 min. The supernates were transferred to hermetically sealable glass tubes bearing a polytef disk in the inner part of the cap and were extracted with 5 ml of 0.5 *M* methyl iodide–methylene chloride solution after the addition of 70 μl of 10 *N* NaOH and 50 μl of 0.1 *M* tetrahexylammonium hydrogen sulfate solution in 0.1 *N* NaOH. Extraction was carried out for 2 hr by shaking at 60° in subdued light.

The organic phase (4 ml) was transferred to conical glass tubes and evaporated to dryness under a gentle nitrogen stream in a water bath at 35°. The residue was resuspended in 50 μl of methylene chloride, and the tetrahexylammonium salt was precipitated by the addition of 2 ml of *n*-hexane. The tubes were capped and centrifuged for 5 min at 4000×*g*. The supernatant fraction (1.8 ml) was transferred to conical glass tubes and evaporated to dryness under a nitrogen stream at 35°. The residue was dissolved in 50 μl of methylene chloride, and a 1–5-μl aliquot of this solution was injected for either GLC or mass fragmentographic analysis. Addition of I to drug-free plasma and urine samples at concentrations

**Table II—Plasma I Kinetic Parameters Determined in Four Healthy Volunteers Given a Single Oral Dose of 50 mg/60 kg of Body Weight**

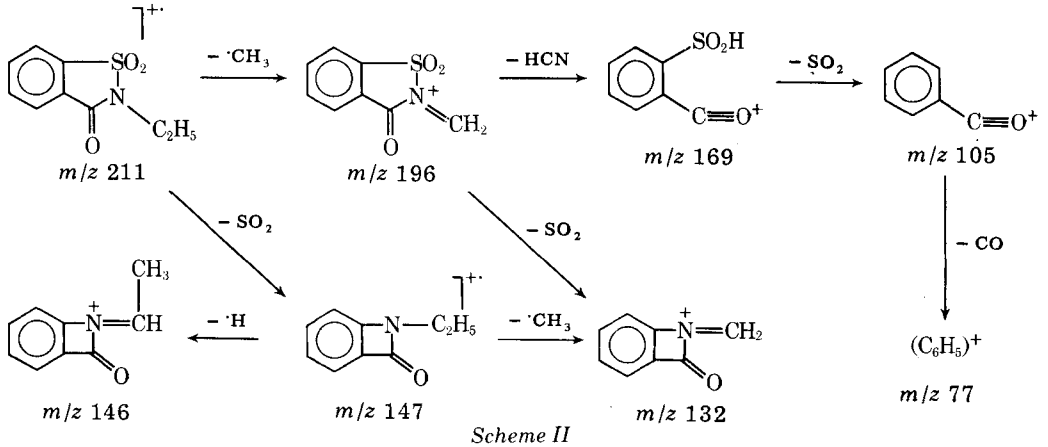
| Parameter[a] | $\bar{X} \pm SE$ |
|---|---|
| $K_a$, $min^{-1}$ | 0.045 ± 0.008 |
| $t_{1/2}$, min | 121 ± 16 |
| *AUC*, μg/ml hr | 5.02 ± 1.17 |
| Peak value, μg/ml | 1.95 ± 0.47 |
| Time of peak concentration, min | 30–60 |

[a] $K_a$ = rate constant of absorption, $t_{1/2}$ = half-life, and *AUC* = area under the curve.

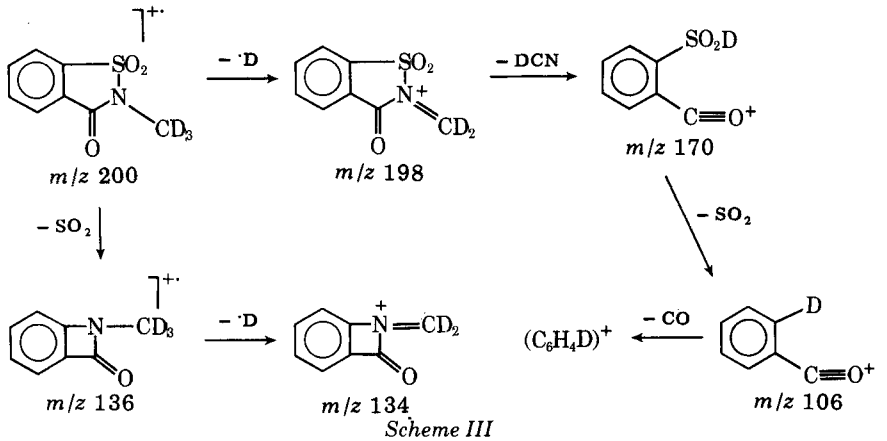
ranging from nanograms to micrograms resulted in overall recoveries of 51 ± 4 and 58 ± 3%, respectively.

**Preparation of Ethylated I and Trideuteromethylated I**—Ethylated I and trideuteromethylated I were prepared according to the described salt–solvent pair procedure by extracting I from water with either 0.5 *M* ethyl iodide or 0.5 *M* trideuteromethyl iodide–methylene chloride solutions.

**Studies in Humans**—In the single-dose experiment, four healthy male volunteers ingested a 0.1% solution of I in water (50 mg/60 kg of body weight) after an overnight fast. Venous blood samples were withdrawn 0, 5, 10, 20, 30, 45, 60, 90, 120, 180, and 240 min after I intake. Urine



*Scheme II*



*Scheme III*

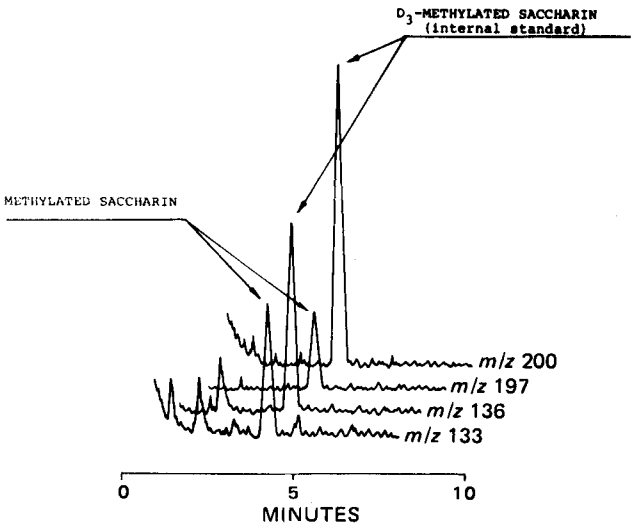


**Figure 4**—*Mass fragmentogram of a plasma extract from a human volunteer after I intake.*

samples were collected at selected intervals up to 24 hr.

In the repeated-dose experiment, another four healthy male volunteers were given I orally at a dose of 130 mg/60 kg of body weight/day for 5 days. These subjects were free to divide the amount of I into three doses daily to be taken between 7 am and 8 pm with meals. On Day 5, plasma and urine samples were collected at regular intervals over 24 hr.

**Data Analysis**—Plasma kinetic parameters of I were determined by the method of residuals (4), and the values of the area under the curve (*AUC*) were determined by the trapezoidal rule (5).

## RESULTS AND DISCUSSION

Figure 1 shows typical chromatograms obtained from the urine extracts of human volunteers before and after intake of saccharin (I). Peak a corresponds to methylated I, and peak b corresponds to an ethylated I structural analog chosen as the internal standard.

[a] Only three values available.

The chemical identity of these peaks was verified by combined GLC–mass spectrometry, and the resulting mass spectra are shown in Fig. 2. The mass spectrum of methylated I showed a prominent molecular ion at *m/z* 197; other intense fragments were present at *m/z* 133 (base peak), 132, 105, 104, 77, and 76, which arose as proposed in Scheme I. The mass spectrum of ethylated I was also consistent with the proposed structure, a molecular ion being present at *m/z* 211 and other intense fragments as shown in Scheme II.

For I determinations at nanogram concentrations, a mass fragmentographic procedure with trideuteromethylated I as the internal standard was used. Trideuteromethylated I has similar physicochemical properties to methylated I, resulting in an identical retention time. The use of such an internal standard reduces column adsorption losses and, consequently, increases the sensitivity.

Figure 3 shows the mass spectrum of trideuteromethylated I. For this compound, the assigned chemical structure was confirmed by the characteristic pattern of fragmentation (Scheme III), which was similar to that of methylated I. Therefore, stable isotope dilution mass fragmen-

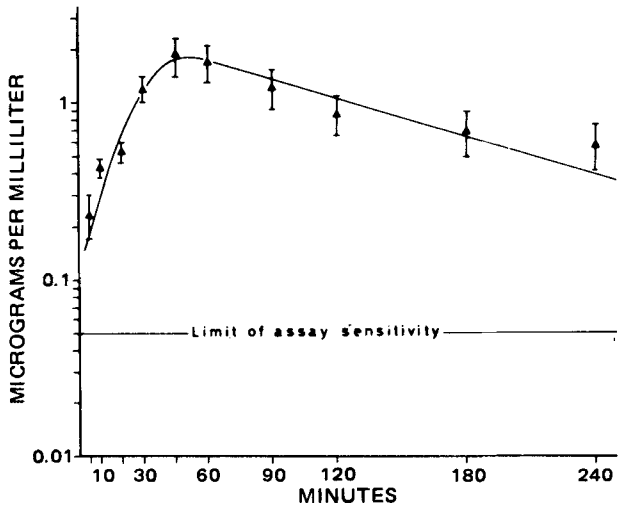

**Figure 5**—*Plasma I kinetics in four healthy volunteers given a single oral dose of 50 mg/60 kg of body weight.*

Table V—Urinary I Excretion by Four Human Volunteers Given 130 mg/60 kg po for 5 Days

| Time Interval | I Concentration, mg |
|---|---|
| 2000–0800 | 13.13 ± 2.30 |
| 0800–1200 | 20.03 ± 1.68 |
| 1200–1600 | 37.44 ± 7.31 |
| 1600–2000 | 29.06 ± 9.31 |
| Excretion, 24 hr | 89.03 ± 15.01 |
| Percent of administered dose | 80.35 ± 14.08 |

tography was carried out by focusing the instrument on the molecular ions of methylated I and trideuteromethylated I occurring at $m/z$ 197 and 200, respectively, and on the fragment ions at $m/z$ 133 and 136, which arise from the loss of sulfurous anhydride from the molecular ions. Figure 4 shows a typical mass fragmentogram obtained from a human plasma extract after I intake.

During both GLC with flame-ionization detection and mass fragmentography, no interference due to endogenous substrates was observed. Good linearity in detector response also was found over a concentration range of 50 ng/ml–10 μg/ml with multiple-ion detection mass fragmentography and from 2 μg/ml up to milligram levels for GLC with flame-ionization detection. The precision (percentage coefficients of variation) was calculated from the standard deviation/mean × 100. Assays were made in quadruplicate at six concentrations of I, thus covering the range expected in *in vivo* experiments. The results summarized in Table I refer to determinations from human plasma and urine.

The validity of this method for *in vivo* determinations was tested by studying the plasma kinetics and urinary elimination of I in healthy volunteers after single (50 mg/60 kg of body weight) or repeated (130 mg/60 kg of body weight/day for 5 days divided over the three main meals) oral doses.

Figure 5 shows plasma I kinetics in human volunteers after acute administration. The compound was absorbed rapidly through the GI tract, reaching peak plasma values between 30 and 60 min. Elimination of I followed a monoexponential decay pattern with a calculated half-life of 121 ± 16 min at the times considered (Table II).

Table III reports the plasma I levels determined in the volunteers given repeated oral doses. Concentrations were higher close to the time of I intake, *i.e.*, breakfast, lunch, and dinner. The *AUC* was about half that after a single dose of 50 mg/60 kg of body weight, although the daily dose was almost 2.5 times larger. However, these differences probably arose from differences in absorption since I was taken with food and not in a fasting condition and since the total daily dose was divided *ad libitum*, an experimental condition that may be considered closer to the real situation.

Urinary I excretion by human volunteers given a single oral dose is reported in Table IV. Compound I was eliminated within a few hours of administration, with ~60% of the dose being excreted unchanged by 6 hr, and reached 79.9% at 24 hr. Excretion of I after repeated administration is shown in Table V. Following this schedule of treatment, the 24-hr excretion again amounted to ~80% of the daily dose. These data are in good agreement with previous reports indicating that I is excreted in the urine rapidly and almost completely in humans and laboratory animals (6, 7). This observation is consistent with the relatively short plasma half-life of I, which is poorly metabolized.

# Size Exclusion Chromatography of Liposomes on Different Gel Media

**GUSTAF JEDERSTRÖM ˣ and GRAHAM RUSSELL**

Received July 24, 1980, from the *Pharmaceutical Research Department, Pharmacia AB, Box 181, S-751 25 Uppsala 1, Sweden.* Accepted for publication January 7, 1981.

**Abstract** □ Uncharged and negatively and positively charged liposomes of egg lecithin were prepared by sonication and chromatographed on three different gel media. The column effluent was investigated by turbidimetric measurements. The operational parameters were selected to obtain baseline separation of the liposomes. Liposome peaks were fractionated and identified by their $K_{av}$ (distribution coefficient) values. Baseline separation into two fractions was obtained with cross-linked dextran gel, and three fractions were obtained with cross-linked agarose gel.

**Keyphrases** □ Liposomes—synthesized and fractionated using size exclusion chromatography on different gel media □ Size exclusion chromatography—of liposomes on different gel media □ Fractionation—size exclusion chromatography of liposomes on different gel media □ Chromatography, size exclusion—liposomes, synthesized and fractionated on cross-linked agarose and cross-linked dextran gels

Parenteral and oral dosage forms with increased drug selectivity are achieved by linking drugs to carriers. Such forms are of pharmaceutical importance, and several concepts using liposomes have been suggested (1, 2). Liposomes are formed when phospholipids are allowed to swell in aqueous media. When suitably dispersed, the liposomes consist of a series of concentric lipid bilayers, which alternate with aqueous compartments. The bilayers and aqueous compartments can entrap lipid-soluble and water-soluble substances, respectively.

Size exclusion chromatography[1] (3) commonly is used to separate liposome-entrapped substances from nonentrapped material (4–6), but there has been little evaluation of different gel media for their ability to separate liposomes of different sizes. Huang (7) described the separation of vesicles of homogeneous size by using size exclusion chromatography on a gel with 4% agarose. Chen and

[1] Gel filtration traditionally is used to describe separation according to size on soft permeation media in aqueous solution (3). However, the term size exclusion chromatography is now recommended by the International Union of Pure and Applied Chemistry.

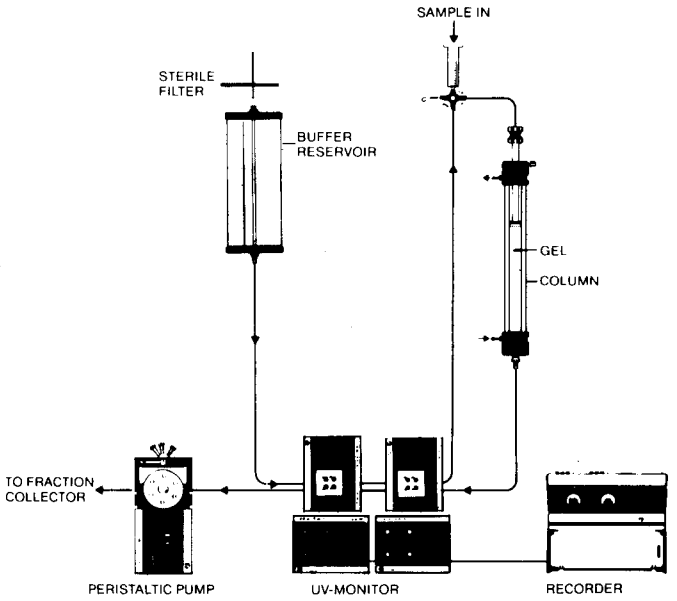

**Figure 1**—*Equipment for size exclusion chromatography.*

Schullery (8) suggested the separation of multilamellar vesicles from small unilamellar vesicles and sonication degradation products using 2% agarose gel.

This study investigated the ability of three different gels to separate liposomes into different fractions. Uncharged and negatively and positively charged liposomes were studied.

## EXPERIMENTAL

**Materials**—The uncharged liposomes were composed of egg lecithin[2]–cholesterol[3], 41:12 μmoles (33:4.64 mg). The negatively charged liposomes were composed of egg lecithin–cholesterol–phosphatidic acid[4]–dicetyl phosphate[5], 41:12:(mol. wt. unknown):6 μmoles (33:4.46:10:3.24 mg). The positively charged liposomes were composed of egg lecithin–cholesterol–stearylamine[6], 41:12:6 μmoles (33:4.46:1.6 mg).

The buffer was 3 m*M* sodium phosphate[5] (pH 7.3), containing 0.9% NaCl; it was sterilized at 121° for 25 min. Two cross-linked gels of 2[7] and 6%[8] agarose and cross-linked dextran gel[9] were used. To determine the fractionating range ($V_0 \rightarrow V_t$) of the gel bed in one separate run, a test solution was prepared from *Serratia marcescens* (ATCC 14756), which was chemically sterilized with pyrocarbonic acid diethyl ester ($V_0$), and sodium azide was dissolved in the buffer ($V_t$). Thirty microorganisms and 1 mg of sodium azide/1 ml of buffer were used.

**Preparation of Liposomal Dispersions**—Positively and negatively charged and uncharged liposomes were prepared aseptically according to a reported method (9). All glassware in contact with the preparations was sterilized by dry heat. Lipids and amphiphiles were dissolved in 5–8 ml of chloroform[10] in a 50-ml flask. The air in the flask was replaced by nitrogen or argon gas filtered through a 0.2-μm membrane filter. The organic solvent was removed in a rotary evaporator[11] at 25°, and evaporation was continued for 30 min. A thin, uniform film was visible on the wall of the flask.

Nitrogen was flushed into the flask, and 0.1–0.2 ml of the buffer solution was added immediately. Disruption of the lipid film was made by gently shaking the flask manually. A milky dispersion resulted after rotation of the flask with 1.8–1.9 ml of buffer and a few sterile glass beads.

The dispersion was stored at 4° for 12–24 hr. Before further treatment, the dispersions were inspected for microbial contamination. Only sterile dispersions were used for further investigation.

**Sonication**—The probes and glassware in contact with the product were sterilized by heat at 160° for 2 hr. Samples were sonicated[12] under nitrogen flush at 0–2°. Liposomal dispersions were transferred from a milky dispersion into a colloidal state when the sonication time exceeded 3 min at an amplitude of 8 μm. A homogeneous colloidal state, *i.e.*, a clear solution, was obtained when sonication was continued for 6 min at 8 μm followed by 2 min at 4 μm. The solution was inspected visually in polarized light immediately after preparation and, for some of the dispersions, after a month. Visually, the colloidal state was unchanged.

**Centrifugation**—All sonicated samples were centrifuged[13] at 2000 rpm for 10 min to remove titanium particles and unidentified fragments. The supernates were collected for evaluation.

**Absorption Spectra**—The absorption of the liposome components, individually and admixed, and of sonicated liposomes was measured between 600 and 200 nm with a recording double-beam spectrophotometer[14]. The concentration of all samples was identical to the concentration used in the liposomes. For components insoluble in water, chloroform was used as the solvent and reference. For liposome dispersions, the buffer was used as the external phase and as a reference.

**Size Exclusion Chromatography**—Two cross-linked agarose (2 and 6%) gels and a cross-linked dextran gel were used. These gel media have an effective fractionation range for globular proteins with a molecular weight between $2 \times 10^4$ and $3 \times 10^7$ daltons, which was of the same order as the liposomes under investigation. All material that would come in contact with the liposomes was sterilized. The gels were autoclaved at 121° for 25 min and then packed into the columns[15] and eluted with the buffer.

Effluent absorption was measured continuously with two UV monitors[16] coupled in series. The first monitor measured UV absorption at 254 or 280 nm. The second monitor was equipped with a high transmittance filter[17], which transmitted the mercury line 546 nm. The 254–280- and 546-nm readings were used to distinguish liposomes of different sizes on an empirical basis. For optimal detector performance, buffer was flushed continuously through the reference cells before entering the column. The effluent was collected in fractions of 0.8–1.2 ml using a fraction collector[18]. The equipment for size exclusion chromatography and the coupling for optimal detector performance are shown in Fig. 1.

The elution characteristics of each gel were determined by eluting 1 ml of the test solution through the column at 20 ± 1°. Flow rates (Table I) were kept constant and were adjusted with a peristaltic pump[19] or hydrostatic pressure. Figure 2 shows the elution profile of the test solution. The void volume ($V_0$), the total volume ($V_t$), and the operational volume ($V_t - V_0$) for each gel were determined as indicated in Fig. 2. The column parameters are presented in Table I.

The distribution coefficients[20] ($K_{av}$) were calculated from the elution

| Cross-linked 6% agarose | 1.6 × 20 | 14.2 | 28.5 | 1.22[a] | 8.1 | 27.2 | 19.0 |
| Cross-linked dextran | 1.6 × 20 | 14.2 | 28.5 | 0.99[a] | 9.4 | 26.6 | 17.2 |

[a] Flow regulated by hydrostatic pressure measured by volume–time measurements.

volume of the peaks of fractionated liposomes ($V_e$), the void volume, and the total liquid volume to yield $K_{av} = (V_e - V_0)/(V_t - V_0)$ (10). Newly packed columns or columns cleaned with a buffer solution of high ionic strength were eluted with three samples of liposomes and then washed with a volume of buffer equal to double the operational volume of the respective column before any test sample was applied. Thus, reproducible $K_{av}$ values for the fractions were obtained. The liposomes were stored at 4–8° and kept at 20° for 2 hr before size exclusion chromatography. Size exclusion chromatography was performed within 24 hr after liposome preparation. Sample volumes were 1–2 ml.

## RESULTS AND DISCUSSION

The liposomal components, when measured individually or admixed, displayed relatively low absorption in the 600–200-nm range. However, a low maximum or measurable absorbance was observed at 254 nm. The absorbance for lecithin was 0.4. The other components had much less absorbance at this wavelength. When the components were mixed, the absorbance at 254 nm decreased to 0.24. No explanation for this observation can be offered.

The absorption of liposome dispersions gradually increased from 600

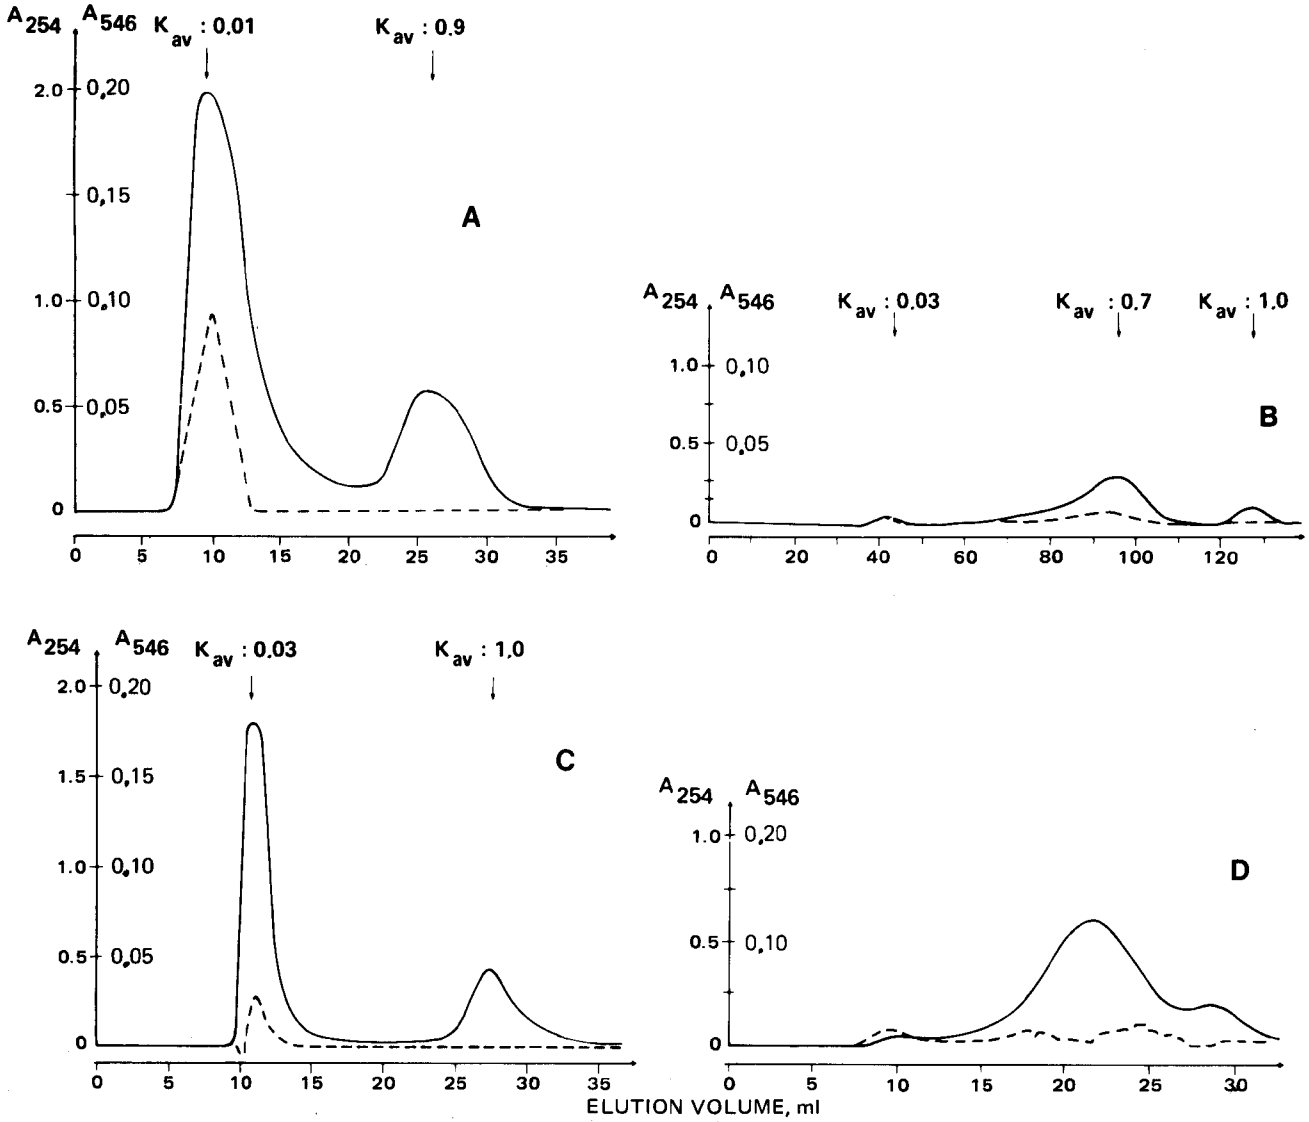

**Figure 3**—*Size exclusion chromatography of uncharged liposomes on different gel media. The eluent was phosphate buffer–saline (pH 7.3), and the temperature was 20°. [a] Different sizes of liposomes were separated and identified by $K_{av}$ values; $K_{av}$ given in parentheses.

to 200 nm. At 254 nm, the uncharged liposomes showed the lowest absorption of ~1.0. All charged liposomes had absorption of >2.0 at 254 nm. The measured absorption of liposomes was due to the light scattered by the particles and was not influenced by their individual components.

The two UV monitors for measuring the eluted peak profiles (Fig. 1) were used as turbidimeters since a decreased transmission was recorded.

Liposome fractions were separated by size, and these fractions were identified by their $K_{av}$ values. Fraction percentages were obtained by weighing the peaks of the liposome absorption profile at 280 nm (Table II).

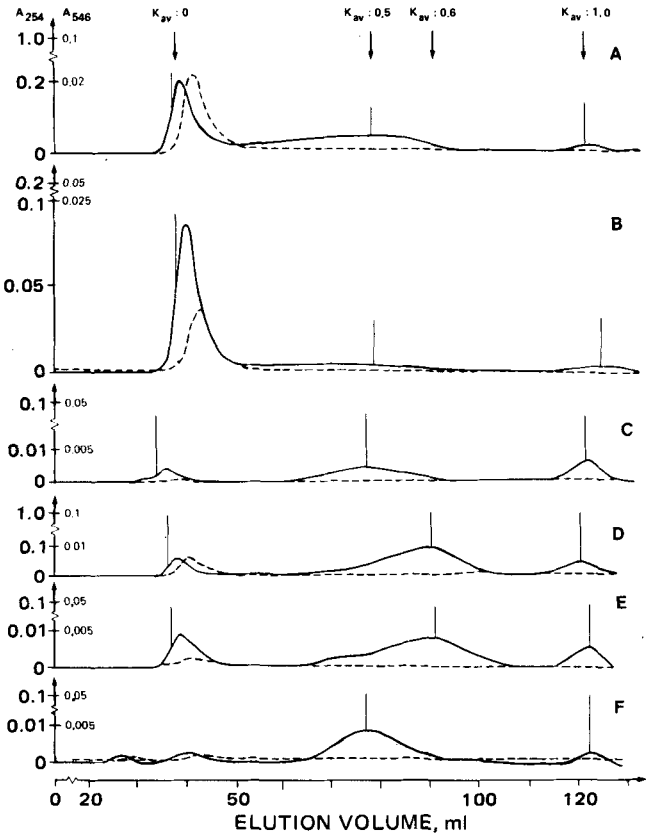

**Figure 4**—*Rechromatography of peak maxima of liposomes on cross-linked 2% agarose: operational volume, 88 ml; bed diameter, 1.6 cm; bed volume, 127 ml; flow rate, 0.19 ml/min; eluent, phosphate buffer–saline (pH 7.3), and temperature, 20°. Key: —, absorption profile at 254 nm; and - - -, absorption profile at 546 nm. A: Size exclusion chromatography of negatively charged liposomes (sample volume, 1.0 ml). B and C: Rechromatography of Peaks 1 (for B, sample volume was 2.0 ml) and 2 (for C, sample volume was 2.0 ml) from separated top fractions of negatively charged liposomes in A. D: Size exclusion chromatography of positively charged liposomes (sample volume, 1.0 ml). E and F: Rechromatography of Peaks 1 (for E, sample volume was 2.0 ml) and 2 (for F, sample volume was 2.0 ml) from separated top fractions of positively charged liposomes in D.*

Two fractions of uncharged, positively charged, and negatively charged liposomes were separated on cross-linked 6% agarose and cross-linked dextran. The largest fraction was eluted in the void volume ($K_{av}$ 0.05), and the other fraction was eluted in the total volume ($K_{av}$ 1.00). On cross-linked 2% agarose, uncharged and negatively and positively charged liposomes were separated into three fractions. The separation properties of different gel media for uncharged liposomes are shown in Fig. 3. Of cross-linked 6% agarose and cross-linked dextran, baseline separation for all liposomes could be obtained only with cross-linked dextran (Fig. 3C). Baseline separation into three different fractions was obtained for all liposomes with cross-linked 2% agarose with an operational volume of 80 ml (Fig. 3B). As the operational volume of the column was reduced (Fig. 3D), the peaks became incompletely separated.

In additional experiments with negatively and positively charged liposomes, fractions from the maxima of the first and second peaks (Fig. 4) were rechromatographed separately on the same gel (cross-linked 2% agarose). The first peak ($K_{av}$ 0.0) was eluted at the same position, but additional smaller peaks were obtained at $K_{av}$ 0.5–0.6 and 1.0. The second peak ($K_{av}$ 0.5–0.6) also emerged at the same position but with small peaks at $K_{av}$ 0.0 and 1.0. Similar results were observed for uncharged liposomes. The position of the peaks indicates that the separation properties of the gel were unchanged. The appearance of extra peaks may be due to a number of factors such as incomplete separation of liposomes, deformation of the liposomes when penetrating the gel pores, or a natural transfer of liposomes into an equilibrium state of different sizes. This observation indicates that size exclusion chromatography of liposome-entrapped material might lead to a loss of some entrapped material.

Chen and Schullery (8) also found three peaks when egg lecithin vesicles were separated on soft 2% agarose gel. The content of these peaks was found to be nonhomogeneous unless the liposomes were in rapid equilibrium. However, these investigators did not obtain a baseline separation. The assumption from the present study that the fractions obtained are homogeneous is supported by Huang (7), who concluded that a homogeneous fraction of vesicles is obtained on rechromatography on soft 4% agarose gel provided no equilibrium between fractions occurs.

Gregoriadis (11) suggested that the need for liposomes to persist in the blood for some time favors the small unilamellar version, indicating that the separation of liposomes into different sizes may be of great importance.

In conclusion, the experiments showed that macroporous agarose gels can be used to separate liposomes into well-defined fractions. These fractions will be investigated further by small-angle X-ray-scattering techniques.

# High-Performance Liquid Chromatographic Determination of Components of Bleomycin Preparations

**A. ASZALOS ˣ, J. CRAWFORD, P. VOLLMER, N. KANTOR, and T. ALEXANDER**

Received September 8, 1980, from the *National Center for Antibiotics Analysis, Food and Drug Administration, Washington, DC 20204.* Accepted for publication January 6, 1981.

**Abstract** □ A fast and sensitive method was developed for the quantitative determination of at least 10 components of pharmaceutical bleomycin sulfate preparations. The method is based on the reversed-phase high-performance liquid chromatographic (HPLC) separation of the components on a μBondapak $C_{18}$ column with a mobile phase having a linear gradient of 10–40% methanol in aqueous 0.005 *M* 1-pentanesulfonic acid at pH 4.3. With this assay, the average standard deviations for components $A_2$ and $B_2$ are 0.92 and 0.87, respectively, for a 7.5–22.5 × $10^{-3}$-mg sample. Regulatory agencies presently use the official Code of Federal Regulations (CFR) method, which is based on CM-Sephadex column chromatography. It was demonstrated that this CFR method does not separate the bleomycin $A_2$ component from some other minor bleomycin components. After elution from the CM-Sephadex column, the "$A_2$ component" was separated into five components by the HPLC method. Bleomycin $A_2$ is stable under these HPLC conditions.

**Keyphrases** □ High-performance liquid chromatography—reversed phase, bleomycin assay, separation of bleomycin components □ Bleomycin—high-performance liquid chromatographic determination, separation of components □ Antineoplastics—bleomycin, high-performance liquid chromatographic analysis

Bleomycins (I) are a family of glycopeptide antibiotics obtained from the fermentation broth of *Streptomyces verticillus* (1). Bleomycins are effective against various human neoplasms, particularly against squamous cell carcinoma, sarcoma, and malignant lymphoma (2–4). Preparations used in the treatment of these neoplasms contain several bleomycins. The main components are bleomycins $A_2$ and $B_2$. Some minor components such as bleomycin acid, demethylbleomycin-$A_2$, and bleomycin $B_4$ also are present. Among these minor components, bleomycin $B_4$ is the most toxic (5).

The Code of Federal Regulations (CFR) (6) requires that bleomycin preparations for therapeutic use meet the following composition specifications: bleomycin $A_2$, not less than 60% and not more than 70%; bleomycin $B_2$, not less than 25% and not more than 32%; bleomycin $B_4$, not more than 1%; and bleomycins $A_2$ and $B_2$ combined, not less than 90% of the total bleomycins. The present established method is based on a lengthy CM-Sephadex column chromatographic procedure, essentially that described by Fujii *et al.* (7).

Reported high-performance liquid chromatographic (HPLC) methods were unsuitable for routine quantitative analysis. With one method (8), baseline resolution was incomplete; another method (9) was not designed for quantitative purposes; and a third method (10), which could be used to determine bleomycins $A_2$ and $B_2$, did not

detect the minor components. The developed HPLC assay is suitable for the fast, quantitative determination of at least 10 components found in commercial bleomycin preparations.

## EXPERIMENTAL

**Materials**—Spectrograde methanol was used throughout the experiments. Acetic acid[1], concentrated ammonium hydroxide[2], and 1-pentanesulfonic acid[3] were used without further purification. Solvents were deaerated under vacuum with stirring for 1 hr before use. Sterile bleomycin sulfate preparations[4] in vials containing 15 units of bleomycin activity were dissolved in 3 ml of deaerated water and stored at 5°.

**Apparatus**—A modular high-pressure liquid chromatograph was equipped with a constant-flow pump[5], a valve-type injector[5], and a fixed-wavelength (254-nm) UV detector[6]. A stainless-steel column (4.6 × 250 mm) was packed with fully porous 10-$\mu$m silica particles to which a monomolecular layer of octadecylsilane was chemically bonded. In this work, generically identical column packing materials from two different suppliers were used (referred to as Columns 1[7] and 2[8]). Columns were washed with methanol–water (1:1) after use each day and with methanol before each weekend. Calculations for the percentage of total UV absorbance at 254 nm were performed for each component by a microprocessor[9] with the peak area calculation program (Figs. 1 and 2). The microprocessor was set as follows: sensitivity, 10%; attenuator, 16; and initial peak width, 0.5.

**Analytical Procedure**—The sample size for injection was 3-9 $\mu$l of bleomycin solution. The solvent system consisted of 0.005 *M* 1-pentanesulfonic acid in 0.5% acetic acid deaerated aqueous solution, adjusted to pH 4.3 (concentrated ammonium hydroxide), and methanol with a linear gradient of 10–40% methanol. Gradient mixing time was 60 min, but chromatography was continued with the final gradient mixture (40% methanol) up to 75 min to allow for the appearance of demethylbleomycin-$A_2$, the last peak. The column pressure at a flow rate of 1.2–1.8 ml/min, depending on column conditions, was equivalent to the initial column pressure of 1600 psi.

The relative percent of each bleomycin component was calculated on the basis of the area under the peak by the microprocessor with the given parameters.

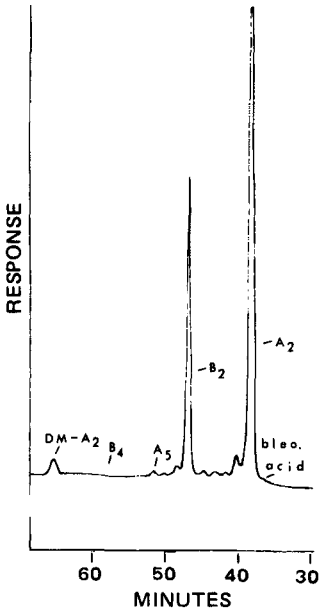

**Figure 1**—*HPLC separation profile of a bleomycin sulfate preparation obtained with Column 1 (6 $\mu$l of bleomycin solution injected). Key: bleo. acid, bleomycin acid; $A_2$, bleomycin $A_2$; $B_2$, bleomycin $B_2$; $A_5$, bleomycin $A_5$; $B_4$, bleomycin $B_4$; and DM-$A_2$, demethylbleomycin-$A_2$. Microprocessor quantitation indicates 58.29, 28.18, and 4.32 "relative %" composition for $A_2$, $B_2$, and demethyl-$A_2$, respectively.*

## RESULTS AND DISCUSSION

In developing this HPLC method, different parameters such as solvent, column, pH, operating time, gradient composition, and flow rate were investigated for optimum separation. Mobile phases of acetonitrile, acetone, or methanol with aqueous solutions of perchloric acid or 1-pentanesulfonic acid in dilute acetic acid were studied. With aqueous 0.005 *M* 1-pentanesulfonic acid solution, adjusted to pH 4.3, and mixed with 10–40% methanol in a linear gradient, 10 or more components were

detected. The last peak was observed at ~70 min, with a gradient mixing time of 60 min. Other gradient compositions and contours did not give satisfactory chromatograms. The same resolution of the 10 components was obtained between pH 4.0 and 6.0.

Another system that showed considerable promise was water, adjusted to pH 2.0 with perchloric acid, and mixed with 10–40% acetonitrile in a linear gradient. A separation profile like that in Fig. 2 was obtained, but the low pH of this solvent system made it impractical for routine use.

An initial column pressure of 1600 psi must be applied to obtain a flat baseline, suitable for area calculations with the microprocessor. Lower pressures result in baseline drift and poor area calculations. Typical separation profiles, obtained with Columns 1 and 2, are shown in Figs. 1 and 2, respectively. As used in this laboratory, Column 1 gave a better separation of the components. Specifically, the components between bleomycins $A_2$ and $B_2$ appeared as one peak with Column 2 but four peaks with Column 1. The quantitative results were comparable, however, for the bleomycin $A_2$, $B_2$, and demethyl-$A_2$ fractions from both columns; quantitative information for the $A_2$, $B_2$, and demethyl-$A_2$ fractions from the same sample is given for Columns 1 and 2 in the legends of Figs. 1 and 2, respectively.

The presumed identities of some individual peaks confirmed by coinjection of reference materials are shown in Fig. 1. No reference materials were available for the unidentified separated components.

Four bleomycin preparations were analyzed eight to 10 times each with Column 1 under the described HPLC conditions. These results (Table I), expressed as average percentages of the $A_2$ and $B_2$ components in bleomycin samples, were compared with those obtained by the official CFR method (6). The respective $A_2$ percentages obtained from the HPLC analyses were lower than those found by the CFR method. To explain this discrepancy, $A_2$ components isolated by the CFR method were collected from several column separations and combined, lyophilized, redissolved, and injected into the chromatograph. As shown in Fig. 3, the HPLC method separated this fraction into five components, with the major component having the retention time of bleomycin $A_2$. The amount of $A_2$ in this fraction was ~92% of the total bleomycin content of the fraction. After the $A_2$ percentages found by the CFR method were recalculated on the basis of the HPLC fraction separation, the official CFR column and HPLC results were in close agreement (Table I). This confirmation is significant since the accurate quantitation of bleomycins $A_2$ and $B_2$ in clinically used preparations is essential.

Bleomycin $A_2$ material collected from HPLC separations showed a single peak when rechromatographed by HPLC. This finding is evidence of the stability of bleomycin $A_2$ (and probably the other components) under these HPLC conditions.

Separate standard deviations for bleomycin $A_2$ and $B_2$ were calculated from multiple determinations of each component in four bleomycin samples (Table I). Calculations with these values give average standard deviations for components $A_2$ and $B_2$ of 0.92 and 0.87, respectively, and demonstrate good reproducibility for the HPLC assay.

# Amino Acid Esters of Phenols as Prodrugs: Synthesis and Stability of Glycine, β-Aspartic Acid, and α-Aspartic Acid Esters of p-Acetamidophenol

**ILDIKO M. KOVACH *, IAN H. PITMAN ‡×, and TAKERU HIGUCHI**

Received August 22, 1980, from the *Department of Pharmaceutical Chemistry, University of Kansas, Lawrence, KS 66045.* Accepted for publication January 7, 1981. *Present address: Department of Chemistry, University of Kansas, Lawrence, KS 66045. ‡Present address: School of Pharmaceutics, Victorian College of Pharmacy, Parkville, Victoria, Australia, 3052.

**Abstract** □ pH–rate profiles were calculated for the hydrolysis of the glycine (II), β-aspartic acid (III), and α-aspartic acid (IV) esters of p-acetamidophenol (I) at 25° and $\mu$ = 1.0 *M*. The hydrolysis of esters II and III occurred predominantly *via* intermolecular reactions involving water, hydroxide ion, and the various ionic forms of the substrates. The hydrolysis of ester IV occurred predominantly *via* intramolecular reactions. The catalytic effects of formate, acetate, and phosphate ions as well as of tromethamine on the degradation on ester II were similar to their effects on the hydrolysis of ethyl dichloroacetate. The efficient catalysis of the hydrolysis of ester II in bicarbonate buffers was consistent with a mechanism that involved carbon dioxide and the formation and decomposition of a carbamate intermediate.

**Keyphrases** □ Prodrugs—of p-acetamidophenol, amino acid esters □ p-Acetamidophenol—amino acid esters as prodrugs, synthesis and analysis □ Phenols—amino acid esters as prodrugs, synthesis and analysis □ Amino acid esters—as prodrugs of p-acetamidophenol, synthesis and analysis

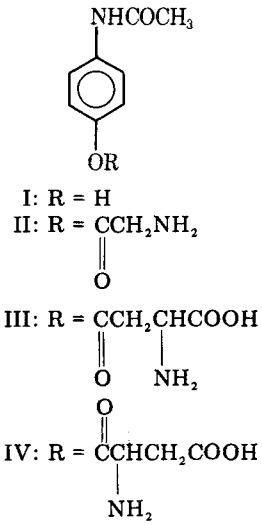
Amino acid esters of p-acetamidophenol (I) were proposed (1) as potentially useful prodrugs. Appropriate selection of the amino acid can yield derivatives having greater or less water solubility than p-acetamidophenol and a range of chemical stabilities with respect to transformation to the parent drug. When the amino acid is a normal dietary constituent, the transformation of the prodrug to I within the body will not yield a toxic byproduct.

Similar arguments can be used to support the investigation of amino acid esters of other phenolic drugs as prodrugs. This paper describes the synthesis and stability against degradation of the glycine (II), β-aspartic (III), and α-aspartic acid (IV) esters of I.

## RESULTS

**Characterization of Reactants**—The elemental analysis and NMR spectrum of the glycine (II) derivative of p-acetamidophenol (I) were completely consistent with the conclusion that it was the hydrobromide salt of II. The I esters of L-aspartic acid had elemental analyses and NMR spectra consistent with the conclusion that they were the hydrochloride salts of the isomers III and IV. Only one isomer could be obtained pure. This isomer was concluded to be ester III rather than ester IV because its pKa value (2.04) was closer to that of β-ethyl aspartate (2.00) (2) than it was to that of α-ethyl aspartate (3.04) (2). Its pKa value also was very close to the first pKa values of aspartic acid (1.88) (3) and histidine (1.78) (3), two molecules in which the carboxyl group adjacent to an ammonium group is the first to ionize. The greater reactivity of IV made it difficult to isolate and characterize.

**Decomposition of Esters II and III**—Esters II and III decomposed by hydrolysis in formate, acetate, and phosphate buffers. Plots of the observed first-order rate constants at each pH value, $k_{obs}$ values, *versus* the total concentration of buffer species, $[buffer]_T$, were linear over at least four buffer concentrations. Values of a buffer-independent first-order rate constant, $k_{hyd}$ values, were calculated from the *y* intercepts, when $[buffer]_T = 0$, of these plots. Values of $k_{hyd}$ are plotted *versus* pH in Fig. 1. Values of catalytic rate constants, $k_{cat}$, for the total buffer species were calculated in the case of hydrolysis of ester II from the slopes of the linear plots of $k_{obs}$ *versus* $[buffer]_T$.



The relationship among $k_{obs}$, $k_{hyd}$, and $k_{cat}$ values is given by:

$$k_{obs} = k_{hyd} + k_{cat}[buffer]_T \quad \text{(Eq. 1)}$$

Values of $k_{cat}$ for decomposition of ester II are listed in Table I.

For phosphate catalysis, a plot of $k_{cat}/f_{EH^+}$ *versus* $f_b$ [where $f_{EH^+}$ and $f_b$ are the fraction of II that exists as its conjugate acid and the fraction of the buffer acid ($H_2PO_4^-$) that exists as its conjugate base ($HPO_4^{2-}$), respectively, for data at the various pH values] was essentially linear with a zero intercept when $f_b = 0$. Hence, the major reactions involved $HPO_4^{2-}$ ions and the conjugate acid of II. On the assumption that the other re-

[a] Fraction of the buffer that exists as $HCO_3^-$, $CH_3COO^-$, $HPO_4^{2-}$, or tromethamine. The pKa values used in the calculations were the pH values of half-neutralized solutions of the acids or conjugate acids and were: $pKa^{HCO_2H}$, 3.53; $pKa^{CH_3COOH}$, 4.68; $pKa^{H_2PO_4^-}$, 6.38; and $pKa^{tromethamine}$, 8.18. [b] Fraction of ester II that exists as the conjugate acid (pKa = 7.44).

actions were similar, values of a pH-independent base catalysis constant, $k_b$ (which is equal to the value of the slope in the described type of plot), were calculated by dividing $k_{cat}$ values by the term $f_{EH^+}f_b$ (Table I).

The decomposition of ester II in tromethamine and carbonate buffers also was studied. In tromethamine buffers (pH 7.44 and 8.18), plots of $k_{obs}$ *versus* $[buffer]_T$ were linear, and $k_{cat}$ values were calculated in the manner described for oxyanion catalysis. At pH 9.22, a plot of $k_{obs}$ *versus* $[buffer]_T$ was paraboloid. This finding suggests that a reaction that was second order in tromethamine concentrations became important at higher pH. The reactions at higher pH were not studied further because they are unlikely to be important in biological systems.

The pH dependence of $k_{cat}$ values also was such that a plot of $k_{cat}/f_{EH^+}$ *versus* $f_b$ was linear with a zero intercept when $f_b = 0$. The value of the pH-independent rate constant, $k_b$, calculated from the slope of this line is given in Table I. This value is only approximate since $k_{cat}$ values were measured at two pH values only.

The hydrolysis of ester II in pH 6.00–8.85 buffers that contained various amounts of sodium bicarbonate was first order in sodium bicarbonate concentration. Phosphate buffers were used between pH 6 and 7, and tromethamine buffers were used at higher pH values. Plots of $k_{obs}$ for these reactions *versus* sodium bicarbonate concentration (up to $10^{-2}$ *M*) were linear, and the $k_{cat}$ values calculated from them are shown in Table II. At pH 6.0, this type of plot was linear up to $4 \times 10^{-3}$ *M* $NaHCO_3$. At higher concentrations, $k_{obs}$ values were independent of the sodium bicarbonate concentration. This behavior probably was caused by the fact that solutions at the higher concentrations were saturated with carbon dioxide.

**Decomposition of Ester IV**—The hydrolysis rate of ester IV was independent of the nature or composition of the buffer in all of the experiments. Hence, $k_{obs}$ values were concluded to be $k_{hyd}$ values (Fig. 1).

## DISCUSSION

The results of this study provide information on the stability *versus* degradation of three potentially useful prodrugs of *p*-acetamidophenol (I). However, analysis of the results also provides information about the effect of substituents in the acyl portion of phenolic esters on their hydrolysis rates. Such information can be used to design esters of other phenolic drugs as prodrugs.

**Mechanism of Water- and Hydroxide-Ion-Catalyzed Hydrolysis of Esters II–IV**—The line for ester II in Fig. 1 was calculated on the basis that the major reactions involved in its hydrolysis at pH 2–13 are:

$$EH^+ + H_2O \xrightarrow{k_A^{II}}$$
$$EH^+ + OH^- \xrightarrow{k_B^{II}}$$
$$E + OH^- \xrightarrow{k_C^{II}}$$

where E represents the ester neutral molecule and $EH^+$ is its conjugate acid in which the amino group is protonated. The rate law for these reactions is:

$$\frac{-d[E]_T}{dt} = k_{hyd}[E]_T = k_A^{II}[EH^+][H_2O] + k_B^{II}[EH^+][OH^-] + k_C^{II}[E][OH^-] \quad \text{(Eq. 2)}$$

where $[E]_T$ is the total concentration of ester at time *t*. The acid dissociation constant of the conjugate acid of ester II was determined to be $3.63 \times 10^{-8}$ at 25° and $\mu$ = 1.0 *M*. The values of $k_A^{II}$ (the water concentration was assumed to be 55.5 *M* in the computation of this second-order rate constant), $k_B^{II}$, and $k_C^{II}$ used to generate the line in Fig. 1 are included in Table III.

**Table II—Effect of pH on the Carbon Dioxide-Facilitated Decomposition of Ester II, $\mu$ = 1.0 *M*, 25°**

[a] Fraction of II that exists as a neutral molecule; pKa = 7.44. [b] Fraction of added sodium bicarbonate that exists as carbon dioxide or carbonic acid = 6.4.

The reaction pathway for the hydrolysis of II that is depicted as $EH^+ + OH^-$ is believed to predominate over the isokinetic pathway $E + H_2O$. This conclusion is based on the previously reported observation (4) that the second-order rate constant for the reaction between hydroxide ion and the methylbetaine methyl ester is virtually identical to that calculated for the reaction between $OH^-$ and the protonated glycine methyl ester. Only the latter compound could alternatively or concurrently be hydrolyzing by the isokinetic reaction; water catalyzed reaction of the neutral molecule. The similarity in the values of the second-order rate constants for the hydroxide-ion reaction strongly suggests that both compounds hydrolyze by the same mechanism.

Further support for this conclusion comes from the fact that the value of the ratio for ester II, $k_B^{II}/k_A^{II}$ ($3 \times 10^{10}$) is of the same order of magnitude as the ratio of the rate constants (5) for the specific base- and water-catalyzed hydrolysis of phenyl acetate ($10^{10}$). The leaving group tendencies of phenol (pKa 9.86) and I (pKa 9.49) are expected to be similar; therefore, the hydrolytic behavior of phenyl acetate appears to be a good model for the hydrolyses studied here. Since the ratio of $k_B^{II}/k_A^{II}$ for ester II is three times larger than the equivalent ratio for phenyl acetate, the presence of the positive charge in the cation of II probably favors hydroxide-ion attack more than it does water attack when these reactions are compared to the same reactions involving neutral phenyl acetate. Previous investigators (6, 7) observed a similar deviation when comparing the ratio of hydroxide-ion- and water-catalyzed hydrolysis rate constants for a series of $\alpha$-substituted *o*-nitrophenyl esters. They concluded that the enhancement for a reaction between hydroxide ion and a cationic ester could be accounted for better by postulating favorable electrostatic interactions in the transition state rather than by invoking electrostatic effects on collision frequency.

Comparison of the rate constants for the reaction between the neutral molecule of II and hydroxide ion ($k_C^{II}$) and between hydroxide ion and the acetate of I (8) indicates that the introduction of an amino group into the acetate (*i.e.*, an $\alpha$-amino group in the acyl moiety) increased the rate of this reaction 4.6 times. This figure is close to the fivefold increase in rate that follows the introduction of an amino group in the $\alpha$-position of ethyl acetate (4). Protonation of the amino group in ester II produced a further 100-fold increase in rate. Hence, the introduction of the $^+NH_3$ group into the acyl moiety of the acetate of I produced a 500-fold increase in the magnitude of the hydroxide-ion catalysis constant. This figure is considerably larger than that (150) found (9) for the introduction of $^+NH_3$ into the acyl portion of ethyl acetate. The difference in magnitude of these two figures is consistent with the generally accepted postulate that the rate of formation of a tetrahedral intermediate is the rate-determining step in the hydroxide-ion-catalyzed hydrolysis of phenolic esters (10), whereas the rate of breakdown of a tetrahedral intermediate also is in-

volved in determining the hydrolysis rate of esters of more basic alcohols (11). Hence, a substituent such as $^+NH_3$, which acts primarily by stabilizing the transition state for tetrahedral intermediate formation (6, 7), should have a greater effect on the hydrolysis rate of phenolic esters than on esters of aliphatic alcohols.

The line for ester IV in Fig. 1 was calculated on the basis that the major reactions of the α-aspartic acid ester (IV) between pH 1.5 and 11.0 were:

$$EH^{\pm} \xrightarrow{k_A^{IV}} \text{products}$$
$$E^- \xrightarrow{k_B^{IV}} \text{products}$$

where $E^-$ and $EH^{\pm}$ are the zwitterion and anion of the ester, respectively. The rate law for these reactions is:

$$\frac{-d[E]_T}{dt} = k_{hyd}[E]_T = k_A^{IV}[EH^{\pm}] + k_B^{IV}[E^-] \qquad \text{(Eq. 3)}$$

The acid dissociation constants of ester IV could not be measured because of its extreme instability in water. However, it was expected that the values would be close to those of α-ethyl aspartic acid (2), *i.e.*, $9.12 \times 10^{-4}$ (for the cation ionizing to yield $EH^{\pm}$) and $3.16 \times 10^{-8}$ (for $EH^{\pm} \rightleftharpoons E^- + H^+$). The values of $k_A^{IV}$ and $k_B^{IV}$ that were used to calculate the curve in Fig. 1 are listed in Table IV.

The pH–rate profile for the hydrolysis of ester IV is markedly different from that of the esters II and III. At pH values slightly above the pKa of the carboxyl group of IV (~3.0), the decomposition rate of IV surpassed that of its isomer, III, almost 900 times. Also, the decomposition rate of IV was not catalyzed by any buffer species used in this study, and it was pH independent when the concentration of the zwitterion or the anion of IV was essentially constant. These phenomena can be accounted for best by postulating that the predominant reactions were intramolecular carboxylate-ion-catalyzed reactions involving the zwitterion IV*a* between pH 2 and 6 and the anion IV*b* between pH 6 and 11. The first-order rate constants for the first two reactions, $k_A^{IV}$ and $k_B^{IV}$, are given in Table IV.

Similar mechanisms previously were proposed (8, 12) to account for the hydrolysis of the acid succinate ester of phenols including *p*-acetamidophenol. The pH–rate profile for the latter reaction (9) is shown as the dashed line in Fig. 1.

The hydrolysis of ester IV is subject to intramolecular nucleophilic catalysis, and its hydrolysis rate is much faster than that of the ester II between pH 2 and 10. It was shown previously (13) that both α- and β-aspartic acid esters of ethanol hydrolyze more slowly than the glycinate ester and that the pH–rate profiles for all three compounds have similar shapes. These results suggest that the predominant hydrolysis reactions of the aliphatic alcohol esters are intermolecular reactions and that intramolecular nucleophilic catalysis is not significant in aspartic acid esters with such strongly basic leaving groups at $C_2H_5O^-$.

The line for ester III in Fig. 1 was calculated on the basis that the major reactions that occurred during its hydrolysis were:

$$EH^{\pm} + H_2O \xrightarrow{k_A^{III}} \text{products}$$
$$EH^{\pm} + OH^- \xrightarrow{k_B^{III}} \text{products}$$
$$E^- + OH^- \xrightarrow{k_C^{III}} \text{products}$$

where $E^-$ represents the anion of III and $E^{\pm}$ is its zwitterionic form. The acid dissociation constant of III was calculated to be $5.01 \times 10^{-9}$ at 25° and $\mu = 1.0\ M$. Values of the microscopic rate constants were calculated in the same way as the corresponding values for ester II (Table III).

The pH–rate profile for the hydrolysis of ester III is similar in shape to that for ester II and differs significantly from that for ester IV. Hence, it can be concluded that the predominant hydrolysis reactions of ester III involve inter- rather than intramolecular reactions. Apparently, the $^+NH_3$ or $NH_2$ substituent adjacent to the carboxylate group in the zwitterion or anion of III makes cyclization so unfavorable relative to the

**Table IV—Values of Microscopic Rate Constants [a] for Hydrolysis of Ester IV in Aqueous Solution at 25°, $\mu = 1.0\ M$**

| Reaction | Rate Constant | Value, $min^{-1}$ |
|---|---|---|
| $EH^{\pm} \rightarrow$ products | $k_A^{IV}$ | 0.135 |
| $E^- \rightarrow$ products | $k_B^{IV}$ | 1.06 |

[a] Calculated by a curve-fitting technique from the data in Fig. 1.

succinate or α-aspartic acid esters that the intramolecular catalyzed reaction is unfavorable relative to the intermolecular reactions. The $k_C^{III}$ and $k_B^{III}$ values are smaller than the $k_C^{II}$ and $k_B^{II}$ values to the extent that could be expected (14, 15) to result from moving the $NH_2$ or $^+NH_3$ group one carbon atom farther away from the ester carbonyl group.

**Buffer Catalysis of Ester II Hydrolysis**—The catalytic effects of oxy anions (and water) on the hydrolysis of II were similar to what was found previously (16) for the same species on the hydrolysis of esters activated in the acyl portion such as ethyl dichloroacetate. This result is demonstrated by the linearity of the plot (Fig. 2) of log $k_b$ values for the reactions of II *versus* the log $k_b$ values for the reactions of ethyl dichloroacetate (log $k_0$). Although the leaving group in the hydrolysis of II is a phenolate ion (*i.e.*, a relatively weak base), it is expected (10) that the rate of breakdown of a tetrahedral intermediate rather than the formation rate would be the rate determining step for nucleophilic catalysis in the reactions of II and ethyl dichloroacetate that are catalyzed by water and the oxy anions except hydroxide ion. Furthermore, on the basis of previous arguments (10, 16), water and formate ion probably are acting as general base catalysts, acetate ion probably is acting as both general base and nucleophilic catalysts, and phosphate ion and hydroxide ion probably are nucleophilic catalysts.

The second-order rate constant for aminolysis of the II cation by a molecule of neutral tromethamine fell close to the line in Fig. 2. Thus, the characteristics of this aminolysis reaction apparently are also similar to those (16) of the aminolysis of other aromatic esters or of aliphatic esters activated in the acyl portion.

The catalysis of the hydrolysis of II in sodium bicarbonate solutions can be accounted for on the basis of the sequence of reactions (Scheme I) proposed by Hay and Main (17) to account for the carbon dioxide-catalyzed hydrolysis of *p*-nitrophenyl esters of glycine and other α-amino acids. Hay and Main observed that values of $k_{cat}/f_E f_{CO_2}$ for reactions of *p*-nitrophenyl esters of α-amino acids were pH independent, and they concluded that a rate-determining reaction between the α-amino acid ester and carbon dioxide was followed by the rapid formation of a Leuchs anhydride and *p*-nitrophenol.

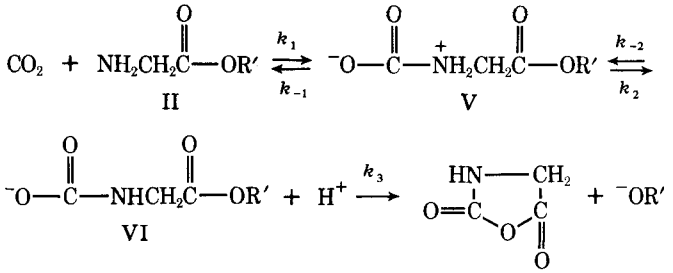
In contrast to this situation, values of $k_{cat}/f_E f_{CO_2}$ for reactions of ester II (Table II) in the presence of sodium bicarbonate were pH dependent throughout the 6.0–8.85 range. A plot of $f_E f_{CO_2}/k_{cat}$ *versus* the activity of hydrogen ion was linear ($r^2 = 0.999$) with an intercept of $5.43 \times 10^{-4}$ and a slope of $2.55 \times 10^4$ when $a_{H^+} = 0$.

This behavior can be accounted for by assuming that, under the experimental conditions, the concentration of carbamate remained essentially constant. This assumption leads to:

$$\frac{f_E f_{CO_2}}{k_{cat}} = \frac{k_3(k_{-1} + k_2) + k_{-1}k_{-2}a_{H^+}}{k_1 k_2 k_3} \qquad \text{(Eq. 4)}$$

where $f_{CO_2}$ is the fraction of bicarbonate buffer that exists as carbon dioxide and $f_E$ is the fraction of ester that exists as a neutral molecule.

This assumption requires that the decomposition rate of carbamate to yield the Leuchs anhydride and phenol is not much greater than the carbamate decomposition rate to yield reactants. Conversely, the conclusion that the formation rate of the carbamate from reactants is rate determining in the reactions of *p*-nitrophenyl esters infers that the decomposition of the carbamates to Leuchs anhydride and *p*-nitrophenol



Leuchs anhydride

*Scheme I*

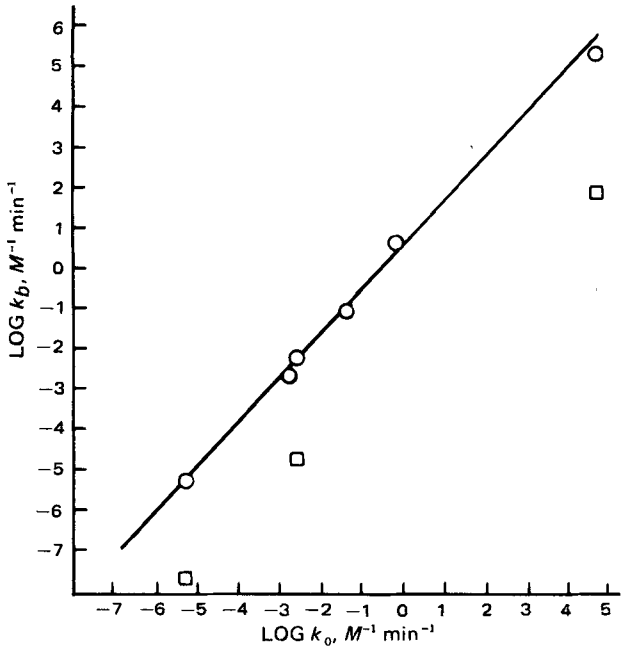


**Figure 2**—*Comparison of the second-order rate constants for the reactions of some general bases and nucleophiles with ester II* ($k_b$) (○) *to those for the reactions of the same reagents with ethyl dichloroacetate* ($k_0$). *The corresponding rate constants for the reactions of water, acetate ion, and hydroxide ion with phenyl acetate also are shown* (□).

in these reactions is substantially faster than its decomposition to yield reactants.

These conclusions are consistent with the expectation that *p*-nitrophenol is a better leaving group than *p*-acetamidophenol.

This efficient type of catalysis of amino acid ester hydrolysis by carbon dioxide is particularly interesting when considering the *in vivo* hydrolysis of amino acid esters of drugs since most biological fluids contain ~$3 \times 10^{-3}$ *M* $CO_2$.

## EXPERIMENTAL

**Materials**—All chemicals were reagent grade unless otherwise specified. Morpholine was dried over anhydrous calcium sulfate and distilled. Freshly boiled double-distilled water was used in all kinetic experiments.

***p*-Acetamidophenyl-*N*-carbobenzoxyglycinate (VII)**—A suspension of *N,N'*-dicyclohexylcarbodiimide (0.26 *M*) in dry methylene chloride was added to an equal volume in dry tetrahydrofuran of a solution of *p*-acetamidophenol (I), and the mixture was stirred at 0 ± 2° for 40 hr. Then *N,N'*-dicyclohexylurea, mp 22–29° [lit. (18) mp 29–30°], was filtered off (70% yield). Gradual reduction in volume of the filtrate under reduced pressure initially resulted in precipitation of I, which was filtered off, and then resulted in an ~1:1 mixture of *p*-acetamidophenol and VII. The filtrate finally yielded a syrup, which, after treatment with acetic acid to decompose excess *N,N'*-dicyclohexylcarbodiimide, filtration, and cooling, yielded more product. The crude ester, together with some I, was recrystallized from acetone, mp 140–142°.

**Hydrobromide of II**—A solution of hydrobromic acid (2–3 *M*) in acetic acid was prepared by bubbling the gas through the acid. The ester VII was dissolved in this solution (10 g/100 ml) and then stirred for 2 hr. Precipitation of the product was completed by the addition of ether–acetic anhydride (9:1). The crude product was washed with warm ether and acetone and recrystallized from methanol–acetone. The resulting product (80% yield) had a melting point of 228–230°; NMR ($D_2O$): δ 1.95 (s, 3H, $CH_3$), 4.05 (d, 2H, $CH_2$), 7.00 (d, 2H, aromatic H *ortho* to oxygen), and 7.24 (d, 2H, aromatic H *ortho* to amide).

*Anal.*—Calc. for $C_{10}H_{13}BrN_2O_3$: C, 41.5; H, 4.5; N, 9.7. Found: C, 41.3; H, 4.6; N, 9.5.

***N*-Carbobenzoxy-L-aspartic Acid Anhydride (VIII)**—One part of *N*-carbobenzoxy-L-aspartic acid, which had been dried and powdered, was mixed with three parts of acetic anhydride. The mixture was agitated for 1 hr and then allowed to react at room temperature for 15 hr. The product that precipitated when the solution was poured over ice was washed with cold water and ether. The waxy platelets had a melting point of 108–109°.

**α- and β-*p*-Acetamidophenyl-*N*-carbobenzoxy-L-aspartates (IX*a* and IX*b*)**—A solution of I in aqueous sodium hydroxide (equimolar) was cooled to 1°. A suspension of VIII in methylene chloride (1 mole of VIII to 2 moles of I) gradually was added to the cooled solution of *p*-acetamidophenoxide with constant stirring. The final ratios of water and methylene chloride in the mixture were 1:2. The mixture was stirred at 1° for 50 min, after which time the layers were separated. The aqueous layer was acidified with sufficient 5 *N* HCl to cause the separation of an oily layer and then was refrigerated. A pasty product, obtained following decantation of the supernatant liquid, was dried over phosphorus pentoxide *in vacuo*.

TLC of the product [on plates[1] impregnated with a 0.4 *M* formate buffer at pH 4; developed with ethyl acetate–butanol (4:1)] indicated that it contained I and two other compounds, which were subsequently identified as IX*a* and IX*b*. A 2% solution of the crude product in ethyl acetate was extracted in succession with pH 5, 0.4 *M* acetate–pH 6.3, 0.2 *M* sodium phosphate (5:1). TLC indicated that the more acidic buffer contained an almost pure sample of one of the isomeric esters. It was expected, and later confirmed, that this ester was the isomer with a pKa of 2.04 at 25°, and it was concluded to be IX*b*. Acidification of this solution yielded a white solid, mp 154–157°.

*Anal.*—Calc. for $C_{20}H_{20}N_2O_7$: C, 59.6; H, 5.0; N, 7.0. Found: C, 58.2; H, 4.9; N, 7.5.

The other buffer, upon acidification, yielded solids with lower melting points than IX*b*. TLC suggested that these solids were mixtures of IX*a* and IX*b*, but no successful method of separating them was found.

**Hydrochloride of III**—A catalyst consisting of 10% palladium-on-charcoal (18) was added to a 10% solution of IX*b* in dry methanol. Hydrogen was washed in dioxane and passed *via* a calcium chloride tube through the solution under moderate pressure for 5 hr. Precipitation of the product was completed by the addition of dry ether. The precipitated product was freed from the catalyst by elution with methanolic hydrochloric acid. Addition of ether to the eluent resulted in the precipitation of the hydrochloride of III which, after recrystallization from methanolic hydrochloride, had the following characteristics: mp 189–190°; NMR ($D_2O$): δ 1.95 (s, 3H, $CH_3$), 3.10 (d, 1H, $CH_2$), 3.25 (s, 1H, $CH_2$), 4.35 (q, 1H, CH), 7.00 (d, 2H, aromatic H *ortho* to oxygen), and 7.24 (d, 2H, aromatic H *ortho* to amide); pKa, 2.04 ± 0.06; $pKa_2$, 8.22 ± 0.06.

*Anal.*—Calc. for $C_{12}H_{15}ClN_2O_5$: C, 47.6; H, 5.0; N, 9.3. Found: C, 47.4; H, 5.0; N, 9.3.

**Mixture (50:50) of Hydrochlorides of III and IV**—When a mixture of the esters IX*a* and IX*b* was treated with hydrogen and catalyst in the manner previously described and the reaction mixture was filtered to remove excess catalyst and then reduced in volume, an ~50:50 mixture of the hydrochlorides of III and IV was recovered. This mixture had the same elemental analysis as the hydrochloride of III, but its NMR spectrum also contained peaks at δ 3.05 (d, 1H, $CH_2$), 3.19 (s, 1H, $CH_2$), and 4.67 (q, 1H, CH). The conclusion that the mixture was 50:50 was based on comparisons of the areas under the proton peaks.

**Acid Dissociation Constants**—Dissociation constants were measured at 25.0 ± 0.1° by using the potentiometric methods described previously (19).

**Rate Constants**—Rate constants were calculated from changes in UV absorbance at 282 or 242 nm that followed the mixing of solutions of the esters (usually 1–3 μl of aqueous solutions of II or III or a methanolic solution of III and IV) with aqueous buffers (2.5 or 5.0 ml). Reactions that had a half-life of <20 sec were followed on a stopped-flow spectrophotometer after equal volumes of aqueous solutions were mixed. The ionic strength of all reaction solutions was 1.0 *M* (adjusted with potassium chloride), and the temperature was maintained at 25.0 ± 0.1°. The buffers and pH ranges used were: formate, 1.9–4.1; acetate, 4.7–5.1; phosphate, 5.4–7.1; glycine, 9.8–10.5; tromethamine, 7.4–9.2; pyrophosphate, 7.7–9.0; morpholine, 8.3–9.3; carbonate, 9.85–10.7; and sodium hydroxide, >11.5. The initial substrate concentration was always $<10^{-3}$ *M*.

Pseudo-first-order rate constants for the hydrolyses of II and III were calculated from linear plots of log ($A - A_\infty$) *versus* time ($A$ and $A_\infty$ being the absorbance at a particular time and infinite time, respectively). Plots of log ($A - A_\infty$) *versus* time were biexponential for the hydrolysis of the mixtures of III and IV. Values of the rate constants for hydrolysis of III were calculated from the terminal slopes of such plots, and they agreed well with values that were determined using pure III. Values of the rate constants for hydrolysis of IV were calculated from the initial portions of the curves by using a feathering technique (20).

Rate constants were reproducible in at least three runs to within ±5%.

# Absorption and Bioavailability of Captopril in Mice and Rats after Administration by Gavage and in the Diet

**S. M. SINGHVI ˣ, K. J. KRIPALANI, A. V. DEAN, G. R. KEIM, J. S. KULESZA, F. S. MEEKER, Jr., J. J. ROSS, Jr., J. M. SHAW, and B. H. MIGDALOF**

Received June 27, 1980, from the *Departments of Drug Metabolism and Toxicology, Squibb Institute for Medical Research, New Brunswick, NJ 08903.* Accepted for publication January 6, 1981.

**Abstract** □ The absorption of captopril (I), a new antihypertensive agent, was studied in mice and rats at doses (50 and 1350 mg/kg) administered in the diet in chronic toxicological studies. $^{3}H$- or $^{35}S$-Labeled I was administered by gavage and in the diet to male and female animals in a two-way crossover study. Animals received daily doses of nonradiolabeled I in the diet for 25 days, except on Days 15 and 22 when radiolabeled I was administered either by gavage or in the diet. Absorption of the total radioactivity in 2-month-old mice averaged 49 and 48%, respectively, of the 50- and 1350-mg/kg doses given in the diet and 57 and 65%, respectively, of the doses given by gavage. The bioavailability of I in 2-month-old mice averaged 48 and 39% (diet) and 44 and 59% (gavage) of the 50- and 1350-mg/kg doses, respectively. In 2-month-old rats, absorption of the total radioactivity averaged 41% of the 50-mg/kg dose given in the diet. In 2- and 15-month-old rats, minimum absorption of the 1350-mg/kg dose averaged 36 and 45% (diet) and 51 and 71% (gavage), respectively; the minimum bioavailability averaged 29 and 29% (diet) and 39 and 44% (gavage), respectively. These studies demonstrate adequate absorption and bioavailability of I over a wide range of doses from the drug–diet mixtures and by young and old animals and also illustrate a useful experimental design for the estimation of relative oral absorption of a drug administered continuously in the diet over several days.

**Keyphrases** □ Captopril—absorption and bioavailability, gavage and dietary administration, mice and rats □ *Metabolism*—absorption and bioavailability of captopril, gavage and dietary administration, mice and rats □ Antihypertensives—absorption and bioavailability of captopril, gavage and dietary administration, mice and rats

Captopril (I), 1-[(2*S*)-3-mercapto-2-methyl-1-oxopropyl]-L-proline, is a potent and specific inhibitor of the enzyme that catalyzes the conversion of angiotensin I to angiotensin II (1) and was an orally effective antihypertensive agent in extensive clinical trials (2–4). The disposition of I in normal subjects was reported recently (5). Specific assays for determination of I as its *N*-ethylmaleimide derivative (II) also were reported (6, 7).

In oral toxicological and pathological studies over a 2-year period, I was administered daily in the diet to mice and rats at 50, 150, and 1350 mg/kg. The present study evaluated the effects of food and of repeated daily administration of 50- and 1350-mg/kg doses of I on its absorption and bioavailability in 2-month-old mice and rats and 15-month-old rats.

Investigations in animals and *in vitro* indicate that I is chemically unstable in biological fluids and undergoes rapid autoxidation to form III, the disulfide dimer of I, and other products. To prevent or minimize such processes, a procedure for immediate conversion of I to II in biological samples was established (5–7) (Scheme I). This procedure was utilized in the determination of nonlabeled I using GLC–mass spectrometry (7) and of radiolabeled I using thin-layer radiochromatography (6). Since radiolabeled I was necessary to determine absorption in the present study, thin-layer radiochromatography was used.

## EXPERIMENTAL

**Materials**—$^{3}$H-Labeled I (uniformly labeled in the proline moiety) and $^{35}$S-labeled I had radiochemical and chemical purities of at least 95%, with a maximum of 5% of III present as an impurity. No other impurities were detected. To administer sufficient radioactivity for good quantitation, each dose contained a minimum of 5 μCi (range of 5–40 μCi). Since the doses ranged from 50 to 1350 mg/kg and since there was an approximate 10-fold difference between the average weights of mice and rats, the specific activities of radiolabeled I also varied greatly, from 0.06 to 1.0 μCi/mg for $^{3}$H-labeled I and from 2.7 to 8.9 μCi/mg for $^{35}$S-labeled I.

**Animals**—Male and female CD-1 outbred albino mice and CD outbred albino rats[1] were used. All mice were ~2 months old at the start of the study and weighed ~35 (males) and 27 (females) g. Two-month-old rats weighed ~260 (males) and 170 (females) g, and 15-month-old rats weighed 550 (males) and 330 (females) g. All animals had access to food and water *ad libitum* and were housed individually in metabolic cages throughout the study.

**Experimental Design**—For each dose level and age group, 16 animals (eight males and eight females) initially were given 14 consecutive daily doses of either 50 or 1350 mg of I/kg (nonradioactive) admixed with the diet. On Day 15, half of the animals (four males and four females) received radiolabeled drug (tritium or sulfur 35) in the diet; the other half received radiolabeled drug in aqueous solution by gavage. Administration of the nonradioactive drug–diet preparation was resumed on Day 16. On Day 22 (crossover), the animals that had received the radioactive drug in the diet on Day 15 were given the radioactive drug in aqueous solution by gavage; those that had received the drug in aqueous solution by gavage on Day 15 were given the radioactive drug in the diet. Administration of the nonradioactive drug–diet preparation was resumed for 3 days. The animals were given a drug-free diet on the days they received the radioactive drug by gavage.

Urine and feces were collected every 24 hr for 4 days after each radioactive dose. To minimize I oxidation, urine samples for the first 2 days after drug administration were collected in vessels containing 2 ml of a 2.5% aqueous solution of *N*-ethylmaleimide (5).

In an early study using 2-month-old rats, single 50-mg/kg doses of radiolabeled I were administered in the diet to six (three males and three females) animals and by intravenous route to four (two males and two females) animals. Thus, in that study, repeated administration of nonradiolabeled drug was not employed, and the animals did not receive radiolabeled I by gavage. Additionally, in separate studies in 2-month-old mice, single 50-mg/kg doses of radiolabeled I were given intravenously to eight (four males and four females) animals, and single 650-mg/kg doses of radiolabeled I were given intravenously to four males. In these studies, urine and feces also were collected for 4 days.

In experiments where 16 animals were used initially, a few animals that received the drug by gavage died of trauma due to misdosing during the first or the second phase of the study. Data were obtained for less than 16 animals.

**Preparation, Administration, and Assay of Dose**—*Nonradioactive I*—The drug–diet preparation was prepared fresh each week. Compound I was mixed with an appropriate amount of ground diet[2] in a mixer[3] to give a drug concentration that provided an estimated daily dose of 50 or 1350 mg/kg. Homogeneity and stability of the drug–diet mixture prepared by this procedure were satisfactory. The animals were offered this drug–diet preparation each day, except when receiving radioactive drug. Food consumption and body weights were determined daily.

*Radioactive I*—Animals were weighed just prior to dosing, and doses were administered based on those weights. For each animal, an accurately weighed amount of radiolabeled I, corresponding to 50 or 1350 mg of drug/kg, initially was combined with an appropriate amount of feed. The feed and drug were mixed thoroughly on glassine paper with a spatula. To facilitate essentially complete consumption of the drug–diet preparation, the total weight of the feed mixed with the radiolabeled drug was ~0.5 g less than the average daily consumption of feed during the 3 days prior to dosing with radiolabeled drug.

The drug–diet preparation was transferred to individual feeding cups and offered to the animal. The material adhering to the glassine paper and spatula and that remaining in the feeding cup after 24 hr were transferred with methanol to a volumetric flask and assayed in duplicate for total radioactivity. The amount of radiolabeled drug consumed with the feed by each animal was determined by subtracting the total amount of radioactivity found in the combined washings from the total radioactivity added initially to the feed. For dosing by gavage, a solution was prepared fresh by dissolving radiolabeled I in distilled water.

**Liquid Scintillation Counting**—The scintillation cocktail of Anderson and McClure (8) was used to count all samples, except feces, in studies using [$^{3}$H]captopril. This cocktail contained 0.2 g of 1,4-bis[2-(5-phenyloxazolyl)]benzene, 3 g of 2,5-diphenyloxazole, and 250 ml of a nonionic surfactant[4], which were brought to volume (1 liter) with xylene. A saturated solution of sodium pyruvate in methanol, acetic acid, and methanol in a ratio of 4:3:1 (by volume) was used to neutralize the contents of the vials before counting. Individual samples were prepared as will be described.

Urine (0.1 ml) was mixed with 0.5 ml of a tissue solubilizer[5], 15 ml of scintillation cocktail, and 0.1 ml of the neutralizing solution. In studies using [$^{35}$S]captopril, fecal samples were shaken with ~2–3 volumes of water for 16 hr. A portion of the suspension (0.2 g) was digested by shaking for 16 hr with 1.0 ml of the solubilizer. The digested sample was bleached with 1.0 ml of 20% benzoyl peroxide and mixed with 0.1 ml of the neutralizing solution and 15 ml of the scintillation cocktail.

Silica gel scrapings from TLC plates were mixed with 1.0 ml of water and counted in 15 ml of the scintillation cocktail.

Fecal homogenates of animals dosed with [$^{3}$H]captopril were combusted in a sample oxidizer[6]. The resulting tritiated water was trapped in 20 ml of scintillation cocktail[7].

All samples were counted in liquid scintillation spectrometers[8]. Counting efficiencies were determined with automatic external standardization and the use of previously prepared quench curves. To correct for the decay of sulfur 35 radioactivity (half-life of 87 days), suitably diluted aliquots of the dosing solutions were counted with each set of biological samples.

**Thin-Layer Radiochromatography**—A thin-layer radiochromatographic assay of I was described previously (5, 6). In the present study, aliquots (20–100 μl) of urine were chromatographed on 0.25-mm silica gel GF plates[9] in chloroform–ethyl acetate–acetic acid (4:5:3). Compounds I, II, and III were used as reference standards and were visualized by exposure to iodine vapor; their $R_f$ values were 0.55, 0.42, and 0.34, respectively. Each TLC plate was divided into three zones based on the location of the reference standards. The zone in the 0.4–0.6 $R_f$ range, which included I and II, was used to determine unchanged I in the sample.

**Data Analysis**—Estimates of absolute absorption of total radioactivity and absolute bioavailability of I were obtained using urinary excretion data; the percentages of the dose excreted in urine as total radioactivity and as unchanged I after oral administration of I were divided by similar data obtained following administration of a single comparable intravenous dose of radiolabeled I.

Statistical analyses were performed using the Student *t* test and analysis of variance. Where necessary, the overall means were adjusted for the unequal number of animals in the different groups.

## RESULTS

For rats and mice at 50- and 1350-mg/kg doses in the diet and by gavage, there were no statistically significant differences in amounts of radioactivity recovered in urine and feces between the sexes or between the two phases of the crossover. Therefore, the data for all animals (males and females) and for both phases of the crossover were combined for each mode of administration, and the overall mean excretion values were determined for mice (Table I) and rats (Table II). For both modes of administration and in both species, most excretion in urine and feces occurred during the first 48 hr after dosing. Between 48 and 96 hr, <3% of the administered radioactivity was excreted in the urine and feces of mice and <8% was excreted in the urine and feces of rats.

**Absorption and Bioavailability in Mice**—For the 50-mg/kg oral dose, mean recoveries of radioactivity in urine were 37.2% (diet) and 43.8% (gavage) of the dose (Table I). Following a single intravenous dose (50 mg/kg), excretion of radioactivity in the 0–96-hr urine was 76.3% of the dose. Thus, the absolute absorption values for the oral radioactive doses

| | | 13 (7 M, 6 F) | *per os* (by gavage) | 51.2 ± 1.80 | 41.4 ± 1.45 | 92.6 ± 1.02 |
| 15 | 1350 | 13 (7 M, 6 F) | *per os* (in diet) | 45.1[c] ± 1.66 | 50.8 ± 2.71 | 95.9 ± 2.64 |
| | | 12 (6 M, 6 F) | *per os* (by gavage) | 71.2 ± 2.98 | 24.5 ± 3.21 | 95.7 ± 2.23 |

[a] All values are the mean ± *SEM*. [b] These values represent minimum absorption of the orally administered dose. [c] Significantly less than the mean for the gavage dose ($p < 0.05$).

were 48.8% (diet) and 57.4% (gavage). These values were not statistically significantly different ($p > 0.05$). Unchanged I excreted in the 0–24-hr urine accounted for 19.4% (diet) and 18.0% (gavage) (Table III). After intravenous administration of a comparable dose, unchanged I in the urine accounted for 40.5% of the dose. Therefore, the absolute bioavailability values for I after oral administration of 50 mg/kg were 47.9% (diet) and 44.4% (gavage). These values were not significantly different ($p > 0.05$).

Based on relative urinary excretion (as a percentage of the radioactive dose) after oral (1350 mg/kg) and intravenous (650 mg/kg) administration, absorption of the oral radioactive 1350-mg/kg dose was 47.6% (diet) and 65.4% (gavage) (Table I)[10]. Thus, absorption of the 1350-mg/kg dose given in the diet was ~73% of that given by gavage. Based on the excretion of unchanged I in urine (0–48 hr) after oral and intravenous administration, the absolute bioavailability of I from the 1350-mg/kg oral dose was 39.2% (diet) and 58.6% (gavage) (Table III). The differences in the absorption and bioavailability values for the two modes of administration were statistically significant ($p < 0.05$).

**Absorption and Bioavailability in Rats**—The absolute absorption of the oral radioactive dose (50 mg/kg) in 2-month-old rats was 40.5% based on recoveries of radioactivity in 0–96-hr urine of 37.7% (diet) and 93.0% (intravenous) of the administered dose (Table II). At the time this study was done, an assay for I was not available and bioavailability estimates could not be obtained.

Excretion in the 0–96-hr urine (representing minimum absorption) after administration of 1350 mg/kg in 2-month-old rats accounted for 35.5% (diet) and 51.2% (gavage) of the dose (Table II). Unchanged I excreted in the 0–48-hr urine (representing minimum bioavailability) accounted for 28.9% (diet) and 39.4% (gavage) of the dose (Table IV).

In 15-month-old rats (1350-mg/kg dose), excretion in the 0–96-hr urine (representing minimum absorption) accounted for 45.1% (diet) and 71.2% (gavage) of the dose (Table II). Unchanged I excreted in the 0–48-hr urine accounted for 29.2% (diet) and 44.0% (gavage) of the dose (Table IV). The differences in minimum absorption values for the two modes of administration were statistically significant in both age groups ($p < 0.05$). The differences in minimum bioavailability values for the two modes of administration were statistically significant for the 2-month-old rats ($p < 0.05$) but not for the 15-month-old rats ($p > 0.05$).

Since urinary excretion of total radioactivity and unchanged I after parenteral administration of 1350 mg of the drug/kg was not determined in rats, the values reported for absorption and bioavailability of I represent minimum estimates.

## DISCUSSION

During chronic oral toxicological studies, test substances are administered to rodents either by gavage or by incorporation in the diet. Boyd (9) reported that administration of the entire daily dose to animals by gavage reveals the maximum toxic potential of chronic human dosing better than administration of a compound in the diet. However, in a more recent pharmacokinetic study in rats, continuous dietary administration of an orally absorbed cephalosporin, cefatrizine, produced higher peak plasma concentrations, longer exposure, and greater drug bioavailability than administration of the same daily dose given once a day orally by gavage (10). Furthermore, in many cases, the convenience of administering a drug in the diet and the elimination of trauma and dangers of pulmonary complications caused by intubation make dietary drug administration the preferred mode during long-term toxicological studies. Moreover, for a drug that is given more than once a day for therapeutic efficacy, dietary administration in toxicological studies mimics more closely the therapeutic dosage regimen and, thus, has a better chance of showing potential accumulation than single daily doses administered by gavage. On the other hand, administration by gavage provides maximum control over quantitation and the dosing time and might be more suitable for drugs with long half-lives and whose absorption is severely impaired by the presence of food.

The present studies demonstrate that the absorption and bioavailability of I in mice and rats were satisfactory at doses of 50 and 1350 mg/kg given in the diet during repeated daily administration. There were no apparent differences in the absorption and bioavailability of I between males and females of either species. The data suggest that the absorption

[10] The comparison between 1350-mg/kg po and 650-mg/kg iv doses was considered to be valid since (in separate studies) absorption of I in the dose range of 50–650 mg/kg was found to be dose independent. The maximum nontoxic intravenous dose in mice was 650 mg/kg.

**Table III—Bioavailability of Captopril after Administration of Radiolabeled Captopril to Mice**

| Dose, mg/kg | Number of Mice | Route/Mode of Administration | Percent of Dose Excreted in Urine: Total Radioactivity | Percent of Dose Excreted in Urine: Unchanged Captopril | Bioavailability, % |

| 15 | 13 (7 M, 6 F) | *per os* (in diet) | 44.4 ± 1.62 | 29.2 ± 4.04 |
| | 12 (6 M, 6 F) | *per os* (by gavage) | 67.5 ± 2.50 | 44.0 ± 3.75 |

[a] All values are the mean ± *SEM;* the 0–48-hr urine was pooled for males and females separately in each group for thin-layer radiochromatography. [b] These values represent minimum bioavailability of the administered dose. [c] Significantly less than the mean for the gavage dose ($p < 0.05$).

and bioavailability of I were actually higher in 15-month-old rats than in 2-month-old rats. This observation indicates that animals were exposed to substantial amounts of I throughout the 2-year toxicological and pathological studies. In general, the absorption and bioavailability of I were greater after gavage doses than after the same doses given in the diet.

Although <19% (mice) and <39% (rats) of the administered dose were excreted as unchanged I in urine after oral administration, there was no evidence for any first-pass biotransformation or biliary excretion (and recycling) of I. In fact, the data in Table III indicate that the ratios of unchanged I to total radioactivity excreted in urine were comparable after oral and intravenous administration. In addition, fecal excretion after intravenous administration of I in rats (~9% of the dose) and in mice (~14% of the dose), in conjunction with biliary excretion of radioactivity determined in bile-cannulated rats (~10% of the dose) after oral administration of radiolabeled $I^{11}$, indicated little biliary excretion of I and its metabolites. Therefore, the lesser amount of unchanged I excreted in urine after oral administration as compared to intravenous administration appeared to be due to incomplete I absorption rather than first-pass biotransformation.

Repeated I administration did not significantly affect the extent of absorption or bioavailability of I in mice, based on a comparison of results obtained in the present studies with results obtained in previous studies in which single oral doses of I were given to fasted mice. The two-way crossover studies also illustrate a useful experimental design for the estimation of relative absorption of a drug administered continuously in the diet over several days. The effect of repeated administration on the absorption rate of I was not determined. However, all absorption and excretion measurements were carried out in animals that had received the drug for a minimum of 2 weeks.

# High-Performance Liquid Chromatographic Analysis of Iodochlorhydroxyquin in Plasma

**F. W. EZZEDEEN *, A. N. MASOUD ‡, S. J. STOHS *x, and S. J. LERMAN §**

Received September 25, 1980, from the **Department of Biomedicinal Chemistry, the* ‡*Department of Anesthesiology, and the* §*Department of Pediatrics, University of Nebraska Medical Center, Omaha, NE 68105.* Accepted for publication January 7, 1981.

**Abstract** □ A simple isocratic high-performance liquid chromatographic procedure for the analysis of iodochlorhydroxyquin in human plasma is described. Protein was precipitated using perchloric acid, and the supernatant and precipitated protein fractions were extracted with ether. The ether phases were evaporated to dryness, reconstituted in mobile phase, and chromatographed. A reversed-phase microparticulate $C_{18}$ column, a precolumn, and a UV detector at 256 nm were used. A mobile phase containing 80% methanol and 20% 0.05 *M* phosphoric acid was employed at a flow rate of 1 ml/min. Quantitation of iodochlorhydroxyquin in the 1–15-μg/ml range in human plasma was demonstrated with a coefficient of variance of 0.1–0.06. Hydrocortisone, which is used in combination with iodochlorhydroxyquin in ointments and creams, does not interfere in the assay.

**Keyphrases** □ Iodochlorhydroxyquin—high-performance liquid chromatographic analysis, plasma □ Anti-infectives—iodochlorhydroxyquin, high-performance liquid chromatographic analysis, plasma □ High-performance liquid chromatography—analysis, iodochlorhydroxyquin, plasma

Iodochlorhydroxyquin[1] (I) has been widely used as an antidiarrheal, antimycotic, and antibacterial agent in many countries.

Tamura *et al.* studied patients with subacute myelo-opticoneuropathy and found I chelated with iron as a green pigment in the urine and feces and also free I crystals in the urine (1). Subacute myelo-opticoneuropathy was subsequently shown to be caused by the long-term oral treatment and high dosage use of I (1–3).

## BACKGROUND

Because of the toxicity associated with the oral usage of I, various analytical procedures have been developed for its determination in biological fluids. Electron-capture GLC, which requires expensive instrumentation and tedious and time-consuming derivatization, has been used (1, 4–8). Tsuji *et al.* (9) reported a method whereby I was chelated with aluminum and measured fluorometrically. A spectrophotometric method also was reported for the determination of I and its conjugates in the urine (10, 11). The spectrophotometric procedure is not sufficiently sensitive for the determination of the drug in plasma or serum. A complicated and time-consuming TLC procedure also was reported (12).

High-performance liquid chromatography (HPLC) has become an increasingly popular analytical technique in clinical and forensic laboratories. A procedure dealing with the separation and analysis of glucuronide and sulfate conjugates of I in urine using HPLC was reported previously (13) but was incapable of assaying for unconjugated I, even when present in high concentrations in the urine (13). The drug occurs predominantly in the unconjugated form in plasma (3).

A single oral dose of I of ~8 mg/kg in humans produces maximum serum levels of 3–6 μg/ml (8). Little research has been conducted on the percutaneous absorption of I. Fischer and Hartvig (14) treated four patients with widespread dermatitis of an unstated type with an ointment containing 3% I, and serum I levels were estimated by electron-capture GLC to be 0.8–1.2 μg/ml.

This report describes the analysis of therapeutic I concentrations in plasma using HPLC. The procedure combines sensitivity, specificity, and simplicity not attainable by previously described methods.

[1] 5-Chloro-7-iodo-8-quinolinol; Vioform, Ciba Pharmaceutical.

## EXPERIMENTAL

**Apparatus**—An isocratic HPLC system assembled in this laboratory consisted of a reciprocating minipump[2]; a stainless steel tube, 6.35 mm (0.25 in.) o.d. and 4.76 mm ($^3/_{16}$ in.) i.d. × 1 m, as a pulsation damper; a 34.5-MPa (5000 psi) pressure gauge[3]; a fixed-volume sample injector[4] with a 20-μl loop; and a variable-wavelength UV detector[5]. A multivoltage 25.40-cm strip-chart recorder[6] was connected to the UV detector.

A microparticulate reversed-phase chromatographic column, 250 × 2.6 mm, packed with ODS-HC-SIL-X-I[7], and a 5 × 40-mm guard column, RP-18-MPLC[8], were connected to the HPLC system. The following reagents were used: iodochlorhydroxyquin[1]; ether anhydrous analytical reagent[9]; methanol distilled in glass, residue free[10]; concentrated perchloric acid; anhydrous sodium sulfate; and water, which was deionized, demineralized, and glass distilled in this laboratory. Iodochlorhydroxyquin (mol. wt. 305.52) decomposed at ~170°, and no impurities were detected by HPLC.

**Standards**—Stock solutions of I were prepared in methanol and contained 1 mg/ml and 100 μg/ml. These solutions could be maintained in the refrigerator for at least 2 weeks without deterioration. Working solutions were prepared fresh daily. Dilutions were made using 80% methanol and 20% 0.05 *M* phosphoric acid to prepare the working standards, which were used to spike plasma samples and to calculate recovery from plasma samples after extraction.

**Extraction**—Aliquots of 1.0-ml plasma samples were transferred to 15-ml screw-capped and polytef-lined centrifuge tubes. Human blood bank plasma was used for all studies. Aliquots of I working standard were used to spike the plasma samples. After the tubes were shaken by hand for 1 min, 100 μl of concentrated perchloric acid was added to each tube; then the tubes were vortexed for another 30 sec and centrifuged[11] at 5000 rpm for 10 min at 15°. Approximately 0.5 ml of the supernatant fractions were extracted twice with 5 ml of ether in 15-ml glass culture tubes with polytef-lined screw caps by vortexing for 10 sec, and the phases were separated by centrifuging for 10 min at 15°.

The protein precipitates were extracted once with 10 ml of ethyl ether by vortexing for 1 min and centrifuged as already described. The ether extracts were dried over anhydrous sodium sulfate[9] and evaporated to dryness at 38° under a nitrogen stream[12]. The residue from each fraction was redissolved in 500 μl of the mobile phase, and 20 μl of each was injected onto the column.

**Chromatography**—The parameters used throughout this investigation included a reversed-phase column and precolumn as previously described, a 20-μl injector loop, and the recorder chart speed set at 0.254 mm (0.1 in.)/min. A mobile phase containing 80% methanol and 20% 0.05 *M* phosphoric acid was used at a flow rate of 1 ml/min. The mobile phase was filtered using a 0.2-μm filter[13], degassed under vacuum, and maintained at 40° during chromatography. The UV detector was set at 256 nm. The column was flushed at the end of each day with 100% methanol. Not more than 30 min was required for column equilibration prior to use each day.

## RESULTS AND DISCUSSION

Suitable retention of I was obtained when a mobile phase containing 80% methanol and 20% 0.05 *M* phosphoric acid was used with the described reversed-phase column. A typical chromatogram of standard I in the mobile phase is presented in Fig. 1. The capacity factor ($k'$) for I was 1.14, calculated according to the following:

$$k' = \frac{Rt_1 - Rt_0}{Rt_0} \qquad \text{(Eq. 1)}$$

where the retention time for I ($Rt_1$) was 3.75 min and the elution time of unretained compounds or the solvent front determined by injecting methanol onto the column ($Rt_0$) was 1.75 min.

Figure 2A is a chromatogram of an extracted plasma supernatant fraction without I addition. Figure 2B is a chromatogram of I extracted from a spiked plasma sample following protein precipitation using perchloric acid. Direct extraction of plasma by ether without protein precipitation resulted in the presence of unknown compounds that interfered with I upon chromatography. Preliminary studies revealed that large amounts of I were precipitated with the proteins. Therefore, both the acidified supernatant and precipitated protein fractions were extracted with ether. Extractions of I at pH values from 1 to 8 with ether, methylene dichloride, and carbon tetrachloride also were conducted. In addition, the use of ammonium sulfate as the protein precipitating agent was attempted, but the extraction efficiency of I was very poor. Ether extraction of both the supernatant and precipitated protein fractions following perchloric acid addition was most efficient and reproducible.

The representative chromatograms presented in Figs. 3A and 3B were obtained from ether-extracted protein precipitate fractions of human plasma (blank) and a plasma sample to which 5 μg of I/ml had been added, respectively. Two interfering substances were present in ether extractions of the precipitated protein fractions. The first of these compounds ($X_1$), which has a retention time close to I, was present in much larger concentrations in the extracts from the precipitated protein fraction (Fig. 3) as compared to the ether extracts of the supernatant fractions (Fig. 2). The second substance ($X_2$) was extracted from the precipitated protein fractions (Fig. 3) but not from the supernatant fractions (Fig. 2) and had a retention time of ~16 min.

Table I shows the percent recovery of I following extraction of the supernatant and precipitated protein fractions, as well as total recovery following the addition of 1–15 μg of I/ml to plasma. Each value represents the mean of three determinations with the standard deviation. The

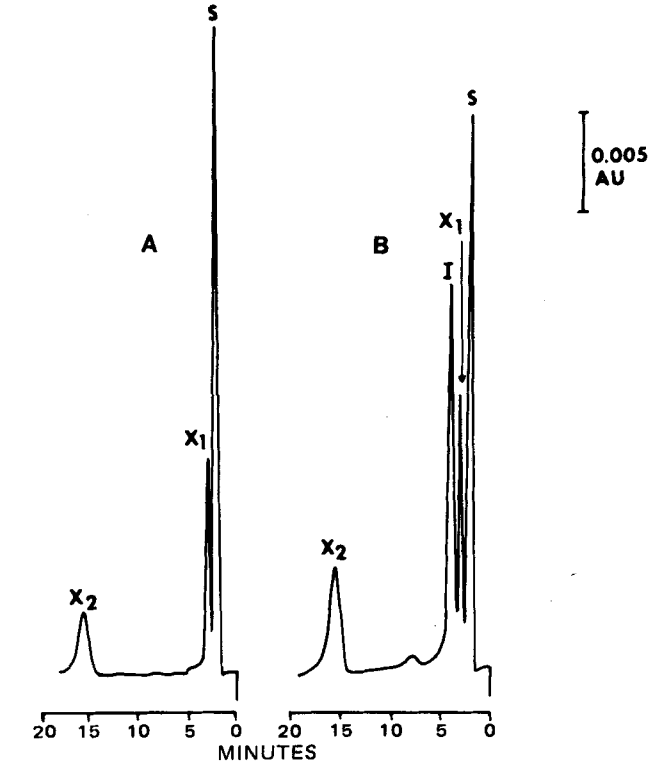

**Figure 3**—*Extraction of protein precipitate of a plasma blank (A) and of plasma containing 5 μg/ml (B). The detector was set at 0.05 aufs, and other chromatographic conditions are as described in Fig. 1.*

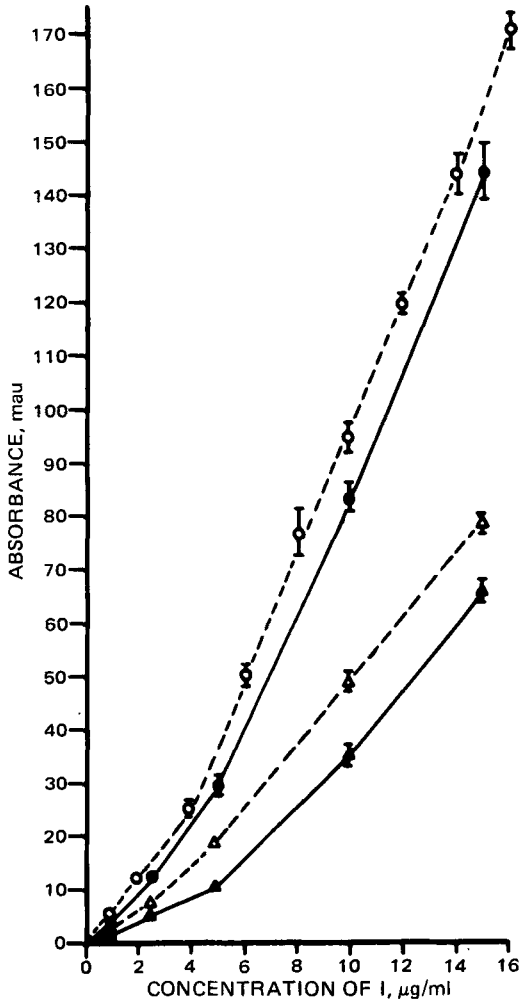

**Figure 4**—*Standard curve of iodochlorhydroxyquin. Key:* ▲—▲, *extracted supernatant fraction reconstituted in 500 μl of mobile phase;* △ - - △, *extracted precipitate fraction reconstituted in 500 μl of mobile phase;* ●—●, *mathematical summation of two aforementioned values; and* O - - O, *standard solutions diluted in the mobile phase. The peak height values were converted to reflect concentration in 500 μl to conform with values of extracted samples.*

coefficient of variance for each sample also is presented. From 28 to 41% of the total I added to plasma was recovered from the supernatant fraction, while 46–54% of I was recovered from the protein fraction. Total recovery of I was 77–91%.

The UV absorbance spectrum of I in the mobile phase exhibited two maxima at 256 ($\alpha = 0.15$) and 204 ($\alpha = 0.11$) nm. For optimum sensitivity, the detector was set at 256 nm. Standard solutions of I in the mobile phase were prepared at 1, 2, 4, 6, 8, 10, 12, 14, and 16 μg/ml, and 20-μl aliquots of each were injected. The standard curve for I is presented in Fig. 4. Each point on the graph represents the mean, and the bars represent the standard deviation of the mean for three injections. Some bars were omitted because the very small standard deviations of the mean could not be graphically represented.

The amounts of I extracted from the supernatant and precipitated protein fractions of plasma samples spiked with 1.0, 2.5, 5.0, 10.0, and 15.0 μg/ml of I are presented in Fig. 4. Concentrations of I higher than 15 μg/ml of plasma resulted in peak splitting for I upon HPLC. The reason for this effect is not known. The total I recovered at each concentration also is given in Fig. 4. Each point represents the mean, and the bars represent the standard deviation of the mean for three extractions. The correlation coefficients ($R$) for the standard curve for I, the extracted supernatant fraction, the extracted precipitated protein fraction, and the total extracted I were 0.995, 0.978, 0.995, and 0.992, respectively, where:

**Table I—Percent Recovery of Iodochlorhydroxyquin from Extracted Plasma** [a]

| Plasma Concentration, μg/ml | From Supernatant Fraction | From Precipitated Protein Fraction | Total |
|---|---|---|---|
| 1 | 30.0 ± 3.0 (0.17) | 54.0 ± 3.1 (0.09) | 84.0 ± 6.1 (0.12) |
| 2.5 | 30.8 ± 2.2 (0.11) | 45.9 ± 2.1 (0.07) | 76.7 ± 4.0 (0.08) |
| 5 | 28.0 ± 1.5 (0.09) | 48.9 ± 2.2 (0.07) | 76.9 ± 2.6 (0.06) |
| 10 | 35.8 ± 3.2 (0.17) | 50.4 ± 2.0 (0.07) | 86.2 ± 3.4 (0.07) |
| 15 | 41.3 ± 2.3 (0.08) | 49.5 ± 1.3 (0.04) | 90.8 ± 3.0 (0.06) |

[a] Each value is the mean with the standard deviation for three determinations. The values in parentheses are the coefficients of variance.

$$R = \frac{m\sigma_x}{\sigma_y} \qquad \text{(Eq. 2)}$$

The slope is:

$$m = \frac{\sum xy - \frac{\sum x \sum y}{N}}{\sum x^2 - \frac{(\sum x)^2}{N}} \qquad \text{(Eq. 3)}$$

where $\sigma$ is the standard deviation, $x$ is the concentration of I, $y$ is the peak height, and $N$ is the number of samples. The $y$ intercept is:

$$b = \frac{(\sum y - m)\sum x}{N} \qquad \text{(Eq. 4)}$$

The primary current application of I is as a topical antibacterial agent, and hydrocortisone is the drug most commonly found in creams and ointments in conjunction with I. Under the experimental conditions described, hydrocortisone elutes with the solvent front and is therefore easily resolved from I. The primary urinary metabolites of I are the glucuronide and sulfate conjugates; with the analytical system employed, these two compounds do not chromatograph.

The HPLC procedure described here provides a rapid and reproducible method for determining plasma I concentrations. Previously described methods are insufficiently sensitive to detect I in small plasma samples (10–12). Chromatography of I by direct ether extract was not possible due to interfering compounds. The most accurate and rapid assay for I was achieved by extracting the plasma supernatant fraction following protein precipitation with perchloric acid. Only a small amount of an unknown compound was extracted as compared to the extraction of two unknown compounds from the precipitated protein fraction.

# Influence of Serum Albumins on Decomposition Rates of *para*-Substituted 1-Phenyl-3-methyltriazenes and 5-(3-Methyl-1-triazeno)imidazole-4-carboxamide in Near Physiological Conditions

**FRANCO DELBEN *x, SERGIO PAOLETTI *, GIORGIO MANZINI *, and CARLO NISI ‡**

Received July 10, 1979, from the **Istituto di Chimica and the* ‡*Istituto di Chimica Farmaceutica, Università di Trieste, Trieste, Italy.*
Accepted for publication January 7, 1981.

**Abstract** □ The influence of human serum albumin on the decomposition rates of some arylmonomethyltriazenes in buffered aqueous solution was investigated. From the experimental data, a model for the triazene–albumin interaction was derived, and the thermodynamic parameters were systematically calculated by two independent methods. The results show marked dependence of the energetics of binding on the substituent in the triazene aromatic ring. For most of the triazenes studied, the binding with albumin was mainly enthalpy driven. Measurements also were performed using bovine and murine serum albumins.

**Keyphrases** □ Arylmonomethyltriazenes—decomposition rates, effect of human serum albumin □ Serum albumin, human—effect on decomposition rates of arylmonomethyltriazenes □ Binding kinetics—triazene–albumin interaction, decomposition rates □ Antitumor agents—arylmonomethyltriazenes, effect of human serum albumin on decomposition rates

Aryldimethyltriazenes are a class of compounds possessing antitumor (1–4), carcinogenic (5–7), and mutagenic (8–10) activities. Evidence exists that metabolites of these triazenes are responsible for their *in vivo* effects. Monomethyltriazenes, produced by oxidative *N*-demethylation of the parent dimethyl compounds, are considered as possible metabolic species active at a systemic level (2, 11, 12) since they can alkylate cellular components by hydrolysis (13). Arylmonomethyltriazenes decompose in aqueous solution buffered at near neutral pH values to the corresponding anilines, nitrogen, and carbon cation derivatives with pseudo-first-order kinetics (14).

Since the possibility of interaction between these drugs and serum components exists, the influence of serum albumins on the decomposition rates of some *para*-substituted 1-phenyl-3-methyltriazenes, 1-(2,4,6-trichloro)-phenyl-3-methyltriazene, and 5-(3-methyl-1-triazeno)-imidazole-4-carboxamide was studied. The last compound is possibly a metabolite of 5-(3,3-dimethyl-1-triazeno)-imidazole-4-carboxamide (NSC 45388), used in the treatment of malignant melanoma. Decomposition kinetic studies of these triazenes also were performed in the absence of serum albumins, because the reported data show a marked dependence of the decomposition rates of arylmonomethyltriazenes on the medium (15) and because accurate data in near physiological conditions are lacking.

Human serum albumin was systematically employed. Bovine and mouse serum albumins also were used for comparison and, in the latter case, to allow correlations between the present results and possible *in vivo* experiments.

## EXPERIMENTAL

**Chemistry**—The monomethyltriazenes (Table I) were synthesized by standard methods, *i.e.*, by coupling aryldiazonium chloride to two equivalents of methylamine in the presence of excess base, usually sodium carbonate. The coupling reactions, with the exceptions of VII and XI, were performed in the presence of large volumes of ether to extract the reaction products. To obtain very pure samples of I–VI and VIII, careful sublimation of small amounts of the raw materials, below their melting points, at ~0.2 torr was necessary. A chilling bath of dry ice–acetone was used to recover the recrystallized products; VII was purified by extracting the dried raw material with boiling ethyl acetate.

Purity of the monomethyltriazenes and the aromatic amines used as reference compounds was checked by NMR spectroscopy, elemental analysis, and TLC. Aluminum oxide and methanol–ethyl acetate–ligroin (3:2:1) or ethyl acetate–hexane (1:1) were used for TLC of monomethyltriazenes. The melting points were determined in open glass capillaries in a Büchi apparatus and were in accordance with the literature values. The references for the melting points are listed in Table I.

The solvents used for crystallizations were petroleum ether (bp 30–50°) for I, *n*-hexane for II–VI, ethyl acetate for VII, methanol for VIII, and benzene for IX.

**Materials**—The solvents used for TLC and crystallizations, as well as potassium dihydrogen *o*-phosphate and potassium hydroxide used in the preparation of buffer solutions, were reagent grade.

Serum albumins were crystallized and lyophilized human albumin, crystallized and lyophilized bovine serum albumin, mouse serum albumin fraction V powder, and crystallized and lyophilized egg albumin.

All serum albumins were used without further purification. Human and bovine serum albumin concentrations were determined spectrophotometrically using $E^{1\%}_{279} = 5.3$ and 6.6, respectively (22). Murine serum and egg albumin concentrations were determined by accurately weighing dried samples. Freshly prepared albumin, triazene, and buffer solutions were used.

**Methods**—All kinetic measurements were performed in 0.065 *M* phosphate buffer prepared using fresh, double-distilled water, specific conductivity $1.0 \times 10^{-6}\ \Omega^{-1}$/cm, adjusted to pH 7.40 at 25° by the addition of potassium hydroxide. The temperature dependence of pH of phosphate buffer solutions between 20 and 45° resulted in $2 \times 10^{-3}$ pH unit per degree. This temperature dependence was taken into account; *i.e.*, all results of the kinetic measurements performed at different tem-

[a] Phosphate buffer, 0.065 $M$; ionic strength, 0.15 $M$. [b] This compound was a gift of Dr. G. F. Kolar, Institute for Toxicology and Chemotherapy, German Cancer Research Center, Heidelberg, West Germany.

peratures and pH values were interpolated at the common value of pH 7.40, using kinetic data determined as a function of pH between 7 and 8 for each triazene.

The decomposition reactions were followed spectrophotometrically at a fixed wavelength in the 310–350-nm range chosen to permit maximum variation of absorbance and minimum interference with the spectrum of the decomposition products. In each case, the spectrum at the end of the reaction was coincident with that of the corresponding aniline.

A freshly prepared solution ($\sim 4 \times 10^{-3}$ $M$) of monomethyltriazene in absolute ethanol was added to a known volume of aqueous phosphate buffer, in a quartz cell thermostated at ±0.05°, so that the ethanol–buffer volume ratio was 1:100 in all cases. The solution was stirred rapidly, and the absorbance was recorded as a function of time. The logarithm of the difference between the absorbance at time $t$ and at the final time was plotted *versus* $t$; from the straight line so obtained, the pseudo-first-order kinetic constant was calculated using the least-squares method.

At the wavelength used, serum albumins gave rise to very low scattering, which was constant with time and did not invalidate the measurements.

The treatment of experimental data was the same both in the absence and presence of albumin, even if the values of the molar absorptivities of free and bound triazene species ($\epsilon_F$ and $\epsilon_B$, respectively) might be different. This event does not invalidate the assumption of proportionality between the normalized optical density and the total triazene concentration during the kinetic measurements. An excess of $C_P$ (protein concentration) with respect to $C_B$ (bound triazene concentration) ensures near proportionality between $C_B$ and $C_F$ (free triazene concentration) and, therefore, between the optical density and $C_T$ (total triazene concentration):

$$\text{optical density} = \epsilon_B C_B + \epsilon_F C_F \qquad \text{(Eq. 1)}$$

and by use of Eqs. 5 and 6, it follows that:

$$\text{optical density} \propto (K_B C_P \epsilon_B + \epsilon_F) C_T = \text{constant } C_T \qquad \text{(Eq. 2)}$$

The possibility that the aniline produced by the decomposition reaction interferes with the triazene binding sites (*e.g.*, by competition) was tested. Some sequential kinetic measurements, performed in the same protein solution that allowed the aniline concentration to rise, gave constant half-lives, indicating that the effect of the aniline in this respect is negligible.

Linearization of data, when necessary, was performed by a computerized least-squares procedure.

## RESULTS AND DISCUSSION

The kinetic law of decomposition of the monomethyltriazenes studied, carried out at various temperatures in pH 7.4 phosphate buffer (ionic strength 0.15 *M*), proved to be pseudo-first order with respect to the triazene concentration in all cases (Table I). Corrections for the slight temperature effect on pH and, therefore, on $k$ were performed (see *Experimental*).

The Arrhenius plots of the kinetic data interpolated at pH 7.40 for all of the triazenes studied were fairly linear in the temperature range investigated (Fig. 1). By application of the empirical Arrhenius equation, $k = A \exp(-E/RT)$, to these kinetic measurements, the activation energies and the natural logarithm of the preexponential terms for the various triazenes were obtained (Table II).

The plot of log $k_{(R)}$ − log $k_{(H)}$ as a function of the Hammett constant $\sigma$ (23, 24) for the different *para*-R-substituted aryl derivatives gives a satisfactory straight line, except for X and, to a lesser extent, for IX (Fig. 2). The slope of such a straight line is negative, in agreement with the expected electrophilic character of the decomposition reaction, with $\rho = -2$ approximately.

The triazenes that follow the Hammett plot are characterized by relatively low and approximately similar activation energies and preexponential terms (36–50 kJ $mole^{-1}$ and 10–13, respectively), whereas higher $E$ and ln $A$ values have been found for XI and XII and for the two triazenes (IX and X) that do not follow this plot (69–91 kJ $mole^{-1}$ and 19–30, respectively). The peculiar behavior of IX and X is likely to be attributed to the different extent of protonation of these triazenes at pH 7.4 as compared to the other compounds. This protonation would affect their behavior with respect to acid catalysis.

The results of the kinetic measurements show that the presence of human serum albumin in solution causes a more or less marked lessening in the decomposition rates of the triazenes considered, without affecting the order of the reaction (Fig. 3 and Table III). Therefore, the reaction rate can be written as:

$$v = -\frac{dC_T}{dt} = k'C_T \qquad \text{(Eq. 3)}$$

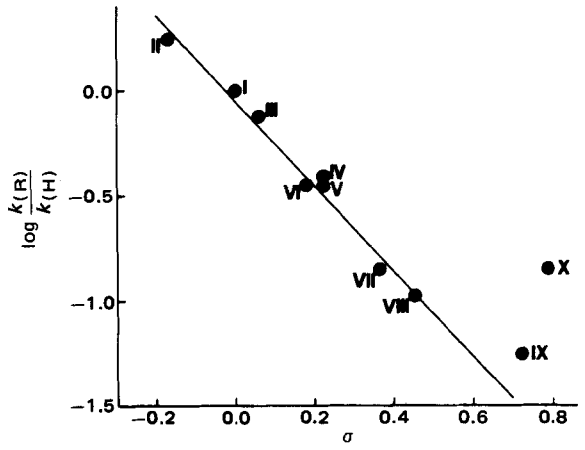

**Figure 2**—*Plot of* log $k_{(R)}$ −log $k_{(H)}$ versus *the Hammett constant,* $\sigma$, *for the various triazenes studied* ($\rho = -2$ *approximately).*

where $k'$ is the apparent kinetic constant in the presence of albumin ($k' < k$).

The observed lessening in the decomposition rates caused by serum albumin may be interpreted by assuming that: (*a*) the triazenes interact rapidly and reversibly with a binding site onto the protein, (*b*) it cannot decompose when bound to this site, and (*c*) the fraction of unbound triazene decomposes in the bulk of the solution with kinetic constant $k$.

On the basis of the first assumption, the stoichiometric constant of association between the triazene and the protein, $K_B$, may be defined as:

$$K_B = C_B/C_F(C_P - C_B) \qquad \text{(Eq. 4)}$$

Since in the present case $C_P$ is always greater than $C_T$ and $C_B$ generally is sufficiently smaller than $C_T$, $C_B$ can be neglected with respect to $C_P$, and it is possible to approximate:

$$\frac{C_B}{C_F} = K_B C_P \qquad \text{(Eq. 5)}$$

and, therefore:

$$C_F = C_T/(1 + K_B C_P) \qquad \text{(Eq. 6)}$$

This approximation induces a slight underestimation of the $K_B$ values, which is more relevant for the highest ones. This underestimation does

not exceed 10% even in the less favorable case of the highest $K_B$ values ($\sim 2.10^4\ M^{-1}$), being slightly greater than the standard deviation due to random errors. This evaluation was done by choosing the values of $C_P$ and $C_T$ in the middle of their concentration range ($\sim 1.5 \times 10^{-4}$ and $2 \times 10^{-5}$ $M$, respectively).

A more rigorous treatment that avoids the approximation leading to Eq. 5 is given in the *Appendix*.

Following the previous assumptions, it is possible to state that:

$$v = -\frac{dC_T}{dt} = kC_F = kC_T/(1 + K_BC_P) \qquad \text{(Eq. 7)}$$

where $v$ is the decomposition rate. Therefore:

$$k' = k/(1 + K_BC_P) \qquad \text{(Eq. 8)}$$

and:

$$t'_{1/2} = t_{1/2}(1 + K_BC_P) \qquad \text{(Eq. 9)}$$

where $t'_{1/2}$ and $t_{1/2}$ are half-life times of the triazenes in the presence and absence of protein, respectively. Equations 8 and 9 are justified in the assumption that $C_P > C_T$.

For the triazenes considered, a plot of $t'_{1/2}/t_{1/2}$ *versus* $C_P$ gives a straight line with slope $K_B$ (Fig. 4). These $K_B$ values are reported in Table IV.

Another possible model, *i.e.*, a tight binding of the triazene onto the protein and the subsequent decomposition *in situ*, is ruled out since, in such a case, $k'$ would be independent of $C_P$ since $C_P$ is always greater than $C_T$ in the experiments.

The proposed theoretical scheme and the $K_B$ values deduced were confirmed by a series of independent kinetic measurements carried out for each triazene at constant $C_P$ and various temperatures between 20 and 45°.

Within the experimental accuracy (±3% approximately), the data also follow the Arrhenius equation in the presence of serum albumin, *i.e.*:

$$\ln k' = \ln A' - E'/RT \qquad \text{(Eq. 10)}$$

where the prime denotes the presence of albumin.

The activation parameters for all monomethyltriazenes studied are reported in Table II.

The introduction of the Arrhenius equation in Eq. 8 gives:

$$K_B = \frac{\frac{A}{A'}\exp\left(-\frac{E-E'}{RT}\right) - 1}{C_P} \qquad \text{(Eq. 11)}$$

Thus, Eq. 11 provides an independent way of obtaining $K_B$; the values so obtained are reported in Table IV. They are in agreement with those values determined from the measurements made as a function of $C_P$.

Moreover, from the temperature dependence of $K_B$, the binding enthalpies of the various triazene molecules onto the protein, $\Delta H_B$, can be estimated using the derivation of Eq. 11:

$$\Delta H_B = -\frac{\partial R \ln K_B}{\partial\left(\frac{1}{T}\right)} = \frac{(E-E')\frac{A}{A'}\exp\left(-\frac{E-E'}{RT}\right)}{\frac{A}{A'}\exp\left(-\frac{E-E'}{RT}\right) - 1}$$

$$= (E-E')\left(1 + \frac{1}{K_BC_P}\right) \qquad \text{(Eq. 12)}$$

Thus, by using $K_B$, the free energy of binding, $\Delta G_B$($\Delta G_B = -RT \ln K_B$), and $\Delta H_B$ values, the variation of binding entropy for the various triazenes can be obtained. Thermodynamic data are reported in Table IV. By inspection of these data, it can be seen that most of the triazenes considered interact with human serum albumin, mainly by an enthalpy-driven process, the entropic contribution to the $\Delta G_B$ values generally being quite low. This effect is more pronounced in VII and VIII, for which a larger enthalpy loss is paralleled by a strikingly larger entropy loss. Different behavior characterizes the trichloro-substituted compound, which completely reverses the signs of $\Delta H_B$ and $\Delta S_B$ and reveals a mainly entropy-driven binding to albumin, possibly related to a large desolvation of the triazene molecule in this process.

The smallest $K_B$ values are shown by triazenes VII and XII, the only compounds characterized by the presence of an amido group. Within the corresponding series of dimethyltriazenes, those carrying the carboxamide function are among the most active against experimental rodent tumors (4).

Kinetic measurements also were performed at constant temperature and in the presence of bovine and murine serum albumins. Although for the latter the quality of the measurements was limited by the low degree of purity of the available sample, in both cases the kinetics of reaction

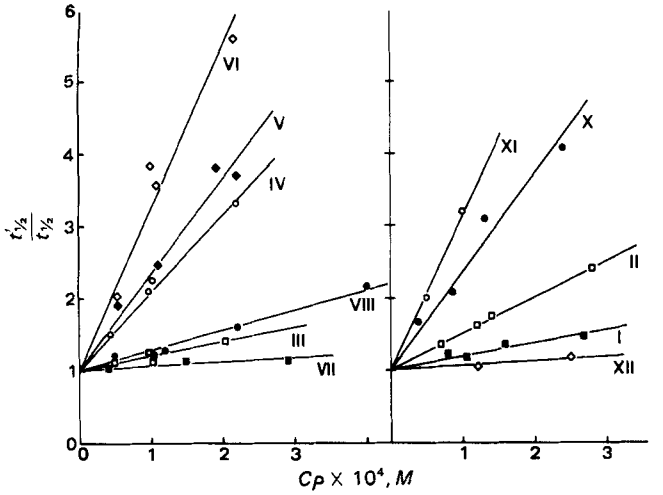

**Figure 4**—*Half-life times ratios, $t'_{1/2}/t_{1/2}$ (where the prime denotes the presence of human serum albumin) as a function of the protein concentration for the triazenes studied. The values refer to 37° and pH 7.40 (0.065 M potassium phosphate buffer).*

clearly remained pseudo-first order and the magnitude of the $K_B$ values was markedly similar to that obtained with human serum albumin. The kinetic and binding parameters are reported in Table V.

However, some kinetic experiments carried out in the presence of egg albumin showed no appreciable effect of this protein on the decomposition rates of the triazenes. This result, obtained in the presence of a protein similar to the serum albumins in some physicochemical properties and in amino acid composition but different in its biological role, confirms that the effect of the serum albumins on the decomposition rates of the triazenes is due to their specific binding abilities.

This protein binding can greatly influence the triazene half-life times in comparison with the values obtained in protein-free solutions. This interaction has to be taken into account in the attempt to correlate kinetic data *in vitro* with biological activities *in vivo*, although the extent of this interaction cannot be predicted easily on the basis of structural or physicochemical parameters.

A preliminary attempt to check, at least qualitatively, the influence of other serum components on the decomposition reactions and binding was performed using whole horse serum. The serum was diluted with phosphate buffer to reach a serum albumin concentration comparable with concentrations used in the previous experiments. The reaction still was pseudo-first order, and the half-lives were definitely close to those obtained in the presence of pure serum albumin (Table V). This result seems to indicate that the major part of the observed effect of the serum components on the triazene decomposition rates is to be attributed to the albumin fraction.

## APPENDIX

Exact solution of Eq. 4 for $C_F$, avoiding the simplifying condition $C_B \ll C_P$, leads to:

$$C_F = \tfrac{1}{2}\left[C_T - C_P - \frac{1}{K_B} + \sqrt{\left(C_P - C_T + \frac{1}{K_B}\right)^2 + \frac{4C_T}{K_B}}\right] \quad \text{(Eq. A1)}$$

The kinetic equation:

$$\frac{dC_T}{C_F} = \frac{dC_T}{\tfrac{1}{2}\left[C_T - C_P - \frac{1}{K_B} + \sqrt{\left(C_P - C_T + \frac{1}{K_B}\right)^2 + \frac{4C_T}{K_B}}\right]} = -k\,dt \quad \text{(Eq. A2)}$$

has to be integrated (from initial conditions: $C_T = C_{T,0}$ at $t = 0$).

This goal can be achieved considering that:

$$\frac{dC_T}{C_F} = \frac{dC_T}{dC_F}\frac{dC_F}{C_F} \quad \text{(Eq. A3)}$$

where:

$$\frac{dC_T}{dC_F} = \frac{C_F^2 + \frac{2C_F}{K_B} + \frac{1}{K_B}\left(C_P + \frac{1}{K_B}\right)}{\left(C_F + \frac{1}{K_B}\right)^2} \quad \text{(Eq. A4)}$$

so that:

$$\int_{C_{T,0}}^{C_T}\frac{dC_T}{C_F} = \int_{C_{F,0}}^{C_F}\left[\frac{C_F + \frac{2}{K_B} + \frac{1}{K_B C_F}\left(C_P + \frac{1}{K_B}\right)}{\left(C_F + \frac{1}{K_B}\right)^2}\right]dC_F = -k\int_0^t dt \quad \text{(Eq. A5)}$$

**Table V—Kinetic and Thermodynamic Data of the Decomposition of Monomethyltriazenes in Buffered Aqueous Solution in the Presence of Different Serum Albumins (0.065 $M$ Potassium Phosphate Buffer, pH 7.40, and 37°)**

| Compound | Protein-Free Solution, $t_{1/2}$, sec | Human Serum Albumin | | Bovine Serum Albumin | | Murine Serum Albumin | | Horse Serum, $t_{1/2}$, sec[c] |
|---|---|---|---|---|---|---|---|---|
| | | $t_{1/2}$, sec[a] | $K_B \times 10^{-3}$, $M^{-1}$ | $t_{1/2}$, sec[a] | $K_B \times 10^{-3}$, $M^{-1}$ | $t_{1/2}$, sec[b] | $K_B \times 10^{-3}$, $M^{-1}$ | |

| X | 439 | 1320 | 13 | 850 | 6 | 1050 | 10 | 1000 |
| XII | 122 | 135 | 0.7 | 145 | 1 | 120 | 0 | 130 |

[a] Values linearly interpolated at albumin concentration $1.5 \times 10^{-4}$ $M$. [b] Experimental values at protein concentration $1.5 \times 10^{-4}$ $M$. [c] Experimental values in whole horse serum diluted 1:4 with phosphate buffer.

Finally, the integrated function $F(C_F)$ results:

$$F(C_F) \equiv K_B C_P \left[\frac{1}{1 + K_B C_F} - \ln\left(C_F + \frac{1}{K_B}\right)\right] + (1 + K_B C_P) \ln C_F = F(C_{F,0}) - kt \quad \text{(Eq. A6)}$$

being obviously $C_F$ expressed as a function of $C_P$ by Eq. A1.

This formal treatment may easily be extended to the case of $n$ identical and independent binding sites present on the protein, simply by substituting $C_P$ by $nC_P$ in these expressions.

The mathematical treatment would be more complicated if nonidentical and possibly cooperative sites were present. Owing to the good agreement between experimental data and the described model, this last case was not considered.

In principle, Eq. A6 implies that the kinetic law for the decomposition of triazenes in the presence of albumin is not first order with respect to triazene concentration. It is easy to realize, by numerical substitution, that the deviation from first-order kinetics is almost negligible in the present case.

For several triazenes, it has been possible to plot the experimental data obtained for each triazene at constant temperature and various $C_P$ values in the form of the general function $F(C_F)$ *versus* $t$ (Eq. A6). All slopes at various $C_P$ values were matched successfully with the value for the kinetic constant, $k$, in the absence of protein by choosing the same $K_B$ value for each triazene. The same data, plotted according to the simplified form of Eq. 9, provided $K_B$ values in good agreement with those obtained by the more rigorous treatment.

# Extreme Vertexes Design in Formulation Development: Solubility of Butoconazole Nitrate in a Multicomponent System

**SHABBIR T. ANIK ˣ and LAKSHMI SUKUMAR**

Received August 22, 1980, from the *Institute of Pharmaceutical Sciences, Syntex Research, Palo Alto, CA 94304.* Accepted for publication January 7, 1981.

**Abstract** □ The extreme vertexes design was shown to be an efficient method for the study of mixture problems, for generating points in the factor space that define a region for response surface analysis. By using this method, the solubility of butoconazole nitrate, an imidazole antifungal agent, was studied as a function of four components, polyethylene glycol 400, glycerin, polysorbate 60, and water, whose levels were subject to given constraints. A fifth component, poloxamer 407, was held constant. The design was used to generate 14 points in the region defined by the constraints. The $G$ efficiency of the design, with the assumption of a quadratic model for the response surface, was 79%. By using the solubilities determined at the 14 points and regression analysis, an equation was generated to characterize the response surface. Contour plots of the response surface illustrate the relationship of the solubility as a function of the components, and solubilities calculated at other points (in the region) agree well with the observed data.

**Keyphrases** □ Extreme vertexes design—formulation development, butoconazole nitrate solubility in a multicomponent system □ Formulation development—extreme vertexes design, butoconazole nitrate solubility in a multicomponent system □ Butoconazole nitrate—solubility, extreme vertexes design in formulation development □ Multicomponent systems—extreme vertexes design in formulation development, butoconazole nitrate solubility

A pharmaceutical formulation generally consists of a mixture of several components, whose levels may often be constrained by factors other than those directly determining its physical properties, such as irritation and cost. In developing this formulation, the component levels must be varied within these constraints to arrive at an optimum formulation with respect to several responses such as solubility, stability, and bioavailability. The conventional

Finally, the integrated function $F(C_F)$ results:

$$F(C_F) \equiv K_B C_P \left[\frac{1}{1 + K_B C_F} - \ln\left(C_F + \frac{1}{K_B}\right)\right] + (1 + K_B C_P) \ln C_F = F(C_{F,0}) - kt \quad \text{(Eq. A6)}$$

being obviously $C_F$ expressed as a function of $C_P$ by Eq. A1.

This formal treatment may easily be extended to the case of $n$ identical and independent binding sites present on the protein, simply by substituting $C_P$ by $nC_P$ in these expressions.

The mathematical treatment would be more complicated if nonidentical and possibly cooperative sites were present. Owing to the good agreement between experimental data and the described model, this last case was not considered.

In principle, Eq. A6 implies that the kinetic law for the decomposition of triazenes in the presence of albumin is not first order with respect to triazene concentration. It is easy to realize, by numerical substitution, that the deviation from first-order kinetics is almost negligible in the present case.

For several triazenes, it has been possible to plot the experimental data obtained for each triazene at constant temperature and various $C_P$ values in the form of the general function $F(C_F)$ *versus* $t$ (Eq. A6). All slopes at various $C_P$ values were matched successfully with the value for the kinetic constant, $k$, in the absence of protein by choosing the same $K_B$ value for each triazene. The same data, plotted according to the simplified form of Eq. 9, provided $K_B$ values in good agreement with those obtained by the more rigorous treatment.

# Extreme Vertexes Design in Formulation Development: Solubility of Butoconazole Nitrate in a Multicomponent System

**SHABBIR T. ANIK ˣ and LAKSHMI SUKUMAR**

Received August 22, 1980, from the *Institute of Pharmaceutical Sciences, Syntex Research, Palo Alto, CA 94304.* Accepted for publication January 7, 1981.

**Abstract** □ The extreme vertexes design was shown to be an efficient method for the study of mixture problems, for generating points in the factor space that define a region for response surface analysis. By using this method, the solubility of butoconazole nitrate, an imidazole antifungal agent, was studied as a function of four components, polyethylene glycol 400, glycerin, polysorbate 60, and water, whose levels were subject to given constraints. A fifth component, poloxamer 407, was held constant. The design was used to generate 14 points in the region defined by the constraints. The $G$ efficiency of the design, with the assumption of a quadratic model for the response surface, was 79%. By using the solubilities determined at the 14 points and regression analysis, an equation was generated to characterize the response surface. Contour plots of the response surface illustrate the relationship of the solubility as a function of the components, and solubilities calculated at other points (in the region) agree well with the observed data.

**Keyphrases** □ Extreme vertexes design—formulation development, butoconazole nitrate solubility in a multicomponent system □ Formulation development—extreme vertexes design, butoconazole nitrate solubility in a multicomponent system □ Butoconazole nitrate—solubility, extreme vertexes design in formulation development □ Multicomponent systems—extreme vertexes design in formulation development, butoconazole nitrate solubility

A pharmaceutical formulation generally consists of a mixture of several components, whose levels may often be constrained by factors other than those directly determining its physical properties, such as irritation and cost. In developing this formulation, the component levels must be varied within these constraints to arrive at an optimum formulation with respect to several responses such as solubility, stability, and bioavailability. The conventional

© 1981, American Pharmaceutical Association

approach is to vary one variable at a time until a satisfactory formulation is developed, which may or may not be the optimum. This process could conceivably involve numerous experiments. Therefore, methods are needed for choosing and determining the adequacy of various groups of possible experimental points.

In this regard, the use of factorial designs has been well established (1). However, classical factorial designs are not suitable for problems involving mixtures because of the constraint $\Sigma X_i = 1$, where $X_i$ is the level of the $i$th component; *i.e.*, the level of one component is fixed by the levels of the others. Furthermore, the classical factorial approach can result in large numbers of experimental points necessary to complete the design. To overcome these problems, McLean and Anderson (2) proposed the extreme vertexes design for mixture problems with upper and lower bounds. The advantages and disadvantages of this method were discussed and compared with other methods of experimental design (3–6).

The objective of this study was to demonstrate the utility of this design in pharmaceutical formulation development. The method is illustrated here by a solubility study of butoconazole nitrate, an antifungal agent, in a multicomponent system.

## THEORETICAL

The general procedure involves constructing, in $n$-dimensional component space, the hyperpolyhedron that defines the region of all possible formulations. This construction and the shape of the region are based on the constraints put on the various formulation components. The extreme vertexes are then just the collection of the vertexes of this hyperpolyhedron. To them are added the face centroids, the overall centroid, and, if necessary, the edge centroids (midpoints of the edges, generally included only for the longer edges).

When developing an experimental design, one generally has a particular model, such as linear, quadratic, or cubic, to be used for the response surface. Given a particular model, a reasonable subset of the derived set of possible formulations must be selected on which to do experimental work. If the full set is small enough, all points can be taken; but when the number of initial points is large, a method is necessary for the rational selection of an experimentally manageable subset of points. Several methods and parameters have been proposed to evaluate the quality and size of the design for a given model. Details of hyperpolyhedron generation, subset selection, and subset evaluation were reported previously (2, 4). The procedure used in this study to determine the design points is as follows.

Table I lists the components, their ranges, and all possible vertexes generated using the method in Ref. 2. Although there are five components, one component, poloxamer 407, was fixed at 0.1 (10%). Therefore, the problem is one of four variables whose sum equals 0.9. From the 32 vertexes generated, there are 10 allowable vertexes where the levels of the components fall within the specified ranges. Normalized distances (2) were calculated between adjacent vertexes of the hyperpolyhedron defined by these 10 allowable vertexes using Eq. 1 (Table II). The normalized distance between the $i$th and $j$th points, $d_{ij}$, is given by:

$$d_{ij} = \sum_{m=1}^{q} [(x_{im} - x_{jm})^2/(b_m - a_m)^2]^{1/2} \qquad \text{(Eq. 1)}$$

where $\mathbf{x}_i$ and $\mathbf{x}_j$ are the $q$-dimensional vectors defining the two points, $b_m$ and $a_m$ are the upper and lower bounds of the $m$th component, and $q$ is the number of variables (in this case four). Since points 3 and 29, 4 and 31, 5 and 13, and 6 and 15 are close to each other relative to the other points, they were replaced by their averages to give six extreme vertexes, which define the region in space shown in Fig. 1. This six-point design was then augmented by addition of centroids, using the method for

centroids as in Ref. 2. Two face centroids, five edge centroids, and the overall centroid were calculated and added to the vertexes obtained above to result in the 14-point design shown in Table III.

For mixture experiments, the quadratic model (Eq. 2) is the most adequate for modeling the response surface (3). The response $Y$, in this case the solubility, is given by:

$$Y = \beta_0 + \sum_i \beta_i X_i + \sum_{1 \le i < j} \beta_{ij} X_i X_j \qquad \text{(Eq. 2)}$$

where $\beta$ is the fitted coefficient for each term and the $X$'s are the formulation component variables. (The quadratic model for mixture does not contain any squared terms due to the constraint $\Sigma X_i = 1$. In this case, a constant term is included since one component, poloxamer 407, is held constant.)

For a given model for characterizing the response surface, one can determine the quality or efficiency of the experimental design. One such criterion is the $G$ or global efficiency (4), which is defined by:

$$\%G = \frac{100p}{nv} \qquad \text{(Eq. 3)}$$

where $p$ is the number of parameters in the model, $n$ is the number of points in the design, and $v$ is $\max[\mathbf{x}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{x}']$. The $\mathbf{x}$ is the $p$-dimensional vector of the model $\mathbf{Y} = \beta\mathbf{x}$ (*e.g.*, for the quadratic model discussed, $\mathbf{x}$ has the elements 1, $X_i$, $X_iX_j$); $\mathbf{X}$ is the $nxp$ matrix of the $\mathbf{x}$'s. For the quadratic model ($p = 11$ here since one component is constant), the values of $v$ and the $G$ efficiency of the 14-point design described are 0.989 and 79%, respectively. High efficiencies are generally not practical, and an efficiency of 50% or greater is ordinarily acceptable (4). Therefore, this design was used to generate the solubility data and response surface.

## EXPERIMENTAL

**Materials**—Polyethylene glycol 400[1] (I), glycerin[2] (II), polysorbate 60[2] (III), and poloxamer 407[3] (IV) were used as received.

**Solubility Determinations**—The drug was equilibrated in the respective solution for up to 7 days. At least two time points were taken for the solubility determinations. The solutions were filtered or centrifuged, and an aliquot of the filtrate or supernate was suitably diluted with methanol and assayed spectrophotometrically.

## RESULTS AND DISCUSSION

The results of the solubility measurements for the different solutions are given in Table III. The solubilities varied from 3 to 12.7 mg/ml and formed an acceptable range for response surface analysis. By using regression analysis[4], the data were fitted to the quadratic model defined by Eq. 2; Table IV gives the equation and regression parameters for the solubility equation:

**Table IV—Regression Parameters for the Solubility Equation [a]**

| Variable | Regression Coefficient | Standard Error | Probability >F |
|---|---|---|---|
| Intercept | 7.66 | | |
| I | 41.1 | 2.3 | 0.0001 |
| III | 30.6 | 6.1 | 0.0015 |
| Water | −4.2 | 1.2 | 0.0088 |
| (I) (II) | −59.9 | 4.8 | 0.0001 |
| (I) (III) | −39.3 | 11.7 | 0.0121 |
| (I) (water) | −74.2 | 6.5 | 0.0001 |
| (III) (water) | 23.3 | 9.4 | 0.0427 |

[a] I is polyethylene glycol 400, II is glycerin, and III is polysorbate 60 ($r^2 = 0.998$, $SE = 0.12$, $n = 14$).

$$\text{solubility} = 7.66 + 41.1\,(\text{I}) + 30.6\,(\text{III}) - 4.2\,(\text{water}) - 59.9\,(\text{I})(\text{II}) - 39.3\,(\text{I})(\text{III}) - 74.2\,(\text{I})(\text{water}) + 23.3\,(\text{III})(\text{water}) \qquad \text{(Eq. 4)}$$

This eight-parameter model gives the best fit to the data with all coefficients significant at the 95% confidence level. As might be expected, both polyethylene glycol 400 and polysorbate 60 have strong linear effects, which also were observed in solubility measurements with independent components. Several two-factor nonlinear terms show synergistic or antagonistic relationships between the different components and the solubility; however, a mechanistic interpretation of these terms must be done with caution since some coefficients are cross-correlated with the linear terms.

The equation, however, can be used for two purposes: (*a*) to calculate solubilities for any combination of components within the defined region, and (*b*) to generate contour plots of the response surface for delineating the behavior of the system within the region. Figure 2 shows a plot of calculated *versus* observed solubilities for some points within the region. The agreement is excellent over the entire solubility range; therefore, the equation may be used for calculating solubilities in any formulation of interest, which is of considerable value in development work.

Contour plots are useful for observing trends within the system, and they also provide a choice of alternative formulations for a given value of the response. Since this is a four-variable system, the effect of all four variables cannot be simultaneously represented. Hence, contour plots were made at the point of maximum solubility within the region, holding one component constant. The maximum solubility of 12.8 mg/ml is at polyethylene glycol 400 = 0.4, glycerin = 0.12, polysorbate 60 = 0.08, and water = 0.3, which is one vertex of the region. Figure 3 shows one such contour plot holding polysorbate 60 at 0.08. The equation below the figure describes the contours and is generated from the original equation by substituting polysorbate 60 = 0.08. The triangle in the center is the region of interest.

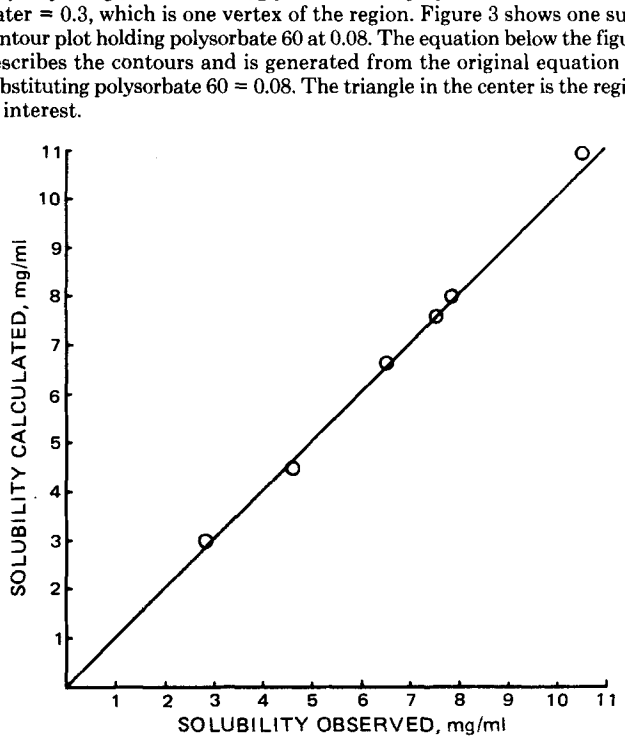

**Figure 2**—*Observed* versus *calculated solubilities (using the regression equation in Table IV).*

[1] Union Carbide Corp.
[2] Emery Industries.

[4] Maximum $R^2$ improvement method, SAS Institute Program.

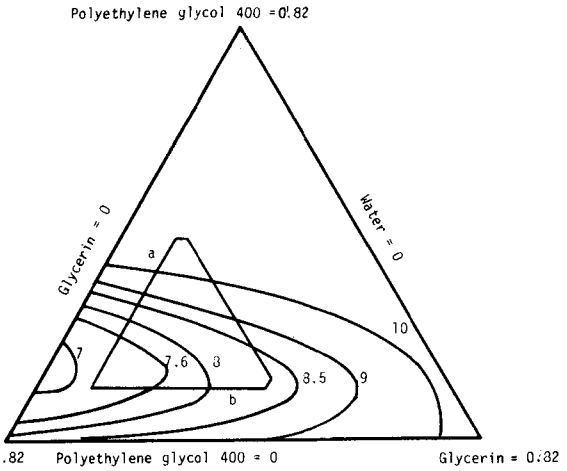

**Figure 3**—*Contour plot at polysorbate 60 = 0.08. Solubility = 10.1 + 38.0 (I) − 2.3 (water) − 59.9 (I)(II) − 74.2 (I)(water).*

The contour plot allows the formulator to choose any desirable solubility value and to determine the corresponding mixture. More importantly, it gives an overall picture of the response surface and the variation of the solubility as a function of the components. This, in turn, can be used to design a more robust formulation, that is, a region where the solubility does not vary greatly with small variations in component concentrations. Minor variations in production, therefore, would not result in drastic effects on the product. In addition, the following observations may be made from Fig. 3:

1. If one moves along the line glycerin = 0.1 (line a in Fig. 3) toward increasing polyethylene glycol 400, the solubility increases more slowly at lower polyethylene glycol 400 concentrations but increases more rapidly at higher levels.

2. If one moves along the line polyethylene glycol 400 = 0.1 (line b in Fig. 3) and replaces glycerin by water, the solubility changes only marginally. Hence, in changing the mixture from 40% glycerin to 10% glycerin by replacing with water, there is a change in solubility of only ~1 mg/ml. This information could be very useful if one were also concerned, for example, with the viscosity of the solution. The viscosity could be decreased considerably without compromising the solubility significantly.

Similar contour plots can be drawn holding different variables constant. These plots are not included here, but the interpretations are analogous to those made earlier.

From this analysis, it is evident that the extreme vertexes method in formulation development is a powerful approach to characterizing a formulation with a minimum number of experiments. (Factorial designs can be used for mixture problems only if one neglects the $n$th component, generally the least responsive, in generating the design. However, this approach may not give an optimum design.) This approach assumes even greater significance when more than one response must be studied since it allows optimization of the formulation with respect to the several responses simultaneously. This is easily done by overlapping contour plots of the different responses and choosing the region that satisfies all response criteria. An additional feature of the method is that one could first perform experiments only at the vertexes; if these experiments gave acceptable values for for the response, the design could be completed. Otherwise, the experimental region could be shifted to another area where the response might be more favorable, and the process could be repeated.

# Radioimmunoassay of Flunisolide in Human Plasma

**C. NERENBERG and S. B. MATIN** ˣ

Received March 4, 1980, from the *Department of Analytical and Metabolic Chemistry, Syntex Research, Palo Alto, CA 94304.* Accepted for publication January 15, 1981.

**Abstract** □ A simple radioimmunoassay was developed for the measurement of flunisolide in human plasma or serum. Plasma extraction was not required. Antiserums were produced in rabbits by immunization against the flunisolide 21-hemisuccinate–bovine serum albumin conjugate. Cross-reactivities were determined for cortisol and a major metabolite of flunisolide and were 0.02 and 0.06%, respectively. Assay sensitivity is in the 100–200-pg/ml range. Accuracy studies gave regression lines of $y = 1.06x$, $r = 1.00$, for a 0.1-ml plasma aliquot and $y = 0.99x$, $r = 0.99$, for a 0.2-ml plasma aliquot. The accuracy of the method was estimated to be at least ±15%. The method was used to determine plasma concentration–time profiles in human subjects after the administration of a 1.0-mg iv dose.

**Keyphrases** □ Flunisolide—radioimmunoassay, human plasma or serum, plasma concentration–time profiles □ Corticoids—flunisolide, radioimmunoassay, human plasma or serum, plasma concentration–time profiles □ Radioimmunoassay—flunisolide, human plasma or serum

Flunisolide (6α-fluoro-11β,16α,17,21-tetrahydroxypregna-1,4-diene-3,20-dione cyclic 16,17-acetal with acetone, I) is a fast acting corticoid designed for use in the treatment of allergic rhinitis, asthma, and other respiratory disorders in humans (1–4).

Since the intended use of this drug was for the treatment of respiratory and upper respiratory disorders, its administration in an inhalation dosage form was a requirement. Since the amount of drug delivered by inhalation is generally small, the plasma levels achieved can be expected to be low.

This paper describes a selective and sensitive radioimmunoassay for the measurement of flunisolide in plasma or serum. This method was developed to provide data for the determination of certain pharmacokinetic parameters in humans, *e.g.*, plasma clearance, elimination half-life, and

Flunisolide (6α-fluoro-11β,16α,17,21-tetrahydroxypregna-1,4-diene-3,20-dione cyclic 16,17-acetal with acetone, I) is a fast acting corticoid designed for use in the treatment of allergic rhinitis, asthma, and other respiratory disorders in humans (1–4).

Since the intended use of this drug was for the treatment of respiratory and upper respiratory disorders, its administration in an inhalation dosage form was a requirement. Since the amount of drug delivered by inhalation is generally small, the plasma levels achieved can be expected to be low.

This paper describes a selective and sensitive radioimmunoassay for the measurement of flunisolide in plasma or serum. This method was developed to provide data for the determination of certain pharmacokinetic parameters in humans, *e.g.*, plasma clearance, elimination half-life, and

extent and rate of absorption. Other analytical methods such as GLC or GLC–mass spectrometry cannot be used for plasma level determinations because flunisolide is a thermally unstable compound.

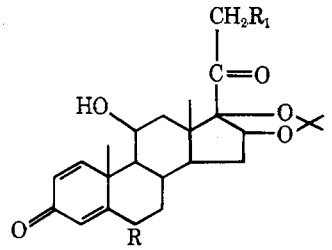
## EXPERIMENTAL

**Materials**—Freund's complete and incomplete adjuvants were purchased in sealed glass ampuls[1]. Activated powdered charcoal[2] was used. The buffer was tris(hydroxymethyl)aminomethane–hydrochloric acid, 0.05 *M*, pH 7.2–7.4, with or without 0.1% gelatin. Flunisolide tritiated at the 1,2-positions with a specific activity of 39.9 Ci/mmole, the 21-hemisuccinate of flunisolide (II), and the flunisolide–bovine serum albumin conjugate were all synthesized in-house[3]. The 6$\beta$-hydroxy metabolite of flunisolide (6$\beta$,11$\beta$,16$\alpha$,17$\alpha$,21-pentahydroxypregna-1,4-diene-3,20-dione-16,17-acetonide) (III) used in the cross-reactivity experiment also was synthesized in-house[3].

**Antiserum Production**—The flunisolide–bovine serum albumin conjugate used for immunization was prepared by coupling II to bovine serum albumin with a water-soluble carbodiimide coupling reagent (5). The reaction mixture was dialyzed exhaustively against normal saline. The extent of conjugation was determined by measuring the protein concentration by the method of Lowry *et al.* (6), and the flunisolide residues were determined by UV absorption. The molar ratio was 57 moles of flunisolide/mole of bovine serum albumin.

An emulsion of the conjugate in saline was prepared by mixing with an equal volume of Freund's complete adjuvant. The bovine serum albumin concentration was 100 $\mu$g/ml, and 0.25 ml was injected subcutaneously into four sites in New Zealand White rabbits. Six weeks after the initial injection, all animals were placed on a regimen of weekly booster shots; the conjugate was prepared in incomplete Freund's adjuvant. After 6–8 months, antiserum dilutions of 1:10,000 to 1:30,000 yielded 50% binding or more. At this stage, assay development was begun.

**Radioimmunoassay**—Flunisolide standards for the standard curve were obtained by dilution of a stock solution of 10.0 mg of flunisolide in 10.0 ml of ethanol. A series of standard solutions, 20, 50, 100, 200, 300, 500, and 600 pg/0.1 ml, was prepared in tris(hydroxymethyl)aminomethane–hydrochloric acid buffer, pH 7.2, 0.05 *M*, without gelatin in 10.0-ml volumes and stored in the refrigerator. Gelatin was withheld from the buffer in the standards to give them a longer shelflife.



I: R = F, $R_1$ = OH
II: R = F, $R_1$ = $CO_2(CH_2)_2COOH$
III: R = OH, $R_1$ = OH

An ethanolic solution of the tritiated flunisolide was diluted with tris(hydroxymethyl)aminomethane–hydrochloric acid buffer, pH 7.2, 0.05 *M*, with 0.1% gelatin such that a 0.1-ml aliquot contained 8000–10,000 cpm. The solution was prepared in a volume sufficient for one assay and then was discarded. Radioisotope purity checks were carried out periodically on silica gel TLC plates[4] with chloroform–methanol–water (40:9:1) as the solvent system. To identify the radioactive band, cold reference standards were cospotted and identified under UV light. The $R_f$ values were ~0.4–0.5.

The antiserums were diluted in tris(hydroxymethyl)aminomethane–hydrochloric acid buffer, pH 7.2, 0.05 *M*, with 0.1% gelatin to yield a total binding of between 35 and 60%. Depending on the quality of the antiserum, this binding was achieved by diluting 1:10,000, 1:20,000, or 1:30,000; a 0.1-ml aliquot was added to each tube.

The charcoal stock suspension (1% in water) was diluted as required with tris(hydroxymethyl)aminomethane–hydrochloric acid, pH 7.2, 0.05 *M*, with 0.1% gelatin immediately before use. A 0.2-ml aliquot of the diluted charcoal suspension (0.4%) was added to blocks of 30–36 tubes at a time. The tubes were vortexed, and the 30-min time cycle was started. Midway through this cycle, charcoal was added to a second block of tubes and they were started on their 30-min cycle. This staggered array procedure was repeated until all tubes were processed. At the end of the 30-min cycle, each block of tubes was centrifuged immediately and sampled for counting.

The centrifuge used was refrigerated with a swingout head[5]. Liquid scintillation counting was done in a scintillation spectrometer[6], using commercially available scintillation fluid[7].

A typical radioimmunoassay protocol is given in Table I, and a stepwise procedure for setting up the assay is as follows. Buffer, tritiated flunisolide, standards, unknowns, antiserums, *etc.*, were added to the appropriate tubes (12 × 75-mm disposable culture tubes). After all additions had been made, the sides of the tubes were washed down by briefly vortexing (1–3 sec). The tubes were covered with sheets of waxed film[8] cut to fit the test tube racks and were incubated overnight at room temperature.

After overnight incubation, the tubes were placed in an ice bath for 2–3 hr. Then 0.2 ml of the charcoal suspension was added to blocks of 30–36 tubes. The tubes were vortexed for 6 sec, and the 30-min time cycle was started. After 30 min, the tubes were centrifuged at 2500 rpm for 4 min and immediately 0.5 ml of the supernate was transferred into scintillation vials. Then 10.0 ml of scintillation fluid was added, and the solutions were counted for 10 min.

**Data Processing**—Data processing was done with the aid of the Rodbard and LeWald Model I computer program (7), a logit–log trans-

formation that linearizes the sigmoid curve normally obtained in a displacement curve. However, the percent bound *versus* the flunisolide concentration can be plotted manually and the unknowns can be determined by interpolation. One advantage of this computer system is that it eliminates operator variation in plotting the standard curve and estimating the unknowns. It also increases the speed with which the computations can be made, especially if a teletype punched-tape system is coupled to the program.

**Accuracy and Precision**—Known amounts of flunisolide were added to plasma and serum, and then these samples were analyzed in triplicate.

## RESULTS AND DISCUSSION

The described method can be used to analyze flunisolide from human plasma directly without prior extraction or purification. This approach was possible because an aliquot of control plasma was added to all points in the standard curve, thereby making it chemically equivalent to that of the unknown samples. A typical standard curve is shown in Fig. 1. Since the control plasma was obtained from each subject prior to flunisolide dosing, it did not contain any endogenous flunisolide.

Pooled plasma from different subjects could be used, but the lower level of sensitivity was not achieved. This observed difference could be due to differences in plasma lipid content or other endogenous components. The exact nature of the component effecting this difference is not known. The effect of this difference is that the lower limit of sensitivity may have to be changed from 20 to 50 or 100 pg. If 50 pg becomes the lowest point on the standard curve that can be measured reliably, then for a 0.2-ml plasma aliquot the lower limit of sensitivity would change from 100 to 250 pg/ml; for a 0.1-ml plasma aliquot, it would change from 200 to 500 pg/ml.

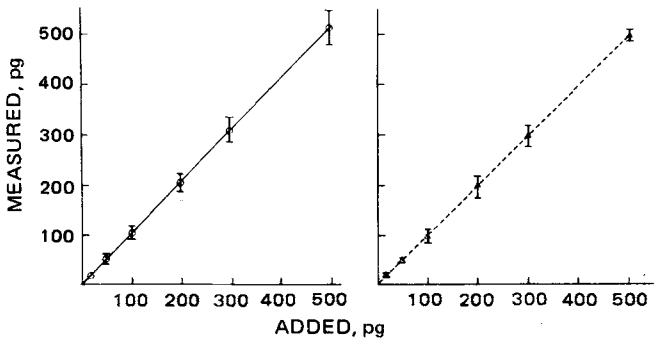

**Figure 2**—*Plots of accuracy measurements using 0.1- (left) and 0.2- (right) ml plasma aliquots. The regression line for the 0.1-ml curve was* y = *1.06*x, r = *1.00; for the 0.2-ml curve, it was* y = *0.99*x, r = *0.99.*

To obtain maximal sensitivity in a radioimmunoassay, certain assay conditions must be optimized. The first parameter to be optimized was the amount of charcoal required to effect the optimum separation of bound from free. This value was established by adding fixed amounts of tritiated flunisolide to a series of tubes containing buffer only and to another series of tubes containing buffer and 0.1 ml of plasma. Graded amounts of charcoal then were added in a constant-volume aliquot (0.2 ml) until the amount of free radioactivity remaining behind, *i.e.*, the nonspecific bound, was 2–4% for tubes containing buffer only and 4–8% for tubes containing an aliquot of plasma. In this laboratory, these conditions were met by using a 0.4% charcoal suspension.

Method sensitivity depends on the size of the aliquot subjected to analysis. If a 0.1-ml aliquot was used, then the lower limit of sensitivity corresponded to 200 pg/ml; for a 0.2-ml aliquot, it was 100 pg/ml. These limits were determined by the lowest concentration on the standard curve that could be reliably measured. With the present method, the lowest concentration that can be reliably measured is 20 pg/0.1-ml aliquot.

Method accuracy was determined by adding known amounts of flunisolide to blank plasma and then assaying these samples using 0.1- and 0.2-ml plasma aliquots. Accuracy measurements were carried out at six different concentrations and covered the entire range of the standard curve. The results were then averaged for each concentration and plotted as measured amounts *versus* added amounts (Fig. 2). The linearity of the plots and the fact that the slopes are essentially equal to unity with no intercept indicate that the measurements can be made accurately over

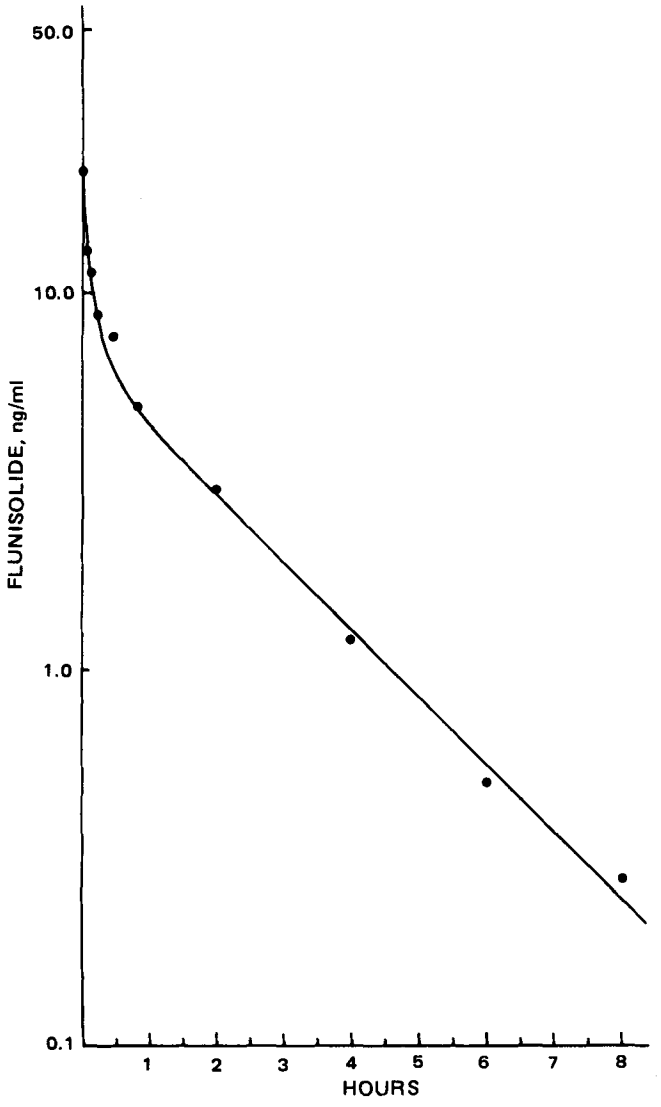

**Figure 3**—*Plasma concentration–time profile in human subjects after administration of a single 1.0-mg iv dose. Data are the average of 12 male volunteers.*

the concentration range tested. The results listed in Table II indicate that the method is capable of measuring within ±15%. The results of quality control experiments carried out during 3 months of routine analyses are given in Table III. The ratios of measured to added flunisolide show that an accuracy of ±15% is possible and can be maintained over time.

Assay validity also was tested by comparing plasma flunisolide levels determined by this method to the levels found by a carbon 14 radiochemical assay (8). A human male volunteer was given a 2.0-mg iv dose of flunisolide containing ~70 $\mu$Ci of $^{14}$C-labeled flunisolide. Blood samples were drawn at 0.5, 1.0, 3.0, 4.0, and 6.0 hr. The plasma was extracted with ethyl acetate, the extracts were evaporated to dryness, and the residue was subjected to TLC. The TLC plates were divided into 1-cm segments, and each segment was assayed for radioactivity. This procedure separated flunisolide from its metabolites. The plasma levels measured at each respective time point were 8.15, 6.07, 1.99, 1.27, and 0.47 ng/ml by radioimmunoassay and 8.26, 5.42, 2.02, 1.19, and 0.55 ng/ml by the radiochemical assay. The inherent variability of the radioimmunoassay is ±15%, and that of the radiochemical method combined with TLC can be as high as ±20%. Therefore, an absolute correlation by the two methods is not possible.

As in any radioimmunoassay, structurally related compounds can interfere. Cortisol is present endogenously at relatively high levels and is structurally related; the 6$\beta$-hydroxy compound is structurally related and is also the major metabolite of flunisolide. These compounds were chosen for cross-reactivity measurements. Cross-reactivities were determined from displacement curves generated for cortisol and the 6$\beta$-hydroxy metabolite of flunisolide, and these curves were compared to the flunisolide displacement curve. The concentration of each compound that corresponded to the 50% inhibition point on the flunisolide curve was then used to calculate the percent cross-reactivity. Cortisol and the 6$\beta$-hydroxy metabolite of flunisolide showed cross-reactivities of 0.02 and 0.06%, respectively.

The developed method was utilized to establish plasma concentration–time profiles in human subjects after the administration of a single 1.0-mg iv dose (8). Twelve male volunteers were used. Blood samples were taken at 2, 5, 10, and 30 min and at 1, 2, 4, 6, 8, and 24 hr and were analyzed in duplicate. The means, determined at each time point, were averaged for all subjects and plotted as concentration *versus* time (Fig. 3). The profile indicated that the method has sufficient sensitivity to be useful in various dosage form experiments.

# Fluoride Remineralization of Demineralized Bovine Tooth Enamel and Hydroxyapatite Pellets

**MASAKATSU YONESE *, JEFFREY L. FOX *, NAOKI NAMBU *, JOHN J. HEFFERREN ‡, and WILLIAM I. HIGUCHI *x**

Received June 30, 1980, from the **College of Pharmacy, University of Michigan, Ann Arbor, MI 48109*, and the ‡*American Dental Association, Chicago, IL 60611.* Accepted for publication January 26, 1981.

**Abstract** □ Both bovine enamel and hydroxyapatite pellets were remineralized in a fluoride-containing remineralization solution after prior demineralization for various lengths of time. In both the enamel and pellet systems, the degree of remineralization attainable was directly related to the extent of prior demineralization, although the demineralized material was never 100% recovered in remineralization. In some cases, fluoride levels up to several thousand parts per million were found at depths as great as 50 μm from the surface. The stoichiometry of the remineralized material and electron microprobe examination were consistent with the formation of fluoridated hydroxyapatite rather than calcium fluoride.

**Keyphrases** □ Fluoride—remineralization of demineralized bovine tooth enamel and hydroxyapatite pellets □ Remineralization—of demineralized bovine tooth enamel and hydroxyapatite pellets □ Hydroxyapatite pellets—remineralization along with demineralized bovine tooth enamel □ Teeth, bovine—remineralization of demineralized tooth enamel and hydroxyapatite pellets

Previous studies performed in these laboratories (1, 2) led to the development of a model for hydroxyapatite dissolution involving two distinct crystalline dissolution sites (3). This model is consistent with dissolution kinetic data and explains the observed morphology of hydroxyapatite dissolution at both the single-crystal level (4) and at the level of a compressed hydroxyapatite pellet or a block of tooth enamel (3).

In studying demineralization of remineralized enamel, it was noted (5, 6) that when enamel was demineralized under conditions where the medium was partially saturated with respect to hydroxyapatite, subsequent remineralization was successful; but when prior demineralization was carried out under more severe conditions, remineralization attempts gave poor results.

Since successful remineralization occurred under conditions where dissolution *via* only Site 1 would be expected, the hypothesis follows that this site might be the principal one for successful remineralization. This remineralization might consist chiefly of the filling of *c*-axis holes.

The present experiments were designed to test for the existence of a relationship between the amount of demineralization *via* Site 1 and the subsequent degree of remineralization attainable.

## EXPERIMENTAL

**Materials**—*Bovine Teeth*—Bovine incisors were used. Labial surfaces were ground with fine sandpaper to remove the pellicle.

*Hydroxyapatite Pellets*—Synthetic hydroxyapatite crystals, prepared using the procedure developed by Moreno *et al.* (7), were used in the preparation of pellets. About 50 mg of hydroxyapatite, preequilibrated in a humidity chamber containing saturated potassium nitrate aqueous solution to maintain the humidity at ~67%, was compressed in a die (0.62-cm diameter) under a force of 10,000 lb using a laboratory press.

**Buffer Solutions**—A solution 16% saturated (on a molar basis) with respect to the thermodynamic solubility of hydroxyapatite was used for demineralization. The solution was a 0.1 *M* acetate buffer containing 3.5 m*M* each of total calcium and total phosphate. The pH was adjusted to 4.5 with sodium hydroxide, and the ionic strength was adjusted to 0.5 with sodium chloride. For remineralization, a 0.1 *M* acetate buffer (pH 4.5) containing 12 m*M* of total calcium (including calcium 45 activity of 0.2 mCi/liter of solution), 12 m*M* total phosphate, 10 ppm of fluoride, and sodium chloride to adjust the ionic strength to 0.5 was used.

The ionic activity of hydroxyapatite, $K_{HAP}$ ($\equiv a_{Ca}^{10} a_{PO_4}^{6} a_{OH}^{2}$), of this buffer was $10^{-120}$. Although not saturated with respect to hydroxyapatite, this solution has a high enough degree of partial saturation so that hydroxyapatite dissolution would be expected to proceed slowly, if at all, based on previous work with solutions approaching this level of calcium and phosphate concentrations (3, 8).

**Demineralization**—A bovine tooth was covered with inlay wax except for 0.25 $cm^2$ of the labial surface. In the pellet experiments, a hydroxyapatite pellet with a surface area of 0.58 $cm^2$ was fixed on a small glass plate by the wax. Either the tooth or pellet then was demineralized in the 16% partially saturated buffer solution for 0.5–6 hr. The solution was shaken gently with a wrist-action shaker[1] and kept at 30°. The volume of the buffer solution was 10 ml/0.25 $cm^2$ of the sample surface.

**Remineralization**—The demineralized tooth or pellet then was given a remineralization treatment for 24–72 hr in 50 ml of the remineralization buffer solution. The solution was shaken gently and kept at 30° as remineralization proceeded.

**Etching and Scraping**—The remineralized sample then was etched in 1 ml of 0.5 *M* $HClO_4$ for successive periods of 15, 15, 30, 60, 120, 200, and 200 sec; the surface was washed with 1 ml of water after each etching step. The depths of the etched layers were estimated from the amounts of phosphate etched. Some hydroxyapatite pellets were scraped evenly

Ho for assistance in the application of the method to studies in human subjects. The authors also thank Leigh Ann Wolfe for her assistance in the preparation of this manuscript.

# Fluoride Remineralization of Demineralized Bovine Tooth Enamel and Hydroxyapatite Pellets

**MASAKATSU YONESE *, JEFFREY L. FOX *, NAOKI NAMBU *, JOHN J. HEFFERREN ‡, and WILLIAM I. HIGUCHI *x**

Received June 30, 1980, from the **College of Pharmacy, University of Michigan, Ann Arbor, MI 48109*, and the ‡*American Dental Association, Chicago, IL 60611.* Accepted for publication January 26, 1981.

**Abstract** □ Both bovine enamel and hydroxyapatite pellets were remineralized in a fluoride-containing remineralization solution after prior demineralization for various lengths of time. In both the enamel and pellet systems, the degree of remineralization attainable was directly related to the extent of prior demineralization, although the demineralized material was never 100% recovered in remineralization. In some cases, fluoride levels up to several thousand parts per million were found at depths as great as 50 μm from the surface. The stoichiometry of the remineralized material and electron microprobe examination were consistent with the formation of fluoridated hydroxyapatite rather than calcium fluoride.

**Keyphrases** □ Fluoride—remineralization of demineralized bovine tooth enamel and hydroxyapatite pellets □ Remineralization—of demineralized bovine tooth enamel and hydroxyapatite pellets □ Hydroxyapatite pellets—remineralization along with demineralized bovine tooth enamel □ Teeth, bovine—remineralization of demineralized tooth enamel and hydroxyapatite pellets

Previous studies performed in these laboratories (1, 2) led to the development of a model for hydroxyapatite dissolution involving two distinct crystalline dissolution sites (3). This model is consistent with dissolution kinetic data and explains the observed morphology of hydroxyapatite dissolution at both the single-crystal level (4) and at the level of a compressed hydroxyapatite pellet or a block of tooth enamel (3).

In studying demineralization of remineralized enamel, it was noted (5, 6) that when enamel was demineralized under conditions where the medium was partially saturated with respect to hydroxyapatite, subsequent remineralization was successful; but when prior demineralization was carried out under more severe conditions, remineralization attempts gave poor results.

Since successful remineralization occurred under conditions where dissolution *via* only Site 1 would be expected, the hypothesis follows that this site might be the principal one for successful remineralization. This remineralization might consist chiefly of the filling of *c*-axis holes.

The present experiments were designed to test for the existence of a relationship between the amount of demineralization *via* Site 1 and the subsequent degree of remineralization attainable.

## EXPERIMENTAL

**Materials**—*Bovine Teeth*—Bovine incisors were used. Labial surfaces were ground with fine sandpaper to remove the pellicle.

*Hydroxyapatite Pellets*—Synthetic hydroxyapatite crystals, prepared using the procedure developed by Moreno *et al.* (7), were used in the preparation of pellets. About 50 mg of hydroxyapatite, preequilibrated in a humidity chamber containing saturated potassium nitrate aqueous solution to maintain the humidity at ~67%, was compressed in a die (0.62-cm diameter) under a force of 10,000 lb using a laboratory press.

**Buffer Solutions**—A solution 16% saturated (on a molar basis) with respect to the thermodynamic solubility of hydroxyapatite was used for demineralization. The solution was a 0.1 *M* acetate buffer containing 3.5 m*M* each of total calcium and total phosphate. The pH was adjusted to 4.5 with sodium hydroxide, and the ionic strength was adjusted to 0.5 with sodium chloride. For remineralization, a 0.1 *M* acetate buffer (pH 4.5) containing 12 m*M* of total calcium (including calcium 45 activity of 0.2 mCi/liter of solution), 12 m*M* total phosphate, 10 ppm of fluoride, and sodium chloride to adjust the ionic strength to 0.5 was used.

The ionic activity of hydroxyapatite, $K_{HAP}$ ($\equiv a_{Ca}^{10} a_{PO_4}^{6} a_{OH}^{2}$), of this buffer was $10^{-120}$. Although not saturated with respect to hydroxyapatite, this solution has a high enough degree of partial saturation so that hydroxyapatite dissolution would be expected to proceed slowly, if at all, based on previous work with solutions approaching this level of calcium and phosphate concentrations (3, 8).

**Demineralization**—A bovine tooth was covered with inlay wax except for 0.25 $cm^2$ of the labial surface. In the pellet experiments, a hydroxyapatite pellet with a surface area of 0.58 $cm^2$ was fixed on a small glass plate by the wax. Either the tooth or pellet then was demineralized in the 16% partially saturated buffer solution for 0.5–6 hr. The solution was shaken gently with a wrist-action shaker[1] and kept at 30°. The volume of the buffer solution was 10 ml/0.25 $cm^2$ of the sample surface.

**Remineralization**—The demineralized tooth or pellet then was given a remineralization treatment for 24–72 hr in 50 ml of the remineralization buffer solution. The solution was shaken gently and kept at 30° as remineralization proceeded.

**Etching and Scraping**—The remineralized sample then was etched in 1 ml of 0.5 *M* $HClO_4$ for successive periods of 15, 15, 30, 60, 120, 200, and 200 sec; the surface was washed with 1 ml of water after each etching step. The depths of the etched layers were estimated from the amounts of phosphate etched. Some hydroxyapatite pellets were scraped evenly

by a sharp razor in lieu of etching. The depths of the scraped layers were estimated from the weights of the powdered scrapings. This powder then was dissolved in perchloric acid and assayed to determine fluoride and calcium 45 concentrations.

**Analytical Techniques for Phosphate, Fluoride, Calcium, and Calcium 45**—Phosphate concentrations were determined by the method of Gee *et al.* (9), in which the phosphoammonium–molybdate complex formed is reduced by stannous chloride. The absorbance of the resulting blue color is determined after 15 min at 720 nm[2]. Fluoride concentrations were determined by a fluoride electrode[3] using a low level total ionic strength-adjusting buffer. Concentrations of calcium 45 were determined by a scintillation counter[4].

**Depth of Etchings**—The depths of the etched layers of the teeth and hydroxyapatite pellets were calculated from the amounts of phosphate removed in the etchings, assuming the density of the samples to be 2.95 g/ml. This information then was used to calculate the fluoride and calcium 45 content of the mineral per unit volume.

**Recovery of Demineralized Mineral by Remineralization**—The extent of remineralization is defined by the molar ratio of the total amount of fluoridated hydroxyapatite formed during remineralization to the amount of hydroxyapatite dissolved during demineralization. In this study, the molar ratio was defined as the cumulative calcium 45 taken up during remineralization to the calcium dissolved during demineralization.

## RESULTS

**Effect of Demineralization on Remineralization**—Bovine teeth were demineralized in 10 ml of the 16% saturated buffer solution for 0–6 hr. Figure 1 shows the total phosphate (milligrams) dissolved per 0.25 cm² of surface. These results show that the buffer solution was not yet saturated with respect to hydroxyapatite after 6 hr of demineralization. That is, dissolution was still occurring.

To investigate the effects of demineralization on subsequent remineralization, the bovine teeth demineralized for 0–6 hr were remineralized for 24 hr. Figure 2 shows calcium 45 concentration profiles for these teeth. The calcium 45 concentration increases with increasing demineralization times, and the enamel not subjected to prior demineralization ($D_0$) was remineralized to a negligible extent. Figure 3 shows the fluoride concentration profiles of the same samples. Fluoride concentrations also increased with increasing demineralization times. However, the fluoride uptake of nondemineralized enamel was not negligible as was the calcium 45 uptake, probably as a result of a higher tendency for superficial ion exchange.

The fluoride concentration gradient of the teeth demineralized less than 1 hr decreased rapidly from the high levels at the surface to <500 ppm at a depth of only 20 μm, but the teeth demineralized more than 1.5 hr had much higher fluoride gradients, decreasing gradually to ~1000–2000 ppm of fluoride at depths of ~50–60 μm. These results are consistent with results in which teeth demineralized under mild conditions are rehardened or remineralized much easier than sound teeth (10, 11).

The effect of remineralization time on the calcium 45 and fluoride uptake was examined by remineralizing the teeth for 24 and 72 hr following 6 hr of demineralization. Figure 4 shows the resulting calcium 45 concentration profiles. They were nearly the same with remineralization being essentially complete at 24 hr.

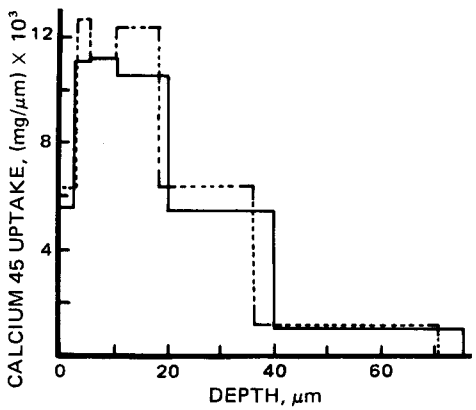

**Figure 4**—*Influence of remineralization time of calcium 45 uptake profiles in bovine teeth, showing that remineralization is essentially complete in 24 hr. Key: ---, $D_6$–$R_{24}$; and —, $D_6$–$R_{72}$.*

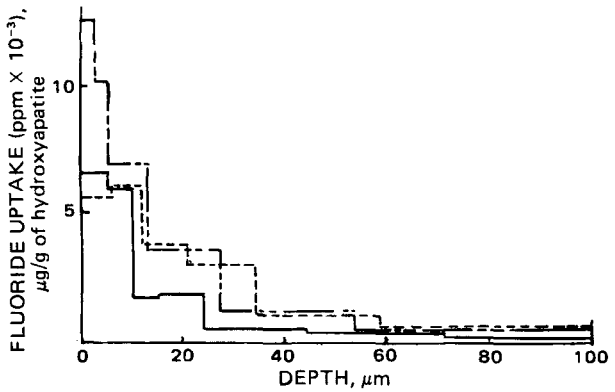

**Figure 5**—*Influence of demineralization time on 24-hr fluoride uptake profiles in hydroxyapatite pellets as measured by the perchloric acid etch technique. Key: —·—, $D_{3.0}$–$R_{24}$; ---, $D_{1.5}$–$R_{24}$; and —, $D_{0.0}$–$R_{24}$.*

To confirm that the demineralization/remineralization dependence seen in bovine teeth was indeed a result of hydroxyapatite behavior as expected from the model and not caused primarily by the enamel matrix, the remineralization of hydroxyapatite pellets was examined by the same method as used for the bovine teeth. Hydroxyapatite pellets were demineralized for 0, 1.5, or 3 hr. Figure 5 shows the fluoride concentration profiles obtained after remineralizing these pellets for 24 hr. The concentrations increased with increasing demineralization time in accord with the results obtained with bovine teeth. Although the calcium 45 uptake data are now shown, they were also coincident with the enamel data. However, fluoride and calcium 45 concentrations in the nondemineralized pellet were noticeably higher than those observed in enamel.

**Mineral Recovery by Remineralization**—The extent of mineral recovery was calculated in several experiments with bovine enamel and hydroxyapatite pellets (Fig. 6). In no case was the demineralized mineral completely replaced during remineralization.

**Form of Incorporated Fluoride**—If fluoridated hydroxyapatite was formed from the ions supplied by the remineralization solution, the molar ratio of calcium 45 to fluoride uptake should be 5.0; a ratio of 0.5 would be expected for the formation of calcium fluoride (I). Figure 7 shows the molar ratio of calcium 45 to fluoride uptake after 24 hr of remineralization for both bovine teeth and hydroxyapatite pellets as a function of demineralization time. The ratios were ~5.0, corresponding to the formation of fluoridated hydroxyapatite. However, for demineralization of <1.5 hr, the ratios were <5 but much higher than the 0.5 ratio expected from the formation of I. This discrepancy from 5.0 might be due to the formation of I to a small extent or to the ion exchanges of calcium and hydroxide ions of hydroxyapatite for calcium 45 and fluoride in the buffer solution.

In a remineralization study with hydroxyapatite powder using a remineralizing solution identical to that described earlier, it was shown by extraction with potassium hydroxide that the fluoride in the remineralized material is not in the form of I and is most likely apatitic (12).

As an independent check of the results obtained by the etching method,

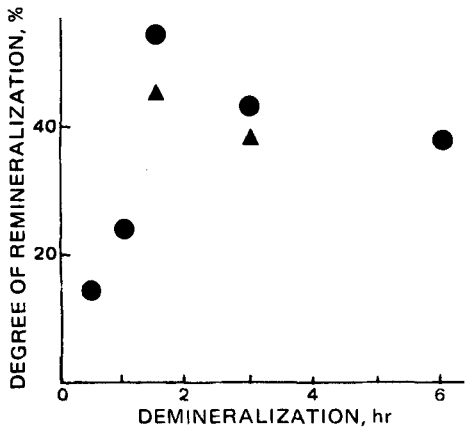

**Figure 6**—*Influence of demineralization time on the degree of subsequent remineralization. Key: ●, bovine tooth; and ▲, hydroxyapatite pellet.*

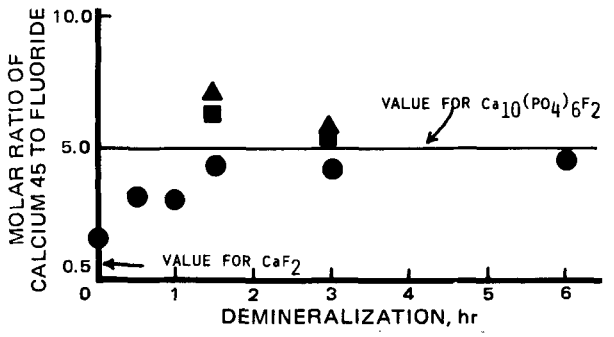

**Figure 7**—*Influence of demineralization time on the calcium 45 to fluoride molar ratio of the subsequently remineralized phase. Key: ●, bovine tooth (etching method); ■, hydroxyapatite pellet (etching method); and ▲, hydroxyapatite pellet (scraping method).*

the remineralization of hydroxyapatite pellets was investigated by the scraping method. Pellets remineralized for 24 hr following 1.5 or 3.0 hr of demineralization were scraped to a depth of ~60 μm, and the scrapings were analyzed for fluoride and calcium 45. The uptakes of fluoride and calcium 45 measured in this way were almost identical to those obtained by the etching method. The molar ratios of calcium 45 to fluoride uptake obtained from the etching and scraping techniques are shown in Fig. 7. The coincidence of the results of the two methods confirms the results obtained from the etching method. As a further check, electron microprobe determinations (calcium, phosphate, and fluoride) as a function of depth were carried out on sectioned, remineralized bovine teeth. The results were in good agreement with the perchloric acid method.

All experiments were carried out in duplicate, with the variation between the two trials typically on the order of 10–15%.

## DISCUSSION

In both bovine enamel and compressed hydroxyapatite pellets, there was a direct relationship between the amount of mineral lost during demineralization and the amount regained during remineralization for the time periods studied. In all cases, there was greater uptake of calcium 45 and fluoride in the pellet than in the bovine enamel. This difference is likely due to the higher porosity of the pellet. These results are consistent with the idea that when there is no prior demineralization, remineralization is restricted to available void spaces in the pellet or enamel. During demineralization, however, additional spaces are created (including *c*-axis holes in the crystals) in which remineralization can occur. It appears that remineralization is occurring both in the initial voids and in the voids created by demineralization.

The extent of remineralization after a 24-hr remineralization treatment was considerably less than 100% both for bovine teeth and hydroxyapatite pellets. However, in the real *in vivo* situation where teeth are continuously undergoing demineralization/remineralization cycles, the extent of remineralization must, on the average, be 100% unless there is an ongoing net growth of lesions.

It was expected that for longer demineralization times, the recovery during remineralization might be <100% because many more crystals would have time to dissolve completely, leaving no templates for subsequent remineralization. Work currently in progress in these laboratories, using microradiography as a tool for measuring mineral density profiles (13), has shown that this is the case. The described demineralization conditions result in a recession of the surface due to complete removal of ~40 μm of enamel, below which there is a lesion ~40 μm deep that is completely filled during the subsequent remineralization treatment.

This mechanism implies that for short demineralization times, nearly 100% recovery might be expected. In actuality, for the shortest demineralization times (<1.5 hr), the extent of remineralization was less than for some longer demineralization times. One possible explanation is that the starting enamel or pellet was not uniform and that the very first material removed in the demineralization was some more soluble phase that did not dissolve *via* the hole-forming mechanism presumably followed by hydroxyapatite under these conditions and, hence, did not leave any such templates for remineralization.

## CONCLUSIONS

Both bovine enamel and hydroxyapatite pellets were remineralized in a fluoride-containing remineralization solution after prior demineral-

alization for various lengths of time. In both the enamel and pellet systems, the degree of remineralization attainable was directly related to the extent of prior demineralization, although in no instance was the demineralized material 100% recovered in remineralization. Fluoride levels up to several thousand parts per million were found at depths as great as 50 μm from the surface in some cases. The stoichiometry of the remineralized material and electron microprobe examination were consistent with the formation of fluoridated hydroxyapatite rather than I. The detailed characterization of the behavior of the remineralized material is now being addressed in studies in these laboratories.

# Novel Topical Fluoride Delivery System I: Remineralization of Ground Bovine Teeth

**MASAKATSU YONESE *, BALA V. IYER *, JEFFREY L. FOX *, JOHN J. HEFFERREN ‡, and WILLIAM I. HIGUCHI *x**

Received June 30, 1980, from the **College of Pharmacy, University of Michigan, Ann Arbor, MI 48109*, and the ‡*American Dental Association, Chicago, IL 60611.* Accepted for publication January 26, 1981.

**Abstract** □ Laboratory studies were carried out on a newly conceived fluoride-containing remineralizing system with bovine teeth. The prototype fluoride delivery device involved micronized calcium fluoride maintained at the tooth surface with a cellulose film. Together with salivary calcium and phosphate (or simulated saliva), this system was able to generate and maintain the appropriate thermodynamic activity driving force for significant fluorapatite deposition in a reasonably short time (~48 hr).

**Keyphrases** □ Delivery devices—fluoride, remineralization of bovine teeth, effect of film thickness and particle size □ Fluoride—delivery devices for remineralization of bovine teeth, effect of film thickness and particle size on remineralization □ Remineralization—bovine teeth, fluoride delivery devices, effect of film thickness and particle size on remineralization □ Teeth, bovine—remineralization using fluoride delivery devices, effect of film thickness and particle size on remineralization

Recent *in vitro* studies in these laboratories (1) showed that the amount of fluoride incorporated in a remineralization treatment can be increased substantially if the tooth is demineralized carefully prior to the remineralization. This finding suggests that successful remineralization might be attained *in vivo* if the teeth could be demineralized to the same extent as in the *in vitro* experiments. This paper describes the initial studies in the development of a fluoride topical delivery system designed to achieve *in vivo* results similar to the results obtained *in vitro*.

*In vitro* remineralization can be very successful when the ionic activity product, $K_{FAP}$ ($a^{10}_{Ca^{2+}} a^{6}_{PO_4^{3-}} a^{2}_{F^-}$), is $\sim 10^{-108}$ (1). Less concentrated solutions provide less driving force for remineralization; more concentrated solutions may result in the rapid precipitation of calcium fluoride (I) or dicalcium phosphate dihydrate (II) in the prepared solutions themselves or in enamel pores, thereby blocking or retarding remineralization. It was decided to control the solution conditions at the enamel surface by supplying fluoride in the form of I suspended in a film adhering to the enamel surface.

Calculations have shown that mixtures of I and II or I alone in the film should result in solution compositions appropriate for remineralization at the enamel surface. Furthermore, the relatively low solubility of I limits the rate at which the suspended particles dissolve, so that fluoride applied in this way is inherently long acting, even with no moderation from the film. This fact makes the film design problem much simpler than when a more soluble fluoride source such as sodium fluoride is used and the film must then control the release rate. Therefore, the problem of film design is not to find a film with a narrowly prescribed set of properties but rather to find a film that can hold the particles of I in place while being porous to saliva and interfering minimally with particle dissolution.

## EXPERIMENTAL

**Materials and Methods**—Bovine teeth from 8-week-old, crate-fed, strictly kosher calves were obtained from packing houses in the Chicago area. These animals were chosen because each is subjected to rigidly controlled and uniform environmental conditions (including diet) and

*In vitro* remineralization can be very successful when the ionic activity product, $K_{FAP}$ ($a^{10}_{Ca^{2+}} a^{6}_{PO_4^{3-}} a^{2}_{F^-}$), is $\sim 10^{-108}$ (1). Less concentrated solutions provide less driving force for remineralization; more concentrated solutions may result in the rapid precipitation of calcium fluoride (I) or dicalcium phosphate dihydrate (II) in the prepared solutions themselves or in enamel pores, thereby blocking or retarding remineralization. It was decided to control the solution conditions at the enamel surface by supplying fluoride in the form of I suspended in a film adhering to the enamel surface.

Calculations have shown that mixtures of I and II or I alone in the film should result in solution compositions appropriate for remineralization at the enamel surface. Furthermore, the relatively low solubility of I limits the rate at which the suspended particles dissolve, so that fluoride applied in this way is inherently long acting, even with no moderation from the film. This fact makes the film design problem much simpler than when a more soluble fluoride source such as sodium fluoride is used and the film must then control the release rate. Therefore, the problem of film design is not to find a film with a narrowly prescribed set of properties but rather to find a film that can hold the particles of I in place while being porous to saliva and interfering minimally with particle dissolution.

## EXPERIMENTAL

**Materials and Methods**—Bovine teeth from 8-week-old, crate-fed, strictly kosher calves were obtained from packing houses in the Chicago area. These animals were chosen because each is subjected to rigidly controlled and uniform environmental conditions (including diet) and

*© 1981, American Pharmaceutical Association*

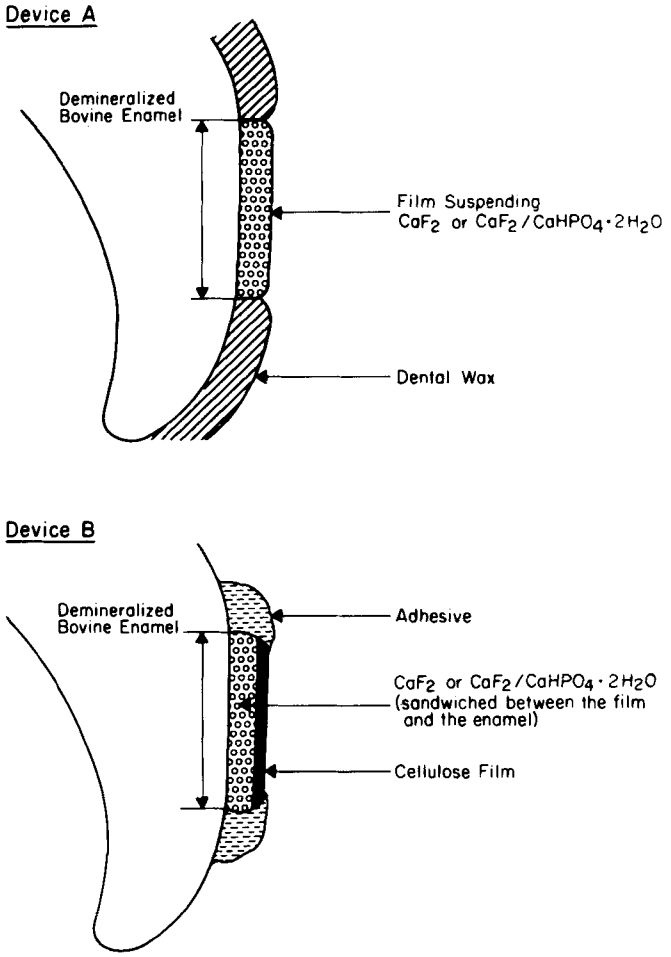

**Figure 1**—*Fluoride delivery devices.*

each is slaughtered at precisely the same age. Thus, each tooth has very nearly the same past history so there is little experimental variation from one tooth to another. In addition, these teeth provide large flat surfaces for kinetic studies and have no detectable fluoride (≪1 ppm in the enamel). All bovine teeth were ground with a rotating sandpaper (No. 600) to remove any pellicle and further reduce any sample to sample variation.

**Chemicals**—Ethylcellulose[1] and povidone[2] (average mol. wt. 10,000) were used as supplied from the manufacturer. The cellulose film was cut from dialysis tubing[3]. All other chemicals were analytical grade, and all water was distilled twice.

**Demineralization Experiments**—In the demineralization experiments, a tooth was covered by inlay wax except for ~0.25 $cm^2$ of the labial surface. The tooth then was demineralized in 10 ml of a 16% saturated buffer solution (0.1 *M* acetate buffer at pH 4.5, containing 3.5 m*M* total phosphate and total calcium, with the ionic strength adjusted to 0.5 by the addition of sodium chloride) with gentle shaking for 1–48 hr. The extent of demineralization was assessed by measuring the amount of phosphate dissolved. The solution was always kept at 30 ± 0.1°.

The attachment of fluoride delivery devices followed demineralization. Two kinds of devices were used (Fig. 1).

**Mixed Polymer Film with Suspended I or I–II (Fluoride Delivery Device A)**—Powders of I or II passed through either a 100-mesh sieve (150-μm openings) or a 270-mesh sieve (52-μm openings) were suspended in a 5% (w/v) ethanolic solution of the selected polymer mixture. The tooth was dipped for various times in the polymer solution. Before each dipping, the polymer solution on the tooth surface was dried so as not to drop off. Therefore, the film thickness could be controlled by the dipping times and was varied from 10 to 60 μm. After 2 min of drying, the tooth with the film was immersed in water for 30 min to permit ethanol to leach from the film.

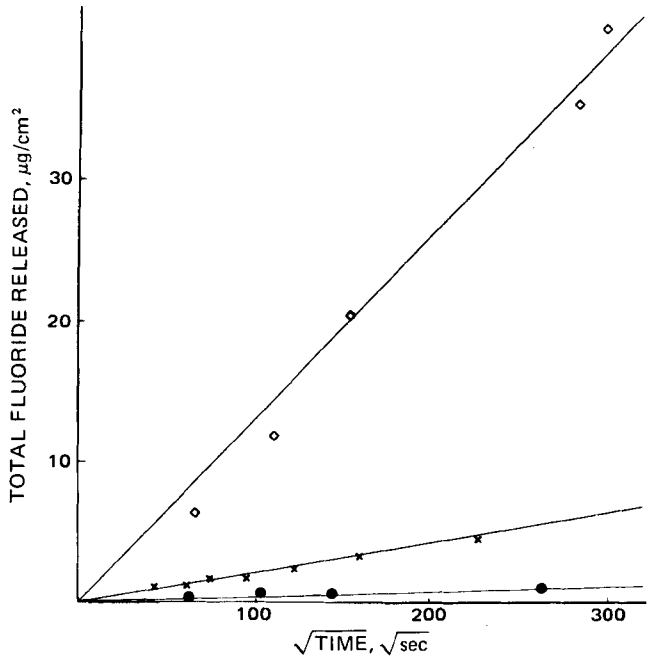

**Figure 2**—*Plots of Q* versus *the square root of time for determining the diffusivity of calcium fluoride in the polymeric films. Key:* ◇, *calcium fluoride–ethylcellulose–povidone (1:4:1);* ×, *calcium fluoride–ethylcellulose (1:5); and* ●, *calcium fluoride–ethylcellulose–glycerin (1:5:0.22).*

**Cellulose Film Containing Micronized I or I–II (Fluoride Delivery Device B)**—Powders of I and II passed through a 270-mesh sieve (52-μm openings) were mixed in various ratios. The mixture was scattered evenly on the surface (0.2 $cm^2$) and was covered by a cellulose film with its periphery fixed by adhesive[4]. The quantities used were 0.5 mg of I or 2 mg of a 1:6 mixture of I and II/0.2 $cm^2$.

**Remineralization Experiments**—In the remineralization experiments, the tooth with the attached fluoride delivery device was remineralized for 24–72 hr in buffer for remineralization (0.1 *M* acetate buffer at pH 4.5 containing 12 m*M* of total calcium and total phosphate with its ionic strength adjusted to 0.5 by the addition of sodium chloride). The buffer solution was shaken gently and kept at 30 ± 0.1° as in demineralization. A buffer solution volume of 100 ml was used so that the buffer composition during remineralization would not change significantly.

The remineralization in saliva was done in a test tube with enough saliva for dipping the tooth. The tooth was fixed at the tip of a small glass rod ~1–2 cm shorter in length than the test tube. The test tube was fixed on a rotating wheel (2 rpm) in an electric oven kept at 37°. This was accomplished in such a way that the tooth was prevented by the glass rod from moving down with the saliva as the tube rotated end-over-end and instead was immersed intermittently in the saliva. All remineralization experiments were done in duplicate.

The fluoride delivery system was removed after remineralization. For Device A, the film was dissolved by ethanol, which was renewed at least five times and shaken vigorously. For Device B, the film was peeled off carefully so as not to damage the tooth surface, and the tooth was washed with water to remove any I or II particles adhering to the surface. Then the surface was rewaxed, except for the remineralized area, and etched in 1 ml of 0.5 *M* $HClO_4$ for successive intervals of 30, 60, 120, 200, and 200 sec. The etched surface was washed with 1 ml of water after each etching step.

**Assay of Phosphate, Fluoride, and Calcium 45**—Phosphate, fluoride, and calcium 45 concentrations in each etching solution were analyzed when the tooth was remineralized in the buffer containing calcium 45. Phosphate and fluoride were analyzed when the tooth with the fluoride delivery device was remineralized in saliva.

Phosphate concentrations were determined by the method of Gee *et al.* (2) in which the phosphoammonium–molybdate complex formed was reduced by stannous chloride. The absorbance of the resulting blue color was determined after 15 min at 720 nm[5].

[4] Endur M, Ormco Co.
[5] Hitachi 690 spectrophotometer.

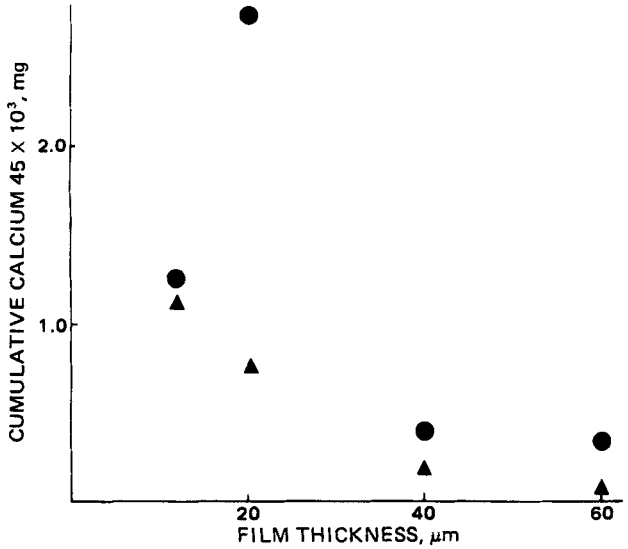

**Figure 3**—*Effect of film thickness and particle size on the cumulative uptake of calcium 45 with Device A. Teeth were demineralized for 6 hr and remineralized for 24 hr. Calcium fluoride particles passed through a 270- (●) or a 100- (▲) mesh sieve.*

Fluoride concentrations were determined by a combination fluoride electrode[6] using a low-level total ionic strength-adjusting buffer.

Calcium 45 was determined by a scintillation counter[7]. Nonradioactive calcium was measured by atomic absorption[8]. Because of possible phosphate interference, strontium chloride was added to each sample in the latter procedure.

**Apparent Diffusivity of I through Ethylcellulose, Ethylcellulose–Glycerin, and Ethylcellulose–Povidone Films**—When a solute is suspended in a film, its diffusivity, $D_e$, through the film can be obtained by measuring the amount of solute released from the film as a function of time according to (3):

$$Q = (2D_e t A C_s)^{1/2} \qquad \text{(Eq. 1)}$$

where $Q$ is the amount of solute released per unit area after time $t$, $A$ is the total amount of solute in the film per unit volume, and $C_s$ is the solubility of the solute in the film.

The diffusivities of I through ethylcellulose, ethylcellulose–glycerin, and ethylcellulose–povidone films were measured as follows. Calcium fluoride (I) was suspended in 0.3 ml of an ethanolic solution of the polymer or polymer mixture. The suspension was poured into a shallow (1-mm depth) cylindrical depression (0.88-cm radius) on a polytef disk and dried for 13 min in an electric oven at 50°. The film on the disk was then immersed into water that was stirred constantly and kept at 30°. The fluoride released from the film was determined at several sampling times with a fluoride electrode.

## RESULTS

**Fluoride Delivery Device A**—*Diffusivity of I in Polymer Films*—The plots for amounts of I released *versus* the square root of time for the three films are shown in Fig. 2. Effective diffusivities of I then were calculated from the slopes using Eq. 1. The values of $D_e$ for I in ethylcellulose, ethylcellulose–glycerin, and ethylcellulose–povidone films were $1.44 \pm 0.18 \times 10^{-10}$, $3.20 \pm 0.58 \times 10^{-12}$, and $2.20 \pm 0.25 \times 10^{-8}$ cm²/sec, respectively. Since the last film had a higher effective diffusivity and adhered to the tooth better, it was selected for Device A.

*Effects of Film Thickness and Particle Size of Suspended I on Remineralization*—The teeth demineralized for 6 hr ($D_6$) were covered by varying thicknesses (10–60 μm) of an ethylcellulose–povidone film containing I, which was sieved by a 100- or 270-mesh sieve (150- or 52-μm openings, respectively). Then these teeth were remineralized for 24 hr in buffer ($R_{24}$). Figure 3 shows the cumulative uptake of calcium 45 at depths up to 80 μm as a function of the film thickness. Fluoride uptake decreased with increasing film thickness for both particle sizes of I studied and were very small, with levels of only ~1/50 or less of those attained previously in solution remineralization experiments (1). Even in the system with smaller particles, appreciable uptake was not found. These results indicate that the diffusion of ions out of or through the film is the rate-limiting step for remineralization in this system and that the ionic activity product, $K_{FAP}$, simply does not reach a high enough value ($>10^{-108}$) in the tooth.

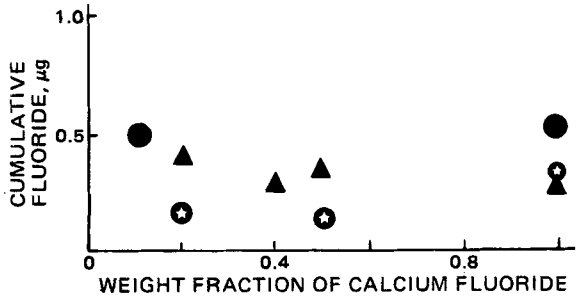

**Figure 4**—*Effect of ratio of calcium fluoride ($CaF_2$) to calcium phosphate dihydrate ($CaHPO_4 \cdot 2H_2O$) on cumulative fluoride uptake with Device A. Key: ●, $D_6$–$R_{24}$, 40-μm film thickness; ◘, $D_6$–$R_{72}$, 40-μm film thickness; and ▲, $D_{24}$–$R_{72}$, 40-μm film thickness.*

*Effects of Longer Remineralization Times and All Three Ion Sources*—Assuming that the solubility of I in the aqueous pores of the film phase is equal to its aqueous solubility implies that the fluoride concentration in the pores of the film is ~7 ppm. This concentration is high enough for the formation of fluoridated hydroxyapatite in the remineralization step, suggesting that higher permeabilities of the film to ions and longer remineralization times could increase the degree of remineralization. Furthermore, higher calcium and phosphate concentrations in the film might improve remineralization even if the permeability remains low. Therefore, the following experimental systems were examined.

Teeth demineralized for 6 or 24 hr were covered by a 40-μm film (ethylcellulose–povidone) containing mixtures of I and II and remineralized for 24 or 72 hr. Although a thinner film would present less of a barrier for ions to diffuse in from the external solution, the 40-μm film was selected to accommodate the particles that ranged in size up to ~50 μm. Figure 4 shows the cumulative fluoride uptake (in micrograms) to a depth of 89–90 μm as a function of the weight fraction of I in the I–II mixture. These results ranged from 0.2 to 0.5 μg and did not depend significantly on either the weight fraction of I or the demineralization and remineralization times. Fluoride concentrations in these teeth were much less than expected, a few hundred parts per million at a depth of ~40 μm.

**Fluoride Delivery Device B**—Calcium fluoride or a I–II mixture was dispersed on the surface of a demineralized tooth and covered by a cellulose film in which the ions were estimated to have an effective diffusivity of $\sim 10^{-6}$ cm²/sec. The tooth was remineralized for 24 hr in the reminer-

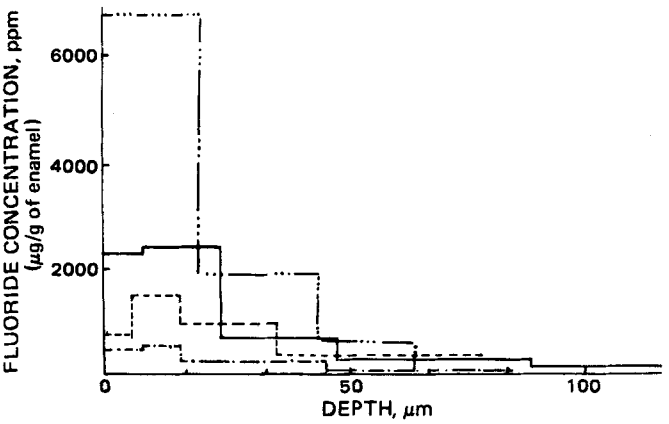

**Figure 5**—*Remineralization of ground bovine tooth using Device B in saliva and in remineralizing solution. Key: -···-, calcium fluoride with remineralization in saliva; —, calcium fluoride with remineralization in buffer solution; - - -, calcium fluoride and calcium phosphate dihydrate (1:6) with remineralization in saliva; and -·-, calcium fluoride and calcium phosphate dihydrate (1:6) with remineralization in buffer solution.*

alizing buffer solution. During remineralization, water, calcium, and phosphate diffuse through the cellulose film and through a region immediately adjacent to the tooth surface, which contains the micronized powders. Therefore, calcium and phosphate ions were supplied from both the buffer and the dissolution of these powders, while fluoride was supplied directly from the dissolution of I. The higher diffusivity of ions through the cellulose film and the lack of a polymer network on the tooth surface would be expected to lead to much more remineralization by Device B than was accomplished using Device A. Figure 5 shows the fluoride concentration profiles measured in the teeth remineralized with Device B. The results were considerably higher (1000–2000 ppm at depths as great as 40–50 μm) than the results obtained with Device A (<300 ppm). Furthermore, Device B containing only I was more effective in remineralizing the teeth than was Device B containing the I–II mixture, implying that calcium and phosphate readily diffused through the film from the solution.

The fluoride concentration profile of teeth remineralized in saliva instead of the buffer solution are shown in Fig. 5. The results were almost the same as those obtained from remineralization in the remineralizing buffer solution. As was the case when remineralizing with buffer solutions, the system containing I was much better than the I–II mixture. Even in saliva, an appreciable fluoride concentration was achieved using Device B.

## DISCUSSION

The results obtained with Device B show that satisfactory remineralization occurred when I was held in proximity to the tooth surface for 24 hr. These initial experiments with Device A, a prototype of a practical means for holding I near the tooth surface, show that the main problem to overcome is to find a polymer film that adheres to the tooth and from which I is released rapidly.

Since these studies showed that remineralization can be achieved in the model systems using bovine teeth, it then was verified that human teeth respond in similar manner (4, 5). These studies provide justification for proceeding in the development of the appropriate polymer system for use with Device A.

## SUMMARY

Delivery Device A, a possible prototype of a clinically feasible remineralization system, was not successful with the polymer systems studied. In each case, the film permeability was not high enough for ions to penetrate at a sufficient rate.

Delivery Device B, while not practical for clinical use, had a much higher permeability to ions than did Device A and was used to simulate behavior that might be expected from Device A if a more permeable film could be developed. Device B was quite effective in remineralizing teeth, yielding fluoride levels of ~1000 ppm at depths up to 50 μm, *even in saliva*. Calcium fluoride alone gave better results than the I–II mixtures studied.

These results imply that a practical clinical remineralization procedure based on Device A is feasible, with the primary problem being development of a suitable polymer film.

# Novel Topical Fluoride Delivery System II: Remineralization of Human Teeth

**JEFFREY L. FOX, MASAKATSU YONESE, BALA V. IYER, LEWIS J. ABRAHAMS, and WILLIAM I. HIGUCHI** ˣ

Received June 30, 1980, from the *College of Pharmacy, University of Michigan, Ann Arbor, MI 48109.* Accepted for publication January 26, 1981.

**Abstract** □ A recently conceived calcium fluoride-containing remineralization system was tested using human teeth *in vitro*. The influence of several variables (surface pretreatment, demineralization time, and remineralization time) was studied. Appreciable levels of fluoride taken up by pumiced human teeth were found at depths up to 50 μm when remineralization was carried out in either the remineralizing solution or saliva. The successful performance of the delivery device in these laboratory studies is encouraging and indicates that the logical evolution of the crude devices studied thus far could lead to clinically practical fluoride delivery devices.

**Keyphrases** □ Delivery devices—fluoride, remineralization of human teeth *in vitro*, effect of surface treatment on remineralization □ Fluoride—delivery devices for remineralization of human teeth *in vitro*, effect of surface treatment on remineralization □ Remineralization—human teeth *in vitro*, fluoride delivery devices, effect of surface treatment on remineralization □ Teeth, human—remineralization *in vitro* using fluoride delivery devices, effect of surface treatment on remineralization

As a result of *in vitro* studies demonstrating the effectiveness of a controlled demineralization pretreatment in enhancing subsequent fluoride remineralization (1), investigations recently were initiated to develop techniques for a practical clinical remineralization procedure. In the previous study, Yonese *et al.* (2) worked with a delivery device that was capable of physically holding particles of calcium fluoride (I) adjacent to the tooth surface while remaining permeable to calcium, phosphate, and fluoride ions as well as water. This device was capable of depositing high levels of fluoride (1000–2000 ppm) at depths of up to 50 μm, using bovine enamel as a test substrate.

This paper demonstrates the effectiveness of demineralization–remineralization for human teeth and examines additional variables that are clinically relevant but that were not studied with the bovine teeth.

## EXPERIMENTAL

Human teeth removed for orthodontic reasons were obtained from dentists in the Chicago area.

The buffer solutions used for demineralization and remineralization were prepared as described previously (2). The demineralizing solution

# Novel Topical Fluoride Delivery System II: Remineralization of Human Teeth

**JEFFREY L. FOX, MASAKATSU YONESE, BALA V. IYER, LEWIS J. ABRAHAMS, and WILLIAM I. HIGUCHI** ˣ

Received June 30, 1980, from the *College of Pharmacy, University of Michigan, Ann Arbor, MI 48109.* Accepted for publication January 26, 1981.

**Abstract** □ A recently conceived calcium fluoride-containing remineralization system was tested using human teeth *in vitro*. The influence of several variables (surface pretreatment, demineralization time, and remineralization time) was studied. Appreciable levels of fluoride taken up by pumiced human teeth were found at depths up to 50 μm when remineralization was carried out in either the remineralizing solution or saliva. The successful performance of the delivery device in these laboratory studies is encouraging and indicates that the logical evolution of the crude devices studied thus far could lead to clinically practical fluoride delivery devices.

**Keyphrases** □ Delivery devices—fluoride, remineralization of human teeth *in vitro*, effect of surface treatment on remineralization □ Fluoride—delivery devices for remineralization of human teeth *in vitro*, effect of surface treatment on remineralization □ Remineralization—human teeth *in vitro*, fluoride delivery devices, effect of surface treatment on remineralization □ Teeth, human—remineralization *in vitro* using fluoride delivery devices, effect of surface treatment on remineralization

As a result of *in vitro* studies demonstrating the effectiveness of a controlled demineralization pretreatment in enhancing subsequent fluoride remineralization (1), investigations recently were initiated to develop techniques for a practical clinical remineralization procedure. In the previous study, Yonese *et al.* (2) worked with a delivery device that was capable of physically holding particles of calcium fluoride (I) adjacent to the tooth surface while remaining permeable to calcium, phosphate, and fluoride ions as well as water. This device was capable of depositing high levels of fluoride (1000–2000 ppm) at depths of up to 50 μm, using bovine enamel as a test substrate.

This paper demonstrates the effectiveness of demineralization–remineralization for human teeth and examines additional variables that are clinically relevant but that were not studied with the bovine teeth.

## EXPERIMENTAL

Human teeth removed for orthodontic reasons were obtained from dentists in the Chicago area.

The buffer solutions used for demineralization and remineralization were prepared as described previously (2). The demineralizing solution

0022-3549/81/0800-0910$01.00/0
© 1981, American Pharmaceutical Association

consisted of an acetate buffer solution 16% saturated with respect to the thermodynamic solubility of hydroxyapatite (0.1 *M* acetate buffer containing 3.5 m*M* calcium and phosphate, adjusted to pH 4.5 by the addition of sodium hydroxide and to an ionic strength of 0.5 by the addition of sodium chloride). The remineralizing solution also was 0.1 *M* acetate buffer adjusted to pH 4.5 with an ionic strength of 0.5 *M*, but it contained 12 m*M* calcium and phosphate and 10 ppm of fluoride. All chemicals used in the buffers were reagent grade, and all water was distilled twice.

Dialysis bags[1] were used for the cellulose film in fabricating the fluoride delivery device.

The experimental procedures were similar to those reported previously (2). In these experiments, the fluoride delivery device was a cellulose film that physically held calcium fluoride (I) or a mixture of I and dicalcium phosphate dihydrate (II) against the tooth surface (Device B).

Teeth surfaces were conditioned in one of two ways. They were ground with rotating sandpaper (No. 400 first, followed by No. 600) to remove pellicle, or they were pumiced with a non-fluoride-containing pumice.

Prior to remineralization, the tooth received the following pretreatment. The tooth surface was covered by a dental inlay wax[2] except for a 0.25-$cm^2$ area on the front surface. Then the tooth was demineralized in 10 ml of the 16% partially saturated buffer solution for 0–48 hr while being shaken gently with a wrist-action shaker. The solution was kept at 30 ± 0.1°. The extent of demineralization was assessed by measurement of the amount of phosphate dissolved.

The fluoride delivery device was attached to the tooth surface prior to remineralization as follows. Calcium fluoride, sieved by a 270-mesh sieve (52-μm openings), was spread evenly on the tooth surface and covered by a cellulose film (0.2 $cm^2$ in area), the periphery of which was fixed in place by adhesive[3]. The teeth with the device attached were remineralized for 24–72 hr in the remineralizing buffer or in saliva. Details of the remineralization procedure were elaborated in the previous paper (2).

All experiments were done in duplicate except where noted, and the two trials generally were within 10–15% of each other. Results of one of the two are presented for clarity in the figures.

The fluoride delivery device was peeled off carefully from the adhesive to avoid damaging the tooth surface. Then the tooth surface was washed with water to remove the particles of I. The teeth were etched in 1 ml of 0.5 *M* $HClO_4$ in a small glass tube without stirring for successive intervals of 30, 60, 120, 200, and 200 sec. The etched surface was washed with 1 ml of water after each etching step. Concentrations of phosphate, fluoride, and calcium 45 in the etching solution were analyzed in the same manner as reported previously (2).

## RESULTS

**Effect of Pellicle on Remineralization**—In the previous experiments, bovine teeth were ground by rotating a fine sandpaper so as to remove the pellicle completely. However, during *in vivo* application of a clinically practical anticaries treatment, the pellicle might not be as readily removable. Therefore, the effects of the pellicle on demineralization and remineralization were investigated.

To test for a possible pellicle effect, one of three types of surface conditioning (grinding, pumicing, or simply washing) was done prior to demineralization. The conditioned tooth was demineralized in 16% partially saturated acetate buffer solution for 0–24 hr and then remineralized in the remineralizing solution. The fluoride delivery device was not used in this experiment.

Figure 1 shows the fluoride concentration profiles obtained for both ground and pumiced teeth. After grinding, the tooth demineralized for 2 hr had a high fluoride uptake while that of the nondemineralized tooth was much lower. The results were similar to those obtained previously with ground bovine teeth. The molar ratio of calcium 45 to fluoride uptake was near the value of 5.0 expected for completely fluoridated hydroxyapatite. For the pumiced teeth, however, the fluoride concentration profiles attained after demineralization–remineralization were lower and at about the same level as for the nondemineralized ground tooth. Thus, the type of surface conditioning greatly affected the degree of remineralization.

Figure 2 shows the cumulative fluoride uptake from the surface to a depth of ~80 μm as a function of the duration of demineralization. The fluoride uptake of both ground and pumiced teeth increased with the duration of demineralization, and the levels attained in the ground teeth were much greater than in the pumiced teeth.

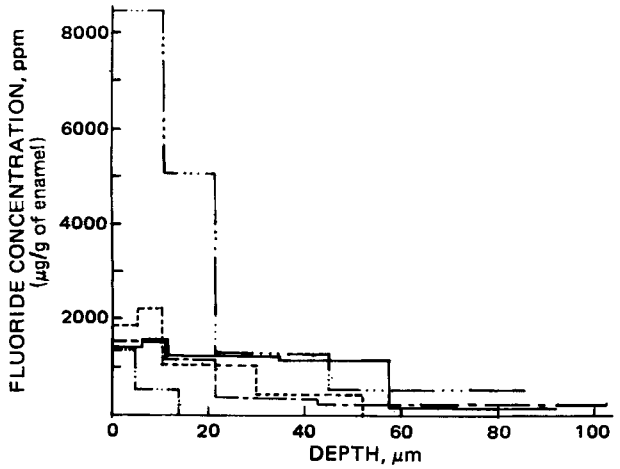

**Figure 1**—*Fluoride concentration profiles of ground and pumiced human teeth remineralized in buffer solution. Key:* - · · · -, $D_2$–$R_{24}$, *ground teeth;* — — —, $D_0$–$R_{24}$, *ground teeth;* - - -, $D_{24}$–$R_{24}$, *pumiced teeth;* —, $D_{16.5}$–$R_{24}$, *pumiced teeth; and* - · - · ·, $D_0$–$R_{24}$, *pumiced teeth. D and R represent demineralization and remineralization, respectively, and the lower subscripts represent the time in hours.*

**Remineralization with Device B in Buffer Solution**—Extrapolation of the data for the pumiced teeth in Fig. 2 suggests that prior demineralization for ~48 hr might be necessary to attain fluoride levels in pumiced teeth comparable to the levels attained in ground teeth demineralized for only 2 hr prior to remineralization. Therefore, all pumiced human teeth in these experiments were demineralized for 48 hr to achieve appreciable fluoride uptake. Figure 3 shows the fluoride concentration profiles of these pumiced human teeth after application of Device B containing only I. These teeth were remineralized for 24–72 hr in the acetate buffer. The fluoride concentrations in these teeth were 1000–2000 ppm at depths as great as 40 μm.

Figure 4 shows the cumulative fluoride uptake from the surface to about an 80-μm depth as a function of the remineralization time after application of Device B containing I or I and II (1:6). The device containing I alone appeared to be marginally more effective than the device containing I–II. Furthermore, fluoride uptake was almost independent of the duration of remineralization; a plateau was achieved after ~24 hr of remineralization, as in the previous study using bovine teeth (2).

As the next step in the approach to the *in vivo* situation, remineralization was carried out in saliva. The fluoride uptake concentration profiles of teeth remineralized in saliva are shown in Fig. 5. The fluoride uptake by the tooth remineralized for only 4 hr was very low, as expected. However, the teeth remineralized for 48 hr had fairly high fluoride levels up to a depth of ~50 μm.

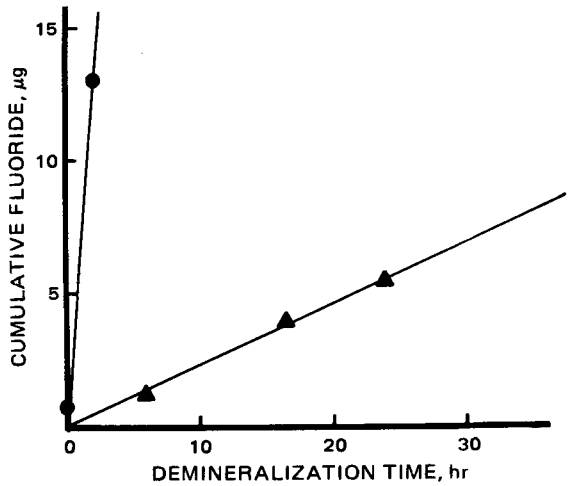

**Figure 2**—*Influence of surface treatment on cumulative fluoride uptake of human teeth demineralized for different time intervals. Key:* ●, *ground; and* ▲, *pumiced.*

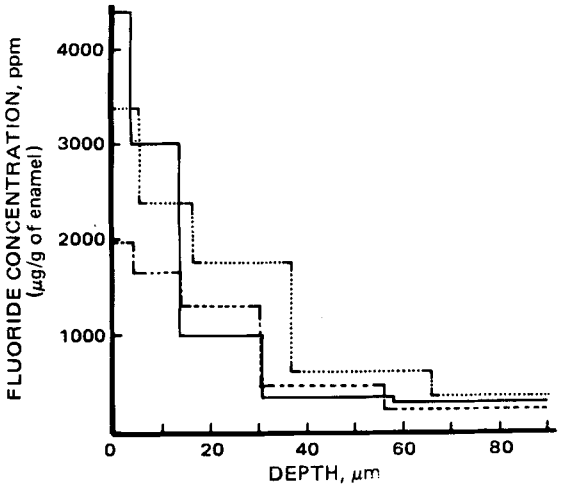

**Figure 3**—*Fluoride concentration profiles of pumiced human teeth treated with Device B containing calcium fluoride. Key: —, $D_{48}$–$R_{72}$; - · · · -, $D_{48}$–$R_{48}$; and - - - -, $D_{48}$–$R_{24}$.*

To determine whether loosely bound material at the tooth surface affects the interpretation of results, a tooth was brushed with a soft toothbrush[4] after remineralization (Fig. 5). The concentration peak seen at a depth of 5–20 μm in nonbrushed teeth was not present after brushing, implying that some relatively loose material may have been included in previous measurements of fluoride levels near the nonbrushed tooth surface. However, even in the brushed teeth, ~1000 ppm of fluoride was found at a depth of ~50 μm.

## DISCUSSION

Teeth used in this study were ground or pumiced prior to demineralization. A few trials also were conducted using teeth with no surface treatment and, therefore, with an intact pellicle. These teeth generally had poor fluoride uptake and considerably larger sample-to-sample variation and, therefore, were not studied further. Although ground teeth had much better fluoride uptake than pumiced teeth, the impracticality of grinding in a clinical setting also limited the number of experiments done with ground teeth. Furthermore, the length of prior demineralization of ground teeth was limited to only 2 hr because of the excessive loss of mineral occurring with longer demineralization times.

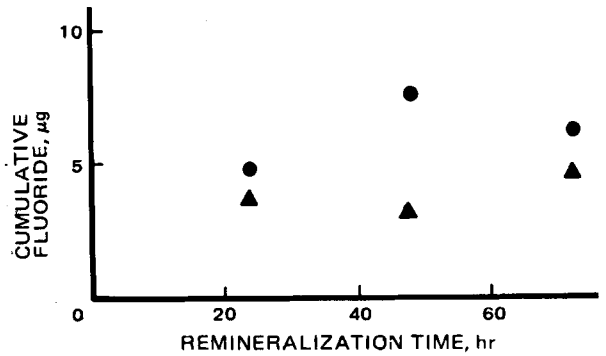

**Figure 4**—*Cumulative fluoride uptake of pumiced human teeth remineralized for different time intervals with Device B. Each point represents a single experiment. Key: ●, $D_{48}$–$R_T$, I alone; and ▲, $D_{48}$–$R_T$, I–II.*

[4] Colgate.

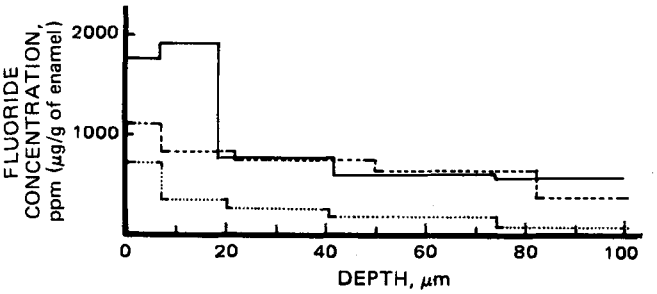

**Figure 5**—*Effect of brushing after remineralization on fluoride uptake of pumiced human teeth with Device B in saliva. Key: —, $D_{48}$–$R_{48}$, nonbrushed; - - -, $D_{48}$–$R_{48}$, brushed; and - · · · -, $D_{48}$–$R_4$, nonbrushed.*

The studies conducted with Device B show that the remineralization approach used has promise. In particular, the results show that remineralization is essentially complete after 24 hr of treatment and that appreciable fluoride levels are achieved at depths up to ~50 μm. Furthermore, the results are not greatly dependent on whether I alone or I–II is used. This finding may mean that there is considerable room to manipulate the formulation so that maximum efficiency of fluoride delivery is achieved. Although the mixture appeared to be slightly less effective in delivering fluoride than I alone, the efficiency was quite good (~3–5% of the total fluoride applied was deposited in the tooth).

The experiments conducted with saliva were encouraging, showing that saliva can be exploited as a source of calcium and phosphate even though a physical barrier exists between saliva and the tooth surface. Furthermore, this barrier prevents salivary proteins and other macromolecules from contacting the surface directly and possibly interfering with remineralization.

## SUMMARY

Although the surface conditioning of a tooth affects both remineralization and demineralization, human and bovine teeth have the same demineralization–remineralization behavior when the pellicle is removed by grinding. The degree of remineralization attainable increases in proportion to the amount of mineral removed during demineralization.

Appreciable fluoride levels by pumiced human teeth with Device B attached were found at depths of up to 50 μm when remineralization was carried out in either the remineralizing buffer solution or saliva.

The salient features of the fluoride delivery system used in this study were the use of a relatively insoluble fluoride salt (I), which is inherently long acting and also provides a source for calcium as well as fluoride, and the provision for a relatively long contact time (24–48 hr) so that the low fluoride levels provided by I could be sustained.

The successive performance of the delivery device in these laboratory studies is encouraging and indicates that the logical evolution of the crude devices studied thus far could likely lead to clinically practical fluoride delivery devices. Pilot *in vivo* studies (3) with Device B have already yielded results comparable to those obtained in these *in vitro* experiments.

# Preparation of Spherical Matrixes of Prolonged-Release Drugs from Liquid Suspension

**Y. KAWASHIMA ˣ, H. OHNO, and H. TAKENAKA**

Received September 30, 1980, from the *Gifu College of Pharmacy, Mitahora, Gifu 502, Japan.* Accepted for publication January 28, 1981.

**Abstract** □ A simple and less expensive method for the preparation of spherical matrixes of prolonged-release drugs was developed from liquid suspension. The drugs dispersed in distilled water were agglomerated with a small amount of organic solution or melt of matrix material. The process, called a "solution" or "melting" method, depended on the state of matrix material. In the present study, sulfamethoxazole and sulfanilamide were agglomerated with white beeswax and ethylcellulose. Furthermore, the parameters affecting the average size and release behavior of the resultant matrixes were investigated. Increasing the amount of matrix material used yielded large matrixes and prolonged-release action. The drugs rendered hydrophobic by surface treatment produced larger matrixes that released drug more slowly than untreated drugs. The sizes of the matrixes decreased and became uniform with increasing agitation speed. The sulfamethoxazole matrixes with wax proved to be enteric coated since the release rate was fast in the alkaline test solution (pH 7.5) but slow in the acidic one (pH 1.2).

**Keyphrases** □ Spherical agglomeration—preparation of spherical matrixes of prolonged-release drugs from liquid suspension, sulfamethoxazole and sulfanilamide □ Prolonged-release drugs—preparation of spherical matrixes from liquid suspension, sulfamethoxazole and sulfanilamide □ Sulfamethoxazole—drug release behavior, preparation of spherical matrixes from liquid suspension □ Sulfanilamide—drug release behavior, preparation of spherical matrixes from liquid suspension

Previous investigators (1) found that the dispersed particles in liquid suspension were spherically agglomerated with a small amount of second immiscible liquid, which preferentially wetted the particles. By developing this research further, other investigators (2–4) established the "spherical agglomeration" technique as a favorable method for agglomeration of fine particles in liquid.

By using a modified spherical agglomeration technique, a simple and less expensive process was developed in the present study to prepare spherical matrixes of prolonged-release drugs as an alternative to spray-congealing methods (5–7). An organic solution (*e.g.*, benzene) or a melt of matrix material such as a wax-like material or ethylcellulose was used as a second immiscible liquid, *i.e.*, a collecting liquid. The parameters affecting micromeritic properties and drug release behavior of the resultant matrixes also were studied.

## EXPERIMENTAL

**Materials**—Sulfamethoxaxole[1], having geometric mean diameters of 6 and 380 μm and geometric standard deviations of 1.4 and 1.2 μm, respectively, was used. Fine sulfamethoxazole particles were supplied by pulverizing the coarse particles. Sulfanilamide[2] particles of a 297-μm geometric mean diameter with a geometric standard deviation of 1.1 μm also were used for agglomeration. White beeswax[3] and ethylcellulose[4] were used as matrix materials.

Surface-treated drugs were rendered strongly hydrophobic to increase their affinity with matrix material to attain a well-coated matrix. Surface treatment was done by allowing adsorption of palmitic acid[4] onto the drug surface. Adsorption was achieved by dispersing 10 g of particles in 200 ml of 3% palmitic acid–alcohol solutions and leaving the system for 2 days. The drugs adsorbed with palmitic acid were filtered and dried at 40° for 1 day. No significant changes in particle size after the treatment were observed.

**Preparation of Matrixes**—*Melting Method*—Sulfamethoxazole particles (10 g) were dispersed in 300 ml of distilled water contained in an 8 × 18.5-cm glass cylindrical vessel. The system was agitated at 241, 382, 620, and 1100 rpm by a turbine-type agitator with four blades, 4 cm in diameter, to examine the effect of agitation speed on product size. The agitator was set 1 cm from the bottom of the vessel.

The system was heated gradually to 90° by a mantel heater. When the system reached 90°, powdered white beeswax, weighing 1.25 or 1.5 g, was added to change the coating thickness of resultant matrixes. Then the system was agitated for 10 min at 90°. The molten white beeswax collected the dispersed drug and yielded spherical agglomerates. By removing the mantel heater, the system was cooled gradually to room temperature while stirring to harden the agglomerates. The resultant agglomerates were filtered and dried for 24 hr at 40°. The average diameter of the dried agglomerates was determined by a sieving method using standard sieves specified in the JP, the opening of which was nearly the same as that of the Tyler sieve. The size range varied from 16 to 84%.

*Solution Method*—A small amount of benzene solution of white beeswax or ethylcellulose was used instead of a white beeswax melt. Sulfamethoxazole particles (5 g) were agglomerated with 0.5, 1.3, or 3.0 ml of a 7% benzene solution of ethylcellulose. Then the system was agitated continuously at 620 rpm for 2 hr to evaporate the benzene and to harden the agglomerates. Sulfanilamide particles (10 g) were agglomerated with 4 or 8 ml of a 9.3% benzene solution of white beeswax. The resultant agglomerates were filtered and dried as described for the melting method.

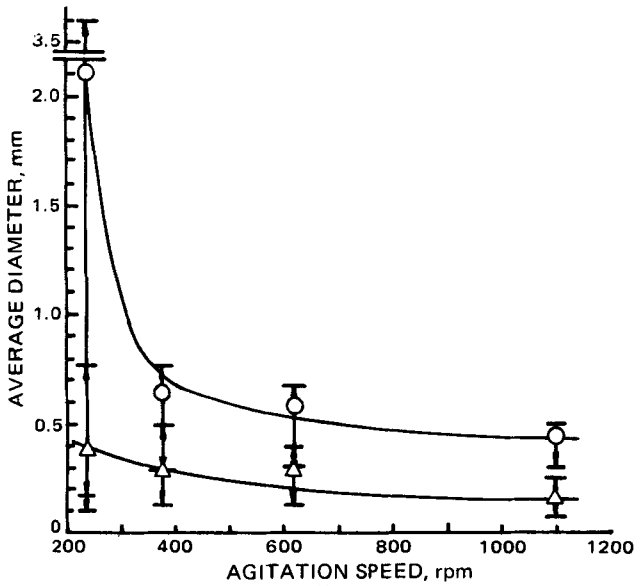

**Figure 2**—*Effect of agitation speed on the average diameter of matrixes. The material was pulverized sulfamethoxazole, and the collecting liquid was 1.5 g of a white beeswax melt. Key: ○, with surface treatment; and △, without surface treatment.*

**Drug Release Test of Agglomerates**—The dissolution tests were conducted by a beaker method. A USP rotating basket was modified by attaching a propeller to the top, which was used as an agitator. Thus, the adsorption of air bubbles to the basket was prevented and agitation was promoted. The agglomerates, fractionated to 500–1000 μm, were used to cancel the surface area effect on the dissolution rate.

The 90-mg test samples were added to 900 ml of distilled water or acidic (pH 1.2) or alkaline (pH 7.5) disintegration test solutions specified in the JP. Adhesion of agglomerates to the basket was slight. The system was controlled thermally at 37° and agitated at 150 rpm. At various adequate intervals, 2-ml aliquots were withdrawn from the system and filtered through a 0.2-μm filter[5]. The dissolved amounts of drug were determined spectrophotometrically at the UV wavelengths of 250 and 257 nm using a double-beam spectrophotometer[6].

## RESULTS AND DISCUSSION

**Parameters Affecting Agglomerate Particle Size**—The products prepared by this technique were fairly rounded spheres, varying from 50 μm to 4 mm in size. Products prepared by the melting method appeared to be coated with white beeswax (Fig. 1).

The effects of the agitation speed of the system on agglomerate size are shown in Fig. 2. The median diameters of the products of the fine sulfamethoxazole particles prepared by the melting method were plotted against the agitation speeds. With increasing agitation speed, the average size of the particle agglomerates without surface treatment decreased gradually from 380 to 150 μm. The surface-treated particles yielded larger agglomerates than particles without surface treatment. The surface-treated particles could be wetted easily by molten wax due to their strong hydrophobic properties, resulting in large agglomerates.

Agitation speed strongly affected the product size of the surface-treated particles. The average particle size decreased sharply from 2.1 to 0.62 mm when the agitation speed was increased from 241 to 382 rpm (Fig. 2). With the coarse sulfamethoxazole particle, the agitation speed similarly affected agglomerate size. However, there was little difference in product size between the particles with and without surface treatment. This result indicates that it is difficult to make the coarse particles hydrophobic by surface treatment because of their poor adsorption of palmitic acid.

The effects of the amount of collecting liquid on agglomerate size are seen in Fig. 3. The median diameter of the products of the fine sulfamethoxazole particles prepared by the solution method increased with the increasing amounts of benzene solutions of white beeswax used. This trend was evident for products of the surface-treated particles and may have been due to increased affinity with the collecting liquid caused by the hydrophobic nature of the particles. The increase in the agglomerate size caused by surface treatment was also confirmed with the sulfanilamide products.

The effects of surface treatment on the size distribution of the agglomerates of the fine sulfamethoxazole particles are seen in Fig. 4. The size distribution of the products without surface treatment was described by a log-normal form (Fig. 4B). The slope of the line, representing a geometric standard deviation, decreased with increasing agitation speed. This result suggests that the agglomerates of a fairly uniform size can be produced by increasing the agitation speed. The size distributions of the products of the surface-treated particles were not represented by a log-normal form (Fig. 4A), because they were heterogeneous mixtures containing some extraordinarily large particles, which increased in number at the lower agitation speed. At the lower stirring speed, the collecting liquid was not dispersed uniformly, resulting in a heterogeneous mixture. Furthermore, the adhesive force between the surface-treated particles

might be stronger than the destructive force brought about by agitation. Therefore, once a large agglomerate was produced, it was rarely destroyed. Similar phenomena were observed for other products of sulfanilamide and sulfamethoxazole.

**Drug Release Behavior from Agglomerates**—Dissolution tests were undertaken to examine the prolonged-release behavior of the products. Dissolution behavior was represented by plotting the percentage of the drug released from the agglomerates on a semi-square root graph. The

release behavior of the sulfamethoxazole and sulfanilamide products in distilled water is seen in Figs. 5 and 6, respectively. Compared with the original particles, all sulfamethoxazole products prepared by both the melting and solution methods released the drug slowly, although the release rates varied extensively, depending on the preparation condition (Fig. 5). The release patterns of the agglomerates with wax became fairly straight lines. This finding indicates that the release process obeys the

Higuchi model (8), which explains the drug release process from a matrix as:

$$Q = [D(2A - C_s)C_s t]^{1/2} \quad \text{(Eq. 1)}$$

where $Q$ is the amount dissolved per unit area of exposure at time $t$, $A$ is the total volume of drug present in the matrix per unit volume, $C_s$ is the solubility of the drug in the external phase of the matrix, and $D$ is the diffusion constant. When $C_s \ll A$, Eq. 1 can be transformed to a more convenient form to exhibit the release patterns described in Figs. 5–10 (9):

$$C_r = 100[S_v(2DC_s t/A)^{1/2}] \quad \text{(Eq. 2)}$$

where $C_r$ is the percentage of the drug dissolved and $S_v$ is the specific surface area.

The surface treatment significantly delayed the drug release rate from the products. The product with surface treatment still retained 90% of the drug after a 5-hr exposure to the solvent. The size reduction of the raw materials adversely affected the prolonged-release action of the products (Fig. 5). This result may have been due to the fact that the fine particles can improve diffusivity in a matrix by their increased dissolution rate. The drug release rate of the agglomerate with ethylcellulose was faster than that of the agglomerates with wax, suggesting that the coating action of the ethylcellulose solution was weak compared with molten wax. The release pattern of the ethylcellulose product without surface treatment coincided with that of original sulfamethoxazole at the initial stage, although it deviated later. Figure 5 indicates that some uncoated drug on the product surface dissolved immediately on contact with the solvent, and the imbedded particles dissolved slowly at the later stage.

The release rates of the sulfanilamide products were faster than those of sulfamethoxazole (Fig. 6). The literature value of sulfanilamide solubility (10) is 7.5 g/liter (25°), whereas sulfamethoxazole is characterized as insoluble in the JP. The higher solubility of sulfanilamide, leading to the higher intrinsic dissolution rate, might be responsible for the increased release rate of sulfanilamide products. However, when a large amount of collecting liquid was used, the release pattern became a straight line with a decreased slope (Fig. 6). The surface treatment also delayed the release rate. Thus, it was confirmed that surface treatment of the raw materials and the amount of collecting liquid played an important role in controlling product release behavior.

The release patterns of the agglomerates in the acidic solution are displayed in Figs. 7 and 8. The release rates of the original and the agglomerates of sulfamethoxazole with ethylcellulose became faster than in distilled water (Fig. 7). While the release rates of the agglomerates with wax were almost the same as in distilled water, the release rates of both original sulfanilamide and its products (Fig. 8) were faster than in distilled water. The effects of the size and surface treatment of the raw materials on the release pattern of the products in Figs. 7 and 8 were similar to those in distilled water.

In the alkaline solution, the product release rates of both sulfamethoxazole and sulfanilamide were faster than in the other two media (Figs. 9 and 10). Enhancement of the release rate of sulfamethoxazole agglomerates with wax was particularly distinguished compared to the other products. The enteric-like action of the agglomerates with wax was proved by this finding. The fatty acid contained in the wax might be more soluble in the alkaline medium than in the acidic medium. In addition, the ester involved in the wax might be hydrolyzed more readily in the alkaline medium. These factors may promote the disintegration of the matrix and increase the release rate in the alkaline medium.

# GLC Analysis of Hydrocortisone, Triamcinolone Acetonide, and Desonide in Culture Media of Mouse and Human Dermal Fibroblasts Using Flame-Ionization Detection

**D. S-L. AU *, J. O. RUNIKIS ˣ, F. S. ABBOTT, and R. W. BURTON**

Received September 2, 1980, from the *Faculty of Pharmaceutical Sciences, University of British Columbia, Vancouver, British Columbia V6T 1W5, Canada.* Accepted for publication February 3, 1981. *Present address: College of Pharmacy, University of Houston, Houston, TX 77030.

**Abstract** □ A quantitative GLC assay with flame-ionization detection capable of detecting nanogram quantities of hydrocortisone, triamcinolone acetonide, and desonide in biological fluids was developed. This assay consisted of two extractions of the glucocorticoids from 1 *N* sodium chloride-treated cell culture media into ethyl acetate and subsequent double derivatization with methoxyamine and *N*-trimethylsilylimidazole. The chemical structures of methoxime–trimethylsilyl derivatives were confirmed by GLC–mass spectrometry. The methoxime–trimethylsilyl derivatives were stable for 24 hr. The applicability of this assay was demonstrated by studies of the glucocorticoid levels in L-929 and human dermal fibroblasts cell culture media over prolonged incubation (0–96 hr).

**Keyphrases** □ Glucocorticoids—GLC–mass spectrometric analysis of hydrocortisone, triamcinolone acetonide, and desonide in cell culture media □ GLC–mass spectrometry—analysis of hydrocortisone, triamcinolone acetonide, and desonide in cell culture media □ Hydrocortisone—GLC–mass spectrometric analysis, cell culture media □ Triamcinolone acetonide—GLC–mass spectrometric analysis, cell culture media □ Desonide—GLC–mass spectrometric analysis, cell culture media

Synthetic glucocorticoids vary in their clinical potencies as well as in their potential for causing dermal atrophy, a major adverse effect of long-term topical glucocorticoid therapy (1). Studies of the pathogenesis of this adverse effect have involved investigations of glucocorticoid effects on cell proliferation, protein synthesis, collagen synthesis, secretion of acid mucopolysaccharides, and other pleiotypic responses such as polyribosome formation and DNA synthesis (2, 3).

## BACKGROUND

Cultured dermal cells have been used previously as models, and the incubation of glucocorticoids with cultured cells lasted from hours to days. However, no reports of assays of glucocorticoids in cell culture media appear to have been published. It was assumed that the amounts of glucocorticoids dissolved represented their biologically active concentrations and that the metabolism of glucocorticoids during incubation was negligible. Therefore, development of a GLC assay should help to clarify the validity of such assumptions. Furthermore, with a quantitative GLC analysis of glucocorticoids in cultured cell systems, the relevant biochemical data of glucocorticoid effects can be more precisely interpreted, especially in terms of dose dependence.

The requirements for the estimation of glucocorticoids in biological systems are that sensitivity should be in the low nanogram range and that the technique should identify possible metabolites or decomposition products. Due to ready instrument availability, GLC using flame-ionization detection was selected for the determination of glucocorticoids in cell culture systems.

Few quantitative high-performance liquid chromatography (HPLC) (4–9) and GLC (10–12) assays have been reported for the analysis of synthetic glucocorticoids in biological fluids. One HPLC assay (4) achieved sensitivity as low as 0.05 ng of budesonide/ml of plasma in dogs with the aid of radioactive detection. Amounts as low as 2–4 ng of triamcinolone acetonide, triamcinolone, and prednisolone were detected in rat muscle by GLC using electron-capture detection and trimethylsilyl derivatization (12).

Martin and Amos (10) reported a GLC–mass spectrometric assay enabling the measurement of plasma concentrations of prednisone and prednisolone as methoxime–trimethylsilyl derivatives to nanogram per milliliter plasma levels. So far, methoxime–trimethylsilyl derivatization has not been applied to the assay of synthetic glucocorticoids except for prednisone and prednisolone (10), although it was used successfully for the assays of naturally occurring glucocorticoids (13). No specific assay techniques have been reported for desonide.

A GLC assay with flame-ionization detection was developed to quantitate hydrocortisone and synthetic glucocorticoids in cell culture media, using methoxime–trimethylsilyl derivatization.

## EXPERIMENTAL

**Materials**—Hydrocortisone[1] (I), triamcinolone[2] (II), triamcinolone acetonide[2] (III), and desonide[3] (IV) were obtained commercially. Progesterone[4] (V) was used as the internal standard. Methanol[5] and ethyl acetate[5] were distilled in glass, and pyridine[6] was silylating grade.

*Purity Confirmation of I–V*—All steroids were dried at 40° for 1 hr and at ambient temperature overnight in a vacuum oven before use. The weight lost due to the drying was <1% in all cases.

The melting points of these compounds were determined by both capillary melting-point determination[7] and differential scanning calorimetry[8]. The purities of I, IV, and V were satisfactory as received.

| Hydrocortisone | 4.09 | 2.10 | 4.50 |
| Triamcinolone | 5.04 | 3.53 | — |
| Desonide | 7.25 | 3.69 | 6.36 |
| Triamcinolone acetonide | 8.59 | 4.38 | 7.37 |

[a] Three or more values were averaged. [b] All compounds except progesterone gave more than one peak due to thermal decomposition. The value given is that of the major peak of each sample.

Samples II and III had to be recrystallized by dissolving the compound in methanol with the aid of steam and allowing the filtered resulting solution to stand in a hood for 3 days before collecting the crystals by filtration. The purities of all compounds were confirmed by HPLC.

*Methoxyamine Hydrochloride*[9]—This compound was dissolved in pyridine (100 mg/ml) (14) and stored in a conical reaction vial fitted with a polytef-lined valve[10] at 5° in a desiccator.

N-*Trimethylsilylimidazole*[11]—This compound was transferred to a conical reaction vial fitted with a polytef-lined valve immediately after each ampul was opened, and the vial was kept at 5° in a desiccator.

**Preparation of Derivatives**—*Methoxime–Trimethylsilyl Derivatives*—The procedure of Pfaffenberger and Horning (14) was adapted as follows. The test glucocorticoid (not more than 800 μg) was placed in a 1-ml conical reaction vial fitted with a polytef-lined screw cap[10]. Then 100 μl of methoxyamine hydrochloride–pyridine stock solution was added to dissolve the compound, and the resulting solution was incubated at 70° for 15 min. Then 100 μl of *N*-trimethylsilylimidazole was added, and silylation was conducted at 100° for 10–30 min, depending on the compound tested. An aliquot (1–2 μl) of the final reaction mixture (volume of 200 μl) was injected directly into the gas–liquid chromatograph or GLC–mass spectrometer.

tert-*Butyldimethylsilyl Derivatives*—The procedure was a modified version of previously reported methods (15–18). The test glucocorticoid (not more than 800 μg) was placed in a 1-ml conical reaction vial fitted with a polytef-lined screw cap. Then 100 μl of *tert*-butyldimethylsilyl chloride mixture[12] (1.0 mmole of *tert*-butyldimethylsilyl chloride and 2.5 mmoles of imidazole/ml of anhydrous *N,N*-dimethylformamide) was added to dissolve the compound, and the resulting solution was incubated at 100° for 1 hr. After the reaction, 100 μl of distilled water was added, and the derivatives were extracted into chloroform prior to GLC or GLC–mass spectrometric analysis.

**Differential Scanning Calorimetry**—A differential scanning calorimeter[8] was employed. All samples were crimped. The rate of temperature increase was 10°/min for each run.

**GLC**—The recording gas–liquid chromatograph[13] was equipped with a terminal[14] and a flame-ionization detector. The coiled glass column, 1.8 m × 2 mm i.d., contained 3% OV-7 coated onto 80–100-mesh Chromosorb W(HP).

All columns were conditioned at 100° for 15 hr, and then the oven temperature was programmed to increase by 0.1°/min up to 285°. The oven temperature was allowed to remain at 285° for ~15 hr to complete the conditioning process. The flow rate of carrier gas during conditioning was 10 ml/min.

The operating temperatures for routine analysis were: injection port, 265°; column, 285°; and detector, 300°. The gas flow rates were: carrier gas (helium), 60 ml/min; hydrogen, 40 ml/min; and air, 300 ml/min.

**GLC–Mass Spectrometry**—A computerized gas chromatograph–electron-impact mass spectrometer[15] was used to study the fragmentation pattern of the methoxime–trimethylsilyl derivatives for confirming their chemical structures. The following conditions were used for GLC: injection port temperature, 230°; column temperature, programmed from 200 to 260° at a rate of 10°/min; and carrier gas (helium) flow rate, 20 ml/min. The 2-m × 2-mm i.d. glass column was packed with 3% OV-17 coated onto 80–100-mesh Chromosorb W(HP). For the mass spectra, the ionization beam energy was 80 ev, the source analyzer temperature was 250°, and the separator was at 280°.

The modes of detection included total ion current and selected ion monitoring.

**Extraction**—The glucocorticoids were double extracted from the cell culture medium[16] containing 10% fetal calf serum as follows. Solid sodium chloride was added to decanted 5–10-ml aliquots of the medium to make it 1 *N*. The aqueous phase was extracted twice with an equal volume of glass-distilled ethyl acetate. After centrifugation to separate the layers, the organic extracts were combined and evaporated to dryness under a gentle nitrogen stream at ambient temperature. The residue was transferred to a 1-ml conical reaction vial containing 100 μl of internal standard (0.50 μg/ml in methanol) by rinsing three times with 0.2 ml of fresh ethyl acetate. The resulting mixture was evaporated to dryness and subjected to derivatization.

A white interface of precipitate occurred in the extraction of glucocorticoids from serum-containing media. The addition of sodium chloride to make a 1 *N* solution avoided this difficulty.

Ethyl acetate, ether, chloroform, and methylene chloride were evaluated for their extraction efficiency of glucocorticoids from serum-free and serum-containing media. Ethyl acetate was chosen because it had a high extraction efficiency and permitted easy withdrawal of the extracts.

Since the presence of serum in the medium decreased the extractability of glucocorticoids by single extraction, double extraction was used.

**Recovery Studies**—A series of known amounts of the test glucocorticoid solution in methanol (I, III, or IV) was added to individual centrifuge tubes and evaporated to dryness under a nitrogen stream. Five milliliters of 10% serum-containing medium, freshly prepared or decanted from control cells, was added to each glucocorticoid residue. The spiked samples were extracted as already described. Percentage recoveries were calculated from the standard curve of the glucocorticoid that was derivatized without extraction.

**Assays on Biological Samples**—*Human Dermal Fibroblasts*—Diploid dermal fibroblasts, isolated from explants of biopsies from 25–35-year-old males and stored at −193° in liquid nitrogen, were grown between the fourth and eighth subcultures in monolayer cultures to confluence in plastic culture plates.

*Mouse L-929 Dermal Fibroblasts*—Aneuploid mouse L-929 fibroblasts[17], originated from a chemically transformed clone in 1943 (19), were used. Both cultured cell lines were maintained in cell culture medium[16] (pH 6.8) supplemented with 10% fetal calf serum, 5 m*M* L-glutamine, 3.7 g of sodium bicarbonate/liter, 100 units of penicillin/ml, 100 μg of streptomycin/ml, and 0.25 μg of amphotericin B[18]/ml. The cells were incubated at 37° in carbon dioxide–air (5:95 v/v). The medium was changed twice weekly. Cellular morphology was examined regularly. Any plate with signs of infection, cellular degeneration, or poor growth was discarded.

**Treatment with Glucocorticoids**—Stock solutions of the test glucocorticoids ($10^3$ μg/ml in a propylene glycol vehicle) were prepared by mixing two volumes of propylene glycol (50% in methanol) and one volume of glucocorticoid solution in methanol ($10^3$ μg/ml) and then removing the methanol under vacuum. A control solution of the propylene glycol vehicle was prepared in a similar fashion.

Desired concentrations of 1 or 10 μg of glucocorticoid/ml of cell culture medium were prepared by adding 1 or 10 μl of the stock solutions/ml to the cell culture medium. The propylene glycol content of these glucocorticoid-treated media did not interfere with cell growth.

The stock solutions as well as the glucocorticoid-containing media were assayed before addition to the cells to ascertain the calculated and actual glucocorticoid concentrations. Some deviations of >15% of expected values were observed because of dilution errors. Only experimentally determined concentrations are reported here.

The glucocorticoid-treated medium was incubated for up to 96 hr with cells that had reached confluence in duplicate culture plates. The decanted media from the two plates containing 6–8 × $10^6$ cells were pooled and stored at −4° until analysis. The cells were harvested simultaneously for biochemical studies of glucocorticoid effects on cellular DNA (not reported here).

## RESULTS AND DISCUSSION

**Selection of Derivatizing Agents**—For initial experiments, *tert*-butyldimethylsilyl chloride was selected as a potential derivatizing reagent based on the advantages described in the literature (15–18). These advantages are: (*a*) high selectivity of the reaction, by which silylation occurs only at the unhindered C-21 hydroxyl group of the glucocorticoid; (*b*) increased stability of *tert*-butyldimethylsilyl ethers toward hydrolysis, which is $10^4$ times higher than that of trimethylsilyl ethers; and (*c*) the simplicity of the mass spectra of *tert*-butyldimethylsilyl ethers because these compounds give intense $(M - 57)^+$ ions. By monitoring this characteristic ion, mass spectrometry has the potential of being a sensitive and selective technique for quantitative analysis of glucocorticoids. The results obtained with this derivative, however, were generally disappointing, and further use of *tert*-butyldimethylsilyl chloride was discontinued. The *tert*-butyldimethylsilyl derivatives had unsatisfactory GLC properties, such as long retention times (longer than those of their parent compounds) and adsorption onto the column due to the remaining free functional groups.

The methoxime–trimethylsilyl derivatives of the test glucocorticoids proved to be superior to their corresponding *tert*-butyldimethylsilyl derivatives based on their satisfactory GLC properties, namely, short retention times and sharp symmetrical peaks with higher responses than their parent compounds.

**Column Selection**—Columns packed with 3% OV-7, OV-17, and OV-25 were examined for their suitability to resolve peaks of the internal standard, glucocorticoids, and any endogenous component in serum. The OV-7 and OV-17 columns gave superior elution profiles to the OV-25 column. However, with OV-17, the serum-associated endogenous peaks prevented satisfactory resolution of the peak of the internal standard, progesterone, a difficulty not present with the OV-7 column (Figs. 1*b* and 1*c*). Therefore, the OV-7 packing was selected, even though longer retention times were observed (Table I).

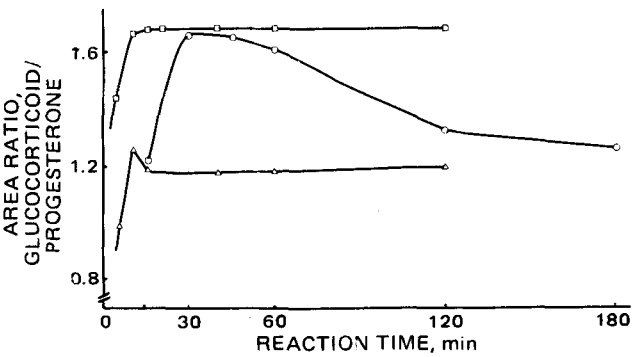

**Figure 2**—*Reaction kinetics of I–III at 100°. Plot of area ratio of derivatives formed to derivatized internal standard as a function of time. (The concentrations of I–III and their concentration ratios to the internal standard did not have to be the same.) Key:* △, *I;* □, *II; and* ○, *III.*

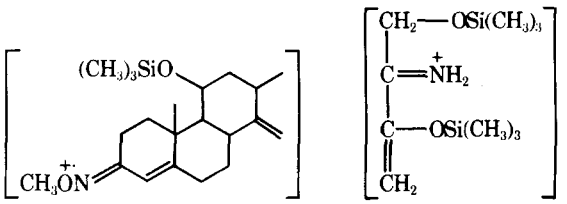
**Optimum Reaction Time for Silylation and Stability of Derivatives**—The optimum derivatization time of silylation was evaluated by reacting samples containing equivalent amounts of I–III for various times at 100°. Known amounts of separately derivatized methoxime internal standards then were added. The yield of the derivative, as observed by its area ratio to that of the internal standard, was monitored. The optimum yield was obtained when reaction times were 10, 15, and 30 min for I, II, and III, respectively (Fig. 2).

The methoxime–trimethylsilyl derivatives were stable in excess of 24 hr at 4° when stored in tightly capped reaction vials.

**Confirmation of Derivative Formation Using GLC–Mass Spectrometry**—The fragmentation patterns of derivatized I–IV when analyzed by electron-impact GLC–mass spectrometry confirmed the formation of methoxime–trimethylsilyl derivatives and V as the methoxime derivative (Figs. 3*a*–3*e*). Little information is available on fragmentation of the methoxime–trimethylsilyl derivatives of the synthetic glucocorticoids. Those of steroids present in rat adrenal gland extracts, primarily corticosterone derivatives, were reported by Prost and Maume (13). Their scheme of characteristic cleavages forms the basis for interpretation of the observed spectra (Figs. 3*a*–3*e*). The well-known losses of *O*-methoxy from *O*-methoxime groups and of silanol from trimethylsilyl groups (13, 20) were observed.

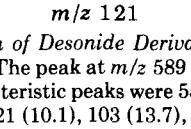
*Fragmentation Pattern of Hydrocortisone Derivative, Di(methoxime)-Tri(trimethylsilyl)-I*—The peak at *m/z* 636 (1.8%) corresponds to the molecular ion peak; other characteristic peaks were observed at *m/z* 605 (10.5%) $[(M - OCH_3)^+]$, 361 (3.5), 246 (6.1), 147 (7.0) $[(CH_3)_2Si = O^+ - Si(CH_3)_3]$ (21), 103 (11.4) $[CH_2 = O^+ - Si(CH_3)_3]$, 89 (12.3) $[O^+ - Si(CH_3)_3]$, and 73 (100) $[Si^+(CH_3)_3]$.



*m/z* 361 *m/z* 246

*Fragmentation Pattern of Triamcinolone Derivative, Di(methoxime)-Tetra(trimethylsilyl)-II*—The peak at *m/z* 739 (0.7%) corresponds to one less than the molecular ion $[(M - 1)^+]$. The characteristic peaks were 709 (3.0%) $[(M - OCH_3)^+]$, 689 (1.4) $[(M - OCH_3 - HF)^+]$, 618 (2.6) $[M - F - (CH_2{-}OSi(CH_3)_3)^+]$, 147 (8.8), 103 (12.3), and 73 (100).

*Fragmentation Pattern of Triamcinolone Acetonide Derivative, Mono(methoxime)-Di(trimethylsilyl)-III*—The peak at *m/z* 607 (0.4%) corresponds to the molecular ion. The characteristic peaks were 587 (1.1%) $[(M - HF)^+]$, 576 (1.6) $[(M - OCH_3)^+]$, 556 (10.7) $[(M - OCH_3 - HF)^+]$, 121 (9.0), 103 (18.1), and 73 (100).



*m/z* 121

*Fragmentation Pattern of Desonide Derivative, Mono(methoxime)-Di(trimethylsilyl)-IV*—The peak at *m/z* 589 (0.8%) corresponds to the molecular ion. The characteristic peaks were 558 (4.9%) $[(M - OCH_3)^+]$, 468 (6.8) $[(M - 121)^+]$, 121 (10.1), 103 (13.7), and 73 (100).

*Fragmentation Pattern of Progesterone Derivative, Di(methoxime)-V*—The peak at *m/z* 372 (100%) corresponds to the molecular ion. The characteristic peaks were 341 (72.8%) $[(M - OCH_3)^+]$, 286 (29.5), 273 (46.2), 220 (11.5), 153 (57.4), 137 (40.2), 125 (65.6), 100 (75.5), and 87 (39.1).

**Resolution of Methoxime–Trimethylsilyl Derivatives on OV-7 and OV-17 Columns**—The GLC chromatograms of all four glucocorticoid derivatives appeared as single peaks when eluted from OV-7 columns (Figs. 1*a* and 1*c*). Compounds III and IV, however, resolved into two peaks, a minor peak A with a shorter retention time and occupying <10% of the peak area and a major peak B, when OV-17 packings were used due to the higher degree of resolution obtainable.

A GLC–mass spectrometric examination showed that the chemical structure of the derivative eluting as the minor peak A corresponded to mono(methoxime)–tri(trimethylsilyl)-IV, *m/z* 660, $[(M - 1)^+]$, whereas that of the major peak B corresponded to mono(methoxime)–di(trimethylsilyl)-IV, *m/z* 589 ($M^+$), as illustrated in Figs. 4*a* and 3*d*, respectively.

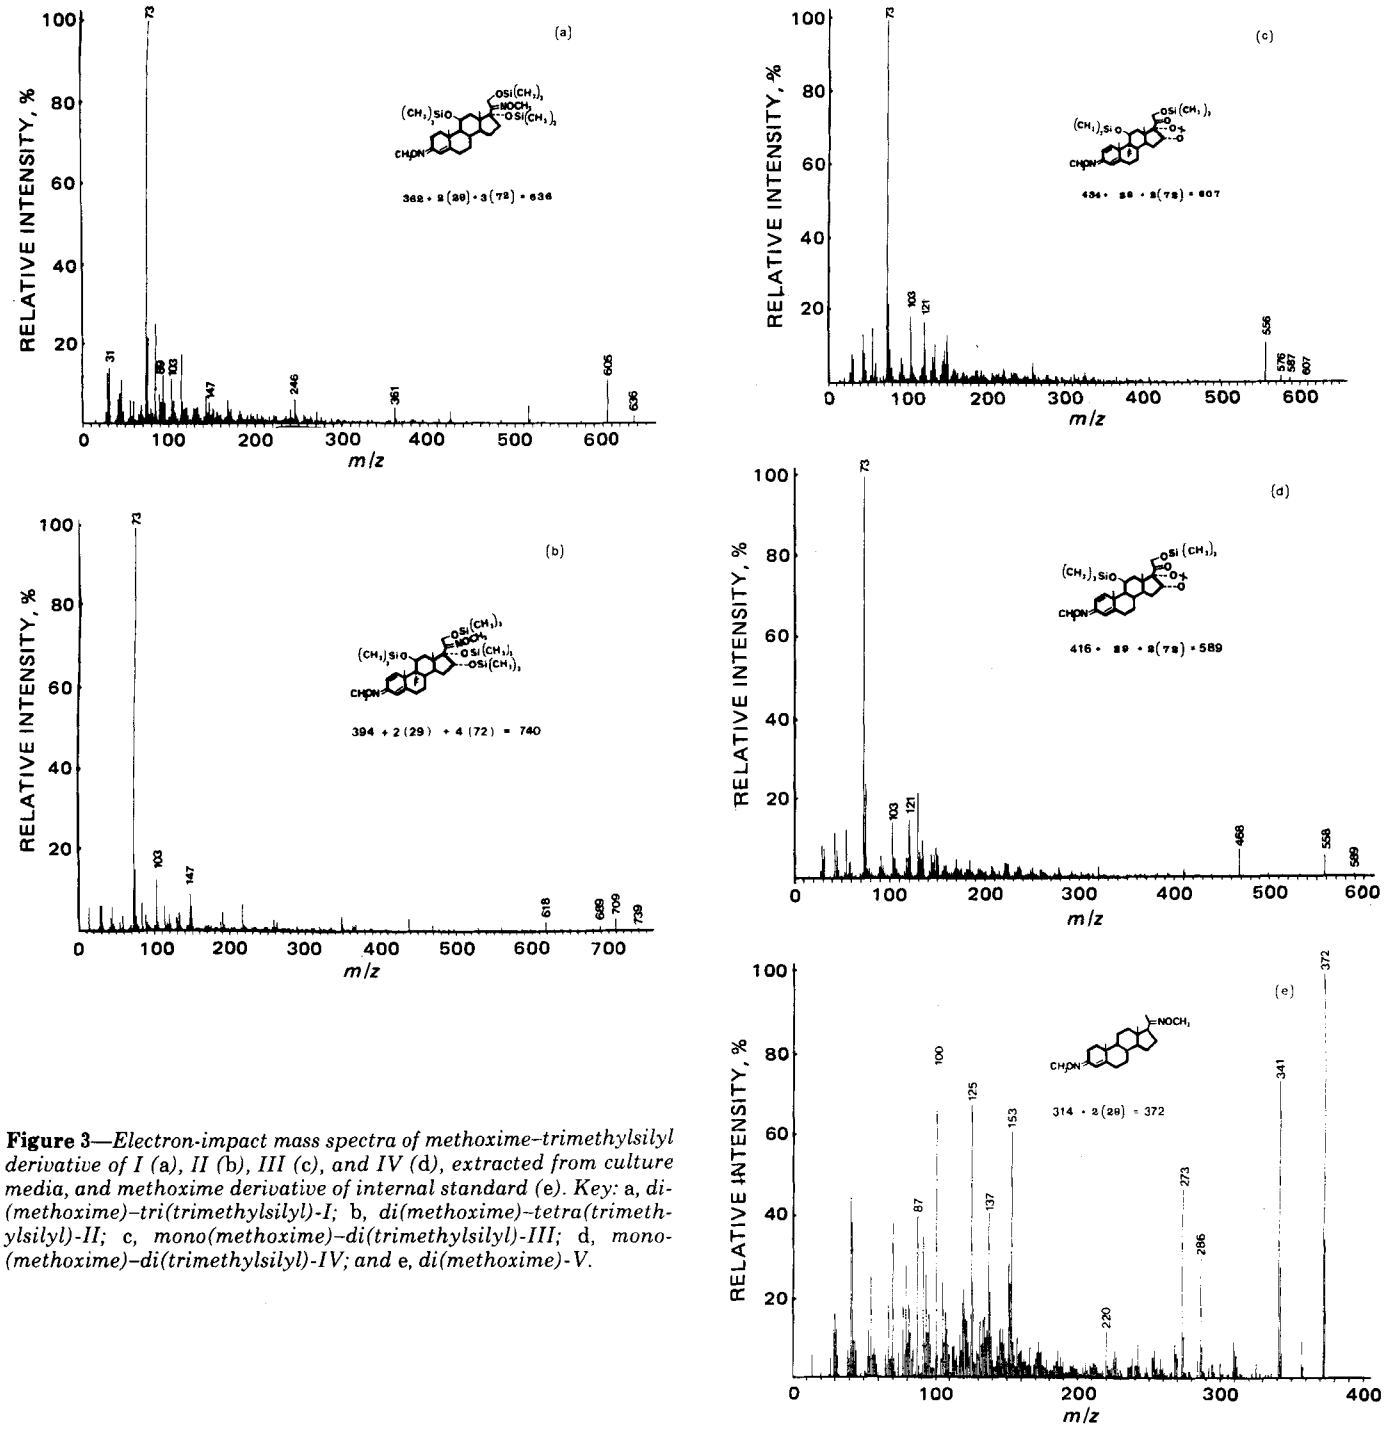


**Figure 3**—*Electron-impact mass spectra of methoxime–trimethylsilyl derivative of I* (a), *II* (b), *III* (c), *and IV* (d), *extracted from culture media, and methoxime derivative of internal standard* (e). *Key:* a, *di(methoxime)–tri(trimethylsilyl)-I;* b, *di(methoxime)–tetra(trimethylsilyl)-II;* c, *mono(methoxime)–di(trimethylsilyl)-III;* d, *mono(methoxime)–di(trimethylsilyl)-IV; and* e, *di(methoxime)-V.*

Formation of peak A is ascribed as being due to partial enolization of the keto group at C-20. The keto group at C-20 in IV as well as in III, in contrast to I and II, is hindered by the C-16,C-17 acetonide group and remains largely resistant to formation of the methoxime derivative. Under favorable conditions, such as exposure of the reaction mixtures to sunlight radiation and excess silylating reagent, some enolization can occur, which then would lead to the formation of the minor tri(trimethylsilyl) derivative observed.

Indirect evidence for the existence of the enolization reaction was obtained on exposure of the reaction mixture to sunlight. Sunlight is a catalyst for the enolization of various ketones (22). Exposure to sunlight increased the relative magnitude of peak A to peak B, as expected of a sunlight-catalyzed reaction. Removal of the reaction mixture from sunlight reversed the magnitude of peak A to its original levels, indicating the reversibility of sunlight-induced enolization. Prolonging the derivatization time led to an increase in peak A at the expense of the magnitude of peak B, suggesting the formation of A from B.

The fact that the chromatographic peaks from OV-7 columns represent two derivatization products of III and IV, however, did not interfere with the assay because the contributions by the tri(trimethylsilyl) derivatives were <10% of the area of the peaks and were in nearly constant ratio to those of the major di(trimethylsilyl) derivatives. The derivatization time should be kept at 30 min, and light should be excluded.

Compound III shared all of the previously mentioned characteristics of derivatization and gave mono(methoxime)–di(trimethylsilyl)-III, *m/z* 607 ($M^+$), as the major product and mono(methoxime)–tri(trimethylsilyl)-III, *m/z* 679 ($M^+$), as the minor product (Figs. 3*c* and 4*b*).

The presence of antibiotics in the medium showed no interference on the chromatograms.

**Calibration Curves**—Calibration curves were constructed for I, III, and IV extracted from medium containing 10% serum. The curves were linear within the ranges studied, namely, 40–1600 ng/μl of derivatized solution for I (equivalent to 1.6–65.8 μg/ml of medium), 60–1600 ng/μl of derivatized solution for III (equivalent to 2.4–63.7 μg/ml of medium),

| 164.48 | 1.3351 | 1.3121 ± 0.0195 | 158.93 | 96.63 ± 1.42 |
| 328.96 | 2.6701 | 2.5330 ± 0.0465 | 305.40 | 92.84 ± 1.69 |

[a] Weight ratio of I/V (internal standard). [b] Peak area ratio of derivatized I/derivatized V. Mean values of triplicate samples, each determined by three measurements. [c] Calculated from the standard curve of I without extraction, $y = mx + c$, where $m = 1.026$ and $c = -0.009$ ($r^2 = 0.999$), and $y = mx + c$, where $m = 0.947$ and $c = -0.005$ ($r^2 = 0.998$) for extracted samples, as plotted for the mean area ratio *versus* weight ratio. The average mean recovery was 93.12 ± 9.74%.

and 20–300 ng/μl of derivatized solution for IV (equivalent to 0.80–12.0 μg/ml of medium) (Tables II–IV).

Two calibration curves of I were determined with a time lapse of 6 months between them. The relative standard deviation in slope values was 3.1%. The combined data gave a straight line of $y = 0.947x - 0.005$ with $r^2 = 0.998$, indicating satisfactory assay reproducibility.

Three calibration curves of III were determined within 1 year. The relative standard deviation of slope values was 7.6%. The combined data gave a straight line of $y = 0.553x + 0.012$ with $r^2 = 0.996$. The satisfactory reproducibility of the assay confirmed the validity of using the sum of double-peak areas, mono(methoxime)–di(trimethylsilyl)-III and mono(methoxime)–tri(trimethylsilyl)-III, based on the assumption that the yield ratio of these two peaks was a constant.

The recoveries of three glucocorticoids added in various amounts also were tabulated (Tables II–IV). The average mean recoveries were 93.12 ± 9.74, 85.64 ± 7.19, and 97.73 ± 4.72% for I, III, and IV, respectively.

Glucocorticoids generally are used in cell cultures at concentrations smaller than those used for preparing the calibration curves. However, these lower concentrations can be compensated readily by extracting >5 ml of the medium employed in the preparation of the calibration curves. On the other hand, the amounts used are realistic for assays of stock solution concentrates and similar solutions of pharmaceutical interest.

**Biological Data**—The applicability of the assay was demonstrated by determining the I, III, and IV levels in serum-containing cell culture medium after various incubation times with cultured human or mouse dermal fibroblasts (Tables V–VII).

The time profile of III indicated that its prolonged incubation of up

[a] Human dermal fibroblasts, F.H. passage 6. [b] Human dermal fibroblasts, W.P. passage 4. [c] The concentration of I recovered from medium containing no cells was defined as 100% of intact drug.

to 83.5 hr with cultured mouse L-929 dermal fibroblasts did not decrease intact III in media. About 20% of III was removed from the culture medium by absorption and/or adsorption by cells 2 hr after administration of III. The levels of III at various incubation periods between 2 and 83.5 hr did not vary appreciably. A significant decrease of III after 94 hr was observed but unexplained.

To eliminate the possibility of decomposition, the stability of III in the medium upon incubation was studied at 37° in the absence of cells for 72 and 96 hr. There was no appreciable decomposition due to the incubation at 37°.

The levels of IV after 4 and 24 hr of incubation with mouse L-929 fibroblasts indicated ~20% loss of IV from the medium.

Therefore, for any biological effect of synthetic glucocorticoids observed at the dose level of 1 μg/ml of medium, the true bioavailable dose was probably not more than 0.2 μg/ml of medium.

The levels of I as a function of time were measured twice at various incubation intervals. The loss of I from the media due to cells was larger than that of the synthetic glucocorticoids. Compound I had rather constant levels when incubated between 0.25 and 48 hr.

**Metabolites**—No extra peaks were observed in samples incubated

with cells for 0–108 hr, and there was no appreciable change in the magnitudes of endogenous peaks in the mixture due to the medium and 10% serum. It was proposed that no metabolite was apparently present unless its methoxime–trimethylsilyl derivative had the same retention time as the derivatized parent compound or that the amounts of metabolites were too small to be detected.

**Applicability of Methoxime–Trimethylsilyl Reaction to Other Glucocorticoids**—Another glucocorticoid, diflorasone diacetate, was derivatized under the same conditions. However, the reaction product gave four peaks in the gas–liquid chromatogram, indicating multiple derivatizing products, presumably due to the hydrolysis of acetates by hydrochloride generated in the reaction with methoxyamine hydrochloride and subsequent silylations at the C-17 and/or C-21 free hydroxyl groups. Therefore, diflorasone diacetate and probably other ester-containing glucocorticoids are not amenable to GLC analysis using the subsequent derivatization with methoxyamine hydrochloride and *N*-trimethylsilylimidazole.

Prednisolone could be derivatized to yield the di(methoxime)–tri(trimethylsilyl)prednisolone derivative with the same reaction procedure.

# Micellar Solubilization of Cetaben Sodium in Surfactant and Lipid Solutions

**SAN-LAUNG CHOW** [x] **and BERNARD E. SIMS**

Received July 2, 1980, from the *Pharmaceutical/Mechanical R&D Section, Medical Research Division/Lederle Laboratories, American Cyanamid Company, Pearl River, NY 10965.* Accepted for publication January 27, 1981.

**Abstract** □ Cetaben sodium solubilities were evaluated by micellar solubilization in various surfactants and lipid solvents. At pH 8, the relationship between cetaben sodium solubility and surfactant concentration delineated apparent saturable kinetics; at pH 4.9, the relationship between the two parameters was linear. In the presence of 0.5% sodium taurocholate and polysorbate 80, cetaben sodium solubility increased as the medium pH was increased; however, in the presence of 0.5% poloxamer 188, cetaben sodium solubility revealed a hyperbola when the pH was changed from 4.9 to 8.0. Cetaben sodium solubility was enhanced greatly by mixed physiological surfactants, full-strength caprylic–capric monodiglycerides or monodiglycerides, when compared to a single surfactant system. Cetaben sodium solubility is influenced by pH, surfactant type, surfactant concentration, lipid solvent type, and the simultaneous presence of surfactants or phospholipids.

**Keyphrases** □ Cetaben sodium—micellar solubilization in surfactant and lipid solutions □ Solubility—micellization of cetaben sodium in surfactant and lipid solutions □ Surfactants—micellar solubilization of cetaben sodium □ Micellization—cetaben sodium solubilization in surfactant and lipid solutions □ Antiatherosclerotic agents—micellar solubilization of cetaben sodium in surfactant and lipid solutions

Cetaben sodium, sodium 4-(hexadecylamino)benzoate, is a new synthetic drug (1) highly effective in preventing and ameliorating the condition of atherosclerosis (2, 3). Cetaben sodium is an odorless, tasteless, white, soapy-textured powder; it is chemically stable under normal conditions and is not expected to present compatibility problems with the usual formulation excipients. However, cetaben sodium is practically insoluble in water at all pH values. As a consequence, analysis, bioavailability, and formulation problems have been encountered.

This paper reports findings that characterize some solubilities for cetaben sodium and describes the solubilization mechanism using surfactants and lipid solvents.

## EXPERIMENTAL

**Materials**—Cetaben sodium, >99% pure, was used as obtained[1]. Purified grade sodium taurocholate[2] was found to have <1% impurities by TLC (4). In some experiments, polysorbate 80[3] and poloxamer 188[4] were used as obtained as nonionic surfactants for solubilizing cetaben sodium. L-$\alpha$-Lecithin[5] (99% pure) and monoolein[6] and oleic acid[6] (>99% pure) were obtained commercially.

Caprylic–capric monodiglycerides[7], monodiglycerides[8], polyoxypropylene 15 stearyl ether[9], caprylic–capric triglycerides[10], triacetin[11], ethyl citrate[12], and medium-chain triglycerides oil[13] were used as lipid solvents as obtained. Analytical reagent grade monobasic and dibasic sodium phosphates[14] were used as buffer components. The total concentration of buffer solution was 65 m*M*. Micellar solutions of the surfactants in phosphate buffer were prepared by ultrasound irradiation for 5 min with a sonifier[15].

**Solubility Determinations**—An excess of cetaben sodium was added to 20 ml of micellar solutions contained in 50-ml amber screw-capped bottles. The bottles were shaken with a wrist-action shaker[16] for 48 hr in a shaker bath[17] (24 ± 0.1°). The time required for equilibration was established by a repetitive sampling technique. After equilibration, samples were filtered through 0.45-$\mu$m filters[18] held in adapters[19] and diluted appropriately if required. The samples were assayed for cetaben content by high-performance liquid chromatography (HPLC).

**Analysis**—Analytical determinations were carried out on an HPLC system consisting of a solvent-delivery unit[20], an injector[21], a 3.9-mm × 30-cm reversed-phase analytical column with 10-$\mu$m particles[22], a variable-wavelength UV detector[23], and a strip-chart recorder[24]. The mobile phase contained 90% methanol[25] in 2.5 m*M* ammonium acetate[25]. The system was operated at 280 nm and ambient temperature, and the mobile phase flow rate was 3 ml/min. Cetaben content was quantitated by comparing peak heights obtained from the chromatograms of experimental samples with those of chromatographed standards. Standard calibration plots of peak height *versus* concentration were linear in the concentration ranges studied.

## RESULTS AND DISCUSSION

**Influence of Surfactants on Cetaben Sodium Solubility**—Surfactants are one of the most important groups of formulation excipients used for pharmaceutical preparations. Their unique physicochemical properties have prompted considerable interest in their possible effects on drug absorption. However, these effects seem to be specific and not unique (5). Since dissolution usually is the rate-determining step for hydrophobic drug absorption, the influence of surfactants on cetaben solubility was investigated.

The solubilities of cetaben sodium in 0.5% sodium taurocholate, polysorbate 80, and poloxamer 188 at pH 4.9 were 0.028, 0.021, and 0.016 mg/ml, respectively; at pH 8, the solubilities were 0.468, 0.129, and 0.004 mg/ml, respectively. With the same surfactant concentration, cetaben sodium was solubilized in the following order: sodium taurocholate > polysorbate 80 > poloxamer 188. This cetaben solubilization is ascribed to the micellization of the drug by the surfactant systems. In such aqueous systems, micellization is due primarily to hydrophobic interactions between lipophilic moieties of the amphiphilic molecules (6).

A striking difference in solubility with respect to pH change also can be noted from these results, as will be discussed.

**Influence of pH on Cetaben Sodium Solubility**—The intralumenal intestinal pH varies under normal absorptive conditions and depends on the proximity of the absorbing segment to the pylorus. Therefore, the influence of pH on cetaben sodium solubility was evaluated. The pH of the aqueous media was varied from 4.9 to 8 by changing the relative amounts of the monobasic and dibasic salts of phosphate in the media.

With sodium taurocholate and polysorbate 80, a significant increase in the cetaben sodium solubility was observed as the medium pH was

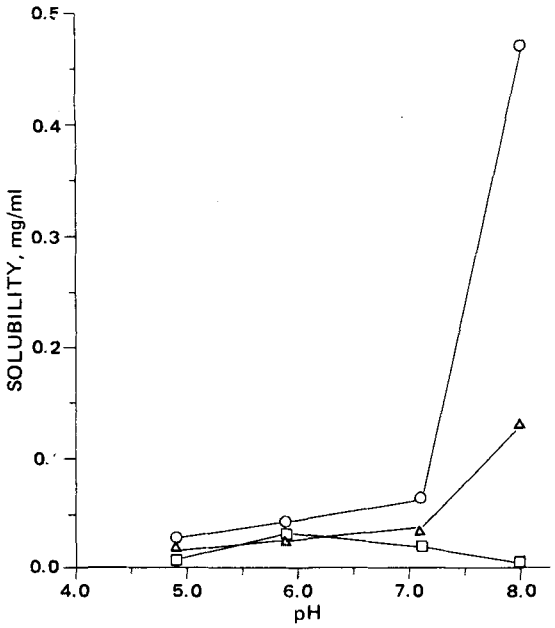

**Figure 1**—*Cetaben sodium solubilities in the presence of 0.5% (w/v) sodium taurocholate (○), polysorbate 80 (△), and poloxamer 188 (□) at pH 4.9, 5.9, 7.1, and 8.0.*

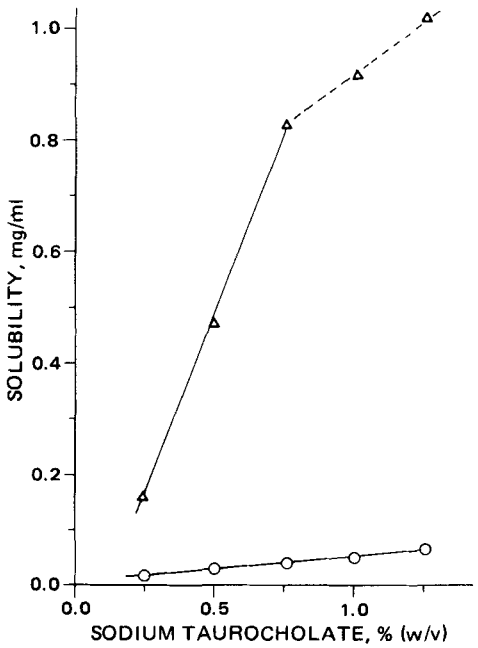

**Figure 2**—*Cetaben sodium solubilities in the presence of various strengths of sodium taurocholate at pH 4.9 (○) and 8.0 (△).*

increased (Fig. 1). Two separate mechanisms may account for this observation. The first mechanism is related to the ionization of cetaben itself. The apparent basic $pKa_1$ and acidic $pKa_2$ of cetaben were 2.6 and 5.3, respectively, in acetic acid when titrated with standardized perchloric acid that also was in acetic acid (7). Therefore, within pH 4.9–7.3, the proportion of cetaben in its anionic form increases as the hydrogen-ion concentration decreases, resulting in an increase in the aqueous solubility of cetaben as the pH is increased. The free acid form of cetaben had a much lower solubility than its sodium salt, indicating a consistency with the pH-partition hypothesis.

Changes in the critical micelle concentration (CMC) and micellar structure may offer another explanation for the changes in cetaben solubility under different pH conditions. Structurally, cetaben itself appears to have micellar properties. The alkaline pH conditions may enhance the mixed micellar formation, which results in a greater increase in cetaben solubility beyond pH 7.1–8. Bloor *et al.* (8) showed that the CMC for polysorbate 40 decreased with the pH increase as a result of the higher entropy change, which, in turn, was due to the greater degree of water structure at higher pH.

No evidence has proved or disproved the general applicability of these findings for surfactants other than polysorbate 40. Nevertheless, these postulations provide a possible explanation for the present experimental observations. It is likely that cetaben would partition more into the micellar phase resulting from a lower CMC at higher pH as compared to the lower pH conditions. The overall magnitude of the changes in cetaben solubility would depend entirely on the relative contribution of each mechanism. At pH values greater than 7.1, cetaben exists >98% as the anionic species. The sharp increase in cetaben solubility from pH 7.1 to 8 (Fig. 1) then is most likely due to changes in the CMC and micellar structure that are predominant under alkaline pH conditions.

In contrast to the sodium taurocholate and polysorbate 80 systems, the pH–solubility profile for poloxamer 188 delineated a hyperbola (Fig. 1). The described mechanisms still are applicable, except to the lowering of cetaben solubilities under alkaline pH values. This exception indicated that poloxamer 188 was not stable at alkaline conditions as compared to acidic conditions, a rationalization that was justified by a control experiment under the same experimental conditions using a UV spectral shift technique. As the medium pH becomes more alkaline, poloxamer 188 may degrade extensively, lose its surfactant properties, and, thus, cause the gradual dropping in cetaben solubility.

The complexity of the mixed micellar system makes analysis of the mechanisms contributing to the observed pH–solubility profiles difficult. The proposed mechanisms should be viewed as reasonable hypotheses explaining the present experimental observations. Further investigation should clarify the actual contribution of each mechanism to the overall pH–solubility profiles.

**Influence of Surfactant Concentration on Cetaben Sodium Solubility**—The low cetaben solubility requires surfactants for solubilization in an aqueous phase. To examine the effect of surfactant concentration on cetaben solubility, the surfactant concentration was increased in a stepwise fashion.

In the first series of experiments, the sodium taurocholate concentration was varied from 0.25 to 1.25% (w/v) at a constant pH of 4.9. The relationship between cetaben sodium solubility and sodium taurocholate concentration was linear (Fig. 2). This linearity suggests a typical solubilization plot for a micellar system where the solubility increases linearly with surfactant concentration beyond the CMC (9). As the surfactant concentration is increased, more drug is dissolved into the micellar phase (10). As a result, at higher sodium taurocholate concentrations, the amount of cetaben in the micellar phase would increase. Similar findings also were observed for nonionic surfactants, polysorbate 80, and poloxamer 188 (Figs. 3 and 4).

In the second series of experiments, all experimental conditions were kept the same but the medium pH was 8. The solubility–concentration profile delineated apparent saturable kinetics, revealing two linear segments with different slopes (Figs. 2–4). This change into two linear segments was statistically significant for sodium taurocholate and polysorbate 80 but not for poloxamer 188. The sudden change in slope could be due to size or shape changes in the micellar structure (11, 12). At

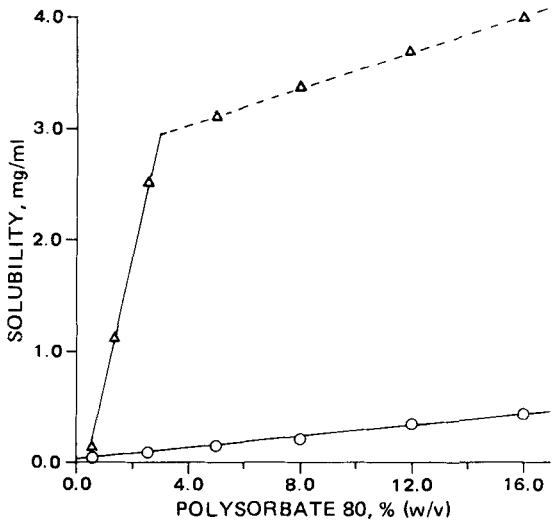

**Figure 3**—*Cetaben sodium solubilities in the presence of various strengths of polysorbate 80 at pH 4.9 (○) and 8.0 (△).*

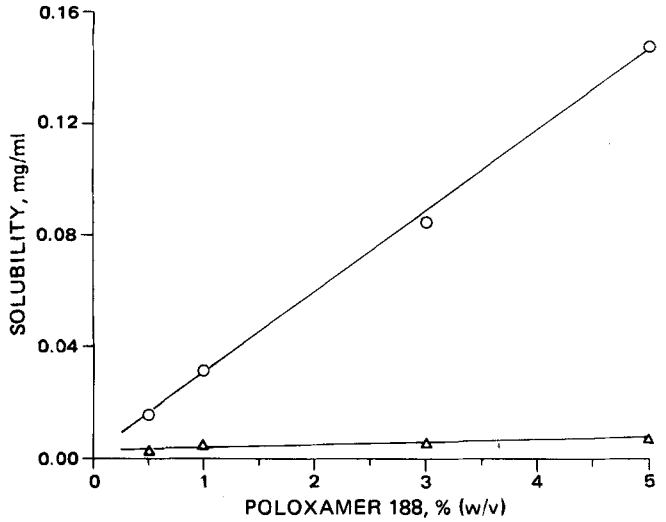

**Figure 4**—*Cetaben sodium solubilities in the presence of various strengths of poloxamer 188 at pH 4.9 (○) and 8.0 (△).*

concentrations higher than the CMC, micelles tend to coalesce into long rod-shaped micelles and cylindrical aggregates; finally, at very high concentrations, a phase transformation into lamellar structures takes place. Each transformation point varies and depends on the type of surfactant, the nature of surfactant, and the medium conditions.

**Influence of Mixed Physiological Surfactants on Cetaben Solubility**—Bile salts and phospholipids have been recognized as physiological surfactants important to lipid absorption (13, 14). The present study examined the effect of some physiological surfactants and mixed surfactant systems on cetaben sodium solubility.

Sodium taurocholate, lecithin, oleic acid, and monoolein were prepared in different proportions (Table I). Cetaben solubility was increased ninefold by taurocholate–monoolein, 23-fold by taurocholate–lecithin, 368-fold by taurocholate–oleic acid, 376-fold by taurocholate–oleic acid–lecithin, and 631-fold by taurocholate–oleic acid–monoolein when compared to taurocholate alone. Solubility enhancement can be attributed to an increased effective surface area when mixed disk micelles are formed (15). It also is possible that the inclusion of a second solubilizate may cause rearrangement of the mixed micelle structure, thereby altering the distribution coefficient favorable to solubilization (16).

**Influence of Lipid Solvents on Cetaben Solubility**—Lipid solvents

**Table I—Cetaben Sodium Solubilities in Solutions Containing Physiological Surfactants Prepared in Different Proportions**

| Surfactant | Molar Ratio[a], m*M* | Solubility, mg/ml | Solubility Ratio[b] |
|---|---|---|---|
| Taurocholate | 10 | 0.029 | 1 |
| Taurocholate–monoolein | 10:5 | 0.243 | 9 |
| Taurocholate–lecithin | 10:5 | 0.647 | 23 |
| Taurocholate–oleic acid | 62.5:3540 | 10.313 | 368 |
| Taurocholate–oleic acid–lecithin | 62.5:3540:0.78 | 10.547 | 376 |
| Taurocholate–oleic acid–monoolein | 62.5:3540:1.75 | 17.658 | 631 |

[a] The 10 m*M* was chosen because of its similarity to physiological concentrations of bile salts and its frequent use in previous studies. The ratios were chosen for convenience in preparation. [b] Solubility ratio = solubility in mixed surfactants/solubility in sodium taurocholate.

greatly enhance the bioavailability of hydrophobic compounds (10). Therefore, the effect of lipid solvents on cetaben solubility was studied to provide additional formulation information.

The selected lipid solvents were used at 100% strength. The solubilization capacity of lipid solvents for cetaben was in the following order: caprylic–capric monodiglycerides (23.191 mg/ml) > monodiglycerides (22.821 mg/ml) > triethyl citrate (0.61 mg/ml) > polyoxypropylene 15 stearyl ether (0.305 mg/ml) > medium-chain triglycerides (0.224 mg/ml) > caprylic–capric triglycerides (0.108 mg/ml) > triacetin (0.043 mg/ml).

Unlike solutions in aqueous media, micelles are formed by a stepwise aggregation rather than by a simple monomer–micelle equilibrium characteristic of aqueous systems (6, 17). The driving force behind aggregation and micellization in these nonaqueous media likely is due to dipole–dipole interactions between polar heads of the amphiphilic molecules (6).

Cetaben sodium is a promising antiatherosclerotic agent. Knowledge regarding the mechanism of its solubilization by surfactants and lipid solvents, as well as factors modifying its solubility, is essential for development of optimal formulation conditions.

# Powder Flow Studies III: Tensile Strength, Consolidation Ratio, Flow Rate, and Capsule-Filling-Weight Variation Relationships

**Z. T. CHOWHAN** ˣ **and I-CHANG YANG**

Received August 18, 1980, from *Syntex Research, Palo Alto, CA 94304.* Accepted for publication January 30, 1981.

**Abstract** □ The tensile strength of consolidated powder beds was studied by applying a series of loads to the surface of the powder beds in a tensile tester. The results were plotted as tensile strength *versus* consolidation pressure. The linearity of these plots suggests a direct relationship between tensile strength and consolidation pressure. The following plots gave linear relationships: (*a*) tensile strength *versus* consolidation ratio, (*b*) tensile strength *versus* coefficient of variation of the filled weight of the capsules, and (*c*) logarithm of the tensile strength *versus* logarithm of the flow rate. These results suggest a direct relationship between tensile strength and consolidation ratio and their usefulness in studying powder flow. The physical significance of the empirical equation used in consolidation studies was explored. A comparison of the empirical equation with a theoretically derived equation, under certain assumptions, suggests that the consolidation ratio is a function of the ratio of the initial volume to the net volume and a function of the coefficient of Rankine. The coefficient of Rankine is a function of the angle of internal friction in the static powder bed.

**Keyphrases** □ Tensile strength—powder flow behavior, relationship to consolidation ratio □ Powder flow—tensile strength, consolidation ratio relationships □ Consolidation ratio—powder flow behavior, relationship to tensile strength

The knowledge of powder behavior is important in understanding the powder properties during storage, transportation, mixing, granulating, capsule filling, and tableting. Tensile strength, defined as the force per unit area of a broken face required to split a powder compact, provides useful information on powder behavior. The effects of powder density, particle-size distribution, and interparticle forces were considered in developing a theory of the tensile strength of powders (1).

Theoretical developments in studying powder flow must make far-reaching simplifying assumptions because of the numerous parameters involved, such as size, shape, and surface texture. These developments, although interesting, are of limited practical utility.

## BACKGROUND

Recent studies (2, 3) reported the consolidation of loosely packed powders and powder mixtures in cylindrical containers by applying a series of loads. The results of simple measurements in which the decrease of powder volume was measured as a function of the compressive load were plotted as the logarithm of the change in volume *versus* the logarithm of the applied pressure. The slopes of these plots were similar, and the intercept (consolidation ratio) gave a linear relationship with the logarithm of the flow rate and the coefficient of variation of the filled weight of capsules produced on an automatic capsule-filling machine.

Simple consolidation measurements and the use of an empirical equation suggested a good relationship to flow properties of the powders and powder mixtures. A literature survey indicated a paucity of any relationship between powder flow behavior and tensile strength.

This paper reports linear relationships between (*a*) tensile strength and consolidation ratio, (*b*) tensile strength and coefficient of variation of the filled weight of capsules, and (*c*) logarithm of the tensile strength and logarithm of the flow rate. These results suggest a direct relationship between tensile strength and consolidation ratio and their usefulness in studying powder flow. A comparison of the empirical equation with a theoretically derived equation, under certain assumptions, suggests that the consolidation ratio is a function of the ratio of the initial volume to the net volume and a function of the coefficient of Rankine. The coefficient of Rankine is a function of the angle of internal friction in the static powder bed.

## EXPERIMENTAL

**Materials**—The drug[1], tromethamine salt of (±)-2-benzoyl-1-azabicyclo[3.3.0]octa-2,4-diene-6-carboxylic acid, was at least 99% pure. The excipients were spray-dried lactose USP[2], starch USP[3], and magnesium stearate USP[4].

**Mixing**—The powders of each formulation were mixed by the geometric dilution method on a piece of glassine paper. The powder mixture was screened through a 40-mesh screen to ensure proper mixing and to avoid powder agglomeration due to compaction. Three types of formulations were used. Drug and spray-dried lactose were mixed in the indicated proportions in the first formulation. The second formulation contained 0.5% magnesium stearate in addition to the drug and spray-dried lactose. The final formulation contained 10% starch, 0.5% magnesium stearate, spray-dried lactose, and drug in the indicated proportions. Powder mixing and all tensile strength measurements were carried out at 24 ± 1° and 40 ± 5% relative humidity.

**Tensile Strength**—The tensile strength of powder mixtures was determined by conducting a tensile test with an instrument[5] consisting of a main unit, an operational amplifier, and an $x$–$y$ recorder. The main unit included four major components: (*a*) a constant-speed motor for exerting a pulling force through a steel string to break the powder bed, (*b*) a cylindrical powder cell with one half fixed to the main unit and the other half movable by suspension onto a metal frame, (*c*) a strain gauge of 200-g force for the quantitative measurement of tensile stress required to break the powder bed, and (*d*) a linear, variable differential transformer for the measurement of powder bed displacement.

The operational amplifier contained a strain amplifier, a displacement meter, and an operational unit. The latter was designed to indicate only the actual load by subtracting the necessary blank load that varied with displacement.

Blank tests were run to ensure that there was no extra load between the two half-cells before the powder was loaded. An accurately weighed amount of the powder was charged evenly through the cell extension tube, and the compaction weight was inserted gently into this tube. After 20 sec, additional weights, from 100 g to 2 kg, were loaded, with 20 sec between each loading. The weights and the cell extension tube were unloaded after 5 min. A steady-state condition in the powder bed thus was reached. The pulling string connecting the powder cell through a strain gauge was tightened under suitable tension before the clamp of the two half-cells was released. Then the constant-speed motor switch was turned on to pull the movable half-cell.

During the breaking process, the $x$–$y$ recorder automatically recorded the tensile force profile over the total displacement of the two half powder beds. The peak value on the vertical axis of the tensile force–displacement curve gave the maximum tensile force of the powder. The area of breakage was normally 5 cm$^2$, provided the compaction weight descended to the proper position. Otherwise, the area was corrected for the powder bed thickness difference. The tensile strength of the powder bed was obtained by dividing the maximum tensile force with the area of powder bed breakage. Three determinations were made, and the mean and the standard deviation were calculated. Only results obtained from the tensile

fracture where the powder bed broke into two halves along the joint of the two half-cells were recorded.

## RESULTS AND DISCUSSION

The tensile strength results of powder mixtures containing 10, 20, 40, and 89.5% drug at various consolidation pressures are given in Table I and Fig. 1. The excipients in these powder mixtures were 10% starch, 0.5% magnesium stearate, and spray-dried lactose to make 100%. The results indicate that the tensile strength is related linearly to the consolidation pressure in the pressure range studied. The dimensionless slope of these lines may be regarded as material constant, which is a measure of the increase in cohesive forces between adjacent particles due to consolidation. The intercept indicates the cohesive forces in an unconsolidated powder bulk. For free-flowing powders, the intercept is zero.

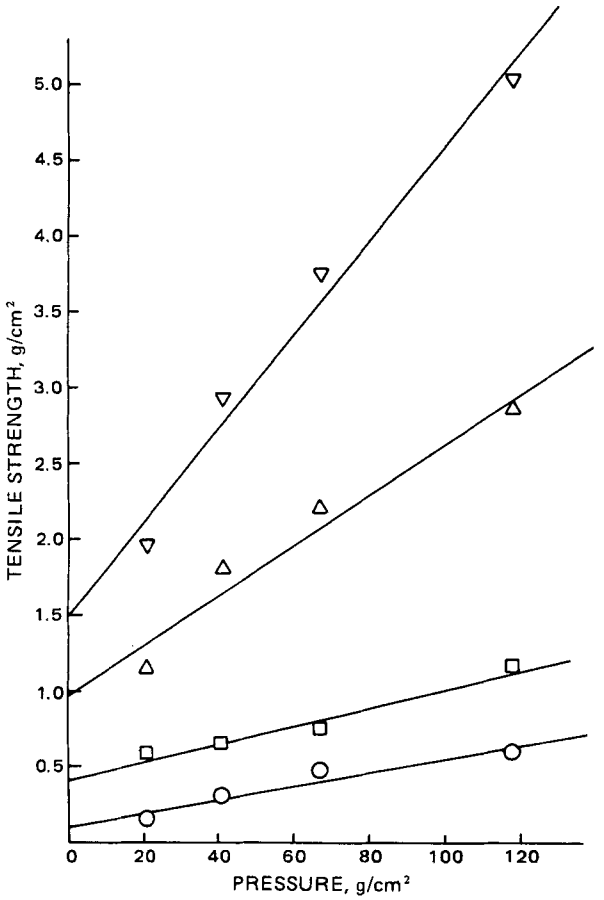

**Figure 1**—*Tensile strength of powder mixtures* versus *consolidation pressure plots showing linear relationships. Key:* ○, *10% drug;* □, *20% drug;* △, *40% drug; and* ▽, *89.5% drug.*

The profiles of the tensile strength *versus* percent drug at a constant consolidation pressure (66.84 g/cm²) are given in Fig. 2. The tensile strength of the mixtures containing 10 and 20% drug, lactose, and magnesium stearate was lower than that of mixtures containing drug, lactose, starch, and magnesium stearate and of mixtures containing drug and lactose. At higher drug concentrations, the tensile strength of the mixtures containing starch and magnesium stearate was higher than that of the mixtures containing only drug and lactose.

The consolidation ratio and the coefficient of variation of the filled weight of capsules reported previously (2) were plotted *versus* tensile strength (Fig. 3). The results indicate linear relationships between tensile strength and consolidation ratio and between tensile strength and coefficient of variation of the filled weight of the capsules. The logarithm of the flow rate reported earlier (3) and the logarithm of the tensile strength are plotted in Fig. 4. These results suggest that the tensile strength and consolidation ratio provide useful information of powder flow behavior.

The powder consolidation ratio was obtained (2) from the intercepts of the relative volume *versus* consolidation pressure plots according to:

$$\ln \frac{V_0 - V}{V} = m \ln \frac{P}{P_0} + I \qquad \text{(Eq. 1)}$$

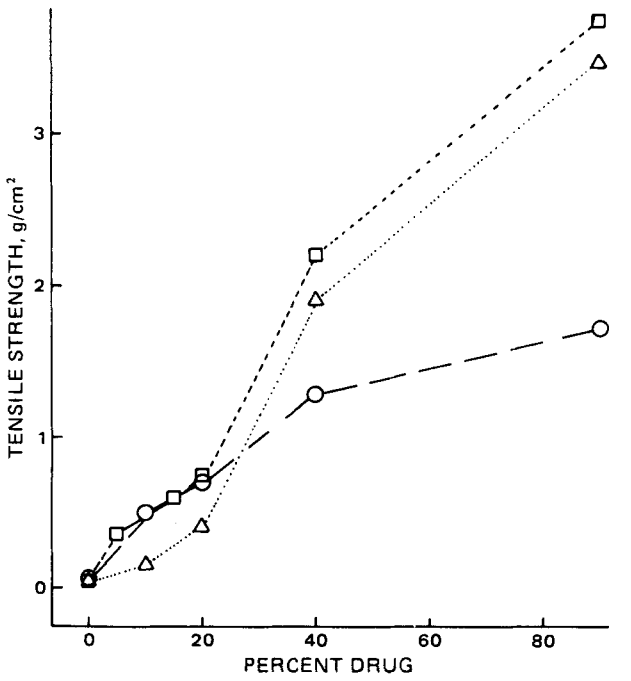

**Figure 2**—*Profiles of the tensile strength as a function of the formulation composition. Key:* ○, *drug and lactose mixture;* △, *drug, lactose, and 0.5% magnesium stearate mixture; and* □, *drug, lactose, 10% starch, and 0.5% magnesium stearate mixture.*

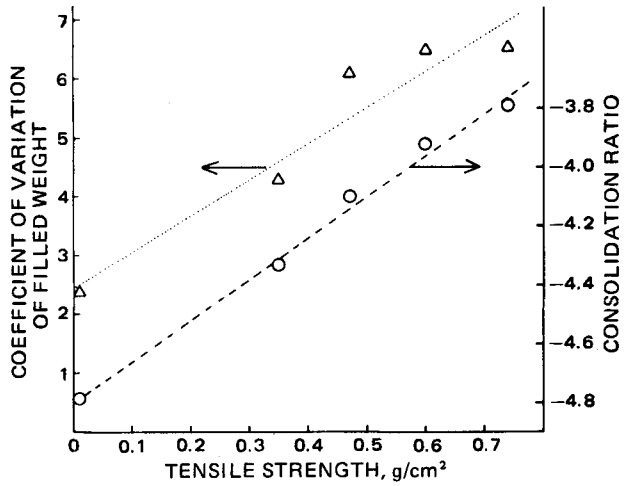

**Figure 3**—*Plots of the tensile strength* versus *consolidation ratio and coefficient of variation of the filled weight of the capsules. Key:* ○, r = *0.9964; and* △, r = *0.9583.*

where $V_0$ is the initial powder volume; $V$ is the powder volume at a given surface pressure, $P$; $P_0$ is the surface pressure $P$ (1 atmospheric pressure approximately equals 1 kg/cm$^2$); and $m$ and $I$ are constants.

By assuming $I = \ln C$, dividing both sides by $V_0$, and rearranging, Eq. 1 can be written as:

$$\frac{1}{V} - \frac{1}{V_0} = \frac{C}{V_0}\left(\frac{P}{P_0}\right)^m \qquad \text{(Eq. 2)}$$

Multiplying both sides by $V_\infty$, adding 1 to both sides, and rearranging give:

$$\frac{V - V_\infty}{V} = \frac{V_0 - V_\infty}{V_0} - \frac{CV_\infty}{V_0}\left(\frac{P}{P_0}\right)^m \qquad \text{(Eq. 3)}$$

where $V_\infty$ is the net volume of the powder.

Since porosity $n$ equals $(V - V_\infty)/V$ and the powder bed is assumed to be homogeneous, Eq. 3 can be written:

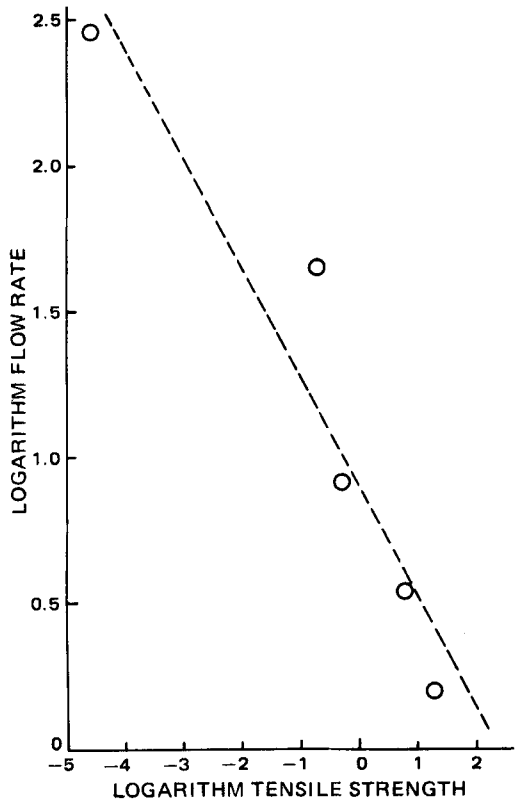

**Figure 4**—*Logarithm tensile strength* versus *logarithm flow rate showing a linear relationship* (r = *0.9523*).

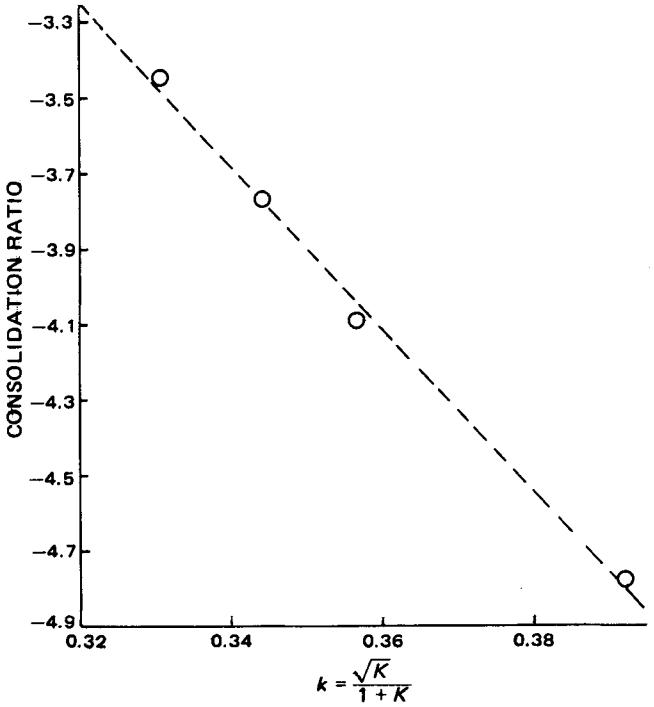

**Figure 5**—*Plots of consolidation on ratio* versus k *showing a linear relationship* (r = *−0.9980*).

$$n - n_0 = -\frac{CV_\infty}{V_0}\left(\frac{P}{P_0}\right)^m \qquad \text{(Eq. 4)}$$

Theories dealing with the pressure and volume change relationship have been reported in the field of powder technology. Kawakita and Ludde (4) obtained a theoretical compression equation using Mohr's circle of stress:

$$\Delta\phi = \frac{\sqrt{K}}{1 + K}\frac{d\sigma_1}{\sigma_1} \qquad \text{(Eq. 5)}$$

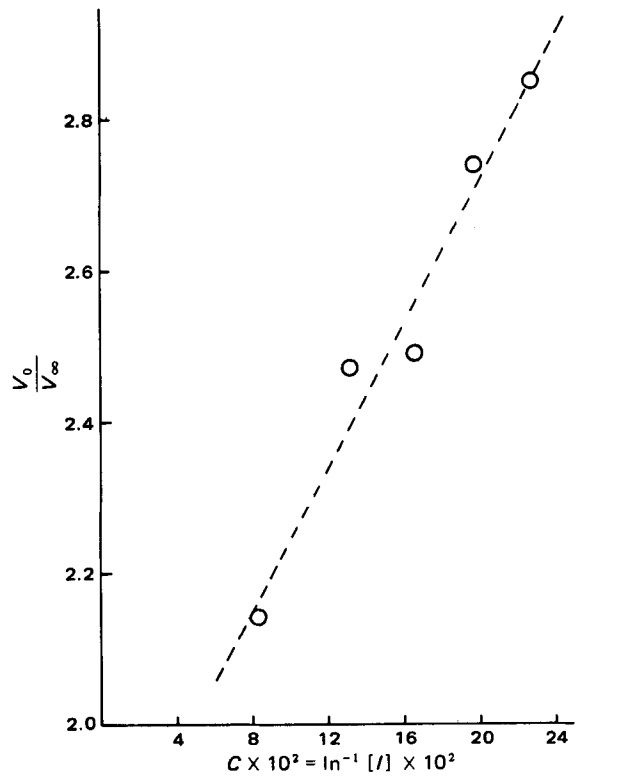

**Figure 6**—*Plots of* $V_0/V_\infty$ versus C *showing a linear relationship* (r = *0.9764*).

**Table II—Values of $\phi$, $K$, $k$, and $I$**

| Drug in Mixture, % | $\phi$ | $K$ | $k$ | $I$ |
|---|---|---|---|---|
| 40 | 48.6 | 0.1428 | 0.3307 | −3.45 |
| 20 | 46.5 | 0.1592 | 0.3442 | −3.77 |
| 10 | 44.5 | 0.1758 | 0.3566 | −4.09 |
| 0 | 38.4 | 0.2337 | 0.3918 | −4.78 |

where $\sigma_1$ is the maximum principal stress, $\phi$ is the angle of internal friction, and $K$ is the coefficient of Rankine (5) as given by:

$$K = \frac{1 - \sin \phi}{1 + \sin \phi} \quad \text{(Eq. 6)}$$

Thus, $\Delta\phi$ represents the probability of a packing change of the particles and is considered to be proportional to some quantities related to the state of packing in one of the several described manners. It was shown that various compression equations could be derived by making different assumptions about the properties that determine $\Delta\phi$.

If $\Delta\phi$ is proportional to the decrease in porosity and inversely proportional to the $m$th power of consolidation pressure, $-dn/P^m$, then:

$$-\frac{dn}{P^m} = k\frac{dP}{P} \quad \text{(Eq. 7)}$$

where $P$ is the consolidation pressure, $m$ is a constant, and $k$ is a function of the coefficient of Rankine.

Equation 7, on rearrangement, gives:

$$-dn = kP^{m-1}\,dP \quad \text{(Eq. 8)}$$

Integration of Eq. 8 from initial porosity $n_0$ to porosity $n$, corresponding to the zero initial consolidation pressure to the consolidation pressure $P$, gives:

$$n - n_0 = -\frac{k}{m}P^m \quad \text{(Eq. 9)}$$

Equation 9 is similar to Eq. 4, which is the modified form of Eq. 1. Equations 4 and 9 suggest that $C$ is a function of $(V/V_\infty)(k/m)$.

A previous study (2) showed that, for different powder mixtures of the same drug, $m$ was a constant. The value $k$ is a function of the coefficient of Rankine $K$ given by Eq. 6, and $\phi$ may be approximated from the angle of repose.

For the powder mixtures containing drug, spray-dried lactose, starch, and magnesium stearate, the values of $\phi$, $K$, $k$, and ln $C$ are given in Table II. A plot of $C$ *versus* $k$ gave a linear relationship with $r = -0.9666$. Figure 5 gives a plot of ln $C$ *versus* $k$. The excellent correlation ($r = -0.998$) indicates that ln $C$ is inversely proportional to $k$.

Figure 6 gives a plot of $V_0/V_\infty$ *versus* $C$ for the same powder mixture. A linear relationship ($r = 0.9809$) between $V_0/V_\infty$ *versus* $C$ suggests that these parameters are directly related.

The results of this study suggest that the consolidation ratio is a function of tensile strength and that both parameters are useful in studying flow behavior of powders and powder mixtures. The physical significance of the consolidation ratio was explored. The consolidation ratio is a function of the ratio of the initial volume to the net volume of the powder and of the coefficient of Rankine, which, in turn, is a function of the angle of internal friction in the static powder bed.

# Quantitation of Solvent Polarity Based on Molecular Structure

**LEMONT B. KIER**

Received October 27, 1980, from the *Department of Pharmaceutical Chemistry, Medical College of Virginia, Virginia Commonwealth University, Richmond, VA 23298.* Accepted for publication February 2, 1981.

**Abstract** □ A numerical index is proposed that ranks solvents according to their polarity. It is based entirely on structure, encoding the relative content of exterjacent electrons in the molecule. The index is the first-order valence molecular connectivity index, $^1\chi^v$. The index is modified for the number of isolated functional groups in the molecule. A comparison with solvent polarity indexes based on several experimental methods reveals a good relationship. The polarity index proposed can be quickly calculated, it does not depend on the availability of the actual molecule, and it permits prediction of solvent polarity or the polarity of mixtures.

**Keyphrases** □ Solvent polarity—quantitative method based on molecular structure ■ Polarity index—solvents, quantitative method based on molecular structure ■ Molecular structure—quantitative method for ranking solvent polarity

The term "solvent polarity" is widely used by chemists to characterize the observed manifestations of intermolecular interactions in a solution process. The processes may be chromatography, dissolution, or chemical reactions. The manifestations of the interactions are recorded as the separation or retention on stationary phases, the solubility, and the partitioning or reaction course and rate. Solvent polarity is a comparative term which the chemist uses intuitively to rank commonly employed compounds. This intuition, based on experience, permits the generalization that hydrocarbons are less polar than esters while alcohols are more polar than esters of the same molecular weight.

## BACKGROUND

The quantitation of solvent polarity is difficult in practice due to the variety of intermolecular forces that may operate between molecules in a given system. Much has been written about solution theory, but the forces influencing solvent–solute interactions can be summarized as those due to dispersion and dipolar and electron donor–acceptor properties (1).

Dispersion forces account for virtually all of the attractive energy between nonbonded atoms among hydrocarbons. These compounds are regarded as nonpolar when their solvent properties are characterized. Dipolar and electron donor–acceptor interactions influence the attractive energy among molecules possessing unsaturation or atoms other than carbon or hydrogen. Solvents possessing structures capable of these interactions are characterized as being polar. Thus, molecular structure governs solvent polarity, but this relationship has yet to be quantified in any simple way.

**Keyphrases** □ Solvent polarity—quantitative method based on molecular structure ■ Polarity index—solvents, quantitative method based on molecular structure ■ Molecular structure—quantitative method for ranking solvent polarity

The term "solvent polarity" is widely used by chemists to characterize the observed manifestations of intermolecular interactions in a solution process. The processes may be chromatography, dissolution, or chemical reactions. The manifestations of the interactions are recorded as the separation or retention on stationary phases, the solubility, and the partitioning or reaction course and rate. Solvent polarity is a comparative term which the chemist uses intuitively to rank commonly employed compounds. This intuition, based on experience, permits the generalization that hydrocarbons are less polar than esters while alcohols are more polar than esters of the same molecular weight.

## BACKGROUND

The quantitation of solvent polarity is difficult in practice due to the variety of intermolecular forces that may operate between molecules in a given system. Much has been written about solution theory, but the forces influencing solvent–solute interactions can be summarized as those due to dispersion and dipolar and electron donor–acceptor properties (1).

Dispersion forces account for virtually all of the attractive energy between nonbonded atoms among hydrocarbons. These compounds are regarded as nonpolar when their solvent properties are characterized. Dipolar and electron donor–acceptor interactions influence the attractive energy among molecules possessing unsaturation or atoms other than carbon or hydrogen. Solvents possessing structures capable of these interactions are characterized as being polar. Thus, molecular structure governs solvent polarity, but this relationship has yet to be quantified in any simple way.

*0022-3549/81/0800-0930$01.00/0*

*© 1981, American Pharmaceutical Association*

In contrast, several experimental observations have been used to construct a numerical ranking of solvent polarity. Hildebrand and Scott (2) reasoned that the molar heat of vaporization for the molar volume relates to the intermolecular interaction strength to give a value for a solubility parameter, $\delta$. Since the derivation of this polarity parameter is based on the assumption of the dominance of dispersion forces, it is less accurate for more specific dipolar forces.

Snyder (3) used the eluting power of solvents on stationary phases to arrive at an eluent strength parameter, $\epsilon^0$. The stationary phase is usually alumina, but other materials can be used with appropriate correction. Since the values for more polar solvents are quite close, the parameter is more discriminating for nonpolar solvents.

Rohrschneider (4) introduced a scale in which the solvent polarity, $P'$, is measured for GLC retention of butane and butadiene. The quality of the parameter increases with more polar solutes.

A polarity index, $Y$, measuring the ionizing power of a solvent from the solvolysis rates of several compounds, was devised (5). The charge transfer band of 1-alkylpyridinium iodide complexes was used (6) as a measure of the solvent polarity, $Z$. Finally, the dielectric constant has been associated with molecular polarity.

Each of these proposals is based on different sets of conditions and molecular behavior, although each is ultimately a function of molecular structure. This fact was recognized by Martin (7) who attempted the prediction of the chromatographic phase distribution of a molecule from structure fragment values. The method is limited to carefully defined functional groups.

The value of a polarity index lies in its ability to predict the relative polarity of a solvent for which experimental data are not available. A second potential value lies in the ability of an index to predict the polarity of a mixture of solvents from their individual values. Thus, a wide range of solvent polarity could be achieved from various proportions of two solvents with desirable physical, chemical, and toxicological properties.

## DERIVATION OF POLARITY INDEX FROM MOLECULAR STRUCTURE

**Structural Influences**—The structure of a molecule governs all physical and chemical phenomena. The solvent characteristics of a molecule depend on intermolecular interactions which, in turn, are dependent on structure. The generalization can be made that molecules classified as nonpolar according to any of the stated methods are molecules that possess few, if any, polar groups or bonds. Nonpolar molecules are distinguished by the absence of unsaturation or lone-pair electrons. Thus, pentane is universally regarded as nonpolar. It has only C–H and C–C bonds, which are devoid of electrons not axially directed between nuclei. In contrast, ether, with virtually the same molecular weight, is more polar. Ether has two lone pairs of electrons on the oxygen atom.

Similar comparisons between hexane and pentanol, cyclohexane and benzene, and methyl ethyl ketone and methyl acetate present the case that molecules, of about the same molecular weight, with $\pi$ and lone-pair electrons are more polar than those without them. This observation is not surprising since lone-pair electrons create significant dipoles capable of intermolecular interactions associated with polar solvents. The task then is to encode this structural information into a molecular index that will quantify solvent polarity from a purely structural basis.

**Calculation of Polarity Index**—The presence of $\pi$ and lone-pair electrons on an atom in its valence state was shown (8) to be encoded into the connectivity delta values, $\delta$ and $\delta^v$. These connectivity deltas are not to be confused with the Hildebrand–Scott polarity index (2). The valence delta, $\delta^v$, is assigned to an atom in its valence state according to the relationship $\delta^v = Z^v - h$, where $Z^v$ is the count of valence electrons and $h$ is the count of bonded hydrogen atoms. For atoms beyond the second quantum level, the expression $\delta^v = (Z^v - h)/(Z - Z^v)$, where $Z$ is the atomic number, is used (9). The simple delta value, $\delta$, is a count of all bonded atoms except hydrogen. It can be expressed as $\delta = \sigma - h$, where $\sigma$ is a count of all $\sigma$ electrons on the atom.

Since:

$$\delta^v = Z^v - h \qquad \text{(Eq. 1}a\text{)}$$

then:

$$\delta^v = \sigma + p + n - h \qquad \text{(Eq. 1}b\text{)}$$

where $p$ is a count of $\pi$ electrons and $n$ is a count of lone-pair electrons.

**Table I—Exterjacent Electrons *versus* ($^1\chi - {}^1\chi^v$)**

| Molecule | $^1\chi$ | $^1\chi^v$ | $\Delta^1\chi$ | Exterjacent Electrons |
|---|---|---|---|---|
| $CH_3CH_2CH_2CH_2CH_3$ | 2.414 | 2.414 | 0.0 | 0 |
| $CH_3CH_2CH_2CH_2NH_2$ | 2.414 | 2.115 | 0.299 | 2 |
| $CH_3CH_2CH_2CH_2OH$ | 2.414 | 2.023 | 0.391 | 4 |
| $CH_3CH_2OCH_2CH_3$ | 2.414 | 1.992 | 0.422 | 4 |
| $CH_3CH_2CH_2CH{=}O$ | 2.414 | 1.851 | 0.563 | 6 |
| $HOCH_2CH_2CH_2NH_2$ | 2.414 | 1.724 | 0.690 | 6 |
| $HOCH_2CH_2CH_2OH$ | 2.414 | 1.632 | 0.782 | 8 |
| $HOCH_2CH_2CH{=}O$ | 2.414 | 1.460 | 0.954 | 10 |
| $O{=}CHCH_2CH{=}O$ | 2.414 | 1.288 | 1.126 | 12 |

It follows that:

$$\delta^v - \delta = \sigma + p + n - h - \sigma + h \qquad \text{(Eq. 2}a\text{)}$$

$$\delta^v - \delta = p + n \qquad \text{(Eq. 2}b\text{)}$$

The count of $\pi$ and lone-pair electrons, called exterjacent electrons (8), is encoded in $\delta^v - \delta$.

By using these delta values assigned to each atom in a molecule, two molecular connectivity indexes are calculated by:

$$^1\chi = \Sigma(\delta_i\delta_j)^{-1/2} \qquad \text{(Eq. 3}a\text{)}$$

$$^1\chi^v = \Sigma(\delta_i^v\delta_j^v)^{-1/2} \qquad \text{(Eq. 3}b\text{)}$$

where $i$ and $j$ are each pair of bonded atoms and the summation is over the entire molecule.

The exterjacency on an atom, enumerated by $\delta^v - \delta$, can be encoded for the molecule by $^1\chi - {}^1\chi^v$. The subtraction of $\chi$ indexes is inverted since the reciprocal of the delta values is used in computing the molecular connectivity indexes. Kier and Hall (8) showed a derivation of the indexes from physical principles.

The effect on the calculated value of $^1\chi - {}^1\chi^v$ due to an increase of exterjacent electrons in a molecule is illustrated in Table I. With increasing numbers of exterjacent electrons in molecules in this series, the value of $^1\chi^v$ for the molecule decreases. For this series with a constant $^1\chi$ value, $^1\chi - {}^1\chi^v$ increases down the list.

In this series with a constant $^1\chi$ value, the $^1\chi - {}^1\chi^v$ value increases as the molecules increase in polarity. For molecules in an homologous series, for example the *n*-alkanols, the solvent polarity decreases with increasing size; however, the value of $^1\chi - {}^1\chi^v$ for such a series remains constant. To account for this effect, the use of $^1\chi - {}^1\chi^v$ to reflect solvent polarity must be modified by a term describing increasing molecular weight. This can be accomplished by diminishing the value of $^1\chi - {}^1\chi^v$ by $^1\chi$, which increases with size in an homologous series.

The index reflecting polarity thus may be described as:

$$\text{polarity} = {}^1\chi - {}^1\chi^v - {}^1\chi = -{}^1\chi^v \qquad \text{(Eq. 4)}$$

To restate this relationship, it is proposed that solvent polarity is inversely related to $^1\chi^v$. Table II shows the calculated values of $^1\chi^v$ for common solvents. Also included are other polarity indexes, $\epsilon^0(Al_2O_3)$, $\delta$, and $P'$, as well as the octanol–water partition coefficient, dielectric constant, and water solubility.

**Functional Group Number Weighting**—A number of molecules in Table II, such as ethylene glycol and dioxane, possess two isolated functional groups. These solvents are more polar than their monofunctional counterparts of about equal molecular weight, propanol and pyran. The two functional groups may be regarded as having twice the opportunity or probability of engaging in dipolar or electron donor–acceptor interactions with a solute.

For purposes of defining this solvent polarity index, a functional group is defined as an ensemble of atoms with exterjacent electrons that engage, as a unit, in essentially a single type of intermolecular interaction. Thus, the two oxygens and the carbon atom of an ester group constitute a functional group in this definition. Similarly, the three atoms of a nitro group represent one functional group in nitrobenzene. The six carbon $\pi$ electrons of the benzene ring also constitute a discrete functional group that acts in concert with the nitro group. Thus, nitrobenzene has two functional groups.

A nitrogen atom in pyridine participates in the $\pi$-electron annulus and contributes to van der Waals interaction. The nitrogen also may participate in hydrogen bonding through the lone-pair electrons. Thus, pyridine has two functional groups by this definition. To account for this, it is proposed that the calculated $^1\chi^v$ value be divided by a factor, $f$, describing the number of discrete, isolated functional groups. This method was

**Table II—Ranking of Solvent Polarity Using $^1\chi^v/f$ Index**

| Molecule | $^1\chi^v/f$ | $P'$[a] | Hildebrand–Scott $\delta$[b] | $\epsilon^0(Al_2O_3)$[c] | Octanol–Water log $P$[d] | Dielectric Constant[e] | Water Solubility[f], g/100 g |

applied to nitrobenzene, benzonitrile, $\alpha$-picoline, dioxane, pyridine, methoxyethanol, ethanolamine, and ethylene glycol (Table II).

The exception to this rule is the case where one or more halogen atoms is present on different carbon atoms, *i.e.*, ethylene dichloride. Chlorine does not make a significant contribution to a molecule in terms of enhancing its solvent polarity. Aryl and alkyl halides are classified among the more nonpolar solvents, *i.e.*, carbon tetrachloride, chlorobenzene, *etc.* Thus, the value of $^1\chi^v$ computed for a halogen-containing molecule would be used unmodified.

Table II lists 36 of the more common solvents, ranked according to increasing solvent polarity computed as a diminishing value of $^1\chi^v/f$. This polarity index, based solely on molecular structure, can be compared with the experimental polarity indexes derived by several methods. In addition, the table lists physical properties associated with solution phenomena. Several observations emerge from comparisons of these indexes.

## DISCUSSION

The diminishing value of $^1\chi^v/f$, associated with increasing solvent polarity, parallels the increase in the values of $P'$, $\delta$, and $\epsilon^0(Al_2O_3)$, with the $P'$ values having perhaps the best correlation. Each of these experimentally derived polarity indexes is based on different experimental methods; thus, a close correlation is not expected among them or with $^1\chi^v/f$. Nevertheless, for a broad definition of solvent polarity, $^1\chi^v/f$ performs quite well in comparison. The distinct advantage of using $^1\chi^v/f$ as a solvent polarity index is the fact that it is based exclusively on structure, so it is nonempirical. It can be computed quickly and simply for any molecule, including those that may not be available.

The physical properties in Table II correlate fairly well with $^1\chi^v/f$. The aqueous solubility is minimal for molecules with $^1\chi^v/f$ values above 2.0, intermediate for $^1\chi^v/f$ values of 1.5–2.0, and miscible for practically all molecules with $^1\chi^v/f$ values of $<\sim 1.5$.

There are exceptions to these observations, but generally the calculated $^1\chi^v/f$ index ranks the molecules according to solvent polarity as well as any of the experimental indexes, the advantage clearly being in the purely structural basis for the calculation.

An additional application of the $^1\chi^v/f$ solvent polarity index is obvious when binary solvent mixtures are considered. If it is assumed that when two nonreacting solvents are mixed the solvent polarity is an average of their polarities, weighted by their mole fractions, then it should be possible to calculate the solvent polarity of any mixture or, conversely, to design a solvent mixture with a specific solvent polarity. This latter course often is desirable when one solvent may possess unfavorable physical, chemical, or toxicological properties.

As an example, ether may have optimum solvent polarity for a particular application; however, its volatility and flammability preclude its use from safety considerations. It is desirable to reproduce approximately the $^1\chi^v/f = 1.992$ ether polarity with a mixture of two solvents. Calculations show that a 1:1 mixture of toluene and propanol has a $^1\chi^v/f$ value of 1.967, while a 2:1 mixture of methyl ethyl ketone and chlorobenzene has a $^1\chi^v/f$ value of 1.973.

Other applications of the index include the basis of selection of a relatively nonpolar solvent that is heavier or lighter than water or miscible, all with about the same polarity. Chloroform, butanol, and tetrahydrofuran, respectively, meet these specific criteria.

Finally, the index will prove useful in estimating the polarity of a molecule not commonly considered as a solvent or perhaps a polymeric structure such as the polyethers. Thus, the $^1\chi^v/f$ values lead to polarity rankings for some additional liquids: methylformamide, 1.024; diethylene glycol, 0.737; dimethoxy polyethylene glycol, $^1\chi^v/f$ approaches a limit of 1.10 with increasing size; morpholine, 1.142; various fluorinated ethanols, 0.0–0.5; glycerol, 0.569; and aniline, 1.100.

# Structure–Activity Studies on Sulfamate Sweeteners II: Semiquantitative Structure–Taste Relationship for Sulfamate ($RNHSO_3^-$) Sweeteners—The Role of R

**WILLIAM J. SPILLANE ˣ and GRAINNE McGLINCHEY**

Received October 1, 1980, from the *Department of Chemistry, University College, Galway, Ireland.* Accepted for publication February 4, 1981.

**Abstract** □ With the use of Corey–Pauling–Koltun space-filling models, measurements of defined parameters ($x$, $y$, and $z$) were made of the R groups in a large number of carbosulfamates, $RNHSO_3^-$. The correlation between sweet and nonsweet sulfamates and the defined parameters for R is good. As a test, 12 new carbosulfamates were synthesized and tasted. The predictions of their sweetness or nonsweetness based on the correlation were >90% correct. To elicit a sweet taste, the R group of the sulfamate should have $x \geq 5.2$ Å and $\leq 7.2$ Å and $V$ (*i.e.*, $xyz$) $\leq 250$ Å$^3$ and probably $\geq 90$ Å$^3$. The receptor site is seen (as for aspartame) as a rather narrow cleft into which R has to fit "properly" or be "locked" so that the AH,B mechanism for initiating the sweet stimulae can operate. Possible applications of this approach are indicated.

**Keyphrases** □ Sweeteners—structure–activity analysis of sulfamates, the role of R side chains □ Sulfamates—sweeteners, structure–activity analysis, the role of R side chains □ Structure–activity relationships—the role of R side chain on sulfamate sweeteners

Synthetic studies of alternative sweeteners have been given impetus since the ban on cyclamates in 1970 and the apparently unresolved question of the toxicity of saccharin, the only synthetic sweetener presently used worldwide. These studies, aimed at the design of new synthetic sweeteners and a fuller understanding of sweetness, have led to the establishment of structure–taste relationships for some classes of alternative sweeteners (1–3).

Most workers have concentrated on the development of intraclass structure–taste relationships since there is good evidence that different classes of sweeteners act by binding at different receptor sites in the taste buds of the tongue (4). Thus, structure–taste information from one class is not transferable to another class.

## BACKGROUND

The structure–activity relationships of sulfamate sweeteners were reviewed in Part I of this study (5). Other investigators (6, 7), using Corey–Pauling–Koltun (CPK) space-filling atomic models, showed that the best $NHSO_3^-$ group conformation for sweet taste stimulation involved an angle ($\theta$) of 60° between the N–H and S–O bonds. The necessity of maintaining this optimal 60° torsional angle for sweetness explains why substitution of an $\alpha$-hydrogen by an alkyl group at C-1 of an alicyclic ring or aliphatic chain destroys sweetness. Similarly, the lack of sweetness of phenylsulfamate is ascribed to steric hindrance due to an *ortho*-hydrogen of the phenyl ring forcing the aminosulfonate group to adopt a conformation with $\theta \approx 0°$.

Pautet and Nofre (6) measured the lengths of various R groups in $RNHSO_3^-$ and found that for sweetness, R should lie between 5 and 7 Å. In their second paper (7), they suggested, on the basis of a few measurements, that R should have a "half-width" of <4 Å. While this approach is satisfactory for simpler aliphatic and alicyclic systems, it appeared to us to be inadequate for various substituted systems for several reasons:

1. Taste response is a function of the size, shape, and functionality of a molecule, *i.e.*, taste response = $f$(size, shape, functionality), and any assessment of size and shape should take into account the three-dimensional structure and conformation of the molecule.
2. Several molecules whose R groups have dimensions falling within the limits given by Pautet and Nofre (6, 7) were prepared (and tasted for sweetness), and it was found that they are not sweet (Table I, Compounds 15, 18, 47, and 49).

In the present work, 12 new sulfamates were synthesized. With the use of CPK space-filling models, measurements were taken on these and other sulfamates reported (and tasted) previously. A good correlation existed between sweet/nonsweet sulfamates and the defined parameters for R, so it is possible to predict whether unknown sulfamates will be sweet. Predictions based on the correlation were >90% correct for the 12 sulfamates synthesized.

## RESULTS AND DISCUSSION

Measurements were carried out on all known carbosulfamates for which taste data were available. Only those sulfamates whose lack of sweetness could be ascribed to a distortion of the angle $\theta$ from 60°, *e.g.*, those substituted at C-1 of a chain or a bridgehead (6, 7), were excluded.

Parameters $x$, $y$, and $z$ were defined and measured for each R group; from these values, a measure of the size or three-dimensional structure ($V$) of R is obtained from the product $xyz$ (see *Experimental*).

Table I lists the sulfamates on which measurements were made. The $x$, $y$, $z$, and $V$ parameters are given together with the literature references. The compounds are listed (Table I) in certain convenient groupings, *e.g.*, straight chain, branched, and increasing ring size.

In Fig. 1, a plot of $x$ (the "length" of R) against $V$ was made using the data for the previously reported sulfamates in Table I. The sulfamates synthesized in the present work (Compounds 15, 18, 20, 21, 35, 41, 43, and 45–49) and those about which predictions were made (Compounds 26–28) were excluded. Figure 1 reveals that nearly all of the sweet sulfamates fall into a rectangle (Fig. 1A) whose boundaries are reasonably well defined on three sides, being ~5.2 and ~7.2 Å on the $x$ axis and ~250 Å$^3$ on the $V$ axis. The fourth boundary appears to be $\leq 90$ Å$^3$ on the $V$ axis. Almost all of the sulfamates lying outside A are not sweet. Some bitter or faintly sweet sulfamates lie at or near one of the three defined boundaries.

Of the 12 sulfamates synthesized, it could be predicted on the basis of Table I and Fig. 1 that 10 of them would not be sweet and two of them would be sweet (*i.e.*, Compounds 46 and 48). Tasting indicated that these predictions were correct in 11 cases. The one exception was the apocamphane compound (Compound 48), which was bitter. All 12 compounds are shown in Fig. 2. Compound 48 might have been excluded since it is an example of a C-1 substituted sulfamate and, therefore, would not be expected to be sweet due to distortion of the angle $\theta$ from 60°. However, it is included because it is bitter and it does lie on a boundary.

In Fig. 1, a plot of $x$ (the "length" of R) against $V$ was made using the data for the previously reported sulfamates in Table I. The sulfamates synthesized in the present work (Compounds 15, 18, 20, 21, 35, 41, 43, and 45–49) and those about which predictions were made (Compounds 26–28) were excluded. Figure 1 reveals that nearly all of the sweet sulfamates fall into a rectangle (Fig. 1A) whose boundaries are reasonably well defined on three sides, being ~5.2 and ~7.2 Å on the $x$ axis and ~250 Å$^3$ on the $V$ axis. The fourth boundary appears to be $\leq 90$ Å$^3$ on the $V$ axis. Almost all of the sulfamates lying outside A are not sweet. Some bitter or faintly sweet sulfamates lie at or near one of the three defined boundaries.

Of the 12 sulfamates synthesized, it could be predicted on the basis of Table I and Fig. 1 that 10 of them would not be sweet and two of them would be sweet (*i.e.*, Compounds 46 and 48). Tasting indicated that these predictions were correct in 11 cases. The one exception was the apocamphane compound (Compound 48), which was bitter. All 12 compounds are shown in Fig. 2. Compound 48 might have been excluded since it is an example of a C-1 substituted sulfamate and, therefore, would not be expected to be sweet due to distortion of the angle $\theta$ from 60°. However, it is included because it is bitter and it does lie on a boundary.

[a] Synthesized in the present work. [b] Not synthesized.

In Fig. 3, the 12 compounds are shown with those in Fig. 1 and three unknown compounds. On examination of Fig. 3, a quantitative assessment of the quality and predictive value of the correlation can be made. Of the 47 compounds synthesized and tasted (Compounds 26–28 can be excluded), there is only one nonsweet compound within area A and one sweet compound outside A if those actually on a boundary are ignored. Thus, the taste, *i.e.*, sweet/nonsweet, of 45 of the 47 compounds can be predicted correctly. This finding indicates that Fig. 3 has a 96% chance of correctly predicting the taste of unsynthesized sulfamates.

The correlation between sweet/nonsweet and the defined parameters for R is good and suggests that Fig. 3 can be used to predict whether certain unknown sulfamates will be sweet. Thus, its usefulness in the design of new sweet sulfamates is clear. For example, although Compound 25 is not sweet, it can be predicted that Compounds 26–28 will be sweet.

Plots of either *y* or *z versus V* did not give such a high correlation between sweet/nonsweet molecules and the magnitudes of *y*/*z* and *V*. A few known carbosulfamates were exluded in addition to the group specifically

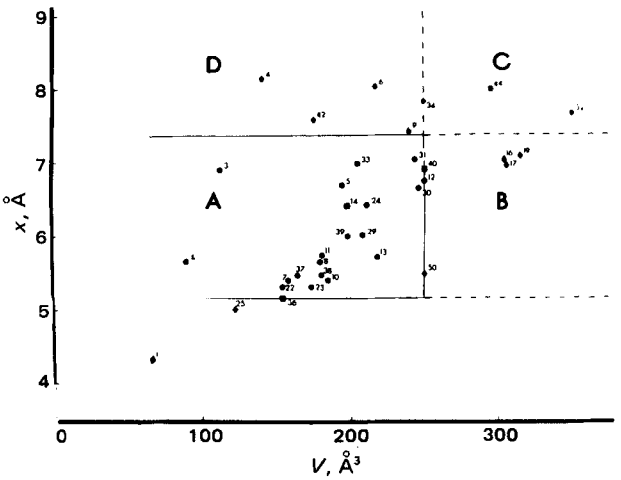

**Figure 1**—*Plot of the lengths of R (x)* versus V *for reported sulfamates. See Table I for key to compounds. Key:* ●, *sweet;* ♦, *nonsweet; and* ■, *bitter.*

mentioned at the beginning of this section. Thus, for example, *n*-hexylsulfamate and higher homologs were not considered since their *x* parameters ($x = 9.26$ Å for *n*-hexylsulfamate) would place them at the outer limits of the figures and, being nonsweet, they add nothing to the correlation. Some sulfamates that were not tasted were excluded.

The space-filling properties of R (as measured by *V* and *x*) are all important in determining whether or not a molecule is sweet; *V* is not a measure of the molecular volume of R, although the actual volumes of dipeptide ester sweeteners have been measured by immersion in 40% methanol using CPK models (8). The present authors found that the solvent penetrates into the hollows in the models; therefore, it was doubtful if this method could give an accurate assessment of volume (unless the models were hermetically sealed first). Recently, relative sweetness data for 33 dipeptide esters were correlated in a multiparameter equation involving parachor, hydrophobic, and STERIMOL parameters (9).

The *V* parameter can be regarded as the volume generated when *x*, *y*, and *z* are multiplied, *i.e.*, *V* gives the dimensions of the space or receptor site into which R will fit. Thus, although *V* is in part a function of *x*, both parameters are highly meaningful and allow one to explain why some sulfamates are sweet and others are not.

The absence of sweetness of some sulfamates (Fig. 3) can be explained if, as in the case of aspartame (10), the receptor site is seen as a rather narrow cleft (10 Å for aspartame) into which R has to be fitted. Thus, those molecules whose R groups have $5.2 \geq x \leq 7.2$ Å but $V > 250$ Å³ (Fig. 3B) are unable to fit into the receptor site and, therefore, cannot be "locked," and the AH,B mechanism for initiating the sweet stimulus cannot operate. Molecules with $x > 7.2$ Å are too long to fit into the receptor site (Fig. 3D), and molecules with $x > 7.2$ Å and $V > 250$ Å³ (Fig.

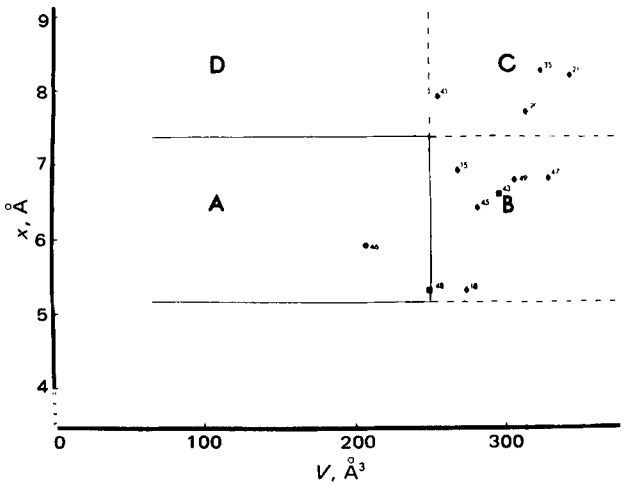

**Figure 2**—*Plot of lengths R (x)* versus V *for the 12 new sulfamates. See Table I for key to compounds. Key:* ●, *sweet;* ♦, *nonsweet; and* ■, *bitter.*

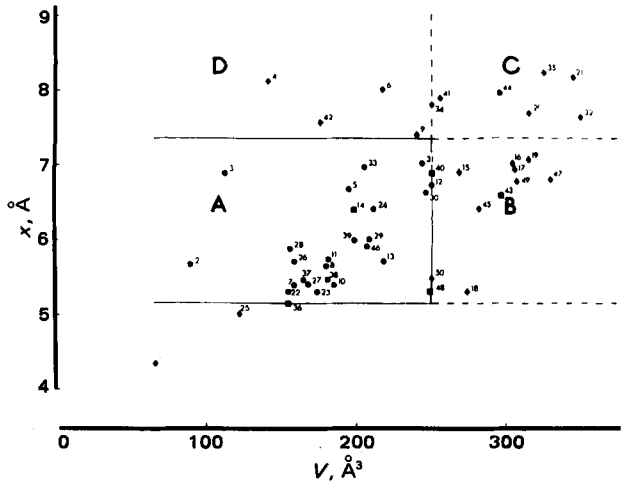

**Figure 3**—*Plot of the lengths of R (x) versus V for reported, newly synthesized, and some unknown (Compounds 26–28) sulfamates. See Table I for key to compounds. Key: ●, sweet; ♦, nonsweet; and ■, bitter.*

3C) are both too long and too large to be accommodated by the restricted three-dimensional geometry of the binding site. Finally, the few sulfamates with $x < 5.2$ Å and $V < 250$ Å$^3$ should give a poor fit at the binding site and might not be expected to be sweet.

The approach to structure–taste relationships developed here may be useful in developing such relationships for other types of sweeteners. An attempt is being made to extend it (both by syntheses and measurements on models) to include the large group of sulfamates whose R groups contain one or more heteroatoms. An advantage of the present method is that relative sweetness data are not required. If such data were available, additional patterns or trends might be discernible in Fig. 3. Seen on a broader canvas, the present approach might find application in the wider area of structure–activity relationship studies in chemoreception.

## EXPERIMENTAL

**Syntheses**—All of the sulfamates were synthesized either by reaction of the appropriate amines by the method of Audrieth and Sveda (11) or by the method of Boyland *et al.* (12). Many of the amines were prepared from the corresponding ketones by conversion to their oximes and subsequent sodium–ethanol reduction. All compounds were isolated as their sodium salts, except Compounds 43 and 48, which were purified as their ammonium salts. Compound 48 was prepared from camphor *via* camphorsulfonic acid, camphorsulfochloride, ketopinic acid (13), apocamphane-1-carboxylic acid (14), and 1-aminocamphane (15).

**Taste Analysis**—All of the sulfamates were tasted by four tasters who were asked to decide whether a solution was sweet or nonsweet, *i.e.*, tasteless or bitter. Prior to commencing, each taster took a concentrated solution of sodium *n*-propylsulfamate, which is very slightly sweet (5, 16). The methodology of the tasting process involved the following: (*a*) rinsing out the mouth with distilled water, (*b*) tasting a concentrated solution of the test sulfamate, (*c*) rinsing out the mouth with distilled water, and (*d*) tasting a concentrated solution of sodium *n*-propylsulfamate. (For many of the compounds taken from the literature and shown in Figs. 1–3, the taste data reported only indicated sweet or nonsweet results.)

**Measurements with Models**—The atoms making up each side-chain R were arranged in the most stretched conformation. For example, in Compound 12, the methyl group was put into an equatorial position; in Compound 15, the two methyl groups were put *trans* to one another. The side-chain R was positioned on a calibrated straight line (in the plane of the paper) so that the apex carbon (C-1) was superimposed on the zero mark and the remainder of the group was positioned on the line. The group R was clamped in this position, and the measurements ($x, y, z$) were made in this fixed position.

The length of R ($x$) could be read off the calibrated line or determined with a vernier. The width of R ($z$) was obtained by locating the widest points of the chain at right angles to the calibrated line in the $x, z$ plane and dropping perpendiculars from the $z$ axis to these points. The sum of the lengths of the two perpendiculars gave $z$. The height of R ($y$) was obtained by locating in the $x,y$ plane (at right angles to the plane of the paper) the highest point of R. Value $V$, in Å$^3$, is the volume generated by multiplication of $x$, $y$, and $z$. Where comparison was possible, measurements were usually within 10% of those previously reported (6, 7).

# Investigation of Gel Structure of Aluminum Hydroxycarbonate Gel Using a Tension Cell

**EDWARD A. LIPKA *, JOSEPH R. FELDKAMP ‡, JOE L. WHITE ‡, and STANLEY L. HEM *x**

Received April 21, 1980, from the **Department of Industrial and Physical Pharmacy and the* ‡*Department of Agronomy, Purdue University, West Lafayette, IN 47907.* Accepted for publication February 6, 1981.

**Abstract** □ A tension cell was designed to measure the gel structure of aluminum hydroxycarbonate gel. Equilibrium measurements of the total water outflow *versus* applied tension give insight into the rigidity of the gel structure. Dynamic measurements of the rate of outflow of water at various applied tensions yield the capillary conductivity of the gel, which is related to the apparent surface area, particle size, and porosity. An aluminum hydroxycarbonate gel with a high apparent viscosity exhibited an increase in viscosity upon aging at 25°, which was accompanied by an increase in the equilibrium tension of the water phase, an increase in $\Delta\overline{G}_{H_2O}$, and a decrease in capillary conductivity. In contrast, the apparent viscosity of a low viscosity aluminum hydroxycarbonate gel, which was precipitated from the same reagents but with different precipitation temperature, pH, and stirring speed, exhibited a decrease in equilibrium water tension, a decrease in $\Delta\overline{G}_{H_2O}$, and an increase in capillary conductivity during aging at 25°.

**Keyphrases** □ Aluminum hydroxycarbonate gel—gel structure measurement using a tension cell □ Gels—aluminum hydroxycarbonate, gel structure measurement using a tension cell □ Tension cell—gel structure measurement of aluminum hydroxycarbonate gel

Many physical properties associated with aluminum hydroxycarbonate gel are simply a reflection of the particular structural arrangement of particles within the gel[1]. The specific structural arrangement is, in turn, a delicate function of various parameters such as particle size, shape, solids concentration, the nature and amount of any solutes present, and the various forces involved, *i.e.*, coulombic and van der Waals forces.

Viscosity is one of the most important physical properties of aluminum hydroxycarbonate gel. However, the viscosity of aluminum hydroxycarbonate gel varies widely, as evidenced by the availability of commercial aluminum hydroxycarbonate gels that are semisolids at 9% equivalent aluminum oxide content or that are pourable liquids at 9% equivalent aluminum oxide. The differences in apparent viscosity as well as the high water content of these systems suggest that considerable variation exists in the gel structure. For this reason, a series of experiments was performed utilizing a specially designed tension cell to obtain greater insight into the gel structure of aluminum hydroxycarbonate gel. The technique developed for this study was based on studies of clay systems (1) and offers the advantage of very little gel disruption during the experiment. The data obtained from the tension cell were compared to the results of more conventional measurements such as viscosity and rate of acid neutralization.

## EXPERIMENTAL

Conditions for the precipitation of aluminum hydroxycarbonate gel by the reaction of aluminum chloride, sodium carbonate, and sodium bicarbonate were varied (Table I) to produce two aluminum hydroxycarbonate gels of significantly different apparent viscosity. The aluminum hydroxycarbonate gel prepared using the conditions described by Kerkhof *et al.* (2) will be termed the high viscosity aluminum hydroxycarbonate gel, and the aluminum hydroxycarbonate gel prepared by Beekman's method (3) will be referred to as the low viscosity aluminum hydroxycarbonate gel.

X-ray[2] (4) and IR[3] (4) analysis confirmed that both the high and low viscosity aluminum hydroxycarbonate gels studied were amorphous aluminum hydroxycarbonate (5).

The rate of acid neutralization was determined by pH-stat titration[4] at pH 3.0 and 25° (6).

Rheograms were obtained using a rotational viscometer[5]. After being stirred to ensure homogeneity, the sample was extruded through a 15-gauge needle into a 600-ml beaker and allowed to stand for 1 hr with the spindle in place prior to the viscosity determination.

The tension cell was a modification of pressure cells used in soil sciences to study the interaction of water with solids (7–9). Preliminary experiments with a pressure cell indicated that pressures of 0.5 atm (68 cm of water) or greater, which are used to characterize water–soil interactions, are too large for studying aluminum hydroxycarbonate gel. To obtain accurately the small driving force needed, a cell capable of applying a small negative pressure or tension to the aluminum hydroxycarbonate gel was developed.

Figure 1 shows the construction of the tension cell. A glass cover fit loosely over the sample chamber to protect the sample and to minimize evaporation. The sample chamber was a plexiglass tube 6.35 cm i.d. × 6.985 cm o.d. × 17.145 cm in length. A 0.9525-cm notch was machined into the outside wall of the sample chamber so that the top base piece could be securely attached. A rubber O-ring and a 0.45-$\mu$m membrane filter were sandwiched between the sample chamber and the bottom base piece. An extracoarse sintered-glass disk, 6.19 × 0.476 cm, fit into the base and served as a filter support. The bottom base piece was machined so a trough system would aid the flow of water to the two outlet ports[6].

Figure 2 is a diagram of the complete tension cell apparatus. The tension cell was fastened to a movable plate[7], which could be accurately positioned by means of a screw gear and vernier system. Water from the samples was collected into a buret that was closed with a stopper containing a capillary which maintained atmospheric pressure in the buret. A three-way stopcock was incorporated in the outlet tubing.

It is essential that the volume comprising the membrane filter's pore volume, the sintered-glass disk's pore volume, and the outlet tubing be completely filled with water before the aluminum hydroxycarbonate gel sample is introduced into the sample chamber. The following procedure was followed in conducting the tension cell experiments:

1. The tension cell was filled from the bottom by adding water through the three-way stopcock. Water was allowed to fill the sample chamber to a height of ~8 cm.

2. The sample chamber cover was replaced with a large one-hole rubber stopper. With the three-way stopcock adjusted to connect the cell to the buret, pressure was applied through the hole in the rubber stopper to remove any air bubbles in the system. The rubber stopper was replaced with the glass cover, and the position of the outlet port was adjusted using the screw assembly so that the outlet port was level with the membrane filter. At this position, the water in the outlet port had a flat surface; *i.e.*, neither a meniscus or a drop was present. The system was allowed to equilibrate for 4–5 hr.

[1] A gel will be viewed as a continuous network of particles extending throughout the entire volume of the system which is, therefore, homogeneous in appearance.

**Table I—Precipitation Parameters** [a]

| Type | Temperature | End-Point pH | Stirring Speed, rpm | Moles of Aluminum Chloride per Liter of Washed Gel | Moles of Sodium Carbonate per Liter of Washed Gel | Moles of Sodium Bicarbonate per Liter of Washed Gel |
|---|---|---|---|---|---|---|
| High viscosity | 25° | 6.5 | 500 | 0.75 | 0.315 | 0.805 |
| Low viscosity | 4° | 5.8 | 15 | 0.80 | 0.315 | 0.805 |

[a] The $AlCl_3$-$6H_2O$ (0.47 *M*) was added to a solution of 0.53 *M* $NaHCO_3$ and 0.23 *M* $Na_2CO_3$.

3. The stopcock was closed to prevent any water flow, and an accurately weighed sample was added to the chamber by extrusion through a 15-gauge needle.

4. The outlet port was raised so it was level with the top surface of the sample. A final adjustment was made in the position of the outlet port by opening the stopcock and adjusting the position of the outlet port to achieve a flat water surface at the outlet port. This was the zero-tension position. The sample was allowed to equilibrate for 30 min.

5. The tension cell was raised 2 cm, and the cumulative volume of water in the collection buret was recorded with time. To maintain a constant tension of 2 cm, the tension cell was raised 0.05 cm for every 1.5 ml of outflow. This manner of correction is permissible since it was observed in separate measurements that the volume change of the column of aluminum hydroxycarbonate gel is identical to the volume of water that has flowed from the aluminum hydroxycarbonate gel.

6. After the outflow from the sample was zero for 2 hr, the tension cell was raised by a predetermined increment (2-cm increments were used), and this step was repeated.

7. After the final tension increment, the sample remaining in the sample chamber was collected and accurately weighed. The sample was dried to constant weight at 110°. Loss during transfer never exceeded 0.05%.

## RESULTS AND DISCUSSION

Both equilibrium and dynamic measurements are possible through the use of the tension cell. Each contributes unique information concerning gel structure so that structural differences are readily ascertained.

In the case of the simple and more easily treated equilibrium data, where total water outflow is examined as a function of applied tension, the particular gel characteristic examined is structural rigidity. Since the volume of water outflow is equal to the volume change of the aluminum hydroxycarbonate gel during the experiment, the ability of a gel to resist collapse of its structural framework may be directly observed by measuring the amount of water released as a consequence of an applied tension. The experiment may be analyzed either in terms of simply plotting the equilibrium water content of the aluminum hydroxycarbonate gel as a function of applied tension or in terms of the following thermodynamic quantity (10–15):

$$\Delta\bar{G}_{H_2O} = -\bar{v}\rho g\tau \qquad \text{(Eq. 1)}$$

where $\bar{v}$ is the molar volume of water, $\rho$ is the density of water, $g$ is the gravitational constant, and $\tau$ is the tension increment. Thus, $\Delta\bar{G}_{H_2O}$ represents the work required per mole of water to remove water from the system with the accompanying compression of the particles into a smaller volume. If $\Delta\bar{G}_{H_2O}$ is large, the particles are pushed closer together only with difficulty due either to large cohesive forces between particles that prevent distortion of the gel structure or to repulsive forces (primarily coulombic repulsion) that prevent particle surfaces from approaching more closely. The latter force becomes much more pronounced only at higher solids concentrations.

Figure 3 shows the equilibrium water content of the high and low viscosity gels. As water was removed from either aluminum hydroxycarbonate gel, the further removal of water became increasingly more difficult. A greater rigidity of gel structure was indicated when the tension *versus* equilibrium water content curve rose more abruptly at low tension

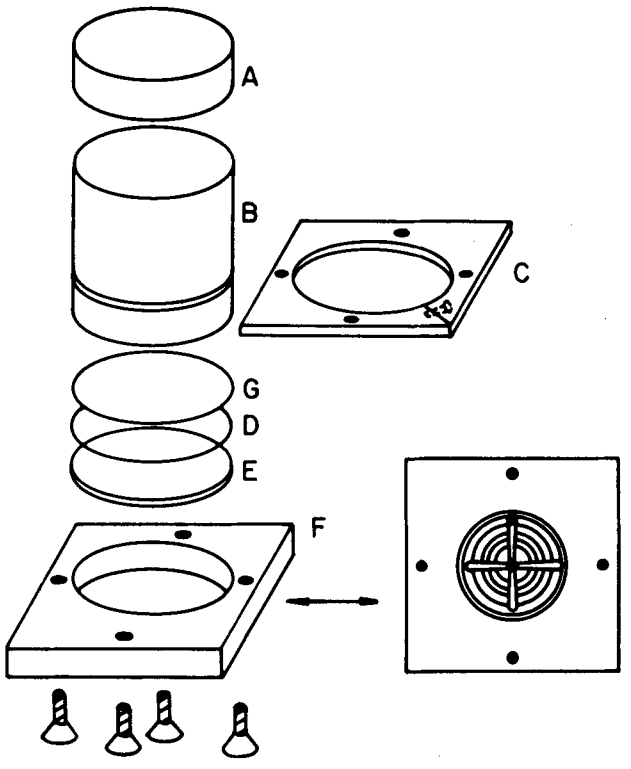

**Figure 1**—*Components of tension cell. Key: A, cover; B, sample chamber; C, top base; D, O-ring; E, sintered-glass disk; F, bottom base; and G, membrane filter.*

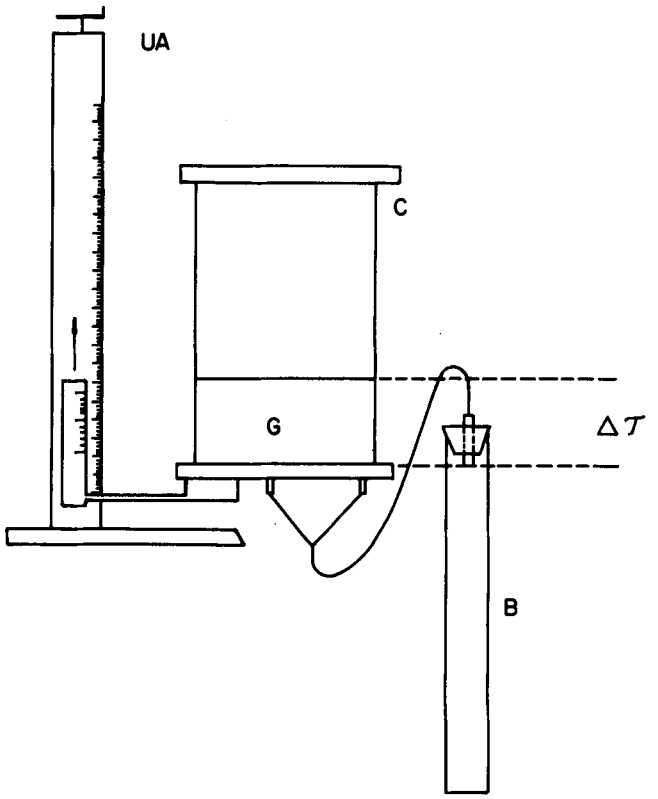

**Figure 2**—*Schematic of tension cell apparatus. Key: C, tension cell; UA, moveable plate assembly; B, collection buret; and G, sample gel.*

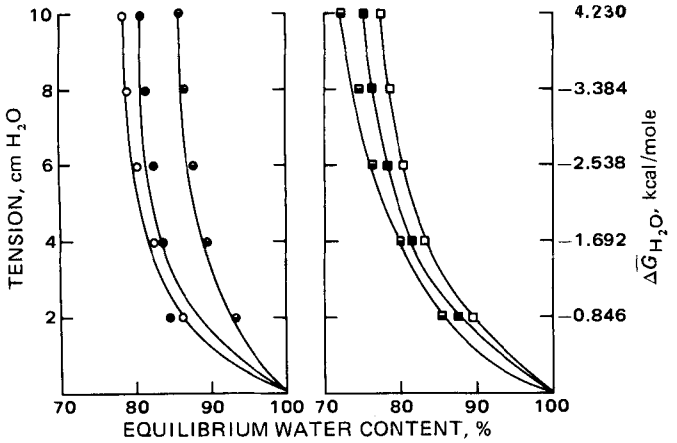

**Figure 3**—*Effect of equilibrium water content on the water tension and change in partial molar Gibbs free energy, $\Delta\bar{G}_{H_2O}$. The high viscosity gel was aged 2 (○), 6 (●), and 14 (◒) weeks at 25°. The low viscosity gel was aged 2 (□), 10 (■), and 14 (◨) weeks at 25°.*

values. The rigidity of the gel structure changed with age (Fig. 3). The high viscosity gel became considerably more rigid as it aged, whereas the low viscosity gel became less rigid with aging. These opposing trends demonstrate that different procedures of aluminum hydroxycarbonate gel preparation can lead to substantially different physical behavior both immediately after precipitation and during aging.

Dynamic measurements also are readily made with the tension cell. Darcy's law (1), which was developed to describe flow through porous media, provides the basis for analyzing the rate of water outflow at various applied tensions:

$$q = \frac{KA\tau}{L} \qquad \text{(Eq. 2)}$$

where $q$ is the rate of flow through the solid phase (cubic centimeters per minute); $K$ is the capillary conductivity (centimeters per minute); $A$ is the cross-sectional area of the solid phase (centimeters squared); $\tau$ is the driving potential, *i.e.*, tension head of water (centimeters); and $L$ is the length of the gel slab (centimeters).

The apparent surface area of the gel, particle size, and porosity all are interrelated. A qualitative measure of these parameters is provided by examining the relative ease with which water may flow through the system. This examination involves time-dependent measurements, whereas only equilibrium measurements were involved in evaluating structural rigidity of the gel structure. The rate of water outflow is measured so that an estimate of capillary conductivity, $K$, may be obtained (8, 9, 16). This quantity reflects the resistance to water flow offered by the gel particles. A large $K$ value implies a low resistance to water flow, which, in turn, indicates lower apparent surface area, larger particles, and higher porosity.

Figure 4 illustrates the capillary conductivity data obtained for the two aluminum hydroxycarbonate gels. With both gels, resistance to the flow of water through the system increased as the water content decreased. Opposite trends were again observed during aging. The high viscosity gel became more resistant to water flow as it aged, whereas the low viscosity gel allowed water to flow more rapidly through its interparticle space upon aging. Both the equilibrium and dynamic measurements indicate that as the gels age, their behavior with respect to water removal changes, which is an important property to consider in the use of aluminum hydroxycarbonate gel dosage forms. The different gel structures exhibited by the two aluminum hydroxycarbonates also will influence manufacturing processes in which the solids concentration is changed, such as in concentrating or washing.

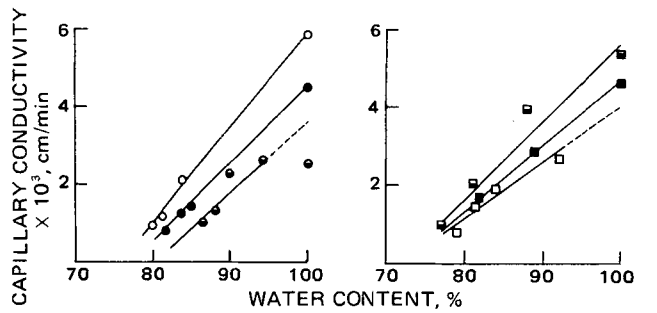

**Figure 4**—*Effect of water content on capillary conductivity. For clarity, the data points are represented by straight lines to emphasize the trends. The $R^2$ values for the straight lines range from 0.64 to 0.99. The high viscosity gel was aged 2 (○), 6 (●), and 14 (◒) weeks at 25°. The low viscosity gel was aged 2 (□), 10 (■), and 14 (◨) weeks at 25°.*

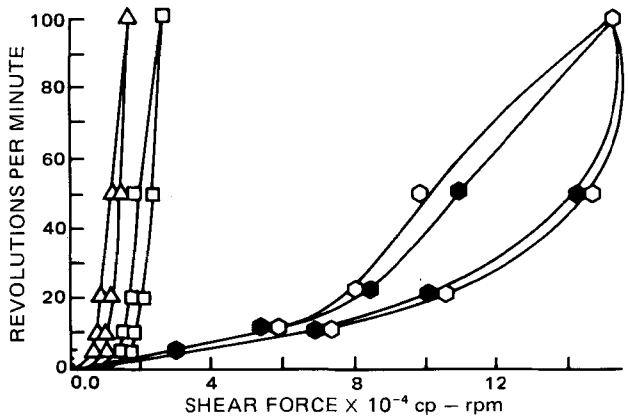

**Figure 5**—*Rheograms of the high viscosity gel during aging at 25°. Key: △, 1 day; □, 4 weeks; ●, 8 weeks; and ○, 12 weeks.*

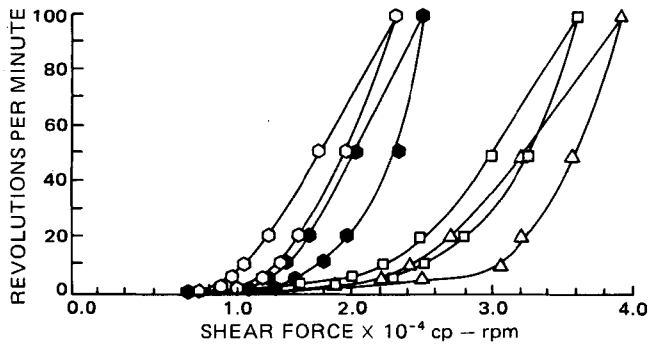

**Figure 6**—*Rheograms of the low viscosity gel during aging at 25°. Key: △, 1 day; □, 4 weeks; ●, 8 weeks; and ○, 12 weeks.*

The rheograms for both the high and low viscosity aluminum hydroxycarbonate gels (Figs. 5 and 6, respectively) indicate thixotropic, shear-thinning systems. The apparent viscosity of the high viscosity gel and the degree of hysteresis increased during aging. In contrast, the low viscosity gel exhibited a decrease in viscosity with aging but no change

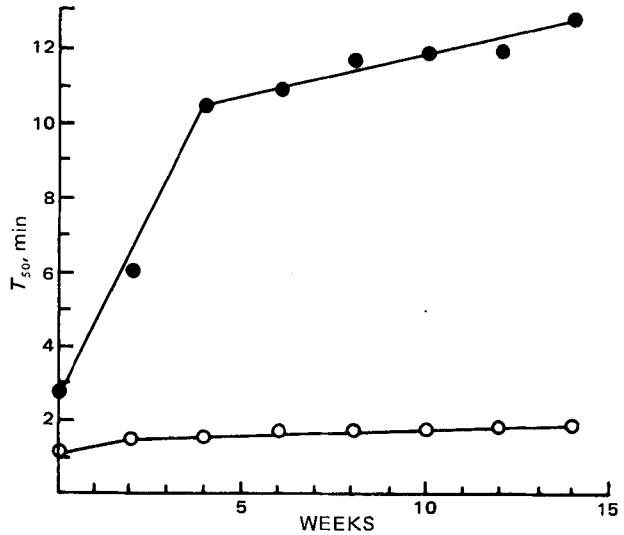

**Figure 7**—*Effect of aging at 25° on the rate of acid neutralization of the high viscosity gel (○) and the low viscosity gel (●).*

in the degree of hysteresis. These facts suggest a substantial increase in the cohesive forces operating between particles of the high viscosity gel and a decrease in the level of cohesion for the low viscosity gel.

Alteration of the degree of particle–particle cohesion due to changes in the level of particle charge was established previously (17). It was shown that additional charge provides sufficient coulombic repulsion to overcome the van der Waals attraction forces so that the apparent viscosity decreases. Examination of the rates of acid neutralization by the two aluminum hydroxycarbonate gels (Fig. 7) indicates a significant decrease in the rate of acid neutralization of the low viscosity gel but no appreciable change for the high viscosity gel. This behavior indicates that crystallinity develops in the low viscosity gel, eventually leading to the formation of a crystalline form of aluminum hydroxide such as gibbsite, which is free of carbonate (5, 18). The transformation to a carbonate-free aluminum hydroxide results in an increased zero point of charge (17) and, therefore, a buildup of charge on the low-viscosity gel. Thus, the apparent viscosity, gel structure rigidity, and resistance to water flow would be expected to decrease as was observed. With the high viscosity gel, the relatively stable rate of acid neutralization during the time period studied indicates that no buildup of charge occurs so that the natural tendency of a gel to form the most stable arrangement of particles with the maximum degree of particle–particle linking is observed. Thus, an increased apparent viscosity, an enhanced gel structure rigidity, and a decreased capillary conductivity are consistent with the proposed mechanism.

## CONCLUSIONS

The tension cell is useful for examining the physical state of a gel, especially when compared to other methods such as viscosity measurement where large inputs of mechanical energy in the form of shear stress may disrupt the gel structure. The tension cell is capable of providing meaningful data with a firm basis provided by thermodynamic and kinetic theory. The data reported here were obtained with considerable difficulty because of the necessity for position readjustment of the tension cell to maintain a constant tension, the long duration of the experiments, and the frequent tabulations of data required for the dynamic measurements. Early experiments, in which adjustments to maintain a constant tension during water outflow were not performed, did not produce satisfactory data. The manual adjustment of cell position to maintain a constant tension was essential in obtaining meaningful results. However, some of the scatter observed in Figs. 3 and 4 may have been due to unavoidable mechanical disturbances of the gel structure through the manual repositioning of the tension cell. Consequently, various methods for automating the tension cell are being tested so that acquiring the necessary data will be more convenient and more precise data may be obtained.

Future experiments are planned with the tension cell to give insight into various roles played by particle charge, size, and shape. The effects of surface charge and particle size on the compressibility of aluminum hydroxycarbonate gel are examined specifically in a subsequent report.

# Effect of Complex Formation between 4-Hexylresorcinol and Ethyl Myristate on Release Rate of 4-Hexylresorcinol from Petrolatum Base

**KATSUMI IGA, ANWAR HUSSAIN ˣ, and TOSHIO KASHIHARA**

Received April 7, 1980, from the *College of Pharmacy, University of Kentucky, Lexington, KY 40506.* Accepted for publication February 5, 1981.

**Abstract** □ The effect of ethyl myristate on the release rate of 4-hexylresorcinol from petrolatum base was studied at pH 7.4 and 37°. 4-Hexylresorcinol was analyzed spectrophotometrically at 278 nm. The release rate of hexylresorcinol from the ointments was directly proportional to the square root of time and depended on the percentage of ethyl myristate in the ointment base. For 0, 0.5, 1, 3, and 5% of ethyl myristate, the release rates were 29.6, 35.4, 38.3, 55.7, and 70.0 $\mu g/hr^{1/2}/cm^2$, respectively. The solubility of hexylresorcinol in the petrolatum base was determined as a function of ethyl myristate using partitioning techniques. The enhancement in hexylresorcinol solubility was rationalized on the basis of 1:1 and 1:2 complexes between hexylresorcinol and ethyl myristate. The complexation constants of these complexes were estimated to be 10 $M^{-1}$ and 206.1 $M^{-2}$, respectively. The diffusion coefficient of hexylresorcinol in the petrolatum base was estimated to be $1.31 \times 10^{-8}$ $cm^2/sec$.

**Keyphrases** □ Release rate—effect of ethyl myristate on release of 4-hexylresorcinol from petrolatum, quantitative analysis □ Ethyl myristate—effect on release rate of 4-hexylresorcinol from petrolatum, quantitative analysis □ 4-Hexylresorcinol—effect of ethyl myristate on release rate from petrolatum, quantitative analysis

Percutaneous absorption depends on both drug release from the vehicle and drug permeability through the skin. Drug release depends on physicochemical factors, such as the drug's solubility and diffusion coefficient in the vehicle.

**Table I—Composition of the Ointments Used in the Release Rate Study**

| Ingredient | Percent of Ethyl Myristate | | | | |
|---|---|---|---|---|---|
| | 0.0 | 0.5 | 1.0 | 3.0 | 5.0 |
| White petrolatum, g | 10 | 10 | 10 | 10 | 10 |
| Hexylresorcinol, mg | 200 | 200 | 200 | 200 | 200 |
| Ethyl myristate, mg | — | 50 | 100 | 300 | 500 |

Simplified equations describing drug release from suspension (1) and solution (2) vehicles have been reported, and numerous studies (3–10) attempted to relate vehicle composition to the *in vitro* release rate. There is, however, relatively little quantitative information correlating the release rate with variations in physicochemical parameters produced by a compositional change in the vehicles. This investigation quantitatively and mechanistically examined the effect of ethyl myristate on the release rate of 4-hexylresorcinol from petrolatum.

## EXPERIMENTAL

**Ointment Preparation**—Table I shows the amounts of hexylresorcinol[1], ethyl myristate[2], and white petrolatum[3] used in ointment preparation. The ointments were prepared by warming hexylresorcinol and ethyl myristate at 40° in a 20-ml beaker. White petrolatum then was added, and the mixture was kept at 40° for 5 min until a homogeneous fluid mixture was obtained. A 5-ml sample of the liquid mixture was poured into a 20-ml polyethylene syringe from which the upper portion had been removed by cutting around the barrel at the 15-ml mark. The ointments were left in the syringe overnight at room temperature.

**Release Rate Measurements**—The half-syringe containing the ointment was attached to the USP dissolution apparatus and was immersed in a 60-ml glass tube containing 40 ml of 0.1 *M* phosphate buffer, pH 7.4, as shown in Fig. 1. The release rate of hexylresorcinol from the ointments was studied at 37° at a rotation speed of 50 rpm. At each sampling interval, the entire 40 ml of the dissolution medium was taken and replaced with 40 ml of fresh buffer. The hexylresorcinol concentration was determined spectrophotometrically[4] at 278 nm using a 10-cm cell.

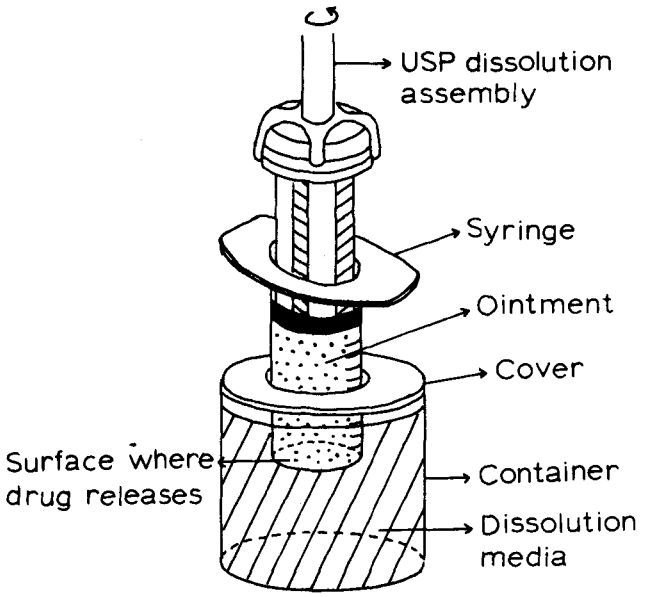

**Figure 1**—*Apparatus used for the determination of release rate of hexylresorcinol from ointment.*

[2] Sigma Chemical Co.
[3] Plough Inc.

**Table II—Composition and Ratio of the Aqueous and Ointment Layers Employed in the Partition Coefficient Determination**

| Aqueous Solution of Hexylresorcinol, ml | White Petrolatum, g | Ethyl Myristate Added to White Petrolatum, mg | Percent of Ethyl Myristate |
|---|---|---|---|
| 20 | 12 | — | 0 |
| 30 | 12 | 60 | 0.5 |
| 40 | 12 | 120 | 1 |
| 30 | 6 | 120 | 2 |
| 40 | 6 | 180 | 3 |
| 60 | 6 | 300 | 5 |

**Partition Coefficient of Hexylresorcinol in pH 7.4 Buffer and in White Petrolatum Containing Different Amounts of Ethyl Myristate**—Ethyl myristate and white petrolatum in the ratios shown in Table II were melted in a 200-ml beaker at 40° and were mixed thoroughly. An aqueous buffer solution containing 200 mg of hexylresorcinol in 500 ml of 0.1 *M* phosphate buffer, pH 7.4, also was prepared. Appropriate volumes of the hexylresorcinol solution (Table II) were added to the petrolatum–ethyl myristate mixtures, which were sonicated for 10 min in 200-ml beakers. The beaker then was shaken at 37° for 7 days, and the aqueous solution was filtered through a 0.45-μm filter[5]. Five milliliters of each filtrate was diluted to 50 ml with pH 7.4 phosphate buffer. The hexylresorcinol concentration was determined spectrophotometrically at 278 nm using a 10-cm cell.

The partition coefficient was calculated as follows:

$$\text{partition coefficient} = \frac{(\text{volume of aqueous layer})\,(\text{absorbance change, } A_0 - A, \text{ in aqueous layer})}{(\text{volume of ointment})\,(\text{absorbance in aqueous layer, } A)} \quad \text{(Eq. 1)}$$

where $A_0$ and $A$ are the initial and final absorbances of the solution, respectively. The volume of the ointment was calculated from the density and weight of the ointment.

## RESULTS AND DISCUSSION

The release profile of hexylresorcinol from the ointments is shown in Fig. 2 as a function of the ethyl myristate concentration. The release of hexylresorcinol from these ointments was proportional to the square root of time.

Higuchi (1) found that the release of drugs suspended in ointment bases obeys the following relationship:

$$Q = \sqrt{Dt(2A - C_s)C_s} \quad \text{(Eq. 2)}$$

where $Q$ is the amount released at time $t$ per unit area of exposure, $A$ is the drug concentration expressed in units per cubic centimeter, $C_s$ is the solubility of the drug in units per cubic centimeter in the external phase of the ointment, and $D$ is the diffusion constant of the drug molecule in the external phase.

Singh *et al.* (11) found that the square root of time dependency also was observed for the release of two interacting drugs incorporated in an inert matrix. These authors found that the release of the individual compounds in benzocaine–caffeine systems, as well as the sum of the two compounds, followed a linear relationship with the square root of time.

It can be shown that the release of hexylresorcinol from ointment bases containing different amounts of ethyl myristate also follows a square root of time dependency (see Eq. A8 under *Appendix*).

The exposed surface area for the release of hexylresorcinol was calculated from the diameter of the syringe (2.0 cm) to be 3.14 $cm^2$. The release rate of hexylresorcinol per unit area from the different ointment bases can be calculated by dividing the slopes of the lines in Fig. 2 by 3.14 $cm^2$. These values are listed in Table III as a function of ethyl myristate. The data indicate that the release rate of hexylresorcinol increased as the percent of ethyl myristate in the ointment increased. Thus, it is apparent that the enhancement in the hexylresorcinol release rate was due to the increase in hexylresorcinol solubility.

To obtain insight into the effect of ethyl myristate on hexylresorcinol solubility in petrolatum and on the nature of the interaction between the two agents, the total solubility of hexylresorcinol was determined in

[4] Varian model 118.
[5] Millipore Corp., Bedford, Mass.

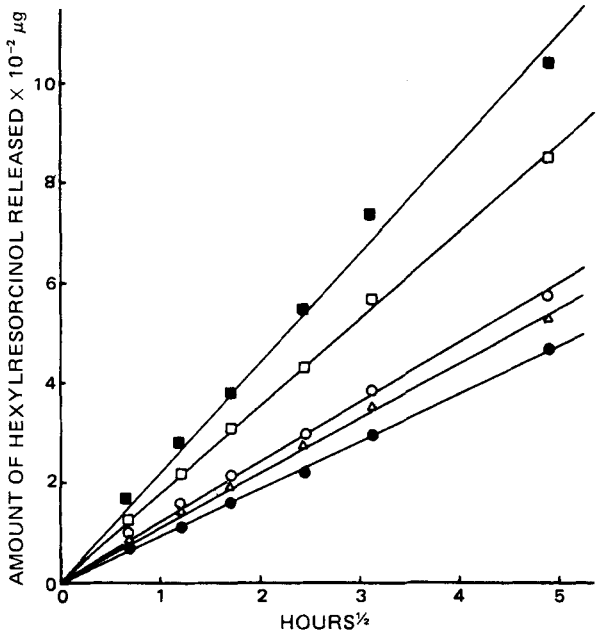

**Figure 2**—*Amount of hexylresorcinol released from ointment as a function of time*$^{1/2}$. *The amounts of ethyl myristate in the ointment were 0 (●), 0.5 (△), 1 (○), 3 (□), and 5 (■) %.*

petrolatum in the presence of ethyl myristate using partitioning. The partition coefficients of hexylresorcinol between the ointment bases and pH 7.4 buffer were calculated using Eq. 1 (Table IV and Fig. 3).

It is apparent from Fig. 3 that the partition coefficient of hexylresorcinol varied in a nonlinear fashion as a function of the ethyl myristate concentration. Previously, it was shown that the partition coefficient of hexylresorcinol between hexane containing various amounts of esters and pH 7.4 buffer also varied in a nonlinear fashion (12). Such behavior was rationalized on the basis of formation of 1:1 and 1:2 complexes between hexylresorcinol and the esters in hexane.

If a similar mechanism is operative in petrolatum, then the following relationships are valid:

$$HR_B \rightleftarrows HR$$

*Scheme I*

$$HR + EM \rightleftarrows HR\cdot EM$$

*Scheme II*

$$HR + 2EM \rightleftarrows HR\cdot EM_2$$

*Scheme III*

$$K_{1:2} = \frac{(HR\cdot EM_2)}{(HR)(EM)^2} \quad \text{(Eq. 6)}$$

$$(HR)_T = (HR) + (HR\cdot EM) + (HR\cdot EM_2) \quad \text{(Eq. 7)}$$

where $P_0$ and $P$ are the partition coefficients of hexylresorcinol between the buffer solution and the ointments without ethyl myristate and with ethyl myristate, respectively; $K_{1:1}$ and $K_{1:2}$ are the complexation constants of 1:1 and 1:2 complexes, respectively; and (HR), $(HR)_B$, $(HR)_T$, (HR·EM), ($HR\cdot EM_2$), and (EM) are the concentrations of free hexylresorcinol in the ointments, free hexylresorcinol in the buffer solution, total hexylresorcinol in the ointments, 1:1 complex of hexylresorcinol in the ointments, 1:2 complex of hexylresorcinol in the ointments, and free ethyl myristate in the ointments, respectively. The combination of Eqs. 3–7 results in:

$$\frac{P - P_0}{P_0} = K_{1:1}(EM) + K_{1:2}(EM)^2 \quad \text{(Eq. 8)}$$

Since a very dilute aqueous solution of hexylresorcinol was employed in the partitioning study, the concentration of the complexes can be considered to be small in comparison with the concentration of free ethyl myristate. It follows that (EM) = $(EM)_T$. Rearranging Eq. 8 results in:

$$\frac{P - P_0}{P_0(EM)_T} = K_{1:1} + K_{1:2}(EM)_T \quad \text{(Eq. 9)}$$

Table V shows the values of the left side of Eq. 9 as a function of $(EM)_T$. A plot of $(P - P_0)/P_0(EM)_T$ *versus* $(EM)_T$ should result in a straight line with the intercept of $K_{1:1}$ and the slope of $K_{1:2}$ as shown in Fig. 4. The values of $K_{1:1}$ and $K_{1:2}$ were 10 $M^{-1}$ and 206.1 $M^{-2}$, respectively. The apparent solubility of hexylresorcinol in the ointment bases can be estimated on the basis of the 1:1 and 1:2 complex formation from the values of the complexation constants ($K_{1:1}$, $K_{1:2}$) as follows.

**Table V—Relationship between Total Ethyl Myristate, $(EM)_T$, and $(P - P_0)/P_0(EM)_T$**

| $(EM)_T$, $M$ | $(P - P_0)/P_0(EM)_T$, $M^{-1}$ |
|---|---|
| $0.0 \times 10^{-2}$ | — |
| $1.53 \times 10^{-2}$ | 12.88 |
| $3.07 \times 10^{-2}$ | 13.29 |
| $6.14 \times 10^{-2}$ | 24.32 |
| $9.21 \times 10^{-2}$ | 30.89 |
| $15.31 \times 10^{-2}$ | 41.29 |

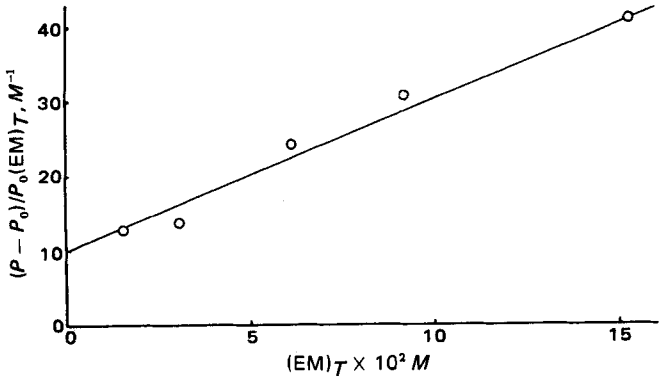

**Figure 4**—*Plot of* $(P - P_0)/P_0(EM)_T$ versus $(EM)_T$.

In the solubility system, $(HR)_T$ and (HR) can be written as:

$$(HR)_T = S_T \quad \text{(Eq. 10)}$$

$$(HR) = S_0 \quad \text{(Eq. 11)}$$

where $S_T$ and $S_0$ are the apparent and the original solubility of hexylresorcinol, respectively. Therefore, the total concentration of ethyl myristate and $S_T$ can be written as:

$$(EM)_T = (EM) + K_{1:1}(EM)S_0 + 2K_{1:2}(EM)^2S_0 \quad \text{(Eq. 12)}$$

$$S_T = S_0 + K_{1:1}(EM)S_0 + K_{1:2}(EM)^2S_0 \quad \text{(Eq. 13)}$$

Elimination of the $(EM)^2$ form gives an equation for the concentration of free ethyl myristate:

$$(EM) = \frac{1}{1 - K_{1:1}S_0}[(EM)_T - 2(S_T - S_0)] \quad \text{(Eq. 14)}$$

The combination of Eqs. 13 and 14 gives:

$$S_T = S_0 + \frac{K_{1:1}S_0}{1 - K_{1:1}S_0}[(EM)_T - 2(S_T - S_0)] + \frac{K_{1:2}S_0}{(1 - K_{1:1}S_0)^2}[(EM)_T - 2(S_T - S_0)]^2 \quad \text{(Eq. 15)}$$

The apparent solubility of hexylresorcinol in the ointment base can be estimated by using the determined values of $K_{1:1}$ and $K_{1:2}$ and $S_0$, which can be estimated as:

$$S_0 = P_0 \times S_B \quad \text{(Eq. 16)}$$

where $S_B$ is the solubility of hexylresorcinol in the buffer solution. The results shown in Table VI strongly suggest that the apparent solubility of hexylresorcinol in the ointment base increases in the presence of ethyl myristate and is due to the complex formation between hexylresorcinol and ethyl myristate.

**Table VI—Apparent Solubility of Hexylresorcinol in the Ointment Bases as a Function of Ethyl Myristate**

| Ethyl Myristate, % | Solubility of Hexylresorcinol in Ointments, $\mu g/cm^3$ |
|---|---|
| 0.0 | $0.680 \times 10^3$ |
| 0.5 | $0.801 \times 10^3$ |
| 1.0 | $0.987 \times 10^3$ |
| 2.0 | $1.479 \times 10^3$ |
| 3.0 | $2.121 \times 10^3$ |
| 5.0 | $3.753 \times 10^3$ |

**Table VII—Relationship between Added Ethyl Myristate and $\sqrt{C_s(2A - C_s)}$**

| Ethyl Myristate, % | $\sqrt{C_s(2A - C_s)}$, $\mu g/cm^3$ |
|---|---|
| 0.0 | $4.578 \times 10^3$ |
| 0.5 | $4.976 \times 10^3$ |
| 1.0 | $5.488 \times 10^3$ |
| 3.0 | $7.894 \times 10^3$ |
| 5.0 | $10.203 \times 10^3$ |

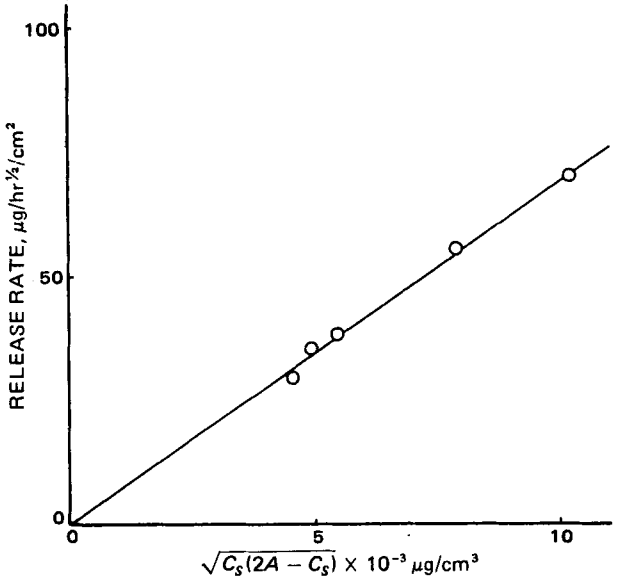

**Figure 5**—*Plot of release rate of hexylresorcinol from ointment* versus $\sqrt{C_s(2A - C_s)}$.

In Eq. 2, if the effective diffusion coefficient of hexylresorcinol in the ointments is the same, then the release rate depends only on the amount of hexylresorcinol and its apparent solubility in the ointments:

$$\text{release rate} = K\sqrt{C_s(2A - C_s)} \quad \text{(Eq. 17)}$$

where $K$ is a constant expressed as $\sqrt{D}$ and $A$ is 15.748 mg/cm³ on the basis of proper dimension. The calculated values of $\sqrt{C_s(2A - C_s)}$ are shown in Table VII.

Plots of the release rate *versus* $\sqrt{C_s(2A - C_s)}$ according to Eq. 17 should result in a straight line with a zero intercept as shown in Fig. 5. It is apparent from Fig. 5 that the enhancement in the release rate of hexylresorcinol is due only to the increase in hexylresorcinol solubility in the presence of ethyl myristate.

The calculated value of the effective diffusion coefficient, $D$, of hexylresorcinol in the ointment base was estimated from the slope of the line in Fig. 5 to be $1.31 \times 10^{-8}$ cm²/sec. By using the values of $D$ and $C_s$, the release rates of hexylresorcinol as a function of ethyl myristate were calculated using Eq. 2. These data (Fig. 6) show that good agreement was obtained between the calculated and experimental values.

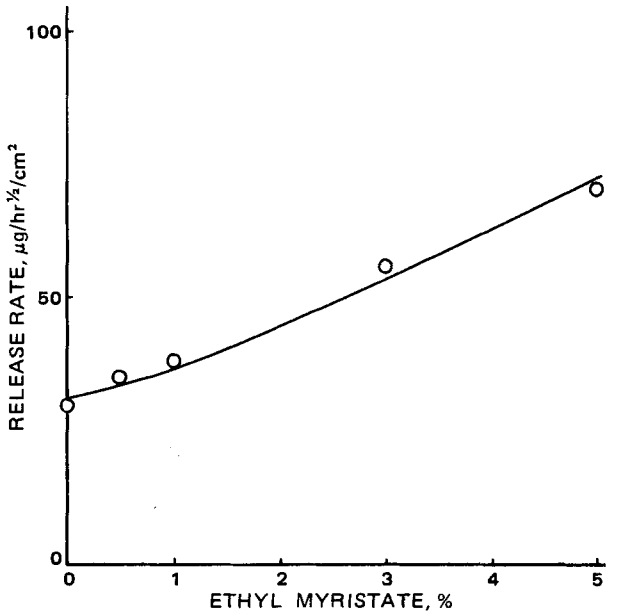

**Figure 6**—*Release rate of hexylresorcinol from ointment as a function of added ethyl myristate. Key:* ○, *experimental values; and* —, *calculated values.*

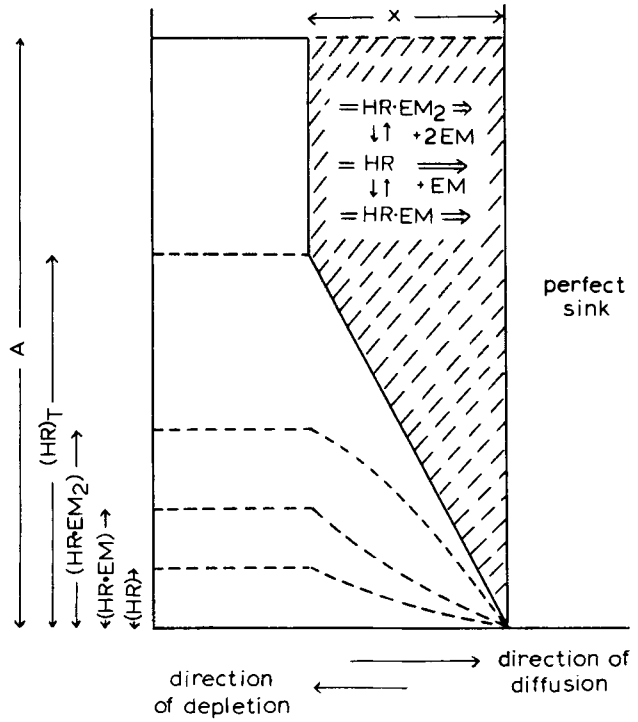

**Figure A1**—*Theoretical model describing the simultaneous release under sink conditions of HR, HR·EM, HR·EM$_2$, and (HR)$_T$ from petrolatum.*

## APPENDIX

In the diffusion layer, the following relationships are valid:

$$HR + EM \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} HR{\cdot}EM$$

*Scheme AI*

$$HR + EM_2 \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} HR{\cdot}EM_2$$

*Scheme AII*

where $k_1$, $k_{-1}$, $k_2$, and $k_{-2}$ are the rate constants for complexation. The combination of Fick's second law and reversible kinetic equations results in:

$$\frac{d(HR)}{dt} = D_1\frac{\partial^2(HR)}{\partial\chi^2} + k_{-1}(HR{\cdot}EM) + k_{-2}(HR{\cdot}EM_2) - k_1(HR)(EM) - k_2(HR)(EM)^2 \quad \text{(Eq. A1)}$$

$$\frac{d(HR{\cdot}EM)}{dt} = D_2\frac{\partial^2(HR{\cdot}EM)}{\partial\chi^2} + k_1(HR)(EM) - k_{-1}(HR{\cdot}EM) \quad \text{(Eq. A2)}$$

$$\frac{d(HR{\cdot}EM_2)}{dt} = D_3\frac{\partial^2(HR{\cdot}EM_2)}{\partial\chi^2} + k_2(HR)(EM)^2 - k_{-2}(HR{\cdot}EM_2) \quad \text{(Eq. A3)}$$

where $D_1$, $D_2$, and $D_3$ are the diffusion coefficients of HR, HR·EM, and HR·EM$_2$, respectively.

The mass balance equation for hexylresorcinol becomes:

$$(HR)_T = (HR) + (HR{\cdot}EM) + (HR{\cdot}EM_2) \quad \text{(Eq. A4)}$$

Differentiating with respect to time of Eq. A4 results in:

$$\frac{d(HR)_T}{dt} = \frac{d(HR)}{dt} + \frac{d(HR{\cdot}EM)}{dt} + \frac{d(HR{\cdot}EM_2)}{dt} \quad \text{(Eq. A5)}$$

The combination of Eqs. A1–A3 and A5 results in:

$$\frac{d(HR)_T}{dt} = D_1\frac{\partial^2(HR)}{\partial\chi^2} + D_2\frac{\partial^2(HR{\cdot}EM)}{\partial\chi^2} + D_3\frac{\partial^2(HR{\cdot}EM_2)}{\partial\chi^2} \quad \text{(Eq. A6)}$$

The diffusion coefficient of compounds is very insensitive to their molecular weights and only varies with $\sqrt[3]{1/\text{mol. wt.}}$. The molecular weights of hexylresorcinol, the 1:1 complex, and the 1:2 complex are 194, 440, and 716, respectively, and $\sqrt[3]{1/\text{mol. wt.}}$ values for the three compounds are 0.173, 0.131, and 0.112, respectively. Then $D_1 = D_2 = D_3 = D$, and Eq. A6 can be rewritten as:

$$\frac{d(HR)_T}{dt} = \frac{\partial^2(HR)_T}{\partial\chi^2} \quad \text{(Eq. A7)}$$

For such a system, the concentration profiles that may exist after the lapse of finite time can be drawn (Fig. A1).

As seen from Eqs. A1–A3 and A7 and Fig. A1, the concentration gradients of (HR), (HR·EM), and (HR·EM$_2$) do not give a straight line, but the concentration gradient of (HR)$_T$ gives a straight line and Eq. A8 can be used to calculate the release rate of hexylresorcinol in this system (1):

$$\text{release rate} = \sqrt{DC_s(2A - C_s)} \quad \text{(Eq. A8)}$$

# High-Pressure Liquid Chromatographic Determination of Ibuprofen in Plasma

**ANWER ALI, SYED KAZMI, and FOTIOS M. PLAKOGIANNIS** ˣ

Received April 17, 1980, from the *Division of Pharmaceutics and Industrial Sciences, Arnold & Marie Schwartz College of Pharmacy and Health Sciences, Long Island University, Brooklyn, NY 11201.* Accepted for publication October 1, 1980.

**Abstract** □ A sensitive, simple, and rapid method for the quantitation of ibuprofen in plasma, using 1-(*p*-fluorobenzoyl)-5-methoxy-2-methylindole acetic acid as the internal standard, was developed. The method is based on reversed-phase high-pressure liquid chromatography with a mobile phase containing acetonitrile–0.1 *M* acetic acid (55:45 v/v). The chromatographic elution time was 8.5 min, and ibuprofen quantities as low as 0.1 μg/ml can be assayed. The suitability of the method is demonstrated.

**Keyphrases** □ Ibuprofen—analysis, high-pressure liquid chromatography, plasma □ Anti-inflammatory agents—ibuprofen, high-pressure liquid chromatographic analysis, plasma □ High-pressure liquid chromatography—analysis, ibuprofen in plasma

Ibuprofen is a nonsteroidal anti-inflammatory, antipyretic, and analgesic drug (1, 2) indicated for the relief of signs and symptoms of rheumatoid arthritis, osteoarthritis, and mild to moderate pain.

Relatively few methods are available for the measurement of blood ibuprofen levels. A paper chromatographic method involving separation and subsequent reaction with bromcresol purple was reported (3) but requires ~48 hr for completion. GLC methods, requiring extraction of the drug from plasma and tedious and time-consuming derivatization steps, were also reported (4, 5).

Recently, the use of paired-ion, reversed-phase, high-pressure liquid chromatography (HPLC) for quantitative drug analysis was demonstrated (6, 7). This paper reports a simple, rapid, and highly sensitive HPLC method for ibuprofen determination in plasma.

## EXPERIMENTAL

**Chemicals and Reagents**—Ibuprofen[1] and 1-(*p*-fluorobenzoyl)-5-methoxy-2-methylindole acetic acid[2] were the reference and internal standards, respectively. Chromatographic grade acetonitrile[3] and acetic acid[4] were used for the mobile phase preparation. All other reagents were analytical grade or better and were used as received.

**Animals**—Adult, male New Zealand rabbits, 2–3 kg, were studied.

**Mobile Phase**—Acetonitrile–0.1 *M* acetic acid (55:45 v/v) was used.

**Internal Standard Solution**—Ten milligrams of the internal standard, accurately weighed, was dissolved in a 10-ml volumetric flask and diluted to volume with methanol; this solution (1 ml) was diluted to 20 ml with methanol and used as the internal standard.

**Standard Solution**—Accurately weighed ibuprofen (100 mg) was dissolved in, and diluted to volume with, methanol in a 100-ml volumetric flask.

**Plasma Level Study**—To demonstrate the applicability of the procedure to the determination of plasma ibuprofen levels from a bioavailability study, suppositories containing 150 mg of ibuprofen were administered rectally to three rabbits. Blood samples (~3 ml) were removed by cardiac puncture at 0, 0.25, 0.5, 0.75, 1, 1.5, 2, 3, 4, 5, and 24 hr. The samples were placed into microcentrifuge tubes and centrifuged to obtain the plasma fraction. Plasma aliquots (0.5 ml) were processed along with spiked plasma standards.

For standard curves, blood samples were removed from the heart of nonmedicated rabbits, placed in centrifuge tubes, and centrifuged to obtain the plasma fraction. Plasma aliquots (0.5 ml) were pipetted into microtest tubes and spiked with ibuprofen to yield a final drug concentration of 0.1–50 μg/ml of plasma. To each microtest tube was added 0.1 ml of the internal standard. The mixture was mixed, diluted to 2.0 ml with methanol, and filtered through an organic filter[5].

**HPLC**—Samples were chromatographed on a high-pressure liquid chromatograph[6] equipped with a universal liquid chromatographic in-

**Table I—Recovery of Ibuprofen from Spiked Plasma** [a]

| Amount Added, μg/ml | Ibuprofen Found, % | *SD*, % |

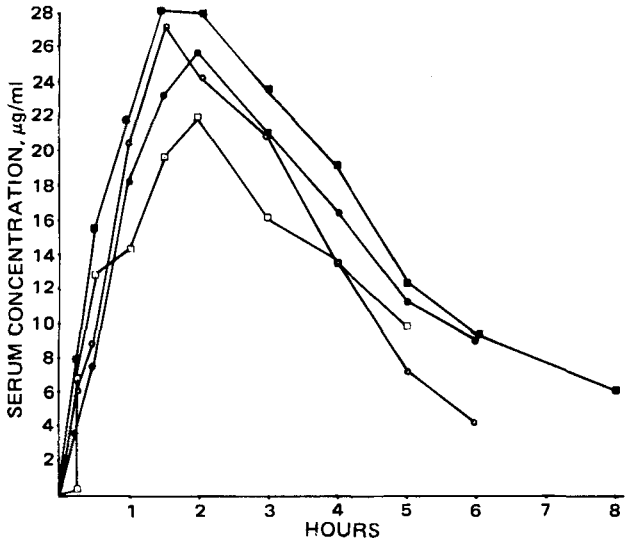

**Figure 2**—*Serum ibuprofen levels after administration of a 150-mg dose of a suppository of three different bases and one oral preparation. Key:* □, *theobroma oil;* ○, *polyethylene glycol 1540;* ●, *fatty acids; and* ■, *suspension.*

jector[5], a UV (254 nm) absorbance detector, and a strip-chart recorder. The deproteinated plasma samples were chromatographed at room temperature on a microparticulate ($\mu$Bondapak $C_{18}$) reversed-phase HPLC column (4 mm × 30 cm) with an eluting mobile phase of acetonitrile—0.1 *M* acetic acid (55:45 v/v). The flow rate was adjusted to 1 ml/min with an inlet pressure of ~1500 psi. The chart speed was 0.2 cm/min. The ratio of the peak height of ibuprofen to that of the internal standard was used to calculate the ibuprofen concentration, based on a calibration curve prepared from spiked plasma samples.

**Calculations**—Peak height ratios were obtained by dividing the peak height of ibuprofen by the peak height of the internal standard. Calibration curves from known ibuprofen concentrations in plasma were prepared by plotting the peak height ratios *versus* the ibuprofen concentration, expressed as micrograms per milliliter of plasma. Values of unknown concentrations of ibuprofen in plasma samples were read directly from the graph.

## RESULTS AND DISCUSSION

Typical chromatograms of blank rabbit plasma (A), blank rabbit plasma spiked with ibuprofen (B), blank rabbit plasma spiked with ibuprofen and internal standard (C), and plasma collected 60 min after administration of 150 mg of ibuprofen in a suppository or oral preparation and spiked with the internal standard (D) are shown in Fig. 1. Ibuprofen and the internal standard were well resolved and eluted with retention times of 8.5 and 5.5 min, respectively. No interference from metabolites was detected under these experimental conditions.

Table I illustrates recoveries of ibuprofen from plasma spiked with 0.1–50 $\mu$g/ml. The standard curve is the average of five determinations; the regression line slope was calculated to be 0.128 with a standard correlation matrix of 0.999, indicating excellent linearity.

The plasma ibuprofen time courses for four rabbits in a bioavailability study are shown in Fig. 2. The *AUC* values for the four formulations were 89.77, 74.38, 96.5, and 128.94 $\mu$g/ml/hr for 150 mg of ibuprofen in polyethylene glycol 1540, theobroma oil, esterified fatty acids ($C_{10}$–$C_{18}$)[7], and an oral suspension, respectively.

# Binding of Prostaglandins $E_1$ (Alprostadil), $E_2$ (Dinoprostone), $F_{1\alpha}$, and $F_{2\alpha}$ (Dinoprost) to Human Serum Proteins

**JOSEPH JUDIS**

Received October 20, 1978, from the *College of Pharmacy, University of Toledo, Toledo, OH 43606.* Accepted for publication January 13, 1981.

**Abstract** □ Prostaglandins $E_1$ (alprostadil), $E_2$ (dinoprostone), $F_{1\alpha}$, and $F_{2\alpha}$ (dinoprost) were characterized in terms of binding to human serum, albumin, γ-globulin II, β-globulin III, α-globulin IV-1, and α-globulin IV-4. By using equilibrium dialysis and tritium-labeled ligands, the percent binding for all four ligands was found to decrease in the following order: human serum, albumin, and α-globulin IV-4. For the other three proteins, the order was not consistent with the four ligands, and <10% binding was observed. In general, prostaglandins $E_1$ and $E_2$ showed a higher percent binding for all fractions than prostaglandins $F_{1\alpha}$ and $F_{2\alpha}$. All four ligands can be characterized as showing significant binding to human serum, albumin, and α-globulin IV-4.

**Keyphrases** □ Prostaglandins—binding to human serum proteins, equilibrium dialysis of radiolabeled prostaglandins □ Protein binding—prostaglandins $E_1$ (alprostadil), $E_2$ (dinoprostone), $F_{1\alpha}$, and $F_{2\alpha}$ (dinoprost) to human serum proteins, equilibrium dialysis of radiolabeled prostaglandins □ Binding, protein—binding of prostaglandins $E_1$ (alprostadil), $E_2$ (dinoprostone), $F_{1\alpha}$, and $F_{2\alpha}$ (dinoprost) to human serum proteins, equilibrium dialysis of radiolabeled prostaglandins □ Equilibrium dialysis—of radiolabeled prostaglandins $E_1$ (alprostadil), $E_2$ (dinoprostone), $F_{1\alpha}$, and $F_{2\alpha}$ (dinoprost) bound to human serum proteins

Since the discovery and description of the prostaglandins, a vast literature has evolved concerning their physiological and pharmacological actions (1). As circulating hormones, these compounds have different rates of disappearance from the circulation after injection. Presumably, the differences reflect differences in metabolic degradation rates (2, 3). The availability of a compound for metabolic degradation could be related to whether or not

In general, prostaglandins $E_1$ and $E_2$ showed a higher percent binding for all fractions than prostaglandins $F_{1\alpha}$ and $F_{2\alpha}$. All four ligands can be characterized as showing significant binding to human serum, albumin, and α-globulin IV-4.

**Keyphrases** □ Prostaglandins—binding to human serum proteins, equilibrium dialysis of radiolabeled prostaglandins □ Protein binding—prostaglandins $E_1$ (alprostadil), $E_2$ (dinoprostone), $F_{1\alpha}$, and $F_{2\alpha}$ (dinoprost) to human serum proteins, equilibrium dialysis of radiolabeled prostaglandins □ Binding, protein—binding of prostaglandins $E_1$ (alprostadil), $E_2$ (dinoprostone), $F_{1\alpha}$, and $F_{2\alpha}$ (dinoprost) to human serum proteins, equilibrium dialysis of radiolabeled prostaglandins □ Equilibrium dialysis—of radiolabeled prostaglandins $E_1$ (alprostadil), $E_2$ (dinoprostone), $F_{1\alpha}$, and $F_{2\alpha}$ (dinoprost) bound to human serum proteins

Since the discovery and description of the prostaglandins, a vast literature has evolved concerning their physiological and pharmacological actions (1). As circulating hormones, these compounds have different rates of disappearance from the circulation after injection. Presumably, the differences reflect differences in metabolic degradation rates (2, 3). The availability of a compound for metabolic degradation could be related to whether or not

Table I—Binding of [$^3$H]Prostaglandins $E_1$, $E_2$, $F_{1\alpha}$, and $F_{2\alpha}$ to Human Serum Proteins [a]

| Serum Protein | | Percent of Prostaglandin Bound [b] | | | |
|---|---|---|---|---|---|
| Fraction | Concentration, mg/ml | $E_1$ | $E_2$ | $F_{1\alpha}$ | $F_{2\alpha}$ |
| Albumin | 40.0 | 81.40 (0.39) | 71.00 (2.57) | 63.3 (1.48) | 42.4 (0.92) |
| $\alpha$-Globulin IV-1 | 1.0 | 12.5 (0.46) | 8.96 (0.92) | 6.86 (0.29) | 5.13 (0.52) |
| $\alpha$-Globulin IV-4 | 5.0 | 55.00 (0.59) | 26.90 (0.58) | 31.0 (0.52) | 24.10 (2.12) |
| $\beta$-Globulin III | 7.0 | 5.04 (0.21) | 9.13 (0.64) | 3.17 (0.32) | 2.92 (0.15) |
| $\gamma$-Globulin II | 11.0 | 6.17 (0.43) | 7.12 (0.38) | 1.67 (0.12) | 0 |
| Human serum | — | 92.60 (0.09) | 80.10 (0.47) | 76.4 (2.56) | 70.9 (1.29) |

[a] Each system contained a total, in moles, of the following: prostaglandin $E_1$, $2.823 \times 10^{-8}$; prostaglandin $E_2$, $2.84 \times 10^{-8}$; prostaglandin $F_{1\alpha}$, $2.82 \times 10^{-8}$; and prostaglandin $F_{2\alpha}$, $2.83 \times 10^{-8}$. [b] Values in parentheses are standard deviations. Data were obtained using equilibrium dialysis method.

the compound is bound to a serum protein and the tightness of the binding (4). Prostaglandins bind to human plasma proteins, and some bind specifically to human serum albumin (2, 5–8).

Interest in serum protein binding capabilities of prostaglandins has centered on the quantitative analytical techniques in which prostaglandin must be quantitatively extractable from serum (8) and on factors involved in their physicochemical state as circulating hormones (2); knowledge of the latter is basic to the investigation of the pharmacological and pharmacokinetic properties of prostaglandins. Therefore, the percent binding of prostaglandins $E_1$ (alprostadil), $E_2$ (dinoprostone), $F_{1\alpha}$, and $F_{2\alpha}$ (dinoprost) to human serum proteins was examined.

## EXPERIMENTAL

**Methods**—Protein binding was measured using a previously described technique (9). Equilibrium dialysis was used to determine whether binding occurred between a ligand and a specific protein and the percent of ligand bound to the protein. Values reported are the averages of at least three replicates. This concentration range was selected to approximate the range of higher concentrations of prostaglandin $E_1$ used by Unger (8) in albumin binding studies. Radioactivity was determined in a liquid scintillation system[1].

**Materials**—[5,6-$^3$H(N)]Prostaglandin $E_1$[2], [5,6,8,11,12,14,15-$^3$H(N)]prostaglandin $E_2$[2], [5,6-$^3$H(N)]prostaglandin $F_{1\alpha}$[3], and [9-$^3$H]-prostaglandin $F_{2\alpha}$[3] had specific activities of 89.5, 117, 40, and 15 Ci/mmole, respectively. Crystalline human serum albumin and other human serum proteins were used as received[4]. A xylene-based phosphor solution[5] was used in all radioactivity determinations, and all other chemicals were reagent grade. Radiopurity was rechecked prior to use utilizing the methods indicated by the suppliers. A radiopurity of 99% was the minimum acceptable.

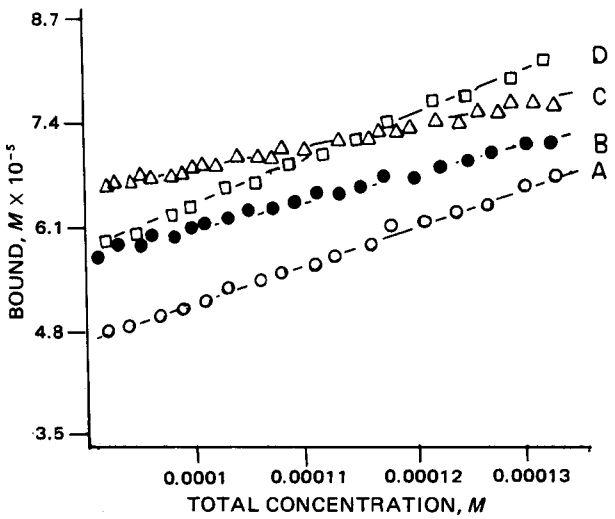

**Figure 1**—*Total concentration of ligand in the system* versus *bound concentration. Albumin concentration was 5.797 × $10^{-4}$ mole (40 mg/ml). Key: A, prostaglandin $F_{2\alpha}$; B, prostaglandin $F_{1\alpha}$; C, prostaglandin $E_1$; and D, prostaglandin $E_2$.*

## RESULTS AND DISCUSSION

The extent to which each prostaglandin was bound to whole human serum and several human serum proteins or fractions is tabulated in Table I. All four prostaglandins were bound to a significant extent (>70% binding) to whole human serum, and prostaglandins $E_1$ and $E_2$ were bound to a higher percentage than prostaglandins $F_{1\alpha}$ and $F_{2\alpha}$. This finding is in agreement with previous studies (5, 6) in which the affinity of prostaglandins for serum proteins decreased with an increase in the number of polar groups in the prostaglandin molecule.

The serum protein to which binding was greatest for all four compounds was albumin. All prostaglandins showed the next highest affinity for $\alpha$-globulin IV-4 and a relatively low affinity for the other serum protein fractions. $\alpha$-Globulin IV-4 contains corticosteroid binding globulin (10); although the latter protein cannot necessarily be implicated in the binding of prostaglandins to $\alpha$-globulin IV-4, the nonpolar nature of corticosteroids and prostaglandins suggests its possible involvement. Evidence for a prostaglandin $A_1$ binding protein in human plasma other than albumin has been presented (11).

There was a significant difference in the affinity of the E prostaglandins for human serum albumin compared to the F prostaglandins. With all four prostaglandins, the concentration of bound ligand increased in relation to the total ligand concentration in the system (Fig. 1).

Under the study conditions, prostaglandin instability was not a factor as demonstrated by Karim *et al.* (12). Membrane binding was determined in all experiments and was uniformly <5%. At least 95% of the counts per minute added could always be accounted for in the sum of the counts per minute in both sides of an equilibrium cell, indicating no significant binding to the plexiglass.

# Hepatic First-Pass Effect of Thiazinamium Methylsulfate (*N*-Methylpromethazine Methylsulfate) in Dogs

**JAN H. G. JONKMAN** *‡x, **HERMAN G. M. WESTENBERG** *§, and **EPPO VAN DER KLEYN** ¶

Received July 16, 1980, from the *Department of Pharmaceutical and Analytical Chemistry, State University of Groningen, Antonius Deusinglaan 2, 9713 AW Groningen, The Netherlands, the ‡Laboratory for Drug Analysis, Assen, The Netherlands, the §Department of Psychiatry, Academic Hospital, Utrecht, The Netherlands, and the ¶Department of Clinical Pharmacy, St. Radboud Hospital, University of Nijmegen, Nijmegen, The Netherlands. Accepted for publication January 26, 1981.

**Abstract** □ Plasma concentration–time curves are described for the intravenous infusion and portal vein infusion of the quaternary ammonium compound thiazinamium methylsulfate to dogs. Comparison of areas under the curve indicate that hepatic first-pass elimination occurred on the order of 25–50%.

**Keyphrases** □ Thiazinamium methylsulfate—hepatic first-pass effect in dogs, plasma concentration–time curves □ *N*-Methylpromethazine methylsulfate—hepatic first-pass effect in dogs, plasma concentration–time curves □ First-pass effect—thiazinamium methylsulfate, dogs, plasma concentration–time curves

Numerous drugs representing several therapeutic groups and chemical classes have been reported to be subject to either intestinal first-pass effect or hepatic first-pass effect (1–4). However, no evidence could be obtained from the literature concerning this phenomenon for quaternary ammonium compounds.

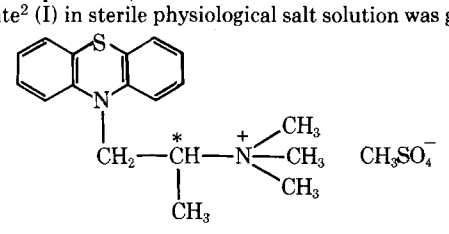
Recently, clinical pharmacokinetic studies on thiazinamium methylsulfate (*N*-methylpromethazine methylsulfate, I), a phenothiazine derivative containing a quaternary ammonium group, were reported (5–7). The drug has anticholinergic and antihistaminic properties and is used as a bronchodilator in patients suffering from generalized chronic obstructive lung diseases.

Absorption of the drug after oral administration was low (~10% of the dose), and considerable inter- and intrasubject variations in bioavailability were found. Such variations are often explained by the hepatic first-pass effect (8). The extent of a hepatic first-pass effect is often related to hepatic clearance (9). Since I is cleared largely by the liver (10), it was decided to investigate whether the hepatic first-pass effect also contributes to its incomplete bioavailability in the dog.

## EXPERIMENTAL

Dogs (Table I) were anesthetized by intravenous injection of pentobarbital sodium (30 mg/kg). Anesthesia was maintained by inhalation of oxygen, nitrous oxide, and halothane[1]. Each dog was used in two experiments with an interval of ~2 weeks.

In the first experiment, a slow continuous infusion of thiazinamium methylsulfate[2] (I) in sterile physiological salt solution was given in the vena cephalica antebrachii sinister for 100 min by pump (20 ml/hr). The dose rate was 1 mg/kg/hr. During and after the infusion, blood samples (~6 ml) were taken from the vena saphena parva dexter by a permanent cannula[3] at the time intervals indicated in Fig. 1.



I

In the second experiment, the same procedure was repeated but the infusion was given in the vena porta (portal vein). The abdomen was opened, and a cannula was inserted *via* a side branch.

Plasma concentrations were determined by ion-pair extraction, followed by GLC separation and alkali flame-ionization detection (11).

The area under the plasma concentration–time curve (*AUC*) was measured by cutting and weighing a standard high-quality paper. The absolute bioavailability was calculated by dividing the *AUC* after portal vein infusion by the *AUC* after the intravenous infusion and was expressed as a percentage.

The pharmacokinetic parameters were calculated using the NONLIN program (12). A three-compartment body model was used, with zero-order input in the central compartment and final elimination from this compartment. The initial estimates of the parameters were determined graphically. Examination of the plot of the weighted residuals against time indicated that a weighting factor of $W = 1/\sqrt{y_i}$ resulted in the best fit.

**Table I—Data for the Four Dogs Used in the Experiment with Linear Infusion of I in the Portal Vein**

| Parameter | Dog 268 | Dog 343 | Dog 367 | Dog 515 |
|---|---|---|---|---|
| Breed | Labrador | Dalmatian | Labrador | Labrador |
| Sex | Female | Male | Female | Male |
| Weight, kg | 22 | 26 | 19 | 24 |
| Dose, mg/kg/hr | 1 | 1 | 1 | 1 |
| $F_{abs}$[a], % | 72.0 | 78.0 | 51.0 | 51.7 |

[a] Absolute bioavailability is expressed as a percentage of the dose.

## RESULTS AND DISCUSSION

The hepatic elimination of thiazinamium methylsulfate (I) during the first passage through the liver was investigated by determining the absolute bioavailability obtained after infusion of a drug-containing solution in the portal vein. In this way, the intestinal first-pass effect and the observed irregular and incomplete absorption were avoided. After intravenous infusion, plasma concentrations of ~600 ng/ml were obtained. After the infusion was stopped, plasma concentrations fell steeply (Fig. 1). The $(t_{1/2})_\alpha$ was estimated to be ~1 min, and the $(t_{1/2})_\beta$ was ~5–10 min; $(t_{1/2})_\gamma$, the elimination half-life, was ~6–7 hr. These figures should be considered as estimations because of the very steep decrease in plasma concentrations immediately after the infusion was stopped and the very low concentrations during the final elimination phase.

Studies in rats (10) indicated that the extremely rapid disappearance of the drug from the plasma was mainly due to both fast biliary elimination of the unchanged drug (3.8% of the dose) and rapid biotransformation to thiazinamium sulfoxide, which also can be excreted rapidly in the bile (16.1% of the dose). Two other metabolites also were excreted in bile (13.1 and 2.7% of the dose).

A substantial part of the dose in humans also was excreted in the bile [16.6% unchanged and 6.9% as the sulfoxide (13)].

After infusion in the portal vein, the plasma concentration–time curve rose somewhat slower than in the intravenous infusion. In Dogs 343 and 367, the plasma concentration–time curves reached a plateau level of

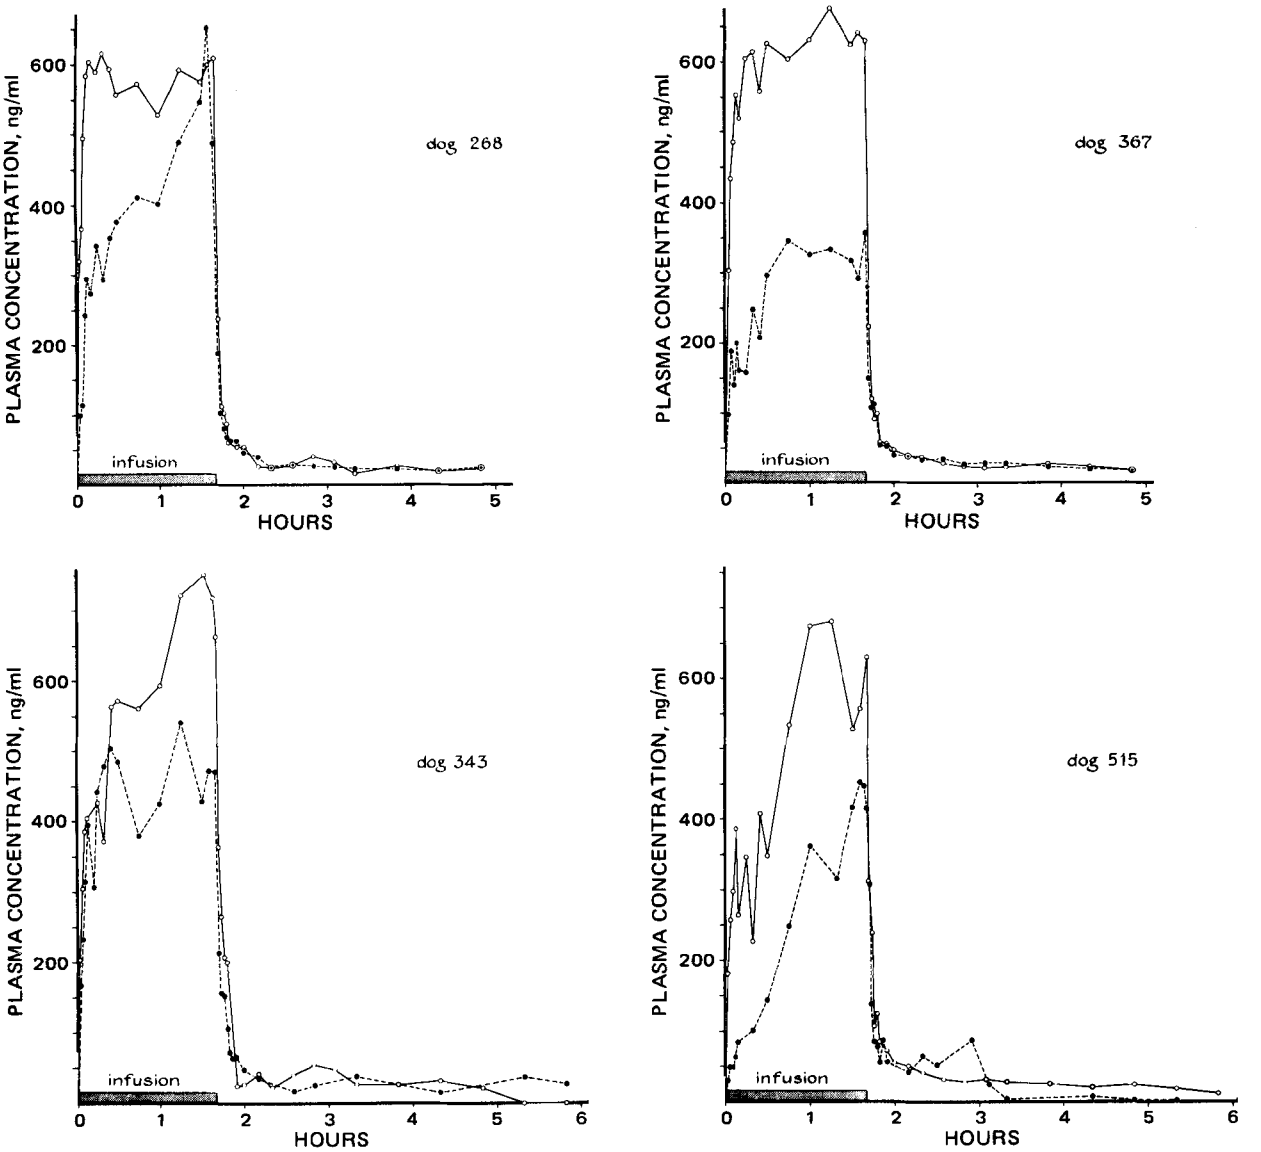

**Figure 1**—*Plasma concentrations in dogs during and after the infusion (1 mg/kg/hr) of I. Key: o—, intravenous infusion; and ●– –, infusion in portal vein.*

~300–400 ng/ml. The phenomenon can be explained by assuming that a substantial part of the drug offered to the liver by portal blood flow is extracted by this organ before the drug can enter the general circulation.

For Dogs 268 and 515, the curve was still going up at the end of the infusion time, suggesting that the biotransformation and/or elimination processes in the liver became saturated and were no longer able to remove the drug from the portal vein to the same extent as before.

The calculated absolute bioavailability ($F_{abs}$) after infusion in the portal vein varied from 51.0 to 78.0% (mean 63.2 ± 13.9 *SD*%), indicating a hepatic first-pass effect that removed 22.0–49.0% (mean 37.8 ± 14.9 *SD*%) of the dose before entering the general circulation.

Oguma *et al.* (14) found that, when valethamate bromide or scopolamine-*N*-butyl bromide (both quaternary ammonium compounds) was infused in the portal vein in the rat, biliary excretion was more pronounced than when infusion was given in a femoral vein. This result is an indirect indication of a hepatic first-pass effect. Gibaldi *et al.* (15) studied the metabolism of *N*,*N*-bis(phenylcarbamoylmethyl)dimethylammonium chloride, a quaternized lidocaine derivative, after intravenous and intraperitoneal administration and found that, during passage of drug through the liver after intraperitoneal administration, a fraction of the dose was irreversibly lost by metabolic conversion and subsequent biliary excretion (hepatic first-pass effect).

The results of this study on I are comparable with the observations of Taylor *et al.* (16) on the tertiary analog promethazine in rabbits. They reported a systemic availability of 59 ± 19% after promethazine injection into the portal vein. Although a different species is involved, the indication is that both the tertiary and the quaternary compound can be subjected extensively to a hepatic first-pass effect.

The results of the present study indicate that the low and variable bioavailability of an oral dose of I can be explained in part by an extensive hepatic first-pass effect.

# High-Performance Liquid Chromatographic Analysis of Triamterene and *p*-Hydroxytriamterene in Plasma

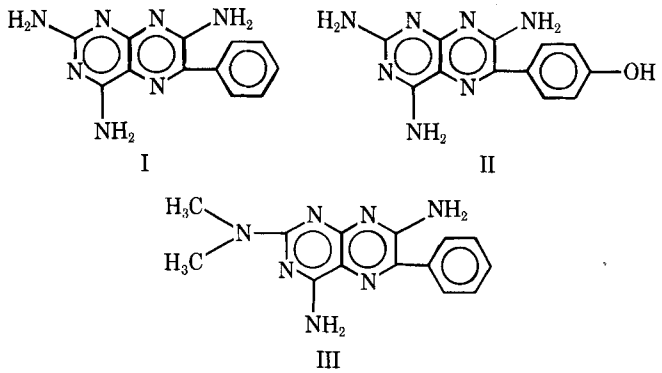
**GERALD J. YAKATAN *x and JOSEF E. CRUZ**

Received September 24, 1980, from the *Drug Dynamics Institute, College of Pharmacy, University of Texas at Austin, Austin, TX 78712.* Accepted for publication January 23, 1981. *Present address: Pharmaceutical Research Division, Warner-Lambert Company, Ann Arbor, MI 48105.

**Abstract** □ A rapid and sensitive high-performance liquid chromatographic assay was developed for triamterene and 6-*p*-hydroxytriamterene in plasma. Plasma (0.5 ml), after addition of the internal standard, was extracted with 10 ml of ether–isopropanol (95:5). After thorough mixing and separation of phases, the organic layer was evaporated to dryness under nitrogen. The residue was reconstituted with 500 μl of mobile phase [acetonitrile–water–acetic acid (60:39.5:0.5)], and 100 μl was injected into the chromatograph. Chromatographic separation was carried out on a $C_{18}$ μBondapak column at a flow rate of 1 ml/min. Detection of compounds in the column eluent was by UV absorption at 365 nm. The retention times for 6-*p*-hydroxytriamterene, triamterene, and the internal standard were 7.5, 9.0, and 12.0 min, respectively. The lower limit of detection for each compound was 20 ng/ml. Recoveries of triamterene and 6-*p*-hydroxytriamterene were 91–99 and 82–95%, respectively, over a 40–240-ng/ml range.

**Keyphrases** □ Triamterene—high-performance liquid chromatographic analysis, plasma □ *p*-Hydroxytriamterene—high-performance liquid chromatographic analysis, plasma □ Diuretics—high-performance liquid chromatographic analysis of triamterene and *p*-hydroxytriamterene, plasma □ High-performance liquid chromatographic analysis—triamterene and *p*-hydroxytriamterene, plasma

Triamterene, 2,4,7-triamino-6-phenylpteridine (I), is a natriuretic and a potassium-sparing diuretic. It is used mainly in combination with hydrochlorothiazide in the treatment of edema associated with congestive heart failure, cirrhosis of the liver, and the nephrotic syndrome.



I

II

III

## BACKGROUND

Studies of plasma and urine concentrations of triamterene and its major metabolite, 2,4,7-triamino-6-*p*-hydroxyphenylpteridine (II), in humans and animals have been performed either with nonspecific fluorescence methods or more specific methods that require time-consuming and involved separation procedures (1–5). The separation techniques utilized have included paper chromatography (4), TLC (5), and liquid–liquid extraction (2, 6). One method (5) detected nanogram levels of the compounds, but the other methods lacked the sensitivity to measure nanogram concentrations of triamterene in plasma. A sensitive and specific assay is particularly desirable for study of triamterene pharmacokinetics since concentrations of the metabolite may be 10-fold those of the parent compound 30 min following oral administration (2).

Recently, two high-performance liquid chromatographic (HPLC) assays for triamterene in plasma were reported. One method (7) involved extraction of triamterene as its perchlorate ion-pair and subsequent normal-phase HPLC utilizing a fluorescence detector. Triamterene concentrations as low as 2 ng/ml could be detected, although the investigators did not employ an internal standard. The other method (8) involved extraction with ethyl acetate and subsequent reversed-phase HPLC with fluorescence detection; it had a sensitivity to 1 ng/ml. Neither research group attempted to quantitate metabolites.

This article describes a rapid, sensitive, and selective assay for triamterene and its major metabolite in plasma. The method involves a simple extraction of plasma with organic solvent and reversed-phase HPLC of the extract using UV detection.

## EXPERIMENTAL

**Reagents**—Acetonitrile[1] and methanol[1] were chromatography grade. Anhydrous ether[2], acetic acid[2], and isopropanol[2] were spectranalytical grade.

**Equipment**—A high-performance liquid chromatograph[3] with a syringe-loading sample injector[4], a recorder[5], and a variable-wavelength

One method (7) involved extraction of triamterene as its perchlorate ion-pair and subsequent normal-phase HPLC utilizing a fluorescence detector. Triamterene concentrations as low as 2 ng/ml could be detected, although the investigators did not employ an internal standard. The other method (8) involved extraction with ethyl acetate and subsequent reversed-phase HPLC with fluorescence detection; it had a sensitivity to 1 ng/ml. Neither research group attempted to quantitate metabolites.

This article describes a rapid, sensitive, and selective assay for triamterene and its major metabolite in plasma. The method involves a simple extraction of plasma with organic solvent and reversed-phase HPLC of the extract using UV detection.

## EXPERIMENTAL

**Reagents**—Acetonitrile[1] and methanol[1] were chromatography grade. Anhydrous ether[2], acetic acid[2], and isopropanol[2] were spectranalytical grade.

**Equipment**—A high-performance liquid chromatograph[3] with a syringe-loading sample injector[4], a recorder[5], and a variable-wavelength

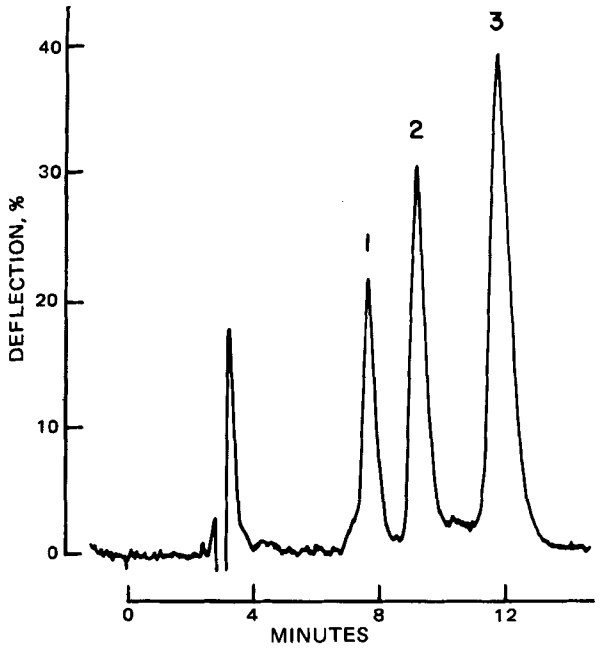

**Figure 1**—*Chromatogram of the extract of 0.5 ml of plasma containing 100 ng/ml each of 6-p-hydroxytriamterene (1) and triamterene (2) and 200 ng/ml of the internal standard (3). The extract was reconstituted with 500 μl of mobile phase, and 100 μl was injected.*

UV detector[6] were used. Chromatography was done on a μBondapak $C_{18}$ column[7].

**Assay Standards**—Stock methanol solutions of triamterene[8] (1 mg/100 ml), 6-*p*-hydroxytriamterene[9] (1 mg/100 ml), and the internal standard[8], 4,7-diamino-2-dimethylamino-6-phenylpteridine (1 mg/100 ml), were prepared and stored in light-resistant flasks to prevent photodecomposition. Plasma standards were prepared by adding appropriate amounts of methanol stock solutions to drug-free plasma to give final concentrations of 40–240 ng/ml of triamterene and 6-*p*-hydroxytriamterene and 200 ng/ml of the internal standard.

**Extraction**—To 0.5 ml of plasma in a silylated tube, 10 ml of anhydrous ether–isopropanol (95:5) was added. The tube contents were mixed with gentle agitation in an aliquot mixer[10] for 10 min and then centrifuged[11] for 20 min at 1300×*g* to separate the phases. The ether–isopropanol layer (top layer) was transferred to a sample concentrator[12] with a disposable Pasteur pipet and evaporated to dryness under nitrogen at ambient temperature. The dried extract was reconstituted with 500 μl of mobile phase, and 100 μl was injected into the chromatograph.

**Chromatography**—All chromatography was done at ambient temperature. The mobile phase was acetonitrile–distilled water–acetic acid (60:39.5:0.5). Prior to use, the mobile phase was filtered through a 10-μm polypropylene filter[13]. The flow rate was set at 1 ml/min, and the UV detector was set at 365 nm. The $\lambda_{max}$ values for triamterene, 6-*p*-hydroxytriamterene, and 4,7-diamino-2-dimethylamino-6-phenylpteridine were 365, 368, and 380 nm, respectively. The recorder was run at a chart speed of 0.635 cm/min.

**Quantitation**—Peak height ratios of triamterene or 6-*p*-hydroxytriamterene to the internal standard were obtained from the chromatograms and plotted against concentration or amount of drug to obtain calibration curves for each compound.

## RESULTS AND DISCUSSION

6-*p*-Hydroxytriamterene, triamterene, and the internal standard were separated and eluted in ~12 min; the retention times were 7.5, 9.0, and 12.0 min, respectively (Fig. 1). Extracts from blank plasma gave no interference from endogenous plasma components.

**Table I—Reproducibility of HPLC Assay of Triamterene and *p*-Hydroxytriamterene in Plasma**

| Concentration, ng/ml | Mean Peak Height Ratio | Mean Peak Height Ratio / Concentration | *RSD*, % |
|---|---|---|---|
| | Triamterene ($n$ = 5) | | |
| 40 | 0.1413 | 0.0035 | 6.44 |
| 80 | 0.2914 | 0.0036 | 8.44 |
| 120 | 0.4071 | 0.0034 | 7.30 |
| 200 | 0.6175 | 0.0031 | 7.37 |
| 240 | 0.8044 | 0.0034 | 2.86 |
| | 6-*p*-Hydroxytriamterene ($n$ = 4) | | |
| 40 | 0.0972 | 0.0024 | 18.88 |
| 80 | 0.2124 | 0.0026 | 5.84 |
| 120 | 0.2902 | 0.0024 | 4.56 |
| 200 | 0.4539 | 0.0023 | 7.45 |
| 240 | 0.5895 | 0.0025 | 5.45 |

Standard curves for both triamterene and 6-*p*-hydroxytriamterene were linear over the 40–240-ng/ml range. At least 20 ng/ml of each component could be detected when the dried plasma extract was reconstituted with 100 μl of mobile phase and most of the extract was injected into the chromatograph. The least-squares linear regression curves did not go through the origin, but the mean $y$ intercepts were not significantly different from zero (0.0099 for 6-*p*-hydroxytriamterene and 0.0235 for triamterene). Table I shows standard curve reproducibility for both triamterene and 6-*p*-hydroxytriamterene from analyses of plasma standards done on different days. By using the equations obtained from linear regression analyses of the data, triamterene and 6-*p*-hydroxytriamterene concentrations were calculated for each observed peak height ratio. The relative standard deviations were between 2 and 9% for both compounds with the exception of the metabolite at the 40-ng/ml level.

Recoveries of triamterene and 6-*p*-hydroxytriamterene from plasma extractions were assessed by comparing the peak height ratios of spiked plasma extracts with those of standard methanol solutions. The recoveries ranged from 82 to 95% for the metabolite and from 91 to 99% for triamterene over the concentration range studied.

4,7-Diamino-2-dimethylamino-6-phenylpteridine was chosen as the internal standard because it exhibited similar chromatographic behavior to triamterene. It eluted near the triamterene peak but was completely separated from triamterene and 6-*p*-hydroxytriamterene. Its retention time did not add significantly to the total analysis time, and its recovery from plasma by extraction was quantitative. This internal standard probably would not be present in the plasma of patients treated with triamterene and will not alter assay specificity.

The described HPLC procedure was developed to study triamterene and 6-*p*-hydroxytriamterene pharmacokinetics in dogs and humans. Unlike recently published procedures (7, 8), this assay quantitates both triamterene and the metabolite after direct extraction of plasma samples with organic solvent. Its simplicity and the short assay time are advantageous in the analyses of the large number of samples often encountered in pharmacokinetic and bioavailability studies. The small plasma volume needed for analysis is also an important consideration in such studies. These factors, coupled with the sensitivity and selectivity of the procedure, should provide an excellent technique for the study of the pharmacokinetics of triamterene and 6-*p*-hydroxytriamterene.

The assay described is not as sensitive as the recently published procedures (7, 8) since the UV absorption of the compounds is determined. An increase in sensitivity is expected by using fluorescence determination, and preliminary data suggest that the detection limit can be lowered to 1 ng/ml for each compound should such sensitivity be required.

Triamterene is often administered in combination with hydrochlorothiazide and other antihypertensives. The potential interference of these drugs was not evaluated since the procedure was developed to study the pharmacokinetics of triamterene and 6-*p*-hydroxytriamterene in dogs and humans not on antihypertensive therapy. However, the monitored UV wavelength is in a region that precludes interferences from the thiazides and many other compounds in the unlikely event that compounds of such widely differing structures are not adequately separated in the system described.

# Antimicrobial Activity of Phenolic Constituents of *Magnolia grandiflora* L.

**ALICE M. CLARK ˣ, FAROUK S. EL-FERALY, and WEN-SHYONG LI ***

Received December 8, 1980, from the *Department of Pharmacognosy, School of Pharmacy, University of Mississippi, University, MS 38677.* Accepted for publication January 14, 1981. *Present address: Taiwan Provincial Pingtung Institute of Agriculture, Pingtung, Taiwan, Republic of China.

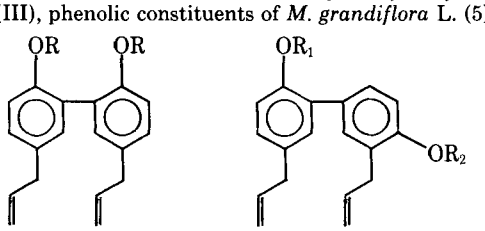
**Abstract** □ Three phenolic constituents of *Magnolia grandiflora* L. were shown to possess significant antimicrobial activity using an agar well diffusion assay. Magnolol, honokiol, and 3,5′-diallyl-2′-hydroxy-4-methoxybiphenyl exhibited significant activity against Gram-positive and acid-fast bacteria and fungi. The minimum inhibitory concentrations were determined for each compound using a twofold serial dilution assay.

**Keyphrases** □ *Magnolia grandiflora* L.—antimicrobial activity of phenolic constituents, agar well diffusion assay □ Magnolol—phenolic constituent of *Magnolia grandiflora* L., antimicrobial activity □ Honokiol—phenolic constituent of *Magnolia grandiflora* L., antimicrobial activity □ 3,5′-Diallyl-2′-hydroxy-4-methoxybiphenyl—phenolic constituent of *Magnolia grandiflora* L., antimicrobial activity □ Antimicrobial activity—phenolic constituents of *Magnolia grandiflora* L., agar well diffusion assay

The search for new antibiotics is no longer restricted primarily to microbial products. Recently, constituents of higher plants have exhibited significant antimicrobial activity (1–4). The isolation and identification of magnolol (I), honokiol (II), and 3,5′-diallyl-2′-hydroxy-4-methoxybiphenyl (III) as phenolic constituents of the seeds of *Magnolia grandiflora* L. were reported (5). All three compounds have significant antifungal and antibacterial activity, and the details of this antimicrobial activity are described here.

## RESULTS AND DISCUSSION

Magnolol (I), honokiol (II), and 3,5′-diallyl-2′-hydroxy-4-methoxybiphenyl (III), phenolic constituents of *M. grandiflora* L. (5), showed significant antimicrobial activity against Gram-positive bacteria, an acid-fast bacterium, and yeast-like and filamentous fungi. All three compounds were tested qualitatively for activity using an agar well diffusion assay (Table I). The corresponding dimethyl ethers, IV and V, showed no significant activity.



I: R = H
IV: R = $CH_3$

II: $R_1 = R_2 = H$
III: $R_1 = H$, $R_2 = CH_3$
V: $R_1 = R_2 = CH_3$

Streptomycin sulfate and amphotericin B also were tested to serve as standards for comparison. All three compounds (I–III) had activity comparable to the standards under the same test conditions.

The minimum inhibitory concentration (MIC) of each active compound was determined using a twofold serial dilution assay (Table II). All three compounds apparently were considerably more active than amphotericin B against *Trichophyton mentagrophytes* but not as active against *Candida albicans* and *Saccharomyces cerevisiae*. Methylation of one phenolic group of II to give III resulted in the loss of activity against *Aspergillus niger* and *C. albicans* but not against other fungi or bacteria. In fact, III was somewhat more active against *Staphylococcus aureus*, *Bacillus subtilis*, and *Mycobacterium smegmatis* than the dihydroxy compounds I and II. All three compounds possessed activity comparable to, or better than, streptomycin sulfate against *B. subtilis*, *S. aureus*, and *M. smegmatis*. Compounds I–III were also tested for activity against Gram-negative bacteria (*Escherichia coli* and *Pseudomonas aeruginosa*), but none showed any activity.

## EXPERIMENTAL

**Qualitative Antimicrobial Screening**—All compounds were tested for activity against the following microorganisms: *Bacillus subtilis* (ATCC 6633), *Staphylococcus aureus* (ATCC 6538), *Escherichia coli* (ATCC 10536), *Pseudomonas aeruginosa* (ATCC 15442), *Mycobacterium smegmatis* (ATCC 607), *Candida albicans* (ATCC 10231), *Saccharomyces cerevisiae* (ATCC 9763), *Aspergillus niger* (ATCC 16888), and *Trichophyton mentagrophytes* (ATCC 9972). Routine qualitative screening of compounds for antimicrobial activity was accomplished as previously described (1) except for the following modifications: plates for the assay were prepared by dispensing 25 ml of sterile agar medium into 100 × 15-mm sterile petri dishes; and using the quadrant streak method, the sterile agar plates were streaked with a dilution of the test organism (1 ml of broth culture in 9 ml of sterile water).

Antimicrobial activity was recorded as the width (in millimeters) of the inhibition zone measured from the edge of the agar well to the edge of the inhibition zone.

**Quantitative Antimicrobial Assay**—For compounds that showed significant activity in the qualitative screen, the MIC values were determined using the twofold serial dilution technique previously described (1). All compounds were initially tested using a concentration of 100 μg/ml in the first tube. After preliminary evaluation to determine the range of the MIC value, the concentrations in the first tube were de-

# Preparation and Antidiabetic Activity of Cyclic Sulfonylthiourea Derivatives

**RAAFAT SOLIMAN *x, HASSAN M. FEID-ALLAH §, and HOSNY F. MOHAMED ‡**

Received September 29, 1980, from the **Department of Pharmaceutical Chemistry and the* ‡*Department of Pharmacology, Faculty of Pharmacy, and the* §*Department of Chemistry, Faculty of Science, University of Alexandria, Alexandria, Egypt.* Accepted for publication January 21, 1981.

**Abstract** □ 3-Substituted 5-methyl-1-{*p*-[(3,5-dimethyl)pyrazol-1-yl]-, 5-methyl-1-{*p*-[(5-methyl-3-carboxy)pyrazol-1-yl]-, 1-{*p*-[(3-methyl-5-phenyl)pyrazol-1-yl]-, and 1-{*p*-[(3-methyl-4-bromo-5-phenyl)pyrazol-1-yl]benzenesulfonyl}-2-thiohydantoin and their 5-methyl-2-thiohydantoin and 5,6-dihydro-4(3*H*)-oxo-2(1*H*)-pyrimidinethione derivatives were prepared for evaluation as hypoglycemic agents. Biological testing showed that some of these compounds possessed antidiabetic activity.

**Keyphrases** □ Cyclic sulfonylthiourea derivatives—preparation and evaluation for antidiabetic activity, IR and PMR spectroscopy □ IR spectroscopy—identification of cyclic sulfonylthiourea derivatives, antidiabetic activity in mice □ Antidiabetic activity—synthesis and evaluation of cyclic sulfonylthiourea derivatives, identification by IR spectroscopy

In spite of the low hypoglycemic effect of substituted pyrazolesulfonylthiourea derivatives (1–3), their cyclic thio analogs showed potent antidiabetic activity (1). This finding initiated the synthesis of new cyclic pyrazolesulfonylthio analogs[1] for the evaluation of their antidiabetic effect.

## EXPERIMENTAL[2]

Substituted *p*-[(3,5-dimethyl)pyrazol-1-yl]-, *p*-[(5-methyl-3-carboxy)pyrazol-1-yl]-, *p*-[(3-methyl-5-phenyl)pyrazol-1-yl]-, and *p*-[(3-methyl-4-bromo-5-phenyl)pyrazol-1-yl]benzenesulfonylthiourea derivatives were prepared by the treatment of their corresponding *p*-sulfamylphenylpyrazole derivatives with the appropriate isothiocyanates.

[1] Application for a patent was made for compounds described in this report.
[2] Melting points were determined on a Kofler block and are uncorrected. IR spectra were determined as Nujol mulls with a Beckman IR-4210 spectrometer. PMR spectra was recorded on a Varian A-60 A spectrometer. Microanalyses were performed by the Microanalytical Unit, Faculty of Science, University of Cairo, Cairo, Egypt.

[a] Numbers in parentheses refer to values obtained on duplicate testing. [b] Not tested.

creased to either 30 or 60 μg/ml.

The MIC was taken as the lowest concentration that inhibited growth after 24 or 48 hr of incubation. Tubes inoculated with *B. subtilis* and *S. aureus* were incubated at 37° for 24 hr, while tubes inoculated with *M. smegmatis* were incubated at 37° for 48 hr. Tubes inoculated with fungi and yeasts were incubated at 30° for 48 hr. Streptomycin sulfate[1] and amphotericin B[2] were used as standard antibiotics for comparison with the phenolic compounds.

# Preparation and Antidiabetic Activity of Cyclic Sulfonylthiourea Derivatives

**RAAFAT SOLIMAN *x, HASSAN M. FEID-ALLAH §, and HOSNY F. MOHAMED ‡**

Received September 29, 1980, from the **Department of Pharmaceutical Chemistry and the* ‡*Department of Pharmacology, Faculty of Pharmacy, and the* §*Department of Chemistry, Faculty of Science, University of Alexandria, Alexandria, Egypt.* Accepted for publication January 21, 1981.

**Abstract** □ 3-Substituted 5-methyl-1-{*p*-[(3,5-dimethyl)pyrazol-1-yl]-, 5-methyl-1-{*p*-[(5-methyl-3-carboxy)pyrazol-1-yl]-, 1-{*p*-[(3-methyl-5-phenyl)pyrazol-1-yl]-, and 1-{*p*-[(3-methyl-4-bromo-5-phenyl)pyrazol-1-yl]benzenesulfonyl}-2-thiohydantoin and their 5-methyl-2-thiohydantoin and 5,6-dihydro-4(3*H*)-oxo-2(1*H*)-pyrimidinethione derivatives were prepared for evaluation as hypoglycemic agents. Biological testing showed that some of these compounds possessed antidiabetic activity.

**Keyphrases** □ Cyclic sulfonylthiourea derivatives—preparation and evaluation for antidiabetic activity, IR and PMR spectroscopy □ IR spectroscopy—identification of cyclic sulfonylthiourea derivatives, antidiabetic activity in mice □ Antidiabetic activity—synthesis and evaluation of cyclic sulfonylthiourea derivatives, identification by IR spectroscopy

In spite of the low hypoglycemic effect of substituted pyrazolesulfonylthiourea derivatives (1–3), their cyclic thio analogs showed potent antidiabetic activity (1). This finding initiated the synthesis of new cyclic pyrazolesulfonylthio analogs[1] for the evaluation of their antidiabetic effect.

## EXPERIMENTAL[2]

Substituted *p*-[(3,5-dimethyl)pyrazol-1-yl]-, *p*-[(5-methyl-3-carboxy)pyrazol-1-yl]-, *p*-[(3-methyl-5-phenyl)pyrazol-1-yl]-, and *p*-[(3-methyl-4-bromo-5-phenyl)pyrazol-1-yl]benzenesulfonylthiourea derivatives were prepared by the treatment of their corresponding *p*-sulfamylphenylpyrazole derivatives with the appropriate isothiocyanates.

[1] Application for a patent was made for compounds described in this report.
[2] Melting points were determined on a Kofler block and are uncorrected. IR spectra were determined as Nujol mulls with a Beckman IR-4210 spectrometer. PMR spectra was recorded on a Varian A-60 A spectrometer. Microanalyses were performed by the Microanalytical Unit, Faculty of Science, University of Cairo, Cairo, Egypt.

3-Substituted 5-methyl-1-{*p*-[(3,5-dimethyl)pyrazol-1-yl]- and 5-methyl-1-{*p*-[(5-methyl-3-carboxy)pyrazol-1-yl]benzenesulfonyl}-2-thiohydantoins (II and III, Scheme I) were prepared by refluxing an alcoholic solution of the appropriate thiourea derivative with ethyl $\alpha$-bromopropionate. The intermediate pseudothio derivatives underwent rapid rearrangement with the formation of 2-thiones. Their IR spectra showed a characteristic absorption band at 1120–1140 $cm^{-1}$, indicative of C=S, and at 1300 $cm^{-1}$, indicative of C–N (amide III band).

3-Substituted 1-{*p*-[(3-methyl-5-phenyl)pyrazol-1-yl]- and 1-{*p*-[(3-methyl-4-bromo-5-phenyl)pyrazol-1-yl]benzenesulfonyl}-2-thiohydantoin (VI and VII, Scheme II) and their 5-methyl-2-thiohydantoin (VIII and IX, Scheme II) and 5,6-dihydro-4(3*H*)-oxo-2(1*H*)-pyrimidinethione (X and XI, Scheme II) derivatives were prepared by refluxing an alcoholic solution of the appropriate thiourea derivative with ethyl bromoacetate, ethyl $\alpha$-bromopropionate, and ethyl $\beta$-bromopropionate, respectively. The intermediate pseudothio derivatives underwent rapid rearrangement with the formation of the 2-thiones.

In addition to the two bands of the $-SO_2N<$ group at 1330–1355 and 1155–1180 $cm^{-1}$, the IR spectra of VI and VII revealed a secondary carbonyl amide absorption at 1740–1755 $cm^{-1}$ and a C=S band at 1100–1120 $cm^{-1}$.

The IR spectra of VIII and IX revealed, in addition to the two bands of the $-SO_2N<$ group at 1330–1350 and 1160–1190 $cm^{-1}$, a secondary carbonyl amide absorption at 1740–1752 $cm^{-1}$ and a C=S band at 1090–1110 $cm^{-1}$.

The IR spectra of X and XI revealed a secondary carbonyl amide absorption at 1640–1665 $cm^{-1}$ and a C=S band at 1080–1100 $cm^{-1}$ in addition to the two bands of the $-SO_2N<$ group at 1330–1350 and 1160–1180 $cm^{-1}$.

**Synthesis of II and III**—A mixture of *p*-[(3,5-dimethyl)- or *p*-[(5-methyl-3-carboxy)pyrazol-1-yl]benzenesulfonylthiourea (I, 0.01 mole) and ethyl α-bromopropionate (0.011 mole) in absolute ethanol (50 ml) was refluxed with stirring for 4–6 hr, concentrated, and allowed to crystallize. The products obtained were recrystallized from ethanol (Table I).

**Synthesis of VI and VII**—A mixture of *p*-[(3-methyl-5-phenyl)- or *p*-[(3-methyl-4-bromo-5-phenyl)pyrazol -1- yl]benzenesulfonylthiourea

[a] Statistically significant.

(IV or V, 0.01 mole) and ethyl bromoacetate (0.011 mole) in absolute ethanol (50 ml) was refluxed with stirring for 4–6 hr, concentrated, and allowed to crystallize. The products obtained were recrystallized from ethanol (Table II).

**Synthesis of VIII and IX**—A mixture of IV or V (0.01 mole) and ethyl $\alpha$-bromopropionate (0.011 mole) in absolute ethanol (50 ml) was refluxed with stirring for 6–8 hr, concentrated, and allowed to crystallize. The products obtained were recrystallized from ethanol as colorless needles (Table II).

**Synthesis of X and XI**—A mixture of IV or V (0.01 mole) and ethyl $\beta$-bromopropionate (0.011 mole) in absolute ethanol (50 ml) was refluxed with stirring for 6–8 hr, concentrated, and allowed to crystallize. The products were recrystallized from 95% ethanol as colorless needles (Table III).

In addition to the aromatic protons at $\delta$ 7.0–8.1, the PMR spectra of VIc showed a multiplet at $\delta$ 0.8–1.7 for the $(CH_2)_3$ protons of the butyl group together with the methylene group of the cyclic ring, a singlet at $\delta$ 2.4 characteristic of the methyl group at C-3 of the pyrazole ring, a singlet at $\delta$ 1.3 for the $CH_3$ of the butyl group, and a singlet at $\delta$ 6.4 for the proton at C-4 of the pyrazole ring.

In addition to the aromatic protons at $\delta$ 6.8–7.9, the PMR spectra of XIc showed a singlet at $\delta$ 2.3 for the two methyl groups together with the two methylene groups of the cyclic ring.

## DISCUSSION

**Biological Testing**—Compounds IIc, IIIc, VI*d*, VIIc, VIII*c*, IX*c*, X*b*, and XI*a* were tested for hypoglycemic activity using alloxanized female albino mice weighing 20–25 g. Alloxan, 100 mg/kg of body weight, was injected into the tail vein in saline solution (10 mg/ml). Three days later, the mice were given the test compounds orally in suspension in 1% carboxymethylcellulose sodium at the rate of 0.2 mmole/kg of body weight.

Each day, four mice were used as a control group and one group of four mice was given the standard drug phenformin in a dose of 100 mg (0.4 mmole)/kg of body weight. Up to six groups of four mice received test compounds. Blood samples were taken at 0, 1, and 3 hr.

Blood was collected into 0.04% NaF solution. Glucose was determined by the microcolorimetric copper reduction technique of Haslewood and Strookman (4). Results are expressed as a percentage reduction of plasma glucose level compared to the control value.

**Statistical Significance**—Statistical significance was assessed using the Student $t$ test. Statistical significance was accepted where the calculated $t$ value exceeded the tabulated $t$ value at the 0.05 level.

From the data presented in Table IV, it is obvious that VIII possesses marked hypoglycemic activity. While IIIc, IX*c*, and XI*a* possess only moderate hypoglycemic activity, the potency of these compounds is more than their corresponding thiourea analogs.

# Synthesis of New Polyamine Derivatives for Cancer Chemotherapeutic Studies

**LOUIS T. WEINSTOCK *, WILLIAM J. ROST ‡x, and C. C. CHENG §**

Received July 28, 1980, from the **Midwest Research Institute, Kansas City, MO 64110*, the ‡*University of Missouri–Kansas City, Kansas City, MO 64110*, and the §*Mid-America Cancer Center, University of Kansas Medical Center, Kansas City, KS 66103.* Accepted for publication January 15, 1981.

**Abstract** □ Selected homologs, analogs, and acylated derivatives of spermine and spermidine, together with several heterocyclic and aromatic compounds containing a novoldiamine side chain, were prepared and evaluated biologically. Several compounds possessed activity against B-16 melanoma and human epidermoid carcinoma of the nasopharynx.

**Keyphrases** □ Polyamines—synthesis of derivatives, cancer chemotherapy □ Chemotherapy—synthesis of polyamine derivatives for cancer chemotherapy □ Derivatives—polyamines, synthesis, cancer chemotherapy

The importance of many naturally occurring polyamines, such as putrescine, spermidine, and spermine, to the growth of living cells is well established (1–4). It was reported recently that increased amounts of certain polyamines were found in rapidly proliferating biological systems (*e.g.*, chick embryo cells, rat regenerating liver cells, and wound-healing tissues) (5–10), as well as in neoplastic cells of animals and humans (11–16). The higher polyamine levels are believed to be contributed by ornithine decarboxylase activity in these tissues (17). Elevated polyamine levels also were detected in the urine of cancer patients (18–20). The high excretion level of polyamines declined when the patients were in remission, and chemotherapy treatment with methotrexate, cytosine arabinoside, 5-azacitidine, or fluorouracil resulted in polyamine depletion in tumor cells (21–23).

Since cellular protein synthesis is affected by polyamines at the transcription and translation level (24) and at least one role of polyamines is to organize the structure and activity of tRNA (25), it was postulated that properly designed analogs of polyamines could be useful in oncology studies. This concept was substantiated by previous reports (26–29) that some spermine and spermidine analogs of both synthetic and plant origin demonstrated inter-

esting *in vitro* and *in vivo* antineoplastic activity. Based on the structure–activity relationship information provided by these investigators and the general biochemical and biological aspects of polyamines, selective analogs, homologs, and acylated derivatives of spermine and spermidine (I–IV), as well as several heterocyclic and aromatic compounds containing a novoldiamine side chain (V–VIII), were prepared and their biological activity was evaluated at the National Cancer Institute.

## EXPERIMENTAL

**Chemistry**—*N*,*N*-Bis(2-cyanoethyl)amine (VIII*a*), prepared by cyanoethylation of ammonia with acrylonitrile (30), was treated with palmitoyl chloride to yield the hexadecaneamide, VIII*b*. Catalytic reduction of VIII*b* with Raney nickel in ethanolic ammonia (31) gave I*a*, isolated as a dihydrochloride salt, mp 240–243° dec. The corresponding dimethyl homolog I*b* was obtained from I*a* and a mixture of formic acid and formamide, according to the method of Clarke *et al.* (32). Compounds Ic and I*d* were prepared by reductive alkylation of 5-diethylamino-2-pentanone (IX) with 3-diethylaminopropylamine (X*a*) and novoldiamine (XI), respectively, followed by acylation. Treatment of 1-methylpiperazine (XII) and 1,4′-bipiperidine (XIII) with palmitoyl chloride in tetrahydrofuran in the presence of triethylamine gave I*e* (isolated as a monohydrochloride salt, mp 150–152°) and I*f* (isolated as a free base, mp 68–69°), respectively.

The tetramethyl homologs of spermidine and spermine, II*a* (isolated as a diphosphate salt, mp 269–271°) and II*b* (disphosphate, mp 239–241°), were prepared by mono- and dicyanoethylation of 2,5-diamino-

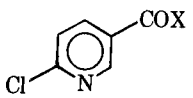
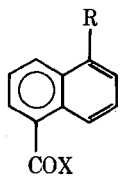
2,5-dimethylhexane (XIV*a*) with acrylonitrile, followed by catalytic hydrogenation. Acylation of the intermediate dinitrile XIV*b* with palmitoyl chloride and subsequent reduction yielded IV*a*, mp 70–73°. Reductive methylation (32) of IV*a* afforded IV*b*. Compounds IV*c* and IV*d* were prepared by similar sequential steps through intermediates III*a*–III*i* from the appropriate α,ω-diamines.

The unsaturated spermine analogs were prepared according to a reported method (33). Treatment of *trans*-1,4-dichloro-2-butene with 3-dimethylaminopropylamine (X*b*), followed by acylation of the intermediate diamine III*j*, yielded IV*l*, mp 58–60°. The novoldiamine analog IV*m* was prepared from III*k* in an analogous manner. Similarly, the corresponding butyne derivatives IV*n* (mp 40–41°) and IV*o* were prepared from 1,4-dichloro-2-butyne through the intermediates III*l* and III*m*, respectively. For the preparation of the cyclohexyl derivative IV*p*, the intermediate tetramine III*n* was obtained by reductive alkylation



XVII*a*: X = OH
XVII*b*: X = $NHCH(CH_3)—(CH_2)_3N(C_2H_5)_2$



XVIII*a*: R = H, X = OH
XVIII*b*: R = $NO_2$, X = OH
XVIII*c*: R = $NO_2$, X = $NHCH(CH_3)—(CH_2)_3N(C_2H_5)_2$
XVIII*d*: R = $NH_2$, X = $NHCH(CH_3)—(CH_2)_3N(C_2H_5)_2$

of 1,4-cyclohexanedione and X*b*. Acylation of III*n* readily yielded IV*p*, mp 110–115°.

The urea derivative IV*q* was prepared as follows. *p*-Nitrotrifluoroacetanilide (XV*a*), prepared from *p*-nitroaniline and trifluoroacetic anhydride, was reduced to the corresponding amino derivative XV*b*. This reaction was followed by reductive alkylation with IX to give XV*c*. Acylation of XV*c* with palmitoyl chloride and subsequent hydrolysis with potassium carbonate gave the *p*-phenylenediamine derivative XVI. Treatment of XVI with diethylcarbamoyl chloride in pyridine, according to a reported method (34), yielded IV*q*, mp 313–315°.

Condensation of 6-chloronicotinic acid (XVII*a*) with novoldiamine in the presence of dicyclohexylcarbodiimide yielded the chloronicotinamide XVII*b*. Amination of XVII with aqueous dimethylamine gave V (monophosphate, mp 105–107° dec.). The orotamide derivative VI (mp 196–198°) was obtained by refluxing a mixture of novoldiamine and the methyl ester of orotic acid (35) in 2-methoxyethanol[1]. The naphthalenesulfonamide VII*a* (dihydrochloride, mp 77–80°) was prepared by treatment of dansyl chloride with novoldiamine. For the preparation of the naphthalenecarboxamide VII*b* (monophosphate, mp 211–214° dec.), the starting material 1-naphthoic acid (XVIII*a*) was nitrated according to previously reported methods (36, 37). Condensation of the resulting nitroacid XVIII*b* and XI, followed by hydrogenation and reductive alkylation, yielded VII*b*.

**Biological Activity**—Test results (Table I) were obtained from the National Cancer Institute. Biological screening was conducted in mice with leukemia P-388 and B-16 melanoma and an *in vitro* system with human epidermoid carcinoma of the nasopharynx (KB cell culture). (For the general procedure and data interpretation, see Refs. 38 and 39.)

None of the polyamines showed good activity against leukemia P-388. On the other hand, *N*,*N*′-bis(3-dimethylaminopropyl)-*N*,*N*′-bis(palmitoyl)-*trans*-1,4-diamino-2-butene (IV*l*) and *N*,*N*′-bis(5-diethylamino-2-pentyl)-1,4-butanediamine (III*i*) exhibited inhibitory activity against B-16 melanoma. Compound IV*l* gave test/control (T/C) values of 155, 163, and 177 at doses of 50, 25, and 12.5 mg/kg, respectively. Compound III*i* had a T/C value of 224 at 25 mg/kg but was toxic at 50 mg/kg.

For the KB cell culture, inhibitory activity was demonstrated when the $ED_{50}$ value was <6 μg/ml. Based on this criterion, several acylated and unacylated polyamines (I*a*–I*e*, III*m*, IV*b*, IV*c*, IV*f*, IV*g*, and IV*l*–IV*o*) demonstrated inhibitory activity. Three of the most active compounds (I*b*–I*d*) are all monoacylated polyamines that showed $ED_{50}$ values at concentrations of 0.024, 0.29, and 0.026 μg/ml, respectively.

# Temperature-Dependent Effect of Edetate Disodium on Neomycin Stability

**N. A. HODGES** [x] **and PETA G. WALTON**

Received November 28, 1980, from the *Department of Pharmacy, Brighton Polytechnic, Sussex BN2 4GJ, England.* Accepted for publication January 26, 1981.

**Abstract** □ When heated at temperatures in excess of 100°, the stability of neomycin in aqueous ophthalmic formulations was improved by the addition of edetate disodium (0.01%). As the exposure temperature was reduced, the degree of stability enhancement diminished until the effect was reversed, and addition of edetate disodium was detrimental to neomycin stability in solutions stored at 30°.

**Keyphrases** □ Neomycin—stability in ophthalmic solutions containing edetate disodium □ Edetate disodium—temperature-dependent effect on neomycin stability □ Stability—neomycin in solutions containing edetate disodium

Edetate disodium (I) has been used to restrict metal-catalyzed oxidation of various drugs including several antibiotics (1–3). Neomycin (II), in common with other aminoglycoside antibiotics, is susceptible to atmospheric oxidation (4), and I has been recommended for inclusion in various neomycin preparations described in national formularies (5, 6). The factual basis for this recommendation is obscure, because few reports directly described the effects of I on the stability of II, although I has been included in formulations of fradiomycin (7), the principal components of which are neomycins B and C (8). The foregoing, together with observations during work on neomycin stability (9) that suggested I was of doubtful value in stabilizing neomycin at room temperatures, prompted the present study.

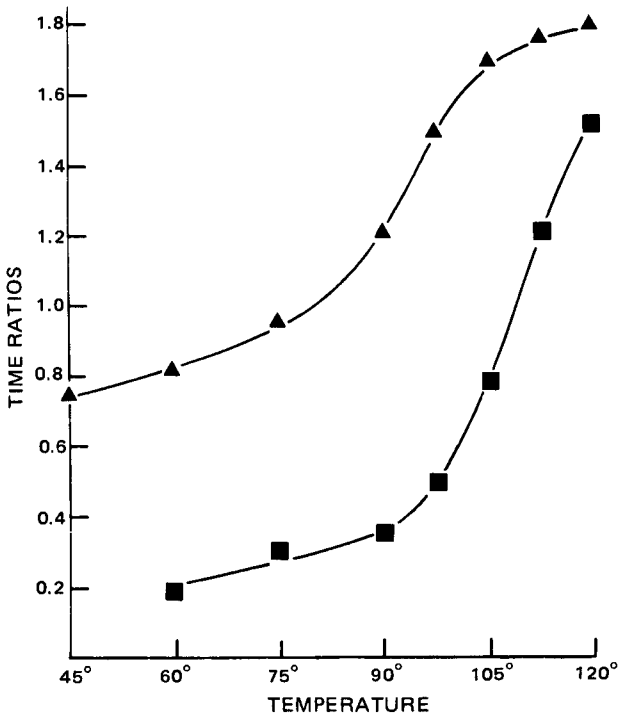

**Figure 1**—*Effect of heating temperature on the ratio of times required to achieve 15% (▲) or 50% (■) neomycin degradation in the presence and absence of edetate disodium.*

## EXPERIMENTAL

All reagents, apparatus, and procedures were described previously (9). The prepared 0.2 and 0.5% neomycin sulfate ophthalmic solutions contained 0.7% $Na_2HPO_4 \cdot 12H_2O$, 0.7% $NaH_2PO_4 \cdot 2H_2O$, and 0.002% phenylmercuric nitrate; 0.01% edetate disodium was included as required.

Initially, 3.5 ml of 0.2% neomycin solutions with and without I were sealed in neutral glass ampuls of nominal 5-ml capacity, leaving ~2 ml of airspace. The ampuls were heated by immersion in an oil bath at 120°, removed at suitable intervals, and rapidly cooled, and the contents were assayed. Plots of log percentage residual neomycin against time were constructed for solutions with and without I. Loss of neomycin did not consistently follow either zero- or first-order kinetics, and it was not possible to represent decomposition by a rate constant. For this reason, the effect of I inclusion was recorded as the ratio of times required to achieve either 15 or 50% neomycin loss in the presence and absence of I. This procedure was adopted also for 0.2% neomycin solutions heated between 45 and 112°.

The 0.5% neomycin solutions with and without edetate disodium were prepared to investigate the effect of changing the ratio of I to II and also to examine the stability of II at 100°, the temperature recommended for the BP process of heating with a bactericide (10). The solutions also were stored at 30°, and the stability of II was monitored.

Discoloration of solutions was recorded as absorbance at 450 nm.

## RESULTS AND DISCUSSION

The relationship between heating temperatures and the benefit resulting from inclusion of edetate disodium in the formulation is shown in Fig. 1. The beneficial effect, in terms of the time required for 50% neomycin loss, declined as the exposure temperature was reduced from 120 to 110°. Thereafter, the benefit was eliminated, and lowering the temperature further resulted in a progressively severe detrimental effect. A similar relationship was observed when a 15% fall in neomycin concentration was considered, but the advantage of edetate disodium inclusion was retained down to 80°. Thus, at temperatures between 80 and 110°, I afforded protection to II during the initial heating, but the reverse situation arose on prolonged exposure. In the 0.2% neomycin solutions, insufficient degradation occurred for values to be plotted at temperatures lower than 45 and 60° for 15 and 50% loss, respectively.

In the 0.5% neomycin solutions heated at 100°, the degradation rates down to ~70% of the initial concentration were almost identical in the

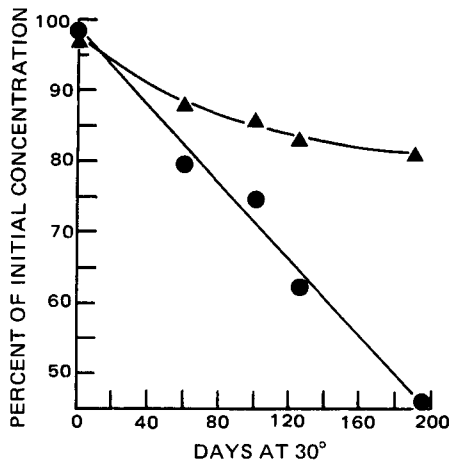

**Figure 2**—*Stability of 0.5% neomycin solutions with (●) and without (▲) edetate disodium during storage at 30°.*

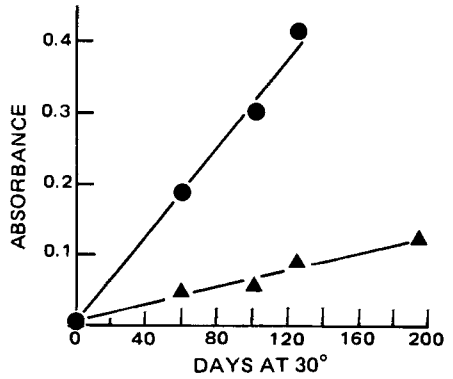

**Figure 3**—*Discoloration of 0.5% neomycin solutions with (●) and without (▲) edetate disodium during storage at 30°.*

solutions with and without I. Thereafter, the rate was slightly greater in the solution containing I (data not shown).

The fall in neomycin concentration and the associated discoloration of the solutions during storage at 30° are shown in Figs. 2 and 3. The data illustrated are for 10 ml of solution in amber ophthalmic dropper bottles. Solutions stored in ampuls at 30° gave qualitatively similar results, but the extent of degradation was somewhat less, due possibly to the smaller proportion of air to liquid in the ampuls. During prolonged storage, II was more stable in the absence rather than the presence of I. This pattern was reflected in the discoloration of the solutions.

Ethylenediaminetetraacetic acid or its disodium salt were observed previously to increase the degradation rate of epinephrine (11), physostigmine (12), and isoproterenol (13), which, like neomycin, all possess basic nitrogen groups in the molecule. With epinephrine (11) and isoproterenol (13), the diminished stability occurred at 37 and 60°, respectively, when ethylenediaminetetraacetic acid was present together with ferric ions at neutral pH values, although the mechanisms responsible for this effect have not been explained adequately. In the experimental system used in the present study, iron was not present other than as a contaminant of other chemicals or if it leached from glass. Furthermore, the same qualitative effects of edetate disodium inclusion were observed regardless of the neomycin batch, buffer concentration, color of the glass container, and presence or absence of phenylmercuric nitrate as a preservative.

The reported results show that inclusion of edetate disodium in neomycin ophthalmic formulations is likely to reduce the stability of the antibiotic during long-term storage at room temperatures. This effect is particularly important if the antibiotic solution is sterilized by filtration because the data indicate that the destabilization is operative even during the early storage period and that the initial protective effect observed at high temperatures is eliminated.

# Physicochemical Properties of Magnesium Salicylate

**A. S. ALAM *x and D. GREGORIADES**

Received July 17, 1980, from the *Department of Preclinical Research, Rohm and Haas Company, Spring House, PA 19477.* Accepted for publication January 28, 1981. *Present address: American Critical Care, McGaw Park, IL 60085.

**Abstract** □ Magnesium salicylate tetrahydrate is a nonhygroscopic, crystalline powder, whereas anhydrous magnesium salicylate is amorphous and very hygroscopic. Magnesium salicylate tetrahydrate tablets formulated with gelatin as a binder showed a dissolution half-life ($t_{1/2}$) of 12 min, whereas a formulation using pregelatinized starch as a binder showed a $t_{1/2}$ of 33 min. The optimum level of calcium stearate in the formulation was determined by the oscilloscope tracings of compressional and ejectional forces from an instrumented rotary tableting machine. Increasing the level of calcium stearate from 1 to 1.5 and 2% resulted in dissolution $t_{1/2}$ values of 12, 18, and 21 min, respectively, and a higher incidence of softer tablets and capping.

**Keyphrases** □ Magnesium salicylate—physicochemical properties, tableted tetrahydrate and anhydrous forms, effect of calcium stearate on dissolution rate □ Calcium stearate—effect on dissolution rate of tableted magnesium salicylate □ Dissolution—effect of calcium stearate on magnesium salicylate tablets □ Analgesics—magnesium salicylate tablets, effect of calcium stearate on dissolution

Magnesium salicylate is a white powder with analgesic, antipyretic, and anti-inflammatory properties similar to those of aspirin (1). Although magnesium salicylate or combinations of magnesium salicylate with other analgesics have been widely used in various diseases, the physicochemical properties of magnesium salicylate are not well characterized. This study characterized the physicochemical properties of magnesium salicylate and determined the effect of several excipients on the dissolution rate from tablet formulations.

## EXPERIMENTAL

**Materials**—Magnesium salicylate tetrahydrate, anhydrous magnesium salicylate, lactose monohydrate, gelatin, pregelatinized starch, FD&C Red No. 3 aluminum lake, and calcium stearate were used for tablet preparations.

**Thermogravimetric Analysis**—Profiles of the tetrahydrate and anhydrous forms were obtained under nitrogen with a heating rate of 20°/min.

**X-Ray Diffraction**—Profiles of the tetrahydrate and anhydrous forms were determined using nickel-filtered radiation with a copper target, a range of 500, and time constant 5.

**Equilibrium Moisture Content**—Sulfuric acid–distilled water admixtures were prepared for the relative humidity chambers; 20, 40, 60,

I II

III

and 80% relative humidities (RH) were obtained (2). The tetrahydrate and anhydrous forms were dried at 105°/4 hr/76 cm vac-vented, weighed into aluminum dishes, and placed in the humidity chambers at ambient room temperature. The dishes were weighed after 1, 2, and 3 weeks.

**Tablet Preparation**—Formulation A was prepared by granulating magnesium salicylate tetrahydrate, lactose, and colorant with 41% aqueous gelatin solution. Formulation B was prepared by adding water to the powder mix of magnesium salicylate tetrahydrate, lactose, pregelatinized starch, and colorant. The granulations were dried, sized in a hammermill, lubricated with calcium stearate, and compressed to a 1.83 × 0.74-cm capsule-shaped tablet on an instrumented rotary machine.

**Dissolution**—Tablet dissolution was determined by placing one tablet in the rotating-basket apparatus immersed in 900 ml of distilled water (3). The basket was rotated at 100 rpm. At 10, 20, 30, 60, and 120 min, a 1-ml sample was withdrawn, filtered through a 0.45-$\mu$m membrane filter, and diluted to 10 ml with distilled water; an aliquot was taken for UV absorbance at 296 nm. The amount dissolved was determined, and the cummulative percentage dissolved was calculated based on assayed values. Six individual tablets were run for each product. A NONLIN program (4) was used to calculate the apparent dissolution rate ($k_d$). The dissolution half-life ($t_{1/2}$) was determined by:

$$t_{1/2} = \frac{0.693}{k_d} \qquad \text{(Eq. 1)}$$

## RESULTS AND DISCUSSION

Magnesium salicylate tetrahydrate did not gain any moisture as reflected by the weights after 1, 2, and 3 weeks of storage of samples at 20, 40, 60, and 80% RH. Although the moisture gain for the 40% RH sample was higher, it was not significant. Anhydrous magnesium salicylate gained 1.7, 5.1, 12.2, and 21.5% of its weight, respectively, in these humidity chambers (Table I). Moisture equilibration was reached within 1 week of exposure in each chamber.

**Table I—Moisture Uptake (Percent) by Magnesium Salicylate Tetrahydrate and Anhydrous Magnesium Salicylate at Various Relative Humidity Storage**

| Product | Weeks | Relative Humidity 20% | 40% | 60% | 80% |
|---|---|---|---|---|---|
| Magnesium salicylate tetrahydrate | 1 | 0.05 | 0.03 | 0.08 | 0.06 |
| | 2 | 0.07 | 0.40 | 0.05 | 0.03 |
| | 3 | 0.06 | 0.90 | 0.60 | 0.04 |
| Anhydrous magnesium salicylate | 1 | 1.70 | 4.70 | 11.50 | 21.50 |
| | 2 | 1.70 | 4.80 | 11.90 | 21.80 |
| | 3 | 1.70 | 5.10 | 12.20 | 21.50 |

**Table II—Dissolution Profile[a] of Magnesium Salicylate Tetrahydrate Tablets**

| Formulation | $k_d \pm SD$, min$^{-1}$ | $t_{1/2} \pm SD$, min |
|---|---|---|
| A, 1% calcium stearate | 0.057 ± 0.012 | 12 ± 2.4 |
| A, 1.5% calcium stearate | 0.038 ± 0.007 | 18 ± 3.2 |
| A, 2% calcium stearate | 0.033 ± 0.007 | 21 ± 3.7 |
| B, 1% calcium stearate | 0.021 ± 0.003 | 33 ± 8.8 |

[a] USP apparatus, 100 rpm in distilled water, mean ± $SD$ of six tablets.

The thermogravimetric profile of magnesium salicylate tetrahydrate (I) showed a 20% weight loss between 75 and 200° (II) and a 35% weight loss between 200 and 350° (III), followed by a plateau region between 350 and 475°. Based on molecular weights and weight losses, the postulated products are as shown in Structures I–III.

X-ray diffraction results showed magnesium salicylate tetrahydrate to be crystalline, whereas anhydrous magnesium salicylate was amorphous. Based on these results, magnesium salicylate tetrahydrate was selected for tablet formulation.

Tablet dissolution data are shown in Table II. Although Formulations A and B were compressed to the same size, weight, thickness, and hardness, with equivalent compressional forces, the dissolution rates were different by as much as threefold. The $t_{1/2}$ values for Formulations A and B were 12 and 33 min, respectively. In both cases, the tablets did not disintegrate, and magnesium salicylate dissolved directly from the tablet matrix. It is postulated that the gelling properties of starch decreased the dissolution rate, whereas gelatin made the drug particles more hydrophilic; thus, the dissolution rate was increased (5).

The optimum calcium stearate level for Formulation A was determined by monitoring the oscilloscope tracings of compressional and ejectional forces during tableting (6). At 1% calcium stearate, tableting proceeded smoothly at the rate of 1500–1700 tablets/min, which was the maximum speed for the tablet machine. However, as the concentration of calcium stearate was increased to 1.5 and 2%, the resulting tablets became softer and showed a higher incidence of capping. Since calcium stearate is a hydrophobic lubricant, the $t_{1/2}$ value was affected adversely with the higher concentrations of lubricant. The dissolution $t_{1/2}$ values from Formulation A tablets containing 1, 1.5, and 2% calcium stearate were 12, 18, and 21 min, respectively.

# Succinimides with Oxyacetate Side Chain as Potential Anticonvulsant Agents

**J. A. OWOYALE ˣ, G. D. LAHAN, G. OSUIDE, and I. O. EDAFIOGHO**

Received September 8, 1980, from the *Department of Pharmacology and Pharmaceutical Chemistry, Ahmadu Bello University, Zaria-Nigeria.* Accepted for publication January 29, 1981.

**Abstract** □ Two new compounds, ethyl *N*-succinimidoxyacetate and methyl *N*-succinimidoxyacetate, were prepared by reacting a solution of freshly recrystallized *N*-hydroxysuccinimide in tetrahydrofuran with a mixture of the corresponding halogenated ester and triethylamine. The compounds possessed some anticonvulsant properties.

**Keyphrases** □ Succinimides—derivatives, anticonvulsant effects, synthesis and analysis □ Anticonvulsants—succinimide derivatives, synthesis and analysis □ Derivatives—of succinimides, synthesis and analysis

Aminooxyacetic acid is a potent anticonvulsant agent, but it causes convulsions at high doses. This convulsive tendency has been attributed to the unsubstituted amino group of this compound, which is very reactive with other groups, such as the aldehyde of pyridoxal phosphate (1). Two analogs of aminooxyacetic acid obtained by derivatizing its amino and carboxylic acid ends, ethyl *N*-phthalimidoxyacetate and methyl *N*-phthalimidoxyacetate, protected chicks against experimentally induced seizures (2, 3). In addition, ethyl *N*-phthalimidoxyacetate lacks the convulsant property of aminooxyacetic acid but is a less potent anticonvulsant (2).

With the aim of producing a very potent anticonvulsant, other cyclic imides were prepared, particularly hybrid compounds based on aminooxyacetic acid and such moieties that are normally associated with anticonvulsant properties. Accordingly, ethyl *N*-succinimidoxyacetate (I) and methyl *N*-succinimidoxyacetate (II) were synthesized, and their anticonvulsant activities were studied in the chick.

## RESULTS AND DISCUSSION

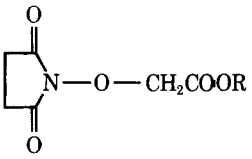
The synthesis of I and II was achieved in a one-step, self-indicating reaction. A light-blue color developed initially and disappeared at the end of the reaction. The major advantage of this reaction is that it proceeds at room temperature, especially since the starting material, *N*-hydroxysuccinimide, is usually hygroscopic and decomposes in warm water (4).

Results from preliminary pharmacological screening indicated that I and II possessed some anticonvulsant properties. Compounds I and II protected young chicks against electrically and chemically induced seizures. The details of the pharmacological screening will be reported elsewhere.

## EXPERIMENTAL

Melting points of the two compounds were determined by an electrothermal melting-point apparatus[1] and are uncorrected.

**Ethyl *N*-Succinimidoxyacetate (I)**—A solution of freshly recrystallized *N*-hydroxysuccinimide (1.15 g, 0.01 mole) in tetrahydrofuran (12 ml, 0.15 mole) was added to a mixture of ethyl bromoacetate (1.4 ml, 0.0125 mole) and triethylamine (2.1 ml, 0.015 mole). The reaction was allowed to proceed at room temperature for 12 hr, during which time the light-blue mixture became colorless. The reaction mixture was filtered, and the precipitate was washed with ether (5 × 20 ml).



I: R = $C_2H_5$
II: R = $CH_3$

The combined filtrates were concentrated and the product was crystallized from ethanol to obtain 1.71 g of white fluffy flakes in an 85% yield, mp 80–81°; IR[2] (mineral oil): 1778, 1712 (C=O for succinimide), 1748 (C=O for ester), 1208, 1098 (C–O–C asymmetric and symmetric stretching for ester, respectively), ~2950, 2880 (C–H stretching), 1436, and 1372 (C–H asymmetric and symmetric deformation for $CH_2CH_3$, respectively) $cm^{-1}$; NMR[3] ($CDCl_3$): δ 2.70 (s, 4H, cyclic H), 4.60 (s, 2H, $-CH_2$), 4.17 (q, 2H, $J$ = 6 Hz, $CH_2$ ethyl), and 1.27 (t, 3H, $J$ = 6 Hz, $CH_3$ ethyl); TLC[4]: h$R_f$ 56.8.

*Anal.*[5]—Calc. for $C_8H_{11}NO_5$: C, 47.76; H, 5.51; N, 6.96. Found: C, 47.82; H, 5.50; N, 7.01.

**Methyl *N*-Succinimidoxyacetate (II)**—A solution of freshly recrystallized *N*-hydroxysuccinimide (1.15 g, 0.01 mole) in tetrahydrofuran (12 ml, 0.15 mole) was added to a mixture of methyl bromoacetate (1.1 ml, 0.0125 mole) and triethylamine (2.1 ml, 0.015 mole). The reaction was allowed to proceed at room temperature for 8 hr, during which time the light-blue mixture became colorless. The reaction mixture was filtered, and the white precipitate, heavily contaminated with triethylamine hydrobromide, was crystallized from ethanol to obtain 1.31 g of white crystals in a 70% yield.

A second crop of 0.13 g was obtained by concentrating the filtrate, and the total yield was 1.44 g (77%), mp 128–130°; IR (mineral oil): 1772, 1706 (C=O for succinimide), 1750 (C=O for ester), 1200, 1086 (C–O–C asymmetric and symmetric stretching for ester, respectively), ~2950, 2880 (C–H stretching), 1440, and 1370 (C–H asymmetric and symmetric deformation for $CH_3$, respectively) $cm^{-1}$; NMR ($CDCl_3$): δ 2.63 (s, 4H, cyclic H), 4.60 (s, 2H, $-CH_2$), and 3.63 (s, 3H, $CH_3$); TLC: h$R_f$ 53.7.

*Anal.*—Calc. for $C_7H_9NO_5$: C, 44.92; H, 4.85; N, 7.48. Found: C, 45.03; H, 4.88; N, 7.47.

**Screening**—Compounds I and II were screened for anticonvulsant properties by subjecting pretreated young chicks to electrically and chemically induced seizures. Maximal electroshock was delivered using electroshock equipment[6]; chemical seizures were achieved using aminooxyacetic acid, bicuculline, pentylenetetrazol, picrotoxin, and strychnine.

# Antimicrobial Activity of Chlorhexidine Gluconate against Natural and Artificial Contamination during Simulation of In-Use Conditions

RAZA ALY

Received October 17, 1980, from the *Department of Dermatology, University of California, San Francisco, San Francisco, CA 94143.* Accepted for publication January 30, 1981.

**Abstract** □ Commercial bottles containing chlorhexidine gluconate (antimicrobial skin cleanser), whether exposed to room atmosphere or experimentally inoculated with *Staphylococcus aureus*, *Pseudomonas aeruginosa*, *Pseudomonas cepacia*, and *Proteus mirabilis*, did not exhibit microbial growth.

**Keyphrases** □ Chlorhexidine gluconate—antimicrobial activity, simulation of natural and artificial contamination □ Antimicrobial agents—chlorhexidine gluconate, simulation of contamination □ Skin cleanser—chlorhexidine gluconate, antimicrobial activity, simulation of contamination

Chlorhexidine gluconate has broad-spectrum antimicrobial activity against bacteria and several fungi (1–3). Although the antimicrobial activity of chlorhexidine when used on human skin is well documented, knowledge about bacterial contamination of commercial preparations during in-use conditions is lacking (4–6).

The present study was designed to determine the potential for bacterial contamination of a commercial chlorhexidine gluconate[1] skin cleanser by repeated exposure of opened bottles to room atmosphere over a prolonged period and to determine the potential for survival or growth of bacteria after repeated bacterial challenges with *Staphylococcus aureus*, *Pseudomonas aeruginosa*, *Pseudomonas cepacia*, and *Proteus mirabilis*. The test organisms were identified by cultural and biochemical reactions (7). Bottle-to-bottle transfers of the preparation were made to reflect certain in-use situations where residual product left in a used bottle is mixed with fresh product.

## EXPERIMENTAL

**Environmental Contamination**—Standard commercial bottles containing ~946 ml of the antimicrobial skin cleanser, tested and found free of contamination, were exposed to room atmosphere for 6 months by removing the tops daily and shaking for 5 min. Samples were taken weekly for the first 2 months and then at monthly intervals.

Two methods were utilized for determining bacterial contamination:

1. A 1-ml sample from each bottle was removed, diluted in trypticase soy broth containing 10% polysorbate 80[2] and 3% soy phosphatides[3] (neutralizer), and cultured on tryptic soy agar (containing 1% neutralizer). Culture plates were incubated at 37° for 48 hr.

2. A 20-ml aliquot was mixed with 250 ml of trypticase soy broth containing 0.3% neutralizer and then passed through a 0.45-μm filter disk. One-half of the filter was transferred to trypticase soy broth and the other half to thioglycollate broth. After 24 hr of incubation at 37°, 1 ml of each broth was cultured on tryptic soy agar.

**Experimental Contamination with *S. aureus*, *P. mirabilis*, *Ps. aeruginosa*, and *Ps. cepacia***—For a given test organism, the experimental contamination procedure comprised seven bacterial challenges and three bottle-to-bottle transfers over 25 weeks. A commercial bottle (Bottle 1) of the chlorhexidine gluconate preparation, previously tested and found to be free of bacteria, was challenged (C-1). The bottle contents were mixed, and the aliquots were tested at 10 min and after 1 week (just before C-2) for bacterial growth. Aliquots (25 ml) were removed *via* the delivery spout of the bottle, employing a hand pump to simulate in-use conditions, and were cultured for environmental contamination. The bottle then was challenged as before (C-2, 1 week). The aliquots were tested at 10 min and after 1 week (just before C-3) for bacterial growth. This contamination and testing for bacterial growth were repeated at 2 (C-3) and 3 (C-4) weeks. Challenge 5 (4 weeks) was performed as described, and the aliquot was tested for bacterial growth at 10 min only.

At this point, periodic bottle-to-bottle transfers of the preparations were begun to mimic certain in-use conditions, where fresh product was poured into a previously used bottle containing residual product with 1 ml containing $10^6$ viable bacteria (for a final concentration of $10^3$ bacteria/ml in the commercial bottle).

**First Transfer (4 Weeks)**—Forty milliliters from Bottle 1 was transferred aseptically into a new bottle (Bottle 2), previously tested and found free of bacteria. The aliquot was tested after 1 week (just before C-6) for bacterial growth. Bottle 2 was challenged (C-6, 5 weeks). The aliquot was tested at 10 min and also after 4 weeks (just before the second bottle-to-bottle transfer) for bacterial growth.

**Second Transfer (9 Weeks)**—Forty milliliters from Bottle 2 was transferred aseptically to a new bottle (Bottle 3). The aliquot was tested after 4 weeks (just before C-7) for bacterial growth. Bottle 3 was challenged (C-7, 13 weeks). The aliquot was tested at 10 min and also after 4 weeks (just before the third bottle-to-bottle transfer) for bacterial growth.

**Third Transfer (17 Weeks)**—Forty milliliters from Bottle 3 was transferred to a new bottle (Bottle 4). The aliquot was tested for bacterial growth after 8 weeks, concluding a total period of 25 weeks from the initial challenge.

## RESULTS AND DISCUSSION

No contamination was noted at the start of the study or after 5-min daily exposures and shaking of the product at room atmosphere for the 6-month duration of the environmental contamination. Delivery spouts of the bottles were cultured with a swab and were free of bacterial contamination.

Bottles of the products contaminated experimentally with *S. aureus*, *P. mirabilis*, *Ps. aeruginosa*, or *Ps. cepacia* were examined for 6 months for bacterial growth and were not contaminated. Delivery spouts also were free of bacterial contamination.

Chlorhexidine has excellent antimicrobial activity against Gram-positive and Gram-negative bacteria (1–6). Due to its broad-spectrum antimicrobial activities, chlorhexidine preparations have become widely used for disinfection.

# Analysis of Methoxsalen in Plasma by Reversed-Phase High-Performance Liquid Chromatography

**J. G. MONBALIU ˣ, M. T. ROSSEEL, and M. G. BOGAERT**

Received September 29, 1980, from the *Heymans Institute of Pharmacology, University of Ghent Medical School, De Pintelaan 135, B-9000 Ghent, Belgium.* Accepted for publication February 2, 1981.

**Abstract** □ A high-performance liquid chromatographic method for the determination of methoxsalen in plasma was developed. The method includes extraction from plasma of the drug and the internal standard (5-methoxypsoralen) into methylene chloride. Chromatography was performed on a reversed-phase $C_8$ column connected with a UV detector set at 254 nm. The mobile phase was methanol–acetonitrile–water (2:30:68). For a plasma sample of 0.25 ml, the maximal sensitivity was ~10 ng/ml. Accuracy was within 7.5% for therapeutic plasma levels, and the coefficient of variation varied between 4.3 and 0.9% for 28 and 300 ng/ml of plasma, respectively.

**Keyphrases** □ Methoxsalen—high-performance liquid chromatographic analysis, human plasma □ High-performance liquid chromatography—methoxsalen, human plasma □ Photosensitizer—methoxsalen, high-performance liquid chromatographic analysis, human plasma

Methoxsalen (8-methoxypsoralen), a furocoumarinic derivative, is used in conjunction with phototherapy in the treatment of psoriasis (1). Different methods of analysis of methoxsalen in plasma have been published. Fluorodensitometric methods (2, 3) are time consuming, and flame-ionization GLC (4) is not sensitive enough for measuring therapeutic plasma levels. Electron-capture GLC (5–7) and GLC–mass spectrometry (8) also have been described.

Since methoxsalen has a very high UV absorbance, a high-performance liquid chromatographic (HPLC) method with UV detection was developed. HPLC using a silica column also has been used (9, 10). HPLC on a reversed-phase column[1] was proposed (11), with the internal standard griseofulvin being added after the extraction. Reversed-phase HPLC on a $C_{18}$ column with trimethylpsoralen as the internal standard also was investigated (8, 12).

This report describes an HPLC method with a simple and rapid extraction procedure using a $C_8$ column and 5-methoxypsoralen as the internal standard.

## EXPERIMENTAL

**Reagents and Solvents**—Methoxsalen[2] (8-methoxypsoralen) and 5-methoxypsoralen[3] were used as received. Methylene chloride[4], methanol[5], and acetonitrile[5] were also used.

**Equipment**—A microprocessor-controlled high-performance liquid chromatograph[6] with a fixed-wavelength UV detector[7] (254 nm), an automatic injector, and a 10-μl sample loop were used.

Separations were performed on a reversed-phase column[8] (250 × 4.6 mm i.d.). The column was operated at 40°. Chromatograms were traced on a printer/plotter[6] at a chart speed of 0.5 cm/min.

**Chromatographic Conditions**—The mobile phase, methanol–acetonitrile–water (2:30:68), was pumped through the column at a flow rate of 1.5 ml/min at 500–1000 psi.

**Procedure**—To 250 μl of plasma in a 5-ml glass conical tube was added 200 ng of the internal standard, 5-methoxypsoralen (20 μl of a 0.001% methanol solution). The sample was extracted with 700 μl of methylene chloride for 30 sec on a mixer[9]. After centrifugation at 5000 rpm at 4° for 10 min, the organic phase was transferred to another 5-ml glass conical tube and evaporated to dryness at room temperature under nitrogen. The residue was stored at −20° until analysis. The extract was reconstituted in 20 μl of methanol just prior to chromatography, and 10 μl was injected.

**Absolute Recovery**—Absolute recovery of methoxsalen from plasma was determined by adding the internal standard after extraction and comparing peak height ratios with peak height ratios of a calibration curve. This calibration curve was obtained by injecting methanol solutions of methoxsalen at concentrations of 7.0, 36.0, and 50.0 ng/ml of plasma. Five replicates were analyzed at each concentration. The results are shown in Table I.

**Table I—Absolute Recovery of Methoxsalen from Plasma [a]**

| Quantity Added to 250 μl of Plasma, ng | Mean, % | Coefficient of Variation, % |
|---|---|---|
| 7.0 | 92.8 | 6.6 |
| 36.0 | 87.2 | 8.8 |
| 50.0 | 87.4 | 5.6 |

[a] $n = 5$.

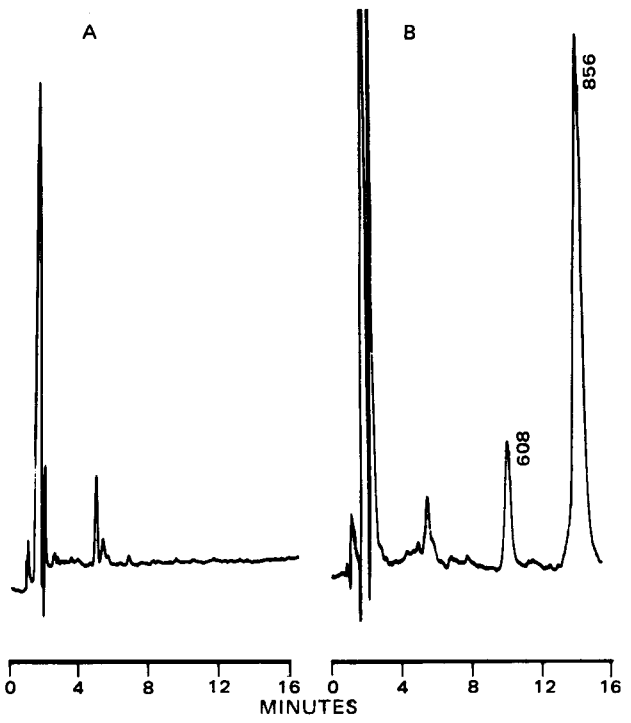

**Figure 1**—*Chromatogram of a 250-μl extract of human blank plasma (A) and of a 250-μl extract of human blank plasma spiked with 25 ng of methoxsalen* ($R_t$ *608 sec) and 200 ng of the internal standard* ($R_t$ *856 sec) (B).*

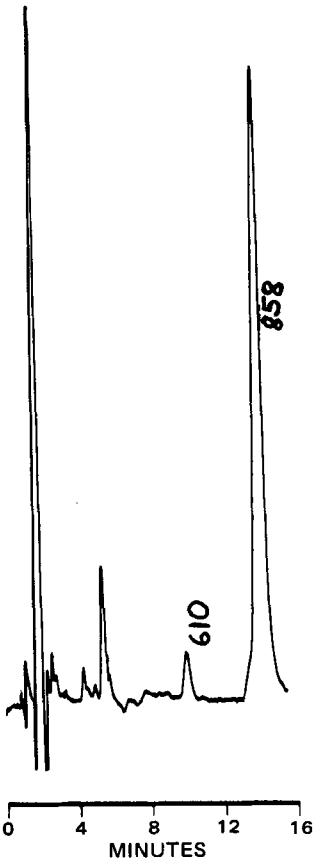

**Figure 2**—*Chromatogram of a 250-μl extract of plasma of a patient after oral intake of 30 mg of methoxsalen ($R_t$ 610 sec); the sample was spiked with 200 ng of the internal standard ($R_t$ 858 sec).*

tions containing 10–80 ng of methoxsalen and 100 ng of the internal standard.

## RESULTS AND DISCUSSION

The extraction gave good recoveries (87–93%) of methoxsalen from plasma (Table I).

Plasma standard curves were linear for concentrations ranging from 12 to 1000 ng/ml. The average slope for 16 standard curves, assayed over 5 months, was 0.008436 ± 0.000422 (mean ± *SD*), with an average correlation coefficient of 0.9980 ± 0.0023 (mean ± *SD*). For a plasma sample of 0.25 ml, the maximum sensitivity was ~10 ng/ml.

Within-run accuracy and precision were acceptable (Table II). For testing of the between-run reproducibility and accuracy, aliquots were taken 16 times over a 5-month period from a pool containing 100.0 ng of methoxsalen/ml of plasma; the average result was 102.4 ± 5.2 ng/ml (mean ± *SD*) ($n$ = 16).

**Table II—Within-Run Precision and Accuracy of Methoxsalen Assay**

| Quantity Added to 250 μl of Plasma, ng | Relative Error, % | Coefficient of Variation, % |
|---|---|---|
| 7 ($n$ = 4) | +7.5 | 4.3 |
| 36 ($n$ = 5) | +2.7 | 5.0 |
| 50 ($n$ = 5) | −2.9 | 2.6 |
| 75 ($n$ = 5) | −3.2 | 0.9 |

Figure 1A shows a representative chromatogram of an extract of human blank plasma. Figure 1B shows a chromatogram of human blank plasma spiked with methoxsalen and the internal standard. Both products were well resolved. Figure 2 shows a chromatogram of a plasma extract of a patient 130 min after the intake of 30 mg of methoxsalen, spiked with the internal standard.

The proposed method is suitable for plasma sample analysis for pharmacokinetic studies of methoxsalen in animals and humans. The extraction is simple and rapid, and only 700 μl of the extraction solvent is needed. This procedure is an improvement in comparison to other methods (8–12). The small volume of plasma used (250 μl) enables repeated sampling.

# Simplified Physiologically Based Method to Estimate Steady-State Volume of Distribution

**Keyphrases** □ Pharmacokinetics—simplified physiologically based method to estimate steady-state volume of distribution □ Volume of distribution—estimation, simplified physiologically based method

*To the Editor:*

Until recently (1–4), few investigators studied the potential effect of arterial–venous plasma concentration differences on the determination of the apparent steady-state volume of distribution ($V_{ss}$) of drugs. When standard methods in linear pharmacokinetics were used, the calculated $V_{ss}$ values based on venous plasma data were invariably greater than those based on arterial data from the same animals (2–4). Differences as much as 2.4-fold were found.

From a physiological point of view, the driving force for elimination and distribution of a drug in the body should generally be its concentration in arterial plasma (especially for elimination by renal filtration) and not in peripheral venous plasma (commonly sampled for assay). Therefore, it seems appropriate to use the arterial data (if possible) for $V_{ss}$ calculations (1–3). A new arterial plasma area method for $V_{ss}$ determinations was proposed earlier (4).

In view of the difficulty and risk involved in arterial blood sampling, two physiologically based venous and excretion rate methods were derived (4).

Method I, the intravenous bolus injection method, is described by:

$$V_{ss} = \frac{\int_0^\infty (D - Ae_t/fe)\,dt}{AUC^V} \qquad \text{(Eq. 1)}$$

where $D$ is the bolus dose, $Ae_t$ is the cumulative urinary excretion of unchanged drug from time zero to $t$, $fe$ is the fraction of the dose excreted unchanged up to time infinity, and $AUC^V$ is the total area under the venous plasma drug concentration–time curve between time zero and time infinity. This method was verified experimentally[1].

Method II, the short-term intravenous infusion method, is described by:

$$V_{ss} = \frac{\int_0^\infty (D_t - Ae_t/fe)\,dt}{AUC^V} \qquad \text{(Eq. 2)}$$

where $D_t$ is the cumulative amount of drug infused up to time $t$.

Both Methods I and II require frequent and accurate urine collection and extensive blood sampling to estimate the $AUC^V$. This report describes a simpler physiologically based method, called the steady-state plasma–urinary method, for calculating $V_{ss}$.

By definition, $V_{ss}$ can be defined as (4 and references cited therein):

$$V_{ss} = \frac{A_{ss}}{C_{ss}} \qquad \text{(Eq. 3)}$$

where $A_{ss}$ is the amount of drug in the body at steady state following a constant-rate infusion and $C_{ss}$ is the steady-state plasma drug concentration. Therefore, $V_{ss}$ can be estimated after the attainment of steady state by:

$$V_{ss} = \frac{D_{ss} - (\text{total amount eliminated up to } t_{ss})}{C_{ss}} \qquad \text{(Eq. 4)}$$

$$V_{ss} = \frac{D_{ss} - Ae_{ss}Cl/Cl_R}{C_{ss}} \qquad \text{(Eq. 5)}$$

where $D_{ss}$ is the total amount of drug infused up to the steady state at time $t_{ss}$, $Ae_{ss}$ is the total cumulative amount of drug excreted unchanged up to time $t_{ss}$, $Cl$ is the total plasma drug clearance (*i.e.*, infusion rate/$C_{ss}$), and $Cl_R$ is the renal drug clearance. The value of $Cl_R$ can be determined by the conventional method, *i.e.*, urinary excretion rate at steady state divided by the $C_{ss}$. The times to reach various fractions of the steady-state plasma level during intravenous infusion initially can be estimated by a noncompartmental plasma area method described previously (5).

Equation 5 has several advantages over Eqs. 1 and 2. First, Eq. 5 requires only one or two venous blood samples at steady state. Second, all urinary samples can be pooled together (both convenient and economical in drug assay), except for the last one or two that are used for renal clearance measurement. Third, a loading bolus and/or loading infusion dose can be given to achieve the steady state rapidly with the final maintenance infusion; with Eq. 1 or 2, the study may have to be carried out for several half-lives. Fourth, the mathematical operation is much easier with Eq. 5. And fifth, it often may be more accurate to assay steady-state specimens due to higher concentrations. Furthermore, the described method is independent of the source of plasma sample since both arterial and venous (usually from a noneliminating leg or arm vein) plasma drug concentrations should be theoretically identical at steady state (4, 6, 7).

The limitation of the proposed method is that it can only be used for drugs excreted to some extent in the urine. Fluctuations in urine pH and flow rate should be minimized during the entire study period if either or both of them have been shown to significantly affect the renal clearance of drug. Several commonly used method to calculate $V_{ss}$ were recently reviewed (4, 8, 9). The use of the steady-state infusion method employing the measurement of plasma concentrations for calculating $V_{ss}$ were described previously (10–12). The recommended symbols in pharmacokinetics (12) are adopted in this communication.

## Modified USP Assay of Calcium Gluceptate

**Keyphrases** □ Calcium gluceptate—modified USP assay □ USP assay—modification for calcium gluceptate

*To the Editor:*

The USP assay procedure for calcium gluceptate consists of the complexometric estimation of calcium with ethylenediaminetetraacetic acid (1). To an accurately weighed amount of calcium gluceptate (~800 mg), 150 ml of water containing 2 ml of 3 *N* HCl is added. While stirring, ~25 ml of 0.05 *M* ethylenediaminetetraacetate disodium is added from a buret. Then 15 ml of 1 *N* NaOH and 300 mg of hydroxy naphthol blue indicator are added, and the titration is continued to a blue end-point.

A similar procedure is described for the assay of precipitated calcium carbonate, calcium chloride, calcium gluconate, calcium hydroxide, calcium lactate, and calcium levulinate and for the calcium content analysis of calcium pantothenate and racemic calcium pantothenate. Although each assay calls for the addition of hydrochloric acid, this step is only necessary where the calcium salt has a limited aqueous solubility (2, 3). Since calcium gluceptate is freely soluble in water (4), we suggest that the addition of hydrochloric acid should be omitted. Table I shows that assay results are not affected by the presence or absence of hydrochloric acid.

**Table I—Assay of Calcium Gluceptate in the Presence and Absence of Hydrochloric Acid**

The sodium hydroxide solution and the hydroxy naphthol blue indicator can be added to the calcium gluceptate solution at the beginning of the assay; thus, it is unnecessary to interrupt titration to make these additions. The estimation of calcium with ethylenediaminetetraacetic acid using hydroxy naphthol blue as the indicator is carried out at pH 12–13 (5). The addition of 15 ml of 1 *N* NaOH solution in the official assay brings the pH to this range. In the absence of hydrochloric acid, ~10 ml of 1 *N* NaOH solution would be sufficient to bring the pH to the required range. Thus, omitting the hydrochloric acid both simplifies the procedure and enables the amount of sodium hydroxide to be reduced.

We suggest that hydrochloric acid might be omitted in the assay of other freely soluble calcium salts.

## Observed Artifacts due to Pellet Preparation in IR Spectrometry

**Keyphrases** □ IR spectrometry—observed artifacts due to pellet preparation □ Pellets—observed artifacts due to preparation, IR spectrometry

*To the Editor:*

IR spectrometry is required for identifying organic substances by most pharmacopeia and official compendia such as the USP XIX and the NF XIV (1, 2). The USP recommends: "Chemically identical substances of differing polymorphic forms often exhibit different infrared spectra when examined in the solid state. If a difference appears in the spectra, dissolve portions of both the sample and the reference standard in a suitable solvent, evaporate the solution to dryness, and repeat the test on the residues" (1). Differences resulting from polymorphism are considered to be the major reason for errors.

Certain secondary and tertiary amine derivatives such as bupivacaine, cinnarizine, and many butyrophenones have the same spectrum, in part or in whole, for their hydrochloride, hydrobromide, and free base forms when they are dissolved in methanol, ethanol, or isopropanol and if grinding with potassium bromide is prolonged.

## Modified USP Assay of Calcium Gluceptate

**Keyphrases** □ Calcium gluceptate—modified USP assay □ USP assay—modification for calcium gluceptate

*To the Editor:*

The USP assay procedure for calcium gluceptate consists of the complexometric estimation of calcium with ethylenediaminetetraacetic acid (1). To an accurately weighed amount of calcium gluceptate (~800 mg), 150 ml of water containing 2 ml of 3 *N* HCl is added. While stirring, ~25 ml of 0.05 *M* ethylenediaminetetraacetate disodium is added from a buret. Then 15 ml of 1 *N* NaOH and 300 mg of hydroxy naphthol blue indicator are added, and the titration is continued to a blue end-point.

A similar procedure is described for the assay of precipitated calcium carbonate, calcium chloride, calcium gluconate, calcium hydroxide, calcium lactate, and calcium levulinate and for the calcium content analysis of calcium pantothenate and racemic calcium pantothenate. Although each assay calls for the addition of hydrochloric acid, this step is only necessary where the calcium salt has a limited aqueous solubility (2, 3). Since calcium gluceptate is freely soluble in water (4), we suggest that the addition of hydrochloric acid should be omitted. Table I shows that assay results are not affected by the presence or absence of hydrochloric acid.

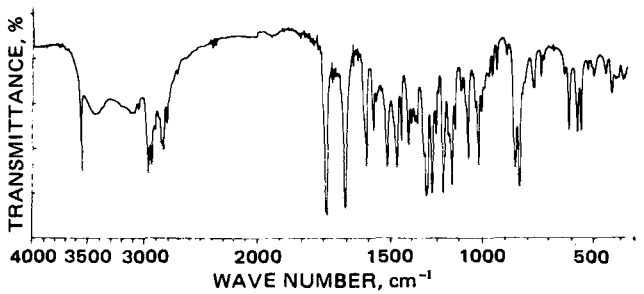

**Figure 1**—*Spectrum of moperone base; grinding with potassium bromide without any solvent.*

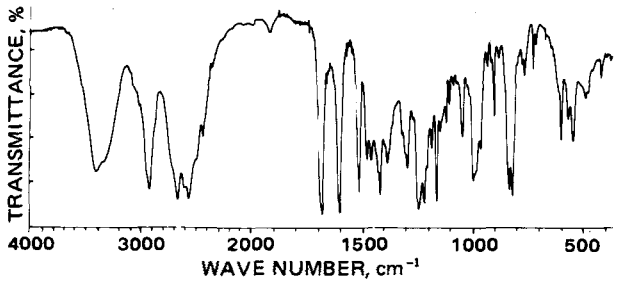

**Figure 2**—*Spectrum of moperone hydrochloride; grinding with potassium bromide without any solvent.*

In the case of amine hydrochloride, the exchange of chlorine ions with bromine ions was reported (3, 4). However, this explanation is unsatisfactory for the free base form. The presence of very intense absorption bands between 2650 and 2500 $cm^{-1}$, indicating nitrogen protonation, was confirmed (Figs. 1–3). In the case of moperone, the hydrobromide reextracted from the potassium bromide pellet by a minimum volume of methanol shows a final melting temperature of 184°, determined by thermomicroscopy, even though melting temperatures of the hydrobromide, hydrochloride, and free base forms are 186, 222, and 123°, respectively. It was reported (5) that amine salts having a protonated nitrogen atom of the $NH_3^+$, $NH_2^+$, or $NH^+$ type possess characteristic frequencies of 4000–2000 $cm^{-1}$.

The hydrobromide form of moperone (reextracted from potassium bromide pellets) was confirmed using X-ray diffraction. The spectra present the characteristic moperone hydrobromide pattern, including intense bands corresponding to *d* values of 0.64, 5.29, 5.16, 4.89, 4.78, 4.25, 3.68, and 3.61 Å. Identical results were obtained with pharmaceutical organic raw materials such as bupivacaine, cinnarizine, diethylpropion, diisopromine, fenfluramine, fluanisone, haloperidol, homatropine, and moperone.

The hydrobromide formation may be attributed to atmospheric carbon dioxide combined with the entropy of the system since the potassium bromide effect persists when sodium redistilled methanol or pyridine and potassium bromide solutions (pH 10) are used. Thus, it is important not to attribute the spectral consequences of this potassium bromide effect to the existence of a new polymorphic form.

# First-Pass Clearance of Lidocaine in Healthy Volunteers and Epileptic Patients: Influence of Effective Liver Volume

**Keyphrases** □ Lidocaine—first-pass clearance in healthy volunteers and epileptic patients compared □ Bioavailability—lidocaine, compared in healthy volunteers and epileptic patients, influence of effective liver volume □ Hepatic retention—effect on first-pass clearance of lidocaine, healthy volunteers and epileptic patients compared

*To the Editor:*

Recent reports (1, 2) compared the absolute oral bioavailability of lidocaine in epileptic patients receiving chronic anticonvulsant drug therapy to that in normal healthy volunteers not receiving enzyme-inducing drugs. The authors of these reports concluded that the greater than twofold reduction in absolute availability observed in the epileptic patients was the result of increased hepatic first-pass metabolism caused by the chronic administration of anticonvulsant drugs.

The present study considers the possible impact of increased hepatic retention, rather than increased metabolic activity, on reduced bioavailability using the first-pass perfusion model presented in Scheme I. The model was used to simulate the effect of increased hepatoportal retention of lidocaine that could result from the induction of nonenzyme-related protein synthesis in the eliminating organ. The product of the liver volume ($V_H$) and liver retention ($R_H$) is the effective liver volume (3). Therefore, by definition, an increase in liver mass or hepatic tissue binding is reflected as an increase in hepatic organ clear-

# First-Pass Clearance of Lidocaine in Healthy Volunteers and Epileptic Patients: Influence of Effective Liver Volume

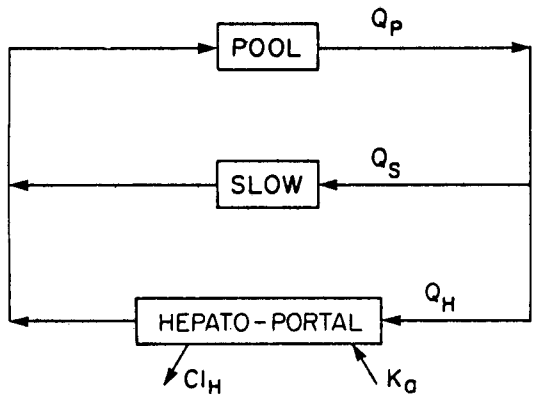
**Keyphrases** □ Lidocaine—first-pass clearance in healthy volunteers and epileptic patients compared □ Bioavailability—lidocaine, compared in healthy volunteers and epileptic patients, influence of effective liver volume □ Hepatic retention—effect on first-pass clearance of lidocaine, healthy volunteers and epileptic patients compared

*To the Editor:*

Recent reports (1, 2) compared the absolute oral bioavailability of lidocaine in epileptic patients receiving chronic anticonvulsant drug therapy to that in normal healthy volunteers not receiving enzyme-inducing drugs. The authors of these reports concluded that the greater than twofold reduction in absolute availability observed in the epileptic patients was the result of increased hepatic first-pass metabolism caused by the chronic administration of anticonvulsant drugs.

The present study considers the possible impact of increased hepatic retention, rather than increased metabolic activity, on reduced bioavailability using the first-pass perfusion model presented in Scheme I. The model was used to simulate the effect of increased hepatoportal retention of lidocaine that could result from the induction of nonenzyme-related protein synthesis in the eliminating organ. The product of the liver volume ($V_H$) and liver retention ($R_H$) is the effective liver volume (3). Therefore, by definition, an increase in liver mass or hepatic tissue binding is reflected as an increase in hepatic organ clear-

0022-3549/81/0800-0969$01.00/0
© 1981, American Pharmaceutical Association



*Scheme I—First-pass perfusion model. The perfusion model contains three compartments: 1, the pool, which includes the serum and highly perfused noneliminating tissues where $V_P$ is the pool volume; 2, more slowly perfused noneliminating tissues where $V_SR_S$ is the effective volume of this more slowly equilibrating pool; and 3, the hepatoportal system, which is responsible for drug elimination and where $V_HR_H$ is the effective liver volume. Blood flow to the more slowly perfused organs and the hepatoportal system are described as $Q_S$ and $Q_H$, respectively, whereas the hepatic clearance is described as $Cl_H$.*

ance ($Cl_H$) as a result of an increase in the effective liver volume. Classic clearance concepts (4) dictate that changes in hepatic organ clearance ($Cl_H$) and hepatic blood flow ($Q_H$) result in changes in the first-pass extraction ($E$) and total body clearances ($Cl_B$) according to:

$$E = \frac{Cl_H}{Q_H + Cl_H} \quad \text{(Eq. 1)}$$

$$Cl_B = \frac{Q_H Cl_H}{Q_H + Cl_H} \quad \text{(Eq. 2)}$$

Hepatic organ clearance is generally assumed to mean metabolic clearance, although, in reality, it includes both metabolic activity and tissue retention in the liver due to tissue binding (3).

The experimental data was obtained from a previous report (1) in which six epileptic patients receiving chronic anticonvulsant therapy with known enzyme-inducing agents (*i.e.*, phenobarbital, primidone, carbamazepine, and phenytoin) and six healthy volunteers were studied. Each person was administered 86 mg of lidocaine base equivalents intravenously as the hydrochloride salt and ingested 608 mg of lidocaine base equivalents orally as the monohydrate salt on two separate occasions. Blood samples were withdrawn over 240 min to assess the pharmacokinetics of lidocaine in serum. Serum concentrations were determined by enzyme immunoassay (1).

The following differential equations describe the model presented in Scheme I and were used to simulate serum concentration–time data for oral and intravenous doses simultaneously using the nonlinear least-squares regression program NONLIN (5):

$$\frac{dC_P}{dt} = [(Q_S C_S/R_S) + (Q_H C_H/R_H) - Q_P C_P]/V_P \quad \text{(Eq. 3)}$$

$$\frac{dC_S}{dt} = [Q_S C_P - (Q_S C_S/R_S)]/V_S \quad \text{(Eq. 4)}$$

For the intravenous dose:

$$\frac{dC_H}{dt} = [Q_H C_P - (Q_H C_H/R_H) - (Cl_H C_H/R_H)]/V_H \quad \text{(Eq. 5)}$$

For the oral dose:

$$\frac{dC_H}{dt} = [k_a D e^{-kat} + Q_H C_P - (Q_H C_H/R_H) - (Cl_H C_H/R_H)]/V_H \quad \text{(Eq. 6)}$$

where $C_P$, $C_S$, and $C_H$ are the concentrations of lidocaine in the sampled compartment that contains the serum and the highly perfused tissues, more slowly perfused tissues, and hepatoportal system, respectively; $V_P$, $V_S$, and $V_H$ are the physiological volumes of these compartments; $Q_P$, $Q_S$, and $Q_H$ are the serum flow rate for these compartments; $R_S$ and $R_H$ are the retention factors for drug in the more slowly perfused tissues and the hepatoportal tissues, respectively; $Cl_H$ is the hepatic clearance rate; $k_a$ is the apparent absorption rate constant; and $D$ is the oral dose.

The parameters used in the simulations are presented in Table I. Both oral and intravenous data were simulated to determine the impact of increased effective linear volume on the pharmacokinetics of both administration routes.

The results of the simultations, together with the experimental data for the normal subjects and epileptic patients, are presented in Fig. 1. The differences between normal subjects and patients receiving enzyme-inducing agents can be adequately described by a perfusion model that allows only for a change in the effective liver volume rather than for changes in the enzyme activity *per se*.

Perucca and coworkers (1, 2) attributed reduced oral bioavailability of lidocaine in epileptic patients ingesting

**Table I—Pharmacokinetic Parameters Used in the Simulation of Lidocaine Serum Concentration–Time Data for Normal Healthy Volunteers and Epileptic Patients**

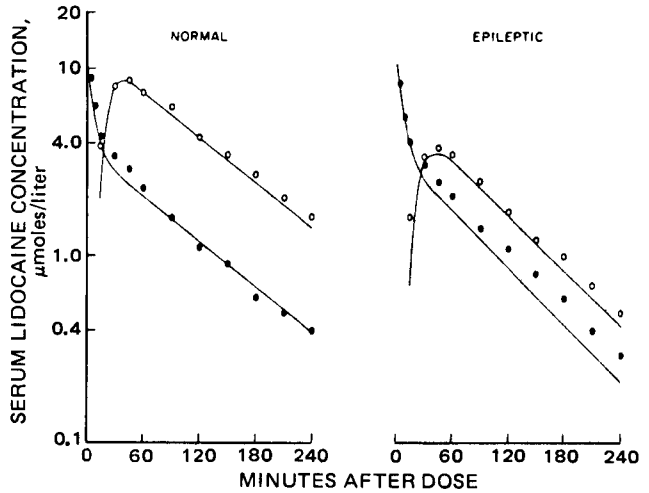

**Figure 1**—*Simulated and observed serum concentrations of lidocaine following intravenous (●) and oral (○) doses to epileptic patients receiving chronic anticonvulsant therapy and normal, healthy volunteers. The solid lines were simulated according to the model in Scheme I, assuming that the effective liver volume $V_HR_H$ was the only difference between the two study groups. (See Table I for parameters used in the simulation.)*

enzyme-inducing agents to a simple increase in hepatic first-pass metabolism. Although the existence of increased first-pass clearance was supported by the present analysis, the data suggest that an alternative mechanism, increased effective linear volume, may be responsible. Due to the increased retention of lidocaine in the liver as a result of increased effective liver volume, the first-pass clearance of lidocaine was much more extensive in epileptic patients than in normal volunteers.

Although the possibility exists for a reduction in the extent of lidocaine absorption in the epileptic patient, no evidence for a similar interaction could be found in the literature. In addition, it is highly unlikely that all of the anticonvulsant drugs used in this study should have the same effect on absorption. However, there is evidence (7–9) for the increase in effective liver volume observed in the present study. An increase in liver mass during anticonvulsant therapy, as well as an increase in binding affinity by the newly synthesized protein, has been postulated as possible mechanisms.

In conclusion, changes in the pharmacokinetics of drugs due to the chronic administration of enzyme-inducing agents has been attributed solely to increases in the intrinsic metabolic activity (6–9). Concomitant changes in blood flow are sometimes postulated as complementary mechanisms for increased clearance (9–11). However, one mechanism that has generally been overlooked is the effect of enzyme-inducing agents on the effective volume of the eliminating organ, *e.g.*, the liver and/or intestinal mucosa, by increasing tissue mass or tissue binding (10–12).

The results of the present analysis indicate that first-pass clearance may be a complex interaction of several pharmacokinetic parameters including blood flow, metabolic activity, and effective tissue volume. The complexity of this interaction may help to explain the apparent discrepancies between enzyme induction observed *in vitro* and *in vivo*.

## Solubility and Partitioning V: Dependence of Solubility on Melting Point

**Keyphrases** □ Solubility—dependence on melting point, crystalline compounds □ Crystalline compounds—polycyclic aromatic hydrocarbons, dependence of solubility on melting point

*To the Editor:*

It is well known that the solubility (in any solvent) of a crystalline solute is at least partially dependent on certain properties of the crystal. The reduction in solubility that is attributable to solute crystallinity is given by:

$$\log \frac{X^C}{X^{SCL}} = \frac{-\Delta S_f(T_m - T)}{2.303RT} + \frac{\Delta C_p(T_m - T)}{2.303RT} - \frac{\Delta C_p}{2.303R} \ln\left(\frac{T_m}{T}\right) \quad \text{(Eq. 1)}$$

where $X^C$ and $X^{SCL}$ are the mole fractional solubilities of the crystalline solute and of the supercooled liquid, respectively; $T_m$ and $T$ are the melting point and temperature of interest, respectively (both in °K); $\Delta S_f$ is the entropy of fusion of the crystal; and $\Delta C_p$ is the difference in heat capacity between the crystal and the supercooled liquid.

The supercooled liquid, SCL, is the result of melting the crystal at the temperature of interest, which is assumed to be below the melting point. It is the equivalent to the "oil" form of the substance. In most cases, it is not possible to produce the oil or molten form below the melting point. For these cases, the supercooled liquid represents a hypothetical state.

To estimate the solubility of crystalline compounds, it is necessary to estimate the crystal–liquid solubility ratio, $X^C/X^{SCL}$. This estimation is normally facilitated by simplifying Eq. 1 to remove the $\Delta C_p$ terms. Two alternative approximations for $\Delta C_p$ are commonly used: $\Delta C_p = 0$ and $\Delta C_p = \Delta S_f$. These approximations lead to the following simplifications.

If $\Delta C_p = 0$:

$$\log \frac{X^C}{X^{SCL}} = -\frac{\Delta S_f(T_m - T)}{2.303RT} \quad \text{(Eq. 2)}$$

If $\Delta C_p = \Delta S_f$:

$$\log \frac{X^C}{X^{SCL}} = -\frac{\Delta S_f}{2.303R} \ln\left(\frac{T_m}{T}\right) \quad \text{(Eq. 3)}$$

Equation 2 was used by Yalkowsky and coworkers (1–4), whereas Eq. 3 was used by Martin *et al.* (5) and was recommended by Hildebrand *et al.* (6).

To verify one or the other of these approximations, it is necessary to find a set of crystalline solutes and a solvent for which $X^{SCL}$ is known. The crystalline polycyclic aromatic hydrocarbons (pah) in benzene are such a system. Since the solutes and solvent have no permanent dipoles, the major cohesive interactions will be the result of London dispersion forces. Dispersion forces are primarily dependent on polarizability, which is proportional to volume for hydrocarbons. Thus, the cohesive energy density of the solutes and the solvent is very similar, and the solutions are very nearly ideal. Because the components of an ideal solution are completely miscible (if they are liquids), it can be assumed that $X^{SCL} = 1.0$ for the polycyclic aromatic hydrocarbons in benzene.

It has been shown that the entropy of fusion of confor-

## Solubility and Partitioning V: Dependence of Solubility on Melting Point

**Keyphrases** □ Solubility—dependence on melting point, crystalline compounds □ Crystalline compounds—polycyclic aromatic hydrocarbons, dependence of solubility on melting point

*To the Editor:*

It is well known that the solubility (in any solvent) of a crystalline solute is at least partially dependent on certain properties of the crystal. The reduction in solubility that is attributable to solute crystallinity is given by:

$$\log \frac{X^C}{X^{SCL}} = \frac{-\Delta S_f(T_m - T)}{2.303RT} + \frac{\Delta C_p(T_m - T)}{2.303RT} - \frac{\Delta C_p}{2.303R} \ln\left(\frac{T_m}{T}\right) \quad \text{(Eq. 1)}$$

where $X^C$ and $X^{SCL}$ are the mole fractional solubilities of the crystalline solute and of the supercooled liquid, respectively; $T_m$ and $T$ are the melting point and temperature of interest, respectively (both in °K); $\Delta S_f$ is the entropy of fusion of the crystal; and $\Delta C_p$ is the difference in heat capacity between the crystal and the supercooled liquid.

The supercooled liquid, SCL, is the result of melting the crystal at the temperature of interest, which is assumed to be below the melting point. It is the equivalent to the "oil" form of the substance. In most cases, it is not possible to produce the oil or molten form below the melting point. For these cases, the supercooled liquid represents a hypothetical state.

To estimate the solubility of crystalline compounds, it is necessary to estimate the crystal–liquid solubility ratio, $X^C/X^{SCL}$. This estimation is normally facilitated by simplifying Eq. 1 to remove the $\Delta C_p$ terms. Two alternative approximations for $\Delta C_p$ are commonly used: $\Delta C_p = 0$ and $\Delta C_p = \Delta S_f$. These approximations lead to the following simplifications.

If $\Delta C_p = 0$:

$$\log \frac{X^C}{X^{SCL}} = -\frac{\Delta S_f(T_m - T)}{2.303RT} \quad \text{(Eq. 2)}$$

If $\Delta C_p = \Delta S_f$:

$$\log \frac{X^C}{X^{SCL}} = -\frac{\Delta S_f}{2.303R} \ln\left(\frac{T_m}{T}\right) \quad \text{(Eq. 3)}$$

Equation 2 was used by Yalkowsky and coworkers (1–4), whereas Eq. 3 was used by Martin *et al.* (5) and was recommended by Hildebrand *et al.* (6).

To verify one or the other of these approximations, it is necessary to find a set of crystalline solutes and a solvent for which $X^{SCL}$ is known. The crystalline polycyclic aromatic hydrocarbons (pah) in benzene are such a system. Since the solutes and solvent have no permanent dipoles, the major cohesive interactions will be the result of London dispersion forces. Dispersion forces are primarily dependent on polarizability, which is proportional to volume for hydrocarbons. Thus, the cohesive energy density of the solutes and the solvent is very similar, and the solutions are very nearly ideal. Because the components of an ideal solution are completely miscible (if they are liquids), it can be assumed that $X^{SCL} = 1.0$ for the polycyclic aromatic hydrocarbons in benzene.

| Fluoranthrene | 11.8 | — | — |

mationally rigid molecules is reasonably constant. Most large aromatic molecules have $\Delta S_f \simeq 13.5$ cal/°K/mole. The values of the entropy of fusion of some polycyclic aromatic hydrocarbons are shown in Table I.

Equations 2 and 3 can be tested by regression analysis of $X^{pah}_{benzene}$ as a function of $(T_m - T)/2.303RT$ and $\ln(T_m/T)/2.303R$, respectively, and comparison of the slopes with the expected value of 13.5 cal/°K/mole.

The values of $(T_m - T)/2.303RT$ and $\ln(T_m/T)/2.303R$ do not differ greatly for low melting solutes studied at room temperature. However, they can significantly deviate from one another at higher temperatures. The values of the two terms as a function of melting point at $T = 300$ and 400 °K are shown in Table II.

The solubilities of 14 polycyclic aromatic hydrocarbons in benzene as determined previously (7) at several temperatures are given in Table III. These data provide an excellent opportunity to test and compare the described equations. Table IV provides a summary of the least-squares regression analysis of the data in Table III against Eqs. 2 and 3. Both curves were forced through the origin.

It is apparent that both equations give excellent correlations with the data. The statistical parameters show better fit with Eq. 2, although the difference is not significant. The major difference between the two equations lies in the value of the slope. If the entropy of fusion of the polycyclic aromatic hydrocarbons is constant, as appears to be the case, the slope is equal to that value. The entropy of fusion calculated from Eq. 2 (16.19 cal/°K/mole) is much closer to the expected value of 13.5 cal/°K/mole than the slope of Eq. 3 (19.58 cal/°K/mole).

The slight difference between the slope obtained with Eq. 2 and 13.5 cal/°K/mole is probably due to a systematic change in cohesive energy density with increasing molecular size and, thus, with increasing melting point. This change would cause the larger and higher melting hydrocarbons to have $X^{SCL}$ progressively less than the ideal value of unity. It would also cause $X^C/X^{SCL}$ to appear to be artifactually high and thus increase the slope over the

**Table IV—Summary of Regression Analyses**

| | Equation 2 | Equation 3 |
|---|---|---|
| Slope = $\Delta S_f$ | 16.19 | 19.58 |
| Correlation coefficient | 0.9945 | 0.9903 |
| Coefficient of variation | 13.49 | 17.91 |
| Standard deviation | 0.120 | 0.159 |
| Number of data points | 67 | 67 |

expected value. (If the analysis is restricted to hydrocarbons that melt at or below 150, the observed slopes are 13.96 for Eq. 2 and 15.40 for Eq. 3.)

Thus, it appears that Eq. 2 is more meaningful than Eq. 3 for quantitating the effects of solute crystallinity on solubility. This finding implies that the value of $\Delta C_p$ for the polycyclic aromatic hydrocarbons is closer to zero than it is to $\Delta S_f$. These results are in agreement with the results obtained for the aqueous solubility of a large number of organic nonelectrolytes of widely varying structure (1).

## REVIEWS

**Analytical Profiles of Drug Substances, Vol. 9.** Edited by KLAUS FLOREY. Academic, 111 Fifth Ave., New York, NY 10003. 1980. 618 pp. 15 × 23 cm.

This book is the ninth in a continuing series that covers the analytical aspects of specific drug entities. It was compiled under the auspices of the Pharmaceutical Analysis and Control Section of the Academy of Pharmaceutical Sciences. The individual profiles or monographs are much more complete than those found in the compendia. The information in the *Analytical Profiles* series not only includes compendial tests but also important supplemental information including synthesis, additional physical properties, data on stability, absorption, metabolism, and excretion, and various analytical methods. In general, each profile is a literature review, but IR, mass spectrometric, UV, and NMR spectra are reproduced along with appropriate crystallographic data. The coverage of the quantitative analytical procedures is usually very complete and includes dosage forms, biological fluids, foodstuffs where appropriate, and related information.

Volume 9 includes 19 new monographs: bacitracin, bretylium tosylate, carbamazepine, cefaclor, cefamandole nafate, cyproheptadine, dibenzepine hydrochloride, digoxin, doxorubicin, fluphenazine decanoate, gentamicin sulfate, haloperidol, khellin, lorazepam, methoxsalen, nadolol, nitrazepam, nitroglycerin, and trifluoperazine hydrochloride. In addition, the *Addendum* contains monographs for griseofulvin and methadone hydrochloride.

While praising *Analytical Profiles* in general, and Volume 9 in particular, this reviewer believes it is time for the editorial board to define more carefully what they want *Analytical Profiles* to become. Some of the drugs covered in Volume 9 are relatively new entities. Others, such as bacitracin, digoxin, haloperidol, khellin, and nitroglycerin, could be called classics. One would have thought that these drugs would have been covered years ago. It is not clear from reading the two monographs on griseofulvin and methadone hydrochloride in the *Addendum* what has been added. Furthermore, a review of the bibliography for griseofulvin shows 18 of 29 references published prior to 1969, six prior to 1974, four prior to 1979, and one unpublished paper authored by the individuals who wrote the monograph. Griseofulvin also appeared in Volume 8 of *Analytical Profiles*. What new information appears that was not published a year ago? This question is not answered. The other drug published in the *Addendum*, methadone hydrochloride, first appeared in Volumes 3 and 4 and probably is in need of updating. But, again, the updated information is not specified. Indeed, this monograph does not even reference the previous material found in Volumes 3 and 4.

The two drugs covered in the *Addendum* brings up another point. There does not seem to be a systematic plan to update the older monographs. With the rapid changes occurring in analytical methodology and instrumentation, such a plan seems to be imperative.

Nevertheless, this series meets a real need by bringing together a concise literature review of the analytical description of important drug entities. Volume 9 is no exception. Its purchase is recommended highly for appropriate libraries, workers in pharmaceutical analysis, and teachers of pharmaceutical chemistry who want to maintain excellent personal libraries.

**Clinical Pharmacokinetics: Concepts and Applications.** By MALCOLM ROWLAND and THOMAS N. TOZER. Lea & Febiger, 600 Washington Square, Philadelphia, PA 19106. 1980. 331 pp. 17 × 25 cm. Price U.S. $29.50 (Canada $35.50).

This book is an important contribution that will facilitate teaching a clinically relevant introductory course in pharmacokinetics. The goal of the authors was to fill a void which, in their own words, "has been the lack of a book that teaches the application of pharmacokinetics in drug therapy" to students, practitioners, and researchers. They are to be congratulated for achieving their goal.

The book is divided into four sections: Concepts, Disposition and Absorption Kinetics, Therapeutic Regimens, and Individualization. Each section is well supported with literature data and computer simulations. Chapters 5, 6, and 11 present a detailed, yet readable, description of clearance concepts (*i.e.*, the factors that determine steady-state plasma concentration). In contrast to most books written in the area of pharmacokinetics, college calculus is not needed to appreciate the textual material. Indeed, the authors remove much of the "mathematical fog" that has shrouded pharmacokinetics.

Several minor limitations to the text should be listed. Nonlinear kinetics is discussed quite briefly; *i.e.*, after reading the text, it is likely that

expected value. (If the analysis is restricted to hydrocarbons that melt at or below 150, the observed slopes are 13.96 for Eq. 2 and 15.40 for Eq. 3.)

Thus, it appears that Eq. 2 is more meaningful than Eq. 3 for quantitating the effects of solute crystallinity on solubility. This finding implies that the value of $\Delta C_p$ for the polycyclic aromatic hydrocarbons is closer to zero than it is to $\Delta S_f$. These results are in agreement with the results obtained for the aqueous solubility of a large number of organic nonelectrolytes of widely varying structure (1).

## REVIEWS

**Analytical Profiles of Drug Substances, Vol. 9.** Edited by KLAUS FLOREY. Academic, 111 Fifth Ave., New York, NY 10003. 1980. 618 pp. 15 × 23 cm.

This book is the ninth in a continuing series that covers the analytical aspects of specific drug entities. It was compiled under the auspices of the Pharmaceutical Analysis and Control Section of the Academy of Pharmaceutical Sciences. The individual profiles or monographs are much more complete than those found in the compendia. The information in the *Analytical Profiles* series not only includes compendial tests but also important supplemental information including synthesis, additional physical properties, data on stability, absorption, metabolism, and excretion, and various analytical methods. In general, each profile is a literature review, but IR, mass spectrometric, UV, and NMR spectra are reproduced along with appropriate crystallographic data. The coverage of the quantitative analytical procedures is usually very complete and includes dosage forms, biological fluids, foodstuffs where appropriate, and related information.

Volume 9 includes 19 new monographs: bacitracin, bretylium tosylate, carbamazepine, cefaclor, cefamandole nafate, cyproheptadine, dibenzepine hydrochloride, digoxin, doxorubicin, fluphenazine decanoate, gentamicin sulfate, haloperidol, khellin, lorazepam, methoxsalen, nadolol, nitrazepam, nitroglycerin, and trifluoperazine hydrochloride. In addition, the *Addendum* contains monographs for griseofulvin and methadone hydrochloride.

While praising *Analytical Profiles* in general, and Volume 9 in particular, this reviewer believes it is time for the editorial board to define more carefully what they want *Analytical Profiles* to become. Some of the drugs covered in Volume 9 are relatively new entities. Others, such as bacitracin, digoxin, haloperidol, khellin, and nitroglycerin, could be called classics. One would have thought that these drugs would have been covered years ago. It is not clear from reading the two monographs on griseofulvin and methadone hydrochloride in the *Addendum* what has been added. Furthermore, a review of the bibliography for griseofulvin shows 18 of 29 references published prior to 1969, six prior to 1974, four prior to 1979, and one unpublished paper authored by the individuals who wrote the monograph. Griseofulvin also appeared in Volume 8 of *Analytical Profiles*. What new information appears that was not published a year ago? This question is not answered. The other drug published in the *Addendum*, methadone hydrochloride, first appeared in Volumes 3 and 4 and probably is in need of updating. But, again, the updated information is not specified. Indeed, this monograph does not even reference the previous material found in Volumes 3 and 4.

The two drugs covered in the *Addendum* brings up another point. There does not seem to be a systematic plan to update the older monographs. With the rapid changes occurring in analytical methodology and instrumentation, such a plan seems to be imperative.

**Clinical Pharmacokinetics: Concepts and Applications.** By MALCOLM ROWLAND and THOMAS N. TOZER. Lea & Febiger, 600 Washington Square, Philadelphia, PA 19106. 1980. 331 pp. 17 × 25 cm. Price U.S. $29.50 (Canada $35.50).

This book is an important contribution that will facilitate teaching a clinically relevant introductory course in pharmacokinetics. The goal of the authors was to fill a void which, in their own words, "has been the lack of a book that teaches the application of pharmacokinetics in drug therapy" to students, practitioners, and researchers. They are to be congratulated for achieving their goal.

The book is divided into four sections: Concepts, Disposition and Absorption Kinetics, Therapeutic Regimens, and Individualization. Each section is well supported with literature data and computer simulations. Chapters 5, 6, and 11 present a detailed, yet readable, description of clearance concepts (*i.e.*, the factors that determine steady-state plasma concentration). In contrast to most books written in the area of pharmacokinetics, college calculus is not needed to appreciate the textual material. Indeed, the authors remove much of the "mathematical fog" that has shrouded pharmacokinetics.

Several minor limitations to the text should be listed. Nonlinear kinetics is discussed quite briefly; *i.e.*, after reading the text, it is likely that

a student could not adequately adjust a patient's phenytoin dose. Since the authors have been involved in pioneering work in this field, it may be that such material will be included in an upcoming text to which they allude. However, in this reviewer's opinion, a more detailed treatment of nonlinear kinetics would have been useful.

Another significant defect of this text is that it is difficult to identify the primary source for some textual material. The source of the data contained in the tables and figures is identified. However, it is generally not possible to identify the source of information within the body of the text.

This book is well written and should be considered as a standard text for introductory courses in Pharmacy Baccalaureate and Doctor of Pharmacy programs and for freshman graduate courses in pharmaceutics and pharmacology.

**Second Supplement to USP XX and NF XV.** Drug Standards Division, United States Pharmacopeial Convention, 12601 Twinbrook Parkway, Rockville, MD 20852. 245 pp. 20 × 29 cm. Price $8.00.

The *Second Supplement* is cumulative with the first one and contains changes that constitute revisions in the USP XX and NF XV effective May 1, 1981. Additions and deletions in the USP XX official monographs comprise the largest section, totaling 133 pages, whereas those in the General Requirements for Tests and Assays section are contained in 12 pages. Under General Information are selected portions of the regulations promulgated under the Controlled Substances Act and portions of the Poison Packaging Act and Regulations, of interest to students and practitioners in pharmacy and medicine. Changes in the official NF XV monographs comprise almost 20 pages and are followed by an appendix containing excerpts from federal regulations on antibiotics and an index to this supplement.

**Solid Pharmaceutics: Mechanical Properties and Rate Phenomena.** By JENS THURØ CARSTENSEN. Academic, 111 Fifth Ave., New York, NY 10003. 1980. 259 pp. 15 × 23 cm. Price $35.00.

This brief book, written in terse mathematical style, is an ambitious attempt to consolidate the more important research in the field of solid pharmaceutics. The first chapter contains an introduction to the characteristics of single-component systems, with emphasis on the properties of crystals. Chapter 2 deals with particulate solids and their dimensions and properties. Chapter 3 extends this treatment to two-component systems and includes such topics as blending and the effect of moisture on solids. The next two chapters are devoted to successive stages in the manufacture of tablets: precompression operations, including wet granulation, dry milling, tablet formulation, and lubrication, followed by compression and hardness testing. The book concludes with a section on the physical properties of solid dosage forms, particularly the dissolution of tablets and capsules and their chemical stability.

Solid pharmaceutics is perhaps the area in which the catholicity of the pharmaceutical sciences is most in evidence. In his scholarly treatment of the subject, Carstensen draws heavily on the literature of powder technology, crystallography, chemical engineering, polymer science, and metallurgy. Yet he does not hesitate to offer his own views on controversial subjects. In discussing the upward curvature observed in Hixson–Crowell plots of the cube root of mass *versus* time, he suggests that deviations from straight-line behavior can be attributed to the lack of isometry of most real particles. He then proceeds to show how one can introduce a shape factor to correct for this deviation. In discussing angle of repose, he points out that the equations usually employed predict that as the particle diameter becomes smaller, the angle of repose approaches an infinite value rather than the value most consistent with the physical model, 90°. To remedy this, the cohesional and frictional coefficients are expressed in terms of trial functions with proper boundary conditions and an equation is obtained based on the force diagram for a powder heap.

Particularly lucid is his treatment of Prout–Tompkins kinetics of solid-state decomposition. Carstensen also shows how the boundary conditions of the Prout–Tompkins model can be modified to treat data that follow first-order kinetics.

Where appropriate, the text is augmented with solved quantitative examples, copious tables of empirical data, and more than 100 beautifully drawn, uncluttered, line figures. Those familiar with Carstensen's earlier treatments of this subject, "Pharmaceutics of Solids and Solid Dosage Forms" and "Theory of Pharmaceutical Systems," will see some of the same figures and numerical examples in the present volume, but repetition has been kept to a minimum. The problems are relatively easy and are mainly computational exercises.

One may make some minor criticisms of the book, especially with regard to topics such as lyophilization and spray drying, which are given short shrift. Symbols often are introduced without definition, and unconventional symbols are substituted unnecessarily for more familiar ones. For example, in the Bragg equation, $R_0$ rather than $d$ is used for interplanar spacing. The Greek letter $\theta$ is used for time. More confusing, $F$ is used for the Helmholtz energy rather than $A$. Formerly, of course, $F$ was used in textbooks for the Gibbs free energy. There are a few errors. An exponent has been omitted in the Shotten–Hersey equation (V-3-24a). In the plot of water vapor pressure *versus* moles of water, one plateau for sodium phosphate is mislabeled (Fig. III-15). But these are minor points and in no way detract from my opinion that the author has treated a comprehensive set of difficult problems with excellent conceptual organization and clarity.

Pharmaceutical development scientists and graduate students who require a quantitative understanding of the operations related to the manufacture of solid dosage forms will find this slender volume very useful. It is not for casual reading, and the nonspecialist who wants a broad overview of the field will have to find it elsewhere.

More confusing, $F$ is used for the Helmholtz energy rather than $A$. Formerly, of course, $F$ was used in textbooks for the Gibbs free energy. There are a few errors. An exponent has been omitted in the Shotten–Hersey equation (V-3-24a). In the plot of water vapor pressure *versus* moles of water, one plateau for sodium phosphate is mislabeled (Fig. III-15). But these are minor points and in no way detract from my opinion that the author has treated a comprehensive set of difficult problems with excellent conceptual organization and clarity.

Pharmaceutical development scientists and graduate students who require a quantitative understanding of the operations related to the manufacture of solid dosage forms will find this slender volume very useful. It is not for casual reading, and the nonspecialist who wants a broad overview of the field will have to find it elsewhere.

# Free Fatty Acid-Induced Platelet Aggregation: Studies with Solubilized and Nonsolubilized Fatty Acids

G. M. ZENTNER *, J. R. CARDINAL ‡, and S. W. KIM ‡x

Received September 15, 1980, from the *School of Pharmacy, University of Connecticut, Storrs, CT 06268, and the ‡College of Pharmacy, Department of Pharmaceutics, University of Utah, Salt Lake City, UT 84112. Accepted for publication February 13, 1981.

**Abstract** □ The aggregation response of washed porcine platelets to the sodium salts of stearic, oleic, palmitic, and myristic acids was analyzed turbidometrically. The fatty acids were prepared as aqueous suspensions and as taurocholate- or albumin-solubilized systems. The final concentration of fatty acid in the platelet preparation varied between 70 and 600 $\mu M$. This range was within or below the normal physiological limits of 300–1200 $\mu M$. Platelet aggregation was observed with both the suspended and taurocholate-solubilized fatty acids. The extent of platelet aggregate formation increased with the fatty acid concentration and chain length. With the exception of stearate, the taurocholate-solubilized fatty acids were more active than the suspensions. Albumin-solubilized fatty acids were devoid of platelet aggregating activity. Particle-size analysis of the solubilized fatty acids indicated that fatty acid precipitation had occurred subsequent to the addition of taurocholate-solubilized fatty acids to the platelets. This precipitation did not occur with the albumin-solubilized systems, suggesting that the fatty acids must assume a particulate physical state to induce aggregation. Platelet aggregation induced by fatty acids was not inhibited by 80 n$M$ epoprostenol, 75 $\mu M$ alprostadil, or 150 $\mu M$ indomethacin. This finding indicated that the fatty acid-induced platelet aggregation was independent of cyclic AMP-related calcium shift, cyclooxygenase–arachidonate, or granular nucleotide release mechanisms.

**Keyphrases** □ Fatty acids—induced platelet aggregation, solubilized and nonsolubilized fatty acids □ Platelets—free fatty acid-induced aggregation, solubilized and nonsolubilized fatty acids □ Coagulation—free fatty acid-induced platelet aggregation, solubilized and nonsolubilized fatty acids

Platelets are capable of several reactions necessary for participation in the hemostatic response. They "stick" to exposed subendothelial components and artificial surfaces (adhesion), as well as to one another (aggregation), in response to seemingly diverse stimuli. In addition, platelets release endogenous, pharmacologically active substances that accentuate adhesion, aggregation, and coagulation reactions. This reaction is referred to as platelet release. Thus, platelets can initiate and stimulate several phases of the overall coagulation process, although the aggregation reaction alone results in effective hemostatic blockage in small blood vessels and capillaries (1).

## BACKGROUND

Thrombin, collagen, adenosine diphosphate (ADP), epinephrine, and long chain ($>C_{14}$) unesterified fatty acids are compounds encountered *in vivo* that have been shown to initiate platelet aggregation (1–10). Platelets normally remain unaggregated in most disease-free individuals. That they aggregate in response to various threats to hemostasis suggests a delicate balance between circulating platelets and the aggregation-initiating substance(s). Disruption of this balance may result in either control or exacerbation of disease. For example, the normal response to vascular injury involves the production of thrombin and subsequent formation of a fibrin network (11). In this case, platelet aggregation induced by thrombin would be a disease controlling reaction through augmentation of thrombus formation to control bleeding. In contrast, disease states that result in elevated blood fatty acid levels are accompanied by an increased incidence of thromboembolism and platelet hyperaggregability in the absence of vascular injury (12–17). Here the platelet aggregation response exacerbates the disease condition.

The delicate balance between platelet aggregation or nonaggregation in response to a stimulus is exemplified by the platelet–fatty acid interaction. Numerous studies (6–10) have demonstrated hypercoagulability and platelet aggregation both *in vivo* and *in vitro* in response to administered fatty acid concentrations within the normal physiological range of 300–1200 $\mu M$. The fact that most individuals are free from platelet aggregation abnormalities when *in situ* fatty acid levels range from 300 to 1200 $\mu M$ suggests that the physical state of the administered free fatty acids is a critical determinant of aggregating activity.

It has been argued that the platelet aggregating activity of free fatty acids is related to micellar aggregates formed in aqueous solution (8–10, 18). Since the critical micellar temperature is >37° for most poorly soluble long chain fatty acids (19), a suspension state, rather than a micellar state, is anticipated. Inspection of data (7, 8, 10, 18) correlating platelet aggregating activity with free fatty acid chain length leads to the generalization that aggregating activity is negligible below $C_{14}$, with activity increasing markedly with chain lengths up to $C_{20}$; *i.e.*, the fatty acids least likely to form micelles exhibit the greatest platelet aggregating activity. This trend holds for both saturated and unsaturated fatty acids when the aggregation of washed platelet preparations *in vitro* is examined (9, 10, 20).

In the present study, the aggregation of washed porcine platelets was investigated as a function of the physical state of various fatty acid preparations. Final washed platelet fatty acid concentrations (70–600 $\mu M$) within normal physiological limits were examined (21, 22). The sodium salts of stearic, palmitic, myristic, and oleic acids were prepared

© 1981, American Pharmaceutical Association

as suspensions in buffered isotonic saline or as solubilized aqueous systems with either sodium taurocholate or albumin as the solubilizing agent. The effects of the nonspecific platelet aggregation inhibitors alprostadil, epoprostenol, and indomethacin (23) serve as a basis for mechanistic interpretations of the fatty acid-induced platelet aggregation reaction.

## EXPERIMENTAL

Slaughterhouse porcine blood was collected into polyethylene vessels containing 7.5 ml of 0.077 *M* edetate disodium[1] and 0.71 *M* anhydrous α-D-glucose[1]/92.5 ml of whole blood as an anticoagulant. The pH of the anticoagulant solution was adjusted to 7.4 with sodium hydroxide. Collected blood was placed into an ice bath until processed further.

Aqueous suspensions of oleic[1], palmitic[1], or myristic[1] acid were gently heated with a slight molar excess of aqueous sodium hydroxide to form the respective sodium salts. The pH values of these solutions were >10.0 after complete dissolution of the fatty acid. The solutions were cooled to room temperature; the insoluble fatty acid salt was collected and washed repeatedly with deionized water to remove excess sodium hydroxide. This product was vacuum dried at 30° for 24 hr. Sodium stearate[1] was used as received. All fatty acids were >99% pure as listed by the supplier.

Cholic acid[1] was recrystallized repeatedly from 95% ethanol. Purity was checked with UV spectroscopy and TLC, using isoamyl acetate[2]–propionic acid[2]–*n*-propanol[2]–water (40:30:20:10) as the developer. Taurine[1] was used as received. Sodium taurocholate was synthesized according to Lack *et al.* (24). The synthesized sodium taurocholate was found to be pure by TLC.

Epoprostenol[3] ($PGI_2$), alprostadil[3] ($PGE_1$), indomethacin[1], disodium adenosine diphosphate[1], fibrinogen[4] (porcine, fraction I), and albumin[1] (porcine, fraction V) were used as received. Reagents[1,2] in the phosphate, tromethamine, Tyrodes, and imidazole buffers were reagent grade and used as received.

Washed porcine platelets were prepared by Haslam's method (25) at 5°. Polycarbonate centrifuge tubes were used for all separations. Final suspension of platelets was in a 9:1 solution of 0.15 *M* NaCl and 0.15 *M* tromethamine buffer, pH 7.4. Platelets that did not resuspend immediately with gentle agitation were discarded. Platelets were counted and examined under phase contrast light microscopy[5] at 600× in a hemocytometer. The platelets were seen as individual entities without pseudopod formation, an observation that was confirmed by scanning electron microscopy[6] at 2K magnification. On this basis, the platelets were judged to be of normal morphology and in the unaggregated state. Platelet counts were adjusted to ~700,000/mm$^3$ for all aggregation experiments. Platelets prepared in this manner, and subsequently stored in an ice bath, remained viable for >6 hr without spontaneous aggregation.

The platelet aggregation reaction was followed turbidimetrically (26) with a commercially available aggregometer[7]. Aggregation was recorded as an increase in the monochromatic (600 nm) light transmittance of a washed platelet suspension with time. Results were relative to blanks containing all reagents except platelets. The 100% transmittance baseline was set with the blanks. Thus, the magnitude of the light transmittance was directly proportional to the extent of platelet aggregation.

For the aggregation experiments, 500 μl of washed porcine platelet suspension was added to a siliconized aggregation cell. Then 20 μl of 0.34 m*M* $CaCl_2$ and 40 μl of 0.11 mg of fibrinogen/ml were added. The system was equilibrated to 37° (~3 min) before proceeding. Under these conditions, the platelets did not aggregate spontaneously during 15 min of observation.

Aggregation was induced with either disodium adenosine diphosphate or fatty acid. Disodium adenosine diphosphate was prepared at a concentration of 2.4 m*M* in an isotonic imidazole–hydrochloric acid buffer, pH 6.8. The fatty acids were prepared at a concentration of 4 m*M* in isotonic phosphate buffer, pH 7.4, with and without 47 m*M* sodium taurocholate or 26 g % albumin as a solubilizing agent. Addition of 80 μl of the disodium adenosine diphosphate solution or 10–100 μl of the various fatty acid preparations to the calcium and fibrinogen equilibrated platelets marked the starting point of the aggregation reaction. Final reagent concentrations were 1.03 m*M* $Ca^{2+}$, 16 μg of fibrinogen/ml, 0.29 m*M* disodium adenosine diphosphate, 70–600 μ*M* fatty acid, 0.83–7.12 m*M* sodium taurocholate, and 4.0 g % albumin.

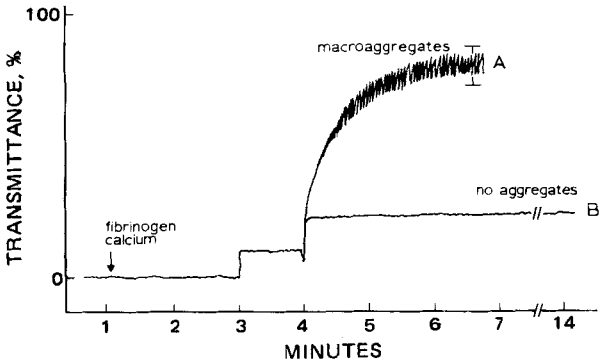

**Figure 1**—*ADP-induced platelet aggregation. Reagent concentrations were: A, 0.29 m*M *ADP; and B, 0.29 m*M *ADP with 75 μ*M *alprostadil or 80 n*M *epoprostenol. Each reagent was administered at 3 min.*

The effects of epoprostenol, alprostadil, and indomethacin on fatty acid-induced platelet aggregation were investigated. The prostaglandins were prepared in buffered solution at the respective pH values of maximum stability[3] immediately prior to addition to the platelets to minimize aqueous degradative effects. Indomethacin was freshly prepared each day. Epoprostenol was prepared at a concentration of 57.0 μ*M* in isotonic tromethamine buffer, pH 8.7. Alprostadil was prepared at a concentration of 0.5 m*M* in isotonic phosphate buffer, pH 7.4. Indomethacin was prepared at a concentration of 1.0 m*M* in Tyrodes' buffer, pH 7.4. The final concentrations in the platelet media were 80 n*M* epoprostenol, 75 μ*M* alprostadil, and 150 μ*M* indomethacin. Additions of these inhibitors to the platelets were made ~1 min prior to the fatty acid or disodium adenosine diphosphate additions.

Behavior of the solubilized fatty acid preparations in the aggregation cell was investigated under simulated conditions. The sodium taurocholate or albumin-solubilized fatty acid preparations were diluted to the same extent as in the aggregation cell. Isotonic phosphate buffer, pH 7.4, filtered three times through 0.22-μm microporous filters[8] was used as the diluent for all procedures. These samples were analyzed as a function of time and particle size with an electronic particle analysis instrument[9] equipped with a 30-μm aperture tube and a 100-μl manometer. The instrument was calibrated with 2.2-μm latex beads. The minimum detection limit was ~0.45 μm (diameter) under these conditions. Analysis of particle size with suspended fatty acid (nonsolubilized) preparation could not be completed due to the blockage of both the 30- and 100-μm aperture tubes. This finding indicated the presence of at least a small percentage of very large particles in these suspensions.

## RESULTS

The aggregation response to 0.29 m*M* ADP was followed turbidimetrically as shown in curve A of Fig. 1. This tracing was the average platelet aggregation response of five animals. The aggregation was immediate and monophasic, leading to macroscopic aggregates (macroaggregates) visible to the unaided eye. Higher concentrations of ADP did not result in further increases in light transmittance. Curve B shows that the addition of either 75 μ*M* alprostadil or 80 n*M* epoprostenol completely inhibited ADP-induced platelet aggregation. The stepwise increases in light transmittance at 3 and 4 min reflected the dilution of the washed platelet preparations by the reagent additions and did not represent aggregation. The imidazole–hydrochloric acid buffer system showed no intrinsic platelet aggregating activity.

The relative platelet aggregating activities of various fatty acid suspensions are compared in Fig. 2. There were no distinguishable differences in the average aggregation patterns elicited by the saturated (stearate) or monounsaturated (oleate) $C_{18}$ fatty acids at a final concentration of 600 μ*M*. Aggregation proceeded rapidly with production of large macroaggregates in a clear medium. The response to 600 μ*M* palmitate ($C_{16}$) differed from the $C_{18}$ fatty acids in the time course to macroaggregate formation. Though immediate in onset, the palmitate-induced aggregation proceeded somewhat slower than the stearate or

**Table I—Final Sodium Taurocholate Concentrations in Relation to Solubilized Fatty Acid Concentrations**

| Final Solubilized Fatty Acid Concentrations, $\mu M$ | Final Sodium Taurocholate Concentrations, m$M$ |
|---|---|
| 600 | 7.12 |
| 320 | 3.85 |
| 170 | 2.01 |
| 70 | 0.83 |

oleate reactions. Myristate ($C_{14}$) was significantly less active than either the $C_{16}$ or $C_{18}$ fatty acid suspension. The aggregation response to myristate was minimal and did not result in visible aggregate formation. Thus, a general trend of aggregating activity increasing with chain length was observed when fatty acid suspensions were added to washed porcine platelets.

The data presented in Fig. 3 show the general relationship between fatty acid concentration and platelet aggregation. The speed and extent of palmitate-induced aggregation increased with fatty acid concentration. The 320 and 600 $\mu M$ additions resulted in macroaggregate formation. Generally, this trend was also followed by oleate and stearate. However, as anticipated from Fig. 2, the $C_{18}$ fatty acids were more active than equivalent amounts of palmitate, with macroaggregates formed at all concentrations examined (70–600 $\mu M$).

The platelet aggregating activities of equal concentrations of fatty acids in suspended and solubilized physical states were compared (Fig. 4). Sodium taurocholate was the solubilizing agent. The final taurocholate concentrations were related to the final fatty acid concentrations (Table I). Figure 4*a* shows that platelet macroaggregates formed more rapidly with taurocholate-solubilized 70 $\mu M$ oleate than with suspended 70 $\mu M$ oleate. Taurocholate-solubilized palmitate and myristate systems also were more active than the suspended counterparts at equivalent fatty acid concentrations (Figs. 4*b* and 4*c*). The 170 $\mu M$ palmitate and 600 $\mu M$ myristate suspensions elicited a weak platelet aggregation reaction. However, taurocholate-solubilized 170 $\mu M$ palmitate and 600 $\mu M$ myristate elicited platelet aggregation responses that led to macroaggregate formation. Comparisons between solubilized and suspended oleate, palmitate, and myristate at concentrations not shown in Fig. 4 followed this same trend; taurocholate-solubilized fatty acids were more active inducers of aggregation than the respective suspension counterparts. Sodium taurocholate alone was devoid of activity at all concentrations examined (Table I).

The suspended 70 $\mu M$ stearate system was more active than the taurocholate-solubilized 70 $\mu M$ stearate (Fig. 4*d*). At higher stearate concentrations, this same pattern was noted; however, macroaggregates were produced with both the taurocholate-solubilized and suspended forms. Thus, a reversal in the trend observed with the other fatty acids was noted with stearate.

The aggregating activities of taurocholate-solubilized oleate, stearate, palmitate, and myristate are compared in Fig. 5. Oleate (70 $\mu M$) elicited a rapid platelet aggregation response with macroaggregate production. Stearate, palmitate, and myristate were completely devoid of aggregating activity at this concentration.

The aggregation response to albumin-solubilized fatty acids is shown in Fig. 6. Turbidimetric tracings and light microscopy both indicated that platelet aggregation had not occurred in response to either albumin-solubilized 600 $\mu M$ oleate or palmitate. In the suspended state, these

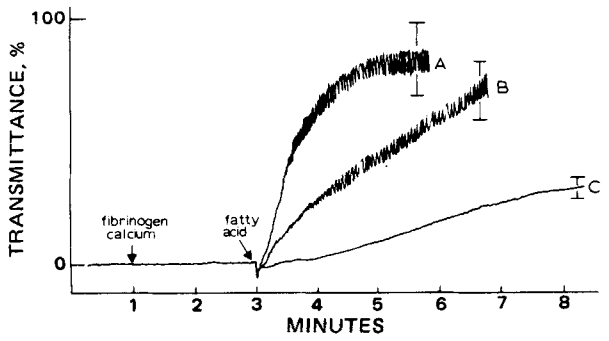

**Figure 2**—*Platelet aggregation response to 600 $\mu$M fatty acid suspensions as a function of chain length. Key: curve A, oleate or stearate ($C_{18}$); curve B, palmitate ($C_{16}$); and curve C, myristate ($C_{14}$).*

concentrations of oleate and palmitate both elicited an immediate platelet aggregation response leading to macroaggregate formation (Fig. 2).

With macroaggregate production, the formation of a fibrous mucoid network subsequent to aggregate appearance was noted and was postulated to be fibrin. In platelet-free blanks, this network did not form. To

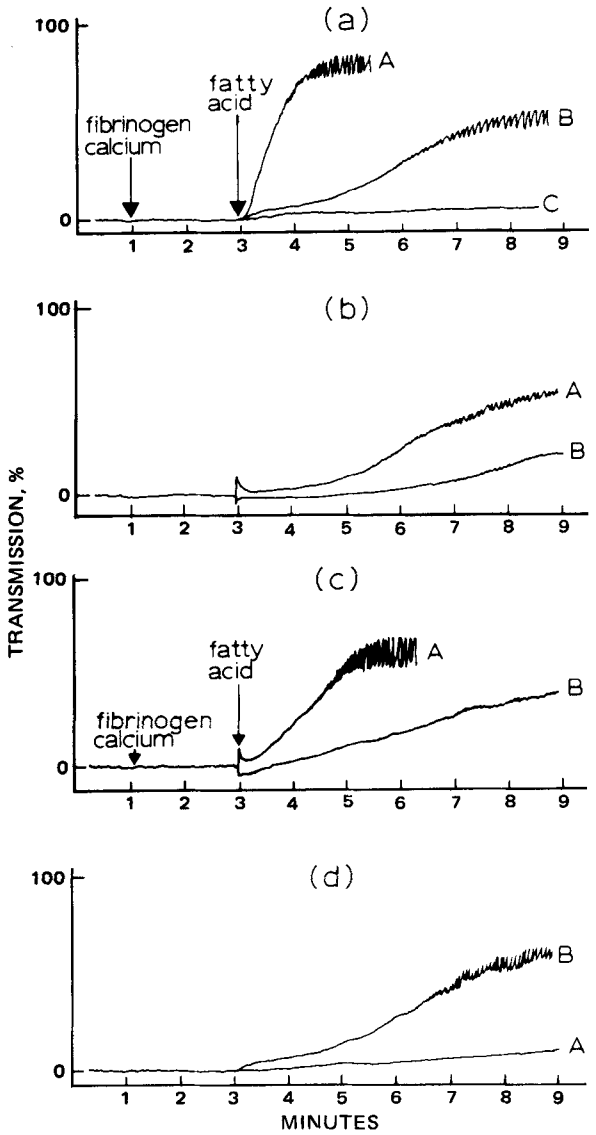

**Figure 4**—*Platelet aggregation as a function of the physical state of 70 $\mu$M oleate (a), 170 $\mu$M palmitate (b), 600 $\mu$M myristate (c), and 70 $\mu$M stearate (d). Key: curves A, sodium taurocholate-solubilized fatty acids; curves B, suspended fatty acids; and curve C, sodium taurocholate without fatty acid.*

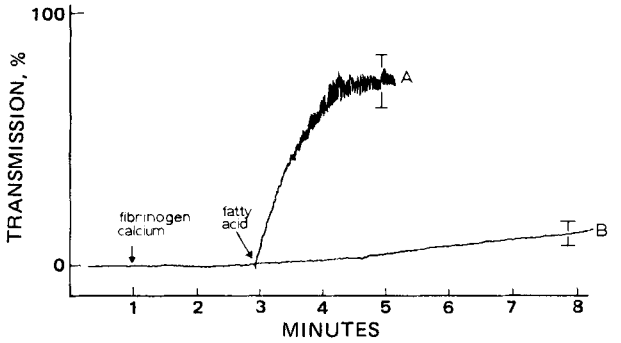

**Figure 5**—*Platelet aggregating activities of taurocholate-solubilized 70 μM fatty acids. Key: curve A, oleate; and curve B, stearate, palmitate, or myristate.*

determine its significance in relation to platelet aggregation, the calcium and fibrinogen requirements of washed porcine platelet aggregation were studied. Aggregation was induced with taurocholate-solubilized 170 *μM* oleate. Curve A in Fig. 7 shows that macroaggregate formation did not depend on fibrinogen. Without fibrinogen, the aggregation pattern was essentially identical to that with fibrinogen, although the fibrous mucoid network did not form in the absence of fibrinogen. Curve B of Fig. 7 reveals that calcium was required for aggregation. Without calcium, neither platelet aggregates nor the fibrous mucoid network formed. Although fibrinogen was not a requirement for aggregation, both fibrinogen and calcium were included in all trials to facilitate comparison with the predominant methodology in the literature.

The effects of alprostadil, epoprostenol, and indomethacin on platelet aggregation induced by suspended fatty acids are given in Fig. 8. A monophasic aggregation pattern leading to macroaggregate formation proceeded with or without the inhibitors. The time courses and extents of aggregation were not altered or inhibited by these agents.

The observed platelet aggregation patterns elicited by suspended or taurocholate-solubilized stearate are given in Fig. 9. Inhibitors were present as indicated. Aggregation activity increased with the taurocholate-solubilized stearate concentration up to 320 *μM*. The solubilized 600 *μM* system was somewhat less active than the solubilized 170 and 320 *μM* systems. However, macroaggregates formed with all but the taurocholate-solubilized 70 *μM* stearate system within the 10-min observation period. The platelet aggregation response to the taurocholate-solubilized stearate systems was unaltered by the inhibitors. The activity of the suspended stearate systems increased with concentration. Platelet aggregation induced by suspended stearate was more rapid than with taurocholate-solubilized stearate at all concentrations. The platelet response to suspended stearate was unaltered by the inhibitors; the possible exception was the aggregation induced by suspended 70 *μM* stearate. In this case, a decreased aggregation response was observed with both alprostadil and indomethacin. However, aggregate formation still was extensive.

Platelet aggregation patterns observed subsequent to additions of taurocholate-solubilized oleate are given in Fig. 10. Inhibitors were present as indicated. The 70 and 170 *μM* solubilized systems (Fig. 10*a*) induced a monophasic macroaggregate reaction. The response to the 320 and 600 *μM* solubilized oleate was anomalous. The 320 *μM* addition (Fig. 10*b*, curve A) elicited a biphasic response. Small aggregates appeared

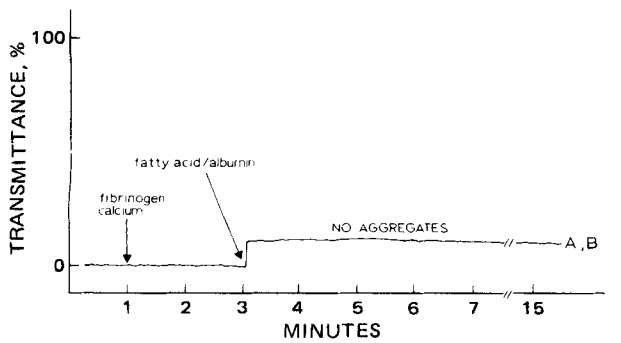

**Figure 6**—*Platelet aggregation response to albumin-solubilized fatty acids. Final fatty acid concentrations were: A, 600 μM oleate; and B, 600 μM palmitate. The final albumin concentration was 4 g %.*

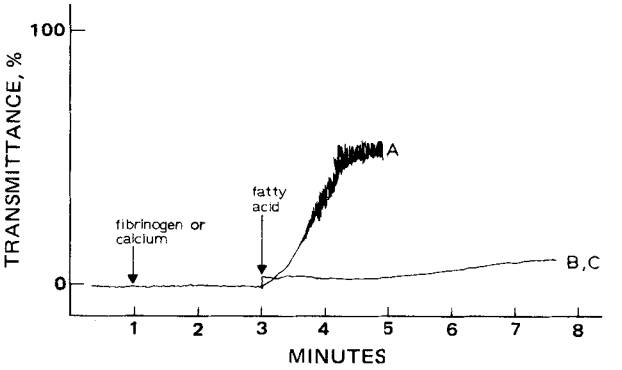

**Figure 7**—*Calcium and fibrinogen requirements of washed porcine platelet aggregation. Aggregation was induced with taurocholate-solubilized 170 μM oleate under the following conditions: curve A, 1 mM calcium without fibrinogen; curve B, 16 μg of fibrinogen/ml without calcium; and curve C, no calcium or fibrinogen.*

during the first phase and then disappeared during the second phase, leaving a clear solution devoid of visible aggregates. The 600 *μM* system elicited a monophasic response that also resulted in a clear, aggregate-free, solution.

Platelets were not visible in either of these clear solutions under 600× phase contrast light microscopy. Scanning electron micrographs at 2200× revealed unidentifiable debris. This finding was viewed as evidence for platelet lysis in response to the taurocholate-solubilized 320 and 600 *μM* oleate systems. This behavior was not observed with taurocholate alone or with any other taurocholate-solubilized fatty acid system examined. The aggregation inhibitors did not alter the observed responses to taurocholate-solubilized oleate except at the 320 *μM* concentration. Curve B of Fig. 10*b* reveals that epoprostenol actually enhanced the aggregate production. In the presence of epoprostenol, a monophasic response resulting in stable macroaggregate formation was observed.

The behavior of the taurocholate-solubilized oleate and stearate solutions was studied. Samples were diluted to the same concentrations used in the aggregation experiments and were examined with an electronic particle-size analyzer (Figs. 11 and 12). In all cases, the number of particles above 0.72 μm was negligible over the 10-min observation period. No particles were detected in the 4 m*M* fatty acid–47 m*M* sodium taurocholate stock solutions prior to dilution.

Dilution of a taurocholate-solubilized stock solution of oleate to 70 and 170 *μM* oleate resulted in rapid particle formation in the 0.45–0.72-μm diameter range. The taurocholate-solubilized 320 and 600 *μM* oleate systems precipitated much less. Particles were not detected in a 7.12 m*M* taurocholate system containing no fatty acid.

The behavior of taurocholate-solubilized stearate contrasted with oleate in that precipitation increased as the stearate concentration increased. However, in all cases, the extent of the stearate precipitation was less than with the taurocholate-solubilized 70 and 170 *μM* oleate systems.

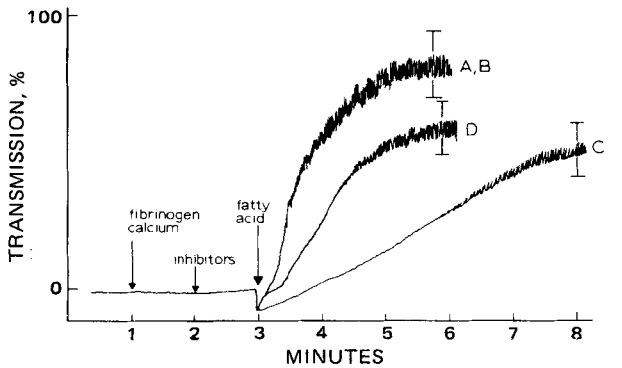

**Figure 8**—*Effects of alprostadil, epoprostenol, and indomethacin on platelet aggregation induced by suspended fatty acids. Key: curve A, 600 μM stearate with and without 75 μM alprostadil, 80 nM epoprostenol, or 150 μM indomethacin; curve B, 600 μM oleate with and without 150 μM indomethacin; curve C, 320 μM palmitate with and without 80 nM epoprostenol; and curve D, 170 μM oleate with and without 80 nM epoprostenol, 75 μM alprostadil, or 150 μM indomethacin.*

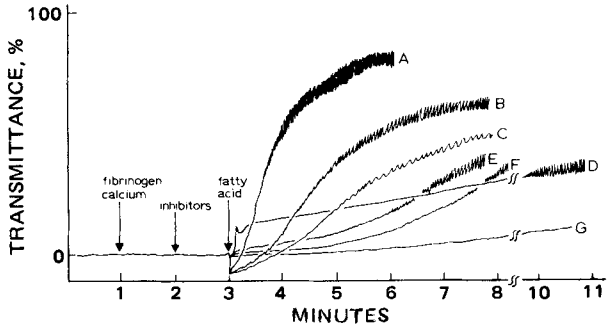

**Figure 9**—*Platelet aggregation as induced by taurocholate-solubilized and suspended stearate. Key (suspended stearate): curve A, 600 μM stearate with and without 75 μM alprostadil, 80 nM epoprostenol, or 150 μM indomethacin; curve B, 70 μM stearate; and curve C, 70 μM stearate with 75 μM alprostadil or 150 μM indomethacin. Key (taurocholate-solubilized stearate): curve D, 600 μM stearate with and without 80 nM epoprostenol; curve E, 320 μM stearate with and without 75 μM alprostadil, 80 nM epoprostenol, or 150 μM indomethacin; curve F, 170 μM stearate with and without 80 nM epoprostenol; and curve G, 70 μM stearate.*

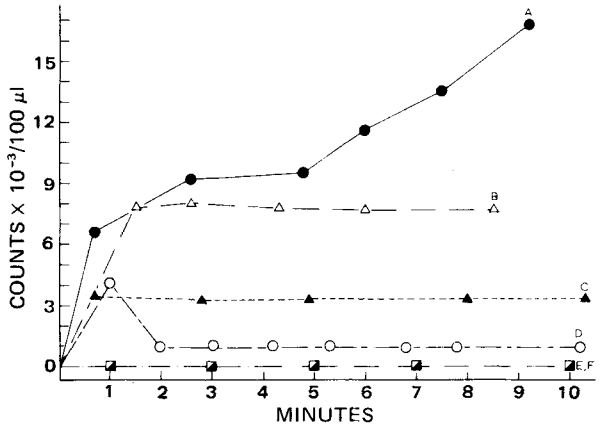

**Figure 11**—*Particle-size analysis of 4 mM oleate solubilized with either 47 mM sodium taurocholate or 26 g % albumin subsequent to dilution to 70 μM oleate/0.83 mM taurocholate (curve A), 170 μM oleate/2.01 mM taurocholate (curve B), 320 μM oleate/3.85 mM taurocholate (curve C), 600 μM oleate/7.12 mM taurocholate (curve D), 7.12 mM taurocholate (curve E), and 600 μM oleate/4 g % albumin (curve F). Size range was 0.45–0.72 μm in diameter.*

Prevention of fatty acid precipitation from the solubilized systems was possible if the final sodium taurocholate concentration was 47 m*M*. However, this concentration resulted in immediate and complete lysis of platelets. To alleviate this problem, it was necessary to replace taurocholate with another solubilizing agent, albumin, that would solubilize the fatty acids without lysing platelets. Particle-size analysis of albumin-solubilized oleate and palmitate (Figs. 11 and 12) indicated that no particle formation occurred above the 0.42-μm limit of detection. Light microscopy confirmed that the platelets were not lysed or visibly damaged by the albumin concentration employed.

## DISCUSSION

Porcine platelets resemble human platelets in several key areas (27): (*a*) membrane proteins; (*b*) monophasic aggregation induced by high concentrations of ADP; (*c*) potent inhibition of ADP, thrombin, and collagen-induced aggregation by alprostadil and inhibition of ADP by AMP; and (*d*) similar nucleotide content in the platelet storage granules. The present report indicates that the washed porcine platelet system can be used to distinguish the platelet aggregating activities of ADP and various fatty acids in suspended or solubilized physical states. Therefore, the porcine platelets were believed to be a reasonable *in vitro* model for the simulated study of human platelet behavior.

The platelet aggregation reaction is complex. To correlate the platelet responses to the many and varied aggregation inducing and inhibiting agents, a basic platelet reaction hypothesis has been proposed (23). Under this system, induction of platelet aggregation occurs with the interaction of inducing agents with receptor sites located on the platelet surface; changes thus induced lead to liberation of a transmitter substance [believed to be calcium ions (23, 28–30)] into the cytosol. The transmitter stimulates ATP-dependent contractile processes leading to aggregation.

Alprostadil and epoprostenol stimulate adenylate cyclase (1, 3, 31–33), which leads to increased production of cyclic adenosine monophosphate (AMP) in platelets. Elevated cyclic AMP results in platelet vesicular uptake of calcium ions from the cytosol (28, 30), which is accompanied by a reduction in platelet aggregation. Other work has shown that alprostadil can effectively inhibit platelet aggregation independent of cyclic AMP (34). The inhibitory effects of prostaglandins on platelet aggregation are thought to occur at the intermediate transmission step in the basic platelet reaction hypothesis and are, therefore, believed to be independent of the type of inducer (23). Literature data support this belief (1, 23, 29–31, 33) and suggest that epoprostenol is 30–40 times more potent than alprostadil (31).

Included in the basic platelet reaction hypothesis is the release of arachidonic acid from platelet membrane phospholipids through the action of phospholipase $A_2$ (31). The arachidonic acid then is converted into the cyclic endoperoxide prostaglandins $G_2$ and $H_2$ by cyclooxygenase. The endoperoxides react by alternate pathways to form thromboxane $A_2$ and epoprostenol. The endoperoxides and thromboxane $A_2$ are potent inducers of platelet aggregation while epoprostenol is a potent inhibitor (31, 35). It has been proposed that the balance among these compounds of common origin determines whether aggregation occurs *in vivo* (31). Indomethacin inhibits cyclooxygenase (36–38), thus preventing platelet aggregation associated with endoperoxide formation.

The aggregation response of the washed porcine platelets to 0.29 m*M* ADP was classically monophasic (Fig. 1), proceeding rapidly to macroaggregate production. The complete inhibition of this reaction by 75 μ*M* alprostadil or 80 n*M* epoprostenol agreed qualitatively with the literature (27, 39). However, on a quantitative basis, the ADP concentration was 10–20 times higher than normally used in *in vitro* aggregation studies (1, 3, 23, 29, 31, 34). This finding suggests that ADP-related aggregation was effectively eliminated by the prostaglandins.

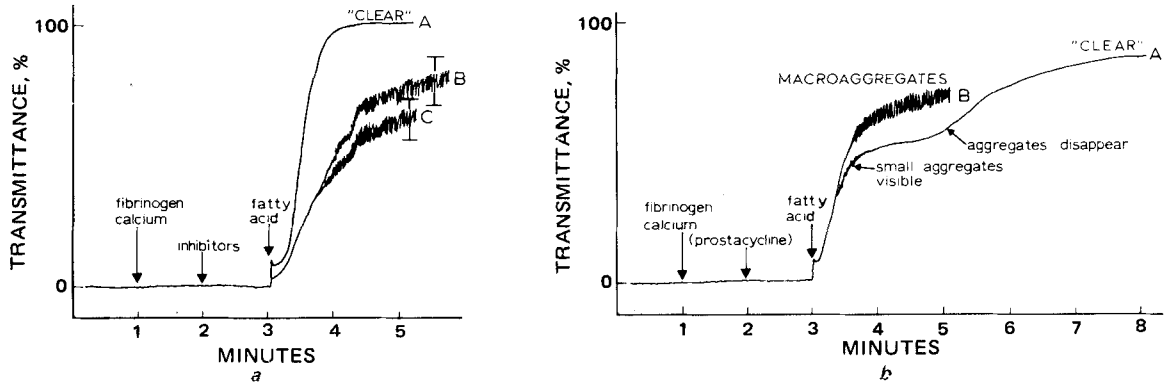

**Figure 10**—*Platelet aggregation as induced by taurocholate-solubilized oleate. Key for* a: *curve A, 600 μM oleate with and without 75 μM alprostadil; curve B, 170 μM oleate with and without 750 μM alprostadil, 80 nM epoprostenol, or 150 μM indomethacin; and curve C, 70 μM oleate with and without 75 μM alprostadil or 150 μM indomethacin. Key for* b: *curve A, 320 μM oleate; and curve B, 320 μM oleate with 80 nM epoprostenol.*

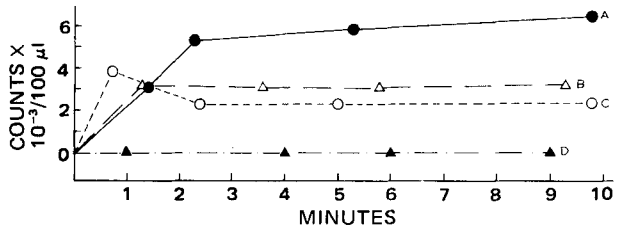

**Figure 12**—*Particle-size analysis of 4 mM stearate solubilized with 47 mM sodium taurocholate and 4 mM palmitate solubilized with 26 g % albumin subsequent to dilution to 600 µM stearate/7.12 mM taurocholate (curve A), 320 µM stearate/3.85 mM taurocholate (curve B), 70 µM stearate/0.83 mM taurocholate (curve C), and 600 µM palmitate/4 g % albumin (curve D). Size range was 0.45–0.72 µm in diameter.*

The platelet aggregating activity of the suspended fatty acid systems increased with both the fatty acid chain length and concentration (Figs. 2 and 3), in agreement with previous work (7, 8, 10, 18). Unsaturation of the hydrocarbon portion of the fatty acid molecule appeared to have no discernible effect on the platelet aggregation activity. This observation was in general agreement with other work where washed platelet aggregation was induced by fatty acids in suspension (9, 10, 20).

The effects of alprostadil, epoprostenol, and indomethacin on suspended fatty acid-induced platelet aggregation were examined (Figs. 8 and 9). With the possible exception of 70 *µM* stearate, these agents did not appear to alter the fatty acid-induced aggregation reaction, although they have been reported to inhibit collagen, thrombin, serotonin, epinephrine, vasopressin, ADP, and divalent cation ionophore-induced platelet aggregation (1, 23, 29–31, 34, 40, 41).

Simple correlation of platelet aggregating activity with the fatty acid chain length and concentration was not possible with the taurocholate-solubilized systems. Complex behavior was noted (Figs. 9 and 10), which differed markedly for the oleate as compared to the stearate systems.

A correlation of taurocholate-solubilized oleate-induced platelet aggregation with precipitate formation was found. The taurocholate-solubilized 70 and 170 *µM* oleate systems elicited immediate platelet aggregation reactions leading to platelet macroaggregates (Fig. 10). Immediate, extensive precipitate formation also was observed with these preparations (Fig. 11). The anomalous platelet response to taurocholate-solubilized 320 and 600 *µM* oleate was accompanied by a marked reduction in precipitate formation. Apparently, these latter systems remained solubilized to a greater extent, which may be attributed to the higher associated concentrations of taurocholate (Table I).

However, the platelet response to these preparations did not correlate strictly with taurocholate concentration. Taurocholate-solubilized 600 *µM* stearate (Fig. 9), myristate (Fig. 4), or palmitate or 7.12 m*M* taurocholate alone did not lyse platelets, although the final taurocholate concentration was equivalent to the solubilized oleate systems that lysed platelets. Thus, the platelet aggregating activity of the taurocholate-solubilized oleate systems appeared to depend on the formation of large numbers of particles subsequent to the addition to the washed platelet preparations. The biphasic response of the platelets to taurocholate-solubilized 320 *µM* oleate appeared to begin with platelet aggregation, ultimately ending in lysis (Fig. 10). This biphasic transition from the monophasic platelet aggregation response, elicited by the lower oleate concentrations, to the monophasic lysis of platelets by the higher oleate concentrations was a property unique to the taurocholate-solubilized oleate systems and corresponded directly with the extent of precipitation (Fig. 11).

All concentrations of taurocholate-solubilized stearate were less active than taurocholate-solubilized 70 and 170 *µM* oleate in the induction of platelet aggregation (Fig. 9). Precipitation from the stearate systems (Fig. 12) also was less extensive than from the oleate systems. Thus, although the taurocholate-solubilized oleate and stearate systems had differences in precipitation patterns and platelet aggregating activity, the development of a particulate physical state subsequent to taurocholate–fatty acid additions to washed platelets appeared to be important.

To investigate the dependence of fatty acid-induced platelet aggregation on a particulate physical state, oleate and palmitate were solubilized with albumin. The final albumin concentration subsequent to the addition to the washed platelets was 4 g %, which was sufficient to prevent precipitation of both 600 *µM* oleate and palmitate (Figs. 11 and 12). Under these conditions, the fatty acids were devoid of aggregating activity (Fig. 6) and did not lyse platelets, suggesting a particulate form of the free fatty acid was necessary to elicit the aggregation response.

The effects of alprostadil, epoprostenol, and indomethacin on the platelet response to taurocholate-solubilized oleate and stearate were examined (Figs. 9 and 10). These agents had no discernible effect on the platelet aggregation reaction except where induced by taurocholate-solubilized 320 *µM* oleate. In this case, epoprostenol appeared to enhance aggregation by preventing the second phase lysis (Fig. 10*b*). This increased resistance to cell damage associated with prostaglandin exposure was previously noted with red blood cells and gastric mucosal cells (42–45).

The ineffectiveness of alprostadil, epoprostenol, and indomethacin at inhibition of solubilized or suspended fatty acid-induced platelet aggregation suggested that the aggregation was independent of nucleotide release from endogenous storage granules within the platelets, cyclic AMP-related cytosol calcium shifts, and endoperoxide–thromboxane $A_2$ mechanisms. A particulate physical state for the fatty acids appeared to be prerequisite for platelet aggregating activity. The greater platelet aggregating activity, in general, of the taurocholate-solubilized systems (Fig. 4) suggests that specific particle-size and number requirements exist for optimal interaction, which are best achieved as the fatty acids precipitate out of the solubilized state. Based on normal particle growth kinetics, it is expected that the average particle size of these precipitates present during the aggregation process would be considerably smaller than the average particle size of the nonsolubilized suspensions.

Thus, fatty acid-induced platelet aggregation did not fit the scheme developed in the basic platelet reaction hypothesis (23). Rather, a direct physical interaction of fatty acid particles with platelets, leading to aggregation, appeared to be consistent with the observations. Although the precise role of calcium in these reactions remains unknown, the formation of calcium bridges between negatively charged fatty acid particles and negatively charged platelets (46) would account for both the particulate fatty acid physical state requirements and the ineffectiveness of the aggregation inhibiting agents.

# Pharmacokinetics of Sulfisoxazole Compared in Humans and Two Monogastric Animal Species

**ROBERT L. SUBER *§x, CHARLES LEE ‡, GEORGE TOROSIAN ‡, and GEORGE T. EDDS ***

Received September 24, 1980, from the **Department of Preventative Medicine and Toxicology and the* ‡*Department of Pharmaceutics, College of Pharmacy, University of Florida, Gainesville, FL 32610.* Accepted for publication February 6, 1981. §Present address: Pathology Services Project, National Center for Toxicological Research, Jefferson, AR 72079.

**Abstract** □ The pharmacokinetic profile of sulfisoxazole was studied and compared in dogs, swine, and humans. The trial was conducted over a 72-hr period after intravenous administration and a 96-hr period after oral administration in dogs and swine. In humans, the trial was conducted over an 8-hr period after oral administration. A two-compartment model system was used to define the pharmacokinetic profile. The mean half-lives for the distribution phase were 4.08, 1.30, and 0.56 hr in dogs, swine, and humans, respectively. For the elimination phase, the mean half-lives were 33.74, 46.39, and 7.40 hr in dogs, swine, and humans, respectively. The mean volume of the central compartment was approximately the same in dogs and swine, 10.6 and 10.5 liters, respectively. Humans had a smaller volume of distribution, 7.7 liters. The steady-state volumes of distribution were 17.2, 30.3, and 16.2 liters in dogs, swine, and humans, respectively. Dogs and swine excreted 42.2 and 30.7%, respectively, of the intravenous dose and 29.4 and 18.3%, respectively, of the oral dose. The bioavailability was 69.8% in dogs and 100.0% in swine. The fraction of drug bound ranged from 30 to 50% in dogs, 40 to 60% in swine, and 25 to 40% in humans.

**Keyphrases** □ Sulfisoxazole—pharmacokinetics in humans, dogs, and swine □ Pharmacokinetics—sulfisoxazole, comparison in humans, dogs, and swine □ Antibacterials—sulfisoxazole, pharmacokinetics in humans, dogs, and swine

Sulfisoxazole is an effective antibacterial agent often used in the treatment of urinary tract infections. Previous studies in dogs, swine, and cattle only measured blood levels of sulfisoxazole and sulfisoxazole acetyl following intravenous (1), subcutaneous (1), oral (2), and peritoneal (1) administrations. No detailed pharmacokinetic analyses were undertaken to characterize the absorption, distribution, metabolism, and excretion of sulfisoxazole in these animals. Likewise, human studies (3–5) of sulfisoxazole after single oral ingestion were limited to the measurement of blood concentrations of the parent drug and the acetyl metabolite. In one study (2), the steady-state blood level was measured following multiple-dose administration.

The first complete pharmacokinetic study in humans was conducted by Kaplan *et al.* (6) in which sulfisoxazole was administered intravenously, intramuscularly, and orally. Pharmacokinetic parameters were determined and availability was assessed. The present study compared sulfisozaxole pharmacokinetics in dogs, swine, and humans.

## EXPERIMENTAL

**Materials**—A 12.5% sulfisoxazole[1] solution was prepared with lithium hydroxide. The solution was filtered and placed in sterile 50-ml ampuls before use. Sulfisoxazole acetyl[2] was used as a reference standard for serum and urinary metabolite assay. All chemicals and solvents used in the high-performance liquid chromatographic (HPLC) assay were high purity solvents[3] and were filtered before use.

**Experimental Model**—The trial consisted of three female dogs (~2

years old, 20.0 ± 1.0 kg), six female pigs (~3 months old, 20.0 ± 1.0 kg), and six male human volunteers (25–30 years old, 70–80 kg). The dogs were administered 100 mg of sulfisoxazole/kg by intravenous and oral routes in two replicates for each route with a 30-day rest period between administrations. The pigs also were administered 100 mg of sulfisoxazole/kg by intravenous and oral routes with a 21-day washout period. All animals were housed in metabolism cages and were maintained on a commercial diet[4] with *ad libitum* access to water.

Sulfisoxazole was administered both orally and intravenously as a 12.5% solution to dogs and swine. The human volunteers received 2.0 g of sulfisoxazole in a single oral dose. Due to the potential toxicity of intravenous administration of sulfisoxazole and its removal from the drug market, the Human Research Committee of the University of Florida would not allow intravenous administration to humans.

**Sampling Schemes**—For dogs and swine, blood samples were taken at 0.5, 1, 2, 3, 4.5, 6, 9, 12, 22, 32, 44, 56, and 72 hr after intravenous administration and at 0, 1, 2, 4, 6, 8, 10, 12, 14, 23, 32, 44, 56, 76, and 96 hr after oral administration. Total urine was collected daily by natural voiding for up to 4 days. Human blood samples were collected at 0, 1, 2, 4, 6, and 8 hr after oral administration. Urine was not collected in the human trial. Blood samples were taken from the cephalic vein in dogs and humans and *via* the anterior vena cava in swine. Serum and urine samples were frozen at −4° for up to 14 days before analysis.

**Assay for Sulfisoxazole and Sulfisoxazole Acetyl**—Sulfisoxazole and sulfisoxazole acetyl in plasma and urine were analyzed by a reversed-phase HPLC technique developed in these laboratories (7), using a 60% distilled water–40% methanol liquid phase with acetate buffer added to reduce the pH to 4.00. The detection limit for this assay was 10 ng/ml for both sulfisoxazole and the acetyl metabolite at 254 nm[5].

Serum samples were injected directly into the HPLC system, which was fitted with an in-line precolumn[6]. Unbound, unmetabolized sulfisoxazole and sulfisoxazole acetyl were extracted by cooling 25.0 ml of urine to 4° in an ice bath; sufficient 6 *M* HCl was added to reduce the pH to 3.0. After 5 min, 15.0 ml of chloroform[3] was added, the solution was removed from the ice bath, and extraction was completed in 5 min by swirling the solution once per minute. The chloroform was removed and evaporated under nitrogen, and the residue was reconstituted with methanol[3]. The peak height ratio was used to calculate the concentration of unbound, unmetabolized sulfisoxazole and sulfisoxazole acetyl with sulfathiazole as the internal standard.

Both serum and urine samples were spotted on TLC plates (8) to determine if other metabolites were present. All spots were accounted for without the elution of other metabolites.

**Plasma Protein Binding**—Human plasma samples, prepared at concentrations of 25, 50, 100, 200, 300, 400, and 500 μg of sulfisoxazole/ml, were dialyzed against 2.0 ml of pH 7.4 phosphate buffer. The dialysate was collected and analyzed for sulfisoxazole content. Protein binding of plasma samples collected from dogs, swine, and humans at various time intervals also was determined by equilibrium dialysis. The fraction of the drug bound was defined as $C_f/C_t$, where $C_f$ is the drug concentration in the dialysate and $C_t$ is the drug concentration in the plasma at the completion of equilibrium dialysis.

**Data Analysis**—A two-compartment open body model was applied to the analysis of plasma sulfisoxazole data after intravenous administration using a NONLIN program (9). Pharmacokinetic parameters, including $\alpha$, $\beta$, $k_{12}$, $k_{21}$, $k_{10}$, $V_1$, and $V_2$, were defined from the curve fitting. Plasma clearance was defined from the model as $k_{10}V_1$, where $V_1$ is the distribution volume of the central compartment. Renal clearance was defined as $f_e Cl_t$, where $f_e$ is the fraction of sulfisoxazole excreted unchanged in the urine. The volume of the peripheral compartment ($V_2$) was defined from the model $k_{12}V_1 = k_{21}V_2$.

Bioavailability of sulfisoxazole following solution administration to dogs and swine was determined by the urinary excretion method. The unchanged sulfisoxazole excreted in the urine in 72 hr was compared for oral and intravenous administration. The *AUC* (area under the plasma concentration–time curve) method was not applied to the determination of bioavailability in this investigation due to the discrepancies in terminal half-lives observed following intravenous and oral administration. This discrepancy could be due to the erratic absorption of the oral dose. The half-life of sulfisoxazole following oral administration to humans was determined from the log-linear slope of the plasma concentration–time curve. No attempt was made to assess the oral bioavailability in humans.

## RESULTS

In the 72-hr period following intravenous administration in the dog, sulfisoxazole levels showed biexponential decay (Fig. 1). The $\beta$-phase half-life in these animals had a mean of 33.74 hr, while the $\alpha$-phase half-life ranged from 3.5 to 5.0 hr (mean 4.08). Mean values for the volume of the central pool and the steady-state volume of distribution were 10.60 and 17.15 liters, respectively. Serum sulfisoxazole clearance ranged from 1.39 to 2.15 liters/hr (mean 1.65). The fraction of the dose eliminated unchanged was 42.2%. Renal clearance averaged 0.7 liter/hr. Pharmacokinetic parameters of the two-compartment model in dogs following intravenous sulfisoxazole administration are summarized in Table I.

The plasma levels in swine following intravenous administration also were biexponential (Fig. 2) and were analyzed by a two-compartment model. The $\alpha$- and $\beta$-phase half-lives in swine had means of 1.30 (range 1.18–1.40) and 53.33 (range 31.64–64.77) hr, respectively. The mean volumes were 10.48 and 30.24 liters for the central and steady-state pools, respectively. Plasma clearance ranged from 3.73 to 7.48 liters/hr (mean 5.29). Based on the percent of dose excreted unchanged (18.2%), the average renal clearance was 0.96 liter/hr. Pharmacokinetic constants of the two-compartment model in six swine following intravenous sulfisoxazole administration are recorded in Table II.

Following oral administration of sulfisoxazole to dogs, the peak plasma concentrations, ranging from 122.3 to 165.0 μg/ml, occurred at 1 hr. The peak time for swine occurred at 1 hr with much lower peak concentrations of 32.8–100.6 μg/ml. Sulfisoxazole acetyl reached a maximum of 12.1–20.0 μg/ml in 2–4 hr in all six pigs. The $\beta$-phase half-life of the acetyl metabolite was estimated to range from 23.2 to 37.9 hr with a mean of 31.0 ± 5.3 hr in pigs. Dogs either do not metabolize many aromatic amine compounds through acetylation or else possess a deacetylase that precludes analysis of the acetyl derivative (10). Sulfisoxazole acetyl was not observed in the urine or serum of dogs administered sulfisoxazole.

Following oral sulfisoxazole administration to humans, the plasma data were analyzed by a one-compartment model. Two-compartment analysis was not possible due to the lack of sampling in the 1st hr. The peak concentration of the unmetabolized sulfisoxazole occurred in <1 hr following oral administration, although the exact time was not known (Fig. 3). The rapid absorption of sulfisoxazole following oral administration was due to the drug being given as a solution. The $\beta$-phase half-life of sulfisoxazole ranged from 6.0 to 8.8 hr with a mean of 7.41 ± 0.59 hr. The half-life of sulfisoxazole in humans was not comparable to either the $\alpha$-phase or the $\beta$-phase half-life in dogs and swine; however, it was consistent with the $\beta$-phase half-life reported in a previous intravenous study in humans (6). The acetyl metabolite peaked at 4 hr and exhibited a longer $\beta$-phase half-life than the parent compound (Fig. 3). The mean biological half-life of sulfisoxazole acetyl was 14.1 ± 2.2 hr.

Table III records the percent of dose excreted as unchanged sulfisoxazole in the urine for the 96-hr period. Dogs and swine excreted 42.2 and 18.2% of the intravenous dose, respectively, during the trial period. In the oral trial, dogs excreted 29.4% of the dose compared to 18.3% excreted in swine.

Sulfisoxazole bioavailability (Table IV), 69.8 and 100% in dogs and swine, respectively, was determined from the unchanged drug excreted in the urine in 72 hr. Bioavailability of the drug in humans, although not available from this study due to a lack of corresponding intravenous data, was demonstrated to be complete (6).

In dogs, the fraction of the drug bound to plasma protein ranged from 30 to 50% in the sulfisoxazole concentration of 0–240 μg/ml (Table IV). In the same concentration range, sulfisoxazole was found to bind swine plasma protein from 40 to 60%. In humans, the bound fraction ranged from 25 to 40% in the concentration range of 80–200 μg/ml during the 8 hr following oral sulfisoxazole dosing. The *in vitro* binding of sulfisoxazole to blank human plasma in the range of 25–500 μg/ml was higher (38.9–63.0%) than *in vivo* binding and showed a concentration dependency. These *in vivo* plasma protein binding data were quite different from the

85% previously reported by Struller (11) but were consistent with the Randall *et al.* (2) report of 25%.

Table IV lists some mean pharmacokinetic parameters of sulfisoxazole in dogs, swine, and humans. Most of these parameters are significantly different from one another among species and can be used to evaluate the pharmacokinetic closeness of one species to another.

## DISCUSSION

The mean volume of the central compartment ($V_1$) was approximately the same in dogs (10.6 liters) and swine (10.5 liters). However, this value may become quite different when expressed in terms of lean body weight because of the much greater fat content in swine. This condition may explain the difference in the extrapolated initial concentration ($C_0$) of 192.0 μg/ml in dogs and 245.5 μg/ml in swine, although both species were given the same total dose. The $V_1$ value in humans was not available from this study; however, it could be derived from the Kaplan *et al.* (6) data as 7.7 liters, ~30% smaller than that of dogs. The $C_0$ was reported as 259.0 μg/ml in humans, a value 30% greater than that of dogs. The discrepancies in $V_1$ and $C_0$ are surprisingly consistent and compensated for each other in dogs and humans. This observation is in agreement with the dog being closer to humans with regard to fat content.

The difference in $C_0$ also can be explained in part by the peripheral volume ($V_2$) of 6.6 and 19.8 liters in dogs and swine, respectively. Humans had a $V_2$ value (8.5 liters) closer to that of dogs. The larger $V_2$ in swine could be due to the greater volume of total body water in young animals (12). Three-month-old swine were used in this experiment to eliminate the large volume of body fat found in adult animals.

The distribution ratio defined as $k_{21}/k_{12}$ was greatest in humans (2.3), followed by dogs (1.6) and swine (0.55), indicating that the drug returned from the peripheral compartment to the central compartment at a faster rate in humans than in swine (Table IV). This result was logically tied to the β-phase half-life of 7.4, 33.7, and 46.4 hr in humans, dogs, and swine, respectively, being in the reverse order to the $k_{21}/k_{12}$ ratio previously discussed. The ratio of $\beta/k_{10}$ (Table IV) was 0.03 in swine and 0.13 in dogs, and it was reported to be 0.66 in humans (6). This is in the same order as $k_{21}/k_{12}$, suggesting that more sulfisoxazole is available for elimination from the postdistributive phase in humans than in dogs and swine. This pattern also correlated reasonably with the β-phase half-life of the drug in these species.

By the end of the 72-hr intravenous trial in dogs, 42.2% of the dose was excreted in the urine as unchanged drug. At the end of 48 and 96 hr after oral administration, 29.1 and 29.4% of the dose were excreted, respectively, indicating that urinary excretion of the drug was complete at 72 hr. Therefore, oral sulfisoxazole bioavailability was determined by comparing the urinary excretion of the drug following these administration routes. Almost 70% of the dose was available to the general circulation after oral administration of the drug as a solution to dogs. The drug bioavailability in swine was determined in the same manner, and a value of almost 100% was obtained (Table IV). Dogs excreted 29.4% of the oral dose compared to 18.3% in swine, yet dogs actually exhibited less

Table IV—Comparison of Mean Pharmacokinetic Constants in Dogs, Swine, and Humans

| Constant[a] | Dogs | Swine | Humans |
|---|---|---|---|
| $k_{21}/k_{12}$ | 1.63 | 0.55 | 2.30[b] |
| $\beta/k$ | 0.13 | 0.03 | 0.66[b] |
| $F$, % | 69.8 | 100.0 | 97.5[b] |
| $r_p$, % | 30–50 | 40–60 | 25–40 |

[a] $F$ = bioavailability; $r_p$ = percent bound. [b] Reference 6.

oral drug absorption. Since both dogs and swine excreted only up to 42.2 and 18.2% of the intravenous dose, respectively, during the trial period, other metabolites probably are present but are not detected by the assay method used. Kaplan *et al.* (6) reported that 52.9% of the dose was excreted as unchanged sulfisoxazole in humans. No urinary data from the present study were available for comparison since the intravenous study was not conducted.

Following oral sulfisoxazole administration to swine and dogs, terminal half-lives deviated significantly from those following intravenous administration in each crossover study, particularly in dogs. This finding may indicate erratic drug absorption in both species, especially in dogs. This erratic absorption may contribute to the incomplete drug absorption in dogs. Different physiology of the GI system also may contribute to the different extent of drug absorption in dogs and swine.

Differences did exist for both α- and β-phase biological half-lives, bioavailability, plasma protein binding, and urinary excretion among all three species. No conclusion can be drawn as to which animal model is pharmacokinetically closer to humans. However, dogs appeared to be a better model than swine for studying the bilirubin toxicity induced by sulfisoxazole administration. The oral dose was responsible for increasing the free, unbound bilirubin in dogs without an increase in total bilirubin. This result did not occur in humans and swine. This topic will be the subject of a separate report.

# Tissue Distribution Studies of [$^{18}$F]Haloperidol, [$^{18}$F]-$\beta$-(4-Fluorobenzoyl)propionic Acid, and [$^{82}$Br]Bromperidol by External Scintigraphy

**G. A. DIGENIS *x, S. H. VINCENT *, C. S. KOOK *, R. E. REIMAN ‡, G. A. RUSS ‡, and R. S. TILBURY ‡**

Received October 1, 1980, from the **Divisions of Medicinal Chemistry and Nuclear Medicine, Colleges of Pharmacy and Medicine, University of Kentucky, Lexington, KY 40506*, and the ‡*Sloan-Kettering Institute for Cancer Research, New York, NY 10021.* Accepted for publication February 12, 1981.

**Abstract** □ Tissue distribution studies of [$^{18}$F]haloperidol and [$^{82}$Br]-bromperidol, two potent neuroleptic drugs, were performed in rats by serial sacrifice. The usefulness of external scintigraphy in obtaining tissue distribution data in large animals is demonstrated by the tissue distribution of [$^{18}$F]haloperidol in rhesus monkeys. Both serial sacrifice and external scintigraphic studies demonstrated that uptake of the two drugs after intravenous administration into their target organ, the brain, was very fast and that the ratio of brain to blood levels was high throughout the 2-hr observation. Bromperidol appeared to reach peak brain levels faster than its chloro analog, haloperidol. Both bromperidol and haloperidol concentrated overwhelmingly in the rat lung. Haloperidol also showed a high affinity for the monkey lung. The disposition pattern in rats of [$^{18}$F]-$\beta$-(4-fluorobenzoyl)propionic acid, an apparent intermediate in butyrophenone metabolism, was entirely different from that of the parent drugs. This metabolite did not concentrate in the rat brain.

**Keyphrases** □ Haloperidol, radiolabeled—tissue distribution studied in rats and rhesus monkeys using external scintigraphy and serial sacrifice □ Bromperidol, radiolabeled—tissue distribution studied in rats and rhesus monkeys using external scintigraphy and serial sacrifice □ Radionuclides—radiolabeled bromperidol and haloperidol, tissue distribution studied in rats and rhesus monkeys using external scintigraphy and serial sacrifice □ Neuroleptic agents—haloperidol and bromperidol, tissue distribution studied in rats and rhesus monkeys using external scintigraphy and serial sacrifice

The increased availability of short-lived radionuclides and radiopharmaceuticals and the growing accessibility of $\gamma$-counting facilities have made external scintigraphy a valuable analytical and diagnostic tool in radiopharmacy and nuclear medicine. Being noninvasive, external scintigraphy is particularly useful for providing information on the disposition of drugs in humans as well as in large mammals where large colonies of isogenic subjects are unavailable. Conventionally, such information is obtained by extrapolation from experimental animal data and measurements of blood and urine levels in humans. Such an approach neglects any inter- or intraspecies difference and assumes that drug levels in the target organ is proportional to blood levels. Unfortunately, this assumption may not be correct with certain neuroleptics of pharmacological interest. Such a discrepancy requires careful consideration, particularly when the dose regimen of a drug has to be adjusted on an individual basis.

External scintigraphic studies using compounds labeled with short-lived radionuclides provide at least a partial answer to this problem since such studies can provide information about tissue levels in humans. Additionally, repeated studies can be done using the same subjects, thus eliminating individual differences. *In vivo* distribution studies with compounds labeled with long-lived radioisotopes such as tritium and carbon 14 suffer from many disadvantages, the main one being that they are often inapplicable to humans.

External scintigraphy is particularly useful for short-term distribution and kinetic studies with compounds that are not metabolized extensively. This is particularly important since one main drawback of external scintigraphy is that it measures total radioactivity levels.

The present study attempted to demonstrate the usefulness of external scintigraphy and short-lived radionuclides as analytical tools in short-term tissue distribution studies of pharmaceutical drugs. Three butyrophenone compounds were chosen: haloperidol (II), $\beta$-(4-fluorobenzoyl)propionic acid (V), and bromperidol (VII).

## BACKGROUND

Butyrophenone neuroleptics are a class of compounds whose blood levels do not necessarily reflect levels in the target organ or therapeutic response. Janssen and Allewijn (1) reported that the neuroleptic activity of haloperidol and several other butyrophenones correlated well with the drug concentrations in the brain but suggested that blood levels need not be related to parameters of interest. Large individual differences also seem to exist in the serum levels attained after butyrophenone administration. Forsman and Ohman (2) examined the steady-state concentration of haloperidol in serum in relation to the daily dose and found up to 10-fold differences between individuals. Zingales (3) reported, in a study of 14 patients, that a patient who gave a poor response to haloperidol therapy always had the highest plasma levels. These and other findings suggest that a simple correlation might not exist between butyrophenone plasma and behavioral changes. Thus, tissue distribution studies should be conducted directly in humans to obtain a correlation between blood levels, brain levels, and central nervous system (CNS) activity.

Haloperidol (II) is the prototype of the butyrophenone neuroleptics and is widely used in the treatment of hypomania, mania, and acute and chronic schizophrenia (4). Bromperidol (VII) is the bromo analog of haloperidol and currently is used in clinical trials. Preliminary reports on its pharmacology indicated that VII may have a faster onset and a longer duration of action (5, 6). Therefore, it seemed of interest to study the tissue distribution patterns of II and VII and to compare the times taken to reach peak levels in the brain, the target organ. The tissue distribution of V, one of their pharmacologically inactive metabolites (7), also was studied and compared to that of II and VII.

Metabolism studies (1) with tritiated butyrophenone neuroleptics have shown that 2 hr after subcutaneous administration, 80% of the radioactivity in the brain of rats is due to intact drug. Hence, during short-term studies, it is expected that metabolites do not contribute significantly to radioactivity levels in the various tissues, particularly the brain.

Neuroleptics II and V were labeled with fluorine 18, whereas VII was labeled with bromine 82.

Fluorine 18 is a pure positron emitter (0.635 Mev, $\beta^+$) with a physical half-life of 110 min. The resulting 511 kev annihilation radiation is detected easily by conventional nuclear medicine instrumentation such as external scintigraphy. Bromine 82 has a longer half-life (35.4 hr), and it decays with the emission of a $\beta$-particle (444 kev maximum energy) followed by several $\gamma$-rays. The principal photon is centered around 777 kev. These high-energy $\gamma$-emissions cause a "shine through" effect that results in distorted scintiphotographs when bromine 82 is used for external scintigraphic studies (8). This problem can be avoided by using bromine 77. Bromine 82 was used for these experiments because it is commercially

available. [$^{77}$Br]Bromperidol can be synthesized in the same manner as [$^{82}$Br]bromperidol.

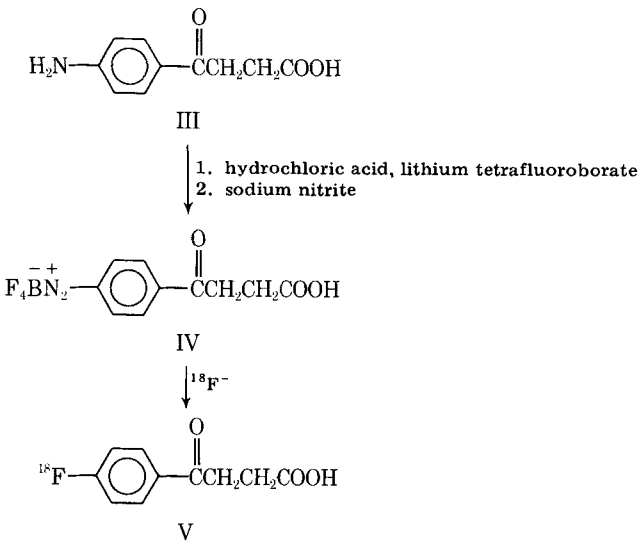
The synthesis of [$^{18}$F]haloperidol and [$^{82}$Br]bromperidol was reported elsewhere (9, 10). The synthesis of $^{18}$F-labeled metabolite V and tissue distribution data of all three compounds in the rat and of [$^{18}$F]haloperidol in the rhesus monkey are reported here.

## EXPERIMENTAL

**Preparation of [$^{18}$F]Haloperidol ($^{18}$F-II)**—Production of the radionuclide fluorine 18, used for the synthesis of $^{18}$F-II, was accomplished by the irradiation of water with 22 Mev helium 3 particles produced by a cyclotron[1].

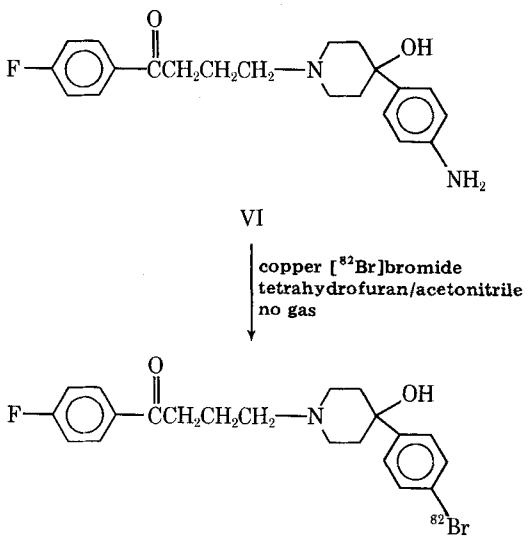
[$^{18}$F]Haloperidol was prepared from the diazonium tetrafluoroborate salt (I) (Scheme I) according to the previously published procedure (9). The specific activity of the purified product (column chromatography on neutral alumina) was 105 μCi/mg.

**Synthesis of β-(4-Fluorobenzoyl)propionic Acid (V)**—To 1.0 g (5.17 mmoles) of β-(4-aminobenzoyl)propionic acid (III) (11, 12) was added 9.0 ml of 18% HCl (Scheme II). The mixture was stirred vigorously and cooled to 5° in an ice bath. Then lithium tetrafluoroborate (1.59 g) in 3 ml of distilled water was added dropwise, followed by 3.0 ml of 10% $NaNO_2$. The solution was stirred vigorously for 15 min, and no precipitation was formed. The clear solution mixture was frozen in a dry ice–acetone bath and freeze dried for ~2 hr until most of the water was removed. The slurry was filtered through a sintered-glass funnel, cooled in dry ice, and washed with cold water. The brown solid (IV) was freeze dried again *in vacuo*.



*Scheme II—Synthetic route for the preparation of [$^{18}$F]-β-(4-fluorobenzoyl)propionic acid ($^{18}$F-V).*

[1] Model CS-15, Sloan-Kettering Institute, New York, N.Y.



*Scheme III—Principal reaction in the preparation of [$^{82}$Br]bromperidol ($^{82}$Br-VII).*

The dry tetrafluoroborate salt (IV) subsequently was pyrolyzed in xylene–dioxane (3:1) at 145° for 15 min, and the solvent mixture was evaporated on a rotary evaporator to dryness. The dark-brown pyrolysate was then dissolved in 5% aqueous sodium hydroxide. The solution was filtered through a sintered-glass funnel, and the filtrate was acidified with 5% HCl until it was acidic to litmus paper. The acidic solution was then extracted with three 15-ml portions of chloroform. The extracts were combined, dried with sodium sulfate, and evaporated to dryness on the rotary evaporator to yield 0.48 g (47.3% yield) of V, mp 100–105° [lit. (13) mp 102–103°]. The identity of V was proven unequivocally by mixed melting point (100–105°) and comparative spectroscopic determinations (IR and NMR) with authentic V[2].

**Synthesis of [$^{18}$F]-β-(4-Fluorobenzoyl)propionic Acid ($^{18}$F-V)**—Fluorine 18 was produced by the Van de Graaff generator through the $^{20}Ne(d,\alpha) \rightarrow {}^{18}F$ nuclear reaction, at the end of which the glass target insert was washed with 7.5 ml of distilled water. The volume of the water was reduced to ~1 ml by heating at 110° and by blowing nitrogen gas into the solution. To the aqueous solution containing 17.2 mCi of fluorine 18 were added 50 mg of the diazonium salt (IV) and 2.0 ml of acetone. After standing for 5 min, the solvents were removed on the rotary evaporator at 50°. The residue was dried further in the freeze drier for 30 min, and the dried salt subsequently was pyrolyzed in xylene–dioxane (3:1) as already described.

The dark pyrolysate was dissolved in 5% NaOH, the solution was filtered, and the filtrate was acidified with 5% HCl. The acidic solution then was extracted with three 5-ml portions of chloroform. The extracts were combined, dried with sodium sulfate, and evaporated to dryness. The residue was washed with ether to yield 24.5 mg (123.2 μCi) of $^{18}$F-V. A radioscan of the thin-layer chromatogram of the product, developed in chloroform–cyclohexane–acetic acid (20:80:10) using a silica gel plate, showed that all activity was coincident with the spot of known V. The incorporation of fluorine 18 into the final product (V) was calculated to be 2.95%. The specific activity was 5.03 μCi/mg.

**Preparation of [$^{82}$Br]Bromperidol ($^{82}$Br-VII)**—[$^{82}$Br]Bromperidol was prepared from the aminoperidol VI according to the previously published procedure (10) (Scheme III). Copper(II) [$^{82}$Br]bromide was prepared *in situ* from potassium [$^{82}$Br]bromide obtained commercially[3]. The specific activity of the purified product (column chromatography on neutral alumina) was 440 μCi/mg.

***In Vivo* Distribution Studies**—*Animals*—Two mature healthy male rhesus monkeys and several male Sprague–Dawley rats, 300–500 g, were used. Monkeys A and B weighed 8.6 and 6.4 kg, respectively. The animals were allowed free access to food and water until the time of the experi-

[2] Aldrich Chemical Co., Milwaukee, Wis.
[3] New England Nuclear, Boston, Mass.

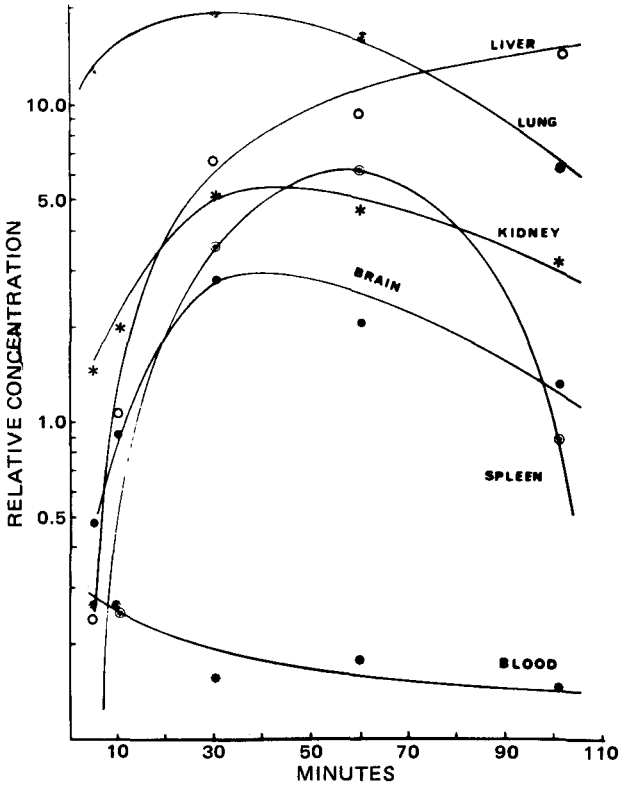


**Figure 1**—*Distribution of radioactivity following intravenous injection of [$^{18}$F]haloperidol (0.01 mg/kg, 0.8–0.9 μCi) in vital organs of the rat as a function of time. Each point represents average values from two rats. Relative concentration as defined by Woodard* et al. *(14) is: (counts of radioactivity in an organ/total radioactivity dose) × (weight of animal/weight of organ).*

ment. The monkeys were anesthetized with phencyclidine, and the rats were anesthetized with pentobarbital sodium solution.

*Dose and Route of Administration*—Solutions of [$^{18}$F]haloperidol ($^{18}$F-II), $^{18}$F-V and [$^{82}$Br]bromperidol ($^{82}$Br-VII) were prepared immediately after their synthesis. Both $^{18}$F-II and $^{82}$Br-VII were dissolved in an appropriate volume of solvent mixture containing propylene glycol, ethanol, and water at pH 4, and $^{18}$F-V was dissolved in the same solvent mixture at neutral pH. An aliquot of each solution was counted to determine the exact dose of radioactivity administered to the animals.

Monkey A was used for three rectilinear scans and received 0.52 mg of $^{18}$F-II/kg (300 μCi) in the left femoral vein. Monkey B was used for

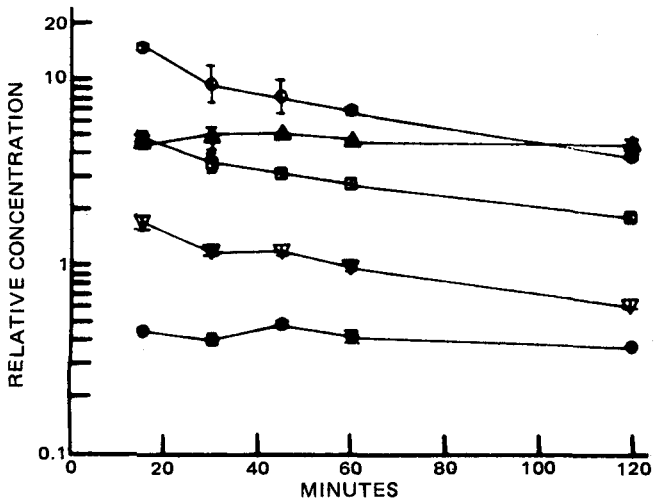

**Figure 2**—*Distribution of radioactivity following intravenous injection of [$^{82}$Br]bromperidol (0.2 mg/kg, 19–22 μCi) in various organs of the rat as a function of time. Each point represents average values in lungs (○), liver (▲), kidneys (□), brain (▽), and blood (●) from five rats.*

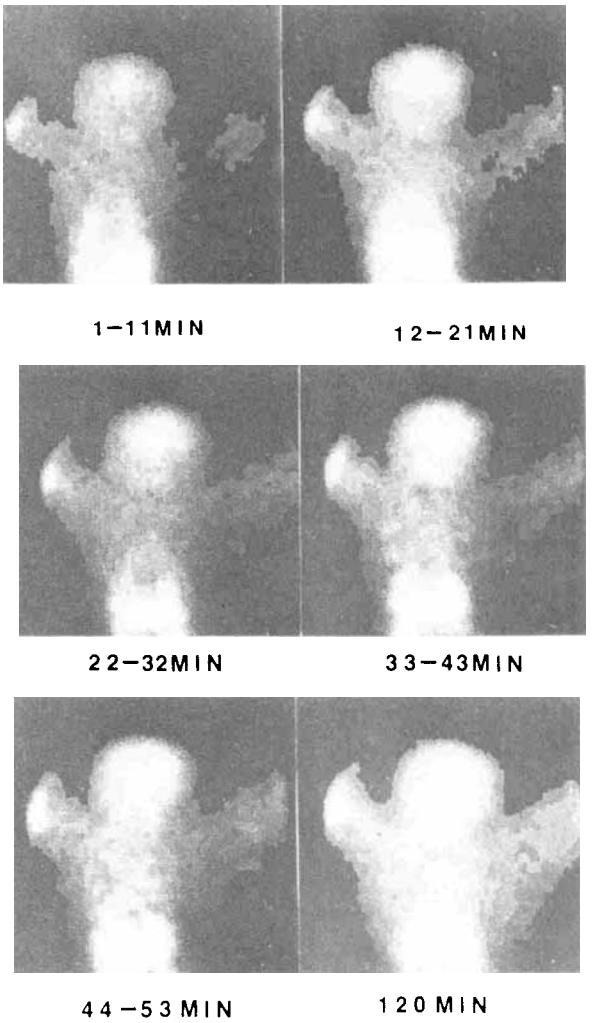

**Figure 3**—*Sequential computer-analyzed displays following intravenous injection of [$^{18}$F]haloperidol to a monkey, illustrating activity concentration in the brain and lung as a function of time.*

γ-camera scannings and received 1.05 mg of $^{18}$F-II/kg (200 μCi). The rats received 0.01 mg of $^{18}$F-II/kg (0.8–0.9 μCi), 0.01 mg of $^{18}$F-V/kg (0.02–0.04 μCi), or 0.2 mg of $^{82}$Br-VII/kg (19–22 μCi).

**Tissue Distribution Studies**—Following drug administration, the rats were sacrificed at various time intervals; a blood sample was withdrawn, followed by removal of the various organs. The samples were counted in a scintillation well-counter and corrected for decay. Radionuclide concentrations in the various organs were expressed by the relative retention method of Woodard *et al.* (14). Relative retention is defined as: (counts of radioactivity in an organ/total radioactivity dose) × (weight of animal/weight of organ). A high-energy γ-scanner was used for the rectilinear scans of Monkey A. The scans were performed 22, 82, and 142 min postinjection. Monkey B was used for the kinetic isotope distribution study with a γ-camera[4] (15).

## RESULTS

The distribution of $^{18}$F-II, $^{18}$F-V, and $^{82}$Br-VII in the vital organs of the rat as a function of time was determined by serial sacrifice of the animals. Figure 1 shows concentrations of fluorine 18 radioactivity (expressed as relative concentration) in various rat organs as a function of time after intravenous administration of $^{18}$F-II. A similar plot for the bromine 82 concentrations obtained after intravenous administration of $^{82}$Br-VII is shown in Fig. 2. The uptake of both II and VII into the target organ (brain) was very rapid. The bromine 82 concentration in the brain was already declining 15 min after administration, whereas the fluorine 18 concentration reached maximum levels 30 min after administration. Both II and VII were found to concentrate overwhelmingly in

[4] Total organ kinetic imaging monitor, TOKIM.

**Table I—Tissue Distribution of [$^{18}$F]Haloperidol ($^{18}$F-II) at Various Time Intervals in Monkey A [a]**

| Organ | Percent Activity | | |
|---|---|---|---|
| | 22 min | 82 min | 142 min |
| Brain | 2.3 | 2.7 | 2.2 |
| Lungs | 5.2 | 5.2 | 3.2 |
| Liver | 12.4 | 9.9 | 7.3 |
| Kidneys | 8.0 | 5.9 | 6.6 |

[a] Values represent percent activity in different areas (rectilinear scanning) over Monkey A. Loading dose was 0.52 mg/kg iv (300 μCi).

the lungs (Figs. 1 and 2, respectively), possibly due to their high lipophilicity. Their uptake by the liver also was very fast and continued throughout the observation period. Their blood levels, however, were relatively constant and much lower than the levels in the other organs. These data are in excellent agreement with those of Lewi *et al.* (16) who did experiments in rats with [$^{3}$H]haloperidol.

External imaging for the distribution of $^{18}$F-II in the monkey was accomplished using the γ-camera (15). Figure 3 shows sequential computer-analyzed displays obtained after intravenous administration of $^{18}$F-II. The results of the dynamic study are presented in Fig. 4. The uptake of II in the monkey lung was extremely rapid and reached a maximum level in the first 13 min. The initial uptake rate in the brain during this period also was fast. Between 10 and 20 min postinjection, the activity in the lungs did not change appreciably while that in the brain increased. After 20 min, the activity in the lung appeared to decrease (Fig. 4); a sharp decrease of activity was noted between 30 and 60 min. In contrast, however, the activity in the brain of the monkey did not change significantly over the same time interval. After 2 hr, the concentration of the drug and its metabolites was considerably decreased in the monkey lungs but remained at high levels in the brain (Fig. 3). In this connection, Janssen and Allewijn (1) showed that ~80% of the intact drug and 20% of its metabolites could be detected in the brain of the rat 2 hr after subcutaneous injection.

To obtain more information on the distribution of $^{18}$F-II, three rectilinear scans were performed on Monkey A at 22, 82, and 142 min postinjection with the high-energy γ-scanner. Areas on the scan images corresponding to brain, lungs, liver, and kidneys were analyzed for activity

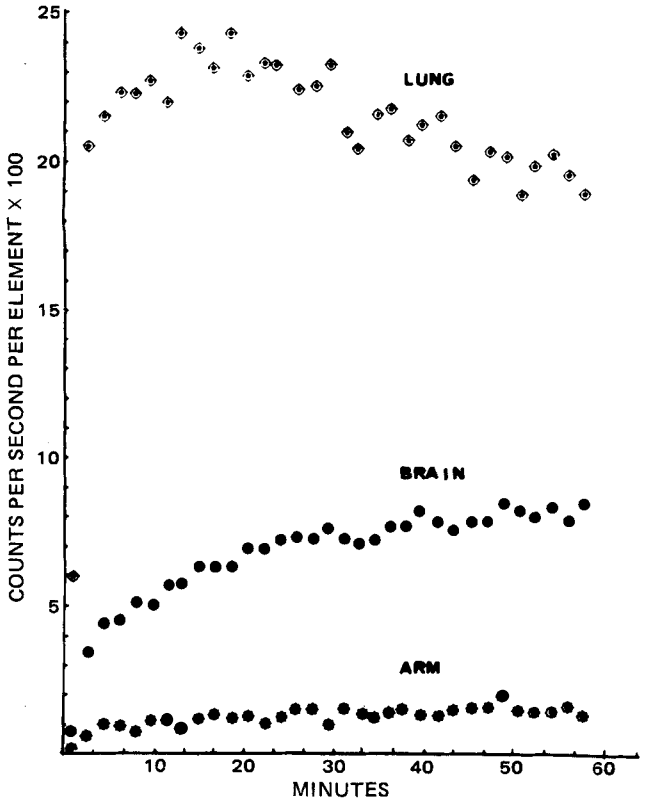

**Figure 4**—*Relative counts per second of [$^{18}$F]haloperidol (31.3 μCi/kg) in observed fields (head, lung, and arm) on Monkey B, obtained with the total organ kinetic imaging monitor technique (15).*

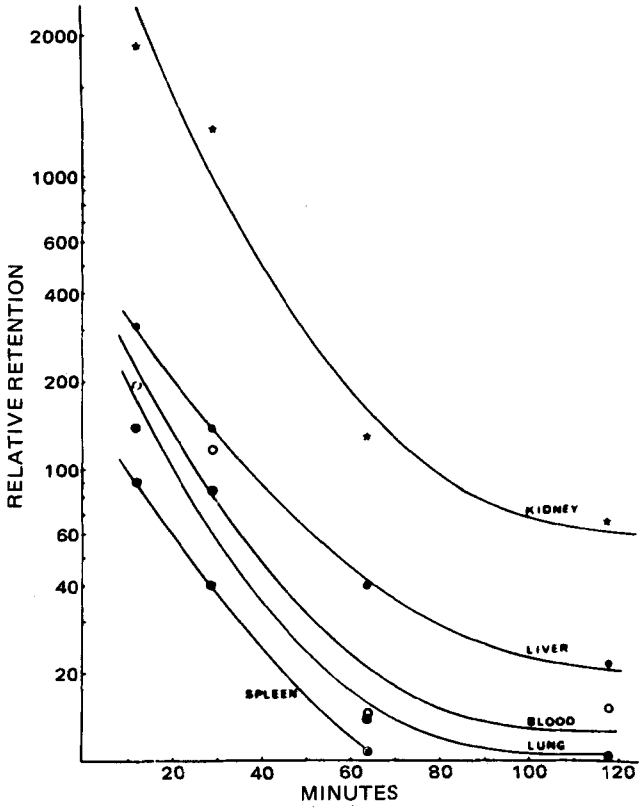

**Figure 5**—*Distribution of $^{18}$F-V (0.01 mg/kg, total radioactivity dose 2–4 × $10^{-2}$ μCi) in vital organs of the rat as a function of time. Each point represents average values from two rats.*

content by computer techniques. The percentage of the injected dose in each area was obtained by dividing the total counts in the selected areas by the counts from the whole body of the monkey. From Table I, it can be seen that the brain uptake of II in Monkey A approached near maximum level in 22 min and remained fairly constant with time. These results are consistent with those obtained with Monkey B utilizing kinetic imaging (Fig. 4). The activity in the lungs and liver reached a maximum within 22 min. After 82 min, the activity in these sites started to decrease. Here again, the results obtained with the scanner on Monkey A paralleled those obtained by imaging on Monkey B. From the computer printouts, it was estimated that ~34.6% of the total radioactive dose could be detected in the bladder of Monkey A 82 min after injection; 44.6% was found after 142 min.

The metabolite of II (V), which was synthesized utilizing a Schiemann-type reaction (Scheme II), was injected into rats. The rats were sacrificed at different times as in the distribution study of II. Each organ was assayed in the scintillation well-counter, and the counts were corrected for decay. The relative concentration of radioactivity in vital organs was calculated according to the method of Woodard *et al.* (14). From Fig. 5, it can be seen that a sharp drop in plasma levels was observed over a 1-hr period following intravenous injection of $^{18}$F-V, indicating a very fast distribution phase. The brain uptake was negligible, and the excretion rate from the kidney was very rapid. Elimination of V from the liver also was rapid.

## DISCUSSION

An attempt was made to demonstrate the usefulness of short-lived radioisotopes coupled with serial sacrifice and/or external scintigraphy in obtaining short-term distribution pharmacokinetic data. The tissue distribution of two butyrophenone neuroleptics and one of their metabolites in rats and monkeys was compared. The main emphasis was on the levels of these compounds in the target organ, the brain. As already discussed, brain levels are the apparent parameter of interest in butyrophenone therapy; in humans, these levels can only be measured using external scintigraphy.

The uptake of haloperidol (II) and bromperidol (VII) by rat brain was faster than the uptake of II by monkey brain. However, the uptake was relatively fast in both animals, with the monkey brain showing an ap-

parent slow but continuous accumulation of fluorine 18 radioactivity. The pattern observed in the monkey was quite similar to that reported for barbiturates and antipyrine (17). Unlike these compounds, however, II and VII exhibited very high brain to blood levels. These results seem to correlate well with the fast onset and prolonged duration of neuroleptic effects of II and VII. It is assumed that during the initial portion of the observation period, radioactivity levels reflect concentrations of intact drug. Literature data (1) indicate that this assumption is valid.

Data obtained in the rat seem to indicate that VII may enter the brain at a faster rate than II. This finding apparently is in agreement with the pharmacological observation that VII has a faster onset of action than II (5, 6). However, the dose of $^{82}$Br-VII administered to rats was much larger than that of $^{18}$F-II. Hence, the observed difference in the profiles of the brain levels of the two drugs also could be attributed to dose-dependent kinetics. Lewi *et al.* (16) obtained data that indicate that early uptake of II into the brain may be proportional to the administered dose. Studies involving brain uptake and dose-dependent kinetics of $^{18}$F-II and $^{82}$Br-VII utilizing external scintigraphy are in progress.

Compound V is an important intermediate in the metabolism of butyrophenone neuroleptics (7). It is believed to be the first metabolite formed during the oxidative *N*-dealkylation of these compounds. Compound V had negligible brain uptake and was eliminated rapidly from the liver and kidney after intravenous administration to rats (Fig. 5). However, this and subsequent metabolites accounted for ~20% of the radioactivity found in the brain of rats 2 hr after subcutaneous administration of $^{3}$H-II (1). Since V apparently is not partitioned into the brain, one may conclude from these findings that the metabolism of II and other butyrophenones may occur within the brain. If only the disappearance of radioactivity from the blood was followed, the relatively fast redistribution of V among the various tissues would be missed. External scintigraphy is a much more effective technique for following the tissue distribution of V since it allows continuous accumulation of data from the beginning of an experiment.

It is known that fluoride ions can replace the hydroxyl groups in hydroxyapatite crystals. Since the resulting fluoroapatite is more stable than hydroxyapatite, most fluoride ions administered to an animal concentrate in its skeleton. The present external scintigraphic studies with the monkey showed no accumulation of radioactivity in the area of the pelvis and knees. These anatomical areas were found to be regions of high free fluoride concentrations in rabbits (18). These data indicated that no $^{18}$F-labeled free fluoride was produced *in vivo* as a result of $^{18}$F-II administration. This finding strongly suggests that the carbon–fluorine 18 bond of the drug was not affected by its metabolism, a fact that is conversant with its high bond strength. Although the carbon–bromine bond is weaker than the carbon–fluorine bond, it is also believed that, during these experiments, there was no loss of bromine 82 from the aromatic ring of $^{82}$Br-VII as the bromide ion. This assumption was substantiated by Sargent *et al.* (8) who found that only 5% of the radioactivity excreted in the urine over 24 hr was due to inorganic bromide following the administration of [4-$^{82}$Br]bromodimethylphenylisopropylamine to human subjects.

# Radioimmunoassay of Carteolol in Human Plasma

**SOU-YIE CHU *x, SERGIO M. VEGA *, AKHTAR ALI ‡, and LAWRENCE T. SENNELLO ***

Received July 7, 1980, from the **Drug Metabolism Department and the* ‡*Radio-Labeling Service Department, Abbott Laboratories, North Chicago, IL 60064.* Accepted for publication February 12, 1981.

**Abstract** □ A radioimmunoassay for the direct measurement of carteolol, a new β-adrenoreceptor blocker, in human plasma was developed. Carteolol was acylated to form *O*-glutarylcarteolol, which was conjugated to bovine serum albumin to provide the immunogen. Antibody to carteolol was raised in New Zealand albino rabbits. The tracer was the radioiodinated derivative of *O*-glutarylcarteolol–tyrosine methyl ester conjugate. The method is highly sensitive, with a lower quantifiable concentration of ~0.4 ng of carteolol/ml using 0.1 ml of plasma, and has good specificity, with the major metabolite (8-hydroxycarteolol) showing only 0.2% cross-reactivity. It is reproducible, with relative standard deviations from triplicate standard curves being mostly within ±8%. The method is currently being used to monitor carteolol levels in clinical samples.

**Keyphrases** □ Radioimmunoassay—determination of carteolol in human plasma □ Carteolol—determination by radioimmunoassay, human plasma □ Antiadrenergics—carteolol, determination by radioimmunoassay, human plasma

Carteolol hydrochloride[1], 5-[3-(*tert*-butylamino)-2-hydroxypropoxy]-3,4-dihydrocarbostyril monohydrochloride, is a β-adrenoreceptor blocker currently under development as a candidate drug. A simple and sensitive fluorometric method was reported (1, 2) for the determination of its concentration in biological fluids. The lower quantifiable concentration was ~20 ng of carteolol (free base)/ml using 2 ml of plasma. This sensitivity is inadequate, especially for pharmacokinetic studies at anticipated therapeutic doses (*e.g.*, <20 mg qid). To provide the needed sensitivity, development of a radioimmunoassay for carteolol was undertaken. Antibody to carteolol was raised in rabbits by immunizing the animals with an immunogen prepared by covalently incorporating carteolol into bovine serum albumin. Radioimmunoassay using this antibody offered great sensitivity and specificity for the measurement of carteolol in plasma.

## EXPERIMENTAL

**Chemicals and Materials**—Commercial reagent grade solvents and chemicals were used. Chloramine-T solution (2.5 mg/ml) was prepared in 0.05 *M* phosphate buffer (pH 7.5). A 3.5-mg/ml solution of sodium metabisulfite also was prepared in the same buffer. The phosphate-buffered saline (saline buffer) was composed of 0.15 *M* NaCl and 0.01 *M* $NaH_2PO_4$–$K_2HPO_4$, pH 7.4.

**Chromatographic Analysis**—TLC was conducted using analytical (250 μm thick) and preparative (1000 μm) silica gel plates. The solvent system was usually ethyl acetate or chloroform–ethanol (2:1 v/v).

High-pressure liquid chromatographic (HPLC) separations were carried out using ion-pair or soap chromatography on reversed-phase columns[2]. The eluent for soap chromatography (soap eluent) was composed of 45% (v/v) acetonitrile, 0.02 *M* phosphoric acid, 0.02 *M* monobasic ammonium phosphate, and 0.15% (w/v) sodium lauryl sulfate. The typical ion-pair eluent was composed of 20% (v/v) acetonitrile, 10% tetrahydrofuran, 10% methanol, and 0.005 *M* *d*-camphorsulfonic acid. Preparative HPLC was conducted using a μBondapak $C_{18}$ column[3] (7.8 mm i.d.)

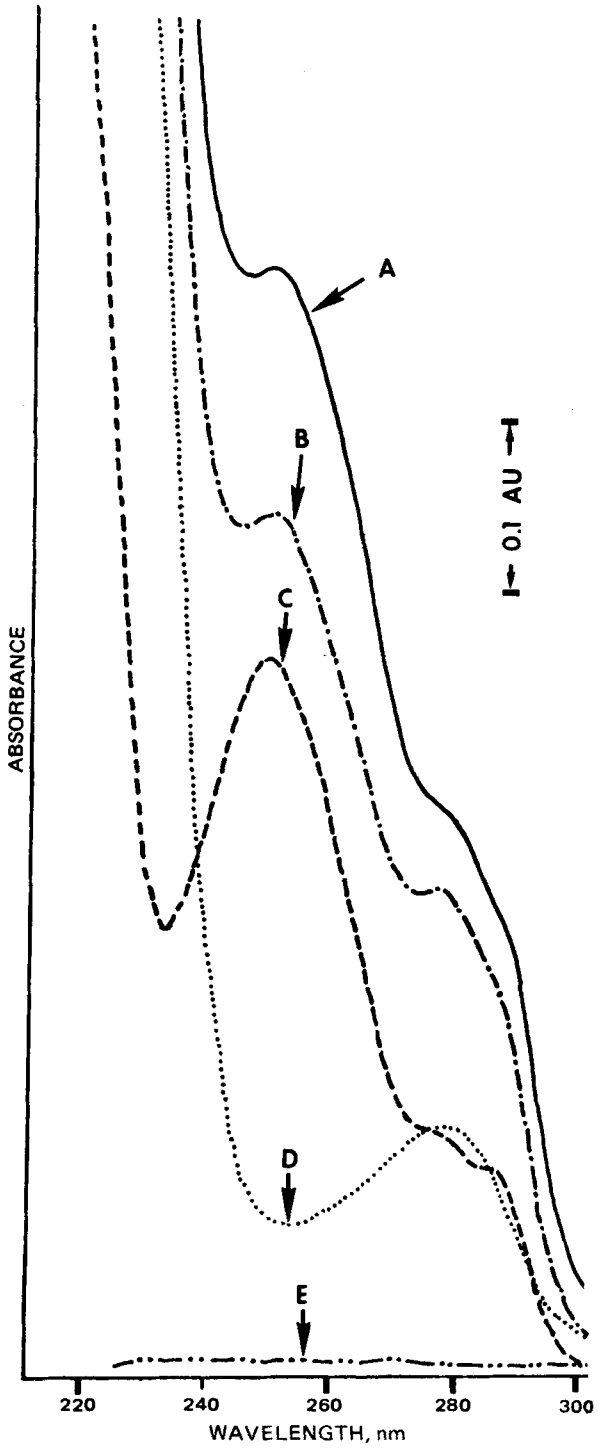

**Figure 1**—*UV absorption spectra of carteolol immunogen (A), mixture of I (20.6 μg/ml) and bovine serum albumin (242 μg/ml) (B), I (20.6 μg/ml) (C), bovine serum albumin (242 μg/ml) (D), and 0.05* M *tromethamine (pH 8.5) as background (E).*

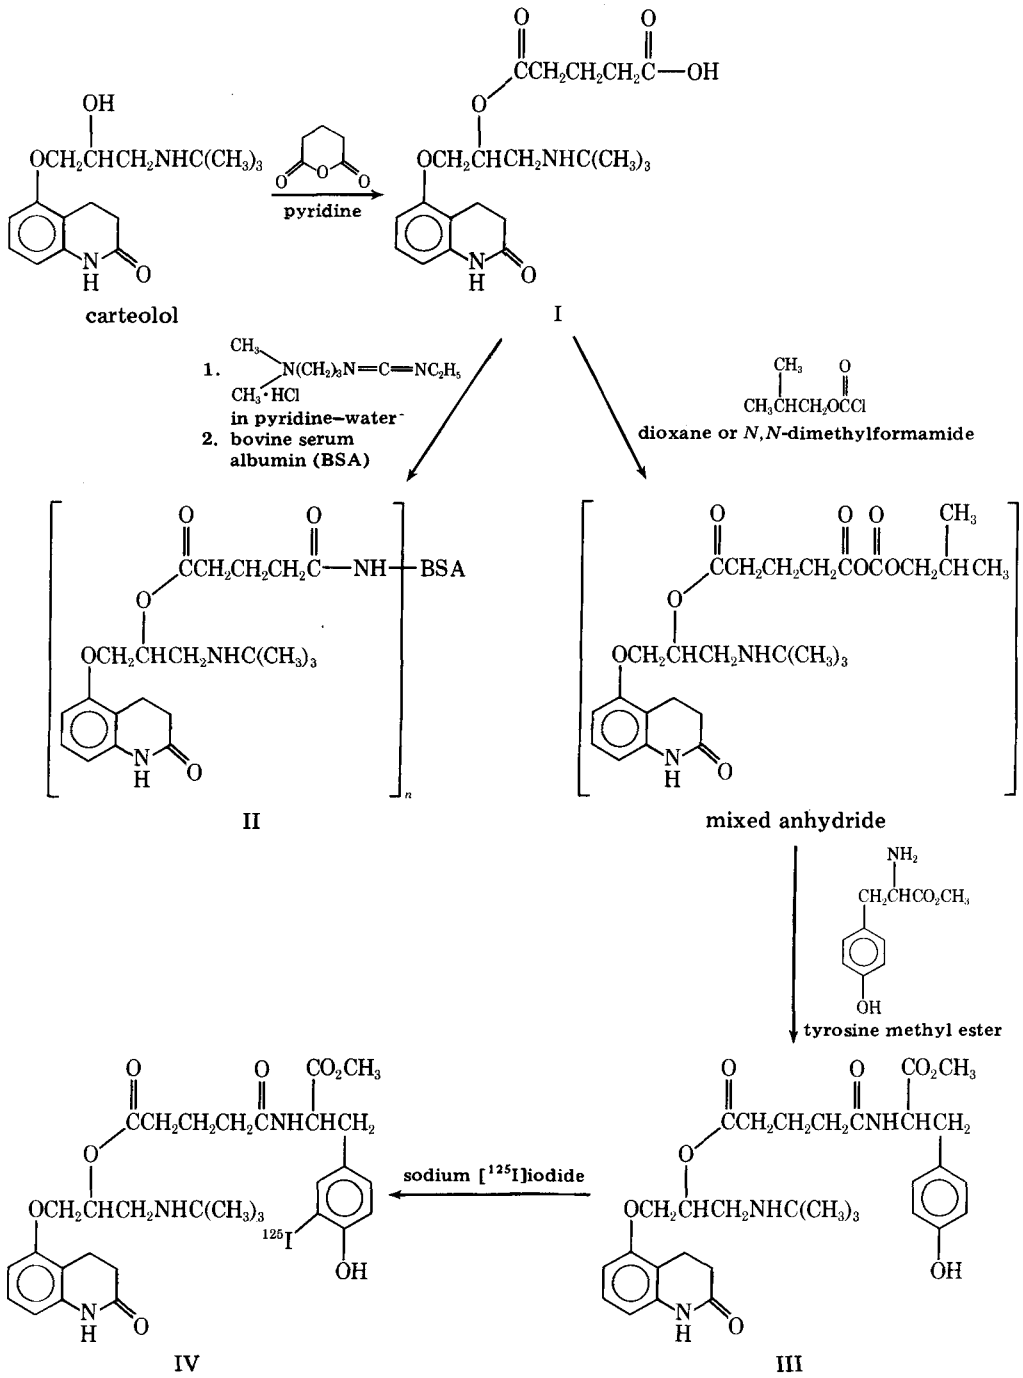

*Scheme I—Procedure for the preparation of carteolol immunogen and radioactive tracer.*

with an eluent of 18% (v/v) acetonitrile, 8% (v/v) tetrahydrofuran, and 0.005 *M* *d*-camphorsulfonic acid. Detection was accomplished by monitoring absorption at 254 nm.

**Preparation of Immunogen**—Scheme I shows the procedure for preparation of the immunogen and the radioactive tracer.

*Synthesis of* O-*Glutarylcarteolol (I)*—Carteolol (450 mg) and 210 mg of glutaric anhydride were dissolved in 7 ml of pyridine. The solution was allowed to stand overnight at room temperature and then was heated at 60° for 3 hr. The solvent was removed under reduced pressure on a rotary evaporator, and the residue was recrystallized from a mixture of ethanol and ethyl acetate. The product, after being air dried, was a colorless solid, mp 184–186°. The yield was 414 mg (66% of theory). The IR spectrum (potassium bromide pellet) showed a strong absorption band at 1740 $cm^{-1}$ (carbonyl absorption for carboxylic acid ester), indicating ester formation. The mass spectral data obtained using a direct-insert probe and electron-bombardment ionization gave the following major ions: *m/z* (ion, % relative abundance), 406.1 ($M^+$, 7.5), 391.0 (M − $CH_3$, 25.6), and 86.1 [$CH_2NHC(CH_3)_3$, 100]. PMR spectral data also were consistent with the proposed structure.

*Anal.*—Calc. for $C_{21}H_{30}N_2O_6$: C, 62.05; H, 7.44; N, 6.89. Found: C, 61.67; H, 7.68; N, 6.69.

*Preparation of Carteolol–Bovine Serum Albumin Conjugate (II)*—*O*-Glutarylcarteolol (200 mg) was dissolved in 4.0 ml of pyridine–water (1:1 v/v) with stirring. To the solution was added 240 mg of 1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride, and the mixture was stirred at room temperature for 30 min. A solution of 140 mg of bovine serum albumin in 5 ml of water then was added, and the mixture was stirred overnight.

The product was dialyzed in a cold room (~4°) against 2000 ml of saline buffer containing 5% (v/v) of dioxane and then twice against 2000 ml of water. A 0.50-ml aliquot of the dialyzed solution (~37 ml) was mixed with 1.5 ml of acetonitrile and subjected to HPLC analysis using the described soap eluent. The results showed no free I (< ~0.4 μg/ml) in the dialyzed solution. Another 0.5-ml aliquot was diluted 1:10 with 0.05 *M* trometh-

**Table I—Competition with Radioiodinated Carteolol Antigen for Antibody Binding Sites**

| Compound | Estimated $ID_{50}$, pg |
|---|---|
| Carteolol | 370 |
| Dehydrocarteolol | $25 \times 10^3$ |
| 8-Hydroxycarteolol | $230 \times 10^3$ |
| Isoproterenol | $>500 \times 10^3$ |
| 5-Hydroxy-3,4-dihydrocarbostyril | $>500 \times 10^3$ |
| Propranolol | No inhibition at $1 \times 10^6$ |

amine[4] and analyzed by UV spectrophotometry. The conjugated product had a UV spectrum (Fig. 1) nearly identical to that of a mixture of bovine serum albumin and I, showing an absorption maximum at 252 nm (similar to the carteolol derivative) and a shoulder at 278 nm (the absorption maximum for bovine serum albumin). It was estimated to contain an average of ~19 carteolol residues/bovine serum albumin molecule based on UV absorption data.

The remaining product solution was lyophilized to give 152.5 mg of white fluffy product, which was used for the immunization of rabbits.

**Preparation of $^{125}$I-Labeled Antigen**—*Preparation of O-Glutarylcarteolol-Tyrosine Methyl Ester Conjugate (III)*—*O*-Glutarylcarteolol (163 mg) was dissolved in 6 ml of hot *N,N*-dimethylformamide, and the solution was cooled in an ice water bath. To the chilled solution were added 100 μl of triethylamine and 80 μl of isobutyl chlorocarbonate. The mixture was stirred briefly on a vortex mixer and then allowed to stand in an ice water bath for 30 min with occasional stirring. To the reaction mixture was added a solution of 160 mg of tyrosine methyl ester in 4 ml of *N,N*-dimethylformamide, and the mixture was stirred briefly and allowed to stand at room temperature for ~2 hr. The solution then was evaporated to dryness, and the residue was dissolved in 2 ml of the described preparative HPLC eluent. Aliquots (~200 μl each) were chromatographed on a μBondapak $C_{18}$ column, and the fractions corresponding to the major UV-absorbing component were collected and used directly for subsequent radioiodination. The concentration of the product was estimated by comparison of its UV absorption at 252 nm to that of standard carteolol solutions (assuming approximately equal molar absorptivities for both compounds).

*Preparation of [$^{125}$I]-O-Glutarylcarteolol-Tyrosine Methyl Ester (IV)*—The procedure was similar to that described previously (3). In a disposable test tube were placed 10 μl of the III solution (~7.1 μg), 25 μl of 0.5 *M* phosphate buffer (pH 7.5), and 17 μl of sodium [$^{125}$I]iodide solution (4.0 mCi). To the solution was added 20 μl of chloramine-T solution, and the mixture was stirred for 60 sec. The reaction was terminated by the addition of 20 μl of sodium metabisulfite, and the solution was extracted with ethyl acetate (2 × 1.0 ml). The ethyl acetate solution (~95% total radioactivity) then was fractionated[5] with an eluent of 0.1% (v/v) acetic acid in ethanol. The effluent was collected in 1-ml fractions (Fig. 2). The peak fractions of the major radioactive component were pooled (1–2 mCi) and used in the radioimmunoassay. The radiochemical purity of this material was ~87% based on TLC and HPLC analyses. The compound was ~100% bound by the carteolol antiserum at a 1:200 dilution.

**Immunization**—New Zealand albino rabbits were used. A solution of II was prepared fresh in physiological saline at a concentration of 1 mg/ml and mixed thoroughly with an equal volume of Freund's complete adjuvant. One milliliter of the emulsion containing 0.5 mg of immunogen was injected into four footpads and two thighs of each rabbit. Each rabbit was immunized once a week for 4 weeks and then once every 2–6 weeks. Blood was obtained by cardiac puncture 6–14 days after the booster injections, allowed to clot overnight at 4°, and centrifuged at 2000 rpm for 20 min to yield the antiserum.

**Immunoassay Procedures**—*Preparation of Reagents*—The gelatin buffer used was saline buffer containing 0.1 mg of thimerosal/ml and 0.1% (w/v) pigskin gelatin. The radioactive tracer (usually with total radioactivity of ~1.5 mCi) was diluted to 100 ml with 0.002 *M* $H_3PO_4$ to form a stock solution, and the solution was refrigerated until used. A working solution of the tracer was prepared weekly by proper dilution (usually 1:100) of the stock solution with 0.002 *M* $H_3PO_4$.

A stock solution of carteolol standard was prepared at 1.0 mg/ml in distilled water, which was diluted 1:100 with gelatin buffer to form a working standard at 10 μg/ml. This latter solution was used to spike blank plasma. Typically, the working standard of carteolol was diluted 1:100 with blank plasma to give a plasma standard at 100 ng/ml, and this plasma sample then was diluted serially 1:2 with blank plasma to provide a set of plasma standards.

[5] A 1 × 17-cm Sephadex LH-20 column.

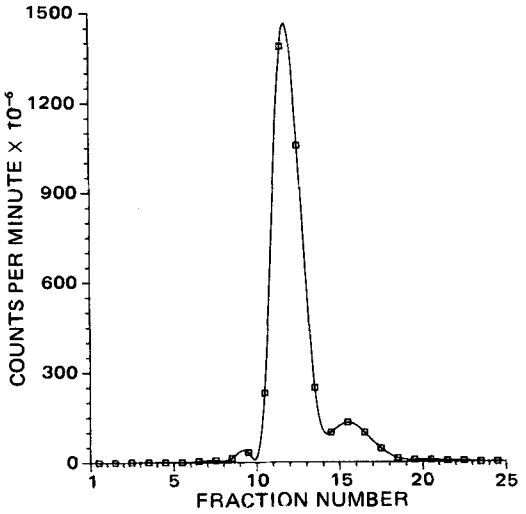

**Figure 2**—*Elution pattern of the radioiodination products on Sephadex LH-20 column. Fractions 12 and 13 were pooled and used as tracer in the radioimmunoassay.*

The antiserum from rabbits was diluted 1:4000 with gelatin buffer. An 18% (w/v) solution of polyethylene glycol 6000 in saline buffer was used to precipitate antibody-bound radioactivity.

*Assay*—A 100-μl aliquot of the diluted antiserum solution was added to 100 μl of plasma and 200 μl of gelatin buffer, followed by the addition of 100 μl of the tracer solution. The mixture was allowed to stand at ~4° overnight. To each sample was added 1.5 ml of polyethylene glycol 6000 solution, and the mixture was stirred briefly. The samples were centrifuged at 2500×*g* for 30 min at ~5°, and the supernate was decanted. The precipitate was mixed again with 1.5 ml of polyethylene glycol 6000 solution and centrifuged. After the supernate was decanted, the remainder was counted in a γ-counter.

A set of standard plasma samples was prepared in the concentration range to suit the intended analysis. A typical set included standards at 0, 0.17, 0.35, 0.69, 1.39, 2.77, 5.56, 11.11, 22.23, 44.46, and 88.91 ng/ml. These standards were carried through the radioimmunoassay in triplicate. The observed radioactivity counts (*B*) were divided by the counts from control plasma ($B_0$). A calibration curve was constructed using the mean ratios of $B/B_0$ *versus* the logarithms of plasma carteolol concentrations.

## RESULTS AND DISCUSSION

**Preparation of Immunogen**—To prepare the immunogen, carteolol hemiglutarate (I) was conjugated to bovine serum albumin. The hemisuccinate also was examined because hemisuccinate derivatives have been the most commonly used intermediates for the incorporation of haptens to carrier proteins (3–6). The *O*-succinylcarteolol showed only limited solubility in the common solvents such as water, methanol, eth-

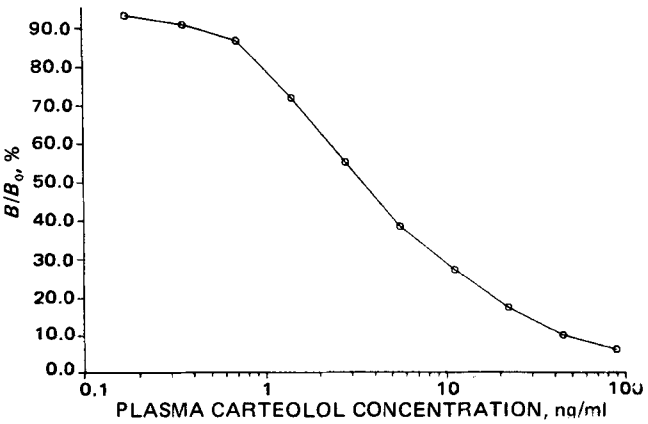

**Figure 3**—*Typical calibration curve for the radioimmunoassay.*

Table II—Within-Day and Day-to-Day Reproducibilities Using Mean Calculated Carteolol Levels (Nanograms per Milliliter) from the Radioimmunoassay

| Item | Theoretical Drug Concentration in Plasma, ng/ml | | | | | | | |

anol, dioxane, *N*,*N*-dimethylformamide, tetrahydrofuran, and acetone. Several attempts to incorporate it to bovine serum albumin using the mixed anhydride method (3, 7), the carbodiimide procedure (8, 9), and the active ester method (*N*-hydroxysuccinimide) (10) were all unsuccessful. In contrast, the *O*-glutaryl derivative was quite soluble in these solvents and could be incorporated readily to bovine serum albumin.

**Immunization**—The production of carteolol antibody in rabbits was monitored periodically by checking the animal's serum for binding to the radioactive antigen. Antibody to carteolol could be found in the rabbit serum after six injections of the immunogen over 10 weeks. After the rabbits received eight or nine injections over 26–27 weeks, serums of very good antibody titers were obtained.

**Assay Procedures**—To obtain radioiodinated tracer, tyrosine methyl ester was conjugated to carteolol through the glutaryl group, using the mixed anhydride method. The reaction was complete after ~2 hr, based on HPLC analysis. Several attempts to obtain a solid product by solvent evaporation and crystallization all were unsuccessful. Preparative TLC also was unsuitable for purification of the product, because the isolated products following these treatments were always contaminated with carteolol. Thus, preparative HPLC was used to isolate the product. The fractionated product exhibited one absorption maximum at 252 nm and a shoulder at 278 nm, being consistent with the proposed structure. The product was hydrolyzed quite readily in neutral or alkaline media to give carteolol, providing additional support to the proposed structure.

One important step in radioimmunoassay is the separation of the antibody-bound and the free fractions of the radioactive antigen. Initially, a saturated ammonium sulfate solution was examined for this purpose according to the published radioimmunoassay procedure for propranolol (6). The nonspecific binding was unacceptably high. A 0.25% (w/v) suspension of activated charcoal in gelatin buffer also was unsatisfactory. Polyethylene glycol 6000 in saline buffer was subsequently tested and showed minimum nonspecific binding while providing good precipitation of the antibody–substrate complex. Thus, 1.5 ml of the polyethylene glycol reagent was adequate for 0.5 ml of the incubation mixture.

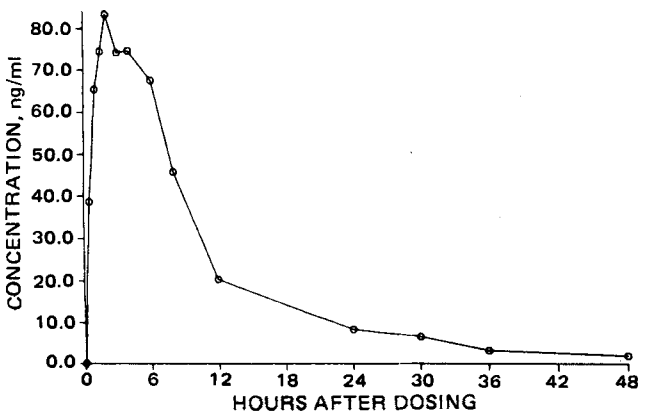

**Figure 4**—*Human plasma carteolol level–time profile determined by radioimmunoassay.*

Antibody specificity was tested against structurally related compounds by allowing each compound being used as a substitute for carteolol to compete with $^{125}$I-labeled antigen for antibody binding sites under the described radioimmunoassay conditions. The amount required to elicit 50% inhibition of initial binding ($ID_{50}$) was estimated by interpolation of the standard curve at $B/B_0$ of 50%. The results are summarized in Table I. The cross-reactivity was expressed as the ratio (percent) of the $ID_{50}$ for carteolol to that for the test compound. The only compound that showed significant cross-reactivity was dehydrocarteolol, being ~1.5%. This compound, however, is not a metabolite of carteolol. 8-Hydroxycarteolol, the major human metabolite, exhibited only very low cross-reactivity, <0.2%. Based on the available data, plasma 8-hydroxycarteolol levels within 12 hr after oral dosing are expected to be quite low compared to the corresponding parent drug levels. Thus, this metabolite should not interfere significantly in the radioimmunoassay of clinical samples.

Figure 3 shows a typical calibration curve generated according to the proposed radioimmunoassay procedure. Polypropylene and glass tubes were equally suitable for the assay. To assess day-to-day and within-day reproducibilities, standard plasma samples were prepared and carried through the radioimmunoassay procedure on 3 different days. On each day, three standard curves were prepared; each standard curve was derived from assays of triplicate samples. These $B/B_0$ ratios *versus* logarithms of concentrations were subjected to a least-squares best fit to a cubic equation using a computer program[1]. The $B/B_0$ ratios then were reinserted into the equation to calculate plasma concentration (Table II).

The radioimmunoassay procedure appears to be most suitable for the determination of plasma carteolol levels in the range of ~0.35–44.5 ng/ml. The daily replicate curves were quite reproducible, with the relative standard deviations ($n$ = 3) mostly within ±8%. The averages of the assayed carteolol levels from the nine standard curves were in good agreement with the theoretical concentrations, all being within 90–113% of theory. The relative standard deviations for these means were between ±5.2 and 13.8%, showing good day-to-day reproducibilities.

Figure 4 shows a plasma concentration–time curve obtained from the analysis of actual clinical samples from a male subject after receiving a 30-mg oral dose of carteolol hydrochloride. In summary, the proposed radioimmunoassay procedure is quite specific and has good within-day and day-to-day reproducibilities. The workup procedure is simple because it does not require solvent extraction or concentration steps. Most importantly, the method offers sensitivity that is far superior to previously reported methods. The lower quantifiable limit of this procedure is ~0.4 ng of carteolol/ml using 0.1 ml of plasma.

# Interactions of Cephalosporins and Penicillins with Nonpolar Macroporous Styrenedivinylbenzene Copolymers

**FRANCISCO SALTO ˣ and JULIO G. PRIETO**

Received December 1, 1980, from the *Departamento de Química, Facultad de Veterinaria, Universidad de León, León, Spain.* Accepted for publication February 11, 1981.

**Abstract** □ The conditions of sorption of penicillins and cephalosporins on nonionic macroporous copolymers of styrenedivinylbenzene were evaluated. By increasing the methanol concentration in the eluent, the sorption decreased. Salts exerted little influence on sorption. However, pH exerted a remarkable effect on sorption, and the capacity factor variations according to the pH are quantitatively described. Some typical separations are shown.

**Keyphrases** □ Cephalosporins—interactions with a nonpolar, macroporous styrenedivinylbenzene copolymer stationary phase □ Penicillins—interactions with a nonpolar, macroporous styrenedivinylbenzene copolymer stationary phase □ Capacity factors—cephalosporins and penicillins, interactions with a nonpolar, macroporous styrenedivinylbenzene copolymer stationary phase □ Antibiotics—cephalosporins and penicillins, interactions with a nonpolar, macroporous copolymer stationary phase

Nonionic polymers have come into use recently as nonpolar stationary phases in high-pressure liquid chromatography (HPLC), primarily because of the work of Pietrzyk and coworkers (1–5). The main advantages of these kinds of packing are their low cost, ability to function at any level, compatibility with most solvents, and high adsorbency properties.

Penicillins and cephalosporins are β-lactam antibiotics produced by acylation with different radicals of the amino groups of 7-aminocephalosporanic, 7-aminodeacetoxycephalosporanic, or 6-aminopenicillanic acids, which give cephalosporins, deacetoxycephalosporins, or penicillins, respectively. They are particularly suitable as models to study the effect of protonic equilibria on retention by nonpolar macroporous copolymers because of their structural similarities and, depending on the medium pH, they can be found in undissociated, anionic, cationic, or zwitterionic form.

In this study, a macroporous styrenedivinylbenzene copolymer[1] adsorbent with an average surface area of 780 $m^2/g$ and an average pore diameter of 50 Å (3) was used. The purposes of this work were to study the variables affecting the retention of penicillins and cephalosporins on resin copolymers and to demonstrate that the equations describing the retention of ionic solutes by the nonpolar stationary phases are applicable to the interactions of penicillins and cephalosporins with the copolymer. The results may assist in the development of new analytical methods and may improve β-lactam antibiotic extraction and purification methods; the optimum conditions of adsorption and elution may then be predicted.

## EXPERIMENTAL

7-Aminodeacetoxycephalosporanic acid (I), 7-phenylacetamidodeacetoxycephalosporin (II), cephalexin (III), cephradine (IV), 7-aminocephalosporanic acid (V), cephalosporin C (VI), cephalothin (VII), cephaloridine (VIII), cefazolin (IX), 6-aminopenicillanic acid (X), ampicillin (XI), penicillin G (XII), penicillin V (XIII), phenoxyethylpenicillin (XIV), 7-aminodeacetylcephalosporanic acid (XV), and deacetylcephalothin (XVI) were used as supplied[2].

The macroporous styrenedivinylbenzene copolymer[1] was supplied as spheres with an average size of ~500 μm. The resin particles were washed by extraction (soxhlet) with methanol and allowed to dry; they then were ground and sieved, with the 40–70-μm particles being selected (1). The size distribution of these particles was analyzed[3].

The chemicals were the highest commercial grade available and were used without any further purification. The buffer solutions were 0.05 *M* phosphate, and sodium sulfate was used to obtain the desired ionic strength. The mixtures of methanol–buffer solution were expressed in volume percent.

**Chromatographic Conditions**—A 2.5 × 600-mm steel column, equipped with suitable fittings and a 10-μm filter, was dry packed with the copolymer between 40 and 70 μm.

The liquid chromatograph was fitted with a pump[4], a 20-μl sample valve injector[5], a 250-nm UV detector[6], and a strip-chart recorder[7].

The chromatographed substances were prepared in the mobile phase at a concentration of 0.5 mg/ml, except for the penicillins, which were dissolved at a concentration of 3 mg/ml. In each case, a 20-μl aliquot was injected. The flow was maintained at 0.5 ml/min, and the sensitivity of the UV detector was set between 0.004 and 0.128 aufs, according to the absorptivity of the analyzed product.

The capacity factors ($k'$) were calculated in accordance with:

$$k' = \frac{V_R - V_0}{V_0} \qquad \text{(Eq. 1)}$$

[a] Zero percent methanol (Ref. 6).

where $V_R$ is the elution volume of the chromatographic peak and $V_0$ is the column void volume, determined as the elution volume of a nonretained peak.

**Analysis of Experimental Data**—The numerical analysis of experimental data was carried out on a calculator[8] programmed for a nonlinear least-squares fit.

**Determination of pKa**—The apparent pKa values were potentiometrically determined previously (6) under the conditions of the mobile phases used, except for an ionic strength of 0.15, 50% water–methanol, and room temperature, which were determined in the present study.

## RESULTS AND DISCUSSION

The structures of the β-lactam substances studied were indicated previously (6).

The apparent pKa values for the penicillins and cephalosporins were studied in a 50% (v/v) methanol solution at an ionic strength of 0.15 and at room temperature (Table I).

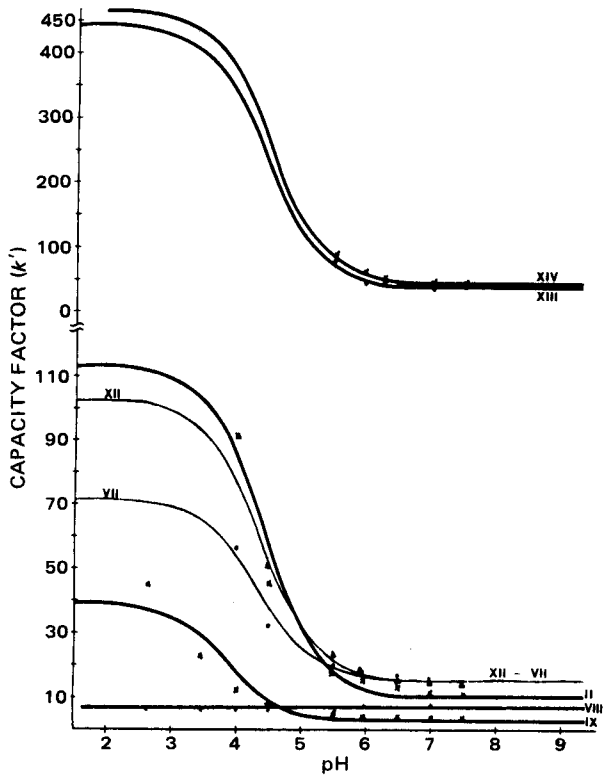

**Figure 1**—*Capacity factors, k', of acidic penicillins and cephalosporins on resin columns as a function of pH using mobile phases of 50% (v/v) methanol–0.05 M phosphate buffer at an ionic strength of 0.15. The continuous lines are the result of the nonlinear least-squares fit of the pairs of experimental k'/pH values to Eq. 2.*

[8] Texas Instruments TI-59.

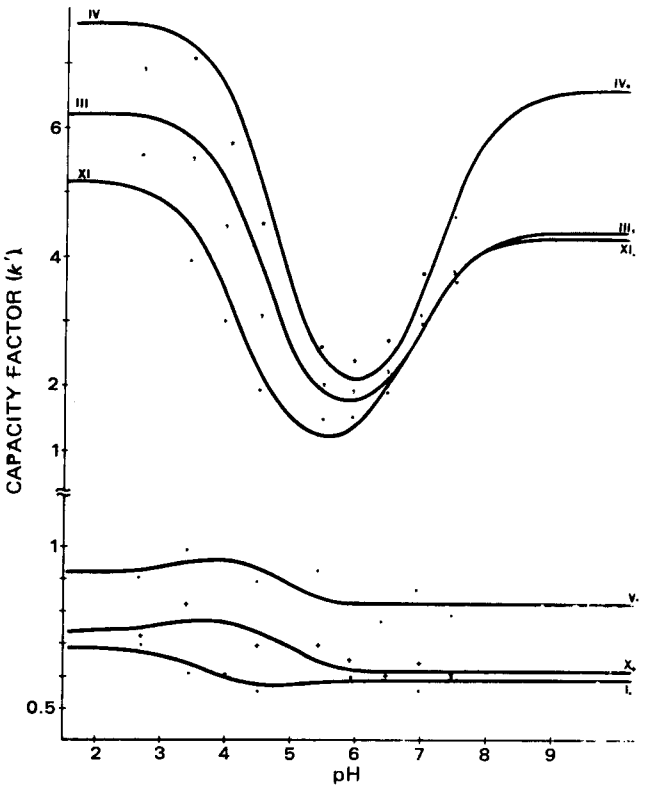

**Figure 2**—*Capacity factors, k', of amphoteric pencillins and cephalosporins on resin columns as a function of pH using mobile phases of 50% (v/v) methanol–0.05 M phosphate buffer at an ionic strength of 0.15. The continuous lines are the result of the nonlinear least-squares fit of the pairs of experimental k'/pH values to Eq. 3.*

Under the microscope, the resin particles were irregular in shape, with no dimension predominating over any other. The average size was ~55 μm. The size distribution analysis showed the particles to be 20–70 μm, with 50% (w/w) being <45 μm. The dry-packed column of resin showed an efficiency in which the height values of the theoretical plate were ~0.06 cm.

The peak tailings shown with the asymmetry factor calculated as 10% of the height of the peaks (7) were similar to those obtained with 30–70-μm octadecylsilica columns. Column permeability was relatively low. The values found for the permeability coefficient (8) were $\sim 4 \times 10^{-10}$ cm$^2$, considerably lower than those estimated by the Kozenzy–Carmen expression (8). This result is probably due to the unevenness of the resin particles since the smallest particles occupy the voids of the largest ones, thus giving a tighter packing than exists when all particles are of equal size.

**Effect of pH**—Although macroporous styrenedivinylbenzene copolymer permits the use of mobile phases at any pH, the instability of penicillins and cephalosporins in highly acidic or alkaline media limited this study to pH levels of 2.7–7.5.

The capacity factors of the penicillins and cephalosporins were studied on the resin column using 0.05 *M* phosphate buffer–methanol 50% (v/v) at different pH as the mobile phase (Figs. 1 and 2).

For nonpolar stationary phases, general equations have linked (6, 9) the variations of capacity factors of each solute ionic form. These general equations, worked out for nonpolar stationary phases and based on hydrophobic interactions, also are valid for describing variations in the capacity factors of penicillins and cephalosporins on macroporous styrenedivinylbenzene resins as a function of the mobile phase pH, as will be shown.

**Acidic Penicillins and Cephalosporins**—Cephalosporins and penicillins, inasmuch as they are weak acids, may be found in neutral, undissociated, or anionic form depending on the medium pH. The hydrophobic interactions of undissociated cephalosporins and penicillins with the nonpolar resin phase will be greater than for the corresponding ionic forms.

At high pH, distant from pKa, capacity factors are small and constant.

**Table II—Capacity Factors of Anionic ($k'_{-1}$) and Undissociated ($k'_0$) Forms of Penicillins and Cephalosporins in 50% (v/v) Methanol**

| | Compound | | | | | |
|---|---|---|---|---|---|---|
| | II | VII | IX | XII | XIII | XIV |
| $k'_0$ | 113 | 71.5 | 39.7 | 103 | 444 | 467 |
| $k'_{-1}$ | 10.0 | 15.6 | 2.66 | 15.2 | 39.5 | 43.3 |

**Table III—Capacity Factors of Anionic ($k'_{-1}$), Zwitterionic ($k'_0$), and Cationic ($k'_{+1}$) Forms of Amphoteric Penicillins and Cephalosporins in 50% (v/v) Methanol**

| | Compound | | |
|---|---|---|---|
| | III | IV | XI |
| $k'_0$ | 0.93 | 1.58 | 0.92 |
| $k'_{-1}$ | 4.69 | 6.59 | 4.32 |
| $k'_{+1}$ | 6.29 | 7.63 | 5.17 |

As the pH is lowered and approaches the pKa values, the anionic and the undissociated forms begin to coexist and the capacity factors increase. At acidic pH, where only the undissociated form may be found, the capacity factors are again constant and higher than those for high pH levels.

The quantitative description of the variations in the capacity factors with the concentration of hydronium ions may be expressed by (6, 9):

$$k' = \frac{k_0 + \frac{K_a}{[H^+]} k_{-1}}{1 + \frac{K_a}{[H^+]}} \qquad \text{(Eq. 2)}$$

where $k_0$ and $k_{-1}$ are the capacity factors of the dissociated and anionic forms, respectively; $K_a$ is the dissociation constant of penicillins or cephalosporins at 50% (v/v) methanol at an ionic strength of 0.05; and $[H^+]$ is the concentration of hydronium ions in the mobile phase.

In Fig. 1, the continuous line is the result of the nonlinear least-squares fit of experimental values of $k'$/pH to Eq. 2. An acceptable agreement exists between the theoretical provisions of Eq. 2 and the experimental values. All of the curves obtained have the same shape. The pH value at the inflection point is that of the pKa, and the pKa values found potentiometrically coincide favorably with those obtained from the curves in Fig. 1.

By applying the experimental data ($k'$/pH) to Eq. 2 using nonlinear least-squares fit, the capacity factors for the undissociated and anionic forms of each penicillin and cephalosporin studied were calculated (Table II).

**Amphoteric Penicillins and Cephalosporins**—The variations in the capacity factors of amphoteric cephalosporins and penicillins on stationary phases of nonpolar resins can be described by (6, 9):

$$k' = \frac{k_0 + k_{-1}\frac{K_{a_2}}{[H^+]} + k_{+1}\frac{[H^+]}{K_{a_1}}}{1 + \frac{K_{a_2}}{[H^+]} + \frac{[H^+]}{K_{a_1}}} \qquad \text{(Eq. 3)}$$

where $k_0$, $k_{-1}$, and $k_{+1}$ represent the capacity factors of zwitterionic, anionic, and cationic forms, respectively; and $K_{a_1}$ and $K_{a_2}$ represent the first and the second dissociation constants of penicillins or cephalosporins at 50% (v/v) methanol at an ionic strength of 0.05, respectively.

In Fig. 2, the continuous lines are obtained from the nonlinear least-squares fit of the experimental $k'$/pH values to Eq. 3. All of the curves obtained have the same shape, with the minimums coinciding with the pH value at the isoelectric point. The minimum of retention is due to the fact that the zwitterion form has a double charge (positive and negative), so the hydrophobic interactions with the resin are less than those of the anionic and cationic forms.

By applying the experimental $k'$/pH values to Eq. 3 by nonlinear least-squares fit, the capacity factors of the anionic, cationic, and zwitterionic forms of the cephalosporins and penicillins were calculated (Table III).

As expected, the capacity factors for the zwitterionic form are considerably smaller than those of the other molecular forms. The capacity factors of cationic forms are somewhat greater than those of anionic ones, which could imply that the undissociated carboxylic acid group contributes to adsorption more than does the uncharged amine group.

Being more polar then penicillins and cephalosporins, I, V, and X are less retained by the nonpolar column. The differences observed in the capacity factors with pH are small so the relative errors are large, which

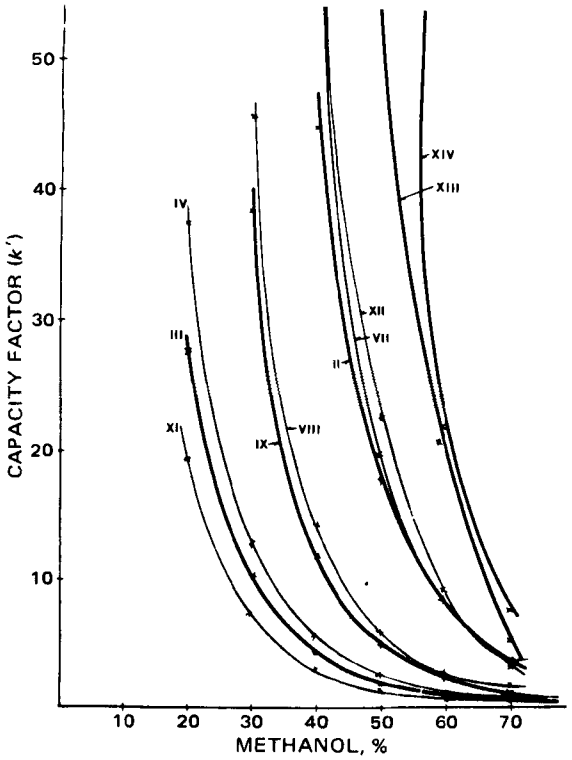

**Figure 3**—*Capacity factors, k', of penicillins and cephalosporins on resin columns using mobile phases of 0.05 M phosphate buffer at pH 5.5 and various methanol concentrations.*

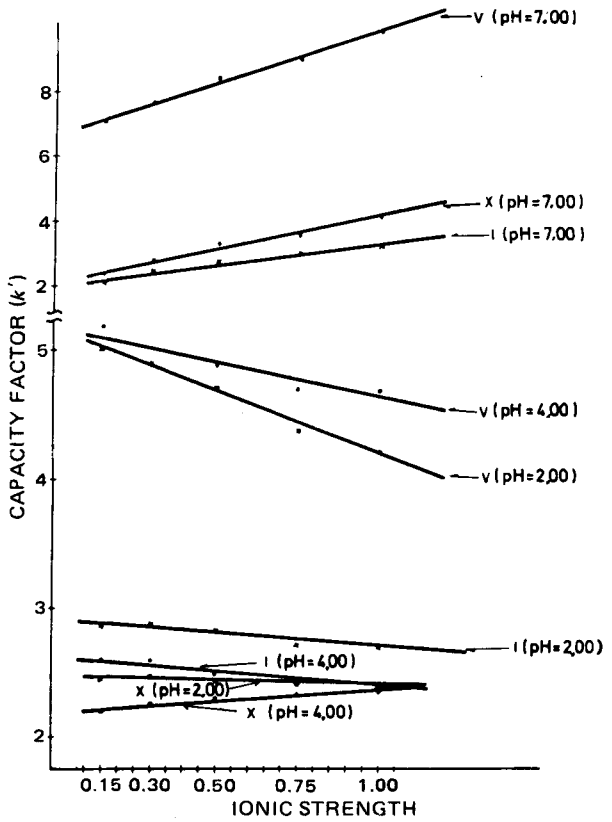

**Figure 4**—*Capacity factors, k', of I, V, and X on resin columns using mixtures of 0.05 M phosphate buffer at the pH indicated with 20% (v/v) methanol and variable ionic strengths as the mobile phases.*

Table IV—Capacity Factors of Anionic ($k'_{-1}$), Zwitterionic ($k'_0$), and Cationic ($k'_{+1}$) Forms of 7-Aminocephalosporanic (V), 6-Aminopenicillanic (X), and 7-Aminodeacetoxycephalosporanic (I) Acids in 50% (v/v) Methanol

| | Compound | | |
|---|---|---|---|
| | V | X | I |
| $k'_0$ | 1.0 | 0.78 | 0.56 |
| $k'_{-1}$ | 0.82 | 0.61 | 0.59 |
| $k'_{+1}$ | 0.92 | 0.73 | 0.69 |

implies that the application of Eq. 3 may be doubtful (Fig. 2). The results obtained for the capacity factors of the various forms are given in Table IV.

**Influence of Penicillin and Cephalosporin Structure on Capacity Factors**—Penicillin and cephalosporin nuclei are retained little by the nonpolar stationary phase of the resin. 7-Aminocephalosporanic acid (V), which has an acetoxy group in position 3 of the thiazine ring, is somewhat more retained than I and X. Acids I and X have very similar retention times, with that of the latter being somewhat greater.

Amphoteric α-aminophenylacetamide penicillins and cephalosporins have substantially higher capacity factors than their respective nuclei. Nevertheless, these factors are remarkably lower than those found for the acidic penicillins and cephalosporins. Within the group of amphoteric penicillins and cephalosporins, the least retained is ampicillin.

Within the deacetoxycephalosporins, cephradine is more retained than cephalexin, probaly due to the fact that the aromatic ring of cephalexin contributes to adsorption less than does the 2,4-cyclodihexene ring of cephradine.

Of the penicillins and cephalosporins studied that possess only one carboxylic group, the least retained is cephaloridine. In position 3 of the cephaloridine thiazine ring, the substitution of the pyridinic cation by the acetoxy group produces cephalothin, which, being much less polar, is retained considerably longer than cephaloridine. Cefazolin has intermediate capacity factors.

7-Aminocephalosporanic acid (V) and 6-aminopenicillanic acid (X), which have the same lateral chain and differ only as regards the nucleus, have very similar capacity factors. However, both V and X possess higher capacity factors than their respective nonacylated nuclei.

The introduction of phenoxy groups in the lateral chain of penicillins produces much higher capacity factors. Phenoxymethylpenicillin and phenoxyethylpenicillin are the most retained of those studied, the latter being somewhat retained owing to its slightly lesser polarity (Fig. 1).

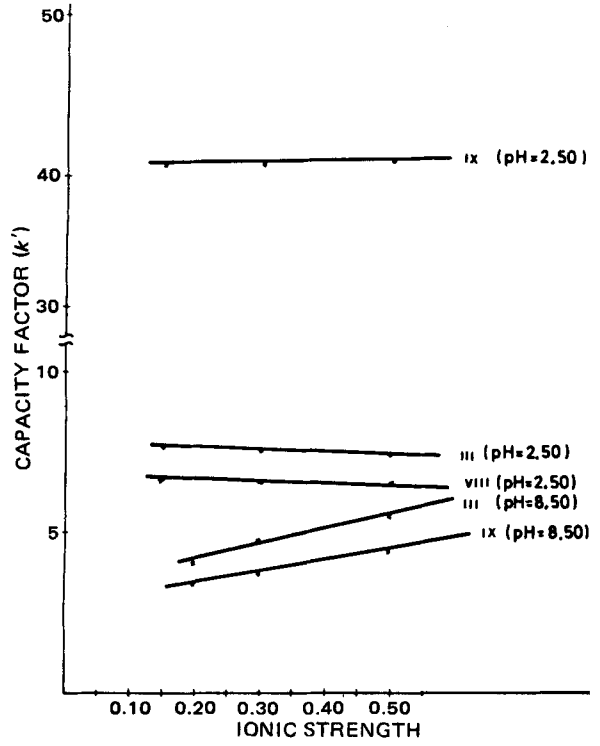

**Figure 5**—*Capacity factors, k', of some penicillins and cephalosporins on resin columns using mixtures of 0.05 M phosphate buffer at the pH indicated with 20% (v/v) methanol and variable ionic strengths as the mobile phases.*

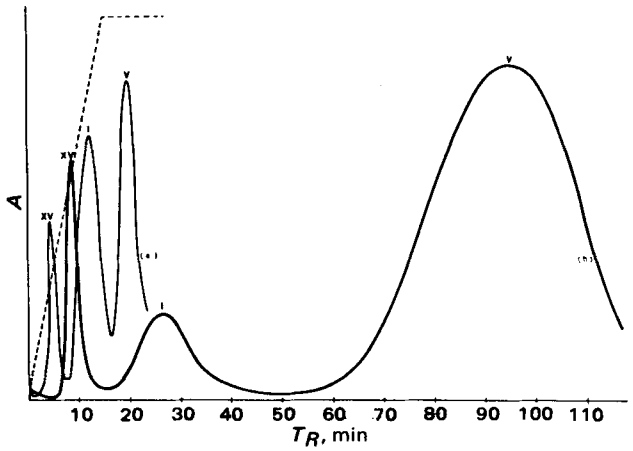

**Figure 6**—*Separation of 7-aminodeacetylcephalosporanic acid (XV), 7-aminocephalosporanic acid (V), and 7-aminodeacetoxycephalosporanic acid (I) on 2.5 × 600-mm resin columns. Key: a, 0.05 M phosphate buffer (pH 4.5) with 5% (v/v) methanol; and b, linear gradient elution (- - -) with 0.05 M phosphate buffer (pH 4.5) with from 5 to 30% (v/v) methanol.*

**Effect of Mobile Phase Methanol Content**—The retention of β-lactam substances by nonpolar macroporous styrenedivinylbenzene copolymers was studied using a mobile phase of 0.05 *M* phosphate buffer (pH 5.5), an ionic strength of 0.15, and different methanol contents.

As the methanol content of the mobile phase rose, the capacity factors decreased (Fig. 3). For the amphoteric substances I, III–V, X, and XI, the effect of the methanol content of the mobile phase on retention was not great, especially when compared with that of methanol on the retention of penicillins and cephalosporins having a single carboxyl group.

At pH 5.5, at which this study was conducted, amphoteric penicillins and cephalosporins are mainly in zwitterionic form whereas acidic penicillins and cephalosporins are principally anionic, so the polarity effect of the mobile phase is much greater on the latter than on the former.

In any event, III, IV, and XI had higher polarities than II and VII. Thus, it seems natural that mobile phase polarity should have a greater effect on the retention of less polar penicillins and cephalosporins.

**Effect of Mobile Phase Ionic Strength**—The effect of the ionic strength on the capacity factors of I, V, and X on resin was studied using mobile phases of 0.05 *M* phosphate buffer at pH 2.0, 4.0, and 7.0 with 20% (v/v) methanol. These pH levels were chosen to study the influence of the ionic strength on each ionic form (anionic at pH 7.0, zwitterionic at pH 4.0, and cationic at pH 2.0).

As shown in Fig. 4, the ionic strength had little influence on the capacity factors of I and X. A slight increase was observed in the retention of these acids as the ionic strength increased at alkaline pH, where both acids are anionic. For V, at pH 2.0 and 4.0, where it exists in cationic or zwitterionic form, respectively, the capacity factors were practically constant, with only a slight decrease as the ionic strength increased. At pH 7.0, the retention increased as the saline concentration increased. This phenomenon may be explained by the formation of ionic pairs between the carboxylate anion and the positive ions of the medium, which could alter their polar nature and/or the orientation of the molecules on the adsorbent surface.

The effect of the ionic strength on the retention of certain cephalosporins on nonpolar copolymers also was studied using mobile phases of 0.05 *M* phosphate buffer at pH 2.5 and 8.5 and a methanol content of 50% (v/v). The capacity factors of the cephalosporins studied varied little with the ionic strength of the mobile phase (Fig. 5). At pH 2.5, where the cefazolin is undissociated and cephalexin and cephaloridine are cationic, the capacity factors did not vary with increasing ionic strengh. At pH 8.5, where the cephalosporins are anionic, the representation $k'/\mu$ gives straight lines with a slightly positive slope. As in the previous case, a possible explanation could be the formation of ion-pairs as the ionic strength is increased, which could entail a rise in the contribution of the carboxylate anion on retention.

**Applications**—The results previously obtained were used to select the conditions for penicillin and cephalosporin separations.

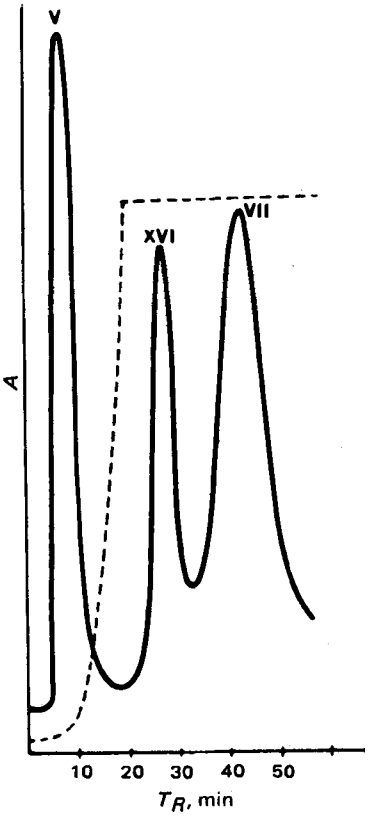

**Figure 7**—*Separation of 7-aminocephalosporanic acid (V), deacetylcephalothin (XVI), and cephalothin (VII) on resin columns; linear gradient elution (- - -) with 0.05 M phosphate buffer (pH 4.5) with from 35 to 60% (v/v) methanol.*

Figure 6 shows the separation from 7-aminocephalosporanic acid of two of its most frequent impurities, 7-aminodeacetoxycephalosporanic acid and deacetyl-7-aminocephalosporanic acid. The results obtained in an isocractic system and with gradient elution are shown in Figs. 6*a* and 6*b*, respectively.

Other examples of separation are shown in Figs. 7 and 8. In the former, cephalothin is separated from some of its possible impurities, 7-aminocephalosporanic acid and deacetylcephalothin. In the latter, cephalexin is separated from 7-aminodeacetoxycephalosporanic acid.

**Comparison of Stationary Phases of Nonionic Styrenedivinylbenzene Copolymers with Octadecylsilica**—The chromatographic interactions of penicillins and cephalosporins with the stationary phase of octadecylsilica were studied previously (6). From comparison of these results with those in the present work using polystyrenedivinylbenzene resins, the following conclusions can be drawn:

1. Polystyrenedivinylbenzene behaves as a reversed phase in a similar manner as the stationary phase of octadecylsilica. The same equations describe the capacity factor variations with pH for each stationary phase.

2. Even if the particle size for each column is similar, that of octadecylsilica has a theoretical plate height of about three times less than resin columns under the same conditions.

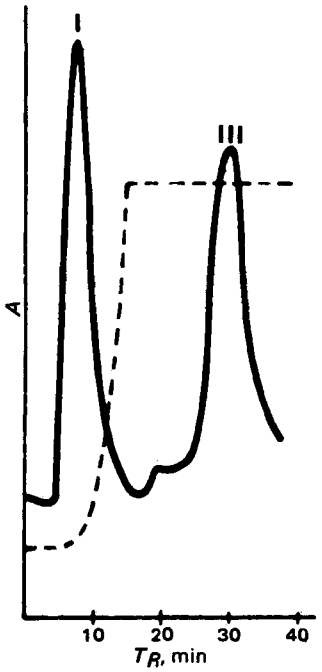

**Figure 8**—*Separation of 7-aminodeacetoxycephalosporanic acid (I) and cephalexin (III) on resin columns; linear gradient elution (- - -) with 0.05 M phosphate buffer (pH 4.5) with from 20 to 45% (v/v) methanol.*

3. The interactions among β-lactam antibiotics are more intense with resins than with octadecylsilica. Therefore, when using the resin column, a greater methanol content in the mobile phase is required than when the octadecylsilica column is used.

The octadecylsilica column is more appropriate for chromatographic separations of penicillins and cephalosporins than are columns of styrenedivinylbenzene copolymer. However, given the low cost of nonionic resins, adsorption–elution conditions may have many applications in extraction and purification processes of penicillins and cephalosporins.

# *In Vitro* Interaction of Quinidine with Kaolin and Pectin

**ARTHUR J. BUCCI *, STEVEN A. MYRE, HENRY S. I. TAN, and LATIF S. SHENOUDA ˣ**

Received October 20, 1980, from the *College of Pharmacy, University of Cincinnati Medical Center, Cincinnati, OH 45267.* Accepted for publication February 17, 1981. *Present address: College of Pharmacy, University of Rhode Island, Kingston, RI 02881.

**Abstract** □ The adsorption of quinidine onto kaolin was studied as a function of pH in aqueous solutions in which the ionic strength was adjusted to 0.1. The interaction of quinidine with pectin also was investigated in water and in phosphate buffer; the buffer pH and ionic strength were adjusted to 6.5 and 0.1, respectively. The *in vitro* results indicated that quinidine was adsorbed onto kaolin. At the highest concentration studied, the extent of adsorption increased from 3.64 mg of quinidine adsorbed/g of adsorbent at pH 2.4 to an average of 5.81 mg/g in the pH 5.5–7.5 range. In the presence of electrolytes, the interaction of quinidine with pectin was relatively small (3–13% bound) as compared to studies performed in water (66–90% bound). The data indicate that some quinidine may be adsorbed when this drug is administered concurrently with kaolin–pectin preparations.

**Keyphrases** □ Quinidine—interactions with kaolin and pectin, *in vitro* □ Kaolin—interactions with quinidine, *in vitro* □ Pectin—interactions with quinidine, *in vitro* □ Antiarrhythmic agents—quinidine, interactions with kaolin and pectin, *in vitro*

Quinidine is used in the treatment of cardiac arrhythmias, and its therapeutic effect is associated with maintaining serum levels of 2.0–6.0 μg/ml (1, 2). Side effects frequently encountered with these therapeutic levels include GI disturbances such as diarrhea (2–4). Pharmaceutical preparations containing both kaolin and pectin are available without prescription and frequently are used to treat diarrhea. Previous *in vitro* studies demonstrated that kaolin adsorbs various alkaloids (5), phenothiazines (6, 7), and cimetidine (8). *In vivo* studies showed that kaolin–pectin preparations concomitantly administered with lincomycin (9) or digoxin (10, 11) decreased the rate and the extent of absorption of these drugs.

Since kaolin adsorbs quinine *in vitro* (5), the cinchona alkaloid quinidine may be adsorbed by kaolin in the kaolin–pectin antidiarrheal preparations. Quinidine was reacted with polygalacturonic acid to form quinidine polygalacturonate (12). Since polygalacturonic acid is derived from pectin, complexation of quinidine with pectin also may occur, thus affecting the amount of quinidine available for absorption in the GI tract.

The purpose of this study was to determine the extent of quinidine adsorption onto kaolin as a function of physiological pH as well as the degree of quinidine–pectin interaction.

## EXPERIMENTAL

**Reagents**—Quinidine sulfate[1], 37% hydrochloric acid[2], monobasic sodium phosphate[3], dibasic sodium phosphate[3], anhydrous sodium sulfate[4], kaolin NF[4], and pectin[1] were used as received. The cellulose membrane tubing[5] employed had a molecular weight cutoff of 12,000–14,000.

**Analytical Method**—Quinidine sulfate concentrations in test solutions were determined using a fluorescence spectrophotometer[6] with a xenon power supply[7] and a recorder[8]. An excitation wavelength of 350 nm and an emission wavelength of 443 nm were used. By using a sensitivity setting of 4 and a concentration range of 0.2–1.0 μg/ml, a standard curve ($r$ = 0.999) was obtained as expressed by:

$$\%F = 100.0C + 0.175 \qquad \text{(Eq. 1)}$$

where $\%F$ is the emission intensity in percent and $C$ is the quinidine sulfate concentration in micrograms per milliliter. To minimize daily variation, a standard curve was obtained on a regular basis using controls subjected to the same conditions as the experimental samples.

**Determination of Equilibrium Time for Quinidine Adsorption onto Kaolin**—One-gram quantities of kaolin were weighed accurately into clean, dry, amber-glass bottles. Then 40.0 ml of quinidine sulfate solution was added. The quinidine concentrations in the time study were 5.0 and 40.0 mg/100 ml, representing the lowest and highest concentrations utilized. The bottles were capped tightly, placed in a thermostatically controlled water bath, and agitated at 37.0 ± 0.5°.

Samples were withdrawn at 6.0, 12.0, and 24.0 hr and were filtered immediately through a 0.22-μm membrane disposable filter[9]. The filtered solution was diluted and analyzed for the remaining quinidine sulfate content. Controls, containing identical concentrations of quinidine sulfate without kaolin, were treated in the same manner to check for any loss of quinidine due to degradation or adsorption onto the glassware and filter. A blank solution that contained kaolin without quinidine sulfate was prepared similarly.

**Kaolin Adsorption Studies**—The adsorption of quinidine onto kaolin was studied as a function of pH. Solution I consisted of 0.01 *M* HCl with a final pH of 2.4. Solutions II, III, and IV were phosphate buffers with final pH values of 5.5, 6.5, and 7.5, respectively. All solutions were adjusted to a final ionic strength of 0.10 by the addition of anhydrous sodium sulfate.

In all solutions studied, 40.0 ml of quinidine sulfate solution of 5.0, 10.0, 15.0, 20.0, 30.0, and 40 mg/100 ml was added to 1.0 g of kaolin in dry, amber-colored bottles. All samples were subjected to the same conditions and treated like those in the time study. All samples were left to equilibrate for 24.0 hr.

**Pectin Studies**—The interaction of quinidine with pectin was studied in water and in Solution III using membrane dialysis techniques similar to those reported previously (13, 14). Membrane bags were prepared from

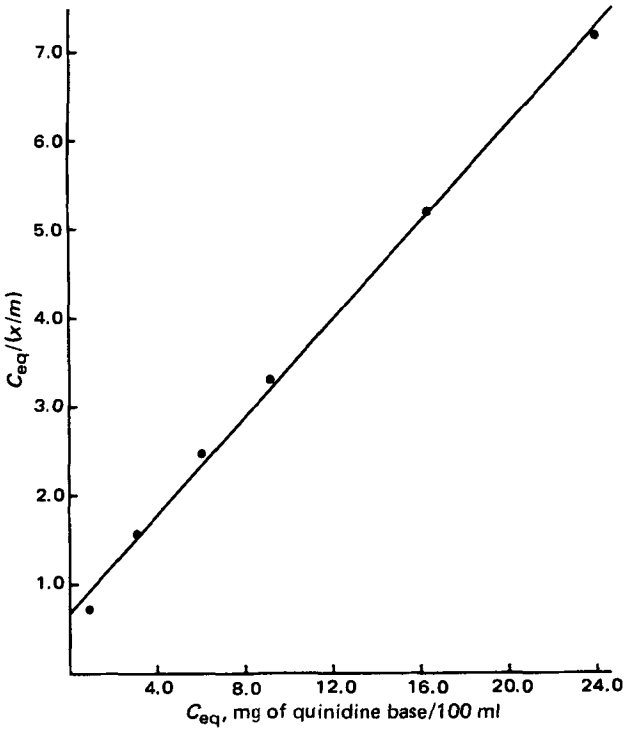

**Figure 2**—*Linear Langmuir plot for the adsorption of quinidine onto kaolin in Solution I (pH 2.4) at 37°, r = 0.999.*

cellulose tubing and were filled with 40.0 ml of pectin solution. Concentrations of 0.2, 0.4, 0.6, 0.8, and 1.0% pectin solution in water or in Solution III were used. The bags were clamped securely at the bottom and tied twice at the top to prevent leakage.

After inspection for leakage, the bags were immersed in a jar containing 60 ml of a 40.0-mg/100 ml quinidine sulfate solution either in water or in a buffered Solution III. The jars were capped tightly and placed in a shaking water bath thermostatically controlled to 37.0 ± 0.5°. The jars were allowed to agitate for 6.0 hr, a time previously determined as sufficient for achieving equilibrium. Additional membrane bags containing the appropriate solution were included in each study to check any loss of quinidine due to binding to the membrane and clamp.

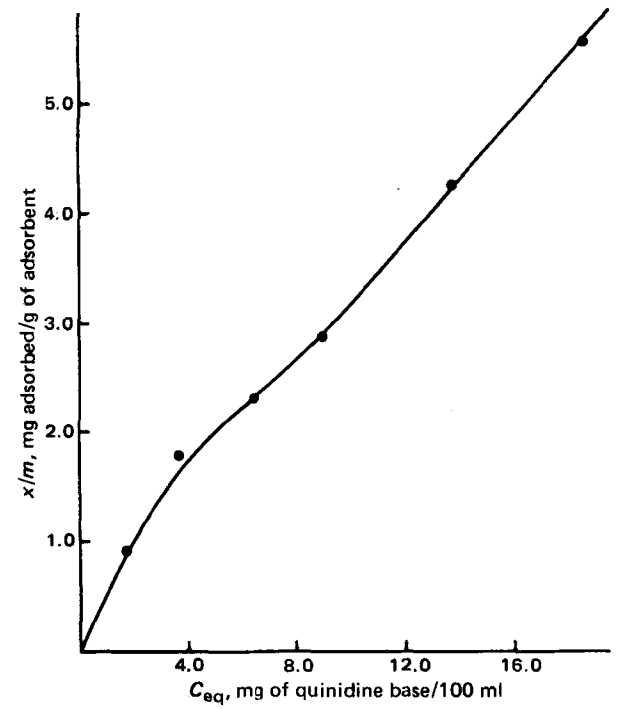

**Figure 3**—*Isotherm illustrating the adsorption of quinidine onto kaolin in Solution II (pH 5.5) at 37°.*

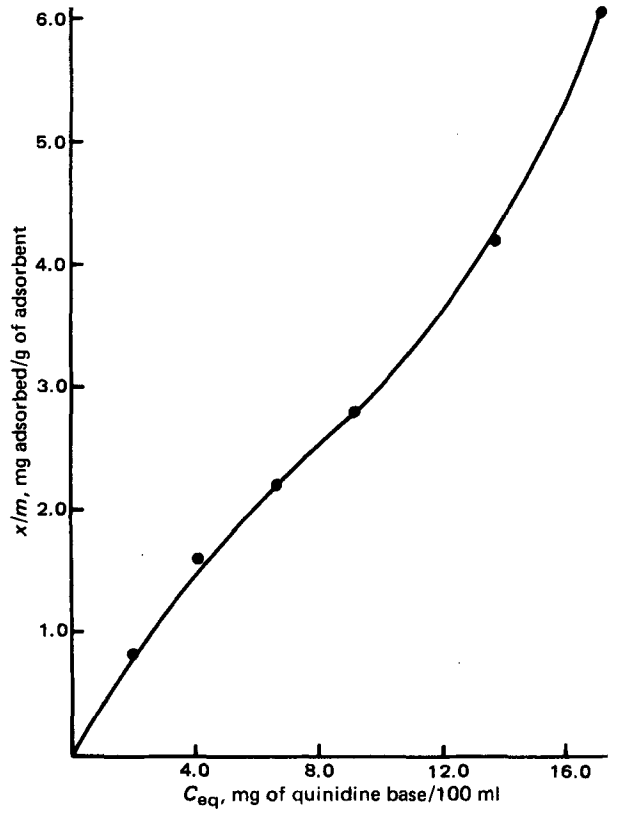

**Figure 4**—*Isotherm illustrating the adsorption of quinidine onto kaolin in Solution III (pH 6.5) at 37°.*

Four runs were performed for each pectin concentration. After achieving equilibrium and appropriate dilution, the quinidine sulfate contents both inside and outside the bag were determined spectrofluorometrically.

## RESULTS AND DISCUSSION

The kaolin time study indicated that equilibrium was achieved between 6.0 and 12.0 hr. To ensure equilibrium, all samples were allowed to agitate in the water bath for 24.0 hr. The membrane filter had no effect on the quinidine sulfate concentration based on assays performed prior to and after filtration. Furthermore, the lack of any significant decrease in the quinidine sulfate concentration in the controls indicated the apparent absence of adsorption of the drug onto the glassware and degradation during equilibration.

The results of the kaolin adsorption studies in Solution I were evaluated according to the Langmuir equation (Eq. 2):

$$\frac{x}{m} = \frac{k_1 k_2 C_{eq}}{1 + k_1 C_{eq}} \qquad \text{(Eq. 2)}$$

where $x/m$ is the weight, in milligrams, of quinidine base adsorbed per gram of kaolin; $C_{eq}$ is the concentration of quinidine base, in milligram percent, remaining in solution at equilibrium; $k_1$ is the adsorption coefficient; and $k_2$ is the maximum amount of drug adsorbed to form a monolayer under the experimental conditions. Figure 1 is a typical Langmuir isotherm obtained by plotting $x/m$ *versus* $C_{eq}$ and illustrates the formation of a quinidine monolayer on kaolin. Figure 2 is the fitted plot according to the following linear form of Langmuir:

$$C_{eq}/(x/m) = C_{eq}/k_2 + 1/k_1 k_2 \qquad \text{(Eq. 3)}$$

The maximum adsorptive capacity calculated from the slope of the line is 3.64 mg/g.

Ionic strength was adjusted with anhydrous sodium sulfate since preliminary studies showed that a high concentration of chloride ions, either in the form of hydrochloric acid (0.1 *M*) or sodium chloride for adjusting the ionic strenth to 0.1, caused quenching and interfered with the assay. The low concentration of hydrochloric acid (0.01 *M*) did not present any analytical problem. With quinidine sulfate concentrations up to 40.0 mg/100 ml, the results of adsorption studies in Solution II indicate that adsorption is not limited to the formation of a monolayer as

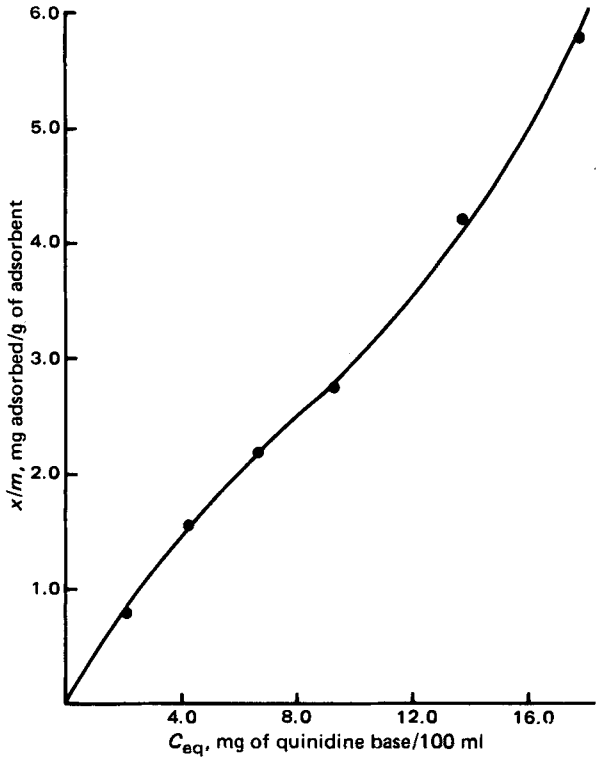

**Figure 5**—*Isotherm illustrating the adsorption of quinidine onto kaolin in Solution IV (pH 7.5) at 37°.*

observed in Solution I. This result is shown in Fig. 3, which indicates that multilayered adsorption occurred. Similar results were obtained from studies in Solutions III and IV (Figs. 4 and 5, respectively). Langmuir linearity was established for Solution II in quinidine sulfate concentrations between 1.0 and 3.0 mg/100 ml (Fig. 6). In this same low concentration range, linearity was not observed for Solutions III and IV.

These results indicate that adsorption of quinidine onto kaolin varies with pH. The apparent multilayered process that occurred in Solutions II–IV indicates that drug adsorption continues at higher pH values. Further experimentation is underway to explain this behavior.

Since increasing electrolyte concentrations may increase the adsorptive capacity of kaolin (7), it is not surprising that there are no apparent differences in the isotherms (Figs. 3–5) since the ionic strength was kept constant in all solutions. For example, at an initial concentration of 32.4 mg of quinidine base/100 ml (equivalent to 40 mg of quinidine sulfate/100 ml in solution) the calculated $x/m$ values are 5.57, 6.07, and 5.79 mg/g for Solutions II, III, and IV, respectively. Therefore, at quinidine sulfate concentrations up to 40.0 mg/100 ml, the amount of drug adsorbed per

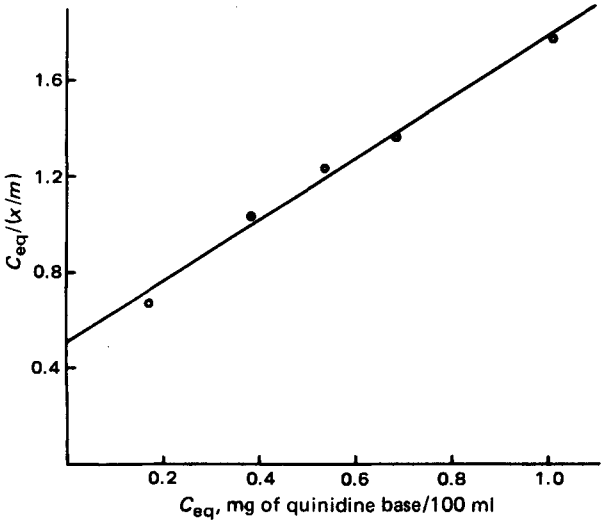

**Figure 6**—*Linear Langmuir plot for the adsorption of quinidine onto kaolin at low concentrations in Solution II (pH 5.5) at 37°, r = 0.994.*

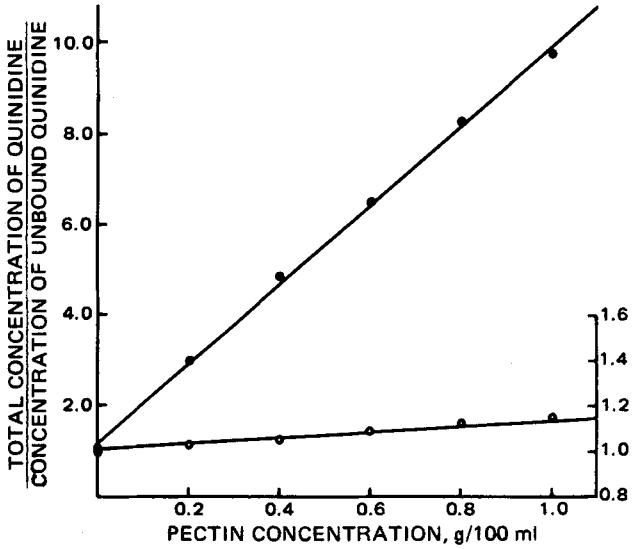

**Figure 7**—*Interaction between quinidine and pectin at 37°. Key: ●, water (r = 0.999); and ○, pH 6.4 buffer at an ionic strength of 0.1 (r = 0.998).*

gram of adsorbent increases as the pH is raised from acidic pH, simulating the stomach environment, to pH 5.5–7.5, which simulates the intestinal environment. The results of the present study parallel the findings of Remon *et al.* (15) who reported that the adsorption of quinidine onto kaolin increases with pH. Their results were obtained under different *in vitro* conditions with much higher quinidine sulfate concentrations. Thus, any firm comparisons between the two studies are difficult.

The data of the pectin study were analyzed by previously reported methods (14). The calculated coefficient of variation for identical runs was 1–4%. Figure 7 shows marked complexation between quinidine and pectin in unbuffered aqueous medium. The extent of binding of quinidine ranged between 66 and 90% at a pectin concentration between 0.2 and 1%. Binding was reduced markedly when the study was repeated in Solution III. The extent of binding ranged between 3 and 13% in the same pectin concentration range (Fig. 7). According to these data, complexation studies performed in water without electrolytes could be misleading. Studies utilizing electrolyte solutions, such as Solution III, may be more representative of an *in vivo* situation. The same pattern of interaction was observed by Remon *et al.* (15) who studied quinidine sulfate complexation with 1% pectin in water and in 0.01 *M* HCl. They reported that quinidine sulfate was 40% bound to pectin in water and was 5% bound in acidic solution. In the current study, ~90% of quinidine was bound by 1% pectin in water. This difference may be accounted for by the higher quinidine concentrations (500 mg/100 ml) used previously (15).

The results of this *in vitro* study indicate that kaolin is capable of adsorbing quinidine and that adsorption increases with pH. Pectin forms a complex with quinidine; however, the effect is less pronounced in Solution III than in water. Although complexation with pectin may afford a controlled and more uniform absorption of quinidine as shown for quinidine polygalacturonate (12), the data suggest that this effect may be minimal. Kaolin and pectin contained in antidiarrheal preparations may alter absorption of the drug from the GI tract. Relative bioavailability studies should be carried out to determine the significance of this interaction.

# Quantification of Phencyclidine in Mainstream Smoke and Identification of Phenylcyclohex-1-ene as Pyrolysis Product

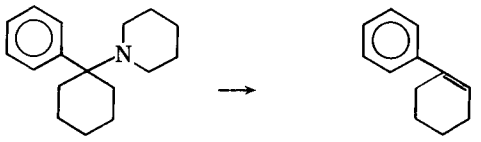
**A. S. FREEMAN and B. R. MARTIN** ˣ

Received September 2, 1980, from the *Department of Pharmacology, Virginia Commonwealth University, Medical College of Virginia, Richmond, VA 23298.* Accepted for publication February 12, 1981.

**Abstract** □ Parsley cigarettes containing [$^3$H]phencyclidine were machine smoked, and the mainstream smoke was trapped in glass wool filters. Radioactivity was extracted from these filters with chloroform. The average recoveries of radioactivity were 76, 85, 70, and 69% for cigarettes containing 3, 10, 30, and 50 mg of [$^3$H]phencyclidine hydrochloride, respectively. TLC and GLC–mass spectrometry were employed to identify and quantify compounds in the filter extracts. Approximately one-half of the recovered radioactivity represented a pyrolysis product, phenylcyclohex-1-ene. Formation of this product involved loss of piperidine from phencyclidine. Piperidine, which was not radiolabeled, also may appear in smoke intact. The remainder of the radiolabeled material represented unchanged phencyclidine. Therefore, the percentage of [$^3$H]phencyclidine delivered was ~40% of the amount smoked. This result was independent of puff frequency and quantity of phencyclidine hydrochloride smoked over the range tested. The [$^3$H]phencyclidine delivery was compared to the quantities of [$^3$H]-$\Delta^9$-tetrahydrocannabinol and [$^3$H]nicotine delivered in mainstream smoke. The recovery of unchanged [$^3$H]-$\Delta^9$-tetrahydrocannabinol from placebo marijuana cigarettes injected with a solution containing 3 mg of $\Delta^9$-tetrahydrocannabinol was 60%. Tobacco cigarettes injected with [$^3$H]nicotine yielded 70% unchanged nicotine in mainstream smoke.

**Keyphrases** □ Pyrolysis—formation of phenylcyclohex-1-ene from phencyclidine in smoke □ Phencyclidine—identification of pyrolysis product phenylcyclohex-1-ene in smoke □ Phenylcyclohex-1-ene—pyrolysis product of phencyclidine identified in smoke □ Smoke—identification of phenylcyclohex-1-ene, a pyrolysis product of phencyclidine

Phencyclidine [1-(1-phenylcyclohexyl)piperidine] has gained popularity as a drug of abuse, probably because it produces euphoria, dissociation, and hallucinations (1). Smoking phencyclidine-impregnated spices is currently a major method of abuse. The high temperature attained in a burning cigarette raises the possibility that phencyclidine may evolve pyrolysis products when smoked. Phencyclidine is converted to phenylcyclohex-1-ene in the gas chromatograph at low temperatures (2) (Scheme I), which may have led to the conclusion that phenylcyclohexene is a metabolite of phencyclidine (3). Preliminary results indicate that phenylcyclohexene also is formed during smoking (4). In this study, the amount of phencyclidine delivered in mainstream smoke was determined and the pyrolysis products were identified and quantified.



phencyclidine → phenylcyclohex-1-ene

*Scheme I*

## EXPERIMENTAL

**Drugs**—Phencyclidine hydrochloride[1], piperidinocyclohexane carbonitrile[1], [*phenyl*-1-$^3$H(*n*)]phencyclidine[1] (17 Ci/mmole), $\Delta^9$-tetrahydrocannabinol[1], and [1′,2′-$^3$H]-$\Delta^9$-tetrahydrocannabinol[1] (43 mCi/mmole) were used. [*pyrrolidinyl*-4′,4-$^3$H]Nicotine (4.7 Ci/mmole) was synthesized according to the procedure of Vincek *et al.* (5).

**Preparation of Cigarettes**—Cigarettes containing phencyclidine were prepared using commercially available parsley flakes[2], 55-mm cigarette tubes[3], and a cigarette machine[4]. Each cigarette (550–600 mg) was prepared immediately prior to its use by injection with 0.5 μCi of [$^3$H]-phencyclidine and 3, 10, 30, or 50 mg of phencyclidine hydrochloride in volumes of 50, 50, 150, or 200 μl of ethanol, respectively. Filterless cigarettes[5] (84 mm) were injected with 0.5 μCi of [$^3$H]nicotine in 50 μl of ethanol, and placebo marijuana cigarettes[1] were injected with 0.5 μCi of [$^3$H]-$\Delta^9$-tetrahydrocannabinol and 3 mg of $\Delta^9$-tetrahydrocannabinol in 50 μl of ethanol. All drug solutions were injected axially and evenly throughout the middle 35 mm of the cigarettes and allowed to dry before smoking.

**Procedure**—Cigarettes were inserted in a holder and attached to the smoking apparatus (Fig. 1). Smoking was effected by negative pressure provided by water aspiration, and smoke was collected on two contiguous filters (each consisting of 1–1.25 g of glass wool stuffed in 16 cm of 0.635-cm i.d. tubing[6]). Interfaced between the filters and vacuum source were an empty trap (for back-siphoning) and a trap containing 10 ml of chloroform.

Puffing was accomplished with an electric switching valve[7] that opened and closed the system to the vacuum every 5.8 sec. Puff frequency was altered by replacement of a capacitor in the circuit board controlling the valve. A vacuum regulator[8] was set to permit delivery of 45 ml of smoke/5.8-sec puff duration. After an entire cigarette was smoked, each

# Quantification of Phencyclidine in Mainstream Smoke and Identification of Phenylcyclohex-1-ene as Pyrolysis Product

**A. S. FREEMAN and B. R. MARTIN** ˣ

Received September 2, 1980, from the *Department of Pharmacology, Virginia Commonwealth University, Medical College of Virginia, Richmond, VA 23298.* Accepted for publication February 12, 1981.

**Abstract** □ Parsley cigarettes containing [$^3$H]phencyclidine were machine smoked, and the mainstream smoke was trapped in glass wool filters. Radioactivity was extracted from these filters with chloroform. The average recoveries of radioactivity were 76, 85, 70, and 69% for cigarettes containing 3, 10, 30, and 50 mg of [$^3$H]phencyclidine hydrochloride, respectively. TLC and GLC–mass spectrometry were employed to identify and quantify compounds in the filter extracts. Approximately one-half of the recovered radioactivity represented a pyrolysis product, phenylcyclohex-1-ene. Formation of this product involved loss of piperidine from phencyclidine. Piperidine, which was not radiolabeled, also may appear in smoke intact. The remainder of the radiolabeled material represented unchanged phencyclidine. Therefore, the percentage of [$^3$H]phencyclidine delivered was ~40% of the amount smoked. This result was independent of puff frequency and quantity of phencyclidine hydrochloride smoked over the range tested. The [$^3$H]phencyclidine delivery was compared to the quantities of [$^3$H]-$\Delta^9$-tetrahydrocannabinol and [$^3$H]nicotine delivered in mainstream smoke. The recovery of unchanged [$^3$H]-$\Delta^9$-tetrahydrocannabinol from placebo marijuana cigarettes injected with a solution containing 3 mg of $\Delta^9$-tetrahydrocannabinol was 60%. Tobacco cigarettes injected with [$^3$H]nicotine yielded 70% unchanged nicotine in mainstream smoke.

Table I—Recovery of [$^3$H]Phencyclidine from Mainstream Smoke

| [$^3$H]Phencyclidine[a], mg | Radioactivity Recovered[b], % | Quantity Recovered[c], mg (micromoles) | |
|---|---|---|---|
| | | Phencyclidine | Phenylcyclohexene |
| 2.62 | 76 ± 4 | 1.43 (5.88) | 0.56 (3.54) |
| 8.73 | 84 ± 4 | 4.62 (19.01) | 2.71 (17.15) |
| 26.20 | 70 ± 4 | 11.19 (48.01) | 7.15 (45.20) |
| 43.63 | 69 ± 5 | 16.26 (66.92) | 13.84 (87.57) |

[a] Quantity of [$^3$H]phencyclidine injected into cigarettes that corresponds to 3, 10, 30, or 50 mg of the hydrochloride salt. [b] Means ± *SE* of $n = 3$. [c] Determined by TLC analysis.

filter tubing unit was washed with chloroform (40 ml), and 50-μl aliquots were placed in scintillation vials with 10 ml of aqueous counting scintillant[9]. A rinse of the cigarette holder was included in the wash of the first filter. Each sample was assayed for radioactivity in a scintillation counter[10]. Quench was corrected by external standardization.

**Temperature of Burning Cigarette**—A thermocouple[11] measured the temperature within a burning parsley cigarette. The temperature-sensitive electrode was inserted perpendicular to the long axis of the cigarette at its midpoint, and the temperature was recorded every 5 sec.

**TLC**—To quantify [$^3$H]phencyclidine and identify pyrolytic products, 150 μl of each chloroform wash of the glass wool was applied as a band to each of two 5 × 10-cm silica gel TLC plates[12] along with 5 μg of phencyclidine and phenylcyclohexene. One plate was developed in chloroform–methanol–concentrated ammonia (90:10:0.15), in which phencyclidine had an $R_f$ value of 0.42 and phenylcyclohexene moved with the solvent front. The other plate was developed in hexane–concentrated ammonia (5:0.04), in which phencyclidine remained at the origin and phenylcyclohexene had an $R_f$ value of 0.42. The bands were visualized by exposure to iodine vapor, and the plates then were divided into bands and scraped into scintillation vials containing 0.5 ml of methanol and 0.5 ml of water. The samples were sonicated for 30 min, and radioactivity was counted in 10 ml of counting fluid[13]. Counting efficiency was corrected by internal standardization using [$^3$H]toluene[14].

The [$^3$H]nicotine and [$^3$H]-$\Delta^9$-tetrahydrocannabinol smoke condensates were analyzed by TLC as already described. The solvent system for [$^3$H]nicotine was ether–acetone–concentrated ammonium hydroxide (4:1:0.15). The samples were cochromatographed with 3 μg of nicotine ($R_f$ 0.67), and the standard was visualized by spraying with Dragendorff solution. The [$^3$H]-$\Delta^9$-tetrahydrocannabinol samples were cospotted with 3 μg of $\Delta^9$-tetrahydrocannabinol. After development in 40–60% petroleum ether–ether (4:1), $\Delta^9$-tetrahydrocannabinol ($R_f$ 0.56) was visualized by spraying with 0.1% Fast Blue B in 1 *N* NaOH.

**GLC–Mass Spectrometry**—The instrument[15] was operated at an accelerating voltage of 1.55 kv, an electron energy of 70 ev, a separator temperature of 250°, an ion source temperature of 250°, and an injector temperature of 200°. The glass column (1 m × 2 mm) was packed with 3% (w/w) SP-2250 on 80–100-mesh Gas Chrom Q[16], and the carrier gas (helium) flow rate was 30 ml/min. The initial column temperature of 160° was increased to 180° immediately after phenylcyclohexene was eluted (0.95 min).

## RESULTS

The smoking interval for the average cigarette (smoked in its entirety) was ~6 min when a puff interval of 5.8 sec was used. The temperature at the midpoint of the parsley cigarettes ($n = 8$) reached a maximum of 671 ± 13°. The midpoint temperature was >400° for ~0.5 min (5 mm of cigarette burned), indicating that the cigarette components were subjected to high temperatures for a considerable time.

**Recovery of Radioactivity from Cigarettes**—After the smoking of a cigarette containing 3 mg of [$^3$H]phencyclidine hydrochloride, 76% of the radioactivity was found in the first filter and none was found in the second (Table I). Increasing the quantity of [$^3$H]phencyclidine hydrochloride in the cigarettes did not affect recovery. The possible effect of puff frequency on recovery also was investigated by increasing the interpuff interval from 5.8 to 30 sec. At the lower puff frequency, 67 ± 6% ($n = 3$) of the radioactivity in a cigarette containing 10 mg of [$^3$H]phencyclidine hydrochloride was recovered, which was slightly less than that recovered with the 5.8-sec interpuff interval.

**TLC Analysis**—In the solvent systems used, either phenylcyclohexene ran with the solvent front or phencyclidine remained at the origin. To ensure complete separation, the samples were chromatographed using two systems. The percentages of recovered radioactivity corresponding to phencyclidine and phenylcyclohexene were the same regardless of the TLC system employed.

All of the condensates contained appreciable quantities of phenylcyclohexene, which ranged from 37 to 54% of the recovered material (Table I). The percentage of phencyclidine converted to phenylcyclohexene increased somewhat as the quantity of phencyclidine was increased. Alteration of puff frequency produced no change in the relative amounts of phencyclidine and phenycyclohexene recovered. Experiments also were carried out to determine whether there was a constant delivery of radioactivity throughout the smoking process. Collection of smoke from the burning of the first third of the cigarette resulted in 16.3 ± 1% of the total recovered radioactivity; the second third accounted for 31 ± 5.6%, and the last third was 52.3 ± 7.0% of the total recovered ($n = 3$/group). The total recovery of the added [$^3$H]phencyclidine was 68 ± 5%.

**Identification and Quantification by GLC–Mass Spectrometry**—To identify phencyclidine and its pyrolytic products, mass spectra of standard compounds were recorded. Piperidinocyclohexane carbonitrile was injected into the GLC–mass spectrometer where it was readily converted to piperidinocyclohex-1-ene (6), which had a retention time of 0.8 min. Piperidinocyclohex-1-ene had a base peak at $m/z$ 164 and abundant ions at $m/z$ 150 (80% relative intensity), 136 (65%), and 122 (39%). Phenylcyclohexene (retention time 0.9 min) had a molecular ion at $m/z$ 158 (75%) and a base peak at $m/z$ 129. The mass spectrum of phencyclidine (retention time 3.7 min) was similar to that reported previously (2) in that $m/z$ 200 was the base peak and abundant ions were at $m/z$ 158 (57%), 129 (54%), and 91 (93%).

Three smoke condensates were selected randomly for continuous GLC–mass spectrometric scanning. Phencyclidine and phenylcyclohexene were present in all three samples, and no other pyrolysis products were identified. These same three samples also were analyzed by single-ion monitoring. Ions $m/z$ 129 and 200 were detected at the appropriate retention times for phenylcyclohexene and phencyclidine (Fig. 2), but there was no detectable $m/z$ 164 for piperidinocyclohex-1-ene. For quantitative purposes, separate calibration curves were constructed for phencyclidine and phenylcyclohexene in the 50–500-ng/μl concentration range by monitoring ions 200 and 129. The average ratio of phencyclidine to phenylclohexene in the three samples was 1.04 ± 0.02 on a molecular basis, which was in good agreement with the TLC analysis. Since phencyclidine is labile in the gas chromatograph (2), phencyclidine standards were analyzed for degradation products. Less than 0.5% of the phencyclidine was converted to phenylcyclohexene under the GLC–mass spectrometric conditions employed (Fig. 2).

**Recovery of Other Drugs of Abuse in Smoke**—Placebo marijuana cigarettes ($n = 3$) spiked with [$^3$H]-$\Delta^9$-tetrahydrocannabinol were smoked, and 94 ± 3% of the radioactivity was recovered in the first filter. Likewise, 73 ± 1% ($n = 3$) of the radioactivity in tobacco cigarettes in-

jected with [$^3$H]nicotine was recovered in the first filter. TLC analysis of the [$^3$H]-$\Delta^9$-tetrahydrocannabinol smoke condensate showed that 63% of the radioactivity was due to unchanged material so that 60% of the starting material was delivered in mainstream smoke. Ninety-five percent of the radioactivity recovered from the [$^3$H]nicotine cigarettes remained unchanged. Therefore, 70% of the original [$^3$H]nicotine was recovered from mainstream smoke.

## DISCUSSION

In cigarettes containing 3–50 mg of phencyclidine hydrochloride, an amount equivalent to that found in some street samples (7), ~40% of the starting material was recovered from mainstream smoke. The pyrolysis product, phenylcyclohexene, was present in concentrations comparable to those of phencyclidine. Therefore, the percentage of both compounds delivered in mainstream smoke was independent of the quantity of phencyclidine present. Since formation of phenylcyclohexene involves loss of the piperidine moiety from phencyclidine, it would be reasonable to assume that equimolar concentrations of piperidine also are delivered in smoke. Alteration of the puff frequency had little effect on the quantities of phencyclidine and phenylcyclohexene evolved, indicating minor importance of this variable on smoke composition.

This independence of smoke composition from the amount of drug and frequency of puffing suggests that illicit use of phencyclidine-containing cigarettes can be expected to yield amounts of phencyclidine and its pyrolysis product, phenylcyclohexene, similar to those found in this study. Also, the concentration of phencyclidine in mainstream smoke increased as the smoking period progressed, indicating that the drug condensed in the butt as smoking proceeded. This observation suggests that smokers are subjected to varying phencyclidine concentrations during the exposure period.

The recovery of phencyclidine in mainstream smoke was somewhat lower than that found for two other drugs of abuse. However, the recoveries of tetrahydrocannabinol and nicotine were higher than previously found (8, 9). The higher recoveries reported may be due, at least in part, to the high capacity of the glass wool filter to trap smoke components. The short cigarette–filter trap distance used, which approximated the actual smoking situation, minimized drug adsorption on the smoking apparatus. Moreover, cigarettes were burned in their entirety since no data are available concerning butt size of phencyclidine cigarettes. Undoubtedly, the length of cigarette that remains unsmoked varies considerably. The delivery of phencyclidine in smoke as reported in this study would be somewhat higher than the exposure to a smoker.

The relevance of phenylcyclohexene and piperidine intoxication and toxicity due to phencyclidine smoking has yet to be determined. Little is known of the pharmacological effects or toxicity of these products to which phencyclidine abusers are exposed. Preliminary results show the acute lethality of phenylcyclohexene to be an order of magnitude less than that of phencyclidine in rats and mice (4). Likewise, the acute toxicity of piperidine in rats appears to be 10-fold less than that of phencyclidine (10). The pyrolysis and delivery in smoke will be important considerations for experimentation involving inhalation of phencyclidine by smoking.

# Energy Relations in Compression of Polymeric Materials and Granulations

**HATEM FESSI *, JEAN-PAUL MARTY *, F. PUISIEUX *, and J. T. CARSTENSEN ‡x**

Received February 25, 1980, from the **Faculte de Pharmacie, Universite de Paris-Sud, 92290 Chatenay-Malabry, France*, and the ‡*School of Pharmacy, University of Wisconsin, Madison, WI 53706.* Accepted for publication February 12, 1981.

**Abstract** □ In tablet compression, a force, $F$, is exerted on a punch penetrating into a tablet die. For a stationary bottom punch, the force on the upper punch is a function, $F = f(x)$, of penetration and this value was previously determined empirically. Since differential energy is force, $f(x)$, multiplied by distance, $dx$, the integral $\int f(x)dx$ between limits should give the energy input into the tablet. The integral yields an expression where energy input is a linear function of the logarithm of the maximally applied pressure, $F^*$, a fact substantiated by the data presented.

**Keyphrases** □ Tablet compression—energy relations, polymeric materials and granulations □ Energy relationships—tablet compression, polymeric materials and granulations □ Parmentier–Führer equation—energy relations in tablet compression, polymeric materials and granulations

Many tablet properties (hardness, disintegration, dissolution, and thickness) are a function of the pressure at which the tablets are made, which essentially is the maximum pressure in the compression cycle. The energy input into the tablet is a more logical parameter for correlation with tablet properties but is less easily derived. The intent of this study was to obtain the pertinent correlations between the maximally applied pressure during the compression cycle and the energy imparted to the tablet in the compression step.

## EXPERIMENTAL

The tablet compositions listed in Table I were used. The polymers were polyvinyl alcohol[1], polyvinyl chloride[2], and a copolymer[3] of the two. Their respective particle sizes were 250–400 μm, <5 μm, and 80–125 μm. The three polymers were compressed first without additives and then as a granulation with the following composition: 20% diphenhydramine hydrochloride, 50% polymer, 1.5% povidone, and a quantity of tribasic calcium phosphate, *qs*. In the last three formulas listed, the polymer quantity was varied (to 60 and 70%) and the amount of tribasic calcium phosphate was reduced.

The granulations were made by mixing the tribasic calcium phosphate and the polymer and granulating with a 3.75% solution of povidone in isopropanol, except in one case where methylene chloride was used. The alcohol-wet granulations were dried in a small fluid bed drier[4] for 20 min at 60° and then were passed through an oscillating granulator through a 1-mm opening. The mesh fraction between 200 and 800 μm was obtained by sieving and was used for compression. Compression was carried out on a single-punch tablet machine[5] equipped with strain gauges for measuring upper and lower punch pressures and punch displacement. Compressions then were effected at a speed corresponding to one-sixtieth of a second per cycle, with upper punch pressures, $P$, of approximately 2, 3, 4, 5, and 6 tons, accurately monitored; 12-mm flat-faced punches were used.

## RESULTS AND DISCUSSION

In a tablet operation, powder first is introduced into the tablet die in loose packing (Fig. 1*a*) since it flows into the die and simply attains its cascaded density. Ideally, the penetration, $x$, of the upper punch starts at this point, denoted $x = -a$ (Fig. 2). The particles then rearrange to their closest packing (Fig. 1*b*), after which they are deformed elastically by further penetration of the upper punch. At a particular point ($x = 0$ in Fig. 2), the limit of elasticity is reached. From $x = -a$ to $x = 0$, the force, $F$, exerted by the upper punch is assumed here to be proportional to $x$ (although this assumption is not crucial).

At $x = 0$, the force has achieved a value of $F_0$; *i.e.*, up to the elastic limit, one may write:

$$F = F_0(x + a)/a \qquad -a \leqq x \leqq 0 \qquad \text{(Eq. 1)}$$

Beyond the elastic limit (1–10), substantial amounts of work, $A$, are required for further penetration of the upper punch, and particle fracture and/or plastic deformation take place (Fig. 1*c*). The deepest penetration is denoted $x = q$ (Fig. 2).

Parmentier (1) and Führer (2) suggested a force–displacement relationship that is hyperbolic; if it is confined to the $x \geqq 0$ region, it may be expressed as follows:

$$F = F'/(b - x) \qquad 0 \leqq x < b \qquad \text{(Eq. 2)}$$

where $F'$ is a constant and $b$ is an upper limit for $x$. It then follows

**Table I—Compounds Used and Least-Squares Fit Parameters from Fitting Areas of Energy Loop to Eq. 8**

| Formula | Correlation Coefficient | Slope, $F_0b$ | Intercept, $-F_0b \ln F_0$ | $F_0 \times 10^{-3}$, N |
|---|---|---|---|---|
| Polyvinyl chloride | 0.995 | 14.6 | −126 | 5.35 |
| Polyvinyl chloride + excipients[a] | 0.991 | 20.2 | −182 | 8.21 |
| Polyvinyl alcohol | 0.99 | 25.0 | −226 | 8.63 |
| Polyvinyl alcohol + excipients | 0.98 | 15.9 | −141 | 7.02 |
| Polyvinyl alcohol–polyvinyl chloride copolymer | 0.97 | 21.3 | −196 | 10.1 |
| Copolymer (50%) + excipients | 0.99 | 18.8 | −168 | 7.61 |
| Copolymer (60%) + excipients | 0.98 | 16.5 | −144 | 6.21 |
| Copolymer (70%) + excipients | 0.96 | 25.5 | −234 | 9.58 |
| Copolymer (50%) + excipients + methylene chloride | 0.96 | 19.1 | −170 | 7.68 |

[a] Excipients denote presence of diphenhydramine, povidone, and tribasic calcium phosphate; granulated with isopropanol unless otherwise stated.

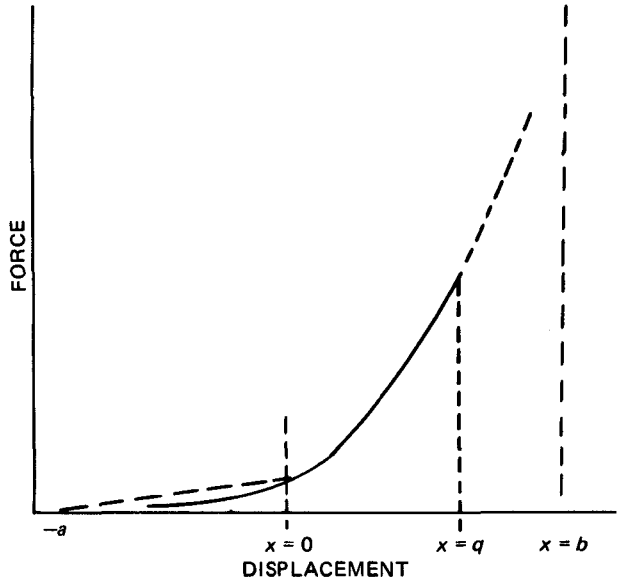

**Figure 2**—*Schematic of force–displacement cycle,* F = f(x).

that:

$$F' = F_0 b \qquad \text{(Eq. 3a)}$$

$$F = F_0 b/(b - x) \qquad \text{(Eq. 3b)}$$

The largest applied force, $F^*$ (corresponding to $x = q$), is given by:

$$F^* = F_0 b/(b - q) \qquad \text{(Eq. 4)}$$

The ideal graph then is as shown in Fig. 2. A typical experimental *F versus* $x$ plot is shown in Fig. 3.

In relating such data to the Parmentier–Führer equation (Eq. 2), it is noted that the value of $b$ is not known and the data in Fig. 3*b* are in the form:

$$\ln F = -Q \ln (b - x) + P \qquad \text{(Eq. 5)}$$

where $Q$ and $P$ are constants. If Eq. 2 holds, then $Q$ should equal −1. A best value of $b$ can be found by iteration as the value giving the least sum

[a] Sum of deviations squared, *i.e.*, $(n-2)s^2_{yx} = \Sigma(y - \bar{y})^2 - \alpha^2(\Sigma\{x - \bar{x}\}^2)$.

of squares of ln $F$ regressed on ln $(b - x)$. This procedure is shown in Table II for the data of the type shown in Fig. 3. It is noted from Table II that the sum of squares is not exceedingly sensitive to the chosen value of $b$; *i.e.*, there is a broad minimum in the value of the sum of squares for $b$ values ranging from 6.45 to 6.7. The data treated according to Eq. 5 are shown graphically in Fig. 4. Based on the best-fit criteria, it would be somewhat difficult to choose one $b$ value over another in this range; what is important is that the range entails the slope $Q = -1$, which is the one dictated by Eq. 2.

The experimental zero point for $x$ is chosen judiciously but nevertheless arbitrarily. However, since the value of $b$ is obtained by iteration, this fact does not matter. If $x' = 0$ is chosen where $x$ is actually 2, then $b$ by iteration also would increase by a value of 2, and $(b - x)$ would have the same value as if $x$ had been accurately chosen.

The value of $b$ is related to (but not identical to) the true density, $\rho$, of the nonporous solid composition. True correspondence would exist if $\rho$ were pressure independent; however, $\rho$ is a function of $F$.

In compression (Figs. 1*b* and 1*c*), the work, $A$, done by the upper punch as it moves an infinitesimal distance, $dx$, against the powder mass is given by:

$$dA = F\,dx \qquad \text{(Eq. 6)}$$

The total work (energy imparted to the tablet during the compression step but excluding the decompression step) then is obtained by integration from zero to $x = q$, *i.e.*:

$$A = \int_0^q F_0 b/(b - x)dx = F_0 b[\ln b/(b - q)] \qquad \text{(Eq. 7)}$$

Introducing Eqs. 3*b* and 4 gives:

$$A = F_0 b \ln F^* - F_0 b \ln F_0 \qquad \text{(Eq. 8)}$$

As mentioned earlier, due to the floating nature of $b$, Eqs. 7 and 8 are independent of the experimental choice of $x = 0$.

Equation 8 predicts that a plot of the energy, $A$, as a function of ln $F$ should be linear and that the ratio of the slope to the intercept should be $-\ln F_0$. These energies were obtained as the areas under the curves of the type shown in Fig. 3. The data are indeed linear, as shown in Fig. 5, and the least-squares fit values of all formulas tested are shown in Table

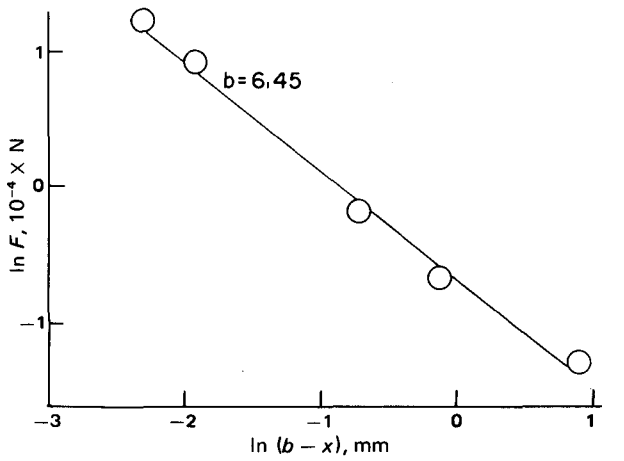

**Figure 4**—*Data in Fig. 3 (upper curve) treated according to Eq. 5.*

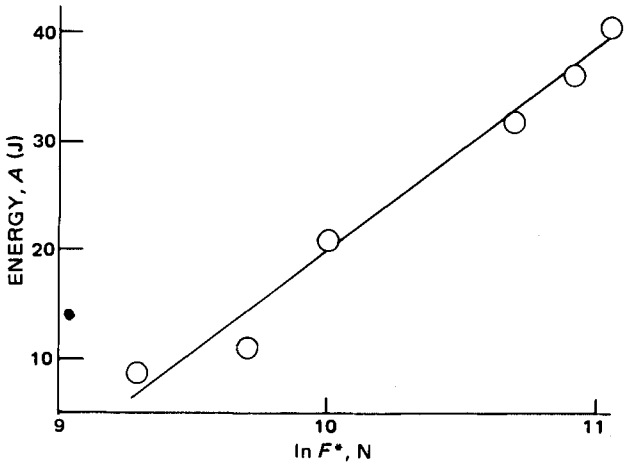

**Figure 5**—*Areas from plots of the type in Fig. 3 at six different pressures, plotted as a function of maximal pressure according to Eq. 6.*

I. The last column gives the $F_0$ value that is the smallest force necessary for actual displacement beyond the rearrangement step. It is seen from Table I that, for example, for "excipient + copolymer (50%)" (the case shown in Fig. 3), $F_0b$ ln $F_0$ = 168 J and $F_0b$ = 18.8 J. In other words, ln $F_0$ = 168/18.8 = 8.94, or $F_0$ = 6610 N. This value corresponds to an ordinate of 0.66 in Fig. 3, which corresponds to a "recorded" abscissa value (with arbitrary zero) of 4.5 mm.

Since $F_0b$ = 18.8, it follows that $b$ = 18.8/$F_0$ = 0.0028 m = 2.8 mm. Hence, in Fig. 3, the final asymptote would be at a recorded abscissa value of 4.5 + 2.8 = 7.3 mm (again recalling that the zero is somewhat arbitrary). At this point, the distance between the upper and lower punch would be 2.4 mm[6]. If the solid achieves its true density at $b$, then the true density can be deduced. The die has a diameter of 12 mm; *i.e.*, the volume between the upper and lower punch is equal to [$\pi$ (1.2$^2$/4) 0.24] = 0.27 cm$^3$.

[6] This value is obtained from knowledge of the lower punch position in relation to the arbitrary zero and does not account for possible compression of the presumably static lower punch.

The weight of the solids is 500 mg, so the true density would have a value of 0.5/0.27 = 1.84 g/cm$^3$, which is reasonable. Since compression can possibly (and presumably does) produce densities that are higher than the true densities at atmospheric pressure, the calculated figure only has interest in that it is of a reasonable magnitude. Furthermore, Eq. 8 deals with the energy input and assumes that the relaxation trace in Fig. 3 (the recovery) is vertical. This approximation becomes poorer the more pronounced the recovery after upper punch release.

## SUMMARY

The present study shows that the Parmentier–Führer equation for the value of the upper punch force as a function of displacement is useful and can be used to deduce mathematically energy *versus* maximum force relationships for energy input. These relationships were validated experimentally. The plots provide an estimate of the point in the displacement of the upper punch where the powder or granulation was rearranged to its closest packing.

# Mevalonic Acid Analogs as Inhibitors of Cholesterol Biosynthesis

**C. ROWAN DeBOLD * and J. C. ELWOOD ˣ**

Received September 26,1980, from the *Department of Biochemistry, State University of New York, Upstate Medical Center, Syracuse, NY 13210.* Accepted for publication February 20, 1981. *Present address: Department of Medicine, Division of Endocrinology, Vanderbilt University School of Medicine, Nashville, TN 37232.

**Abstract** □ A series of 20 mevalonic acid analogs was synthesized and tested for their ability to inhibit cholesterol biosynthesis from [2-$^{14}$C]-mevalonate in rat liver homogenates. Removal of the 5-hydroxyl group from mevalonic acid produced an active inhibitor, 3-hydroxy-3-methylpentanoic acid. Removal of the 3-hydroxyl group, addition of an aromatic group in the 3-position, or insertion of a double bond reduced inhibitory activity. Compounds with an aromatic group or halide on the 5-position were active inhibitors. The most active inhibitor was 5-phenylpentanoic acid, with 50% inhibition at 0.064 m*M*.

**Keyphrases** □ Mevalonic acid—analogs synthesized as potential cholesterol biosynthesis inhibitors □ Cholesterol—inhibitors, synthesis and testing of mevalonic acid analogs □ Structure–activity relationships—mevalonic acid analogs as inhibitors of cholesterol biosynthesis

Considerable progress has been made in understanding the biosynthesis of cholesterol (1, 2). Mevalonic acid, the product of the major rate-limiting reaction of cholesterol biosynthesis, is converted to isopentenyl pyrophosphate by three enzymes, each requiring $Mg^{2+}$ and ATP. The first step is phosphorylation at position 5 by mevalonate kinase (EC 2.7.1.36). Next, 5-pyrophosphomevalonate is formed by phosphomevalonate kinase (EC 2.7.4.2). This product is decarboxylated and dehydrated by pyrophosphomevalonate decarboxylase (EC 4.1.1.33), possibly involving 3-phospho-5-pyrophosphomevalonate as an intermediate.

Interest has focused on these reactions for various reasons. For example, the role of cholesterol in atherosclerosis prompted a search for inhibitors of these reactions with the prospect of decreasing cholesterol synthesis (3–7). It also has been suggested that the decreased brain cholesterol levels seen in phenylketonuria may be due to inhibition of these steps by elevated levels of phenylalanine

and its deaminated metabolites (8, 9). Furthermore, the development of specific inhibitors could be used to study the mechanism of these reactions and their importance as a secondary regulatory site of cholesterol synthesis. In addition, such inhibitors could help elucidate the mechanism and control of the recently observed nonsterol metabolic pathway of mevalonic acid (10, 11).

This paper describes the synthesis and testing of mevalonic acid analogs for their ability to inhibit the incorporation of [2-$^{14}$C]mevalonate into cholesterol by rat liver homogenates.

## EXPERIMENTAL[1]

All mevalonic acid analogs were either prepared in this laboratory or obtained commercially[2]. The 3-hydroxy esters were prepared by the Reformastki reaction (12). The products were purified by fractional vacuum distillation through a Vigreux column. The structures were verified by NMR spectroscopy. Elemental analyses were performed on those compounds for which there were no analytical data in the literature for comparison.

**Ethyl 3-(4-Chlorophenyl)-3-hydroxypentanoate (E-8)**—Compound E-8 was prepared by the careful dropwise addition of *p*-chloropropiophenone (15 g, 89 mmoles) and ethyl bromoacetate (15.5 g, 93 mmoles) in ether (20 ml) and benzene (20 ml) to granular zinc (11 g, 168 mmoles) while stirring mechanically. After the exothermic reaction subsided, the mixture was stirred and refluxed for 3 hr, cooled, acidified to pH 3 with 10% HCl, and extracted twice with chloroform.

The organic portions were combined, washed with 5% $NaHCO_3$, and dried over anhydrous magnesium sulfate, and the solvents were removed under reduced pressure. The residue was distilled, yielding 20 g (88%) of a colorless liquid, bp 111–112.5°/0.15 mm Hg; NMR ($CDCl_3$): $\delta$ 0.74 (t, 3H, $CH_3$), 1.09 (t, 3H, $CH_3$-ester), 1.78 (q, 2H, $CH_2$), 2.85 (s, 2H, $CH_2$=O), 4.08 (q, 2H, $COOCH_2$), 4.37 (s, 1H, OH), and 7.42 (s, 4H, aromatic) ppm.

*Anal.*—Calc. for $C_{13}H_{17}ClO_3$: C, 60.82; H, 6.67; Cl, 13.81. Found: C, 60.69; H, 6.74; Cl, 13.69.

**Ethyl 5-Chloro-3-hydroxy-3-phenylpentanoate (E-9)**—Compound E-9 was prepared by the slow addition of $\beta$-chloropropiophenone (5 g, 30 mmoles) and ethyl bromoacetate (4.95 g, 30 mmoles) in ether (13 ml) and benzene (13 ml) to zinc dust (1.9 g, 60 mmoles) while stirring mechanically. After the exothermic reaction subsided, the mixture was refluxed overnight and worked up as already described. Vacuum distillation yielded 4.0 g (52%) of a faint-yellow liquid (E-9), bp 120–122°/0.3 mm Hg; NMR ($CDCl_3$): $\delta$ 1.03 (t, 3H, $CH_3$), 2.27 (t, 2H, $CH_2$), 2.88 (s, 2H, $CH_2C$=O), 3.34 (m, 2H, $CH_2Cl$), 4.00 (q, 2H, $COOCH_2$), 4.54 (s, 1H, OH), and 7.33 (s, 5H, aromatic) ppm.

*Anal.*—Calc. for $C_{13}H_{17}ClO_3$: C, 60.82; H, 6.67; Cl, 13.81. Found: C, 60.51; H, 6.75; Cl, 13.88.

**Ethyl 3-Hydroxy-3-methylpentanoate (E-1)**—Methyl ethyl ketone (69 g, 0.96 mole) and ethyl bromoacetate (167 g, 1.0 mole) in ether (450 ml) were added to zinc dust (120 g, 1.84 moles) with mechanical stirring. The mixture was refluxed overnight and worked up as already described. Vacuum distillation yielded 108 g (70%) of a colorless liquid (E-1), bp 38–39°/0.015 mm Hg [lit. (13) bp 83–88°/13 mm].

**Ethyl 3-Hydroxy-3-phenylpentanoate (E-7)**—Propiophenone (33.5 g, 0.25 mole) and ethyl bromoacetate (42 g, 0.25 mole) in ether (50 ml) and benzene (50 ml) were added to zinc dust (33 g, 0.51 mole) with mechanical stirring. The mixture was refluxed overnight and worked up as already described. Distillation resulted in 35 g (63%) of a faint-pink liquid (E-7), bp 86.5–88°/0.15 mm Hg [lit. (14) bp 104°/0.5 mm].

**Ethyl $\Delta^2$-3-Methylpentenoate (E-2)**—The Emmons modification (15) of the Wittig reaction was used to prepare E-2. Ethyl bromoacetate (83.5 g, 0.5 mole) was added dropwise to a stirred solution of triethyl phosphite (83.1 g, 0.5 mole). After complete addition, the temperature was increased, and ethyl bromide began to distill off. As the liberation of ethyl bromide decreased, the temperature was increased slowly, finally remaining at 170–175° for 1 hr. The cooled solution was added dropwise to sodium ethoxide formed from the addition of absolute ethanol (23 g, 0.5 mole) to sodium ribbon (11.5 g, 0.5 mole) in tetrahydrofuran (300 ml) under nitrogen. Then, methyl ethyl ketone (36 g, 0.5 mole) was added slowly at a rate to keep the temperature below 35°.

After addition of the ketone, the mixture was stirred and refluxed overnight, cooled, and filtered. The precipitate was washed with ether, ethanol, and finally water. The aqueous phase was washed twice with ether. The combined organic phases were dried over anhydrous magnesium sulfate, and the solvents were removed under reduced pressure. Distillation yielded 48 g (68%) of a colorless liquid (E-2), bp 72–74°/23 mm Hg [lit. (16) bp 68°/14 mm]; NMR ($CDCl_3$): $\delta$ 1.06 (t, 3H, $CH_3$), 1.25 (t, 3H, $CH_3$-ester), 2.10 (m, 2H, $CH_2C$=), 2.16 (s, 3H, $CH_3C$=), 4.14 (q, 2H, $COOCH_2$), and 5.65 (s, 1H, HC=C) ppm.

**Methyl $\Delta^3$-3-Methylpentenoate (E-3)**—Kon and Linstead (17) claimed that ethyl $\Delta^3$-3-methylpentenoate could be selectively prepared by the dehydration of E-1 by heating in the presence of potassium hydrogen sulfate. However, this procedure resulted in a mixture of the $\Delta^2$- and $\Delta^3$-esters, as confirmed by NMR. Thus, the more complex procedure of Wagner (13) had to be utilized, which would specifically locate the double bond in the $\Delta^3$-position and result in the *trans*-isomer. Briefly, the procedure involved four steps: (*a*) aldol condensation of acetaldehyde and methyl ethyl ketone in the presence of base to yield 4-hydroxy-3-methylpentanone, (*b*) dehydration of the $\beta$-hydroxyketone to 3-methyl-3-penten-2-one, (*c*) formation of 3,4-dibromo-3-methyl-2-pentanone by the addition of bromine to the unsaturated ketone, and (*d*) Favorskii rearrangement of the $\alpha,\beta$-dibromoketone in the presence of sodium methoxide to form methyl $\Delta^3$-3-methylpentenoate (E-3) (25% yield), bp 47–50°/11 mm Hg [lit. (13) bp 74°/50 mm]; NMR ($CDCl_3$): $\delta$ 1.5 [m, 6H, ($CH_2C$=)$_2$], 3.0 (d, 2H, $CH_2$), 3.65 (s, 3H, $OCH_3$), and 5.42 (m, 1H, CH=C) ppm.

**Saponification of Esters**—Two general procedures similar to those of Stewart and Woolley (4) were used.

*Procedure 1*—To a stirred solution containing an ester (40 mmoles) in 80% ethanol (30 ml) at 60°, 40 ml of sodium hydroxide (1 *N*, 40 mmoles) was added dropwise over 90 min. After the mixture was stirred at 60° for 18 hr, the solvent was removed under reduced pressure. The remaining solution was extracted twice with ether, and the combined ether extractions were backwashed once with 5% $NaHCO_3$. The combined aqueous portion was acidified to pH 3 with 1 *N* HCl.

If the acid was a solid at room temperature, it precipitated out of the acidic solution and was collected by filtration and purified by recrystallization. If no precipitate formed, the aqueous solution was extracted twice with ether and twice with ethyl acetate. The combined organic extracts were washed with water until neutral, dried over anhydrous magnesium sulfate, and concentrated under reduced pressure. The residue was vacuum distilled.

*Procedure 2*—Because dehydration or isomerization was a problem during the saponification of E-1, E-2, E-3, a gentler procedure was used. The ester (40 mmoles) in 80% ethanol (60 ml) was cooled in an ice bath while 40 ml of sodium hydroxide (1 *N*, 40 mmoles) was added over 24 hr. The solution was stirred at room temperature for 1–2 days and the product was worked up as already described.

**3-(4-Chlorophenyl)-3-hydroxypentanoic Acid (A-8)**—Compound E-8 was hydrolyzed according to Procedure 1 producing A-8 (93%), which was recrystallized from benzene–hexane (1:1), mp 97–98°; NMR ($CDCl_3$): $\delta$ 0.71 (t, 3H, $CH_3$), 1.78 (q, 2H, $CH_2$), 2.91 (s, 2H, $CH_2C$=O), and 7.40 (s, 6H, aromatic, OH, COOH) ppm.

*Anal.*—Calc. for $C_{11}H_{13}ClO_3$: C, 57.79; H, 5.73; Cl, 15.50. Found: C, 57.67; H, 5.71; Cl, 14.88.

**3-Hydroxy-3-phenylpentano-5-lactone (E-10)**—Hydrolysis of E-9 by Procedure 1 unexpectedly resulted in a lactone, E-10. Recrystallization in ethyl acetate gave white crystals (56%), mp 133–135°; NMR ($CDCl_3$): $\delta$ 2.16 (broad, 2H, $CH_2$), 2.84 (s, 2H, $COCH_2$), 3.08 (s, 1H, OH, not present with $D_2O$), 4.44 (m, 2H, $OCH_2$), and 7.34 (s, 5H, aromatic) ppm.

*Anal.*—Calc. for $C_{11}H_{12}O_3$: C, 68.74; H, 6.29. Found: C, 68.48; H, 6.40; Cl, none.

**3-Hydroxy-3-phenylpentanoic Acid (A-7)**—Hydrolysis of E-7 by Procedure 1 resulted in A-7. Recrystallization from benzene gave white crystals (71%), mp 122–123° [lit. (14) mp 120–121°].

**$\Delta^2$-3-Ethoxybutenoic Acid (A-4)**—Hydrolysis of E-4 by Procedure 1 resulted in A-4. Recrystallization from absolute ethanol gave white crystals (31%), which decomposed on melting at 139–141° [lit. (18) mp 140°].

**3-Hydroxy-3-methylpentanoic Acid (A-1)**—Hydrolysis of E-1 by Procedure 2 resulted in A-1 (52%), bp 78–81°/0.02 mm Hg [lit. (3) bp 93–95°/0.03 mm].

**$\Delta^2$-3-Methylpentenoic Acid (A-2)**—Hydrolysis of E-2 by Procedure

[1] Melting points were determined on a Fisher-Johns apparatus and are uncorrected. NMR spectra were determined using a Varian A-60A spectrometer with tetramethylsilane as an internal standard. Elemental analyses were performed by Bristol Laboratories, Syracuse, N.Y.

[2] Compounds E-5, A-11, A-12, A-13, and A-14 were from Aldrich Chemical Co., and E-4 and A-6 were from Frinton Laboratory.

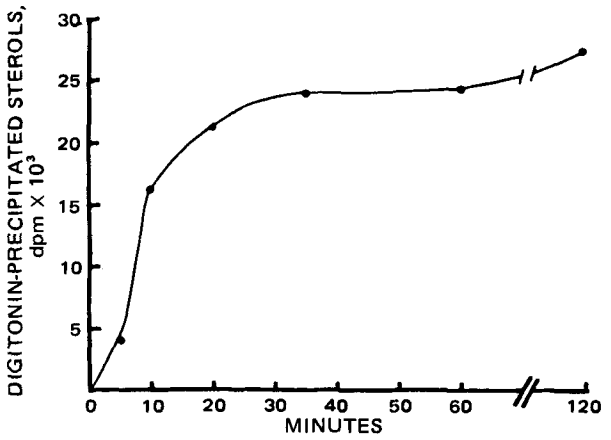

**Figure 1**—*Incorporation rate of [2-$^{14}$C]mevalonate into digitonin-precipitated sterols in rat liver homogenate. Each point represents the average of two determinations.*

2 resulted in A-2 (51%), which separated on standing into the *trans*-isomer (23%), mp 43–45° [lit. (19) mp 46–47°], and the *cis*-isomer (77%), bp 61°/0.55 mm Hg [lit. (20) bp 96°/5 mm]. Since complete separation could not be effected, a mixture of roughly equal parts of the isomers was used for testing in the homogenate system.

***trans*-$\Delta^3$-3-Methylpentenoic Acid (A-3)**—Hydrolysis of E-3 by Procedure 2 resulted in A-3 (97%), bp 51–53°/0.015 mm Hg [lit. (13) mp 35°]; NMR: $\delta$ 1.70 [m, 6H, $(CH_3C{=})_2$], 3.06 (d, 2H, $CH_2$), 5.45 (m, 1H, CH=C), and 11.56 (s, 1H, COOH) ppm.

***In Vitro* Assay of Cholesterol Biosynthesis**—The rat liver homogenates from mature male Wistar rats were prepared following the general procedures described previously (21). The homogenization medium consisted of 100 m*M* potassium phosphate, 30 m*M* nicotinamide, 4 m*M* magnesium chloride, 5 m*M* glutathione, and 1 m*M* ethylenediaminetetraacetic acid at pH 7.4. The final cofactor concentration[3] in each incubation flask was 2 m*M* ATP, 1 m*M* NAD, 1 m*M* NADP, 8 m*M* glucose-6-phosphate, and 2 units of glucose-6-phosphate dehydrogenase (baker's yeast, type XV).

To each 25-ml incubation flask were added 2 ml of homogenate, 0.1 ml of cofactor solution, and 0.1 ml of solution containing the compound to be tested. The acids were added as the potassium salt in water at pH 7.4, while the esters were added in 50% ethanol. Every compound was tested in duplicate. The appropriate controls, either water or 50% ethanol, also were run in duplicate in every assay. The assay was started by the addition of 0.1 ml of water containing the potassium salt of [2-$^{14}$C]mevalonate (0.1 $\mu$Ci, 0.0124 $\mu$mole) prepared from the dibenzylethylene ammonium salt[4]. Incubation continued for 20 min at 37° in a Dubnoff shaker at 100 oscillations/min. The incubation was terminated by the addition of 2 ml of 11% KOH (w/v) in ethanol.

The contents of each incubation flask were poured into 16 × 150-mm screw-capped tubes. Each flask was washed twice with 2-ml portions of 11% KOH (w/v) in ethanol, and the washings were added to the appropriate tube. Each sample was capped and saponified in a boiling water bath for 30 min. When the sample was cool, 7.5 ml of water and 2 ml of ethanol were added. The nonsaponifiable fraction containing the cholesterol was removed by three extractions with 9-ml portions of petroleum ether. This extraction procedure removed >99% of the cholesterol.

The procedure for the precipitation of cholesterol by digitonin was based on the method of Zak *et al.* (22). The digitonin precipitates were dissolved by warming in 2.0 ml of absolute methanol. A 1-ml aliquot was added to a toluene-based scintillation cocktail containing 2,5-diphenyloxazole (3.92 g/liter) and *p*-bis(*o*-methylstyryl)benzene (0.08 g/liter)[5].

## RESULTS AND DISCUSSION

The incorporation rate of [2-$^{14}$C]mevalonate into the digitonin-precipitated sterols by rat liver homogenates is shown in Fig. 1. Although digitonin precipitates all 3-$\beta$-hydroxysterols, this is almost entirely cholesterol in the liver. The incorporation rate was rapid for the first 20 min of incubation and leveled off by 30 min. By 120 min, ~25% of the biologically available optical isomer of mevalonic acid was incorporated into cholesterol. A 20-min incubation period was chosen for testing the inhibitory compounds because this point was at the end of the period of maximal sterol synthesis.

The effects of 20 mevalonic acid analogs on cholesterol biosynthesis from [2-$^{14}$C]mevalonate in rat liver homogenates were studied. All

compounds were initially tested at a concentration of 1 m*M*. Table I shows the series of analogs with a methyl group at position 3. Removal of the 5-hydroxyl group resulted in an effective inhibitor, 3-hydroxy-3-methylpentanoic acid (A-1). These data agree, in part, with those of Klimov *et al.* (23, 24), which showed that, in a series of mevalonic acid analogs with aromatic groups in position 2 or 3, the absence of a hydroxyl group in the 5-position increased the ability of the compound to inhibit cholesterol biosynthesis from [$^{14}$C]mevalonate in rat liver homogenates.

For bacterial and yeast assay systems, Stewart and Woolley (4, 5) concluded that the hydroxyl group at position 3 was necessary for highest antimevalonic activity. Table I shows that this conclusion also applies to the rat liver homogenate since several compounds (A-2, A-3, and A-6) that have similar structures to the active 3-hydroxyl inhibitor (A-1), but lack the 3-hydroxyl group, all showed lower activity.

Table I also shows that alterations of the backbone structure by introduction of a double bond at position 2 or 3 (A-2 or A-3) reduced inhibitory activity. These results confirm earlier work (3) that was questionable because the synthetic procedures used would not necessarily lead to the pure isomers and the structures were not proven adequately. On the other hand, Klimov *et al.* (23) found that a double bond at position 2 increased the activity compared to a saturated 3-hydroxyl analog. However, these data are not directly comparable since all compounds also contained an aromatic group at position 2 or 3.

The substitution of an aromatic group for the 3-methyl group produced inactive acids (A-7 and A-8) (Table II). In contrast, Klimov *et al.* (23) found increased activity of 3-hydroxyl compounds by adding a phenyl group to position 2 and/or a tolyl group to position 3. However, these data are not directly comparable since different aromatic groups were used.

In contrast to the acids, the ethyl esters of these 3-hydroxy-3-aromatic compounds showed considerable inhibitory activity. In general, there was little relationship between the activity of a compound as an ester and its activity as an acid. Compound E-10, resembling mevalonolactone with a phenyl ring replacing the 3-methyl group, was inactive.

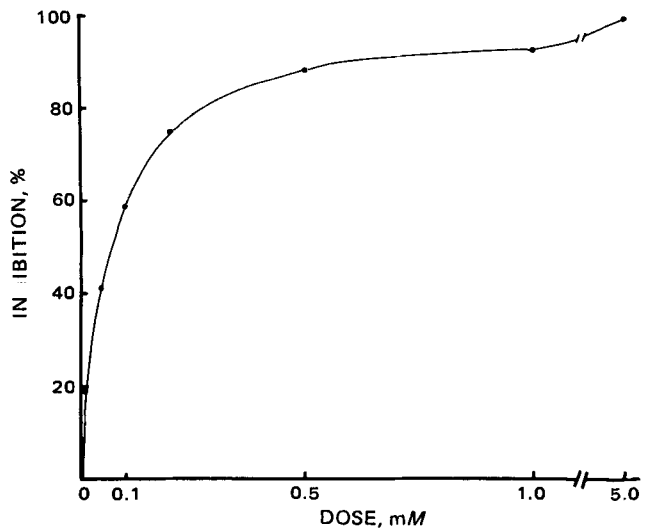

**Figure 2**—*Inhibition by 5-phenylpentanoic acid (A-11) of incorporation of [2-$^{14}$C]mevalonate into cholesterol by rat liver homogenates.*

Table III shows several compounds with an aromatic group or halide on the 5-carbon, all of which caused inhibition. The most active inhibitor was 5-phenylpentanoic acid (A-11), with 92.4% inhibition of cholesterol biosynthesis. Of the two 5-halogenated pentanoic acids, the bromo derivative was more inhibitory. Not all modifications of the 5-position yield inhibitors. Humber *et al.* (25) replaced the 5-hydroxyl group of mevalonic acid with a methoxy, ethoxy, or dimethylamino group and found that none of the compounds inhibited cholesterol biosynthesis in rat liver homogenates at concentrations of 1 m*M*.

The relationship between the dose and the effect of the most active compound, A-11, is shown in Fig. 2. There was 50% inhibition of cholesterol biosynthesis from labeled mevalonate in rat liver homogenates at a 0.064 m*M* concentration.

The results of this study show that A-11 is a very potent inhibitor of cholesterol biosynthesis from mevalonate in rat liver homogenates. Other investigators (3–6, 23, 24) tested mevalonic acid analogs that were effective inhibitors at concentrations of ≥1 m*M*. Compound A-11 showed significant inhibition of 20% at 0.01 m*M*, a 100-fold difference. The only compounds that rival its activity are 3,5-dihydroxy-3-fluoromethylpentanoic acid (26) and 3-hydroxy-3-methyl-6-phosphonohexanoic acid (7), which caused 50% inhibition of mevalonic acid metabolism at 0.07 and 0.145 m*M*, respectively.

# Antiproliferative Activity of Doxorubicin and Aminoanthraquinone Derivatives on Chinese Hamster Ovary Cells

**EDWIN M. UYEKI *, AKIRA NISHIO *, PHILIP J. WITTEK ‡, and C. C. CHENG *‡x**

Received October 14, 1980, from the **Department of Pharmacology and the* [1]*Mid-America Cancer Center, University of Kansas Medical Center, Kansas City, KS 66103.* Accepted for publication February 13, 1981.

**Abstract** □ A study of the antiproliferative activity of doxorubicin and several substituted aminoanthraquinone derivatives on Chinese hamster ovary cells was conducted. Doxorubicin and a derivative each inhibited cell proliferation at low concentrations, the latter being more potent than doxorubicin. A structure–activity relationship of these compounds is discussed in connection with an earlier postulated N–O–O triangulation hypothesis.

**Keyphrases** □ Aminoanthraquinone derivatives—synthesis and evaluation for antiproliferative activity, Chinese hamster ovary cells □ Doxorubicin—substituted aminoanthraquinone derivatives synthesized and evaluated for antiproliferative activity, Chinese hamster ovary cells □ Antiproliferative activity—aminoanthraquinone derivatives synthesized and evaluated for activity in Chinese hamster ovary cells □ Structure–activity relationships—substituted aminoanthraquinone derivatives synthesized and evaluated for antiproliferative activity

Based on a working hypothesis involving the recognition of a common N–O–O triangular pharmacophore among several antineoplastic agents (1, 2), 1,4-dihydroxy-5,8-bis{[2-(2-hydroxyethyl)amino]ethyl}amino-9,10-anthracenedione (I) was synthesized and found to possess outstanding antineoplastic activity in several experimental tumor systems (3, 4). Recently, a number of structural modification (5, 6), structure–activity (5, 7), pharmacological (7, 8), mechanistic (9, 10), and clinical trial (11) experiments were conducted. Since several analogs of I exhibited antineoplastic activity *in vivo* but do not contain the entire N–O–O triangular pattern, an *in vitro* study of their antiproliferative activity on Chinese hamster ovary cells was undertaken to obtain additional structure–activity relationship information.

V

## EXPERIMENTAL

**Chemical Agents**—Seven compounds, including the antibiotic doxorubicin[1] (II), were evaluated. Preparation of I, IIIa, IV, and V was reported previously (3, 5).

*Preparation of 1-Amino-5,8-bis{[2-(2-hydroxyethyl)amino]ethyl}-amino-9,10-anthracenedione (IIIb)*—To a mixture of 8 g (0.031 mole) of 5-amino-2,3-dihydro-1,4-dihydroxy-9,10-anthracenedione (prepared by the reduction of 5-nitro-1,4-dihydroxy-9,10-anthracenedione in zinc and acetic acid) in 55 ml of 2-propanol at 50° was added 30 g (0.29 mole) of 2-[(2-aminoethyl)amino]ethanol with mechanical stirring under nitrogen. The resulting reaction mixture was stirred at 50° for 4.5 hr, during which time a precipitate formed. The mixture was cooled to room temperature and filtered.

The solid was washed with 2-propanol and ether and dried to give 8.3 g (60% yield) of the dihydro analog of the target compound, 1-amino-5,8-bis{[2-(2-hydroxyethyl)amino]ethyl}amino-9,10-dihydroxyanthracene, as gold-colored plates. Recrystallization from 2-propanol yielded an analytical sample, mp 135–145° dec.; UV: $\lambda_{max}$ (0.1 *N* HCl) 488 ($\epsilon$ 9800), 460 (15,300), 435 (11,700), and 252 (25,200) nm; $\lambda_{sh}$ (0.1 *N* HCl) 280 ($\epsilon$ 17,000) nm.

*Anal.*—Calc. for $C_{22}H_{31}N_5O_4$: C, 61.52; H, 7.28; N, 16.31. Found: C, 61.35; H, 7.11; N, 16.12.

The mother liquor from the initial filtration was allowed to stir uncovered for 10 days at room temperature. The solution gradually turned dark blue and deposited a blue gummy solid. Filtration of this material

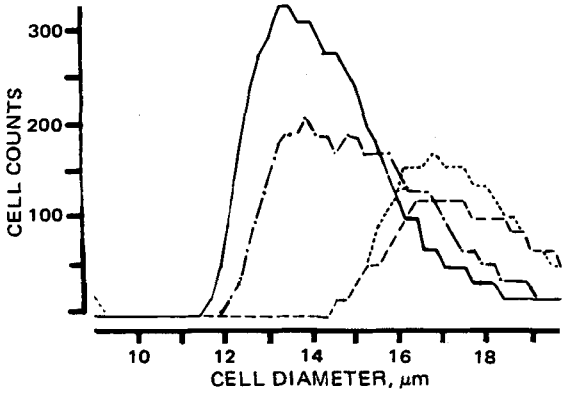

**Figure 1**—*Cell counts and cell-sizing data for I. The data were stored and processed in a microprocessor. Every point of each line represents the average value of I on triplicate cultures. Key: —, control; – –, 1000 nM; ·····, 200 nM; and -·-, 10 nM.*

and recrystallization from a mixture of methanol and 2-propanol gave 0.5 g (4% yield) of III*b* as a dark blue-black amorphous powder, mp 131–141° (dampening at 110°); UV: $\lambda_{max}$ (0.1 *N* HCl) 634 ($\epsilon$ 14,400), 590 (13,500), and 252 (27,500) nm; $\lambda_{sh}$ (0.1 *N* HCl) 550 ($\epsilon$ 7500) and 272 (14,500) nm.

*Anal.*—Calc. for $C_{22}H_{29}N_5O_4$: C, 61.81; H, 6.84; N, 16.38. Found: C, 61.53; H, 6.81; N, 16.04.

Compound III*b* could be obtained also from the dihydroanthraquinone product as follows. To 100 ml of refluxing nitrobenzene with magnetic stirring was added 5.0 g of the dihydroanthraquinone. After 20 min, the reaction mixture was allowed to cool, and 200 ml of ether was added. Filtration and drying of the solid product gave 3.4 g of III*b*.

*Preparation of 1-Hydroxy-5,8-bis{[2-(2-hydroxyethyl) amino]ethyl}amino-9,10-anthracenedione (IIIc)*—To 30 g (0.29 mole) of 2-[(2-aminoethyl)amino]ethanol at room temperature under nitrogen was added 8.5 g (0.033 mole) of 1,4,5-trihydroxy-2,3-dihydroanthraquinone in one portion with stirring. A slight exothermic reaction developed. The reaction mixture was stirred at room temperature for 3 hr and then was warmed at 50° for 1 hr. To this mixture was added 250 ml of 2-propanol, and the dark solution again was warmed to 50°. Air was bubbled into the reaction mixture for 4 hr at that temperature, and then it was cooled to 30° and filtered.

The solid was washed with 2-propanol followed by ether to give 4.0 g (28% yield) of III*c*, mp 118–122°. A second crop of 3.7 g (26% yield) was collected by addition of 400 ml of ether to the mother liquor. Recrystallization from propanol–ether gave an analytical sample of III*c* as a dark-blue amorphous powder, mp 120–125°; UV: $\lambda_{max}$ (0.1 *N* HCl) 636 ($\epsilon$ 9500), 593 (10,300), and 240 (23,800) nm; $\lambda_{sh}$ (0.1 *N* HCl) 550 ($\epsilon$ 6200) and 270 (11,900) nm.

*Anal.*—Calc. for $C_{22}H_{28}N_4O_5$: C, 61.67; H, 6.59; N, 13.08. Found: C, 61.65; H, 6.69; N, 13.09.

**Biological Methods**—Chinese hamster ovary cells[2] were grown in a

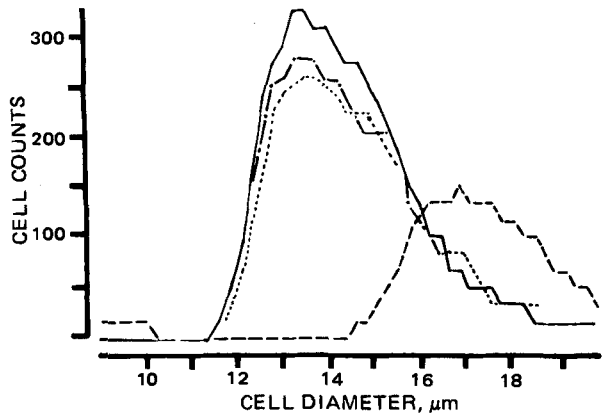

**Figure 2**—*Cell counts and cell-sizing data for II. Every point of each line represents the average value of II on triplicate cultures. Key: —, control; – –, 1000 nM; ·····, 200 nM; and -·-, 10 nM.*

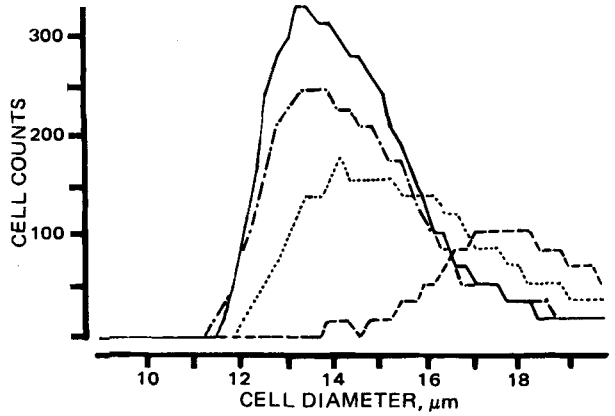

**Figure 4**—*Cell counts and cell-sizing data for IV. Every point of each line represents the average value of IV on triplicate cultures. Key: —, control; – –, 1000 nM; ·····, 200 nM; and –·–, 10 nM.*

data for each graph are given in terms of the number of cells for a given cell diameter.

## RESULTS

Cell counts and cell-sizing data for I and doxorubicin (II) are shown in Figs. 1 and 2, respectively. At 1000 n*M* ($1 \times 10^{-6}$ *M*), both I and II inhibited cell proliferation and shifted the population toward larger cells. In addition, I inhibited cell replication in concentrations as low as 10 n*M*, whereas II did not. However, at 10 n*M* I, the size distribution indicated a return to cells of a smaller diameter. Moreover, 10 n*M* I (72% of controls) was significantly lower than 200, 50, and 10 n*M* II, using Duncan's new multiple-range test at the 0.01 level of significance.

Compounds IIIc (Fig. 3) and IV (Fig. 4) showed activity comparable to II; *i.e.*, they were inhibitory at concentrations of 50 and 200 n*M* but not at 10 n*M*. At 200 and 1000 n*M*, IIIc and IV demonstrated that cell-size distributions shifted to a larger diameter.

Under similar culture conditions, V (Fig. 5), III*a*, and III*b* were much less effective, showing no statistically significant inhibition of cell proliferation compared with controls (Table I).

## DISCUSSION

Although both I and III*a* were reported to possess an inhibitory effect on cell survival and cell cycle progression in cultured mammalian cells (12–14), I appeared to be 200 times more potent than III*a* *in vitro* (12). Consequently, I and related aminoanthraquinones, as well as doxorubicin (II), were studied at concentrations between 1000 and 10 n*M* and the following results were obtained:

1. Compound I was significantly inhibitory to Chinese hamster ovary cell proliferation at concentrations as low as 10 n*M* I (Fig. 1).
2. Doxorubicin exhibited inhibitory activity as low as 50 n*M* (Fig. 2).
3. The other ring-dihydroxylated bis(aminoalkylamino)-substituted anthraquinone (IV) also was active at that concentration, but the magnitude of inhibition was not like that of I (Fig. 4).
4. The ring-monohydroxylated bis(aminoalkylamino)-substituted anthraquinone (III*c*) was active at 200 n*M* (Fig. 3).
5. Compound III*b* showed borderline activity at 1000 n*M* (Fig. 5).
6. Compounds III*a* and V (Fig. 5) were ineffective at the highest concentration (1000 n*M*) tested.

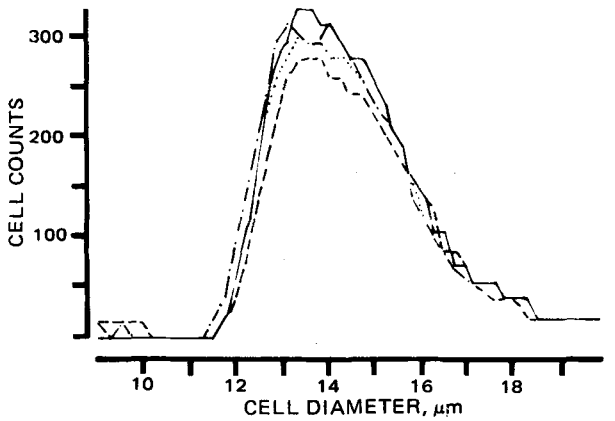

**Figure 5**—*Cell counts and cell-sizing data for V. Every point of each line represents the average value of V on triplicate cultures. Key: —, control; – –, 1000 nM; ·····, 200 nM; and –·–, 10 nM.*

[a] Represents the area under the curve between 11.5 and 17.0 $\mu m$ in cell diameter; >95% of the cells from control cultures are included within these boundaries. Values are expressed as mean ±*SE* (number of determinations). [b] Values were analyzed, using analysis of variance and Duncan's new multiple-range test for significance. Asterisk represents differences between drug treated and controls at the 0.01 level of significance.

The importance of the N–O–O triangular pharmacophore to the antiproliferative activity of compounds of this type on Chinese hamster ovary cells was revealed since, theoretically, both I and IV possess two N–O–O sets, doxorubicin and IIIc possess one N–O–O set, and none of the other compounds contains this triangulation. The fact that III*b* showed borderline activity could be interpreted as due either to the presence of another electronegative element at the strategic position or to a gradual and incomplete replacement of the amino by a hydroxyl function under experimental conditions.

Most of the compounds studied showed good antineoplastic activity *in vivo*. Judging from the reports (3, 4, 7) that the dosage required for the unhydroxylated anthraquinones, such as III*a*, is at least 10 times higher than that required for the corresponding dihydroxyl analog, such as I, the possibility of *in vivo* hydroxylation to "complete" the N–O–O triangulation cannot be disregarded. In fact, chemical hydroxylation of 1,4-diamino-9,10-anthracenedione diboroacetate with an oxidizing agent such as sodium persulfate yielded the corresponding 5,8-dihydroxyl derivative (15), which further indicated that positions 5 and 8 are electronically preferred for hydroxylation.

# Simultaneous Determination of Vitamins $B_1$, $B_2$, $B_6$, and Niacinamide in Multivitamin Pharmaceutical Preparations by Paired-Ion Reversed-Phase High-Pressure Liquid Chromatography

**RODERIC P. KWOK *x, W. P. ROSE *, RICK TABOR ‡, and THOMAS S. PATTISON ‡**

Received March 3, 1980, from the **Foremost-McKesson Research and Development Center, Dublin, CA 94566*, and the ‡*Forrest C. Shaklee Research Laboratories, Hayward, CA 94545.* Accepted for publication February 20, 1981.

**Abstract** □ A high-pressure liquid chromatographic procedure for the simultaneous determination of vitamins $B_1$, $B_2$, $B_6$, and niacinamide in multivitamin pharmaceutical preparations was developed and evaluated. The method uses paired-ion reversed-phase partition chromatography for baseline separation of the four water-soluble vitamins. This method was applied to the analysis of a multivitamin and multivitamin–multimineral tablets, and a technique was developed to reduce vitamin adsorption by the minerals. The results obtained by this method were compared with those obtained by the official methods. It was concluded that this method is fast, accurate, specific, and suitable for routine quality control use.

**Keyphrases** □ Vitamins, water soluble—simultaneous high-pressure liquid chromatographic analyses in multivitamin preparations □ High-pressure liquid chromatography—simultaneous analyses of various water-soluble vitamins in multivitamin preparations □ Multivitamin preparations—simultaneous high-pressure liquid chromatographic assay of various water-soluble vitamins

Progress in vitamin preparations is being impeded by methodological problems. Current official methods (1, 2) for the assay of water-soluble vitamins involve a complicated sample workup, tend to reproduce poorly because of the instability and pH sensitivity of the color development, and require that each vitamin be analyzed individually. These methods also are subject to interferences from various sources when analyzing samples with complex matrixes (3, 4).

High-pressure liquid chromatographic (HPLC) procedures for the simultaneous determination of water-soluble vitamins in pharmaceutical preparations have been described (5–7), but no mechanism has been developed to control vitamin adsorption by the minerals in multivitamin–multimineral tablets. This paper describes an HPLC procedure for the simultaneous determination of vitamins $B_1$, $B_2$, $B_6$, and niacinamide in multivitamin and multivitamin–multimineral tablets by paired-ion reversed-phase HPLC.

## EXPERIMENTAL

**Apparatus**—The HPLC system included two solvent pumps[1], a solvent programmer[2], a UV absorbance detector[3] at 280 nm, and an autoinjector[4]. A μBondapak phenyl (10 μm) 30-cm × 3.9-mm i.d. column and a 10-mv full-scale recorder[5] were used. Peak areas were determined using a laboratory data system[6]. The column temperature was regulated at 30° by a constant temperature bath[7]. A high-speed centrifuge was used[8], and the samples were disintegrated in a shaker bath[9] set at 60°.

**Materials and Reagents**—Thiamine hydrochloride, riboflavin, pyridoxine hydrochloride, and niacinamide were obtained as USP reference standards. 1-Hexanesulfonic acid was used as received[10]. Anhydrous citric acid[11] was obtained commercially and used without further purification. Solvents, all distilled-in-glass[12] grade, were obtained commercially. Commercial multivitamin preparations were obtained from local pharmacies.

**Preparation of Mobile Phases**—The two pumps used 0.0025 *M* 1-hexanesulfonic acid in water and in methanol, respectively. Prior to use, the mobile phases were degassed by vacuum filtration through a 0.5-μm pore, 47-mm diameter filter[13]. With a linear solvent program[14], a gradient was run at a constant flow rate of 2.0 ml/min for 18 min. Solvent conditions varied from 0 to 80% methanol in water. Five minutes was allowed between sample injections.

| Pyridoxine hydrochloride, 2.0 mg/tablet | 88.3 ± 1.70 | 84.2 ± 0.78 | 100 ± 1.58 |
| Niacinamide, 2.0 mg/tablet | 101.9 ± 3.26 | 100.6 ± 0.85 | 100 ± 3.11 |

[a] Vita Lea, Shaklee Corp.; each value is the mean ± *SD* of five determinations.

**Preparation of Standard Solutions**—Stock standard solutions of thiamine hydrochloride, pyridoxine hydrochloride, and niacinamide (0.5 mg/ml each) were prepared separately by dissolving accurately weighed USP reference standards in 0.1 *N* HCl. Due to poor solubility, only the riboflavin working standard solution was prepared in a more diluted form; <0.1 g accurately weighed USP reference standard was dissolved in 1000 ml of 0.1 *N* HCl, heated, and constantly stirred in a low actinic volumetric flask.

Different aliquots from each stock standard vitamin solution were combined and diluted with the riboflavin working standard solution. This procedure resulted in a working standard solution containing all four water-soluble vitamins at the desired concentration.

**Preparation of Sample Solutions**—*Multivitamin Tablets*—A suitable number of tablets containing no more than 10 mg of riboflavin were placed in a low actinic glass-stoppered erlenmeyer flask. Exactly 100 ml of 0.1 *N* HCl was pipetted into the flask, and the flask was stoppered and shaken for 45 min in a constant-temperature bath at 60°. The sample was allowed to cool to room temperature and then was centrifuged at 44,000×*g* for 18 min. Then 10 μl of the clear supernate was injected into the liquid chromatograph.

*Multivitamin–Multimineral Tablets*—A suitable number of tablets containing no more than 10 mg of riboflavin were placed in a low actinic glass-stoppered erlenmeyer flask. Exactly 100 ml of dimethyl sulfoxide containing 1% citric acid (anhydrous) was delivered into the flask. The solution then was shaken for 45 min in a constant-temperature bath at 60°. It was allowed to cool to room temperature and then was centrifuged at 44,000×*g* for 18 min. Then 10 μl of the clear supernate was injected into the liquid chromatograph.

## RESULTS AND DISCUSSION

HPLC can provide a quick and accurate evaluation of multivitamin and multivitamin–multimineral tablets, and paired-ion reversed-phase HPLC is particularly attractive for determining water-soluble vitamins because polar constituents that dissolve in the aqueous mobile phase elute at or near the solvent front. Lipophilic constituents with very limited solubility in the aqueous mobile phase partition with the stationary phase, thereby eluting much later. Under these conditions, separation can be achieved. Thus, sample preparation time is greatly reduced and the accuracy of the method also is enhanced.

In the present study, 0.1 *N* HCl was used to extract the water-soluble vitamins from the multivitamin preparations. Dimethyl sulfoxide containing anhydrous citric acid was used to disperse the multivitamin–multimineral preparations since neither 0.1 *N* HCl nor dimethyl sulfoxide alone extracts pyridoxine completely. This may be due to adsorption of the vitamin by one or more of the minerals. Kwok *et al.* (8) established that vitamin A acetate adsorbs to ferrous gluconate and that a complexing agent can minimize this effect.

With a similar approach, it was demonstrated in these laboratories that, in 0.1 *N* HCl solution, pyridoxine hydrochloride adsorbs strongly to ferrous gluconate and magnesium oxide (Table I) and that a complexing agent like citric acid in dimethyl sulfoxide can minimize this effect (Table II). Thus, anhydrous citric acid was dissolved first in dimethyl sulfoxide to allow for the exposure to the minerals as soon as possible. Table I shows the effect of ferrous gluconate and magnesium oxide on pyridoxine hydrochloride in 0.1 *N* HCl solution. Table II demonstrates the percentage of recovery of all four water-soluble vitamins in multivitamin–multimineral tablets by different modes of extraction. It is obvious from Table II that 1% citric acid in dimethyl sulfoxide reduced the effect of ferrous gluconate and magnesium oxide to an insignificant level. The extraction of the other vitamins (thiamine, riboflavin, and niacinamide) was not impaired by the addition of the anhydrous citric acid in dimethyl sulfoxide.

Linearity of response over the range studied can be achieved using standard solutions. In these laboratories, the ratios of the concentration of the standard solution (expressed in nanograms per 10 microliters) to the area under the peak were consistent for all four water-soluble vitamins studied. These ratios were determined over 6 days, and their relative standard deviations were <1%. This finding indicates that the procedure can be used as a single-point standard for each vitamin.

Chromatographic traces of vitamin B standards, vitamin B complex, and the multivitamin–multimineral tablet extracts are presented in Figs. 1, 2, and 3, respectively. Using paired-ion reversed-phase HPLC, baseline

separation of all four water-soluble vitamins is possible (Figs. 1 and 2). There also is a baseline separation of the vitamins in the dimethyl sulfoxide extract (Fig. 3).

To validate the selectivity of the procedure, placebo formulations spiked with known amount of the vitamins were employed. The results are tabulated in Table III. All four vitamins were quantitatively recovered in both multivitamin and multivitamin–multimineral tablets.

To verify the applicability of this procedure further, various commercial multivitamin and multivitamin–multimineral tablets were assayed simultaneously by the HPLC and the USP methods (Tables IV and V). In each case, the precision of the HPLC procedure was greater than that of the current official procedure. This result may be attributed to the less complicated sample workup required by the former procedure. However, the results of the two methods compared favorably in terms of accuracy.

The described HPLC method appears to be attractive in terms of analysis time and should be adapted to various commercial products. The column lifetimes under these conditions of minimum sample preparation initially was a subject of concern. However, over 500 preparations were processed without change in the chromatographic characteristics of the system. This stability may be due in part to the small quantities of sample injected and in part to the proper care as recommended by the column supplier. The methodology for the HPLC determination of other vitamins is currently under investigation and will be published later.

# *In Vivo–In Vitro* Correlations with a Commercial Dissolution Simulator I: Methenamine, Nitrofurantoin, and Chlorothiazide

**MARTIN K. T. YAU and MARVIN C. MEYER** ˣ

Received October 20, 1980, from the *Division of Biopharmaceutics and Pharmacokinetics, Department of Pharmaceutics, College of Pharmacy, University of Tennessee Center for the Health Sciences, Memphis, TN 38163.* Accepted for publication February 20, 1981.

**Abstract** □ Dissolution profiles were determined for nine methenamine, 14 nitrofurantoin, and six chlorothiazide dosage forms using a dissolution simulator. Various *in vivo–in vitro* correlations were examined. The best correlation for methenamine was between the maximum urinary excretion rate and the time for 15% dissolution. A good correlation for the 50-mg nitrofurantoin tablets was also found between cumulative percent of drug excreted in 12 hr and the percent dissolved in 1 hr. There were no significant correlations for the 100-mg nitrofurantoin dosage forms. Good correlations were also observed for the 250- and 500-mg chlorothiazide tablets between the percent of drug dissolved in 1 min or the time for 15% dissolution and the maximum excretion rate.

instrument developed recently is a dissolution simulator[1], which is designed to be utilized in conjunction with an absorption simulator[2]. It is claimed (2) that these devices provide *in vitro* data that correlate well with *in vivo* bioavailability data. However, relatively little data demonstrating the applicability of these devices (3–5) have been published.

## BACKGROUND

The dissolution simulator is composed of two identical dissolution systems that permit the simultaneous evaluation of two dosage forms.

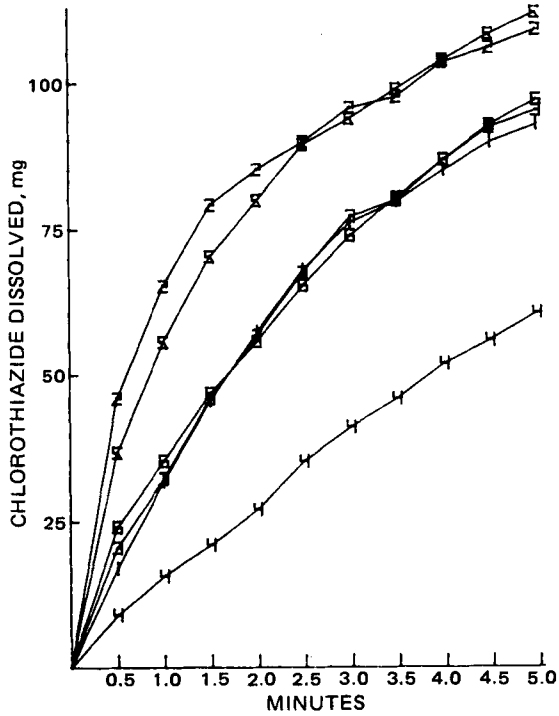

**Figure 4**—*Dissolution profiles for three 250-mg chlorothiazide tablet formulations (Products 1, 3, and 4) and three 500-mg chlorothiazide tablet formulations (Products 2, 5, and 6) in simulated gastric fluid. Each data point represents the mean of two determinations.*

The dissolution process takes place in two plastic cylinders. Dissolution fluid (100 ml) is placed in each cylinder, along with the dosage form and 70 g of glass beads. The cylinders rotate around a horizontal axis at 1.2 cpm to provide gentle agitation. The cylinder contents are maintained at 37°, and the pH of the dissolution fluid may be changed during the dissolution process by the addition of buffer salts. Samples ranging from 2.5 to 7.5 ml are automatically withdrawn and collected for analysis at sampling intervals of 0.5–60 min. The volume of dissolution fluid removed by sampling is replaced by fresh solution contained in a reservoir. The manufacturer recommends that the rate of sample withdrawal should be determined from data obtained in preliminary studies with the absorption simulator. The sampling rate for the dissolution simulator is directly related to the rate of drug diffusion in the absorption simulator.

The absorption simulator is essentially a dialysis cell designed to determine the diffusion rate of a drug, dissolved in either simulated gastric or intestinal fluid, across a membrane coated with a lipid substance into a pH 7.5 buffer. The diffusion rate is reported to be related to the rate of drug diffusion across the membranes of the GI tract.

Since little data were available to permit an evaluation of the correlation between *in vitro* dissolution data obtained with the dissolution simulator and the bioavailability of oral dosage forms in humans, a series of studies was initiated. The present study reports dissolution data for nine methenamine, 14 nitrofurantoin, and six chlorothiazide dosage forms. Each formulation was the subject of previous *in vivo* urinary excretion studies with healthy human subjects (6–8).

## EXPERIMENTAL

**Absorption Simulator Studies**—Each drug was dissolved in 100 ml of simulated gastric fluid (pH 1.1) containing hydrochloric acid, sodium chloride, and aminoacetic acid or in simulated intestinal fluid (pH 6.5) containing phosphate buffer. The initial drug concentrations were 200 μg/ml for the methenamine and chlorothiazide solutions and 100 μg/ml for the nitrofurantoin. A membrane with an effective surface area of 80 $cm^2$ was used for both the simulated gastric and intestinal phase diffusion studies. The composition of the lipid coating of the membrane was different for the two studies, but the nature of the coating was not available from the supplier.

The gastric and intestinal phase studies used artificial gastric and intestinal membranes[3]. The drug diffused from the gastric or intestinal phase, across the membrane, into the simulated plasma phase, which was a pH 7.5 phosphate buffer. At least three samples were collected from each phase at equal time intervals, and each study was done in duplicate. The resulting data were employed to calculate a diffusion rate constant, which was subsequently used to estimate an appropriate sampling rate for the dissolution simulator, according to a previous method (9).

**Dissolution Simulator Studies**—Each dosage form of the three drugs was initially placed into the simulated gastric fluid. The sampling rates for each drug were as follows: methenamine, 2.5 ml every 15 min for 30 min; nitrofurantoin, 2.5 ml every 16 min for 32 min; and chlorothiazide, 7.5 ml every 0.5 min for 5 min. At the end of the gastric phase, phosphate buffer was added to the dissolution fluid to increase the pH to 6.5 for methenamine and nitrofurantoin. Dissolution studies of the chlorothiazide formulations were only studied using the gastric phase. The sampling rates during this intestinal phase were as follows: methenamine, 2.5 ml every 5.5 min for 278 min; and nitrofurantoin, 2.5 ml every 16 min for 240 min. Two units of each drug formulation were studied. In addition, six tablets of one lot of nitrofurantoin were used to measure the reproducibility of the dissolution process.

The methenamine dosage forms, identified previously in a 10-subject study (6), consisted of a compressed tablet with 500 mg of methenamine base (Product 1), a suspension containing 50 mg of methenamine mandelate/ml (Product 2), a 500-mg methenamine hippurate tablet (Product 10), and six formulations of enteric-coated methenamine mandelate (Products 4–9). A 10th dosage form (Product 3), given as a solution in a previous study (6), was not included.

The nitrofurantoin dosage forms, included in earlier *in vivo* studies using 14 subjects (7), were six 50-mg tablets of microcrystalline drug (Products 1, 2, 8, 9, 11, and 14) and six 100-mg tablets of microcrystalline drug (Products 3–6, 12, and 13). A 50-mg macrocrystalline capsule (Product 10) and a 100-mg macrocrystalline capsule (Product 7) also were studied.

The chlorothiazide tablets contained either 250 (Products 1, 3, and 4) or 500 (Products 2, 5, and 6) mg of chlorothiazide and also were identified in an earlier study in which each dosage form was administered to a group of 12 subjects (8).

[3] Artificial gastric lipid barrier, SM 15701, and artificial intestinal lipid barrier, SM 15702, Sartorius Filters, San Francisco, Calif.

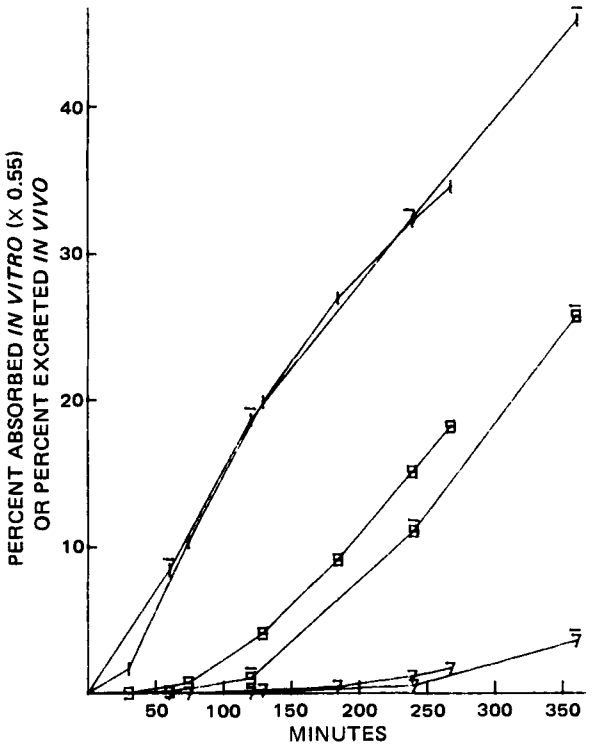

**Figure 5**—*Comparison of the total amount of methenamine withdrawn from the* in vitro *dissolution system (× 0.55) (Products 1, 7, and 9) and the cumulative amount of methenamine excreted in the* in vivo *studies (Products 1, 7, and 9) for three methenamine formulations. Each* in vitro *data point is the mean of two determinations. Each* in vivo *data point is the mean of 10 subjects.*

**USP Dissolution Tests**—Dissolution testing, using the USP rotating basket, was described previously for *in vivo* studies of the nitrofurantoin (7) and chlorothiazide (8) dosage forms. Studies using this dissolution apparatus were not conducted for the methenamine tablets.

**Analytical Methods**—Samples of methenamine solutions obtained with both the dissolution and absorption simulators were assayed by a colorimetric procedure based on a method developed to determine urine concentrations (10). Samples were diluted, and 0.5-ml aliquots were acidified with 0.5 ml of 6 *N* HCl and heated in a 70° water bath in a closed tube for 2 hr to hydrolyze the methenamine to formaldehyde. The solution was then cooled to 5°, and 1 ml of 0.1% tryptophan in 50% ethanol, 0.2 ml of 1% ferric chloride, and 1 ml of 90% sulfuric acid were added. The solution was heated for an additional 70 min at 70°.

After cooling to room temperature, the absorbance was determined at 575 nm and the methenamine concentration was calculated from a standard curve obtained by carrying aqueous solutions of known methenamine composition through the assay procedure. Preliminary studies indicated that the materials contained in the enteric coating of some of the products did not interfere in the assay at the dilution levels employed for the *in vitro* samples.

Nitrofurantoin samples obtained with either the absorption or dissolution simulator were diluted as necessary with pH 6.5 or 7.5 phosphate buffer, and the absorbance was determined at 278 nm. Standard curves also were prepared with nitrofurantoin solutions of known composition at pH 6.5 and 7.5.

Chlorothiazide samples were assayed at 278 nm after dilution with pH 6.5 or 7.5 phosphate buffer. Solutions of known chlorothiazide concentration also were assayed.

**Treatment of Dissolution Data**—Three types of data treatment were employed to evaluate the relationship between *in vitro* dissolution and *in vivo* urinary excretion data.

*Simulated Absorption Data*—The cumulative amount of drug excreted in the urine and the cumulative amount of dissolved drug withdrawn from the dissolution chamber were plotted *versus* time and were compared visually.

*General Correlations*—*In vivo* measurements, such as the cumulative

**Table I—Diffusion Characteristics and Sampling Rates Determined with the Absorption Simulator**

| Drug | $K_d \times 10^3$ cm/min$^{-1}$ (±SD) | | Calculated Time, between Samples, min[b] | | Actual Time between Samples, min | |
|---|---|---|---|---|---|---|
| | Gastric Phase[a] | Intestinal Phase[a] | Gastric Phase | Intestinal Phase | Gastric Phase | Intestinal Phase |

| Nitrofurantoin | 0.16 (0.01) | 0.34 (0.00) | 67.9 | 16.0 | 16.0 | 16.0 |
| Chlorothiazide | 0.12 (0.00) | 0.44 (0.04) | 110.0 | 9.8 | 0.5 | — |

[a] Diffusion rate constant, calculated according to Stricker (9). [b] Theoretical sampling rates for the dissolution simulator, calculated from the absorption simulator diffusion rate according to Stricker (9).

percent of drug excreted at specific times and maximum urinary excretion rates, were correlated with *in vitro* data such as the cumulative percent of drug dissolved and the time for a specific percent of drug to dissolve *in vitro*. The latter values for $T_{15\%}$, $T_{50\%}$, and $T_{70\%}$ were determined using the logarithmic-probability method of Sullivan *et al.* (11).

*Quadrant Analysis*—This relatively new approach (12, 13) utilizes *in vivo* data from individual subjects rather than just mean data from a group of subjects. The performance of each dosage form in each subject is evaluated relative to a reference dosage form. An arbitrary guideline, *e.g.*, 75%, is selected, and the percent of subjects exhibiting a relative bioavailability of at least 75% is determined and plotted *versus* the *in vitro* dissolution measurement of interest for each test dosage form. For example, if five out of 10 subjects exhibit a maximum urinary excretion rate for a test product that is at least 75% that of a reference product, 50% would be used for correlation with the *in vitro* measurement for that specific dosage form. The other formulations included in the *in vivo* and *in vitro* evaluations would be treated similarly to develop a possible correlation.

## RESULTS AND DISCUSSION

**Absorption Simulator**—The apparent first-order diffusion rate constants determined in simulated gastric and intestinal fluids using the absorption simulator are given in Table I. A direct comparison of the diffusion rates for a given drug in both gastric and intestinal fluid is not possible because the composition of the membranes was different for the two fluids.

The diffusion rate constants, which according to Stricker (9) are related to the *in vivo* drug absorption rate, were used to compute the optimum sampling intervals for the *in vitro* dissolution studies. The resulting sampling times are given in Table I. Since the dissolution simulator is supposed to involve dissolution studies using gastric fluid for 30 min to simulate gastric residence time, the calculated sampling intervals for methenamine, nitrofurantoin, and chlorothiazide were not appropriate. Thus, arbitrary sampling times were chosen for the gastric fluid dissolution studies of these drugs. In particular, the 0.5-min time used for chlorothiazide was based on a preliminary study that indicated that the gastric dissolution fluid was rapidly saturated with this drug within 5 min. Furthermore, because of the limited solubility of chlorothiazide, the dissolution study was terminated after 5 min.

The results obtained with the absorption simulator indicated that it was of little value for these three drugs in the determination of appropriate sampling intervals for the dissolution studies. While the absorption simulator may be useful in the study of diffusion characteristics of drugs through lipid membranes, such studies were beyond the scope of the present investigation.

**Dissolution Profiles**—Figures 1–4 illustrate the dissolution rate profiles for the various drug products as determined in the dissolution simulator. The enteric-coated methenamine formulations (Products 4–9) shown in Fig. 1 exhibited a delay in the onset of dissolution until the dissolution fluid pH was increased from 1.1 to 6.5. These dissolution profiles were utilized to develop the correlations described later with the previously determined *in vivo* data.

While the dissolution of only two units of each formulation was routinely studied for each drug, six tablets of one 50-mg nitrofurantoin product were used in one instance to evaluate the reproducibility of the dissolution process. The mean amount of nitrofurantoin dissolved after 16 min was 9.2 mg (range 8–11 mg); after 32 min, the mean was 21.3 mg (range 20–22 mg); and after 48 min, the mean was 34.7 mg (range 34–36 mg). Generally, this good agreement among the six replicates also was seen between the duplicate determinations for each formulation of the three drugs.

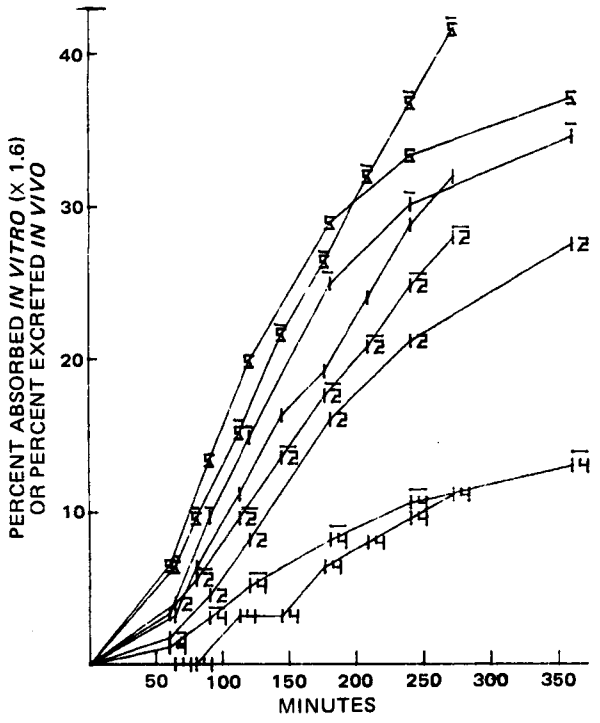

**Figure 6**—*Comparison of the total amount of nitrofurantoin withdrawn from the* in vitro *dissolution system (× 1.6) and the cumulative amount of nitrofurantoin excreted in the* in vivo *studies for four nitrofurantoin tablet formulations. Each* in vitro *data point (Products 1, 5, 12, and 14) is the mean of two determinations. Each* in vivo *data point (Products 1, 5, 12, and 14) is the mean of 14 subjects.*

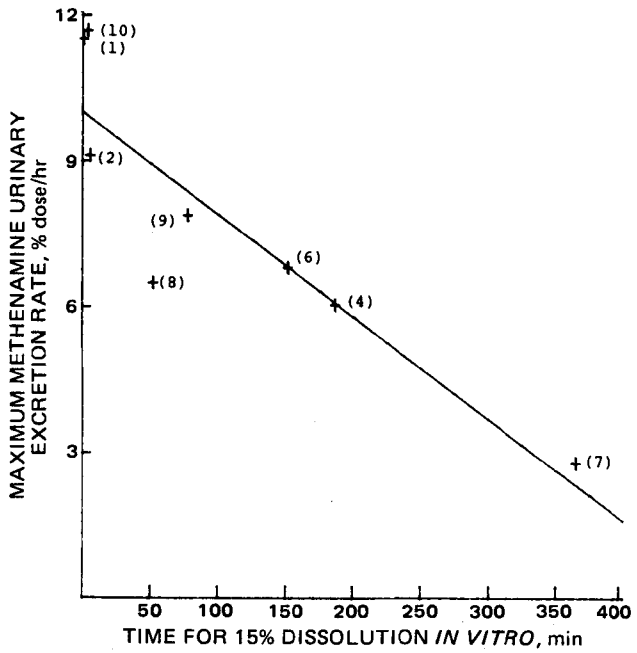

**Figure 7**—In vitro–in vivo *correlation for eight methenamine formulations,* $r = -0.894$ ($p < 0.01$). *Each data point represents the mean of two* in vitro *and 10* in vivo *values.*

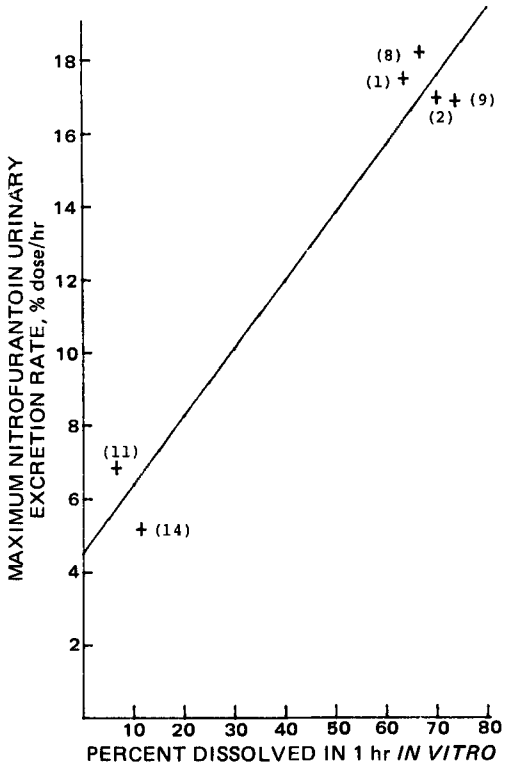

**Figure 8**—In vitro–in vivo *correlation for five 50-mg nitrofurantoin tablet formulations,* r = *0.976* (p < *0.01*). *Each data point represents the mean of two* in vitro *and 14* in vivo *values.*

**Simulated Absorption Profiles**—The dissolution simulator is reported by the manufacturer to be capable of providing data that can simulate *in vivo* absorption profiles (2). To evaluate this claim, plots were constructed of cumulative urinary excretion of each drug and the cumulative amount of dissolved drug withdrawn from the dissolution chamber at the corresponding times. Since the dissolution studies for the chlorothiazide tablets were carried out only for 5 min, simulation of *in vivo* data was not possible for these dosage forms.

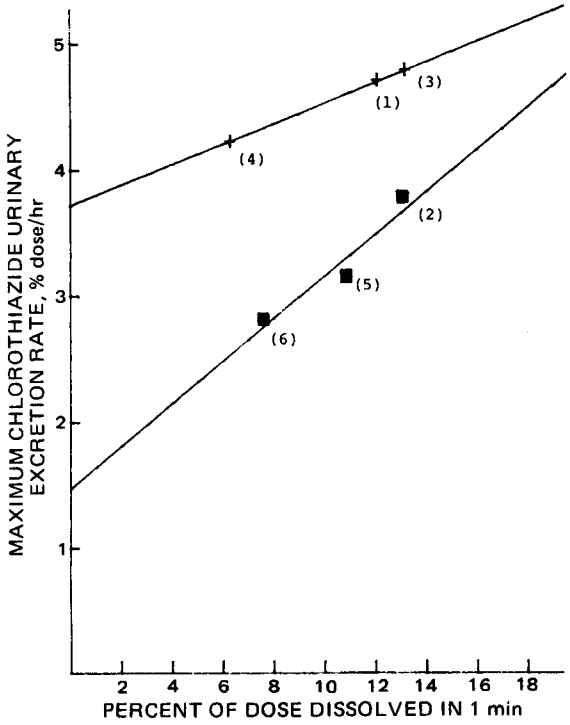

**Figure 9**—In vitro–in vivo *correlations for three 250- (+) and three 500- (■) mg chlorothiazide tablet formulations,* r = *0.999* (p < *0.05*) *and* r = *0.962* (p > *0.10*), *respectively. Each data point represents the mean of two* in vitro *and 12* in vivo *values.*

*Methenamine Tablets*—All data were expressed as the percent of dose to normalize for differences in methenamine content among products. Product 1, a compressed tablet of methenamine, was selected as a reference, and plots were made of the cumulative percent of dissolved drug withdrawn from the dissolution chamber and the mean cumulative percent of drug excreted in the urine of the 10 subjects receiving the drug in an earlier study (6). The *in vitro* curves paralleled the *in vivo* data but were somewhat higher. An empirical correction factor of 0.55, applied to the *in vitro* data, resulted in good correspondence between the two data sets.

The data shown in Fig. 5 illustrate the comparison between the *in vitro* data, corrected by a factor of 0.55, and the corresponding *in vivo* urinary excretion data for Product 9, with an intermediate dissolution rate, and Product 7, with a relatively slow dissolution rate. A similar good correspondence also was obtained for Products 4–6 and 10. The relationship between *in vitro* and *in vivo* data was not nearly as good for Products 2 and 8, with the *in vitro* data predicting greater urinary excretion than was actually seen.

*Nitrofurantoin Dosage Forms*—Figure 6 illustrates good correspondence between the *in vivo* and *in vitro* data for Products 1, 5, 12, and 14. Each *in vitro* data point was adjusted by a factor of 1.6, based on the observed parallelism for the *in vivo* and *in vitro* data for Product 9, which was taken as the reference product. Similar good correspondence was observed for Products 2 and 8, but there was a significant difference between the *in vivo* and *in vitro* data sets for Products 3, 4, 6, 11, and 13. As will be discussed, Products 7 and 10, the macrocrystalline capsules, exhibited dissolution characteristics that were quite different from the microcrystalline tablets. Therefore, these two dosage forms were not included with the microcrystalline formulations in this data treatment.

**General Correlations**—These correlations attempted to relate various *in vitro* and *in vivo* measurements. Only the best correlations will be discussed, although other correlations were examined.

*Methenamine Tablets*—The best correlation, $r = 0.928$ ($p < 0.01$), was seen between the area under the dissolution–time curve at 4.5 hr *versus* the cumulative percent excreted at 6 hr. When using $T_{15\%}$ as the *in vitro* measurement, good correlations were observed with the cumulative

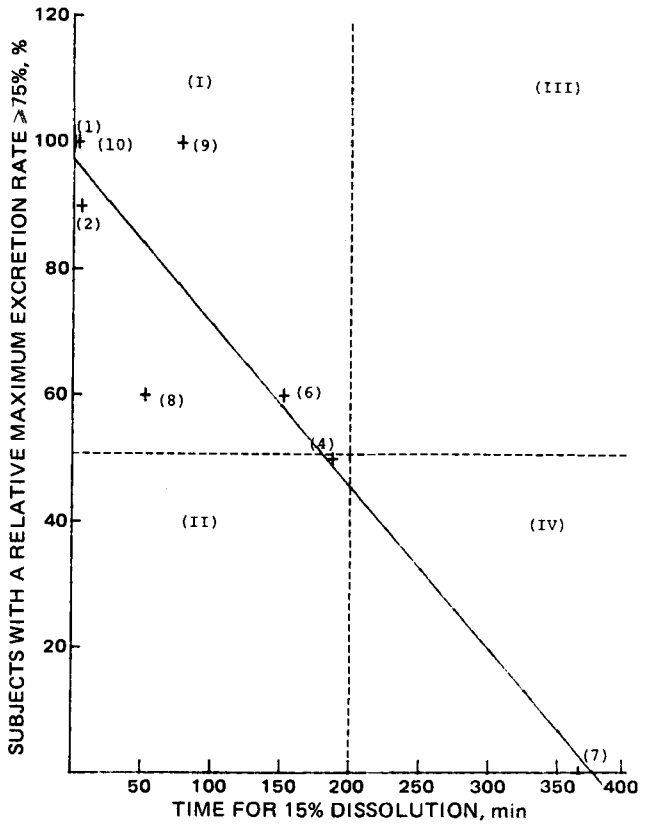

**Figure 10**—*Quadrant analysis for eight methenamine formulations,* r = *−0.93* (p < *0.01*). *Each data point represents the mean of two* in vitro *and 10* in vivo *values. Product 9 was the reference product.*

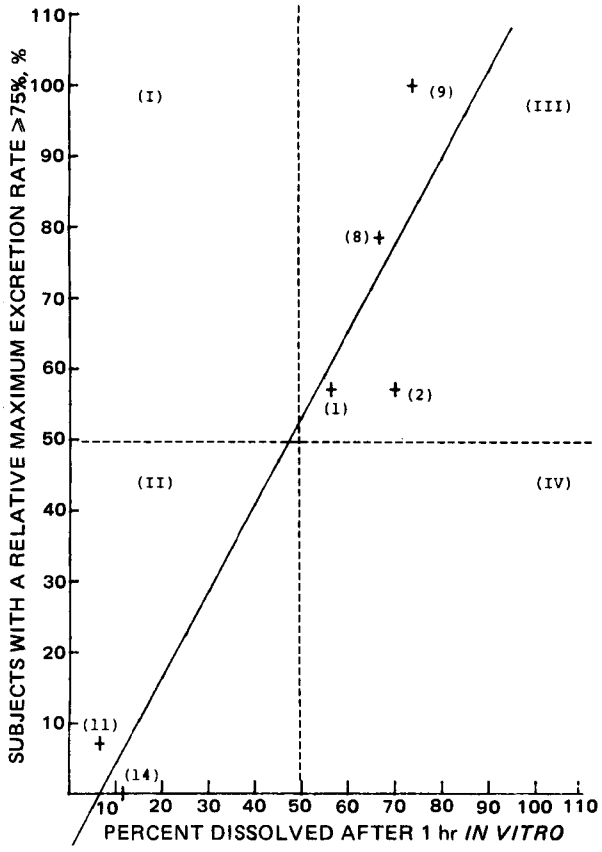

**Figure 11**—*Quadrant analysis for six 50-mg nitrofurantoin tablet formulations,* r = *0.943 (*p < *0.01). Each data point represents the mean of two* in vitro *and 14* in vivo *values. Product 9 was the reference product.*

percent excreted at 48 hr, $r = -0.875$ ($p < 0.01$), and the maximum excretion rate, $r = -0.894$ ($p < 0.01$) (Fig. 7). Since Products 4, 5, and 7 were <30% dissolved after 5 hr, correlations with $T_{\%}$ values beyond 15% could not be used. Product 5 is not illustrated because <1% of the drug had dissolved after 5 hr, and the tablet retained its original shape during the dissolution period.

*Nitrofurantoin*—Attempts to obtain *in vivo–in vitro* correlations that included Products 7 and 10 were not successful. Both dosage forms exhibited relatively good dissolution properties (Figs. 3 and 4). However, these two products ranked below eight of the other products in earlier bioavailability studies involving determination of cumulative urinary excretion. Thus, these two products, which represented capsule formulations of the macrocrystalline drug, were omitted from the correlations.

The percent of drug excreted in 12 hr and the maximum urinary excretion rate were correlated with the percent of drug dissolved at various times. Generally, the correlations with the 100-mg tablets were less satisfactory than with the 50-mg tablets. The correlation coefficient for the 100-mg tablets, using a variety of measurements, was <0.8 ($p < 0.10$), while correlation coefficients exceeded 0.93 ($p < 0.01$) for the 50-mg tablets. The best correlation for the 50-mg tablets is shown in Fig. 8, $r = 0.976$ ($p < 0.01$), using the maximum excretion rate and the percent of drug dissolved in 1 hr. Cumulative percent excreted in 12 hr also correlated well with the 1-hr dissolution value, $r = 0.960$ ($p < 0.01$). The poorer correlation with the 100-mg tablets may be due to the fact that the maximum excretion rates for the six tablets were much closer than for the 50-mg tablets. Previous investigators (14) noted a similar poorer correlation for 100-mg nitrofurantoin tablets, using the same lots as employed in the present study, but obtained *in vitro* data with a dissolution–dialysis system.

As part of the earlier *in vivo* studies (7), the individual tablets also were subjected to dissolution testing as described in USP XVIII. The present dissolution simulator data correlated much better than the earlier USP data for the 50-mg tablets, $r = 0.673$ ($p > 0.10$), although the degree of correlation was approximately the same for the 100-mg tablets using either the dissolution simulator, $r = 0.704$ ($p < 0.10$) or the USP rotating basket, $r = 0.793$ ($p < 0.10$).

*Chlorothiazide Tablets*—The data obtained for these dosage forms demonstrated one major limitation in the design of the dissolution simulator, namely that the total volume of dissolution fluid was limited to 100 ml. As shown in Fig. 4, this fluid was rapidly saturated with dissolving drug; as a result, dissolution was not continued beyond 5 min. The best correlations for both the 250- and 500-mg tablets were seen between the cumulative percent of drug dissolved in 1 min and the maximum excretion rate (Fig. 9). The data for the 250- and 500-mg tablets were not combined into a single correlation because the *in vivo* data did not exhibit a dose proportionality in urinary excretion, with a lower percent recovery for the 500-mg tablets (8).

The correlation was significant for the 250-mg tablets, $r = 0.999$ ($p < 0.05$), but not for the 500-mg tablets, $r = 0.962$ ($p < 0.10$). Good correlations, $r > 0.9$, existed between the maximum excretion rate or the cumulative percent excreted at 24 hr and $T_{15\%}$ or the percent dissolved at 2.5 min for the 250-mg tablets. However, these correlations were based on only three data points; the general applicability of the relationships need to be established for a larger group of dosage forms.

A good correlation, $r = 0.999$ ($p < 0.05$), also was obtained for the 250-mg tablets between the maximum excretion rate and the time for 30% dissolution using the USP rotating basket. However, for the 500-mg tablets, the correlation was much poorer for these same parameters, $r = 0.773$ ($p > 0.10$). Thus, on the basis of cost and convenience, the USP method is preferred over the dissolution simulator for the 250-mg tablets since both procedures result in comparable *in vitro–in vivo* correlations. However, the correlations for the 500-mg tablets were somewhat better for the dissolution simulator compared to the USP method.

**Quadrant Analysis**—This approach evaluates *in vivo* data using each subject as his or her own control, relating the bioavailability of a dosage form in a given subject to the performance of a reference dosage form in the same subject. For illustration, an arbitrary specification was selected such that 50% of the subjects participating in an *in vivo* study should exhibit a relative bioavailability of at least 75% for a test dosage form to be considered acceptable. The *in vivo* data were plotted *versus* an *in vitro* measurement for the individual dosage forms, and an *in vitro* dissolution specification was selected. While the *in vitro* specifications described for the three drugs under consideration are admittedly somewhat arbitrary,

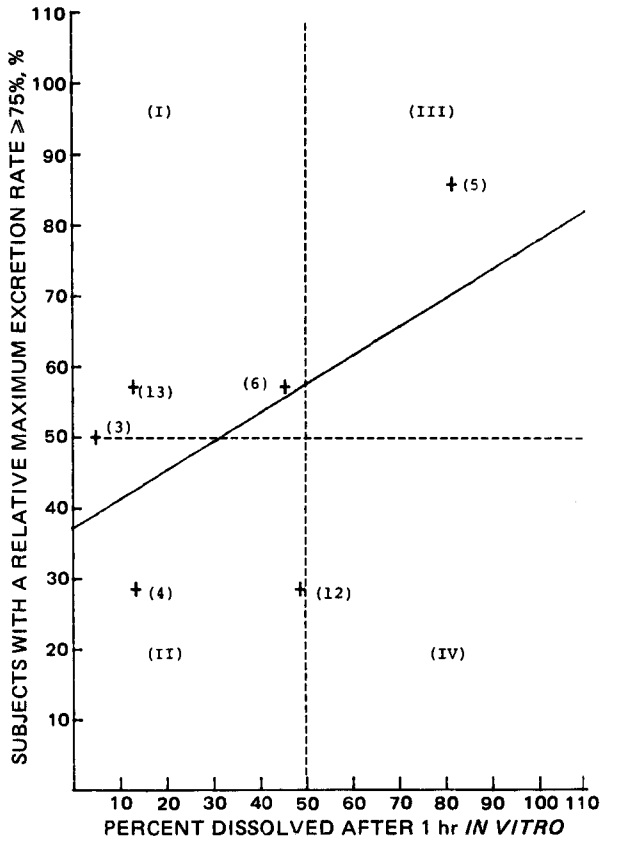

**Figure 12**—*Quadrant analysis for six 100-mg nitrofurantoin tablet formulations,* r = *0.557 (*p > *0.1). Each data point represents the mean of two* in vitro *and 14* in vivo *values. Product 9 was the reference product.*

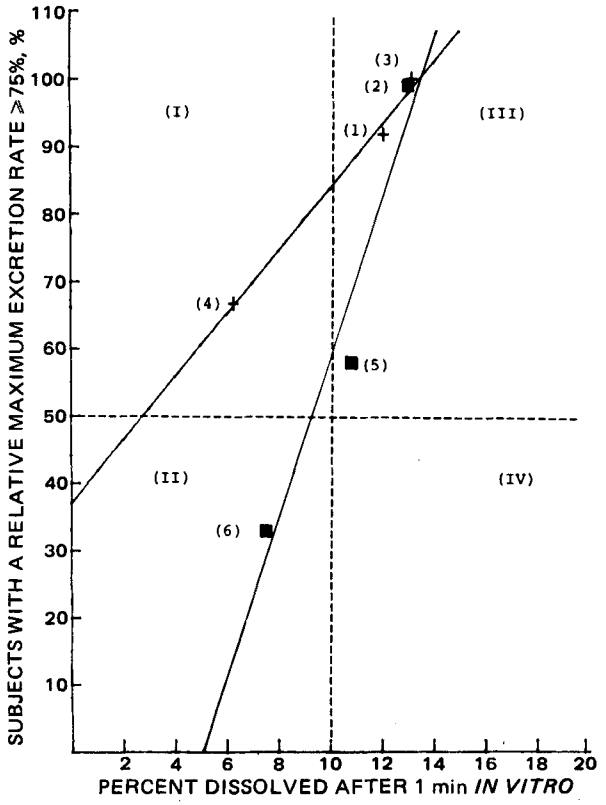

**Figure 13**—*Quadrant analysis for three 250- (+) and three 500- (■) mg chlorothiazide tablet formulations, r = 0.995 (p < 0.1) and r = 0.967 (p > 0.1), respectively. Each data point represents the mean of two* in vitro *and 12* in vivo *values.*

they serve to illustrate an alternative approach to setting such specifications.

*Methenamine*—Figure 10 illustrates the results of the quadrant analysis approach for methenamine. The selection of 200 min as the maximum permissible time to achieve 15% dissolution was based on the *in vivo* data, which indicated that Products 5 and 7 were unacceptable. Note that Product 5 does not appear in this figure since it did not achieve 15% dissolution within 6 hr. With the exception of Products 5 and 7, all other dosage forms were confined to Quadrant I and thus exhibited acceptable bioavailability and dissolution properties.

*Nitrofurantoin*—Figures 11 and 12 show the quadrant analysis for the 50- and 100-mg dosage forms, respectively. With the exception of Products 11 and 14, all other dosage forms represented in Fig. 11 were in Quadrant III and thus met both the *in vivo* and *in vitro* specifications. Using the same specifications for the 100-mg tablets illustrated in Fig. 12 did not yield a satisfactory result. Only Product 5 was in Quadrant III; Products 3, 6, and 13 failed the *in vitro* specification, although each exhibited adequate bioavailability. Furthermore, Product 12 nearly passed the dissolution requirement, although only 30% of the subjects exhibited a maximum urinary excretion rate that was at least 75% that of the reference product.

*Chlorothiazide*—A dissolution specification of 10% dissolution within 1 min was selected for the 250- and 500-mg tablets shown in Fig. 13. With this criterion, Product 4 exhibited an adequate excretion rate for the 250-mg tablets but failed the dissolution specification. For the 500-mg tablets, Product 6 failed both the *in vitro* and *in vivo* specifications. Because of the small number of dosage forms and the brief duration of the dissolution test, these data may be of limited value in establishing the utility of this approach as a predictor of the bioavailability of chlorothiazide dosage forms.

**Study Limitations**—All dissolution studies were carried out on production lots used in previous *in vivo* bioavailability studies. Thus, some formulations had been stored at room temperature for up to 4 years, and in some instances the expiration date indicated on the package had been exceeded. Furthermore, only a few tablets or capsules remained for many of the products, and it was not possible to reassay them for content and content uniformity. As a result, drug content and/or dissolution characteristics of these dosage forms may have changed since the earlier studies.

Evidence suggesting that significant changes in the characteristics of the dosage forms had not occurred may be obtained by comparing the extent of dissolution observed in the present studies with that obtained previously. The maximum amount of methenamine recovered during the dissolution studies with the dissolution simulator corresponded with the labeled quantity of drug in the product for those dosage forms that totally dissolved. With nitrofurantoin, a range of 7–80% of the labeled amount of drug was dissolved after 80 min in the dissolution simulator. In the earlier study (7), between 10 and 70% of the drug was dissolved after 90 min using the USP procedure. Furthermore, the two products with the slowest dissolution rate in the dissolution simulator were the same two products that dissolved the slowest in the previous study (7). Similarly, the extent of dissolution of the chlorothiazide tablets in the dissolution simulator was quite similar to the results obtained earlier (8) using the USP apparatus.

## CONCLUSIONS

The absorption simulator was evaluated as a tool to determine optimum sampling times for dissolution studies using the dissolution simulator. It was determined that the sampling times computed from the absorption simulator were not essential for the subsequent dissolution studies.

Reasonably good correlations generally were observed between the *in vitro* data obtained with the dissolution simulator and the *in vivo* data obtained in earlier human studies. However, the general applicability of the device to a wide variety of drugs is limited because only two dosage units can be tested simultaneously. Moreover, the 100-ml capacity of the dissolution system is insufficient for drugs with very low water solubility. The dissolution properties of the methenamine, chlorothiazide, and 50-mg nitrofurantoin tablets could all be satisfactorily correlated with one or more *in vivo* parameters. The correlations for the 100-mg nitrofurantoin tablets and the macrocrystalline nitrofurantoin capsule dosage forms were less satisfactory.

Attempts also were made to predict urinary excretion profiles using the *in vitro* data. After application of an adjustment factor, good predictions were seen for the majority of the methenamine dosage forms and seven of the 14 nitrofurantoin formulations. The method was not applicable for the chlorothiazide tablets.

Finally, *in vivo–in vitro* correlations were examined using a quadrant analysis approach. The method was shown to be of value in setting *in vitro* specifications that have at least some relevance to the *in vivo* performance of the dosage form.

# High-Performance Liquid Chromatographic Determination of Free Myxin and Its Reduction Product as Impurities in Cuprimyxin-Containing Creams

**G. MANIUS ˣ, R. TSCHERNE, R. VENTEICHER, and A. SECKER**

Received November 28, 1980, from the *Quality Control Department, Hoffmann–La Roche Inc., Nutley, NJ 07110.* Accepted for publication February 20, 1981.

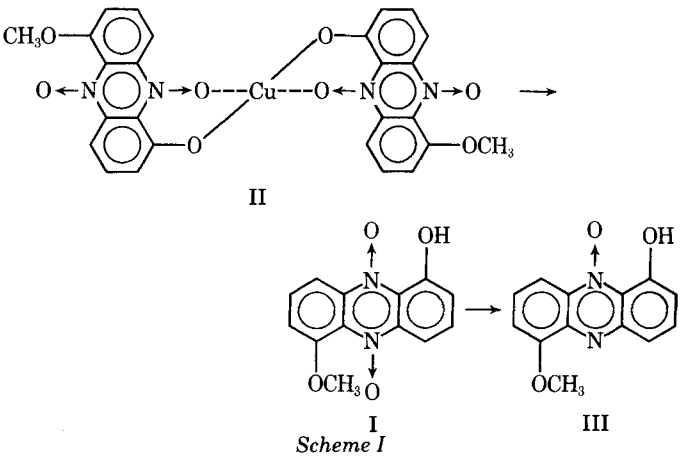
**Abstract** □ A stability-indicating high-performance liquid chromatographic method was developed that can detect and quantitate low levels of the two most likely breakdown products of cuprimyxin. These degradation compounds, free myxin and its reduction product, can be determined in topical cream preparations in which cuprimyxin is formulated at the 0.5% (w/w) level. The method requires a simple two-step extraction, the addition of an internal standard, and chromatography on an amine-bonded column.

**Keyphrases** □ Myxin—high-performance liquid chromatographic assay in cuprimyxin-containing creams □ Cuprimyxin—high-performance liquid chromatographic determination of free myxin and its reduction product □ High-performance liquid chromatography—determination of free myxin and its reduction product in cuprimyxin-containing creams □ Antibacterial agents—high-performance liquid chromatographic determination of myxin and its reduction product in cuprimyxin-containing creams

Myxin (6-methoxy-1-phenazinol 5,10-dioxide) (I) was first isolated from the soil (1) and identified as a phenazine-type product from the broth of a myxobacter (2). Its correct structure was established by Weigele and Leimgruber (3), and it was realized in its most effective antimicrobial form as the cupric complex (II) (4, 5). When applied topically, II was found to have considerable antibacterial, antiyeast, and antifungal activity in veterinary applications without the irritation side effects experienced with I (6). It was formulated in a cream and tested *in vitro* against Gram-positive and Gram-negative bacterial and fungal pathogens (7) and yeast infections (8), *in vivo* as a cream for otic and ophthalmic infections (9), and as a suspension with hydrocortisone acetate for the treatment of otitis (10). The apparent biological mechanism of action involves alteration of the invading bacterial DNA template (11).

## BACKGROUND

A polarographic investigation found the electrochemical behavior of I to be a function of pH, reducing to 6-methoxy-1-phenazinol at pH < 3, to the anionic species 6-methoxyphenazinol at pH > 9, and to the intermediate 6-methoxy-1-phenazinol 10-oxide (III) at pH 3–9 (12). Compound III can be further reduced by intramolecular hydrogen bonding to 6-methoxy-1-phenazinol. The major degradation product of I in acid media and in pH 3–9 buffer solutions was found to be III[1]. Although the copper complex of II is readily dissociated in acid media to form I (Scheme I), pharmaceutical creams containing excess copper ions minimize dissociation when formulated at pH 5.7–6.2 (13).



*Scheme I*

The rapid conversion of II to I was used to assay for II by measurement of the amount of I found spectrophotometrically[2] and by TLC (14). Microbiological assay methods for determining II directly from seeded agar plates also were reported[3].

The determination of I and III as probable impurities in formulations involving II is difficult for two reasons: (*a*) the relative ease of conversion of II to its free form (I), and (*b*) the inability to differentiate I and III spectrophotometrically. A separation technique that minimizes dissociation of the copper complex is essential. This paper describes the development of a high-performance liquid chromatographic (HPLC) method that meets these requirements.

## EXPERIMENTAL

**Apparatus**—A constant-flow solvent delivery system[4] was connected to a loop injector[5]. An amine-bonded silica column[6] was coupled to a spectrophotometric detector[7] set at 280 nm. A 10-mv recorder[8] was set at a chart speed of 50 cm/hr.

**Reagents and Chemicals**—Distilled-in-glass grade ethyl acetate[9] and heptane[9] and reagent grade acetic acid[10] were used. Samples and

reference materials were obtained from the same source[11], except for the internal standard, 3-acetylindole[12].

**Mobile Phase**—A mixture of ethyl acetate–heptane–acetic acid (30:69.5:0.5) was prepared and run at a flow rate of 3.0 ml/min.

**Reference Standard Stock Solution**—Approximately 18 mg of I reference standard and 10 mg of III reference standard were weighed into a 500-ml volumetric flask and then dissolved and diluted to volume with ethyl acetate. A 10-ml aliquot was transferred into a 25-ml volumetric flask, which then was diluted to volume with heptane.

**Internal Standard Stock Solution I**—Approximately 80 mg of 3-acetylindole was weighed into a 500-ml volumetric flask and then dissolved and diluted to volume with ethyl acetate.

**Internal Standard Stock Solution II**—A 10-ml aliquot of internal standard stock solution I was transferred into a 25-ml volumetric flask, which then was diluted to volume with heptane.

**Working Reference Standard Solution**—Equal volumes of the reference standard stock solution and the internal standard stock solution II were pipetted.

**Extraction Solution**—The internal standard stock solution I (250 ml) was transferred into a 500-ml volumetric flask and diluted to volume with ethyl acetate.

**Sample Preparation**—Approximately 1.0 g of sample was weighed into a 50-ml centrifuge tube. Then 10 ml of the extraction solution was pipetted into the centrifuge tube, which was stoppered and shaken vigorously by hand until the sample was dispersed in the extracting solvent (~1 min). The tube then was centrifuged, and the liquid was decanted into a 25-ml volumetric flask. The extraction was repeated with 15 ml of a 2:3 ethyl acetate–heptane mixture, and the tube again was centrifuged. The liquid was decanted and combined with the first extraction, and the final volume was adjusted to 25 ml with heptane.

**Procedure**—The working reference standard solution (50 μl) was injected to determine retention times and relative response ratios. This injection was followed by 50-μl injections of the sample solutions. Peaks were quantitated by measurement of their heights in millimeters.

**Calculations**—The level of I in the sample was determined by the following:

$$\% \text{ (w/w) I in sample} = \frac{(H_I)(C_A)(25)(100)}{(H_A)(W)(RR)} \qquad \text{(Eq. 1)}$$

where $H_I$ and $H_A$ are the respective peak heights of I and 3-acetylindole in the sample solution, $C_A$ is the 3-acetylindole concentration in the sample solution, $W$ is the sample weight (milligrams), $RR$ is the relative response ratio, 25 is the dilution factor, and 100 is the conversion to percent.

The level of I as II was determined by:

$$\% \text{ (w/w) I as II} = \frac{(\% \text{ I in sample})(1.12)(100)}{(0.5)} \qquad \text{(Eq. 2)}$$

where 1.12 is the factor to convert I to II, 0.5 is the percent of II in the sample, and 100 is the conversion to percent.

The level of III was calculated in the same manner as I except that the 1.12 factor was omitted.

## RESULTS AND DISCUSSION

A representative chromatogram showing the elution of III, I, and the internal standard (IV) at 4, 7, and 10.5 min, respectively, is presented in Fig. 1. Table I lists data obtained on several lots of cream containing 0.5% II by weight. The data reflect double extractions of several samples encompassing a wide range of storage time.

Ethyl acetate was selected as the extracting solvent because of the high solubility of I and III and the very low solubility of II in it. In addition, ethyl acetate contributed only slightly to the dissociation of the copper complex. Conversely, solvents such as hexane and heptane incompletely dissolved I at the level required for preparation of the reference standard. Solvents such as methylene chloride, chloroform, and water produced dissociation of the complex, resulting in substantial amounts of I being formed for each extraction. Furthermore, ethyl acetate was complementary to heptane as a mobile phase in that it helped achieve reasonable retention times on the HPLC column.

Dissociation of the copper complex, facilitated by the nature of the cream, was singularly the most difficult aspect in developing the analytical method. For example, II was maintained as a 50% aqueous paste since it is subject to violent decomposition in the dry state (15). Investigations showed that extracts of the paste, even after several days of standing in contact with the paste, resulted in little I formation. Yet creams to which water was added as an extraction aid produced extensive amounts of I when extracted. It is believed that water in the presence of another ingredient in the cream, perhaps acid, causes this degradation.

**Table I—Levels of I and III in Creams Containing 0.5% II**

| Sample Lot | Age of Sample, months | I as Percentage of Cream | I as Percentage of II | III as Percentage of Cream | III as Percentage of II |
|---|---|---|---|---|---|
| A | 60 | 0.0055 | 1.2 | 0.015 | 3.0 |
| B | 52 | 0.0025 | 0.5 | 0.005 | 1.0 |
| C | 52 | 0.0072 | 1.6 | 0.038 | 7.5 |
| D | 47 | 0.0058 | 1.3 | 0.03 | 6.0 |
| E | 45 | 0.0055 | 1.2 | 0.036 | 7.1 |
| F | 25 | 0.0017 | 0.4 | 0.004 | 0.7 |
| G | 23 | 0.0045 | 1.0 | 0.002 | 0.4 |
| H | 16 | 0.0018 | 0.4 | 0.002 | 0.4 |
| I | 4 | 0.0025 | 0.5 | 0.007 | 1.4 |
| J | 3 | 0.0023 | 0.5 | 0.002 | 0.3 |
| K | 2 | 0.0038 | 0.9 | 0.001 | 0.2 |

Some dissociation of the complex was observed regardless of the solvent chosen to extract the cream. The extent was about the same for hexane as for ethyl acetate. A study[2] that included hexane, methanol, and ether found the stability of II in hexane to be the greatest. Of interest is the apparent equilibrium established so that a finite and consistent amount of I is always formed with each additional extraction. The level of I generated thus can be related to the extent of dissociation.

The destruction of the complex, at least within the framework of the cream matrix, is both time and heat dependent and, to a certain degree, water dependent. Therefore, it is necessary to proceed swiftly during and after extractions.

Allowing the extract to contact the paste for any length of time increases the likelihood of dissociation. Furthermore, conversion of I to III accelerates in solution. Similarly, the introduction of heat during the extraction, even from mechanical shaking or ultrasonication, resulted in an increased formation of I. Although the effect of water has already been cited, no difference was obtained for extractions that incorporated sodium sulfate. Therefore, its use is not obligatory. Extraction data are shown in Table II.

It was demonstrated[13] that II is more stable than I, except under acidic conditions whereupon the complex is irreversibly dissociated. The instability of I was observed in the reference solution, both visually, as a color change, and chromatographically, as a gradual diminishing of peak size over 1 day. If necessary, it may be better to prepare a new standard

than to rely on a reduced value for reference response. The small amount (0.5%) of acetic acid added to the mobile phase to suppress solute ionization was not a factor and did not appear to convert any extracted II significantly.

Linearity studies performed on both I and III showed each to be completely linear within the concentration range selected, 0.0008–0.008 and 0.008–0.03 mg/ml, respectively. For I, the $y$ intercept was −0.07, the slope was 0.996, and the correlation coefficient was 1.000. For III, these values were 1.89, 1.49, and 0.999, respectively. An amount of I equivalent to 1.5% of II was added to 1 g of sample, which then was extracted. The recovery was 97.6%.

# Mechanistic Studies on Transcorneal Permeation of Fluorometholone

**JAMES W. SIEG * and JOSEPH R. ROBINSON ˣ**

Received December 1, 1980, from the *School of Pharmacy, University of Wisconsin, Madison, WI 53706.* Accepted for publication February 19, 1981. *Present address: College of Pharmacy, University of Kentucky, Lexington, KY 40506.

**Abstract** □ The mechanism of corneal fluorometholone penetration was studied using albino rabbits, and the apparent rate and extent of steroid accumulation in the various cell layers of the cornea and aqueous humor were determined for normal and abraded eyes. The results are compared and contrasted to the mechanism previously reported for pilocarpine. Fluorometholone readily penetrates the intact corneal epithelium and accumulates in the hydrophilic stromal layers of the cornea. The kinetic profile is similar to that of pilocarpine and is largely a result of the precorneal dynamic processes. Pharmacokinetic parameters for each tissue were determined to establish an overall mechanism for corneal permeation of the steroid.

**Keyphrases** □ Fluorometholone—mechanistic studies on transcorneal permeation, compared with pilocarpine, rabbits □ Corneal permeation—transport mechanism, fluorometholone, compared with pilocarpine, rabbits □ Pharmacokinetics—fluorometholone compared with pilocarpine, mechanistic studies on transcorneal permeation, rabbits

The ocular penetration of steroids has been widely studied (1–8), but with emphasis primarily on quantitating specific tissue levels of drug rather than on establishing the mechanism for drug movement through the cornea. Previous work with pilocarpine defined the role of various corneal tissue layers in the permeation of a drug with both water and oil solubility (9), and the techniques can be used to study a representative steroid with low water solubility

such as fluorometholone. This report compares and contrasts the corneal transport mechanism of fluorometholone to that established for pilocarpine.

## EXPERIMENTAL

**Materials**—Tritiated fluorometholone[1] was prepared using catalytic exchange. The specific activity of the steroid was 1.2 Ci/mmole, and the product was purified by vacuum distillation immediately prior to use.

Male albino rabbits, 2.0–2.5 kg, were fed a regular diet with unrestricted food and water.

**Preparation of Fluorometholone Solution**—A sufficient quantity of the tritiated steroid was added to sterile normal saline to make a $4 \times 10^{-5}$ *M* solution. The saline containing the steroid was equilibrated on a shaker bath at room temperature for 24 hr to ensure complete solution. The small amount of added tritiated steroid did not significantly alter the osmolarity of the saline solution.

**Removal of Corneal Epithelium**—The epithelial layer of the cornea was removed under local anesthesia to simulate an abraded eye or was harvested following death of the animals. In the first case, 2 drops of 0.5% tetracaine hydrochloride was used as a topical anesthetic prior to epithelium removal.

**Aqueous Humor Drug Concentration *versus* Time Profiles**—The techniques used were presented previously (1, 9). Unanesthetized animals were used, and a standard 50-$\mu$l dose was instilled with a microliter syringe. The dose was placed carefully onto the upper margin of the corneal surface and allowed to collect in the lower cul-de-sac.

At specified times following dosing, animals were sacrificed using an overdose of pentobarbital sodium. Eyes were rinsed with saline, and aqueous humor was aspirated from the anterior chamber. Aqueous humor samples (100 $\mu$l) were delivered into plastic liquid scintillation vials[2] containing refrigerated liquid scintillation counting solution[3]. The samples were counted using a scintillation spectrometer[4], and the data were converted to micrograms of steroid per milliliter of aqueous humor.

**Corneal Drug Concentration *versus* Time Profiles**—Cornea samples were taken immediately after aqueous humor was aspirated from the anterior chamber. Each cornea sample was rinsed with saline and blotted on tissue to remove excess water. The corneas were placed into tared combustion cones[5], and the wet weight was determined using an analytical balance. The cornea-containing combustion cone then was placed in a plastic vial[6] containing scintillation solution[7]. A tissue oxidizer[8] was used to burn each cornea, and samples were analyzed for steroid content. The final count for each sample was converted to micrograms of steroid per gram of cornea.

The only modification to this basic procedure occurred when only specific tissue layers of the cornea were monitored for steroid content; the described techniques were used.

## RESULTS

**Aqueous Humor Steroid Levels after Dosing with Fluorometholone Solution**—Aqueous humor steroid levels were monitored for 2 hr after topical instillation of fluorometholone solution into intact eyes (Fig. 1). A peak level was attained within 30 min. A semilog plot of the data gave a log-linear decline of concentration immediately following this peak, with an associated rate constant of 0.013 $min^{-1}$. Further pharmacokinetic analysis yielded an apparent absorption rate constant of 0.07 $min^{-1}$. In addition, estimates of the area under the curve for up to 2 hr postinstillation indicated that at least 20–30% of the instilled dose ultimately reached the aqueous humor.

**Corneal Steroid Concentration following Dosing with Fluorometholone Solution**—The corneal fluorometholone levels for the various tissue layers of intact eyes are presented in Figs. 1 and 2. The steroid reached a peak concentration in the whole intact cornea (Fig. 1) within 5 min; this result also was reflected by the data for the corneal epithelium (Fig. 2). A semilog plot of the data for the epithelium showed that drug concentration in this tissue was biphasic with two linear elim-

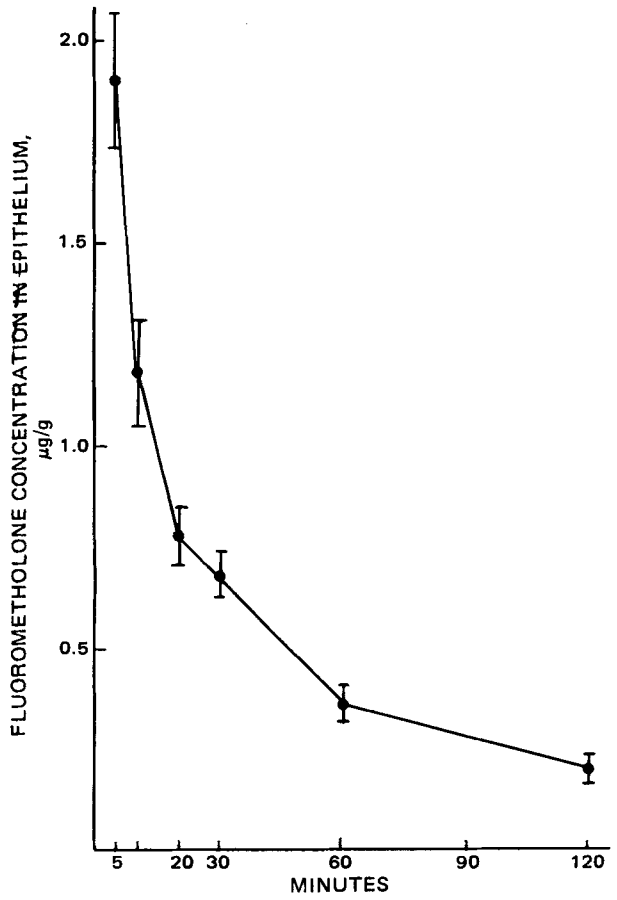

**Figure 2**—*Concentration of steroid in the epithelium after dosing intact eyes with $4 \times 10^{-5}$ M fluorometholone solution.*

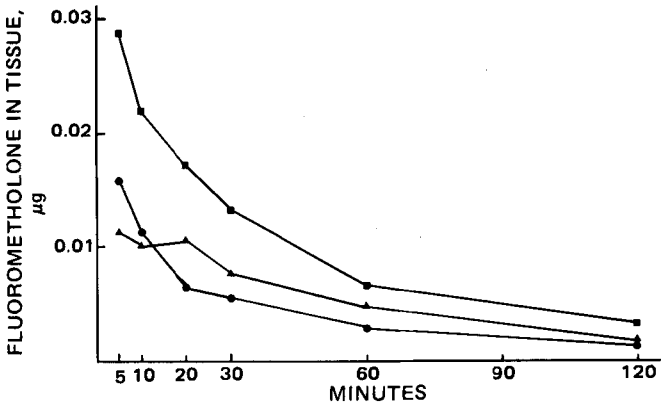

**Figure 3**—*Amount of steroid in ocular tissues after dosing intact eyes with 4 × $10^{-5}$ M fluorometholone solution. Key: ●, epithelium; ■, intact cornea; and ▲, stroma–endothelium.*

ination segments. This finding is almost identical to that previously seen with pilocarpine (9). The first-phase elimination rate constant was 0.06 $min^{-1}$, and the terminal phase rate constant was 0.014 $min^{-1}$.

The steroid also quickly reached the stroma–endothelium of the intact eye and built up to a relatively high concentration when compared with the aqueous humor levels. These levels decreased with an associated rate constant of 0.16 $min^{-1}$ and remained higher than the respective aqueous humor concentrations at all times up to 2 hr after dosing.

The amount of steroid in each tissue was also calculated using the experimentally determined tissue weights. Data of this type often can provide a clearer understanding of drug movement through the various ocular tissues. Although drug concentration is the driving force for drug permeation through these tissues, the large differences in tissue weights and distribution volumes sometimes give a misleading representation of the actual amount of drug involved. A comparison of the various amount *versus* time profiles can be made by referring to Fig. 3. The amount of fluorometholone in the epithelium fell below that in the stroma–endothelium rather quickly, even though the epithelial concentration remained higher at all times up to 2 hr. These differences are due to the almost 10-fold difference in weights between these two tissue layers.

**Ocular Penetration of Fluorometholone in Abraded Eyes**—The concentration of fluorometholone in aqueous humor and the cornea following topical instillation of a 4 × $10^{-5}$ *M* solution into intact and abraded eyes is presented in Figs. 4 and 5. Removal of the epithelium increased the aqueous humor levels of fluorometholone by ~60%, even though the peak was shifted from 30 min in intact eyes to ~10 min in abraded eyes. In addition, the elimination rate from the aqueous humor was about twice that obtained for intact eyes, being ~0.027 $min^{-1}$. The net result of these effects was that the areas under the curve for intact and abraded eyes were nearly identical.

## DISCUSSION

A true solution of the drug was selected as the dosing system to avoid slow absorption of undissolved drug in a suspension. Thus, the $t_{1/2}$ of fluorometholone in aqueous humor was ~54 min for intact eyes. This amount corresponds well with the turnover rate of aqueous humor, and

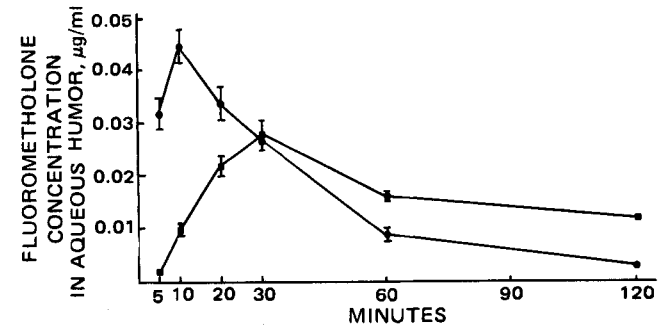

**Figure 4**—*Aqueous humor steroid concentration in intact (●) and abraded (○) eyes after dosing with 4 × $10^{-5}$ M fluorometholone solution.*

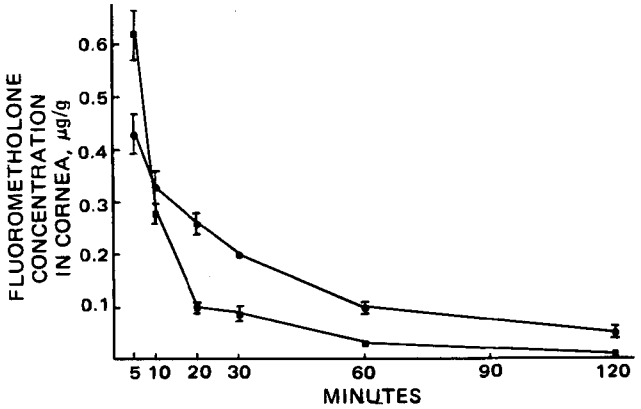

**Figure 5**—*Corneal steroid concentration in intact (●) and abraded (○) eyes after dosing with 4 × $10^{-5}$ M fluorometholone solution.*

presumably removal of fluorometholone from the anterior chamber is governed by this mechanism. However, previous corneal transport studies with fluorometholone suspensions reported a $t_{1/2}$ of ~100 min (10) because they did not extend beyond absorption of the suspension to obtain the true elimination rate constant.

The peak times for fluorometholone in the ocular tissues were similar to those previously obtained for pilocarpine (9). This observation would be somewhat puzzling when the vastly different water solubilities of these two drugs are considered. However, the effect of the parallel elimination process in the precorneal area on the observed apparent kinetic constants for ocular drug permeation already has been extensively discussed (9, 11). This parallel loss process is responsible for the apparent peak times and is essentially the same for both fluorometholone and pilocarpine.

The kinetic constants obtained for the various tissues are consistent with a mechanism consisting of a series of first-order absorption and elimination steps occurring in a succession of compartments with little or no lateral drug diffusion. The first-phase absorption rate constant calculated from the epithelium data was ~0.5 $min^{-1}$ for fluorometholone. This value again coincides well with the apparent absorption rate constant derived from previous rinsing studies and further reinforces the premise that this apparent kinetic constant is a direct reflection of the precorneal drainage process ($k_d$ = 0.545 $min^{-1}$). The first-phase corneal

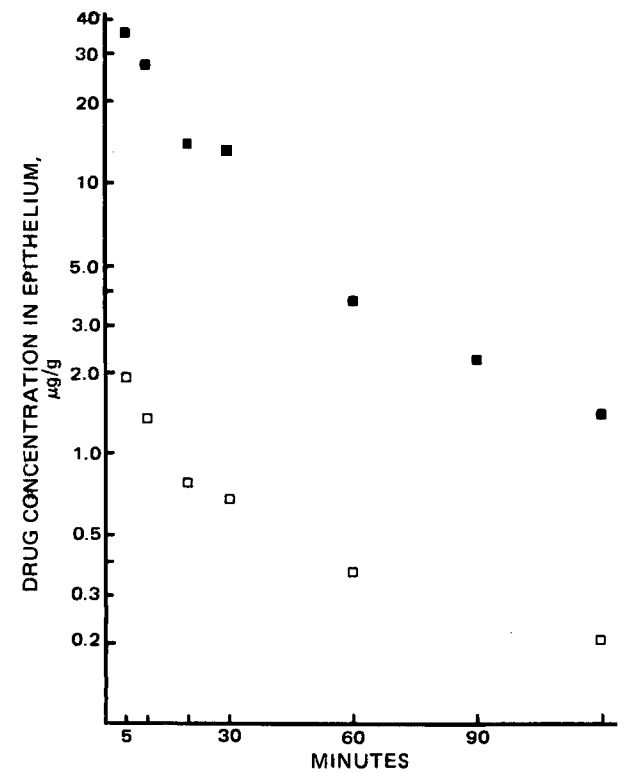

**Figure 6**—*Epithelial concentration* versus *time profiles for pilocarpine (▲) and fluorometholone (△).*

**Table I—Percent of Total Corneal Drug Content Present in Epithelium at Various Times after Dosing with Pilocarpine and Fluorometholone Solutions**

| Minutes | Percent in Epithelium | |
|---|---|---|
| | Pilocarpine | Fluorometholone |
| 5 | 92 | 56 |
| 10 | 85 | 52 |
| 20 | 68 | 40 |
| 30 | 72 | 42 |
| 60 | 67 | 45 |
| 120 | 73 | 44 |

elimination rate constant (0.06 $min^{-1}$) corresponds well with the apparent absorption rate constant into the aqueous humor (0.07 $min^{-1}$). In addition, the terminal phase elimination rate constant (0.014 $min^{-1}$) is almost equal to the measured aqueous humor elimination rate constant (0.013 $min^{-1}$).

The stroma–endothelium acts as a separate, distinct compartment from the aqueous chamber in the case of fluorometholone, unlike the situation for pilocarpine where free diffusion of drug between the aqueous humor and the stroma–endothelium occurred (9). The differences may be ascribed to possible binding of the steroid to some substance in the stroma (*e.g.*, collagen) or to an involvement of the endothelium. Owing to the oil solubility of fluorometholone, it is not unlikely that the drug may directly enter the cell membranes of the endothelium and pass *via* a transcellular route. On the other hand, being relatively fat insoluble, pilocarpine may pass directly into the anterior chamber *via* the intercellular spaces or pores. The difference in the elimination rate constants is particularly significant for the aqueous humor and cornea when comparing intact and abraded eyes. The increased elimination rate for abraded eyes suggests that the steroid leaves these tissues largely by back-diffusion into the tear film when the epithelium is not present. This effect was not apparent in the previous studies with pilocarpine. The extent of back-diffusion might argue against a protein binding mechanism for fluorometholone in the stroma in favor of a role for the endothelium.

The true absorption rate constant for pilocarpine is small, ~0.002 $min^{-1}$ (9). The data for fluorometholone indicate a much larger true rate constant for the steroid. The initial precorneal conditions were similar for both drugs, yet the total bioavailability of fluorometholone from solution was much greater. Nearly 30% of the instilled fluorometholone dose appeared to penetrate the cornea as opposed to only ~3% of pilocarpine. This finding suggests that the true rate constant for absorption into the epithelium is about 10 times higher than that of pilocarpine, or on the order of 0.02 $min^{-1}$. However, this still would not change the observed apparent absorption rate constant (0.5 $min^{-1}$) since the overriding influence is the rate constant for drainage. Thus, even though the apparent rate constant is the sum of all rate constants in the precorneal area, the increased magnitude of $k_{true}$ for fluorometholone is not sufficient to show up in the experimental measurement of $k_{apparent}$.

The results of the abraded eye studies (Fig. 4) show that the epithelium is not as great a barrier for fluorometholone as for pilocarpine. Thus, removal of the epithelium only increased the peak aqueous humor concentration by ~60%, whereas the observed increase with pilocarpine was a factor of 7 (9). This observation was noted previously (5) in an *in vitro* perfusion study where a three- to fourfold increase in corneal permeability was noted for water-soluble steroids and little or no increase was observed for lipid-soluble corticosteroids such as fluorometholone. This effect is also apparent when the percent of total corneal drug content present in the epithelium is calculated and compared for both drugs (Table I). Drug disposition in the cornea clearly favors the epithelium for pilocarpine, whereas fluorometholone distributes somewhat equally between the epithelium and stroma–endothelium. Previous work with pilocarpine showed the epithelium acting as both a barrier and a reservoir for pilocarpine, but this effect is less prominent with fluorometholone.

The epithelial drug concentration–time profile for fluorometholone is biphasic when plotted semilogarithmically. Similar circumstances exist for pilocarpine; in fact, the two drugs have remarkably similar profiles for this tissue (Fig. 6). Except for the absolute magnitude of the tissue concentrations, the shapes of the profiles are virtually identical. When the vastly different physical properties of fluorometholone and pilocarpine are considered, it seems likely that the explanation for this similarity is linked to some process involving the ocular tissues rather than to some specific property of both drugs.

# Combined High-Performance Liquid Chromatographic Procedure for Measuring 4-Hydroxypropranolol and Propranolol in Plasma: Pharmacokinetic Measurements following Conventional and Slow-Release Propranolol Administration

**O. H. DRUMMER ˣ, J. McNEIL, E. PRITCHARD, and W. J. LOUIS**

Received November 3, 1980, from the *Clinical Pharmacology & Therapeutics Unit, Austin Hospital, University of Melbourne, Heidelberg, 3084, Victoria, Australia.* Accepted for publication February 17, 1981.

**Abstract** □ An assay is described for the simultaneous determination of propranolol and its active metabolite, 4-hydroxypropranolol, in human plasma. Both compounds were separated from an ethereal extract by high-performance liquid chromatography employing a $C_{18}$ bonded-phase column. Detection of the effluent was by fluorescence. Suitable fluorescent spectrometers and wavelength settings that allow optimum detection of both compounds have been described. The limit of sensitivity was 2 ng/ml for both propranolol and 4-hydroxypropranolol. Mean peak plasma levels of propranolol and 4-hydroxypropranolol in six patients receiving a single dose of a slow-release 160-mg formulation of propranolol were 28 and 6 ng/ml, respectively. These levels were about one-tenth the level obtained following a single conventionally prepared dose of propranolol (160 mg). Peak levels were delayed and plasma levels of propranolol persisted for a longer period with the slow-release formulation. Area under the curve estimates suggested that the bioavailability of the slow-release formulation following single-dose administration was about one-third that of the conventional preparation.

**Keyphrases** □ High-performance liquid chromatography—simultaneous assay of propranolol and 4-hydroxypropranolol, conventional and slow-release formulations compared □ Propranolol—high-performance liquid chromatographic assay with 4-hydroxypropranolol, conventional and slow-release formulations compared □ Pharmacokinetics—propranolol, conventional and slow-release formulations compared □ Bioavailability—propranolol, conventional and slow-release formulations compared

4-Hydroxypropranolol is formed by hepatic microsomal enzymes (1) following oral administration of propranolol (2). This active metabolite possesses β-adrenoceptor blocking activity (2–4). To date, GLC and high-performance liquid chromatographic (HPLC) methods involving the simultaneous detection of both 4-hydroxypropranolol and propranolol (5–12) have not been satisfactory. Sample preparation has not been uniform, and the selection of suitable fluorometric detection systems and the conditions for chromatography have varied considerably.

The present method provides a sensitive HPLC assay for the simultaneous measurement of propranolol and its active metabolite. Preliminary pharmacokinetic studies on the administration of conventional and slow-release oral propranolol formulations were conducted.

## EXPERIMENTAL

**Materials**—4-Hydroxypropranolol[1], propranolol hydrochloride[2], labetalol hydrochloride[3], ether[4], sodium metabisulfite[5], sodium carbonate[5], and monobasic potassium phosphate[6] were used.

**Apparatus**—A constant-flow high-performance liquid chromatograph[7] was equipped with a universal injector[8], a fluorometer[9], and a spectrofluorometer[10]. The stainless steel 30-cm long × 3.9-mm i.d. column was obtained prepacked[11].

**Chromatography**—The mobile phase consisted of 50% methanol[12] in 10 m*M* monobasic potassium phosphate buffer adjusted to pH 3.4 with 5 *M* HCl. It was pumped at a flow rate of 1.5 ml/min (1500 psi).

The retention volumes for 4-hydroxypropranolol, labetalol, and propranolol were 6.0, 7.2, and 9.0 ml, respectively.

The column eluate was monitored on a fluorometer set at excitation[13] and emission[14] wavelengths of 310 and 380 nm, respectively, which were optimal for 4-hydroxypropranolol fluorescence. When a spectrofluorometer was used, the wavelengths were set to be optimal for propranolol, at 295 and 360 nm, respectively. The bandpass was 20 nm. When propranolol levels were >10 ng/ml, a second fluorometer using excitation and emission wavelengths of 310[13] and 334[15] nm, respectively, occasionally was substituted for the spectrofluorometer.

Sensitivity settings on the fluorometer usually were maintained on high gain and lamp power settings; attenuations varied from ×2 to ×5 while the spectrofluorometer sensitivity range (0.3–1.0 μ*A*) gave a full-scale deflection.

**Standards**—Fresh solutions of propranolol and the internal standard, labetalol, were prepared weekly as aqueous solutions at concentrations of 1 and 4 μg/ml, respectively. Solutions of 4-hydroxypropranolol were prepared daily in water containing 1 m*M* HCl and 2% (w/v) sodium metabisulfite. For preparation of plasma standards, drug-free plasma was spiked with known amounts of aqueous stock solutions of both 4-hydroxypropranolol and propranolol in the 0–2000-ng/ml of plasma concentration range.

**Controls**—Control heparinized plasma containing 60 ng of 4-hydroxypropranolol/ml and 100 ng of propranolol/ml was prepared and stored until use in 1-ml aliquots at −20°.

**Procedure**—Labetalol (400 ng, 100 μl) was added to chromium trioxide-washed glass tubes containing 1 ml of unknown plasma, plasma standards, or control plasma. To each tube, 100 μl of freshly prepared sodium metabisulfite (20% w/v), 1 ml of sodium carbonate (1 *M*, pH 10.2), and 8 ml of ether then were added in turn. The tubes were stoppered, gently shaken for 10 min on a reciprocating automatic shaker[16], and centrifuged at 2000 rpm for 10 min. The ether phase was transferred to a fresh tube and evaporated to dryness under a gentle nitrogen stream in a water bath kept at ambient temperature. The residue was reconstituted with 100 μl of chromatography mobile phase, transferred to a microfuge tube[17], and centrifuged[18] for 4 min. An aliquot of the supernate (50 μl) then was injected into the liquid chromatograph.

**Quantitation**—Calibration curves were constructed for both 4-hydroxypropranolol and propranolol by calculating the peak height ratios of both components to the peak height of labetalol and plotting these ratios against the amount of standard added to each tube. For routine

**Table I—Assay Parameters for Measurement of 4-Hydroxypropranolol and Propranolol from Plasma**

| Parameter | 4-Hydroxy-propranolol | Propranolol |
|---|---|---|
| Detection limit, ng | 2 | 2 |
| Recovery, % | 75 ± 4 ($n$ = 20) | 68 ± 3 ($n$ = 23) |
| Reproducibility within-day, % | 6 ($n$ = 5) | 7 ($n$ = 5) |
| Reproducibility day-to-day, % | 21 ($n$ = 27) | 12 ($n$ = 19) |

assays, the peak height ratios of drug to the internal standard obtained from a plasma standard containing 50 ng of 4-hydroxypropranolol/ml, 100 ng of propranolol/ml, and 400 ng of labetalol/ml were used to calculate the concentrations of propranolol and 4-hydroxypropranolol in unknown plasma. An aliquot of control plasma was included in each batch to ensure day-to-day reproducibility.

**Clinical Study**—Six healthy volunteers, mean age of 21.8 ± 0.2 years and weight of 62 ± 4 kg, participated in the double-blind crossover study. After an overnight fast, each subject was given a single oral dose of propranolol. Three subjects were given a conventional 160-mg formulation, and the other three were given a slow-release 160-mg formulation. Venous blood samples (10 ml) were taken prior to drug administration and then at 0.33, 0.66, 1.0, 1.5, 2.0, 2.5, 3.0, 4.0, 5.0, 6.0, 8.0, 12, and 24 hr. One week later, the same volunteers were given the other formulation of propranolol (160 mg of conventional or slow-release formulation) and a similar set of blood samples were taken.

**Pharmacokinetic Analysis**—Area under the concentration–time curves were calculated by the trapezoidal method and extrapolated to infinity by dividing the final concentration point (24 hr) by the slope of the terminal phase.

## RESULTS AND DISCUSSION

Both propranolol and 4-hydroxypropranolol exhibit natural fluorescence, allowing their separation by liquid chromatography and detection with a fluorescence detector. The excitation wavelengths (205 or 295 nm) are the same for both compounds, but the fluorescence emission spectra of propranolol and 4-hydroxypropranolol differ in that the wavelength maximum for emission in aqueous solution are 360 and 435 nm, respectively. Thus, there is a need for compromise in setting the wavelength of the detector to balance the loss of sensitivity for propranolol when the wavelength chosen is maximal for its metabolite.

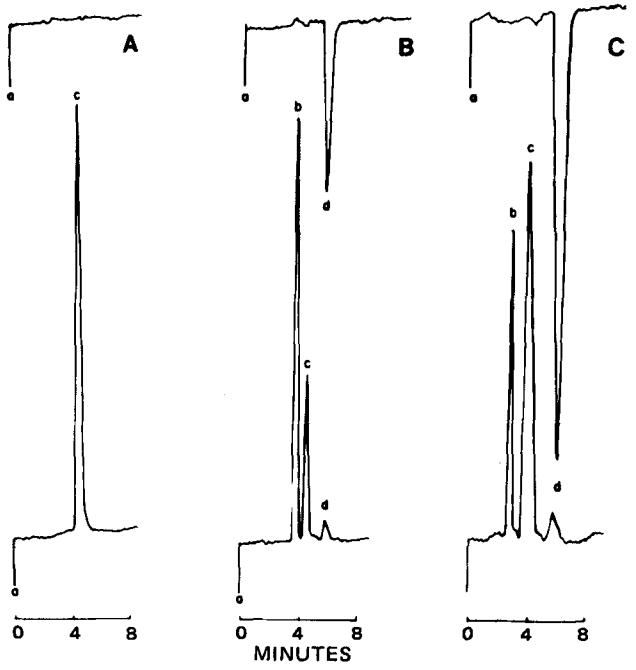

**Figure 1**—*High performance liquid chromatographs for: (A) a blank plasma extract, (B) an aqueous injection of 50-ng amounts of 4-hydroxypropranolol, propranolol, and (C) an extract of a patient plasma sample after receiving a single oral dose of conventional propranolol (propranolol level = 229 ng/ml; 4-hydroxypropranolol level = 47 ng/ml). Key: a, injection site; b, 4-hydroxypropranolol; c, labetalol; and d, propranolol.*

**Table II—Stability of 4-Hydroxypropranolol and Propranolol in Serum when Stored Frozen at −20°**

| Weeks of Storage | 4-Hydroxypropranolol, ng/ml | Propranolol, ng/ml |
|---|---|---|
| 1 | 66 | 88 |
| 2 | 59 | 79 |
| 3 | 61 | 94 |
| 4 | 60 | 91 |
| 5 | 64 | 90 |
| 9 | 62 | 90 |
| Mean ($SD$) | 62 ± 3 ($n$ = 21) | 90 ± 3 ($n$ = 19) |

Previous assay methods partially overcame this problem by using deuterium light sources, setting the excitation wavelength at 205 nm (5), and introducing a 340-nm cutoff filter for emission. Other assays (7, 9) using inefficient fluorometers suffered from inadequate sensitivity. Some investigators (8, 11) overcame the sensitivity problem by measuring each compound separately. This time-consuming process required injecting each extract twice, once at the chosen wavelengths for 4-hydroxypropranolol and then with the detector set at wavelengths optimal for propranolol. A recent study (12) avoided multiple injections; but to detect the 4-hydroxypropranolol and propranolol peaks, it was necessary to change the emission wavelength manually during each chromatographic run. This procedure is not suited for processing more than a few samples and does not lend itself to automatic injection techniques.

The present assay allows simultaneous detection of both compounds using an inexpensive tungsten light source. A filter fluorometer with an interference filter for the excitation light (310 nm) was used in conjunction with a combination of cutoff filters for emission, thus allowing light with a wavelength of >380 nm to be transmitted. This filter combination was optimal for 4-hydroxypropranolol fluorescence but still allowed satisfactory measurement of propranolol. The detection limit for 4-hydroxypropranolol was 2 ng/ml of plasma; for propranolol, it was 20 ng/ml (Table I). At these concentrations, peaks three times the baseline noise were obtained.

When more sensitive conditions were required for propranolol, a spectrofluorometer was connected in series with the fluorometer and set at wavelengths optimal for propranolol (295 nm/360 nm). Under these

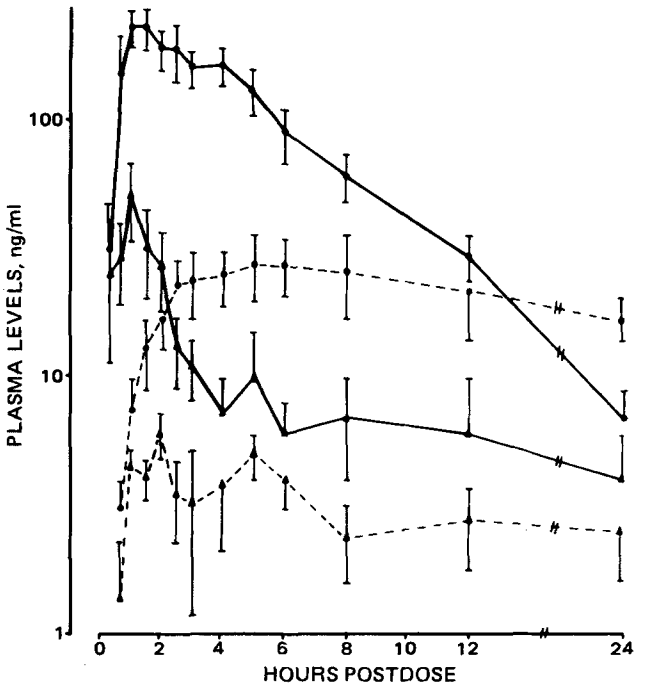

**Figure 2**—*Semilogarithmic plot of the mean plasma 4-hydroxypropranolol and propranolol levels* versus *time following single oral doses of a conventional propranolol formulation (160 mg) and a slow-release preparation (160 mg). Key: ●—●, propranolol (conventional); ●---●, propranolol (slow release); ▲—▲, 4-hydroxypropranolol (conventional); and ▲---▲, 4-hydroxypropranolol (slow release).*

conditions, the detection limit for propranolol was 2 ng/ml of plasma. 4-Hydroxypropranolol was not detected in the latter system due to the relatively narrow bandpass (20 nm) on the spectrofluorometer and the higher emission wavelengths for this compound.

If a spectrofluorometer is not available, a second fluorometer can be set at 310 nm/334 nm with interference filters; a sensitivity of 10 ng/ml for propranolol is obtained.

Methanol–10 m*M* phosphate buffer, pH 3.4 (50:50), was used as the mobile phase for reversed-phase chromatography on this bonded column and gave excellent resolution between 4-hydroxypropranolol, labetalol, and propranolol with retention volumes of 6.0, 7.2, and 9.0 ml, respectively. This separation was more reproducible than that reported with other published mobile phases, *e.g.*, acetic acid (7–10, 13) or phosphoric acid (6, 12, 14), and less harmful to the column than heptane–sulfonic acid (8).

Conjugation as the glucuronidate or sulfate is a major route of elimination of both propranolol and 4-hydroxypropranolol (15). Although the present assay method was designed primarily to measure the biologically active unconjugated drug, modification of the procedure utilizing an enzyme-catalyzed hydrolysis step prior to extraction with ether allows measurement of total propranolol and 4-hydroxypropranolol. This procedure has been well characterized (9, 12).

Figures 1A and 1B show liquid chromatograms for a blank plasma extract and an aqueous injection of 50-ng amounts of each compound. Figure 1C represents a patient plasma extract with 4-hydroxypropranolol and propranolol levels of 47 and 229 ng/ml, respectively. The upper tracing in each case represents the tracing for propranolol obtained on the spectrofluorometer. No other peaks interfered with the peaks for propranolol and 4-hydroxypropranolol. However, prazosin and quinidine interfered with the peaks for the internal standard. In the presence of either drug, 4-methylpropranolol is a suitable alternative internal standard (6).

Calibration curves were constructed by spiking drug-free plasma with aqueous solutions in the concentration range of 0–100 ng/ml for 4-hydroxypropranolol and of 0–2000 ng/ml for propranolol. The peak heights of both drugs were divided by the peak height for labetalol (internal standard) and plotted against concentration. Both drugs exhibited linear calibration curves with intercepts through the origin.

Reproducibility for both drugs was evaluated by performing replicate assays of the control plasma containing both drugs. Within-day variability was 6 and 7% for 4-hydroxypropranolol and propranolol, respectively. When the same control plasma was assayed over 5 weeks, values of 21 and 12% were obtained (Table I). The stability of 4-hydroxypropranolol was cited as a major problem (5, 8), so although sodium metabisulfite was added as a stabilizer to the plasma prior to extracting, it was feared that the plasma stored frozen without stabilizer might deteriorate with time. When control plasma was assayed at weekly intervals over 9 weeks, no deterioration was evident (Table II). This result was confirmed by Taburet *et al.* (8), who found that the metabolite was stable for at least 4 weeks at −20°.

No data have been published on plasma level profiles of both unconjugated propranolol and 4-hydroxypropranolol following oral administration of a slow-release propranolol formulation. The mean (±*SEM*) plasma concentrations of these two compounds were compared in six volunteers receiving, on separate occasions 1 week apart, a single oral 160-mg dose of propranolol in a conventional formulation and a 160-mg slow-release preparation (Fig. 2). Peak levels of propranolol after the conventional formulation were 236 ± 38 ng/ml at 60 min, consistent with previous reports (7, 16). Peak levels for the slow-release preparations were considerably lower and delayed (28 ± 8 ng/ml, obtained 5 hr postdose).

The slow-release formulation was not associated with an increased rate of formation of the active metabolite 4-hydroxypropranolol. In fact, in all patients, peak levels (conventional, 51 ± 17 ng/ml; slow release, 6 ± 1 ng/ml) and area under the curve values (*AUC*) (conventional, 218 ± 17 ng hr/ml; slow release, 141 ± 32 ng hr/ml) for the 4-hydroxy metabolite were considerably less following single doses of the slow-release formulation. The persistence of propranolol in plasma for >24 hr with the slow-release formulation suggests that drug accumulation may occur with chronic daily therapy and that attainment of steady state may require several days of treatment. Calculation of the bioavailability for the slow-release preparation by extrapolation of the 24-hr data is likely to overestimate the *AUC*. Nevertheless, bioavailability of the slow-release preparation was poor; corresponding propranolol *AUC* estimations suggest that the bioavailability of single doses of the slow-release formulation was at least 2.9 times lower than that of the conventional preparation. The association of low propranolol levels and low levels of the 4-hydroxy metabolites is consistent with the suggestion that high 4-hydroxypropranolol levels are formed only in the presence of high concentrations of the parent drug in the liver (17).

# Thermochemical Investigations of Nearly Ideal Binary Solvents VII: Monomer and Dimer Models for Solubility of Benzoic Acid in Simple Binary and Ternary Solvents

**WILLIAM E. ACREE, Jr., and GARY L. BERTRAND** ˣ

Received November 10, 1980, from the *Department of Chemistry, University of Missouri-Rolla, Rolla, MO 65401.* Accepted for publication March 2, 1981.

**Abstract** □ Solubilities are reported for benzoic acid at 25.0° in binary mixtures of carbon tetrachloride with cyclohexane, *n*-hexane, or *n*-heptane and of cyclohexane with *n*-hexane or *n*-heptane and in ternary mixtures of carbon tetrachloride–cyclohexane–*n*-hexane and carbon tetrachloride–cyclohexane–*n*-heptane. Solubilities also are reported for benzoic acid in some binary solvents at 30.0° and for *m*-toluic acid in binary mixtures of cyclohexane and *n*-hexane at 25.0°. The results are compared to the predictions of equations developed previously for solubility in systems of purely nonspecific interactions, with the benzoic acids considered as either monomeric or dimeric molecules in solution. The dimer model gave more accurate predictions, with a maximum deviation of 4.4% between observed and predicted solubilities in all systems studied. Solubility maxima were predicted and observed for benzoic and *m*-toluic acids in cyclohexane–*n*-hexane and for benzoic acid in cyclohexane–*n*-heptane. The application of these solubility relationships to liquid–liquid partition coefficients is discussed.

**Keyphrases** □ Binary solvents—thermochemical study of monomer and dimer models for benzoic acid solubility □ Benzoic acid—thermochemical study, monomer and dimer models for solubility in simple binary and ternary solvents □ Solubility—benzoic acid in simple binary and ternary solvents, monomer and dimer models □ Thermochemistry—monomer and dimer models for solubility of benzoic acid in simple binary and ternary solvents

The use of mixed solvents for influencing solubility and multiphase partitioning has great potential application in pharmaceutical research. Maximum realization of this potential depends on the development of equations that predict solubilities or partition coefficients in mixed solvents from the properties of the individual components. This study continued the testing (1–4) of applications and limitations of the nearly ideal binary solvent (NIBS) model for predicting solution enthalpies (1, 2), solubilities (3), and gas–liquid partition coefficients (4) of solutes in binary solvent mixtures relative to their properties in pure solvents.

## BACKGROUND

The NIBS model predicts that any partial molar thermodynamic excess property of a solute at infinite dilution in a binary solvent is a volume fraction average (a weighted mole fraction average gives somewhat better predictions for solution enthalpies) of its properties at infinite dilution in a pure solvent, with a correction for solvent "unmixing" by the presence of the solute. This model gives good predictions for solute properties in systems of nonspecific interactions, but it fails for systems with specific solvent–solvent or solvent–solute interactions. The solubility equations have been successfully applied to solubilities as high as 0.3 mole fraction (3) for solutes that do not self-associate or form solvent–solute complexes.

Benzoic acid presents an interesting test for these equations because of its very strong self-association in "inert" solvents, even at high dilution. Calculations with reported dimerization constants in cyclohexane (5), carbon tetrachloride (5, 6), and benzene (5, 7, 8) indicate that <4% of the benzoic acid molecules are monomers at saturation at 25°. Thus, this approach should give relatively poor predictions of the solubility of benzoic acid in terms of a monomer model, but it has a reasonable chance of success if a dimer model is used.

The dimer model may be an oversimplification, however, since Krishnan *et al.* (8) presented evidence for trimers of benzoic acid in benzene. The reported equilibrium constants for benzoic acid at saturation in benzene at 25° led to estimates that 2.5% of the benzoic acid molecules are monomers, 66% are dimers, and the remainder are trimers. To avoid the complications of trimeric forms, the present study was confined to solvents in which benzoic acid is considerably less soluble than in benzene.

During this work, the nearly ideal binary solvent model was found to predict maxima for benzoic acid solubility in mixtures of cyclohexane with *n*-hexane or *n*-heptane. Such maxima are usually explained with solubility parameter theory (9) in terms of the solubility parameter of the solute lying between the solubility parameters of the solvents. However, all estimates of the solubility parameters of benzoic acid monomers or dimers give values greater than any of the solvents studied, so these measurements provide a test of the more general applicability of the present approach. Similar predictions for maximum solubility of *m*-toluic acid also were tested.

The equations for solubility in binary solvents were expanded to include ternary solvents. Since these equations require excess free energy data (data that are often not available), an approximation was developed from the original nearly ideal binary solvent model for estimating the excess properties of a multicomponent system from the properties of the contributing binary systems. The resultant equations give good predictions for the solubility of benzoic acid in two simple ternary solvents.

## EXPERIMENTAL

Benzoic acid (99%) was dried at 60° for several hours, mp 122.5 ± 0.5° [lit. (10) mp 122.4°]. *m*-Toluic acid (99%) was recrystallized twice from aqueous ethanol and dried at 80°, mp 109.5 ± 0.5° [lit. (10) mp 111–113°]. The recrystallized acid was titrated to a thymol blue end-point with freshly standardized sodium methoxide solution by the method of Fritz and Lisicki (11), except toluene was substituted for benzene. The purity of the *m*-toluic acid was calculated to be 100.1 ± 0.5%. Cyclohexane (99+%), *n*-heptane (99+%), and *n*-hexane (99%) were stored over molecular sieves (Type 4A) and distilled shortly before use. Carbon tetrachloride (99+%) was purified by the method of Scatchard *et al.* (12), stored in contact with mercury under an argon atmosphere, and distilled shortly before use.

Solvent mixtures were prepared by weight with sufficient accuracy to allow calculation of compositions to 0.0001 mole fraction. Solvents and excess carboxylic acid were placed in brown glass containers and allowed to equilibrate in a constant-temperature bath at 25.00 ± 0.01 or 30.00 ± 0.01°, maintained constant to ±0.002°, for several days. The attainment of equilibrium was verified by repetitive measurements after several

[a] $X_s^{sat}$ is calculated as if the solute is monomeric. [b] Percent deviation = $100 \ln (X_s^{sat})_{calc}/(X_s^{sat})_{obs}$.

additional days. Acid solubility was determined by transferring a weight aliquot through a coarse filter into a flask containing blank nonaqueous titration solvent. The solutions were titrated with freshly standardized sodium methoxide solution to the thymol blue end-point, giving solubilities reproducible to within 1%.

Solubilities in pure solvents (Table I), in binary solvents (Tables II and III), and in ternary solvents (Table IV) are reported as formal mole fractions, calculated as though the solute were monomeric, and solvent compositions ($X_i^0$) are calculated as if the solute were not present. Table I results are in good agreement with previously reported values.

## DISCUSSION

**Monomer and Dimer Models for Solubility in Binary Solvents**—The following two equations for solubility in systems of nonspecific interactions were developed from the general equation (3), depending on whether a regular solution model (Eq. 1) or Flory–Huggins model (Eq. 2) is used:

$$RT \ln(a_s^{solid}/X_s^{sat}) = (1 - \Phi_s^{sat})^2[\Phi_1^0(\Delta\overline{G}_s^e{}^*_{X_1^0=1} + \Phi_2^0(\Delta\overline{G}_s^e)^*_{X_2^0=1} - \overline{V}_s(X_1^0\overline{V}_1 + X_2^0\overline{V}_2)^{-1}(\Delta\overline{G}_{12}^e)] \quad \text{(Eq. 1)}$$

$$RT\left[\ln(a_s^{solid}/\Phi_s^{sat}) - (1 - \Phi_s^{sat})\left(1 - \frac{\overline{V}_s}{(X_1^0\overline{V}_1 + X_2^0\overline{V}_2)}\right)\right] = (1 - \Phi_s^{sat})^2[\Phi_1^0(\Delta\overline{G}_s^{fh})^*_{X_1^0=1} + \Phi_2^0(\Delta\overline{G}_s^{fh})^*_{X_2^0=1} - \overline{V}_s(X_1^0\overline{V}_1 + X_2^0\overline{V}_2)^{-1}(\Delta\overline{G}_{12}^{fh})] \quad \text{(Eq. 2)}$$

in which $\overline{V}_i$ is the molar volume of a pure liquid, $X_i$ is the mole fraction, $\Phi_i$ is the volume fraction, $\Delta\overline{G}_{12}^e$ is the molar excess Gibbs free energy of the mixed solvent, and:

$$\Delta\overline{G}_{12}^{fh} = \Delta\overline{G}_{12}^e + RT[\ln(X_1^0\overline{V}_1 + X_2^0V_2) - X_1^0\ln(\overline{V}_1) - X_2^0\ln(\overline{V}_2)] \quad \text{(Eq. 3)}$$

The superscript (0) indicates that the solvent mole fraction or volume fraction is calculated as if the solute were not present. The activity of the solid solute ($a_s^{solid}$), relative to the supercooled liquid (also equal to the mole fraction solubility in an ideal solution), can be calculated from the melting point ($T_m$) and the molar enthalpy of fusion ($\Delta H_s^{fus}$):

$$\ln(a_s^{solid}) = \int_{T_m}^{T} (\Delta H_s^{fus}/RT^2)\,dT \quad \text{(Eq. 4)}$$

The use of these equations for solubility predictions in mixed solvents is as follows. The quantities $(\Delta\overline{G}_s^e)^*_{X_1^0=1}$ or $(\Delta\overline{G}_s^{fh})^*_{X_1^0=1}$ are calculated from the mole fraction or volume fraction solubility of the solute in the pure solvents (the asterisk indicates that these are approximations of infinite dilution properties). Then these properties are used in the appropriate equation to calculate the solubility as $X_s^{sat}$ or $\Phi_s^{sat}$ in a solvent mixture, using a reiterative process. The quantity $(1 - \Phi_s^{sat})$ is taken as unity in

the first approximation, and convergence is rapid unless the solubility is quite large.

Applications of the monomer and dimer models to these equations are straightforward, taking the molecular weight, molar volume, and molar enthalpy of fusion of the dimer to be exactly twice the values for the monomer[1], and lead to the relationships:

$$(a_{ss}^{solid}) = (a_s^{solid})^2, ss = \text{dimer} \quad \text{(Eq. 5)}$$

$$X_{ss}^{sat} = X_s^{sat}/(2 - X_s^{sat}) \quad \text{(Eq. 6)}$$

$$\overline{V}_{ss} = 2\overline{V}_s \quad \text{(Eq. 7)}$$

$$\Phi_{ss}^{sat} = \Phi_s^{sat} \quad \text{(Eq. 8)}$$

Activities and molar volumes used in these calculations are given in Table V. The same molar volumes are used for calculations at 25 and 30° since, in the original equations, molar volumes are used as approximations of temperature-independent parameters. The major difference between the monomer and dimer models appears to be due to the different values calculated for the activity of the solid; while important for absolute predictions of solubilities, this effect is relatively unimportant for predictions of solubility in mixed solvents from values in pure solvents. For example, the predictions of Eqs. 1 and 2 are completely independent of the value assigned to the activity of the solid for solutes of very low solubility. The important difference between these models is in the ratio of the molar volume of the solute to that of the solvent, operating on the excess free energy of solvent mixing.

The results of calculations with monomer and dimer models in Eqs. 1 and 2 are given in Tables II and III as percentage deviations between calculated and observed values. The dimer model is definitely superior to the monomer model, and Eq. 2 is slightly more accurate than Eq. 1 for benzoic acid and $m$-toluic acid in these systems. While none of these models gives predictions within experimental uncertainty for these solutes, the accuracy of the dimer model is comparable to that of the monomer model for solutes such as iodine, naphthalene, and benzil, which are not considered to be capable of self-association. The limitation here appears to be due to the very simple solution model on which the equations are based rather than on the exact description of the chemical species in solution. The monomer model, however, is such a poor description of the real condition of carboxylic acid solutions that predictions are limited by the accuracy of the description.

**Solubility in Multicomponent Solvents**—Rigorous development of the multicomponent forms of Eqs. 1 and 2 from the original model (3) leads to equations containing the excess free energy $(\Delta\overline{G}_1^e \ldots N)$ of the multicomponent system. Since data of this type are available for very few ternary systems and fewer systems of higher order, an approximation is necessary. The following equations, based on the original model, give very good predictions for simple multicomponent systems (13):

$$(\Delta\overline{G}_1^e \ldots N) = \sum_{i=1}^{N-1} \sum_{j>i}^{N} (X_1^0 + X_j^0)(\Phi_i^0 + \Phi_j^0)(\Delta\overline{G}_{ij}^e)^* \quad \text{(Eq. 9)}$$

$$(\Delta\overline{G}_1^{fh} \ldots N) = \sum_{i=1}^{N-1} \sum_{ji}^{N} (X_i^0 + X_j^0)(\Phi_i^0 + \Phi_j^0)(\Delta\overline{G}_{ij}^{fh})^* \quad \text{(Eq. 10)}$$

with:

$$X_i^* = X_i^0/(X_i^0 + X_j^0) \quad \text{(Eq. 11)}$$

$$(\Delta\overline{G}_{ij}^{fh})^* = (\Delta\overline{G}_{ij}^e)^* + RT[\ln(X_i^*\overline{V}_i + X_j^*\overline{V}_j) - X_i^*\ln(\overline{V}_i) - X_j^*\ln(\overline{V}_j)] \quad \text{(Eq. 12)}$$

and $(\Delta\overline{G}_{ij}^e)^*$ is the excess Gibbs free energy of the binary solvent mixture at composition $X_i^*$. The solubility equations for a solid solute then become:

$$RT\ln(a_s^{solid}/X_s^{sat}) = (1 - \Phi_s^{sat})^2 \left[\sum_{i=1}^{N} \Phi_i^0(\Delta\overline{G}_s^e)_{X_i^0=1}^* - (\overline{V}_s/\overline{V}_m)(\Delta\overline{G}_1^e \ldots N)\right] \quad \text{(Eq. 13)}$$

and:

$$RT\left[\ln(a_s^{solid}/\Phi_s^{sat}) - (1 - \Phi_s^{sat})\left(1 - \frac{V_s}{\overline{V}_m}\right)\right] = (1 - \Phi_s^{sat})^2 \times \left[\sum_{i=1}^{N} \Phi_i^0(\Delta\overline{G}_s^{fh})_{X_i^0=1} - (\overline{V}_s/\overline{V}_m)(\Delta\overline{G}_1^{fh} \ldots N)\right] \quad \text{(Eq. 14)}$$

with:

$$\overline{V}_m = \sum_{i=1}^{N} X_i^0\overline{V}_i \quad \text{(Eq. 15)}$$

These equations, while unfortunately rather complex, are rigorous within the model and are easily adaptable to computerized calculations. An important feature of Eqs. 9 and 10 is the ability to use binary data in any form, independent of the form of the equation by which the binary data may be represented. As previously noted (4), the contribution of the binary or multicomponent mixing term may be negligible if the system is nearly ideal and the molar volume of the solute is small in comparison

Table V—Solvent and Solute Properties Used in Calculations

| | Temperature | $a_i^{solid}$ | $\overline{V}_i$, cm³/mole |
|---|---|---|---|

| $c$-$C_6H_{12}$ + $n$-$C_7H_{16}$ | | | Ref. 21 |

[1] The enthalpy of fusion is actually for the transition of the solid to a mixture of monomers and dimers; but for consistency in these calculations, the melt is considered to be completely monomeric for the monomer model and completely dimeric for the dimer model.

[a] Reference 22. [b] Estimated from data in Ref. 10. [c] Estimated by approximating the difference between the molar volumes of $m$-toluic acid and benzoic acid as the difference between toluene and benzene. [d] The excess Gibbs free energy was assumed to be the same at 25 and 30°.

to the solvents. Large solute molecules magnify the contribution of the unmixing term and, in the application to multicomponent solvents, also magnify the errors in the approximations of Eqs. 9 and 10. Thus, Eqs. 13 and 14 can be expected to become increasingly less accurate with increasing complexity of the solvent mixture. For the simple ternary solvents studied, the dimer model predicts solubilities of benzoic acid as accurately as in binary solvents. The results of calculations with the monomer model are not shown since they were very similar to results for binary systems and considerably less accurate than those of the dimer model.

The authors have serious doubts about the applicability of these equations to the solubility of benzoic acids in mixtures of aromatic and aliphatic solvents, partly because of the possible existence of trimers in aromatic solvents. Of more concern, however, is the possibility of specific $\pi$–$\pi$ interactions between the solvent and solute, which would violate the basic assumptions of the NIBS model.

## CONCLUSIONS

The dimer model of the nearly ideal binary solvent equation gives very good predictions for the solubility of benzoic and *m*-toluic acids in these simple solvent mixtures and should be equally applicable to solubilities of most monofunctional carboxylic acids in multicomponent systems of nonspecific solvent–solvent and solvent–solute interactions. The solubility of solid phenol in systems of this type is expected to obey similar equations based on a trimer model (14), but the solubility of gaseous phenol at high dilution (or the Henry's law constant) should be best described by a monomer model. Extraction equilibria present an interesting case in that the appropriate model may depend on the concentration range studied.

The nearly ideal binary solvent equations cannot be rigorously developed for liquid–liquid extraction in systems of practical importance because of the thermodynamic complexity of these systems, but equations developed for idealized systems may have some practical applicability. The simplest system of this type involves the distribution of a solute between two completely immiscible liquid phases, one phase consisting of a mixture of solvents and a reference phase in which the activity coefficient of the solute may be expected to remain fairly constant over the concentration range studied. For solutions sufficiently dilute to allow approximation of $(1 - \Phi_s)$ as unity, Eq. 2 becomes:

$$\ln(K_s)_m \approx \sum_{i=1}^{N} \Phi_i^0 \ln(K_s)_{X_i^0=1} + (\overline{V}_s/\overline{V}_m)(RT)^{-1}(\Delta\overline{G}_1^{fh} \ldots N) \qquad \text{(Eq. 16)}$$

with the distribution coefficient ($K_s$) based on molar (moles per liter) concentrations ($C_s$):

$$(K_s)_m = (C_s)_m/(C_s)_{\text{reference}} \qquad \text{(Eq. 17)}$$

The distribution of benzoic acid between water (reference) and mixtures of inert solvents should be best described by a dimer model ($\overline{V}$ = 209 cm$^3$/mole) at high concentrations and by a monomer model ($\overline{V}_s$ = 104 cm$^3$/mole) in very dilute solutions. Experiments are being conducted to determine whether the presence of water in the organic phase interferes with these predictions.

# Instantaneous Input Hypothesis in Pharmacokinetic Studies

**WIN L. CHIOU ˣ, GILBERT LAM, MEI-LING CHEN, and MYUNG G. LEE**

Received December 1, 1980, from the *Department of Pharmacy, College of Pharmacy, University of Illinois at the Medical Center, Chicago, IL 60612.* Accepted for publication February 20, 1981.

**Abstract** □ Observed venous plasma concentrations of furosemide, propranolol, griseofulvin, and theophylline at 0.33 and 0.66 min after intravenous bolus injections to unanesthetized dogs were compared with those extrapolated using the instantaneous input hypothesis. At 0.33 min, extrapolated/observed plasma level ratios as high as 20.5, 65.5, 226, and 1.17 were found for these four drugs, respectively. Venous plasma levels peaked at 1 min postinjection in all studies. Total plasma areas ($AUC_{0\to\infty}$) estimated using the instantaneous input principle were higher by as much as 6.0, 6.8, and 19.6% for propranolol, griseofulvin, and furosemide, respectively, when compared with experimental data. The effect on theophylline was negligible. These results suggest the need for cautious interpretation of some venous pharmacokinetic data. More studies in animals and humans are required to assess the magnitude of deviation from the instantaneous input hypothesis for drugs in general.

**Keyphrases** □ Pharmacokinetics—instantaneous input hypothesis, comparison with conventional extrapolation method, dogs □ Instantaneous input hypothesis—comparison with conventional extrapolation method, dogs □ Venous pharmacokinetics—instantaneous input hypothesis and conventional extrapolation method compared, dogs

In pharmacokinetic studies, venous plasma (blood or serum) level data, usually obtained 1–30 min (1–3) after a rapid intravenous bolus injection, often are employed to fit a polyexponential equation, $\sum_{i=1}^{n} A_i e^{-\lambda_i t}$. The obtained equation, also called the disposition function, then is used for pharmacokinetic analysis (1–10). This method assumes that, after injection, the drug is instantaneously distributed into an initial apparent volume of distribution or the volume of the central compartment as defined in the multicompartmental mammillary modeling analysis. The initial volume of distribution or the volume of the central compartment is calculated by dividing the dose by the extrapolated plasma concentration at time zero, $C_p^0$, which, in turn, is calculated by the summation of the polyexponential coefficients, $\sum_{i=1}^{n} A_i$. The total area under the plasma concentration–time curve from zero to infinite time, $AUC_{0\to\infty}^{ext}$, usually is obtained by:

$$AUC_{0\to\infty}^{ext} = \sum_{i=1}^{n} \frac{A_i}{\lambda_i} \qquad \text{(Eq. 1)}$$

In Eq. 1, the plasma area from time zero to the first plasma concentration point is, in essence, estimated by the extrapolation based on experimental data obtained later.

The present report compares experimentally obtained plasma concentrations and plasma areas between time zero and 1 min with those estimated by the conventional extrapolation method.

## EXPERIMENTAL

**Intravenous Bolus Studies**—Propranolol[1], furosemide[2], theophylline[3], and griseofulvin[4] were studied in mongrel male conditioned dogs, 18.7–23.7 kg. The drug in solution was injected through an indwelling catheter placed in the cephalic vein. Blood samples were withdrawn from a permanent cannula placed in the femoral vein *via* the saphenous vein. Bolus injection was completed in 10 sec for propranolol and furosemide and in 20 sec for theophylline and griseofulvin. Normal saline, 3–5 ml, was used immediately to flush the catheter to ensure complete drug delivery.

Blood samples were collected before injection and at 0.33, 0.66, 1, 2, 3, 6, 9, 15, 30, 45, 90, 120, 150, 180, 210, 240, 300, and 360 min postinjection. They were centrifuged immediately and stored frozen prior to analysis. The midpoint of injection was set as time zero. Concentrations of drugs in plasma were quantitated by the specific and sensitive high-performance liquid chromotagraphic methods developed previously in this laboratory (11–14).

Two dogs were studied for each drug; five dogs were used in the entire study. At least 3–5 days elapsed between studies for each dog. The doses and body weights of the dogs are summarized in Table I.

**Data Analysis**—Plasma data from 1 min were fitted to either a two- or three-exponential equation by using a nonlinear least-squares regression program, NONLIN (15), on a digital computer. Plasma data were weighted by the reciprocal concentration squared.

## RESULTS AND DISCUSSION

The coefficients and exponents of the polyexponential disposition function based on the NONLIN computer analysis are summarized in Table I. Goodness of fit is supported by the $r^2$ values, which were all very close to 1.000 (Table I). There is good agreement between the experimental data and the computer-generated curves (Figs. 1–4). However, the plasma concentrations found at 0.33 and 0.66 min were lower than those estimated by the extrapolation method from the polyexponential decay equations in all studies. The differences between the observed and extrapolated levels at 0.33 min are summarized in Table II. Ratios of the extrapolated to observed concentrations up to 20.5, 65.5, and 226 were found for furosemide, propranolol, and griseofulvin, respectively (Table

[a] Mean of the two dog studies.

II). For theophylline, the difference at 0.33 min was relatively much smaller (13 and 17%). The inserts in Figs. 1–4 show the experimental and extrapolated plasma level profiles of the individual dog study for the first 2 min postdosing.

In dogs, the peak plasma levels occurred at 1 min after intravenous injection; but in preliminary studies using anesthetized rabbits, peak plasma (from femoral vein) levels for procainamide (16) and griseofulvin occurred at 2 min after a rapid intravenous bolus injection.

The overestimations of the initial plasma concentrations from the extrapolation of the polyexponential equation probably could be attributed to several factors, such as the lag time due to drug transport from the injection site to the sampling site (17), mixing of the drug in the blood circulation, and drug extraction by the sampling tissue through diffusion across capillary walls. The last factor was supported by the fact that drug concentrations in plasma of blood collected simultaneously from the femoral artery of the same leg were higher than those in venous plasma (16). It has been stated (17) that the zero-time plasma concentration at the normal sampling site immediately after intravenous injection theoretically should be zero. The present data (Figs. 1–4) appear to support this statement.

The areas under the plasma curve between time zero and 1 min after injection were calculated by the "extrapolated" integration method (Eq. 2) and also by the linear trapezoidal rule method using experimentally observed plasma concentrations and assuming zero drug concentration at time zero:

$$AUC^{ext}_{0\text{–}1\ min} = \sum_{i=1}^{n} \frac{A_i}{\lambda_i}(1 - e^{-\lambda_i t}) \qquad \text{(Eq. 2)}$$

where $t$ was set to be 1 min. The overestimation of the plasma area in the first 1 min ($\Delta AUC$) by the extrapolation method is assumed to be equal

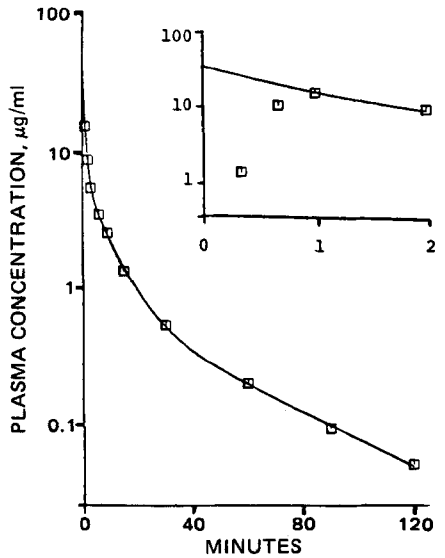

**Figure 2**—*Venous plasma concentration profile of furosemide following an intravenous bolus injection of 40 mg to Dog 3.*

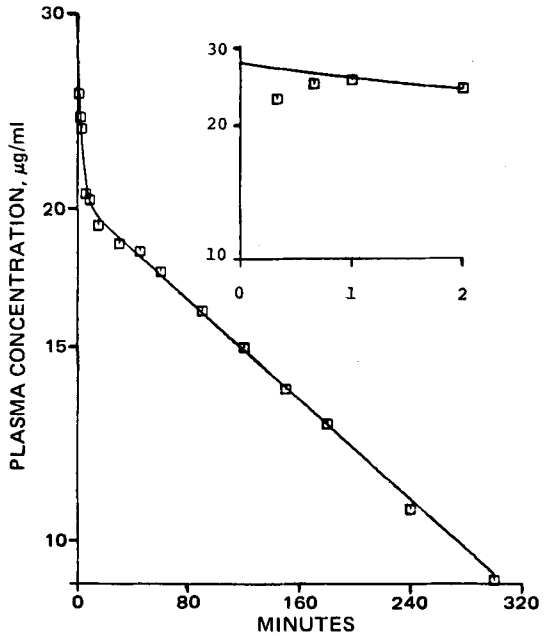

**Figure 3**—*Venous plasma concentration profile of theophylline following an intravenous bolus injection of 400 mg to Dog 4.*

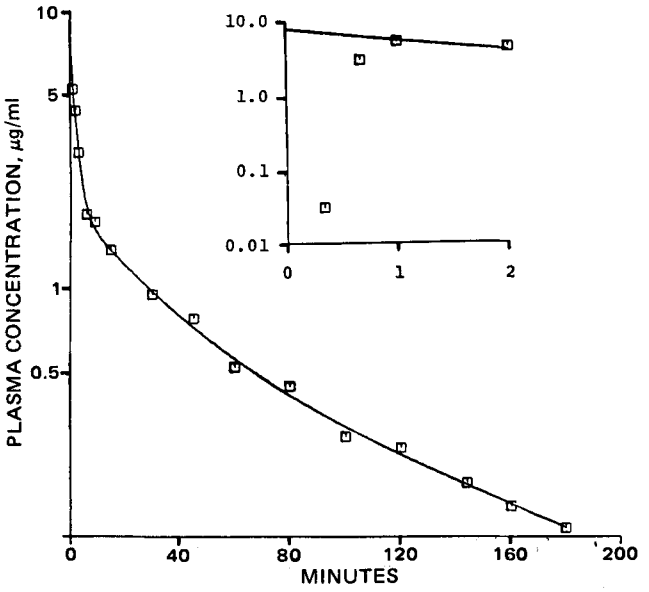

**Figure 4**—*Venous plasma concentration profile of griseofulvin following an intravenous bolus injection of 60 mg to Dog 5.*

to the difference between the areas estimated by the described two methods. The "correct" (actual) total plasma area, $AUC^{act}_{0\to\infty}$, may be calculated by:

$$AUC^{act}_{0\to\infty} = AUC^{ext}_{0\to\infty} - \Delta AUC \qquad \text{(Eq. 3)}$$

Therefore, the percentage of overestimation in plasma area for the first 1 min by the extrapolation method as compared with the actual total plasma area can be calculated by:

$$\%\ \text{overestimation} = \frac{\Delta AUC}{AUC^{act}_{0\to\infty}} \times 100 \qquad \text{(Eq. 4)}$$

The results of the analyses for the four drugs are summarized in Table II. The mean overestimations for theophylline, propranolol, griseofulvin, and furosemide were 0.13, 4.86, 5.38, and 17.9%, respectively.

The plasma concentration and area data within the 1st min after intravenous injection are different from the prediction using the conventional polyexponential disposition function or multicompartmental mammillary modeling analysis. These results appear to indicate that a very intensive early blood sampling schedule may be required to characterize accurately the plasma level profile during the early period. Although the four drugs studied have markedly different physicochemical properties (two weak acids, one weak base, and one neutral compound), more studies in animals and humans are needed to assess the general magnitude of deviation from the instantaneous input hypothesis.

These findings may have some significant implications in pharmacokinetic studies. For example, the difference between the actual and the extrapolated total plasma area for furosemide in Dog 3 was 19.6% (Table II). This value would result in a difference of 19.7% in the calculated total body clearance (467 *versus* 390 ml/min based on dose/$AUC_{0\to\infty}$). By using the extrapolated total plasma area as a reference, the absolute bioavailability from a completely bioavailable dosage form (assuming correct plasma area measurement) in this dog can be calculated as only ~80%. Furosemide in solution or tablet was reported to be incompletely absorbed (usually <73%) in humans (18–22), although the total diuretic response (relationship with plasma level or dose appears to be complicated, Ref. 22) was often the same following oral or intravenous administration of the same dose (18, 19, 21). If the phenomenon observed in the two dogs in the present study happened similarly in humans, then the absolute bioavailability of furosemide might be greater than reported. Further studies are required to prove this hypothesis.

The results of the present study support the contention (23, 24) that the constant blood withdrawal method may be useful to determine accurately the $AUC_{0\to\infty}$ after an intravenous bolus injection, especially in humans. Furthermore, the extensive blood sampling procedure can be avoided (23–25).

# Aminoglutethimide Bioavailability, Pharmacokinetics, and Binding to Blood Constituents

THOMAS A. THOMPSON ˣ, JEANNETTE D. VERMEULEN, WILLIAM E. WAGNER, Jr., and ANNE R. LE SHER

Received December 1, 1980, from the *Research Department, Pharmaceuticals Division, Ciba-Geigy Corporation, Ardsley, NY 10502.* Accepted for publication March 2, 1981.

**Abstract** □ The bioavailability of aminoglutethimide tablets was examined using a spectrophotometric assay. For six subjects receiving 500 mg of aminoglutethimide as an oral solution, the average peak concentration was 6.2 μg/ml with a median time of 0.8 hr. The corresponding average peak concentration for tablet administration was 5.9 μg/ml with a median time of 1.5 hr. Average values for the area under the curve (*AUC*) extrapolated to infinity were 89.0 and 96.8 μg hr/ml for the solution and tablets, respectively. The tablets had a 9% larger mean for the *AUC* than the solution and a 5% lower value for the mean maximum concentration. The bioavailability of the tablets is considered equal to that of oral solution. Data for individual concentration *versus* time curves were treated by nonlinear least-squares curve fitting. A two-compartment model with first-order absorption gave an acceptable fit for most data sets, but the individual absorption rate coefficients were not reliably determined. Values were estimated for plasma clearance, renal clearance, and volume of distribution. The distribution of aminoglutethimide between plasma and cells of human blood was examined *in vitro*; the drug concentration in cells was 1.4–1.7 times the concentration in plasma. The binding of aminoglutethimide to plasma proteins of human blood was measured by equilibrium dialysis at starting concentrations of 5 and 10 μg/ml. The binding ranged from 21.3 to 25.0% without concentration dependence.

**Keyphrases** □ Aminoglutethimide—bioavailability, pharmacokinetics, binding to blood constituents □ Bioavailability—aminoglutethimide, pharmacokinetics, binding to blood constituents □ Pharmacokinetics—aminoglutethimide, bioavailability, binding to blood constituents

Aminoglutethimide, α-(*p*-aminophenyl)-α-ethylglutarimide, is an inhibitor of adrenal corticosteroid biogenesis (1) used for the treatment of Cushing's syndrome (2). The urinary excretion of aminoglutethimide in humans was measured and accounted for 39 and 54% of 250- and 500-mg oral doses, respectively (3). Acetamidoglutethimide was reported as a metabolite in human urine (4). An assay procedure for aminoglutethimide in plasma and information about its half-life, clearance, and compliance in patients were reported previously (5). The purposes of the present study were to evaluate the bioavailability of a commercial dosage form[1], to explore the pharmacokinetics, and to measure the binding of aminoglutethimide to blood constituents.

## EXPERIMENTAL

**Clinical Study Protocols**—Eight healthy adult male volunteers, 25–54 years of age, were given a copy of the appropriate protocol and full information about the drug; they signed statements of informed consent. Each subject was screened regarding general health and history of drug hypersensitivity and underwent a physical examination, urine analysis, and a hematologic and blood chemistry analysis. The subjects ranged in height from 173 to 188 cm and in weight from 64 to 91 kg. Each subject was instructed to avoid any medication during the study and during the preceding week. The consumption of alcoholic beverages was prohibited during and for 3 days preceding the study.

Two subjects participated in a pilot study, and six others participated in a random crossover bioavailability study with a washout period of 14 days.

[1] Cytadren, 250-mg tablets, E-10447, Ciba-Geigy Corp.

Aminoglutethimide (500 mg) was administered in the morning after an overnight fast. No food or liquid other than water was permitted until 2 hr after drug administration, when a simple standard breakfast was allowed. Samples (10 ml) of venous blood were collected[2] at 0, 0.25, 0.50, 0.75, 1, 2, 3, 4, 5, 6, 12, 24, and 48 hr in the pilot study and at 0, 0.33, 0.66, 1, 1.5, 2, 2.5, 3, 6, 9, 12, 15, and 24 hr in the bioavailability study. The heparinized blood samples were centrifuged, and the plasmas were separated. Saliva production was stimulated during the bioavailability study by having the subjects chew a small piece of paraffin[3], and 2-ml saliva samples were obtained at the same time that the 0-, 1-, 2-, 3-, 6-, 9-, and 12-hr blood samples were drawn. Total urines were collected during the pilot study at intervals ending at 2, 4, 6, 12, 24, and 48 hr. Samples were frozen until analysis.

**Assay Methodology**—Plasma, urine, and saliva samples were analyzed for aminoglutethimide by the quantitative spectrophotometric method described previously, which involves extraction with chloroform and reaction with diazotized *p*-dimethylaminobenzaldehyde (5). The method was tested before use by analysis of control samples to which aminoglutethimide had been added. Frozen samples of human control plasma were thawed, pooled, and centrifuged to remove solids. Syringes[4] were used to add 0, 23, 30, 52, 57, 80, and 160 μl of a 1-μg/μl solution of aminoglutethimide in ethanol to seven 40-ml centrifuge tubes. The alcohol was evaporated, and 10.0 ml of plasma was added to each tube. Polytef-lined screw-capped tubes were rotated for 15 min. Approximately 2.5 ml of each concentration of aminoglutethimide in plasma was placed in triplicate into vials. Two blanks were added, and the vials then were number coded in random sequence. All samples were frozen as soon as prepared and stored at −10° pending analysis.

The specificity of the method was examined with respect to the metabolite acetamidoglutethimide and three other metabolites isolated from rat urine[5]. Aliquots (8, 25, and 40 μl) of a 1-μg/μl solution of each metabolite were placed in duplicate into test tubes, evaporated, redissolved in ethanol, and analyzed without extraction.

The stability of aminoglutethimide in plasma during frozen storage at −10° was examined. Aminoglutethimide was added to plasma from control volunteers to provide concentrations of 5, 10, and 15 μg/ml. Replicate aliquots of each concentration and blank were placed into separate vials. One set was analyzed immediately; the other sets were stored in a freezer pending analysis after 1, 5, 15, and 30 days.

**Binding Methodology**—For the whole blood distribution experiments, a 2.0-mg/ml stock solution of aminoglutethimide in ethanol was diluted 10-fold with 0.9% saline. The resulting 0.2-mg/ml solution was added to heparinized whole blood obtained within 2 hr from three healthy human volunteers. Concentrations of 0, 5, and 10 μg/ml were prepared and equilibrated in a shaking water bath for 30 min at 37°. Plasma was prepared by centrifugation and stored overnight in a freezer pending analysis. The concentration of drug in cells was calculated as follows:

$$\mu g/ml \text{ in cells} = \frac{\mu g/ml \text{ in blood} - \mu g/ml \text{ in plasma}}{\text{hematocrit}} + \mu g/ml \text{ in plasma} \quad \text{(Eq. 1)}$$

Binding of aminoglutethimide by plasma proteins was measured by equilibrium dialysis against pH 7.4 isotonic buffer. Aminoglutethimide in ethanol (1.0 mg/ml) was added to heparinized plasma from different individuals to produce 5- and 10-μg/ml concentrations. The dialysis buffer was prepared by mixing 8.7 ml of 5.4 g/liter $KH_2PO_4$ with 30.4 ml of 10.7 g/liter $Na_2HPO_4 \cdot 7H_2O$, adding 4.5 g of NaCl, and diluting to 500 ml. The pH was adjusted to 7.4. Dialysis membranes were prepared for

**Table I—Number of Subjects Having Treatment Emergent Signs and Symptoms during Aminoglutethimide Administration**

| Sign or Symptom | Ethanolic Solution | | | Tablets | | |
|---|---|---|---|---|---|---|
| | Mild | Moderate | Severe | Mild | Moderate | Severe |
| Dizziness | 1 | 4 | — | 1 | — | — |
| Light headedness | — | — | — | 2 | — | — |
| Sedation | 1 | — | — | 2 | 1 | — |
| Headache | 1 | — | — | — | — | — |

use by boiling in distilled water for 5 min and rinsing thoroughly. The membranes were stored under water in a refrigerator. Dialysis was carried out for 18 hr using 5-ml cells in a shaking water bath at 37°. Aliquots (2.0 ml) of both the dialyzed plasma and buffer were analyzed for aminoglutethimide.

**Data Evaluation**—The bioavailability of the aminoglutethimide tablets was evaluated by comparison of the area under the curve ($AUC$) extrapolated to infinity for plasma concentration curves resulting from two 250-mg tablets and from 500 mg of aminoglutethimide dissolved in a special vehicle containing 10% ethanol, 30% propylene glycol, and 10% glycerin. The $AUC$ values were obtained by application of the trapezoidal rule. Peak plasma concentrations ($C_{max}$), times of peak concentration ($T_{max}$), and half-lives ($T_{1/2}$) also were examined.

**Pharmacokinetic Analysis**—Nonlinear least-squares curve fitting was carried out using AUTOAN and NONLIN computer programs. Values for clearance and the volume of distribution were calculated as follows, where $t_1 - t_2$ is elapsed time:

$$\text{renal clearance} = \frac{\text{amount excreted } t_1 - t_2}{AUC\ t_1 - t_2} \quad \text{(Eq. 2)}$$

$$\text{plasma clearance} = \text{dose}/AUC \quad \text{(Eq. 3)}$$

$$V_c = \frac{\text{dose}}{(AUC)\,(K_{el})} \quad \text{(Eq. 4)}$$

$$V_\beta = 1.44 V_c K_{el} T_{1/2\beta} \quad \text{(Eq. 5)}$$

$$V_{ss} = V_c \frac{K_{21} + K_{12}}{K_{21}} \quad \text{(Eq. 6)}$$

## RESULTS AND DISCUSSION

**Assay Validation**—The assay procedure was tested by blind analysis of a group of 20 samples of human plasma to which known amounts of aminoglutethimide from 2.3 to 16 μg/ml had been added. Replicates and blank samples were included. The samples were analyzed in random sequence, and the concentrations were unknown to the analyst until later. The mean and standard deviation for the percent recovery in the blind validation experiment were 97.4 ± 3.8, demonstrating good accuracy and precision. Plasma calibration standards of three different concentrations were freshly prepared and analyzed on 14 occasions during several months. The mean of slopes for the standard curves and also the mean analytical response for each drug level had relative deviations of 2%, showing excellent agreement.

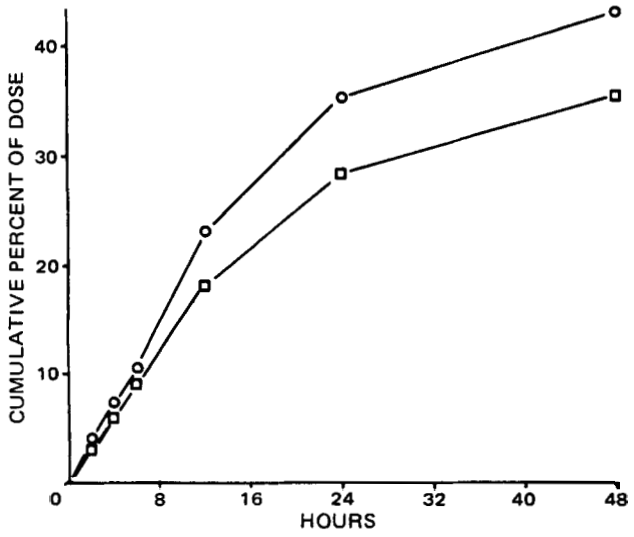

**Figure 1**—*Urinary excretion of aminoglutethimide by two subjects after two 250-mg tablets.*

**Table II—Renal Clearance of Aminoglutethimide**

| Subject | Interval, hr | $R_c$, ml/min | Mean ± $SD$ |
|---|---|---|---|
| 1 | 0–2 | 24 | 30.4 ± 5.9 |
| | 2–4 | 25 | |
| | 4–6 | 31 | |
| | 6–12 | 38 | |
| | 12–24 | 34 | |
| 2 | 0–2 | 33 | 37.6 ± 8.4 |
| | 2–4 | 28 | |
| | 4–6 | 36 | |
| | 6–12 | 50 | |
| | 12–24 | 41 | |

The stability of aminoglutethimide in plasma during frozen storage was examined. Aminoglutethimide was added to human control plasma to obtain concentrations of 5.0, 10.0, and 15.0 μg/ml. Aliquots were analyzed after 0, 1, 5, 15, and 30 days of frozen storage, and the percent recoveries ranged from 96 to 103% with no apparent trend. All samples in the bioavailability study were analyzed before 30 days of storage had elapsed.

The assay is applicable to urine and saliva as well as to plasma. Five 2.0-ml aliquots of human urine to which 2.5–15.0 μg/ml of aminoglutethimide had been added were analyzed to test the procedure. The average recovery and standard deviation were 91.4 ± 3.2%. A similar recovery experiment with saliva gave 99.4 ± 1.1%.

Acetamidoglutethimide and three metabolites of unknown structure from rat urine did not cause any response in the assay.

**Clinical Observations**—Each subject completed the study as planned. Table I shows that no severe signs or symptoms appeared, although four subjects complained of moderate dizziness after receiving aminoglutethimide in ethanolic solution. This effect probably resulted from ingestion of ethanol while fasting. In no case did the symptoms prevent the subjects from performing their usual activities.

**Cumulative Percent of Dose Excreted**—The cumulative percent of aminoglutethimide excreted unchanged in urine was measured for the two subjects who ingested two 250-mg tablets in the pilot experiment (Fig. 1). Renal excretion of unchanged drug proceeded slowly and accounted for 35.0–42.6% of the dose during 48 hr. These values are in accord with those reported previously (3). Urine was not obtained in the six-subject bioavailability experiment.

**Renal Clearance**—Renal clearance was calculated for the two subjects for whom both urine and plasma samples were obtained (Table II). The values suggest that aminoglutethimide may be processed renally by glomerular filtration with passive tubular reabsorption of some filtered drug.

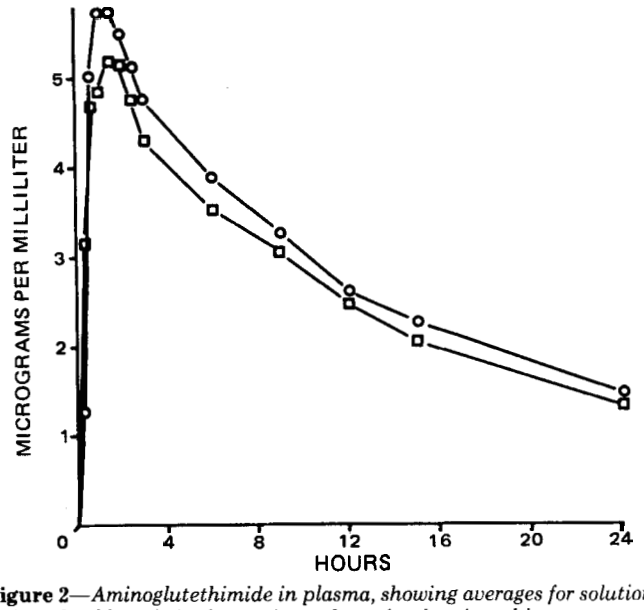

**Figure 2**—*Aminoglutethimide in plasma, showing averages for solution (□) and tablets (○) after 500-mg doses in the six-subject crossover study.*

| | 8 | 0.998 | 3.906 | 0.210 | 0.0690 | 0.064 | 7.6 | None |

**Plasma Concentration–Time Curves**—The concentration–time curves were similar for all subjects. Maximum concentrations of 4.9–7.4 μg/ml were found 0.3–2.0 hr after ingestion of 500 mg of aminoglutethimide in solution, and two 250-mg tablets resulted in peak concentrations of 5.6–6.3 μg/ml occurring 0.7–1.5 hr after ingestion (Table III). An initially rapid decline was followed by a slower decline having a half-life of 9–16 hr for the solution and 10–15 hr for the tablets.

A graph of the average plasma concentrations (Fig. 2) shows similar, but not superimposable curves. The tablets had a 9% larger average for the *AUC* than the solution (Table III). A difference in *AUC* of this magnitude has little practical significance, and the tablet formulation may be considered bioequivalent to the solution. It is common practice to assess the absorption efficiency of tablets relative to an oral solution by calculating a ratio of average *AUC* values. According to pharmacokinetic theory, the ratio of areas equals a ratio of the fraction of each dose absorbed if the plasma clearance ($C_p$) is the same (6). The tablets and solution had average $C_p$ values of 86.2 and 95.7 ml/min, respectively. Since the tablets and solution were administered at the same dose level in a random crossover pattern, the apparent differences in $C_p$ and *AUC* values probably are artifacts of the data. The $C_{max}$ value for the solution was 5% larger than for the tablets, and the average terminal half-life value was 12.5 hr for both the tablets and solution. This value for aminoglutethimide half-life agrees well with the average 13.3 hr reported for an initial dosage of six patients (6). The time of peak concentration was slightly earlier for solution, 0.8 hr *versus* 1.5 hr for tablets.

**Table V—Plasma Clearance and Volumes of Distribution for Aminoglutethimide**

| Dosage Form | Subject | $C_p$, ml/min | $V_c$, liters | $V_\beta$, liters | $V_{ss}$, liters |

| | 6 | 86 | 64.3 | 121.1 | 97.4 |
| | 7 | 114 | 82.8 | 116.5 | 118.3 |
| | 8 | 79 | 69.0 | 82.1 | 90.0 |
| | Mean | 95.7 | 66.68 | 101.57 | 100.33 |
| | *SD* | 17.0 | 22.14 | 14.71 | 10.09 |

Nonlinear least-squares curve fitting of plasma data using AUTOAN and NONLIN computer programs with equal weighting of data gave equations of acceptable fit using a two-compartment model with first-order absorption. Values for the squared correlation coefficient were >0.99 in all but one instance (Table IV). However, the standard deviations for the individual absorption rate constants were too great for meaningful evaluation of this parameter.

Values for $C_p$ are shown in Table V. The observed average $C_p$ values of 86.2 and 95.7 ml/min indicate a moderate clearance rate. Table V also shows values for principal volume of distribution parameters. In the absence of intravenous data, the dose was assumed to be completely absorbed. The values for clearance and volumes of distribution are overestimated if this assumption is incorrect.

**Binding to Blood Cells and Plasma Proteins**—The distribution of aminoglutethimide between plasma and cells of human blood was calculated after *in vitro* equilibration of drug with heparinized blood and analysis of the drug in plasma. The concentration of aminoglutethimide in cells was 1.4–1.7 times the concentration in plasma. The binding of aminoglutethimide *in vitro* to plasma proteins of three subjects was measured by equilibrium dialysis at 37°. Initial drug concentrations of 5 and 10 μg/ml showed binding of 21.3–25.0%. No concentration-dependent trend was apparent.

**Saliva Concentrations**—Saliva samples were obtained to determine whether saliva assay is an acceptable alternative to plasma assay. Saliva production was stimulated by chewing a small piece of paraffin. Paraffin was reported to absorb significant amounts of propranolol and indomethacin (7), and a preliminary test for glutethimide absorption was carried out as described previously (7). Little or no absorption was found. However, the concentrations of aminoglutethimide found in saliva of the bioavailability subjects were too low for the analytical method. Measurable concentrations were found in only a few samples, and no correlation with plasma concentrations was apparent.

# High-Performance Liquid Chromatographic Assay for Nanogram Determination of Chlorpromazine and Its Comparison with a Radioimmunoassay

**K. K. MIDHA *x, J. K. COOPER *, I. J. McGILVERAY ‡, A. G. BUTTERFIELD ‡, and J. W. HUBBARD §**

Received June 6, 1980, from the **College of Pharmacy, University of Saskatchewan, Saskatoon, Saskatchewan S7N 0W0, Canada*, the *‡Drug Research Laboratories, Health Protection Branch, Health and Welfare Canada, Ottawa, Ontario K1A 0L2, Canada*, and the *§Faculty of Pharmacy, University of Manitoba, Winnipeg, Manitoba R3T 2N2, Canada.* Accepted for publication February 17, 1981.

**Abstract** □ A specific and sensitive high-performance liquid chromatographic (HPLC) method for the quantitative determination of plasma chlorpromazine concentrations is described. The procedure is capable of determining 1 ng of chlorpromazine/ml and is adequate for following plasma concentration–time profiles after 7-mg single intravenous doses. After a simple organic extraction of the drug and an internal standard (mesoridazine) from plasma, the organic layer was transferred to a vial and evaporated to dryness at 55° under nitrogen. The residue was dissolved in 200 μl of HPLC grade acetonitrile. Aliquots (70–100 μl) were chromatographed, and the drug was quantitated in the range of 1–15 ng/ml of plasma using a fixed-wavelength UV detector. Plasma concentrations determined by the method were compared with those obtained by a previously reported radioimmunoassay specific for chlorpromazine and *N*-desmethylchlorpromazine. The two methods agreed favorably with a correlation coefficient of 0.993 and a slope of 0.994.

**Keyphrases** □ Chlorpromazine—high-performance liquid chromatographic analysis in plasma and comparison with a radioimmunoassay □ Psychotropic agents—chlorpromazine, high-performance liquid chromatographic analysis □ Antipsychotic phenothiazines—chlorpromazine, high-performance liquid chromatographic analysis and radioimmunoassay comparison

Chlorpromazine is widely used in the treatment of certain psychiatric disorders (1). It undergoes extensive metabolism, and several of its metabolites (2) are considered to be psychoactive. Some of the metabolites can be quantitated in plasma; in some studies, the ratio of plasma concentrations of active to inactive metabolites was correlated with clinical improvement in schizophrenic patients (3–5).

The various chemical methods of quantitation that have been used include GLC with electron-capture detection (6), GLC with mass spectrometric detection (7, 8), fluorescent labeling with dansyl chloride (9), labeled derivative formation (10), and TLC of a quaternary ammonium derivative formed by reaction with 9-bromomethylacridine, followed by UV photolysis and spectrofluorometric determination (11). These methods may have adequate sensitivity to determine plasma concentrations following therapeutic dosage regimens, but they are generally cumbersome and not easily amenable to routine clinical monitoring.

The radioimmunoassay procedures are generally simple, sensitive, and readily applicable to routine analysis. Although sensitive, radioimmunoassays generally are suspect from the aspect of specificity. In the case of chlorpromazine radioimmunoassay (12–14), this specificity concern is augmented by the extremely large number of identified metabolites. To verify the specificity of the radioimmunoassay procedure reported previously (14), which was based on proper designing of the antibody (15), high-performance liquid chromatographic (HPLC) assay, specific and sensitive to 1 ng/ml of plasma, was developed. This HPLC assay is described and compared with the radioimmunoassay reported earlier (14).

## EXPERIMENTAL

**Materials**—Chlorpromazine hydrochloride[1], prochlorperazine[1], mesoridazine besylate[2], 2-chlorophenothiazine[3], chlorpromazine sulfoxide[4], 7-hydroxychlorpromazine sulfoxide[4], *N*-monodesmethylchlorpromazine[4], *N*-monodesmethylchlorpromazine sulfoxide[4], *N*-didesmethylchlorpromazine[4], *N*-didesmethylchlorpromazine sulfoxide[4], and chlorpromazine *N*-oxide[4] were used. All solvents were HPLC grade[5], and all other chemicals were commercial analytical reagent grade.

**Apparatus**—A liquid chromatographic pump[6] and a valve-loop injector[7] fitted with a 1000-μl loop were connected to a fixed-wavelength detector[8] operated at 254 nm. The detector was attenuated to 0.005 aufs for chlorpromazine and to 0.5 aufs for the internal standard.

**Column**—A 250 × 3.2-mm i.d. column, packed with 5-μm cyano-bonded column packing[9], was used at ambient temperature with a mobile phase flow rate of 1.6 ml/min.

**Mobile Phase**—The mobile phase consisted of 10% aqueous 0.015 *M* sodium acetate–acetic acid buffer (pH 6.5) and 90% acetonitrile. It was degassed by refluxing for 5 min and transferred to the solvent reservoir.

**Internal Standard**—A stock solution of mesoridazine besylate (1000 μg/ml, calculated as free base) was prepared in double-distilled water, stored in the absence of UV light at 4°, and used throughout the experiments. Dilutions of 50 μg/ml were prepared weekly and used for analysis.

**Preparation of Standard Curves**—An aqueous solution of chlorpromazine hydrochloride (100 μg/ml, calculated as free base) was prepared weekly in double-distilled deionized water and stored in the ab-

[a] $y = mx$, where $m = 0.0975 \pm 0.0011$; $r^2 = 0.999$. [b] Mean = 3.00.

sence of UV light at 4°. Appropriate final dilutions of 1.0, 2.5, 5.0, 7.5, 10.0, and 15.0 ng/ml were made directly in plasma just prior to analysis.

**Extraction of Samples**—Plasma samples were extracted using a modification of a method previously used for GLC–mass spectrometric analysis (8).

To a 15-ml centrifuge tube[10] were added 2 ml of plasma, 1 ml of aqueous internal standard (50 μg of mesoridazine), and 0.1 ml of 1 *N* HCl. The sample was mixed[11] for 30 sec, and 4 ml of HPLC grade isopropanol then was added. The sample was mixed[12] for an additional 5 min and then centrifuged[13] at 5000 rpm for 20 min at 0°. The supernate was poured into another tube[10], and the pH was adjusted to 12.5 with 200 μl of 5 *N* NaOH. After mixing[12] for 10 sec, 4 ml of HPLC grade *n*-heptane was added. The sample was mixed[12] for an additional 10 min and centrifuged[14] at 2500 rpm at room temperature.

The upper organic layer then was transferred by pasteur pipet to a 5-ml conical vial[15]. The sample was evaporated[16] to dryness under nitrogen and then cooled to room temperature. Then 200 μl of acetonitrile was added, and the sample was mixed[12] for 2 min. The clear yellow solution was transferred by pasteur pipet to a 1-ml screw-capped disposable vial. For analysis, 75–100 μl was injected into the chromatograph.

**Plasma Level Study**—Two normal healthy volunteers, 64 and 87 kg, participated in a clinically supervised study. The antecubital veins on both arms of each subject were catheterized by means of infusion sets[17]. The intravenous solutions were prepared by diluting a commercial injectable preparation[18] with 50 ml of normal saline solution. The solutions were infused over a 2-min period *via* the left catheter. The 64-kg subject received 10 mg, and the other subject received 7 mg of chlorpromazine as the hydrochloride. Blood samples were collected in heparinized tubes[19] without touching the rubber stoppers. After centrifugation, the plasma was removed and stored at 4° until just prior to analysis.

**Recovery Study**—For the determination of chlorpromazine recovery, blank plasma was spiked with 2.5 and 5.0 ng of chlorpromazine/ml as the hydrochloride salt and the samples were analyzed as already described.

The absolute peak heights obtained from the standards were compared with those of fresh standards of chlorpromazine free base in acetonitrile.

**Quantitation**—Spiked plasma extracts were chromatographed, and standard curves were constructed by plotting the ratios of chlorpromazine to internal standard peak heights *versus* the concentration of the drug (nanograms per milliliter of plasma). Calibration standards were chromatographed each day when the unknown samples were analyzed. The concentrations of the unknown samples were determined by comparison of the peak height ratios to the standard curve obtained that day.

## RESULTS AND DISCUSSION

Under the described conditions, chlorpromazine and the internal standard (mesoridazine) gave sharp and symmetrical peaks that eluted in 8 min (Fig. 1B). No interference from endogenous plasma constituents was observed, as can be seen from the chromatogram obtained when the method was applied to blank plasma (Fig. 1A). Figure 1B shows a chromatogram of a spiked plasma sample containing 2.5 ng of chlorpromazine/ml and 50 μg of mesoridazine. Figure 1C shows a chromatogram of a 5-hr postdose plasma sample (2 ml) from the volunteer who received 7 mg of chlorpromazine intravenously, the chlorpromazine concentration being estimated as 6.5 ng/ml. The specificity of the method was established further by chromatographing all available metabolites under the assay conditions. Several of these metabolites are considered to be major metabolic components in humans. All of the metabolites tested eluted at retention times different from those of chlorpromazine and mesoridazine (Table I).

Mass spectral analyses of collected peaks from chromatographed plasma extracts of bulk plasma samples from dosed volunteers and spiked blank plasma were identical, suggesting that there was no interference from chlorpromazine metabolites that were not tested.

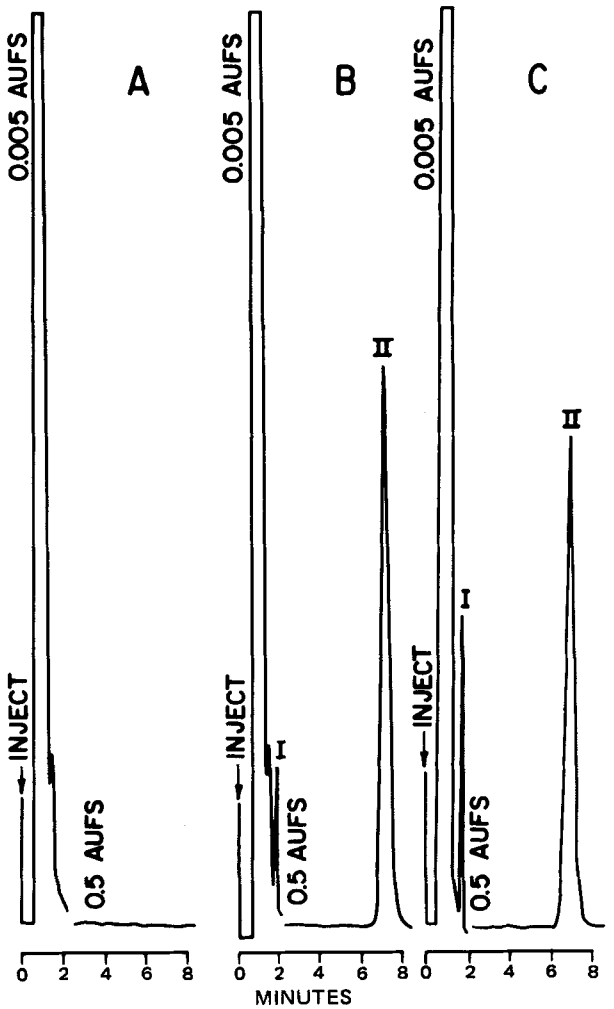

**Figure 1**—*Chromatograms of an extract of 2 ml of plasma. Key: A, blank; B, spiked with chlorpromazine (2.5 ng/ml) and the internal standard mesoridazine (25 μg/ml); and C, sample from a volunteer 5 hr postdose (7 mg iv) estimated to contain 6.5 ng of chlorpromazine/ml. Peak I is chlorpromazine, and peak II is mesoridazine.*

**Table III—Recovery of Chlorpromazine from Plasma**

| Nanograms Added to 1 ml of Plasma | $n$ | Mean Nanograms Recovered | Percent Recovery, mean ± $SD$ |
|---|---|---|---|
| 5.00 | 8 | 1.73 | 34.59 ± 0.57 |
| 2.5 | 6 | 0.86 | 34.31 ± 0.76 |

During the development of this assay, one major problem was the loss of chlorpromazine during plasma precipitation, drug extraction, or solvent evaporation. This problem was reported previously (16–18), and a simple method requiring minimum sample manipulation was sought to overcome it. Precipitation of plasma proteins was the process chosen because it would improve recovery of chlorpromazine by facilitating its release from high affinity bound plasma protein sites (19). Of the various reagents tried for plasma protein precipitation, trichloroacetic acid and acetonitrile resulted in complete occlusion of chlorpromazine. Precipitation with methanol was abandoned since evaporation was required before chlorpromazine could be extracted into nonpolar organic solvents. The use of isopropanol not only precipitated plasma proteins without occlusion of the drug but also reduced its loss due to adsorption and/or absorption onto the surfaces of the glass tubes used. Furthermore, the miscibility of isopropanol with a nonpolar solvent like heptane avoided the evaporation step completely. Mixtures of isopropanol and heptane were successfully used for extracting chlorpromazine and its metabolites from plasma (8).

The problem of the loss of chlorpromazine at the lower nanogram levels (≤10 ng) still existed and was visibly evident from the negative intercepts of the standard curves compiled using 50 ng of prochlorperazine/ml as the internal standard. To avoid the loss of chlorpromazine due to adsorption and/or absorption onto glass surfaces, the concentration of the internal standard was raised to 600 ng/ml in the hope that it would saturate the adsorption and/or absorption sites. This amount did not rectify the problem completely since the standard curves still showed some negative intercepts. A further increase in the prochlorperazine concentration resulted in a peak that interfered with that of chlorpromazine. This peak was thought to be due to a small impurity present in the prochlorperazine used.

A solution of 10 μg of 2-chlorophenothiazine used as an antioxidant (11) along with 50 ng of prochlorperazine was tried to solve the described problem. However, on chromatographic analysis, the peak due to 2-chlorophenothiazine tailed into that of chlorpromazine. Ultimately, the use of mesoridazine as an internal standard at a concentration of 50 μg appeared to prevent adsorption and/or absorption as indicated by the lack of negative intercept observed with other internal standards tried. It also provided an acceptable retention time with no interference from plasma constitutents.

Table II shows a composite standard curve for the quantitation of chlorpromazine from plasma. The curve is linear with a negligible intercept over the concentration range of 1–15 ng/ml. The ratio of chlorpromazine to mesoridazine plotted against chlorpromazine concentration gave a straight line passing through the origin ($r^2$ = 0.999). A mean slope

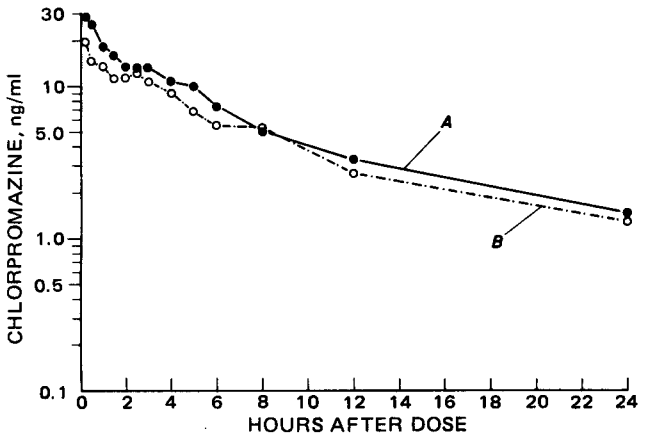

**Figure 2**—*Chlorpromazine concentrations in the plasma of two normal healthy volunteers. Key: A, volunteer (64 kg) who received 10 mg of an injectable chlorpromazine; and B, volunteer (87 kg) who received 7 mg of the same preparation.*

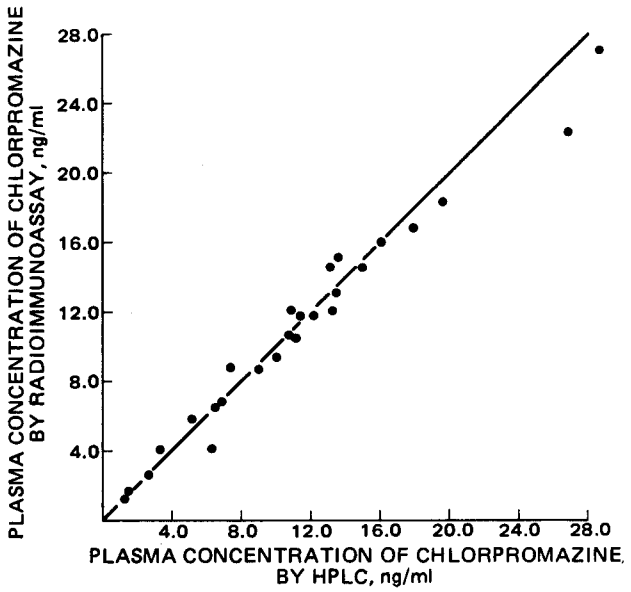

**Figure 3**—*Plot of plasma chlorpromazine concentration in humans by radioimmunoassay (14)* versus *plasma concentration of chlorpromazine measured by the described HPLC method;* n = *26,* $r^2$ = *0.993, and slope = 0.994.*

value of 0.0975 ± 0.0011 was obtained. This linearity of the curve was observed to 30 ng/ml, the highest concentration tested. For plasma samples containing concentrations of >30 ng/ml, aliquots smaller than 2 ml should be extracted.

The sensitivity of the described assay 1 ng/ml of plasma was adequate for following plasma concentration–time profiles of subjects receiving low single intravenous doses of the drug (7–10 mg). However, it was not adequate for following plasma profiles in volunteers who were orally administered single low doses (up to 25 mg) of the drug.

The overall recovery of chlorpromazine is given in Table III. Results were from at least six determinations at the 2.5- and 5.0-ng/ml plasma levels. A mean percent recovery of 34.45 ± 0.67 was obtained. Although the recoveries of chlorpromazine in the present assay are low, they are reproducible. Attempts to improve the recovery of the drug led to either added complexities or irreproducibility.

Application of the described HPLC procedure to plasma concentration determinations in subjects who received single intravenous doses of chlorpromazine[17] (7 or 10 mg) is shown in Fig. 2. As can be seen, the method is of sufficient sensitivity to analyze specimens obtained as late as 24 hr after this low single intravenous dose.

The described HPLC procedure was compared to the earlier radioimmunoassay procedure in which the antibody used cross-reacted only with chlorpromazine and *N*-desmethylchlorpromazine (14). There was excellent agreement between the values obtained by the two methods (Fig. 3). The correlation coefficient ($r^2$) of 0.993 and the slope value of 0.994 were obtained for 26 samples from the two volunteers, analyzed by the two methods. This excellent correlation suggests that *N*-desmethylchlorpromazine is not a major metabolite following single low intravenous doses.

The described HPLC procedure is precise, accurate, and specific for the drug. Furthermore, it is of sufficient sensitivity to determine plasma levels following single intravenous doses (7 or 10 mg) of the drug and should be suitable for single- or multiple-dose pharmacokinetic or bioavailability studies. It compared favorably with a correlation coefficient of 0.99 with the radioimmunoassay procedure reported earlier, thereby suggesting that both procedures are suitable for therapeutic monitoring of patients undergoing treatment with chlorpromazine. However, it may not have the sensitivity for following plasma profiles in volunteers who are orally administered single doses of up to 25 mg of the drug.

# Analysis of Pilocarpine and Isopilocarpine in Ophthalmic Solutions by UV Spectrophotometry–Polarimetry

**BRITT S. SCOTT ˣ, DANNY L. DUNN, and EDWIN D. DORSEY**

Received September 12, 1980, from *New Product Research/Analytical Chemistry, Alcon Laboratories, Inc., Fort Worth, TX 76101.* Accepted for publication March 4, 1981.

**Abstract** □ An improved analytical method was developed that simultaneously quantitates pilocarpine and isopilocarpine in the presence of each other and pilocarpic acid. Pilocarpine and isopilocarpine are first separated from any pilocarpic acid present in the sample by eluting with water-washed chloroform through a column packed with acid-washed diatomaceous earth. The concentrations of pilocarpine and isopilocarpine then are determined by a combination of UV spectrophotometric and polarimetric measurements. UV absorbance is measured at the absorption maximum (215 nm), and optical rotation is measured at the 254-nm line of mercury. Standard curve and standard recovery data are presented. The method is applicable to several commercially available ophathalmic solutions of pilocarpine and is compared to both the USP colorimetric method and a high-performance liquid chromatographic method.

**Keyphrases** □ Pilocarpine—analysis in the presence of isopilocarpine and pilocarpic acid, ophthalmic solutions □ Isopilocarpine—analysis in the presence of pilocarpine and pilocarpic acid, ophthalmic solutions □ UV spectrophotometry—analysis of pilocarpine and isopilocarpine, ophthalmic solutions □ Polarimetry—analysis of pilocarpine and isopilocarpine, ophthalmic solutions

Pilocarpine is an alkaloid used in the treatment of glaucoma to lower intraocular pressure. It has been reported to isomerize into isopilocarpine or to form pilocarpic acid reversibly in basic solution (1, 2). Both processes result in a loss of pharmacological activity (3, 4).

## BACKGROUND

Several satisfactory nonspecific methods have been developed for the analysis of pilocarpine (5–11), but only recently have numerous specific analytical methods been reported (1, 2, 12–17). Two procedures combine colorimetry and polarimetry (1, 12); the first measures a chromium complex of pilocarpine (5), and the second measures an iron complex of the hydroxamic acid of pilocarpine (8). While both methods are theoretically sound in that the colorimetric methods should quantitate total pilocarpine and isopilocarpine and the polarimetric measurements should determine the amount of pilocarpine, these methods are not widely used for routine analysis.

One specific NMR spectrometry method, requiring a 100-MHz instrument, distinguishes between pilocarpine, isopilocarpine, pilocarpic acid, isopilocarpic acid, and pilocarpate and isopilocarpate ions (2). However, this procedure is not designed for multiple analyses and requires expensive instrumentation and reagents. A GLC method that separates pilocarpine and isopilocarpine was also described, but it involves a tedious derivatization of pilocarpine prior to analysis (13). Several specific high-performance liquid chromatographic (HPLC) methods for the quantitation of pilocarpine and isopilocarpine were reported (14–17) and were discussed previously (18).

The present report describes a specific procedure involving a combination of column chromatography, UV spectrophotometry, and polarimetry to analyze for pilocarpine and isopilocarpine in the presence of each other and pilocarpic acid. Validation data for the procedure and data resulting from the analysis of commercially available ophthalmic solutions by this and two other analytical methods are presented.

## EXPERIMENTAL

**Reagents**—USP reference standard pilocarpine nitrate, USP grade pilocarpine hydrochloride[1], and ACS reagent grade isopilocarpine nitrate[2], hydrochloric acid, dibasic potassium phosphate, monobasic potassium phosphate, water-washed chloroform, and acid-washed diatomaceous earth[3] were used.

**Solutions**—The following were used: 0.1 *M* HCl and pH 5.8 potassium phosphate buffer (prepared by mixing one volume of 1 *M* dibasic potassium phosphate with nine volumes of 1 *M* monobasic potassium phosphate and adjusting to pH 5.8 with the appropriate potassium phosphate solution).

**Equipment**—A UV spectrophotometer[4], polarimeter[5], and 60-MHz NMR instrument[6] were used.

**Optical Rotation Measurements**—Stock solutions of pilocarpine hydrochloride and isopilocarpine nitrate were prepared in 0.1 *M* HCl. From these stock solutions, a series of solutions was prepared in concentrations ranging from 0.17 to 1.70 mg/ml of pilocarpine or isopilo-

carpine. Several solutions containing both pilocarpine and isopilocarpine were also prepared. The pilocarpine and isopilocarpine concentrations of these solutions varied inversely at intervals of 20% and ranged from 0.00 to 1.70 mg/ml. The total concentration was kept at a constant 1.70 mg/ml.

The optical rotation of each solution was measured as will be described under *Procedure*.

**Standard Preparation**—Approximately 100 mg of pilocarpine hydrochloride or the pilocarpine nitrate equivalent was accurately weighed into a 10.0-ml volumetric flask. The standard was dissolved and diluted to volume with purified water. After mixing, a 2.0-ml aliquot was pipetted into a 250-ml beaker.

**Commercial Product Preparation**—Sufficient sample to contain the equivalent of 20 mg of pilocarpine hydrochloride was pipetted into a 250-ml beaker.

**Standard Curve Preparation**—Aqueous stock solutions of pilocarpine and isopilocarpine were prepared similarly to those already described, and appropriate volumes were pipetted into 250-ml beakers. The resulting concentrations of the optical rotation solutions ranged from 0.35 to 1.04 mg/ml for the pilocarpine standard curve.

The total pilocarpine–isopilocarpine concentration of the combined solutions was 0.68 mg/ml. Again, the pilocarpine and isopilocarpine concentrations varied inversely (at intervals of 25%).

**Standard Addition Sample Preparation**—A series of pilocarpine nitrate samples containing ~17 mg as pilocarpine free base was prepared. Isopilocarpine nitrate was added to the pilocarpine solutions in intervals of 2%. The amount of isopilocarpine in the standard addition samples ranged from 2 to 10%.

**Procedure**—Six milliliters of pH 5.8 buffer was added to each standard and sample in the 250-ml beakers and thoroughly mixed. Approximately 12 g of acid-washed diatomaceous earth was added to each beaker and mixed well by stirring with a spatula. The contents of each beaker were transferred into separate glass chromatographic columns containing a pledget of glass wool at the bottom. Each beaker was then dry washed with ~3 g of acid-washed diatomaceous earth, which was also transferred to the columns. Another pledget of glass wool was placed at the top of each column. The contents of the columns were packed by gentle tapping, and the carpines were eluted with 200 ml of water-washed chloroform into separate 250-ml separators containing 25.0 ml of 0.1 *M* HCl. The separators were then vigorously shaken for 1 min.

The optical rotations of the acid layers and a 0.1 *M* HCl blank were measured at 254 nm, using a mercury vapor lamp. The optical rotation of the blank was subtracted from all other optical rotation measurements. Two milliliters of each optical rotation solution was then accurately diluted to 100.0 ml with 0.1 *M* HCl. The UV absorbance of these solutions was measured at the peak maximum (215 nm) by scanning from 245 to 205 nm after the spectrophotometer was zeroed at 215 nm with a 0.1 *M* HCl blank. Pilocarpine and isopilocarpine concentrations, as percent label pilocarpine, were calculated using the following:

$$C_p = (R/a_p - 0.165A/e_p)/0.835 \quad \text{(Eq. 1a)}$$

$$\%\ \text{label pilocarpoine} = 100\ C_p/C_t \quad \text{(Eq. 1b)}$$

$$\text{isopilocarpine (expressed as \% label pilocarpine)} = 100\ (AC_{std}/A_{std}C_t) - \%\ \text{label pilocarpine} \quad \text{(Eq. 1c)}$$

where all concentrations are those of the optical rotation solutions, in milligrams per milliliter, and:

$C_p$ = calculated pilocarpine concentration in sample
$R$ = degrees of optical rotation of sample
$a_p = R_{std}/C_{std}$
$R_{std}$ = degrees of optical rotation of standard
$C_{std}$ = pilocarpine concentration in standard
$A$ = absorbance of sample
$e_p = A_{std}/C_{std}$
$A_{std}$ = absorbance of standard
$C_t$ = theoretical pilocarpine concentration in sample

## RESULTS AND DISCUSSION

**Optical Rotation**—Pilocarpine and isopilocarpine both have the same molar absorptivity at their absorbance maximum of 215 nm, *i.e.*, $\log \epsilon = 3.77$ (19). Although both compounds rotate light in a positive manner in aqueous solution at 254 nm, pilocarpine exhibits a larger optical rotation than isopilcarpine. These two physical characteristics form the basis for the present analytical method.

**Table I—Analysis of Isopilocarpine at Levels Commonly Found in Pilocarpine Ophthalmic Solutions**

| Theoretical Pilocarpine, % | Experimental Pilocarpine, % | Theoretical Isopilocarpine, % | Experimental Isopilocarpine, % |
|---|---|---|---|
| 98.0 | 97.9, 98.0 | 2.0 | 2.2, 3.1 |
| 96.0 | 95.7, 95.3 | 4.0 | 4.0, 4.5 |
| 94.4 | 94.1, 93.9 | 5.6 | 6.2, 6.6 |
| 92.3 | 92.3, 90.9 | 7.7 | 7.9, 8.1 |
| 90.5 | 90.6, 90.6 | 9.5 | 9.6, 8.6 |

Three sets of aqueous standards, containing either pilocarpine, isopilocarpine, or a mixture of both, were prepared, and the optical rotations were measured. A least-squares analysis of the optical rotation *versus* concentration gave a correlation coefficient for pilocarpine of 1.0000 and a $y$ intercept of −0.0018°. The relative standard deviation was 1.01%, and the slope was 1.330°/mg/ml. The correlation coefficient for the isopilocarpine data was 0.9993, and the $y$ intercept was 0.0012°. The relative standard deviation was 2.07%, and the slope was 0.219°/mg/ml. The optical rotations of the pilocarpine and isopilocarpine solutions were additive, and the observed optical rotations of the pilocarpine–isopilocarpine mixtures agreed well with predicted values (99.2 ± 0.9%)[7].

**Calculations**—Equations for determining the pilocarpine and isopilocarpine content of the solutions were derived based on the UV and optical rotation measurements of pilocarpine and isopilocarpine standards. The derivations are as follows:

$$R = R_p + R_i \quad \text{(Eq. 2a)}$$

$$R = a_pC_p + a_iC_i \quad \text{(Eq. 2b)}$$

At a constant temperature and wavelength:

$$ya_p = a_i \quad \text{(Eq. 3)}$$

From the slopes of the pilocarpine and isopilocarpine optical rotation curves:

$$a_p = 1.330°/\text{mg/ml} \quad \text{(Eq. 4a)}$$

$$a_i = 0.219°/\text{mg/ml} \quad \text{(Eq. 4b)}$$

So:

$$y = a_i/a_p = 0.219/1.330 = 0.165 \quad \text{(Eq. 5)}$$

Thus:

$$R = a_p(C_p + 0.165C_i) \quad \text{(Eq. 6)}$$

Since:

$$A = A_p + A_i \quad \text{(Eq. 7)}$$

And then:

$$A = e_pC_p + e_iC_i \quad \text{(Eq. 8)}$$

Since:

$$e_p = e_i \quad \text{(Eq. 9)}$$

$$A = e_p(C_p + C_i) \quad \text{(Eq. 10)}$$

$$C_i = (A/e_p) - C_p \quad \text{(Eq. 11)}$$

So:

$$R = a_p[C_p + 0.165(A/e_p - C_p)] \quad \text{(Eq. 12a)}$$

$$R = a_p(C_p + 0.165A/e_p - 0.165C_p) \quad \text{(Eq. 12b)}$$

$$R = a_p[C_p(1 - 0.165) + 0.165A/e_p] \quad \text{(Eq. 12c)}$$

Therefore:

$$C_p = (R/a_p - 0.165A/e_p)/0.835 \quad \text{(Eq. 13)}$$

and:

$$\%\ \text{label pilocarpine} = 100\ C_p/C_t \quad \text{(Eq. 14)}$$

Isopilocarpine, expressed as percent label pilocarpine, equals the concentration of total carpine as determined by UV analysis after elution

[7] Mean ± *SD*.

Table II—Determination of Pilocarpine and Isopilocarpine in Commercially Available Pilocarpine Ophthalmic Solutions

| Sample Concentration as Hydrochloride, % | Pilocarpine Analysis[a], % | | | Isopilocarpine Analysis[a], % | |
|---|---|---|---|---|---|
| | UV–Polarimetry | HPLC[b] | USP[c] | UV–Polarimetry | HPLC[c] |
| 2 | 97, 99 | 98, 99 | 99, 99 | 0.0, 1.0 | 0.9, 1.0 |
| 1 | 96, 95 | 94, 96 | 95, 96 | 2.7, 4.4 | 1.4, 1.4 |
| 2 | 99, 100 | 102, 101 | 103, 104 | 3.7, 3.9 | 3.7, 3.6 |
| 2 | 99, 98 | 101, 100 | 100, 98 | 0.0, 0.8 | 0.7, 0.8 |

[a] Percent label as pilocarpine salt. [b] Reference 18. [c] The USP procedure is the colorimetric method described in Ref. 8.

from the column, minus the pilocarpine concentration as already determined:

isopilocarpine, as % label pilocarpine

$$= 100\,(AC_{std}/A_{std}C_t) - \%\text{ label pilocarpine} \quad \text{(Eq. 15)}$$

where all concentrations are those of the optical rotation solutions, in milligrams per milliliter, subscripts $p$ refer to pilocarpine, subscripts $i$ refer to isopilocarpine, and:

$R$ = degrees of optical rotation
$a = R/C$
$C$ = sample concentration
$e = A/C$
$A$ = absorbance
$C_{std}$ = pilocarpine concentration in standard
$A_{std}$ = absorbance of standard
$C_t$ = theoretical pilocarpine concentration in sample.

The pilocarpic acid concentration can then be calculated by subtracting the total carpine concentration from the total imidazole concentration, which can be obtained without chromatographic separation from the direct UV comparison of sample and standard dilutions. All concentrations in this calculation are expressed as percent label pilocarpine.

**Analysis of Pilocarpine and Isopilocarpine**—Pilocarpine standard solutions with concentrations of 0.007–0.021 mg/ml (0.34–1.04 mg/ml for the optical rotation concentrations) were analyzed by this procedure. A least-squares analysis of the absorbance plotted *versus* the concentration gave a correlation coefficient of 0.9996 and a $y$ intercept of 0.014 absorbance unit. The relative standard deviation was 2.16%. The average log $\epsilon$ was 3.77, which agreed well with the published value (19). The correlation coefficient for the optical rotation plotted *versus* concentration was 0.9999 with a $y$ intercept of −0.0071°, and the relative standard deviation was 0.48%. Complete elution of pilocarpine from the column was indicated by the good agreement of the observed optical rotation values with the predicted optical rotation values (102.0 ± 0.5%)[7].

A standard curve containing known mixtures of pilocarpine and isopilocarpine was evaluated using USP reference standard pilocarpine nitrate as the standard. The concentration of pilocarpine and isopilocarpine ranged inversely from 0 to 100% at intervals of 25%. The results showed that the method was specific for pilocarpine and isopilocarpine in the presence of each other; the experimental values agreed within 3% of the theoretical percent label.

A series of pilocarpine samples was analyzed after making standard additions of isopilocarpine ranging in concentration from 2 to 10% of the amount of pilocarpine present. The results showed that isopilocarpine can be analyzed accurately at levels commonly found in pilocarpine ophthalmic solutions. The results for pilocarpine and isopilocarpine were within 1% of the theoretical amount present (Table I).

Eluting the pilocarpine solutions through an acid-washed diatomaceous earth column with chloroform leaves methylcellulose (7) and most other interfering excipients of commercially available ophthalmic solutions, as well as pilocarpic and isopilocarpic acids (carpic acids) and pilocarpate and isopilocarpate ions (carpate ions), on the column. The pH 5.8 phosphate buffer prevents pilocarpine protonation, which, in turn, ensures that it will not be retained by the column. The retention of carpic acids and carpate ions by the column was confirmed by analyzing a sodium hydroxide-hydrolyzed solution of pilocarpine hydrochloride by NMR spectrometry (2) and the described UV–optical rotation method. This method detected 13% pilocarpine and 49% isopilocarpine, equal to 62% total carpines. NMR analysis detected 60% total carpines (pilocarpine plus isopilocarpine) and 40% total carpate ions. The results from these two methods were consistent and confirmed that carpic acids and carpate ions are not eluted from the column.

**Analysis of Commercially Available Pilocarpine Solutions**—Commercially available pilocarpine ophthalmic solutions were analyzed by the described method, a normal-phase HPLC method (18), and the USP colorimetric method (9). These solutions contained excipients commonly found in ophthalmic formulations such as benzalkonium chloride, chlorobutanol, disodium edetate, sodium acetate, citric acid, boric acid, menthol, camphor, and hydroxypropyl methylcellulose. Overall, the results of the UV–polarimetric method were in good agreement with the results from the HPLC and USP colorimetric methods. With the described procedure, the total pilocarpine and isopilocarpine content of the formulations approximately equaled the value obtained by the nonspecific USP colorimetric method, as expected (Table II). Thus, this method exhibits specificity and appears to be an improved analytical procedure for pilocarpine in ophthalmic solutions.

The only inconsistent results among the three methods were obtained on a 2% pilocarpine nitrate formulation containing polyvinyl alcohol and chlorobutanol. Average pilocarpine percent label values of 106, 94, and 127% were obtained for the UV–polarimetry, HPLC, and USP methods, respectively. The UV–polarimetry and HPLC methods produced average results for isopilocarpine of 2.0 and 1.2% label, respectively.

# Interspecies Difference in Drug Protein Binding–Temperature and Protein Concentration Dependency: Effect on Calculation of Effective Protein Fraction

YASUTAKA IGARI *x, YUICHI SUGIYAMA *, SHOJI AWAZU ‡, and MANABU HANANO *

Received November 13, 1979, from the *Faculty of Pharmaceutical Sciences, University of Tokyo, Bunkyo-ku, Tokyo, Japan, and the ‡Division of Biopharmacy, Tokyo College of Pharmacy, Horinouchi, Hachioji-shi, Tokyo, Japan. Accepted for publication March 2, 1981.

**Abstract** □ The effects of temperature and protein concentration on the binding of thiopental to bovine and rat serum albumin and to rat plasma were examined using flow and equilibrium dialysis techniques. The effects of temperature and protein concentration were peculiar to each species. The binding of thiopental to rat serum albumin or rat plasma was sensitive to temperatures between 4 and 37°, whereas the binding to bovine serum albumin was sensitive to a protein concentration difference of 0.1–4.44%. Therefore, the effective protein fraction is affected by various sets of binding parameters of albumins determined under various temperatures and protein concentrations. Thus, a semipredictive method for plasma or tissue binding may be unsuccessful unless proper binding parameters are used.

**Keyphrases** □ Thiopental—effects of temperature and protein concentration on plasma and tissue binding, interspecies differences □ Effective protein fraction—effects of temperature and protein concentration, interspecies differences □ Drug protein binding—effects of temperature and protein concentration, interspecies differences □ Dialysis—equilibrium and flow techniques, effects of temperature and protein concentration on plasma and tissue binding, interspecies differences

Drug protein binding has an important role in drug distribution, disposition, and excretion. Numerous reports have dealt with drug protein binding under various conditions of drug level, protein concentration, and temperature. Some authors (1–3) adopted experimental conditions different from physiological ones, such as a lower temperature or lower plasma protein concentration. In addition, they discussed *in vivo* situations based on the inadequate experimental data obtained in this way.

## BACKGROUND

Recently, important critical information on these points was reported (4–6). Shen and Gibaldi (6) provided significant criticism on a previous report (7) that dealt with the application of *in vitro* drug protein binding data to the prediction of an *in vivo* situation utilizing a physiologically based pharmacokinetic model. To construct a physiologically based pharmacokinetic model, both tissue and plasma protein binding are important. However, tissue and organs are not as accessible as plasma for the determination of drug protein binding.

Dedrick and Bischoff (7) proposed the concept of the effective protein fraction to depict tissue binding, taking into consideration that little information was available on the binding of barbiturates to tissues. They calculated effective protein fractions based on the binding data of various rabbit organ homogenates at an initial drug concentration of 0.5 m*M* using the binding parameters (8) of 1% bovine serum albumin for barbiturates. However, Shen and Gibaldi (6) concluded that the use of the effective protein fraction in developing pharmacokinetic models for drug distribution might not be feasible for the following reasons:

1. Binding parameters were assumed to be constant over the concentration range of both bovine serum albumin and rabbit organ homogenate.
2. Interspecies differences were not considered.

Nevertheless, since the concept of the effective protein fraction is useful for the prediction of drug distribution in tissues where there is a shortage of information on tissue binding, the effects of protein concentration and temperature on drug protein binding were studied here using bovine and rat serum albumin and rat plasma. By considering these effects and interspecies differences, a semipredictive method for plasma protein or tissue binding was tested by measuring binding levels in plasma or a homogenized tissue sample.

Thiopental, which was studied previously (6, 7), was chosen as the model drug for the present study. Flow dialysis was used to assess protein binding of thiopental to bovine and rat serum albumin and rat plasma, while equilibrium dialysis was used for the rat plasma and homogenized rat tissue samples.

## EXPERIMENTAL

**Chemicals**—Rat serum albumin[1] and bovine serum albumin[2] were Fraction V powder. Stock albumin solutions were prepared by dissolving serum albumin powder in 0.05 *M* tromethamine buffer (I) adjusted to pH 7.4 with hydrochloric acid. Thiopental sodium[3] was prepared fresh daily.

**Quantitation of Thiopental**—Standards were carried through the entire procedure. A previous method (9) was used with slight modification (*i.e.*, dual-wavelength measurement[4] and *n*-heptane were employed). The recoveries from extraction were >90% and linear within the concentration range used.

**Rat Plasma and Tissue Sample**—Plasma was obtained by centrifuging, 30 min after intravenous injection of heparin, the fresh blood of a male Wistar rat (250–300 g) fed a normal laboratory diet. After the body was perfused with cold saline, the muscle was excised, rinsed in ice-cold saline, blotted, weighed, cut into small pieces, and homogenized by a motor-driven polytef glass homogenizer in 0.05 *M* I to yield 25% (w/v) homogenate. Rat plasma and homogenized muscle sample were predialyzed through cellulose dialysis tubing against 100 volumes of I at pH 7.4 for 18–24 hr at 4° with stirring. Little volume change was found during predialysis.

**Dialysis**—Flow dialysis of serum albumin solutions and rat plasma were carried out according to a reported method (10) using I at pH 7.4. Flow rates of I were 25 ml/hr at 37° and 12 ml/hr at 4°, respectively. Thiopental permeability through cellulose dialysis membrane remained almost constant before and after each experiment, which was checked by carrying out dialysis using I at pH 7.4 instead of protein solution.

Equilibrium dialyses of rat plasma and homogenized rat tissue samples were carried out according to the method of Sugiyama *et al.* (11) using I at pH 7.4. Equilibrium was established by 12 hr of dialysis at 37° and by 24 hr of dialysis at 4°, respectively. Equilibrium dialyses of homogenized tissue were carried out only at 4°.

**Data Analysis**—Results from binding experiments presented in Figs. 1–4 were subjected to curve fitting to Eq. 1 by a digital computer program (12):

$$r = \frac{n_1 k_1 C_f}{1 + k_1 C_f} + \frac{n_2 k_2 C_f}{1 + k_2 C_f} \qquad \text{(Eq. 1)}$$

where $k_1$ and $k_2$ are the association constants corresponding to $n_1$ and $n_2$, the number of primary and secondary binding sites; $C_f$ is the free drug concentration, and $r$ is the molar ratio of the bound drug to the binding protein assuming a molecular weight of 69,000. Results from binding experiments presented in Figs. 5 and 6 were subjected to curve fitting to Eq. 2 by means of a digital computer program (12). Data were weighted with the reciprocals of their variance:

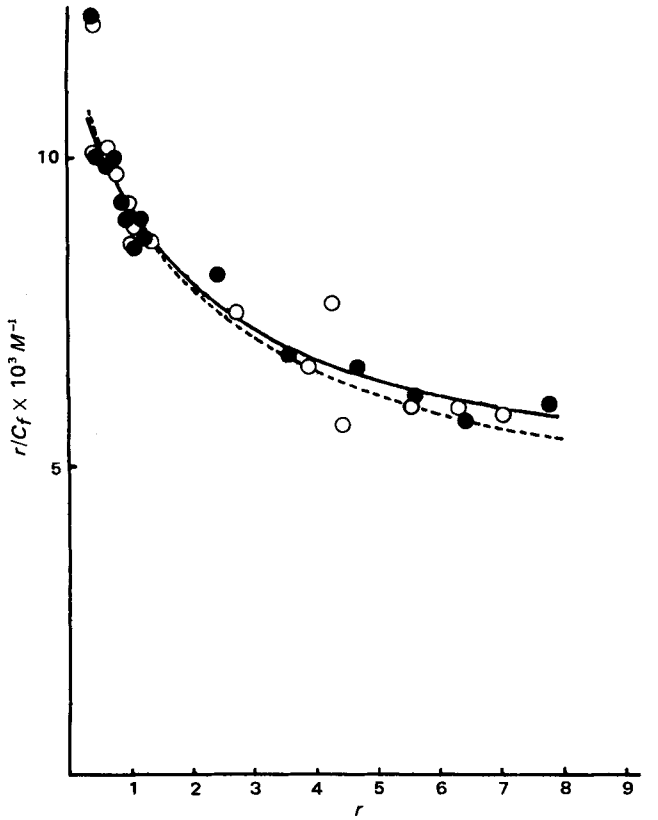

**Figure 1**—*Effect of temperature on thiopental binding to 1% (w/v) bovine serum albumin in 0.05* M *tromethamine buffer at pH 7.4 by flow dialysis [4° (●) and 37° (○)]. Each point represents the mean of three experiments. The smooth curves at 37° (- - -) and 4° (—) are the best fit to these data using the predetermined values for the number of sites* $n_1 = 1.0$ *and* $n_2 = 83.4$.

$$C_b = \frac{n_1(P)k_1C_f}{1 + k_1C_f} + \frac{n_2(P)k_2C_f}{1 + k_2C_f} \qquad \text{(Eq. 2)}$$

where $(P)$ is the protein concentration and $C_b$ is the bound drug concentration in plasma or tissue homogenates. Value $n_1(P)$ or $n_2(P)$ is presumed to be the composite parameter.

The $n_1$ and $n_2$ values obtained from experiments using each protein source at various protein concentrations and temperatures were averaged and constrained, and revised sets of $k_1$ and $k_2$ values were derived corresponding to the constrained average $\bar{n}_1$ and $\bar{n}_2$ values according to a previous report (5).

## RESULTS

**Comparison of Two Dialysis Methods**—Figure 5 displays, in the form of a Scatchard plot, the binding of thiopental to rat plasma at 4° assessed by flow and equilibrium dialyses. At low thiopental concentrations, there was a slight difference in binding, probably due to the sensitivity limit of the analytical technique, especially in the flow dialysis experiment. (Flow dialysis was employed mainly for the advantages of reduced incubation time and smaller volume of protein sample compared to equilibrium dialysis.)

**Thiopental Binding to Bovine Serum Albumin**—The effects of temperature and protein concentration on thiopental binding to bovine serum albumin were examined. As shown in Fig. 1, there was little, if any, temperature dependency of thiopental binding to 1% (w/v) bovine serum albumin between 4 and 37°, especially at low thiopental concentrations. Thiopental binding to 1 and 4% (w/v) bovine serum albumin at 37° is shown in Fig. 2. At low thiopental concentrations, there was a protein concentration dependency of thiopental binding to bovine serum albumin. In addition, thiopental binding to a range of bovine serum albumin at an initial thiopental concentration of 1 m$M$ was examined (Fig. 2, inset). This relationship resembles that presented previously (6). Thus, it seems that bovine serum albumin is sensitive to albumin concentration and practically insensitive to temperatures between 4 and 37°.

**Thiopental Binding to Rat Plasma**—Figure 6 presents the data on thiopental binding to undiluted rat plasma at 4 and 37°. Figure 7 represents thiopental binding to undiluted rat plasma and 50 and 25% (v/v) diluted rat plasma at 37°. These data imply that the characteristics of thiopental binding to rat plasma are contrary to those of bovine serum albumin, *i.e.*, very sensitive to temperatures between 4 and 37° and practically insensitive to protein concentration within at least a fourfold dilution of rat plasma.

**Table I—Thiopental Binding to Rat Serum Albumin and Bovine Serum Albumin**

| Serum Albumin Concentration | Temperature | $k_1$[a] | $k_2$[a] | $n_1$[b] | $n_2$[b] |
|---|---|---|---|---|---|
| Rat | | | | | |
| 1% (w/v) | 4° | 40.9 | 1.31 | 1.0[c] | 8.0[c] |
| 1% (w/v) | 37° | 19.4 | 0.806 | 1.0[c] | 8.0[c] |
| 4% (w/v) | 37° | 20.1 | 0.990 | 1.0[c] | 8.0[c] |
| Bovine | | | | | |
| 1% (w/v) | 4° | 5.84 | 0.068 | 1.0[c] | 83.4[d] |
| 1% (w/v) | 37° | 6.31 | 0.0654 | 1.0[c] | 83.4[d] |
| 4% (w/v) | 37° | 1.62 | 0.636 | 1.0 | 11.6 |

[a] Association constant ($\times 10^3\ M^{-1}$). [b] The number of binding sites. [c] Predetermined and constrained (see text).

**Thiopental Binding to Rat Serum Albumin**—Thiopental binding to 1 and 4% (w/v) rat serum albumin and to 1% (w/v) rat serum albumin at 4 and 37° is shown in Figs. 3 and 4, respectively. These data suggest similar binding characteristics of rat serum albumin to those of rat plasma, *i.e.*, sensitive to temperatures between 4 and 37° and practically insensitive to protein concentrations between 1 and 4% (w/v).

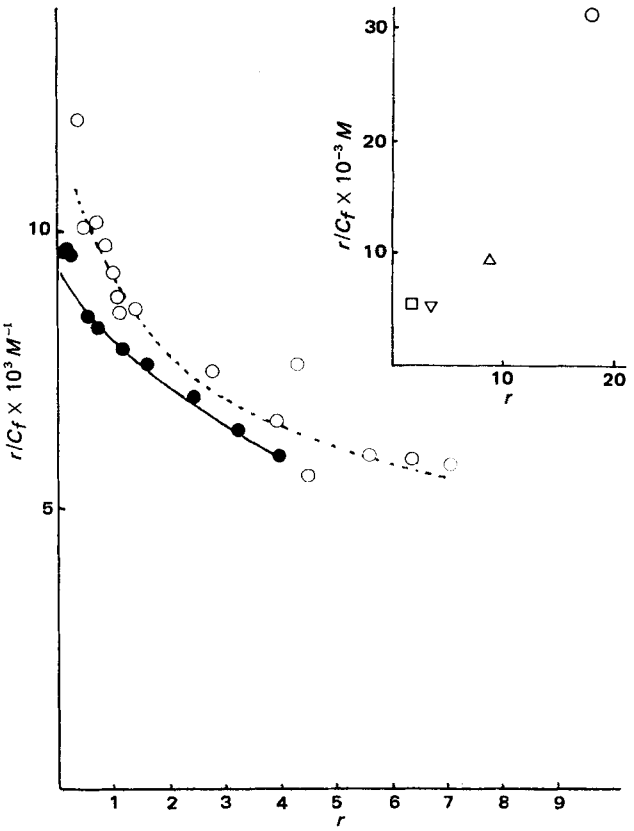

**Figure 2**—*Effect of protein concentration on thiopental binding to bovine serum albumin in 0.05* M *tromethamine buffer at pH 7.4 and 37° by flow dialysis [1% w/v (○) and 4% w/v (●)]. Each point represents the mean of three experiments. The data points and the smooth curve for 1% (w/v) bovine serum albumin are the same as those in Fig. 1. The smooth curve for 4% (w/v) bovine serum albumin (—) is the best fit to these data. [Inset: Scatchard plot for the binding of a single thiopental concentration (1 m*M*) to a bovine serum albumin concentration range in 0.05* M *tromethamine buffer at pH 7.4 and 37° by flow dialysis. Each data point represents the mean of two experiments. Key: ○, 0.1% (w/v); △, 0.5% (w/v); ▽, 1.74% (w/v); and □, 4.44% (w/v)].*

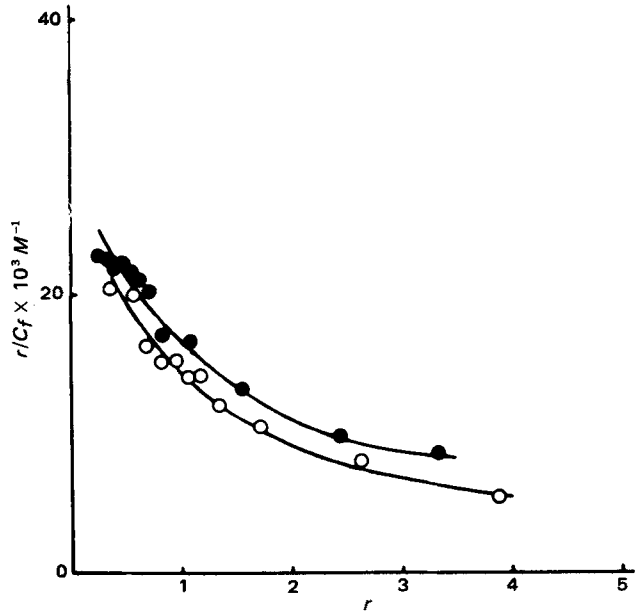

**Figure 3**—*Effect of protein concentration on thiopental binding to rat serum albumin at 37° in 0.05* M *tromethamine buffer at pH 7.4 [1% w/v (○) and 4% w/v (●)]. Each point represents the mean of three experiments. The smooth curves are the best fit to these data using the predetermined values for the number of sites* $n_1 = 1.0$ *and* $n_2 = 8.0$. *Flow dialysis was used.*

**Binding Parameters**—For the binding parameters of thiopental binding to rat serum albumin of 1% (w/v) at 4 and 37° and of 4% (w/v) at 37°, $n_1$ and $n_2$ values first were calculated without constraint and then averaged ($\bar{n}_1 = 1.0 \pm 0.221$ and $\bar{n}_2 = 8.0 \pm 3.52$). Then a revised set of $k_1$ and $k_2$ values was derived for each experiment corresponding to the constrained $\bar{n}_1$ and $\bar{n}_2$ values. In this way, the values for the number of binding sites were predetermined and constrained. The binding data for thiopental to rat plasma were analyzed in the same manner as for rat serum albumin [$\bar{n}_1(P) = 0.136 \pm 0.0251$ and $\bar{n}_2(P) = 2.42 \pm 1.12$ (m$M$)]. However, for bovine serum albumin, because of protein concentration-dependent binding, the constrained average $\bar{n}_1$ and $\bar{n}_2$ values were not proper for deriving revised sets of $k_1$ and $k_2$ values since the residual sum of squares became significantly larger than that derived without constraint. Therefore, the binding data of thiopental to 1% (w/v) bovine serum albumin at 4 and 37° were analyzed in the same manner as for rat serum albumin [$\bar{n}_1$ = 1.0(1.57 and 0.431) and $\bar{n}_2$ = 83.4(101.0 and 65.8)]

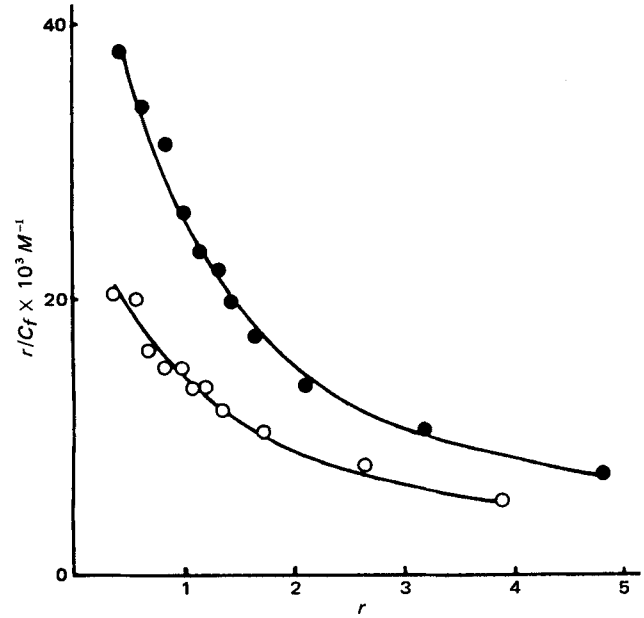

**Figure 4**—*Effect of temperature on thiopental binding to 1% (w/v) rat serum albumin in 0.05* M *tromethamine buffer at pH 7.4 by flow dialysis [4° (●) and 37° (○)]. Each point represents the mean of three experiments. The smooth curves are the best fit using the predetermined values for the number of sites* $n_1 = 1.0$ *and* $n_2 = 8.0$. *Flow dialysis was used.*

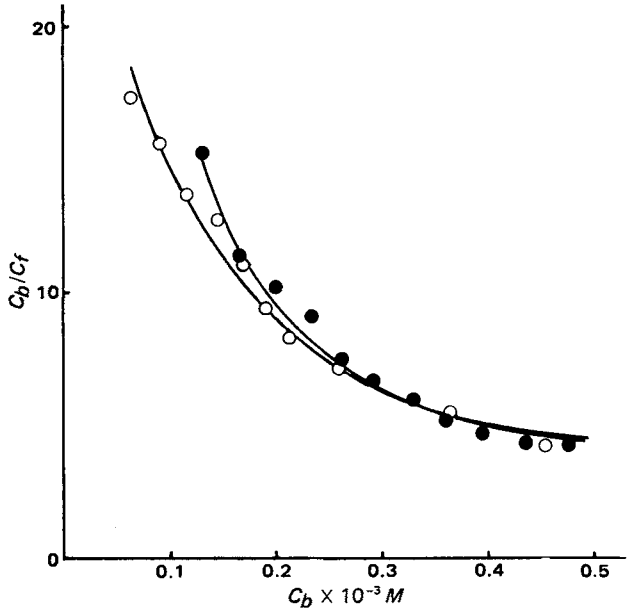

**Figure 5**—*Scatchard plots for the binding of thiopental to rat plasma at 4° by flow dialysis (●) and equilibrium dialysis (○). Each point represents the mean of three experiments. The smooth curves are the best fit to these data using the predetermined values for the binding capacities [*$n_1(P) = 0.136$ *and* $n_2(P) = 2.42$ *(m*M*)].*

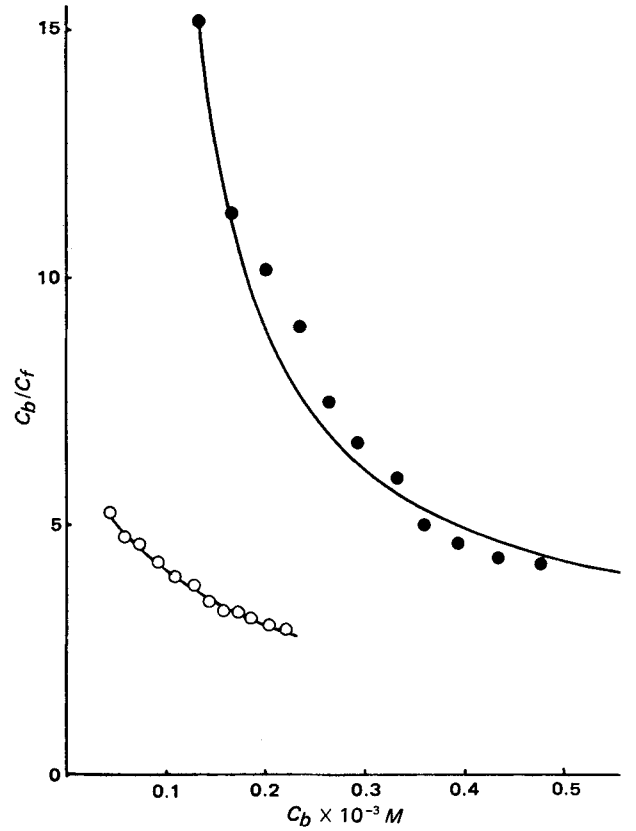

**Figure 6**—*Effect of temperature on thiopental binding to rat plasma by flow dialysis [4° (●) and 37° (○)]. Each point represents the mean of three experiments. The smooth curves are the best fit to these data using the predetermined values for the number of sites [*$n_1(P) = 0.136$ *and* $n_2(P) = 2.42$ *(m*M*)]. The smooth curve and the data points for rat plasma at 4° are the same as those in Fig. 5.*

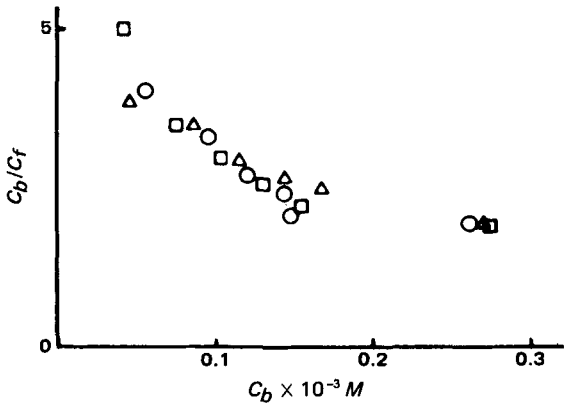

**Figure 7**—*Scatchard plots for the binding of thiopental to rat plasma at 37° by flow dialysis. Key: ○, 25% (v/v); △, 50% (v/v); and □, undiluted. Diluted rat plasma was prepared by adding 0.05 M tromethamine buffer at pH 7.4. Dilution factors of 2 for 50% (v/v) and 4 for 25% (v/v) rat plasma were corrected respectively. Each point represents the mean of three experiments.*

and then revised sets of $k_1$ and $k_2$ values were derived corresponding to the constrained average $\bar{n}_1$ and $\bar{n}_2$ values.

For the binding data for thiopental to bovine serum albumin of 4% (w/v) at 37°, $n_1$ was assigned a value of 1.0, obtained from the data analysis of the other two experimental results of bovine serum albumin. Then a revised set of $n_2$, $k_1$, and $k_2$ values was derived corresponding to the constrained $n_1$ value since $n_1$ became negative without constraining. The residual sum of squares was not significantly larger than the residual sum of squares in the other cases. The results are summarized in Tables I and II.

**Prediction of Tissue Binding Utilizing Binding Parameters of Serum Albumin**—Dedrick and Bischoff (7) proposed the concept of effective protein fraction using the binding parameters of 1% bovine serum albumin and the bound fraction of rabbit organ homogenates at an initial drug concentration of 0.5 m$M$ previously reported (8). In the absence of additional information, Dedrick and Bischoff (7) combined these data to express thiopental content in various tissues as:

$$C_t = (1 - f_p)C_f + f_p X \qquad \text{(Eq. 3)}$$

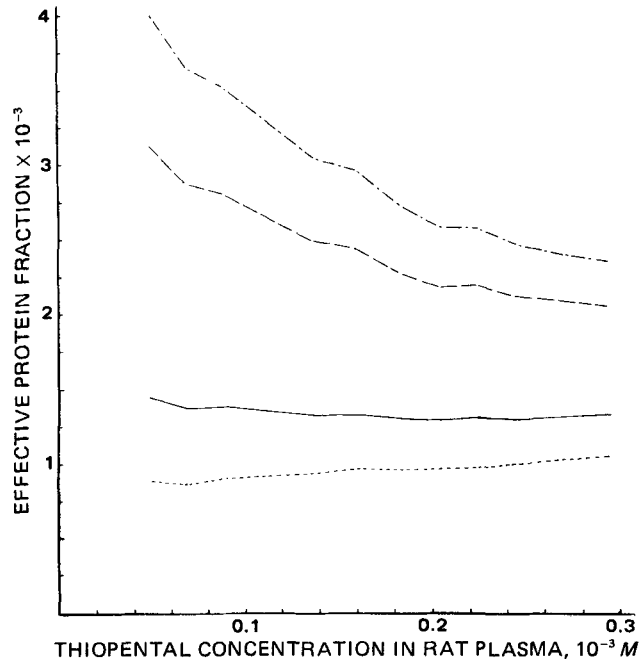

**Figure 8**—*Total thiopental concentration in rat plasma* versus *effective protein fractions* ($f_p$) *calculated according to Eq. 3 using the binding parameters of 4% (w/v) rat serum albumin at 37° (—), 1% (w/v) rat serum albumin at 4° (- - -), 4% (w/v) bovine serum albumin at 37° (- - -), and 1% (w/v) bovine serum albumin at 37° (– –).*

**Table II—Thiopental Binding to Rat Plasma** [a]

| Temperature | Dialysis | $k_1$ [b] | $k_2$ [b] |
|---|---|---|---|
| 37° | Flow | 32.8 | 0.686 |
| 4° | Flow | 320.6 | 1.57 |
| 4° | Equilibrium | 173.3 | 1.65 |

[a] The binding capacity, predetermined and constrained (see text), was $n_1(P)$ = 0.136 and $n_2(P)$ = 2.42 (m$M$) in all cases. [b] Association constant ($\times 10^3\ M^{-1}$).

where $C_t$ is the total drug concentration [assumed to be present initially in rabbit organ homogenate, *i.e.*, 0.5 m$M$ (7)], $C_f$ is the free drug concentration, $X$ is the bound drug concentration described using the binding parameters of 1% bovine serum albumin in the form of Eq. 1, and $f_p$ is a dimensionless parameter of the effective protein fraction.

Thus, the values of the effective protein fraction for tissues were calculated at an initial drug concentration of 0.5 m$M$, but the assumption (7) that the values of the effective protein fraction were constant at all drug concentrations has not been proved. In the present study, comparable precise information on plasma and tissue binding were available, so the relationship between the effective protein fraction and the drug concentration was investigated. Figure 8 displays the $f_p$ values calculated according to Eq. 3 at various thiopental concentrations in rat plasma. The $f_p$ values based on the binding parameters of other than 4% (w/v) rat serum albumin at 37° proved to be dependent on thiopental concentrations in rat plasma. In particular, the binding parameters of bovine serum albumin gave decreasing $f_p$ values with increasing thiopental concentrations in rat plasma. Hence, a $f_p$ value calculated at one thiopental concentration in rat plasma could not readily be extrapolated to another. However, since the concept of the effective protein fraction is useful only when little information is available, the predicted thiopental binding to rat plasma or tissue homogenate based on a single $f_p$ value and on the binding parameters of serum albumin was compared with the observed data.

Figure 9 shows the simulation curves calculated according to Eq. 3 using the $f_p$ values at thiopental concentrations of 0.160 m$M$ in rat plasma (A) and 0.391 m$M$ in muscle homogenate (B). As can be expected from the results shown in Fig. 8, the simulated curves based on the binding parameters other than 4% rat serum albumin at 37° diverted slightly from the observed data (Fig. 9A). In Fig. 9B, the simulated curves based on the binding parameters of bovine serum albumin rather than of rat serum albumin seem to give better prediction for rat muscle homogenate thiopental binding. However, at low thiopental concentrations (those of pharmacological interest), a single $f_p$ value can give good prediction with both serum albumins. Therefore, the effective protein fraction should be calculated from the bound fraction of plasma or tissue homogenate samples measured within a drug concentration range (especially free drug concentration) of pharmacological interest. The $f_p$ value calculated at a pharmacologically meaningless drug concentration will give a wrong prediction when compared to the observed data for meaningful concentrations (Fig. 9B inset) and may lead to failure in construction of physiologically based pharmacokinetic models.

## DISCUSSION

As already pointed out (6), extrapolation of thiopental binding data for one concentration of bovine serum albumin to another will produce errors because of protein concentration-dependent binding. Thus, in the present study, the values of effective protein fractions (Fig. 8) decreased 42% for 4% bovine serum albumin and 35% for 1% bovine serum albumin with increasing thiopental concentrations in rat plasma. Similar results were obtained by calculating the values of effective protein fractions from the binding data of salicylate to human plasma (13) as well as the binding parameters of salicylate to human serum albumin (14). The calculated values of effective protein fractions of 1% human serum albumin at salicylate concentrations of 100 and 300 μg/ml were nearly equal, but the effective protein fractions of 0.1% human serum albumin changed twofold. If it is assumed that the association constants of 0.1% human serum albumin are equal to those of 1% human serum albumin, the effective protein fractions of 0.1% human serum albumin become nearly equal at 100 and 300 μg/ml of salicylate. Thus, the effects of protein concentration-dependent drug protein binding on the calculation of effective protein fraction will be ascribed to the change of association constants and/or the number of binding sites. Therefore, protein concentration-dependent drug protein binding greatly affects the effective protein fraction.

The present study shows that there was little, if any, temperature effect

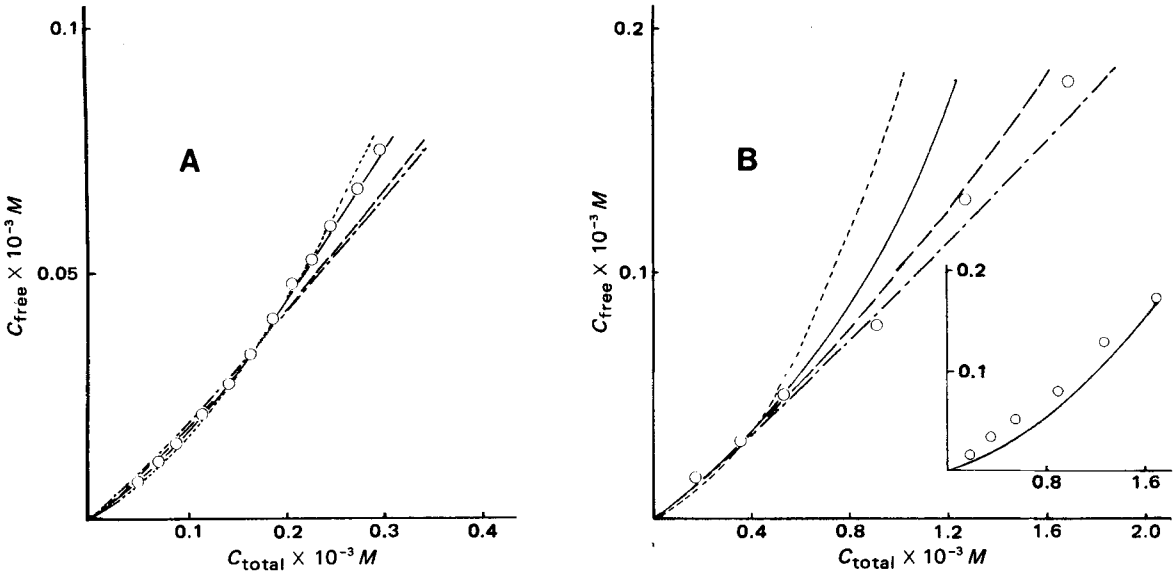

**Figure 9**—*Simulation curves calculated according to Eq. 3 using the $f_p$ values for thiopental concentration of 0.160 mM in rat plasma (A) and of 0.391 mM in muscle homogenate (B) and the binding parameters of 4% rat serum albumin at 37° (—), 1% rat serum albumin at 4° (- - -), 4% bovine serum albumin at 37° (- - - -), and 1% bovine serum albumin at 37° (– –). Each point (○) represents the mean of three experiments. [B, inset: simulation curves calculated according to Eq. 3 using the binding parameters of 4% rat serum albumin and the $f_p$ values for thiopental concentrations of 0.391 mM ($f_p$ = 0.00357) and 1.86 mM ($f_p$ = 0.00534).]*

on thiopental binding to bovine serum albumin but that temperature greatly affected thiopental binding to rat serum albumin and rat plasma. As shown in Fig. 8, because of the temperature effect on thiopental binding to rat serum albumin, the binding parameters obtained at 4° different from body temperature gave concentration-dependent effective protein fractions. Similar results are expected for the binding of salicylate to human serum albumin (5) whose association constants are highly dependent on temperature.

The binding parameters of rat serum albumin gave a better fit to the observed rat plasma binding data than those of bovine serum albumin (Figs. 8 and 9A). The binding parameters of bovine serum albumin gave a better fit to the observed muscle homogenate binding data than those of rat serum albumin (Fig. 9B). Thus, interspecies and tissue differences in drug protein binding (other than temperature and protein concentration effects) should be considered.

The concept of the effective protein fraction is not applicable to the *in vivo* situation when there is a significant protein concentration effect on drug tissue homogenate binding or when the binding profile of the tissue homogenate differs greatly from that of serum albumin. Furthermore, the homogenated tissue sample does not always reflect the *in vivo* situation. The concept of the effective protein fraction is not a perfect method for predicting tissue binding. However, since it is difficult to measure tissue binding in a direct and perfect manner at present, appropriate use of the effective protein fraction will facilitate the development of useful physiologically based pharmacokinetic models.

Consequently, *in vitro* binding experiments for predicting *in vivo* situations would be best performed at approximate body temperature, using physiological protein levels, and at free drug concentrations in the pharmacologically useful range. In addition, interspecies differences in drug protein binding should be considered.

# Nitroglycerin Pharmacokinetics after Intravenous Infusion in Normal Subjects

E. F. McNIFF *, A. YACOBI ‡, F. M. YOUNG-CHANG §, L. H. GOLDEN §, A. GOLDFARB §, and HO-LEUNG FUNG *x

Received December 8, 1980, from the *Department of Pharmaceutics, State University of New York at Buffalo, Amherst, NY 14260, the ‡American Critical Care, McGaw Park, IL 60085, and the §Millard Fillmore Hospital, Gates Circle, Buffalo, NY 14209. Accepted for publication March 2, 1981.

**Abstract** □ The purpose of this investigation was to examine the pharmacokinetics of nitroglycerin in normal volunteers after intravenous drug administration. Eight subjects (including one subject on two occasions) received a dose of ~0.6 mg iv of nitroglycerin at a rate of 18 μg/min. Plasma concentrations of intact drug during and after the infusion were determined using a GLC method. Intra- and intersubject variability in nitroglycerin plasma kinetics was substantial. Generally, however, plasma nitroglycerin disposition was characterized by: (*a*) a large apparent plasma clearance (0.3–1 liter/min/kg), (*b*) a large volume of distribution (~3 liters/kg), and (*c*) a rapid plasma half-life (~3 min). From the apparent volume of distribution obtained, plasma drug can be estimated to account for only ~1.3% of total drug in the body. Minor fluctuations in tissue distribution, which can be produced by a myriad of external and internal stimuli, could cause dramatic fluctuation in plasma nitroglycerin concentrations and, hence, in the calculated pharmacokinetic parameters. For example, in two subjects studied, plasma nitroglycerin concentrations oscillated to such an extent that pharmacokinetic analysis could not be performed. In some subjects, steady-state concentrations were not observed in spite of the apparent short plasma half-life, and rebound in plasma concentrations during the postinfusion phase were evident. These phenomena were also observed in other kinetic studies involving organic nitrates.

**Keyphrases** □ Nitroglycerin—pharmacokinetics, intravenous infusion in normal subjects □ Pharmacokinetics—nitroglycerin, intravenous infusion in normal subjects □ Vasodilators—nitroglycerin, pharmacokinetics, intravenous infusion in normal subjects

Sublingual nitroglycerin has been used extensively for the relief of acute attacks of angina pectoris. Recently, intravenous nitroglycerin was shown to be effective in patients with congestive heart failure following myocardial infarction, for the treatment of coronary artery spasm in patients with variant forms of angina, for the reduction of arterial hypertension during coronary artery bypass, and for the induction of controlled hypotension during surgery.

## BACKGROUND

Although the hemodynamic response to nitroglycerin infusion has been studied extensively, little is known about nitroglycerin pharmacokinetics. Wei and Reid (1) reported plasma nitroglycerin concentrations in patients receiving intravenous infusions, but their data were limited to measurements of single plasma concentrations obtained after a 1-hr infusion. Recently, Armstrong *et al.* (2) studied nitroglycerin pharmacokinetics from arterial blood samples in patients with congestive cardiac failure. Their pharmacokinetic calculations of clearance and the volume of distribution also were based on one steady-state nitroglycerin concentration obtained at the time of the maximum infusion rate. Data was not presented to confirm that steady state was indeed achieved.

Nitroglycerin is known to have a high affinity for plastic materials used in intravenous infusion bags and administration sets (3–5). A significant fraction of the dose can be lost to the delivery system during intravenous nitroglycerin infusion, thus leading to significant errors in the estimation of pharmacokinetic parameters. Since the available literature on nitroglycerin kinetics (1, 2) does not make explicit reference to this factor, pharmacokinetic parameters generated from these reports may be subject to additional degrees of uncertainty.

The present investigation examined the pharmacokinetics of intravenously administered nitroglycerin in normal subjects. Methodological problems were avoided by preequilibrating the infusion administration sets with nitroglycerin solution and determining the actual dose infused into each subject directly from the nitroglycerin concentration in the infusion solution immediately before and after drug administration. Plasma nitroglycerin concentrations were determined during and after infusion. Additionally, noninvasive hemodynamic parameters were monitored during the study.

## EXPERIMENTAL

Eight healthy, nonsmoking, male adult volunteers underwent normal screening for vital signs, ECG, and laboratory parameters. Exclusion criteria included: (*a*) history of abnormalities of the cardiovascular, renal, or hepatic systems, blood, GI tract, or endocrine organs or any other significant disease state; (*b*) drug addiction including chronic marijuana use or alcoholism; and (*c*) chronic use of any medication.

**Screening for Nitroglycerin Hypersensitivity**—Prior to the study and at least 1 week before receiving the nitroglycerin infusion, each subject was prescreened for nitroglycerin hypersensitivity. This screening was done by sublingual administration of 0.15-mg doses of nitroglycerin[1] at 0, 7.5, 15.0, and 22.5 min for a total dose of 0.6 mg. Subjects who did not show any adverse reactions or nitrate hypersensitivity were included.

**Preparation of Infusion Solutions**—Nitroglycerin[2] was supplied in 10-ml ampuls containing 5 mg of nitroglycerin in a buffered solution of 10% ethanol. Five milliliters of this solution was added to 100 ml of normal saline (0.9%) in a glass intravenous container just prior to use.

**Saturation of Infusion Tubing**—Nitroglycerin adsorption to the infusion tubing was minimized by using a short length of tubing and preinfusion to saturate adsorption sites. The infusion solution was drawn first into a 50-ml glass syringe, which then was connected with the infusion tubing[3]. With an infusion pump[4], 10 ml was infused through the tubing at a rate of 0.382 ml/min, which then was increased to 0.764 ml/min until an additional 4 ml flowed through the tubing. The final 2 ml from this preinfusion procedure was collected for drug content assay (preinfusion sample). Following completion of the infusion into the subject, another 2-ml sample of the infusion solution was collected (postinfusion sample). The concentration of nitroglycerin in these two samples was compared with a sample taken directly from the glass intravenous bottle.

**Drug Administration**—Nitroglycerin solution was infused into a peripheral forearm vein through a polytef catheter[5] at a flow rate of 0.764 ml/min for 32 min. The nitroglycerin concentration in the infusion solutions was ~22 μg/ml, and the infusion rate was ~18 μg/min. The actual rate and the total amount of nitroglycerin administered to each subject were calculated from the assayed concentration of the infusion solutions.

**Blood Samples**—Disposable plastic syringes, previously determined not to cause drug loss (5), were used to draw blood samples through a peripheral vein cannula[5] in the arm not used for infusion. Following blood withdrawal, the cannula was flushed with heparin (100 U/ml) in 0.9% sodium chloride. Samples (5 ml) were drawn at 0 (just prior to infusion), 10, 20, 32, 34, 36, 38, 42, 47, 52, 62, and 77 min. Following transfer to silanized glass culture tubes and immediate centrifugation, the plasma was

separated and placed on ice until transported to the assay laboratory for storage at −20°. Sample analysis was performed as soon as possible and generally no later than 1 month after collection. These collection and storage conditions previously were shown to preserve nitroglycerin adequately (6).

**Hemodynamic Monitoring**—To ensure subject safety, hemodynamic status was determined periodically throughout the study. Blood pressure was determined by sphygmomanometry, and heart rate was measured manually or by an ECG monitoring device.

**Assay**—Plasma samples were assayed in duplicate according to a previously reported (7) GLC procedure. To increase sensitivity, the volumes of the plasma sample and the extraction solvent were increased to 0.5 ml. Caprylene was the internal standard. Recovery of nitroglycerin (~90%) was not affected by this modification.

A kinetic assay procedure (8, 9) was used to measure the nitroglycerin concentration of the infusion solutions.

**Calculations**—The actual infusion rate ($k_0$) for each subject was obtained by multiplication of the flow rate (0.764 ml/min) by the average of the nitroglycerin concentration in the preinfusion and postinfusion samples. In instances where no postinfusion sample was taken, the preinfusion concentration was used. The product of $k_0$ and the infusion time (32 min) yielded the total dose of nitroglycerin administered to each subject. Rebound in nitroglycerin plasma concentration occurred in several subjects, usually 10–20 min after infusion was terminated.

Estimates of pharmacokinetic parameters were obtained by using only those postinfusion data points that decreased in concentration chronologically. The elimination rate constant ($K$) was estimated by linear regression of the postinfusion log nitroglycerin plasma concentration *versus* time plot under such conditions. The area under the plasma nitroglycerin concentration *versus* time curve during the infusion period ($AUC_{0-32}$) was obtained using the spline method on a desk-top computer[6]. The postinfusion area ($AUC_{32-\infty}$) was computed by dividing the plasma nitroglycerin concentration at 32 min ($C_{32}$) by the estimated elimination rate constant. The total area then was obtained from the sum:

$$AUC_{0-\infty} = AUC_{0-32} + AUC_{32-\infty} \quad \text{(Eq. 1)}$$

The apparent systemic clearance ($Cl_s$) was calculated from:

$$Cl_s = \frac{\text{dose}}{AUC_{0-\infty}} \quad \text{(Eq. 2)}$$

and the apparent volume of distribution ($V_d$) was computed as:

$$V_d = \frac{Cl_s}{K} \quad \text{(Eq. 3)}$$

An additional estimate of the systemic clearance of nitroglycerin was obtained from:

$$Cl_s^* = \frac{k_0}{C_{32}} \quad \text{(Eq. 4)}$$

## RESULTS

An *in vitro* experiment was conducted to determine whether the adopted regimen for the saturation of the infusion tubing was adequate in delivering a constant nitroglycerin concentration during dosing. Figure 1 shows the results of two separate runs in which the infusion systems were presaturated as described and the concentration of nitroglycerin emerging from the infusion system during a simulated infusion was determined as a function of time. It is apparent that the procedure produced a relatively stable effluent nitroglycerin concentration during the 32 min of infusion. The infusion concentration calculated from the mean of the preinfusion and postinfusion samples appeared to represent the actual infusion concentration adequately. The mean of the absolute difference

[a] Number in parentheses represents total body clearance ($Cl_s$ × body weight), liters per minute.

of each sample concentration from the calculated infusion concentration was 2.8 and 4.1% for Runs 1 and 2, respectively.

Nitroglycerin concentrations in the infusion bottle, preinfusion, and postinfusion samples are shown in Table I. Analysis of variance (one way) showed that there was no statistical difference ($p > 0.35$) between these concentrations. Thus, the infusion system was apparently saturated with respect to adsorption, and the administered dose can be estimated from the infusion concentrations as described.

Subject 1 experienced nausea and fainting after the test sublingual doses were administered and was excused from the intravenous study. Subject 2 was not affected by the sublingual doses but was so nervous during the intravenous study that blood samples could not be easily withdrawn. No pharmacokinetic data were obtained from this subject.

Subjects 3–10 completed the study without any undesirable effects. Subject 5 was studied twice, separated by a period of 4 months. Intersubject variability in plasma nitroglycerin concentrations was quite large. Based on the shape of the plasma nitroglycerin concentration *versus* time profile, the data can be conveniently divided into three groups. Group A included three profiles (Fig. 2) in which steady-state nitroglycerin concentration was apparently achieved. Group B consisted of four profiles (Fig. 3) in which no steady state was apparent. Group C included two profiles (Fig. 4) in which plasma nitroglycerin concentrations were fluctuating erratically such that pharmacokinetic analysis was impossible.

Table II summarizes the individual data and the estimated pharmacokinetic parameters. The systemic clearance values were calculated according to both Eqs. 2 and 4. When an apparent steady state in plasma concentration was achieved during the infusion period, the two methods yielded essentially identical values. When an apparent steady state was not achieved, the value calculated by dose/$AUC$ was always larger than that obtained by $k_0/C_{32}$. Irrespective of the calculation method, the systemic nitroglycerin clearance was extremely rapid (~0.3–1 liter/min/kg). The apparent volume of distribution at 3.3 liters/kg also was high. Since plasma volume is ~42 ml/kg (10), the apparent volume of distribution for nitroglycerin was ~80 times the plasma volume.

Except in Subjects 6 and 10, nitroglycerin elimination was rapid; an average half-life of ~3 min was observed. In several subjects, an apparent rebound in plasma nitroglycerin concentration occurred at ~15 min after the infusion was stopped (Figs. 2–4). Fortunately, this phenomenon occurred generally after the washout elimination phase had gone through two or three apparent half-lives. Thus, pharmacokinetic analysis of the remaining infusion data could be performed without these later time points.

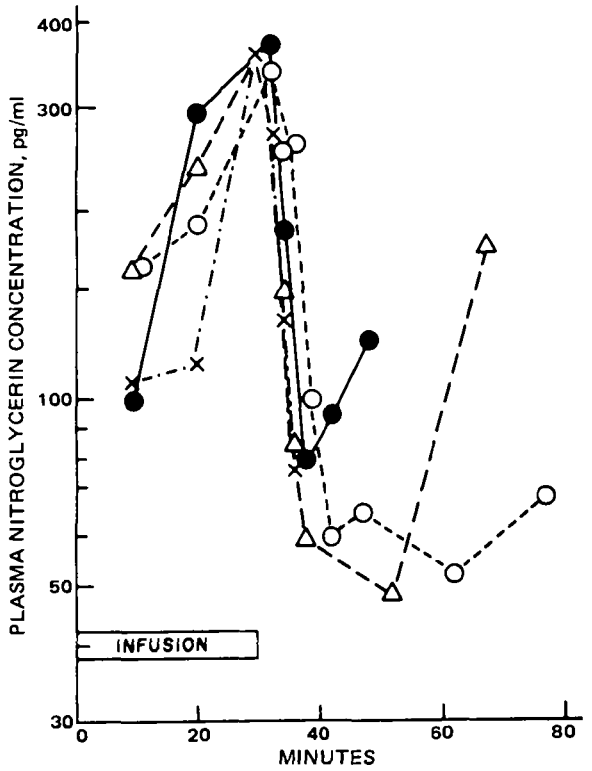

**Figure 3**—*Plasma nitroglycerin concentrations after intravenous administration to Subjects 3 (●), 4 (○), 5A (△), and 9 (×).*

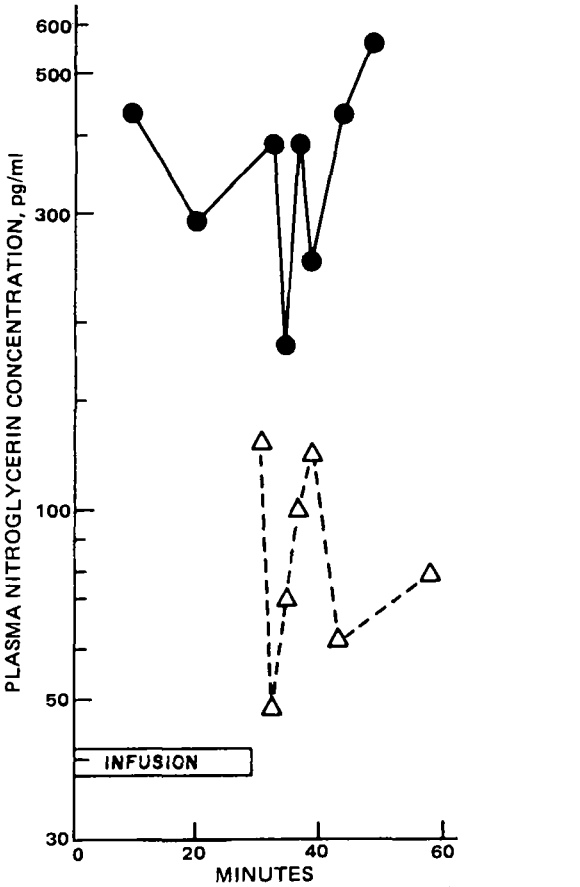

**Figure 4**—*Plasma nitroglycerin concentrations after intravenous administration to Subjects 6 (●) and 10 (△).*

**Table III—Mean Heart Rate and Systolic and Diastolic Blood Pressure in Seven Normal Subjects [a] following Intravenous Infusion of 0.6 mg of Nitroglycerin during 30 min**

| Parameter | Mean | *SD* |
|---|---|---|
| Heart rate per minute | | |
| Preinfusion, control | 67.7 | 14.0 |
| Postinfusion, maximum | 75.4 | 14.9 |
| Postinfusion, minimum | 61.4 | 11.1 |
| Systolic blood pressure, mm/Hg | | |
| Preinfusion, control | 117.1 | 20.6 |
| Postinfusion, maximum | 118.7 | 16.8 |
| Postinfusion, minimum | 106.0 | 15.3 |
| Diastolic blood pressure, mm/Hg | | |
| Preinfusion, control | 76.6 | 10.4 |
| Postinfusion, maximum | 80.3 | 8.8 |
| Postinfusion, minimum | 72.6 | 9.3 |

[a] In two subjects, these parameters were monitored but not reported.

In the early part of this study, the cannula used for infusion was removed from the subjects as soon as possible. This step was taken ~15 min after cessation of the infusion. Initial data analysis suggested that removal of the cannula might be coincidental with the rebound in plasma drug concentrations. It was reasoned that manipulation of the cannula during removal might cause disturbance and release of tissue bound drug near the infusion site or of a small volume of infusion solution from the cannula into plasma, resulting in transient increases in plasma nitroglycerin concentrations. To test this hypothesis, Subject 5 was used again and Subjects 9 and 10 were studied without disturbing the infusion cannula during the entire postinfusion sampling period. Inspection of the respective plasma concentration profiles indicates that this procedure had no apparent effect. In fact, Subject 10 was one of the two subjects whose plasma kinetics showed the most fluctuation. In cases where the infusion cannula remained in place during the postinfusion sampling period, no postinfusion sample of the dosing solution was collected.

The dose infused (0.6 mg over 0.5 hr) did not produce any significant changes in heart rate or systolic and diastolic blood pressures in the subjects (Table III).

## DISCUSSION

Plasma nitroglycerin kinetics are characterized by rapid disappearance and an apparently large plasma clearance. The plasma half-life of nitroglycerin determined from this study (2.8 ± 0.9 min, mean ± *SD*) is in good agreement with values reported by Armstrong *et al.* (2, 11) for arterial samples after intravenous administration (1.9 min) and after sublingual nitroglycerin dosing (4.4 min). Recently, these authors also reported (12) a half-life of *in vitro* nitroglycerin degradation in human blood of ~6 min at 37°. Therefore, *in vivo* blood (plasma) elimination of nitroglycerin is at least a result of both blood degradation and organ metabolism, the latter most probably by the liver (13).

The apparent plasma clearance determined in this study ranged from 0.31 to 1.03 liters/min/kg, corresponding to values of total body clearance of 29.8–78.3 liters/min. Although there are some methodological differences among this study and previous ones (1, 2), the apparent systemic clearance values determined from each of the three studies were all quite high (Table IV).

The data of Armstrong *et al.* (2) require some additional comments. These authors utilized arterial samples, and preliminary reports (14, 15) suggested that arterial nitroglycerin concentrations might be substantially higher than those found in peripheral veins. The somewhat lower systemic clearance values obtained by these authors are consistent with this suggestion. In addition, their patients were classified into two groups. Patients in Group 1 were generally responsive to hemodynamic management with nitroglycerin infusion, while those in Group 2 seemed to be refractory to nitroglycerin treatment. Group 1 patients received a lower infusion rate than patients in Group 2 (15–94 *versus* 59–440 μg/min, respectively) and showed higher ($p < 0.005$) systemic clearances (13.8 *versus* 3.6 liters/min, respectively). Based on the infusion rate, it is perhaps more appropriate to compare results from the normal subjects in the present study with those of Group 1 patients from the previous study.

Substantial intersubject variability in nitroglycerin kinetics was observed in the present study. The plasma nitroglycerin concentrations of Subjects 5B (second trial), 7, and 8 seemed to reach apparent steady state during the 32-min infusion. The good agreement obtained between $Cl_s$ values calculated from Eqs. 2 and 4 confirmed that steady state was achieved. The average clearance from these three subjects was 0.45 liter/min/kg, which agreed well with a value of 28 liters/min (0.4 liter/min/kg assuming an average body weight of 70 kg) reported previously (11) following sublingual nitroglycerin administration.

In contrast, the plasma nitroglycerin concentrations of Subjects 3, 4, 5A (first trial), and 9 did not approach apparent steady-state values. In these cases, the clearance value estimated with the *AUC* was much larger than that calculated using $k_0/C_{32}$ and also larger than that found with the first group. This result suggests that a significant portion of the area may be unaccounted for in these subjects. The estimated plasma half-lives in these subjects, however, were not dissimilar from those found with the first group, nor were they substantially different from values of 4.4 min reported after sublingual nitroglycerin (11) and of 1.9 min in arterial samples (2) after intravenous infusion. Nevertheless, a terminal disposition phase that is below the present limits of detection possibly may exist. The presence of a prolonged $\beta$-phase is consistent with the lack of attainment of steady-state plasma concentrations in these subjects. However, Subject 5 behaved differently in two separate trials: in the first trial (5A), steady state was achieved while in the second trial (5B), it was not. This information suggests that plasma nitroglycerin kinetics could vary substantially.

By using the apparent clearance values obtained, an apparent volume of distribution of 3.3 ± 1.2 liters/kg (mean ± *SD*) can be estimated. By using a plasma volume of 42 ml/kg (10), the amount of nitroglycerin residing in the plasma compartment can account for 1.3% of the total body load. Minor fluctuations in nitroglycerin content in the nonplasma (tissue) compartment, which may result from a host of internal and external stimuli, could cause dramatic fluctuations in plasma nitroglycerin concentrations. In Subjects 6 and 10, such wide fluctuations in plasma nitroglycerin concentrations occurred that no pharmacokinetic analysis was possible. Coincidentally, there was difficulty in placing the intravenous catheter in these two subjects. It is interesting to speculate that the release of endogenous substances after minor tissue damage may have some effect on the tissue distribution of nitroglycerin.

Although this study was not designed to examine the hemodynamic response to nitroglycerin infusion in detail, no significant change was observed in the monitored parameters. This finding is not surprising in view of the small doses and low infusion rates employed. In fact, nitroglycrin has been infused in normal subjects at rates as high as 200 μg/min with no significant adverse hemodynamic effect (16).

The observation of apparent rebound and oscillations in plasma nitrate concentrations in some subjects is not unique to this study. A similar phenomenon (17) was recently reported following intravenous infusion of isosorbide dinitrate. Because of its extensive tissue distribution, rapid plasma clearance of nitroglycerin during the postinfusion period may lead to a nonequilibrium redistribution of tissue drug back to the plasma compartment. The situation may be analogous to that observed for serum procainamide concentrations in patients immediately after hemodialysis (18). In that case, rebound and oscillations of procainamide concentra-

tions were attributed to shifts of drug into and out of various body compartments following drug clearance by hemodialysis (18).

Finally, the very large apparent plasma nitroglycerin clearance observed in this and other studies (1, 2) after intravenous administration warrants some comments. The apparent plasma clearance is not only greater than liver plasma flow but it also exceeds cardiac output. Physiologically, it is difficult to conceive how any drug can be cleared, in reality, faster than cardiac output. However, several possibilities might have led to the present experimental observation.

First, the dose actually infused into each subject was substantially less than that used in the pharmacokinetic calculation. For the apparent plasma nitroglycerin clearance to equal cardiac output [~7 liters/min for a 70-kg man at rest (19)], the dose infused would have to be ~10–25% of the dose used in calculation. This wide divergence in dose is considered unlikely because of the great care taken in the present study to minimize and account for drug adsorption in the infusion sets and because nitroglycerin concentrations emerging at the end of the infusion line were actually determined before and after infusion.

Second, there is substantial nitroglycerin degradation in the blood itself due to spontaneous hydrolysis or enzymatic breakdown. Armstrong *et al.* (12) gave a $t_{1/2}$ of 6 min for *in vitro* nitroglycerin degradation in human blood at 37°. If it can be assumed that this half-life reflects *in vivo* spontaneous blood degradation, the contribution of this process to the total apparent clearance will be $0.693/6 \times 69 \simeq 8.0$ ml/min/kg [using a blood volume of 69 ml/kg of body weight (10)], which is ~1% of the total apparent clearance (Table II). Even if the half-life of *in vivo* blood degradation is assumed to be equal to the systemic *in vivo* plasma half-life ($t_{1/2}$ = 3 min, Table II), the maximum contribution of spontaneous blood degradation to the apparent clearance will still be only ~2%.

Third, the *AUC* used in the calculation of clearance does not represent the total *AUC; i.e.*, a much longer secondary or tertiary plasma half-life exists but cannot be experimentally determined because of assay limitations. However, in the present study the plasma nitroglycerin concentrations in three subjects appeared to have reached steady state within the short infusion period of 15 min. In these subjects, a hidden and prolonged half-life probably does not exist.

Fourth, when the drug is infused into the systemic circulation, a first-pass removal process possibly may be present in the vascular bed so that the infused dose is not totally available to the systemic circulation. In other words, the vascular bed functions as a first-pass extraction tissue towards an intravenous dose of nitroglycerin in much the same way that the liver serves as a first-pass extraction organ for an oral dose. If this assumption is correct, then the apparent clearance values obtained will have to be corrected by an apparent bioavailability factor, which is less than unity. The demonstration of substantial differences in arterial *versus* venous nitroglycerin concentrations (14, 15) is not inconsistent with the hypothesis that blood vessels can clear nitroglycerin. Experiments conducted in rats (20) suggested that first-pass vessel uptake of nitroglycerin does occur. The apparent bioavailability factor, however, was not quantitated. The extent of the contribution of this phenomenon to the observed clearance value in humans also is unknown at present.

In conclusion, nitroglycerin kinetics in humans are characterized by apparent extensive tissue distribution and rapid plasma clearance. Because of these factors, plasma nitroglycerin concentrations may be subjected to high intra- and intersubject variabilities. This does not necessarily mean, however, that the effects produced by intravenous nitroglycerin also may be highly variable. Indeed, data from this laboratory (20) suggested that the presumed target tissue of nitroglycerin, the blood vessels, has a much higher concentration of drug compared to plasma. The systemic pharmacological effects of nitroglycerin may be better related to drug concentrations in the blood vessels than to those in plasma. Studies are in progress to characterize the pharmacokinetics of nitroglycerin in these presumed target tissues.

# Synthesis of *N*-Glycosylthioureas, *N*-Glycosylrhodanines, and *N*-Glycosyl-2-aminothiazoles and Their Antimicrobial Activity

**WILLIAM O. FOYE** ˣ **and SEUNG HO AN**

Received December 5, 1980, from the *Samuel M. Best Research Laboratory, Massachusetts College of Pharmacy and Allied Health Sciences, Boston, MA 02115.* Accepted for publication March 4, 1981.

**Abstract** □ A method for obtaining *N*-β-D-glucopyranosylthioureas was found in the aminolysis of *N*-(2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl)-5-aralkylidenerhodanines. Aminolysis of the triacetylated or tribenzoylated ribosylrhodanines generally did not give ribosylthioureas but resulted in glycosidic cleavage, although *N*-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)thioureas were obtained using morpholine and hydroxylamine. Ring closure of *N*-β-D-glucopyranosylthiourea with ethyl bromopyruvate gave ethyl 2-(*N*-β-D-glucopyranosyl)aminothiazole-4-carboxylate, and ammonolysis led to the corresponding 4-carboxamide. Antimicrobial screening against five microorganisms showed that *N*-(2,3,5-tri-*O*-acetyl-β-D-ribofuranosyl)rhodanine and the glucosylaminothiazole-4-carboxylate had the broadest spectrum of inhibitory activity, although the thioureas usually showed inhibition of some organisms.

**Keyphrases** □ *N*-Glycosylthioureas, rhodanines, and 2-aminothiazoles—synthesis, screened for antimicrobial activity □ Glucopyranosylthioureas—synthesis, screened for antimicrobial activity □ Antimicrobial activity—*N*-glycosylthioureas, *N*-glycosylrhodanines, and *N*-glycosyl-2-aminothiazoles

A method for obtaining *N*-β-D-glucopyranosylthiourea in good yield was previously reported (1). It involved the ammonolysis in methanol of *N*-(2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl)-5-aralkylidenerhodanines (I), resulting in deacetylation, ring cleavage, and formation of the thiourea (II). Fischer (2) synthesized tetra-*O*-acetyl-

glucopyranosylthiourea from tetra-*O*-acetylglucopyranosylisothiocyanate and ammonia and obtained the deacetylated product in good yield. Other investigators utilized the Fischer procedure to obtain deacetylated glucopyranosylthioureas but got only poor yield (3) or none at all (4). Fusion of glucose and thiourea resulted in a very low yield of glucopyranosylthiourea (5).

A logical extension of this reaction is the use of amines, in place of ammonia, to obtain *N*-substituted glucopyranosylthioureas. Such compounds have potential as antibacterial, antiviral, and anticancer agents. A number of thioureas have demonstrated activity as antiviral (6, 7) and as antibacterial–antifungal (8, 9) agents. Rhodanine and its derivatives have shown antibacterial (10) and antifungal (11) activities, as well as antiviral activity against Echovirus 12 (12) and activity as inhibitors of neuraminidases (13). To provide compounds with anticancer potential, attempts were made to prepare ribosyl derivatives of both rhodanine and the thioureas; ring closure of the glucosylthiourea to glucosylthiazoles also was performed.

## DISCUSSION

**Chemistry**—The glycosylrhodanines (I and III) were synthesized by glycosidation of 5-benzylidenerhodanine sodium salt with either 2,3,4,6-tetra-*O*-acetyl-α-D-glucopyranosyl bromide or 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl bromide in acetone or acetonitrile. Yields of 65–82% were obtained. Another procedure, particularly useful for obtaining ribosylrhodanines, involved reaction of a silylated rhodanine with either 2,3,5-tri-*O*-acetyl-β-D-ribofuranosyl bromide or 1-*O*-acetyl-2,3,5-tri-*O*-benzoyl-β-D-ribofuranose in the presence of stannic chloride. With unsubstituted rhodanine, 92 and 93% yields of the triacetyl (IV) and tribenzoyl (V) derivatives were realized, respectively; with the 5-benzylidene derivatives, 57 and 65% yields were obtained, respectively. Silylation was carried out using hexamethyldisilazane, chlorotrimethylsilane, and toluene. The glycosylation reactions are shown in Scheme I.

Aminolysis of *N*-(2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosyl)-5-benzylidenerhodanine was carried out using an excess of various amines in methanol in a pressure bottle at room temperature for 1–4 days. Yields of 41–92% of the glucosylthioureas were obtained (Table I). The by-products, α-mercaptocinnamyl amides (13) and acetamides, were separated by column chromatography where fractional recrystallization was unsuccessful. The $R_f$ values for the thioureas and the by-products are listed in Table II. Aminolysis of *N*-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)-5-benzylidenerhodanine was attempted with several amines, using the same procedure. Ribosylthioureas were not obtained, apparently because of the instability of the glycosidic linkage. In the case of morpholine, however, *N*-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)morpholine-4-thiocarboxamide (VI) was isolated. When this compound was treated with methanolic ammonia, cleavage of the glycosidic linkage was again observed, and morpholine-4-thiocarboxamide was isolated. An *N*-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)thiourea was also isolated on reaction with hydroxylamine and triethylamine, but the ethoxythiourea was the product. Aminolysis of *N*-(2,3,5-tri-*O*-acetyl-β-D-ribofuranosyl)-5-benzylidenerhodanine and *N*-(2,3,5-tri-*O*-acetyl-β-D-ribofuranosyl)rhodanine using several amines again resulted in glycosidic cleavage. Aminolyses are shown in Scheme II.

The *N*-β-D-glucopyranosylthiourea prepared from I (R = benzylidene) and methanolic ammonia was treated with ethyl bromopyruvate to give ethyl 2-(*N*-β-D-glucopyranosyl)aminothiazole-4-carboxylate (VII) in a 92% yield (Scheme III). Ammonolysis of this compound in methanol gave the corresponding 4-carboxamide (VIII).

IR spectra of the glucosylthioureas revealed broad, hydrogen-bonded hydroxyl groups at 3300–3500 $cm^{-1}$ and the appearance of NH at 1520–1570, C=S at 1060–1080, and a β-glycosidic linkage at 890–920 $cm^{-1}$. The characteristic acetylglucopyranosylrhodanine peaks at 1750 (acetyl C=O), 1675–1700 (rhodanine C=O), and 1240 (C=S) $cm^{-1}$ were absent. The PMR spectra showed an absence of acetyl hydrogens in the 1.9–2.1-ppm region. A peak for the anomeric proton appeared at 5.07–5.40 ppm ($J$ = 8–9 Hz), which also indicated a β-configuration (14). The NH

glycoside peak appeared at 7.25–8.40 ppm ($J$ = 8 Hz) and was replaceable with deuterium oxide.

The ribosylrhodanines and ribosylthioureas gave the expected IR absorptions, with benzoyl C=O stretching frequencies appearing at 1725–1730 $cm^{-1}$ for the benzoylribose compounds and acetyl C=O stretching appearing at 1750 $cm^{-1}$ for the acetyl derivatives. The C=S stretching vibration appeared at 1230–1270 $cm^{-1}$ in the rhodanine ring and at 1110–1115 $cm^{-1}$ in the thioureas. The C=O stretching vibration in the ribosylrhodanines was at 1720–1740 $cm^{-1}$, a higher frequency than that for the C=O of the 5-substituted rhodanines (1675–1700 $cm^{-1}$).

The most characteristic PMR peaks of the ribosylrhodanines were of the benzylidene CH or 5-$CH_2$ of the rhodanine ring, appearing as singlets at 7.67–7.78 or 3.90–4.19 ppm, respectively. The anomeric proton was seen as a doublet ($J$ = 2–4 Hz) at 6.15–6.77 ppm. The anomeric proton of the ribosylthioureas was found as a broad singlet at 5.80–5.86 ppm, and the NH glycosidic proton appeared at 8.40–9.10 ppm. In general, the β-glycosidic linkages of heterocyclic ribosides have been observed (15) rather than the α-forms. The three protons on C-4 and C-5 of the ribose ring overlapped as a multiplet at 3.57–4.70 ppm.

The anomeric proton of the glucosylaminothiazoles was unclear in the PMR spectrum. The NH proton appeared at 8.20 ppm ($J$ = 8 Hz), and the C-5 proton of the thiazole ring was seen as a singlet at 7.30–7.62 ppm. The methylene protons of the glucosyl moiety appeared as a multiplet at 3.50 ppm.

**Antimicrobial Activity**—Antimicrobial activities were observed by the agar plate screening method using *Staphylococcus aureus*, *Escherichia coli*, *Pseudomonas aeruginosa*, *Candida albicans*, and *Aspergillus niger*. These organisms represent a Gram-positive and two Gram-negative bacteria, a yeast, and a mold, respectively. Compounds showing some inhibitory activity were then measured by the serial tube dilution method previously described (1) to obtain minimal inhibitory concentrations (Table III).

Most prepared compounds showed inhibitory activity against *S. aureus*. All glucosylthioureas showing inhibitory activity were derived from primary amines, except those prepared from piperidine and dimethylamine, indicating that antimicrobial activity tends to decrease as the degree of substitution on the thiourea nitrogen increases.

A good percentage of the compounds were inhibitory to *C. albicans* and *A. niger*, *N*-β-D-glucopyranosyl-*N'*-butylthiourea being the most active against these organisms. Ethyl 2-(*N*-β-D-glucopyranosyl)aminothiazole-4-carboxylate showed inhibitory activity against four organisms, comparable to that from rhodanine, but not against *A. niger*. The glucosylthioureas derived from diethylamine, *N*-methylpiperazine, morpholine, and thiomorpholine did not show any antimicrobial activity. This result could be due to poor solubility, except in the case of diethylamine.

Among the ribosylrhodanines and ribosylthioureas, none of the benzoyl-protected compounds revealed any activity. *N*-(2,3,5-Tri-*O*-acetyl-β-D-ribofuranosyl)rhodanine was active against all five organisms, however, possibly because of *in vivo* hydrolysis of the acetyl groups. The corresponding 5-benzylidene derivative was active against only *S. aureus* and *C. albicans*.

The best activity of the compounds reported here was shown by *N*-(2,3,5-tri-*O*-acetyl-β-D-ribofuranosyl)rhodanine, which had comparable activity to that of rhodanine itself. Nearly as broad antimicrobial activity was found with ethyl 2-(*N*-β-D-glucopyranosyl)aminothiazole-4-carboxylate, which showed comparable activity against four organisms and slightly better activity against *S. aureus* than rhodanine itself. The thioureas generally were inhibitory against two or three of the five organisms observed.

## EXPERIMENTAL[1]

**Glucopyranosylthioureas: *N*-β-D-Glucopyranosyl-*N'*-butylthiourea** — *N*-(2,3,4,6-Tetra-*O*-acetyl-β-D-glucopyranosyl)-5-(3,4-dimethoxybenzylidene)rhodanine (1) (1 g, 0.0016 mole) was added to a solution of *n*-butylamine (1.08 g, 0.016 mole) in 50 ml of methanol in a pressure bottle. The reaction mixture was stirred at room temperature for 20 hr with the pressure bottle well closed. The mixture was filtered, and the filtrate was evaporated to dryness *in vacuo* below 30°.

The residue was dissolved in the minimum amount of acetone and stored at 5° for 18 hr. The white precipitate was filtered, washed with acetone, and dried *in vacuo* at room temperature, yielding 0.426 g (80%), mp 94–96° dec.; $[\alpha]_D^{25}$ −15.4° (*c*, 0.54); IR (KBr): 3500–3300 (OH, NH), 3100 (NH), 1550 (NH), 1080 (C=S), and 900 (β-form) $cm^{-1}$; NMR (dimethyl sulfoxide-$d_6$ + $D_2O$): δ 5.07 (d, H1, *J* = 8 Hz), 3.52 (m, 2H6), 3.17 (m, $NCH_2$), 1.40 (m, 4H, $CH_2CH_2$), and 0.96 (m, 3H, $CH_3$) ppm.

*Anal.*—Calc. for $C_{11}H_{22}N_2O_5S \cdot \frac{2}{3}(CH_3)_2CO$: C, 46.87; H, 7.83; N, 8.41; S, 9.63. Found: C, 46.40; H, 7.68; N, 8.42; S, 9.60.

**Ethyl 2-(*N*-β-D-Glucopyranosyl)aminothiazole-4-carboxylate Hydrobromide**—Ethyl bromopyruvate (8.99 g, 0.047 mole) was added to a suspension of *N*-β-D-glucopyranosylthiourea (10 g, 0.042 mole) in 120 ml of hot ethanol, and the mixture was heated for 30 min. The resulting solution was evaporated to dryness *in vacuo*, and the residue was crystallized from ethanol–acetone, filtered, and dried *in vacuo* at room temperature, yielding 16.03 g (91.9%) of white powder, mp 162–163° dec.; $[\alpha]_D^{25}$ −48.4° (*c*, 1.1); IR (KBr): 3500–3300 (OH, NH), 3160 (NH), 1725 (C=O), 1090 (β-ring), and 895 (β-form) $cm^{-1}$; NMR (dimethyl sulfoxide-$d_6$): δ 7.62 (s, H5), 6.09 (bs, OH, NH), 4.24 (q, $CH_2$), 3.51 (m, 2H6′), and 1.30 (t, $CH_3$) ppm.

*Anal.*—Calc. for $C_{12}H_{18}N_2O_7S \cdot HBr$: C, 34.71; H, 4.61; N, 6.75; S, 7.72. Found: C, 34.88; H, 4.71; N, 6.72; S, 7.92.

**2- (*N*-β-D-Glucopyranosyl)aminothiazole-4-carboxamide**—Ethyl 2-(*N*-β-D-glucopyranosyl)aminothiazole-4-carboxylate hydrobromide (4.15 g, 0.01 mole) was added to a solution of methanol (50 ml) saturated with ammonia at 0° in a pressure bottle. The mixture was stirred at room temperature for 48 hr in the stoppered bottle and then evaporated to dryness *in vacuo*. The residue was mixed with a small amount of ethyl acetate and chromatographed on a silica gel column (2.54 × 20 cm) using acetone as the first solvent (300 ml) and methanol as the second (300 ml).

The methanol effluent was concentrated to 75 ml, and ethyl acetate (500 ml) was added. The creamy-yellow precipitate was filtered and dried *in vacuo* at room temperature, yielding 2.77 g (76%), mp 96° dec.; $[\alpha]_D^{25}$ −22.2° (*c*, 1.4); IR (KBr): 3500–3300 (OH, NH), 1660 (NH), 1080 (β-ring), and 895 (β-form) $cm^{-1}$; NMR (dimethyl sulfoxide-$d_6$): δ 8.20 (d, NH, *J* = 8 Hz), 7.30 (s, H5), and 3.50 (m, 2H6′) ppm.

*Anal.*—Calc. for $C_{10}H_{15}N_3O_6S \cdot 2H_2O \cdot \frac{1}{2}C_2H_5OH$: C, 36.26; H, 6.09; N, 11.53; S, 8.80. Found: C, 36.41; H, 5.72; N, 11.92; S, 8.84.

***N*-(2,3,5-Tri-*O*-acetyl-β-D-ribofuranosyl)rhodanine**—To a suspension of rhodanine (1.34 g, 0.01 mole) in toluene (25 ml), hexamethyldisilazane (4 ml, 0.02 mole) and chlorotrimethylsilane (10 ml, 0.08 mole) were added. The mixture was refluxed 2 hr with exclusion of moisture. It was filtered, and the filtrate was evaporated to a syrup *in vacuo*. A solution of 2,3,5-tri-*O*-acetyl-D-ribofuranosyl bromide (16) (3.2 g, 0.01 mole) in acetonitrile was added at 0°, along with molecular sieves (8–12 mesh, 1 g) and stannic chloride (0.29 ml, 0.0025 mole) in acetonitrile (10 ml). The mixture was stirred at 0° for 3 hr and filtered, and the filtrate was evaporated to a syrup.

This syrup was dissolved in chloroform (50 ml) and filtered. The chloroform solution was washed with 10% potassium iodide solution (50 ml) and water (50 ml). The resulting solution was dried (sodium sulfate), evaporated to a thin syrup, and dried below 25° *in vacuo*, yielding 3.61 g (92%) of amorphous material; $[\alpha]_D^{25}$ +34.9° (*c*, 1.86, chloroform); IR (KBr): 1750 (C=O), 1380 (ring $CH_2$), 1240–1220 (C=S), and 890 (β-form) $cm^{-1}$; NMR (chloroform-$d_1$): δ 6.37 (d, H1′, *J* = 3.5 Hz), 5.80 (m, H2′), 5.45 (m, H3′), 4.30 (m, 3H4′,5′), 3.95 (s, 2H5), and 2.15 (9H, s, $3CH_3$) ppm.

*Anal.*—Calc. for $C_{14}H_{17}NO_8S_2$: C, 42.96; H, 4.38; N, 3.58; S, 16.38. Found: C, 42.76; H, 4.43; N, 3.71; S, 16.08.

***N*-(2,3,5-Tri-*O*-acetyl-β-D-ribofuranosyl)-5-benzylidenerhodanine**—A solution of 1,2,3,5-tetra-*O*-acetyl-β-D-ribofuranose (3.18 g, 0.01 mole) in dry methylene chloride (20 ml) was added at −60° to dry methylene chloride (40 ml) saturated with dry hydrogen bromide. The mixture was protected from moisture and allowed to warm to room temperature. The solvent was removed *in vacuo* below 30°, and the residue was evaporated with dry toluene (20 ml).

[a] Solvent system: acetone–butanol–water (5:4:1); silica gel plate. [b] *N*-(2,3,4,6-Tetra-*O*-acetyl-β-D-glucopyranosyl)-5-benzylidenerhodanine. [c] Aluminum oxide plate. [d] $R_f$ value of amine.

[1] Melting points were determined in capillaries with a Mel-Temp block and are uncorrected. IR absorption spectra were recorded with a Perkin-Elmer 457A grating spectrophotometer. NMR spectra were determined with a Varian T60 spectrometer with tetramethylsilane as the internal standard. Optical rotations were measured with a Perkin-Elmer 241MC polarimeter and a Carl Zeiss polarimeter. Elemental analyses were performed by Dr. F. B. Strauss, Oxford, England. TLC was carried out on Eastman silica gel plates with fluorescent indicator or alumina plates. For the glycosides, an efficient solvent system was *n*-butanol–acetone–water (4:5:1).

Rhodanine, the amines, 1,2,3,5-tetra-O-acetyl-β-D-ribofuranose, 1-*O*-acetyl-2,3,5-tri-*O*-benzoyl-β-D-ribofuranose, 1,1,1,3,3,3-hexamethyldisilazane, chlorotrimethylsilane, and stannic chloride were supplied by Aldrich Chemical Co. Silica gel and alumina for column chromatography were supplied by Fisher Scientific Co. Anhydrous ammonia, hydrogen bromide, and dimethylamine were obtained from Matheson Gas Products. The amines were purified by distilling with zinc powder prior to use. Solvents were dried with 3- or 4-Å molecular sieves.

The sodium salt of 5-benzylidenerhodanine was prepared by adding 5-benzylidenerhodanine (2.21 g, 0.01 mole) to a suspension of sodium hydride (0.24 g, 0.01 mole) in anhydrous ether (40 ml) (prepared from 57% sodium hydride oil suspension by removing mineral oil with hexane under nitrogen). The mixture was stirred at room temperature until no hydrogen was evolved. The solvent was removed by evaporation, and the residue was dried *in vacuo*.

To a suspension of the sodium salt of 5-benzylidenerhodanine (2.43 g, 0.01 mole) in acetonitrile (70 ml) was added a solution of 2,3,5-tri-*O*-acetyl-D-ribofuranosyl bromide (16) (3.39 g, 0.01 mole) in acetonitrile (30 ml), followed by 7 g of molecular sieves (8–12 mesh). The mixture was stirred at room temperature for 4 days. The insoluble material was filtered and washed with acetonitrile, and the combined filtrates were evaporated *in vacuo* below 30°. The residue was dissolved in chloroform (50 ml), and the solution was washed with 10% potassium iodide solution (20 ml) and water (40 ml), dried (sodium sulfate), and evaporated to a thin syrup.

The residue was dissolved in the minimum amount of methanol and chromatographed on an alumina column (neutral, 2.54 × 20 cm) with methanol as the eluant. The fast moving component was collected (150 ml) and evaporated to dryness. The residue was dissolved in the minimum amount of 95% ethyl alcohol and stored at −20°, and the crystals were collected and dried *in vacuo* at room temperature, yielding 2.76 g (57%),

mp 89–92°; $[\alpha]_D^{25}$ −78.5° (*c*, 2.42, chloroform); IR (KBr): 1750 (C=O), 1250–1220 (C=S), 900 (β-form), and 780 (=CH) $cm^{-1}$; NMR (chloroform-$d_1$): δ 7.67 (s, =CH), 7.45 (s, 5H, aromatic), 6.52 (d, H1′, $J$ = 3 Hz), 5.95 (m, H2′), 5.65 (m, H3′), 4.35 (m, 3H4′,5′), and 2.15 (9H, s, $3CH_3$) ppm.

*Anal.*—Calc. for $C_{21}H_{21}NO_8S_2$: C, 52.60; H, 4.41; N, 2.92; S, 13.37. Found: C, 52.41; H, 4.63; N, 2.83; S, 13.23.

***N*-(2,3,5-Tri-*O*-benzoyl-β-D-ribofuranosyl)rhodanine**—To a suspension of rhodanine (0.64 g, 0.005 mole) in toluene (20 ml), hexamethyldisilazane (2 ml, 0.01 mole) and chlorotrimethylsilane (5 ml, 0.04 mole) were added. The mixture was stirred at 65° for 2 hr with exclusion of moisture. It was then filtered and evaporated to a thin syrup. A solution of 1-*O*-acetyl-2,3,4-tri-*O*-benzoyl-β-D-ribofuranose (2.52 g, 0.005 mole) in ethylene dichloride (10 ml) was added, and stannic chloride (0.44 ml, 0.0037 mole) in ethylene dichloride (10 ml) was added dropwise with stirring at 0°. The mixture was diluted with 15 ml of ethylene dichloride, and the resulting mixture was neutralized with saturated sodium bicarbonate solution (70 ml).

The emulsion was filtered over a layer of sand–diatomaceous earth, and the organic phase was separated, extracted with 10% potassium iodide solution (60 ml), washed with water (60 ml), and dried (sodium sulfate). The separated organic layer was evaporated to a semisolid below 30° and dried *in vacuo* at room temperature, yielding 2.69 g (93%); $[\alpha]_D^{25}$ −17.5° (*c*, 0.86, chloroform); IR (KBr): 1750–1720 (C=O), 1450 (ring $CH_2$), 1280–1240 (C=S), and 890 (β-form) $cm^{-1}$; NMR (chloroform-$d_1$): δ 8.00–7.10 (m, 15H, aromatic), 6.65 (d, H1′, $J$ = 3 Hz), 6.28 (m, H2′), 6.00 (m, H3′), 4.68 (m, 3H4′,5′), and 3.90 (s, 2H5) ppm.

*Anal.*—Calc. for $C_{29}H_{23}N_2O_8S$: C, 60.32; H, 4.01; N, 2.42; S, 11.10. Found: C, 60.12; H, 4.24; N, 2.26; S, 10.89.

***N*-(2,3,5-Tri-*O*-benzoyl -β- D-ribofuranosyl)-5-benzylidenerhodanine**—To a solution of 5-benzylidenerhodanine (1.77 g, 0.08 mole) in acetonitrile (50 ml) was added 2,3,5-tri-*O*-benzoyl-D-ribofuranosyl bromide (17) (4.1 g, 0.008 mole), followed by 3.2 ml of 10% NaOH. The mixture was stirred at room temperature for 6 days and then was filtered and evaporated to a semisolid *in vacuo* below 30°. The residue was triturated with methanol (15 ml) to give a yellow precipitate, which was filtered and chromatographed on alumina (neutral) with methanol as the eluant. The first effluent (100 ml) was collected and evaporated. The resulting precipitate was filtered and dried *in vacuo* at room temperature, yielding 3.46 g (65%), mp 146–148°; $[\alpha]_D^{25}$ −128.6° (*c*, 1.0, tetrahydrofuran); IR (KBr): 1730 (C=O), 1270–1250 (C=S), and 770 (=CH) $cm^{-1}$; NMR (dimethyl sulfoxide-$d_6$): δ 8.10–7.50 (m, 20H, aromatic), 7.78 (s, =CH), 6.77 (d, H1′, $J$ = 2 Hz), 6.28 (m, 2H2′,3′), and 4.70 (m, 3H4′,5′) ppm.

*Anal.*—Calc. for $C_{36}H_{27}NO_8S_2$: C, 64.95; H, 4.09; N, 2.10; S, 9.63. Found: C, 65.20; H, 4.48; N, 1.83; S, 9.82.

***N*-(2,3,5-Tri-*O*-benzoyl -β- D-ribofuranosyl)morpholine-4-thiocarboxamide**—To a suspension of *N*-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)-5-benzylidenerhodanine (3.32 g, 0.005 mole) in acetonitrile (40 ml) were added 0.5 ml of water and then morpholine (4.38 g, 0.05 mole) in small portions with stirring over 10 min. The solution was stirred at room temperature for 2 days, and a small amount of precipitate was filtered. The filtrate was evaporated to a syrup and dried *in vacuo*. The residue was dissolved in the minimum amount of acetone and chromatographed on silica gel with acetone as the eluant. The fast moving band was collected (50 ml) and evaporated to dryness *in vacuo* at room temperature, yielding 2.86 g (96%), mp 75–77°; $[\alpha]_D^{25}$ −19.5° (*c*, 2.3, chloroform); IR (KBr): 1725 (C=O), 1115 (C=S), and 880 (β-form) $cm^{-1}$; NMR (dimethyl sulfoxide-$d_6$): δ 9.10 (bs, NH), 7.70 (m, 15H, aromatic), 5.86 (bs, H1′), 3.80 (m, 2H5′), 3.68 (m, 4H, $CH_2OCH_2$), and 3.54 (m, 4H, $CH_2NCH_2$) ppm.

*Anal.*—Calc. for $C_{31}H_{30}N_2O_8S$: C, 63.04; H, 5.12; N, 4.74; S, 5.43. Found: C, 63.12; H, 5.67; N, 4.89; S, 5.64.

***N*-(2,3,5-Tri-*O*-benzoyl -β- D-ribofuranosyl)-*N*′-ethoxythiourea**—A solution of *N*-(2,3,5-tri-*O*-benzoyl-β-D-ribofuranosyl)-5-benzylidenerhodanine (1.66 g, 0.0025 mole) in acetonitrile (40 ml) was treated with pulverized hydroxylamine hydrochloride (0.7 g, 0.01 mole), and triethylamine (1.4 ml, 0.01 mole) was added dropwise with stirring over 5 min. The mixture was stirred for 1 hr, the precipitate was filtered, and the filtrate was treated with ethyl acetate (100 ml) to give a precipitate. This precipitate was filtered, and the filtrate was extracted with 0.1 *N* HCl (40 ml), water (100 ml), and saturated sodium chloride solution (50 ml). It was dried (sodium sulfate) and evaporated, and the residue was chromatographed on alumina (neutral), using 2-propanol as the first solvent (200 ml) and methanol as the second (200 ml).

The methanol effluent was evaporated to 40 ml to give a yellow precipitate, which was filtered and dried at room temperature *in vacuo*, yielding 1.32 g (93%), mp 106° dec.; $[\alpha]_D^{25}$ −13.2° (*c*, 1.1, chloroform); IR (KBr): 1725 (C=O), 1270 (C—O), and 1120 (C=S) $cm^{-1}$; NMR (chloroform-$d_1$): δ 8.40 (bs, NH), 7.88–7.30 (m, 15H, aromatic), 5.80 (bs, H1′), 4.05 (q, $CH_2$), 3.95 (m, 2H5′), and 1.14 (t, $CH_3$) ppm.

*Anal.*—Calc. for $C_{29}H_{28}N_2O_8S$: C, 61.69; H, 5.00; N, 4.96; S, 5.68. Found: C, 61.88; H, 4.76; N, 4.88; S, 5.62.

**Antimicrobial Activity**—Tests were first carried out by the agar plate method, using 20–30 mg of each compound and measuring the zones of inhibition. The organisms used were *S. aureus* (ATCC 6538), *E. coli* (ATCC 11229), *P. aeruginosa* (ATCC 15442), *C. albicans* (ATCC 10259), and *A. niger* (ATCC 1015). Portions of four or five discrete colonies of the organisms were inoculated into 10.0 ml of a suitable broth medium and streaked on agar plates. Trypticase soy agar (BBL) was used for bacteria, and Sabouraud maltose agar (BBL) was used for the yeast and mold. Incubations were at 37° for 24–48 hr for the bacteria and at 25° for 48–72 hr for the yeast and mold.

Minimum inhibitory concentrations by the serial tube dilution procedure were carried out for the compounds found active by the agar plate procedure as previously described (1). Inhibitory concentrations were expressed in moles.
