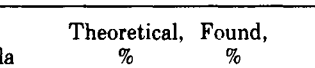
occur, followed by oxidation to 5-nitrofuroic acid. The latter is found in the urine of experimental animals (14).

It should be noted that nitrofurans are reduced in a number of bacterial enzyme systems, and a number of researchers have advanced the theory that in accepting electrons, the nitrofurans interfere with the oxidation–reduction linked metabolism of the organism. It has been suggested that nitrofurazone interferes with normal metabolism by virtue of its capacity to be reduced (15). In addition, previous authors have concluded from a study of nitrofurans, nitrothiophenes, nitrobenzenes, and related compounds, that ease of reducibility plays a major role in the antibacterial effectiveness of heterocyclic nitro compounds (16). These authors also proposed a relationship between the redox potential developed by the organism in culture and that required by the inhibitory nitrofuran, implying that interference with microbial reproduction was associated with formation of a reduction product (hydroxylamine) from the nitro compound (17). Other workers have measured these reduction potentials and confirmed these proposals (18).

It is reasonable to assume that the well-known antibacterial activity of nitrofuranyl hydrazones and the *in vitro* antitumor activity observed against mouse leukemia L-1210 may have similarities with regard to their mechanisms of action. The dramatic increase in cytotoxicity with increasing electron deficiency of the pi system in IV*i*, (see Table II) suggests that biological activity may well be associated with a reductive process. The furanyl nitro group in IV*i* should be much more readily reduced than that in IV*a*. The relationship between L-1210 cytotoxicity and electron deficiency can qualitatively be seen by examining measures of the latter, *i.e.*, the summation of the σ_p and σ_0 values for the six-membered ring substituents, and/or the methine ^1H chemical shifts (Table II). Surprisingly, the antibacterial activity of IV*i*, one of the more active compounds against L-1210, was negligible against 18 Gram-positive and Gram-negative organisms compared with nitrofurazone and nitrofurantoin. It possessed somewhat better activity against two staphylococci (64 μg/ml minimal inhibitory concentration) but not as much activity as nitrofurazone (8 μg/ml) or nitrofurantoin (16–32 μg/ml). In contrast, the cytotoxicity of IV*i* is still very high against both HeLa cells and P-388 cells. The differential activity of IV*i* in the antineoplastic and antibacterial screens could result from an inability of the compound to penetrate the bacterial cell wall. The compound is extremely insoluble and is completely inactive in an *in vivo* L-1210 screen.

Perhaps the most surprising result of this report is that 5-nitrofurancarboxaldehyde is more cytotoxic than any of the hydrazones studied (Table II). This introduces the interesting possibility that hydrazone activity may, in part, result from hydrolytic cleavage to the parent aldehyde. The variation in hydrazone cytotoxicity may, in fact, be partially related to the variable rates of hydrolytic cleavage.

Table II—Antitumor Activity and Electron Deficiency Determinations of Nitrofuranylhydrazone Compounds



R = Ar-(Y)n		L-1210 ID_{50}, μg/ml	$\Sigma\sigma$[a]	δ ppm[b] CH=N

5-nitrofurancarboxaldehyde		0.1	—	

[a] Substituent constants (σ) were obtained from Ref. 19. In calculating the sums ($\Sigma\sigma$), the assumption was made that $\sigma ortho = \sigma para$. [b] NMR spectra were obtained in dimethyl sulfoxide d_6 solution with tetramethylsilane as an internal reference. They were recorded on a JEOL MH-100 NMR spectrometer.

Toxicological studies of many nitroheterocycles have revealed a substantial mutagenic and carcinogenic liability. Since mutagenic and antibacterial modes of action are probably intimately related at the molecular level, it is unlikely that important nonmutagenic antibacterial nitroheterocycles will be found. Because most antineoplastic agents have substantial carcinogenic acitivity, a liability of this type associated with an antineoplastic nitrofuran is not severe, and the potential use of such compounds in cancer chemotherapy should not be overlooked.

Edetate Disodium-Mediated Chloramphenicol Resistance in *Pseudomonas cepacia*

P. A. NIELSEN ˣ and JO-ANN CLOSE

Received March 18, 1981, from the *Microbiology Section, Vick Divisions Research & Development, Richardson-Vicks, Inc., Mt. Vernon, NY 10553.* Accepted for publication October 16, 1981

Abstract □ The presence of edetate disodium decreased the susceptibility of a particular strain of *Pseudomonas cepacia* to chloramphenicol. The mechanism of this edetate disodium effect, which may be unique to this strain, remains obscure. Tests showed no enzymatic destruction by the microorganism of the chloramphenicol nor any chemical complexation of the antibiotic by the salt. The possibility does exist that edetate disodium alters the cell envelope or cytoplasmic membrane so as to block the transport of chloramphenicol to its site of action within the cell. This possibility is now under investigation.

Keyphrases □ Edetate disodium—mediated chloramphenicol resistance in *Pseudomonas cepacia* □ *Pseudomonas cepacia*—edetate disodium-mediated resistance □ Chloramphenicol—edetate disodium-mediated resistance in *Pseudomonas cepacia*

A house isolate (Strain 2487[1]) of *Pseudomonas cepacia* lost its normal susceptibility to chloramphenicol in the presence of edetate disodium. This was considered unusual since edetate disodium has been shown to reverse antibiotic resistance in some species of *Pseudomonas* (1), and chloramphenicol is one of the few antibiotics effective against *P. cepacia*. This report presents the results of an investigation of this phenomenon.

EXPERIMENTAL

Cultures of Strain 2487 and, for comparison, other house isolates or strains[2] were maintained on agar slants[3], incubated at 35°, and subcultured weekly. The desired concentration of sterile-filtered edetate disodium[4] was added to assay plates, either under aseptic conditions or just prior to autoclaving the media. The plates were seeded by swabbing over the agar surface in three planes 10^{-2} dilutions of cultures of the organisms as grown for 24 hr in broth[5] at 35°. Susceptibility determinations were done with disks[6] impregnated, respectively, with chloramphenicol (30 μg), colistin (10 μg), sulfisoxazole (50 μg), gentamicin (10 μg), and polymyxin B (50 μg), and applied to the surfaces of the seeded agar. These plates, in turn, were incubated for 24–48 hr at 35°, the longer period being necessary in some instances because high concentrations (0.1%) of edetate disodium slowed the growth of *P. cepacia*.

RESULTS AND DISCUSSION

The effect of edetate disodium on the activity against Strain 2487 of various antibiotics was mixed (Table I): Susceptibility to gentamicin was increased; susceptibility to chloramphenicol was decreased; and the activity of the other three agents was not altered.

The observed degree of resistance of Strain 2487 to chloramphenicol was related directly to the concentration of the salt. A linear response was obtained over a range of 0.0–0.1% of edetate disodium in the assay medium. This suggested the possibility that edetate disodium triggers the release of a substance from *P. cepacia* cells which destroys chloramphenicol or modifies the antibiotic to render it ineffective against the organism.

Accordingly, an experiment was carried out following the procedure of Miyamura (2) to determine whether edetate disodium promoted the release of a cell wall-bound enzyme such as chloramphenicol acetyltransferase which would inactivate the antibiotic, as is known to occur in other organisms (3).

Results (Table II) indicate there is present in *P. cepacia* no enzymatic inactivating mechanism for chloramphenicol. Apparently, this is not so in the case of *P. aeruginosa*; ~25–50% of the chloramphenicol was lost in the cultures of this species. This suggests, as previously reported (4), some uptake or destruction of the antibiotic.

Another possibility, that edetate disodium chelates chloramphenicol to make it unavailable to act upon *P. cepacia*, does not seem likely. In fact, additional sensitivity tests showed that edetate disodium actually enhanced the action of the antibiotic against *P. aeruginosa* and *Escherichia coli* (Table III). The data in Table III further suggest that this phenomenon may not be a uniform characteristic in *P. cepacia*. Strain 25416[2] failed to grow in the presence of edetate disodium, while another wild strain (Strain C) was essentially resistant to chloramphenicol.

In the apparent absence of enzymatic destruction or chemical complexation of chloramphenicol, the actual mechanism of the edetate disodium effect remains obscure. The possibility exists that edetate disodium chemically alters the cell envelope or cytoplasmic membrane so that transport of chloramphenicol to its point of action within the cell is blocked. More direct evidence might be obtained with the use of labeled chloramphenicol, and this is a subject for further investigation.

Detection of Phytonadione in Vegetable Oil

DAVID EMLYN HUGHES

Received March 3, 1981, from the *Analytical Chemistry Division, Norwich-Eaton Pharmaceuticals, Box 191, Norwich, NY 13815.* Accepted for publication October 13, 1981.

Abstract □ A simple detection test for phytonadione (vitamin K_1) in vegetable oil is presented. A saturated sodium ethoxide solution was used to saponify vegetable oil and react with the freed phytonadione to form a blue compound. The specificity and mechanism of the colored compound formation is discussed.

Keyphrases □ Phytonadione—detection in vegetable oil □ Vegetable oil—detection of phytonadione □ Vitamins—detection of phytonadione in vegetable oil

Although many methods are available in the literature for the determination of phytonadione in standard solutions, pharmaceuticals, and infant formulas, no simple detection procedure for phytonadione determination in oil has been reported. Detection of phytonadione in oil is of use since vegetable oil solutions of phytonadione are used in the manufacture of multivitamin preparations and elemental diets (1, 2). The present report discusses the chemical (noninstrumental) detection of phytonadione in vegetable oil and aspects of the specificity and mechanism of the reaction.

Reviews for the determination of phytonadione by gas chromatography (3), fluorometric analysis (4), and thin-layer and paper chromatography (5) are available. Circular TLC (6), thin layer silica gel impregnated with silver nitrate or paraffin (7), and more recently UV derivatization (8) and electrochemical detection (9) have been employed for phytonadione analyses. Any of the described phytonadione determinations can be used if the phytonadione is contained in hexane, petroleum ether, acetone, or ethanol standard or sample solutions. Few determinations of phytonadione in vegetable oil samples have, however, been reported.

Phytonadione in vegetable oil presents complex sample-handling problems. The lipophilic nature of phytonadione prevents easy extraction and its alkaline sensitivity prohibits saponification of the vegetable oil without destroying the vitamin (10, 11). Phytonadione is photosensitive (12). Determination of phytonadione in vegetable oil has only been accomplished after time-consuming and complex sample preparation such as reduction by Raney's nickel catalyst (13) or enzymatic hydrolysis (11), conditions not desirable for a simple detection procedure.

Quality control laboratories, and others with similar time and financial limitations, may not find the time-consuming and complex methods presented thus far satisfactory for the detection (presence or absence) of phytonadione. In nonlipid media, some simple chemical detection tests have been reported. Phytonadione may be detected visually in ethanolic solution by reaction with sodium diethyldithiocarbamate (15), or 2,4-dinitrophenylhydrazine (16). No color tests have been reported for phytonadione in vegetable oil solutions.

A procedure has been developed in which detection of phytonadione in vegetable oil is based on the blue complex formed by sodium ethoxide. The procedure differs from that described previously (14) insofar as a saturated (3.4 *N*) sodium ethoxide solution saponifies the lipid medium. The sensitivity of the test is increased by the white background provided by saponification of the vegetable oil. The saponification results in the extraction of some solvent-dissociated phytonadione, which then reacts with sodium ethoxide.

EXPERIMENTAL

Reagents—All chemicals were analytical reagent grade and were used without further purification.

Procedure—One milliliter of a safflower oil solution of phytonadione was added to 1 ml of a saturated (3.4 *N*) solution of sodium hydroxide in ethanol. After the saponification process, a solid blue mass remained. Standards (in ethanol) and samples ranged in concentration from 50–5000 μg phytonadione/ml. In samples containing ≥500 μg/ml, an intensely blue-colored solution was formed almost immediately. The color then faded to gray or brown over a 10-min period. A blank of safflower oil treated with the alkaline alcoholic solution yielded a white soap. Cotton and peanut oil samples yielded identical results. Ascorbyl palmitate and polysorbate 80 did not interfere. The procedure was then applied to 1,4-naphthoquinone, menadione, and the bromination product of phytonadione.

The standards and samples were then tested with sodium diethyldithiocarbamate and 2,4-dinitrophenylhydrazine reagents using the reported procedures (15, 16).

RESULTS AND DISCUSSION

The standard solutions reacted with sodium ethoxide, sodium diethyldithiocarbamate, and 2,4-dinitrophenylhydrazine to form the colors reported in the literature. The sensitivity was found to be satisfactory to repetitively detect (6 trials) 50-μg/ml phytonadione/ml standard with sodium ethoxide and 10-μg/ml standard with sodium diethyldithiocarbamate. The 2,4-dinitrophenylhydrazine was formed an average of 50% of the trials at the 100-μg/ml level. No further investigation of this procedure was attempted. Neither the sodium ethoxide nor diethyldithiocarbamate procedure detected phytonadione in samples.

Detection of phytonadione in vegetable oil then was attempted by

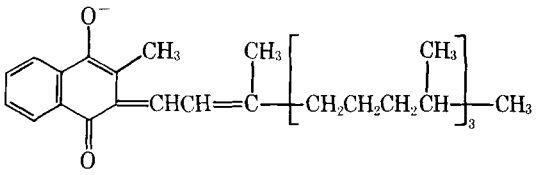
III



IV

saponification of the oil with sodium hydroxide. Potassium hydroxide did not consistently saponify the vegetable oil at room temperature. In the absence of degradation or dissolution in the saponified matrix or remaining lipid material, reaction with sodium ethoxide or sodium diethyldithiocarbamate should be possible. The sodium diethyldithiocarbamate color test was negative on all sample solutions. The limit of detectability was found to be 50 ppm for the sodium ethoxide color reaction. Of the reactions mentioned, only the sodium ethoxide reaction gave a positive test in vegetable oil, and then, only when the vegetable oil was saponified.

The specificity of the reaction of phytonadione with sodium ethoxide has not been reported. Some confusion concerning even the family of compounds that react to form a blue complex in dilute sodium ethoxide appears in the literature. It was noted (17), in part, that phytonadione dissolved in petroleum ether yielded a positive (blue) test with dilute sodium ethoxide, whereas the vitamin dissolved in oil gave a negative test. It was speculated that phytonadione was less stable in petroleum ether than in oil and that a reaction with an unspecified degradation product of phytonadione was actually responsible for the blue color. The selectivity of the reaction towards phytonadione analogs, therefore, has not been specified. It also is not clear whether the reaction occurs with a parent species or a degraded species.

In an attempt to examine the selectivity of the ethoxide reaction, 1,4-naphthoquinone (I) was subjected to the detection test. The absence of blue color indicated the 1,4-naphthoquinone nucleus was not sufficient for reaction. Menadione (vitamin K_3, II) did not give a positive test. Since phytonadione (III) differs only from menadione by a phytyl group, the phytyl group was found essential for the blue complex formation. Bromination of the double bond originating on the β-carbon of the phytyl group of phytonadione yielded a product that did not form a blue complex. The blue complex formed in the reaction with phytonadione was soluble in water, and it eluted before phytonadione on a reversed-phase LC column. The polar species formed was consistent with the structure of IV. The structure predicts that vitamin K_2 (which contains a polyprenyl group in place of the phytyl group) would form the same extended conjugation system. The vitamin K_2 family of compounds yield blue colors with ethoxide (16, 17). The shift from yellow (in phytonadione) to blue (IV) is consistent with increasing the conjugation of 1,4-naphthoquinone to the phytyl side chain to form an extended π or quasi-π system (18).

A previous report (17) has been cited (15, 16) as evidence that the reaction between phytonadione and ethoxide ion may actually be a reaction with a degradation product of phytonadione. It now appears that the reason ethoxide reacted with petroleum ether samples, but not with vegetable oil samples, may have been due to the lipophilic nature of phytonadione and solution conditions conducive to the formation of IV rather than with the selectivity of the reaction.

A simple detection method for phytonadione in vegetable oil has been developed in which an alkaline ethanolic solution simultaneously transforms the vitamin into a blue compound (consistent with IV) which can be easily visualized on a background of white, saponified vegetable oil. The reaction in standard ethanol solutions and vegetable oil samples is sensitive to phytonadione and vitamin K_2. The test is postulated to be specific to 1,4-naphthoquinones containing alkyl side chains with β-carbon double bonds which may form extended conjugation systems. The selectivity was found to be identical in ethanol standards and vegetable oil samples.

The Direct Analysis of Tetracycline in Urine by Circular Dichroism Spectropolarimetry

JOHN M. BOWEN and NEIL PURDIE ˣ

Received August 4, 1981, from the *Chemistry Department, Oklahoma State University, Stillwater, OK 74078.* Accepted for publication October 23, 1981.

Abstract □ A method is described for the direct analysis of tetracycline in human urine using circular dichroism spectropolarimetry. The general applicability of the method to other drugs is discussed.

Keyphrases □ Circular dichroism—spectropolarimetry, tetracycline analysis in urine □ Tetracycline—analysis in urine, circular dichroism spectropolarimetry □ Spectropolarimetry—tetracycline analysis in urine, circular dichroism

Circular dichroism is the effect caused by the simultaneous absorption and rotation of an incident beam of plane polarized light measured as a function of wavelength (1). Ordinarily the technique is used in the study of electronic transition polarizations and in the investigation of molecular conformations or configurations (2).

In previous work its analytical potential was demonstrated in the qualitative analysis (3, 4) and quantitative determination of drugs of abuse, such as opiates (5), L-cocaine (6), and lysergide (7). The analyses were made directly on confiscated solid samples of forensic interest, meaning no prior sample preparation or separation was performed, nor was it necessary.

This report describes the preliminary results from the first application of circular dichroic spectropolarimetry to the direct analysis of drugs in biological fluids, namely tetracycline in human urine.

EXPERIMENTAL

An analytical standard sample of tetracycline hydrochloride was obtained[1]. Urine samples were taken from 10 volunteers who were known not to be on a program of administering drugs, legal or illegal. One volunteer was maintaining an established program of a 1.0-g daily dosage of tetracycline[2] using 500-mg capsules.

Circular dichroic spectra were taken on a spectropolarimeter[3] over the 240–360-nm wavelength range. Measurements were made on freshly collected specimens which had been diluted 50 times with distilled water. The pH of the solution was not controlled. Samples were placed in a 1-cm cell and measurements were made against a distilled water blank.

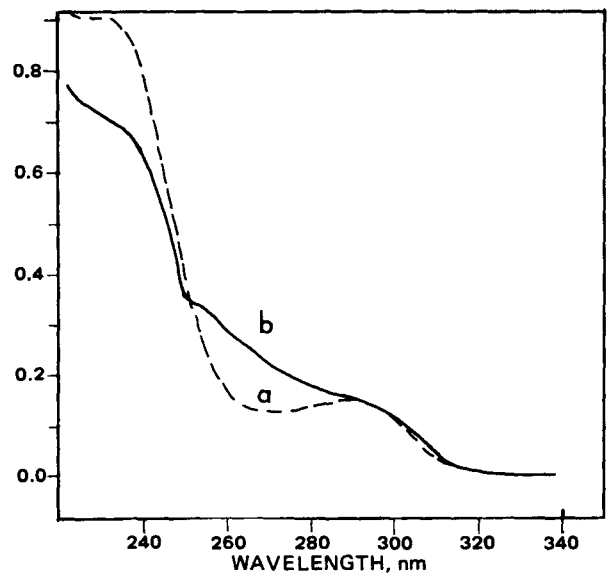

Figure 1—*UV absorption spectra of (a) urine (50 times dilution) and (b) urine with tetracycline (50 times dilution).*

RESULTS

The UV absorption spectra of urine with and without tetracycline from the prescribed volunteers are shown in Fig. 1. The principal difference in absorption, ~270 nm, is insufficient to quantitate with any degree of certainty. Even qualitative identification is speculative. Circular dichroic spectra of the same specimens are shown in Fig. 2. Samples had been diluted 50 times to prepare these solutions. The observed circular dichroic spectrum for urine shows small deviations from the baseline: negative at ~310 nm and positive at ~280 nm. Tetracycline in urine shows a large positive Cotton band at 295 nm and two smaller negative bands at 323 and 270 nm, respectively. Superimposed on the urine spectra of Fig. 2 is the spectrum for a 2.0×10^{-5} *M* or 8.9 μg/ml aqueous tetracycline solution. Positive qualitative identification is elementary.

The quantitativeness of circular dichroic spectropolarimetry in analysis can be demonstrated from a linear plot of experimental ellipticity, Ψ, at 295 nm *versus* molar concentration of standard tetracycline[1] in water. The slope of the calibration curve is the molar ellipticity coefficient $[\theta]_{295}$ and is calculated to be equal to +540. Using this value in the analysis of the urine samples, the concentration of dissolved tetracycline was calculated to be 2.4×10^{-5} *M* after dilution by 50 times, or 11 μg/ml in the excreted specimen.

With the present instrument, the limit of detection was found to be ~1.8 μg/ml for tetracycline.

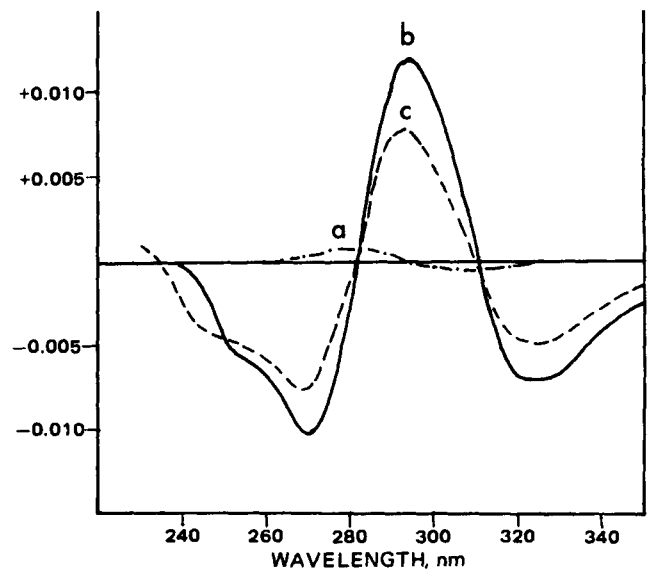

Figure 2—*Circular dichroic spectra of (a) urine (50 times dilution), (b) urine with tetracycline (50 times dilution), and (c) 2×10^{-5} M aqueous solution of tetracycline.*

DISCUSSION

Circular dichroic spectropolarimetry is a modified form of UV absorption spectrophotometry applicable to compounds which are both optically active and absorb light (2). All of the accepted procedures for UV absorption apply equally well to circular dichroism, and the data obey the simple Beer's Law dependence. Adjusting instrument parameters is not a problem as it is with GC, high-pressure liquid chromatography, or mass spectrometry (8) which reduces the routine analysis time. The time is reduced even further where separation is not a prerequisite to identification.

The detection limit for tetracycline in urine is 1.8 μg/ml. This value easily could be improved with a more modern instrument equipped with computer data handling accessories. A lower limit of detection is also possible if tetracycline is first separated from other species which absorb in the UV because of an improved signal–noise ratio. Based upon known $[\theta]$ values for other drugs such as morphine (5), codeine (5), cocaine (6), and lysergide (7), and comparing these to the value for tetracycline, calculations show that these drugs also can be quantitated, but only at overdose levels with the spectropolarimeter[3].

In general terms the most difficult analytical problem will arise when a mixture of optically active drugs are present (7); then separation will again be necessary. Dissolved sugars or proteins and glucuronide derivatives of extracted metabolites do not absorb for the most part, and they are not interfering.

Tick Repellents I: Ethylene Glycol Acetamides

W. A. SKINNER ˣ, U. ROSENTRETER *, and T. ELWARD

Received July 7, 1981, from the *Life Sciences Division, SRI International, Menlo Park, California 94025.* Accepted for publication September 25, 1981. * Present address: Bayer AG, Postfach 101709, 5600 Wuppteral, West Germany.

Abstract □ Acetamides derived from ethylene glycol were synthesized and evaluated as repellents for the brown dog tick *Rhipicephalus sanguineus*. Several of these compounds showed repellency equal to the standard repellents, *N,N*-diethyl-*m*-toluamide and butopyranoxyl.

Keyphrases □ Tick repellents—ethylene glycol acetamides, synthesized □ Acetamides—ethylene glycol, synthesized, tick repellents □ Ethylene glycol—synthesized acetamides, tick repellents

A previous study of insect repellents showed that alkyl triethylene glycol monoethers had good mosquito repellency, being superior to *N,N*-diethyl-*m*-toluamide in certain tests against *Aedes aegypti* mosquitoes (1). Amides in general are known to be repellent to mosquitoes and other insects, the most widely used amide repellent being *N,N*-diethyl-*m*-toluamide.

During World War II, an extensive repellent screening program took place at the USDA Laboratories in Orlando, Florida. Compounds were screened for repellency both to yellow fever and malaria mosquitoes, and against fleas and ticks (2, 3). The ticks used for that program were the lone star tick, and about one thousand compounds were evaluated as tick repellents.

Since that time, major emphasis has been on mosquito repellents, largely supported by the U.S. Army Medical Research and Development Command. However, recently more emphasis has developed with regard to other militarily important insects: sand flies and ticks.

A previous study (3) evaluated a series of amides against ticks (*Amblyomma americanum*) and found that the di-*n*-butyl toluamides were best. Another study (4) found that certain amides and esters were effective against hard and soft ticks (*Ixodes persulcatus* P. Sch., *Dermacentor pecitus* Herm., *D. marginatus* Salz., *Hyalomma asiaticum* P. Sch., and *Alectorobius tholozan papillipas* Birula). Evaluated were butylacetanilide, tetrahydroquinoline, a mixture of ethyleneoxide–carbon dioxide (1:9)[1], dibutyl adipate, dimethyl phthalate, *N,N*-diethyl-*m*-toluamide benzimide, isoamyl acetamide, and benzoyl piperidine.

In the present study, a combination of the amide function with the ethylene glycol moiety were examined for repellent activity against ticks.

EXPERIMENTAL[2]

2-(Hydroxyethyoxy)acetamides—2-(2-Hydroxyethoxy) - *N*, *N* - diisopropylacetamide was prepared as follows: Sodium (1.4 g, 0.006 mole) was dissolved in 13 ml (0.24 mole) of ethylene glycol. After cooling to room temperature, 12 g (0.0676 mole) of *N,N*-diisopropyl-chloroacetamide (prepared from chloroacetylchloride and diisopropylamine) was added. The mixture was stirred at 90° for 1 hr. The ethylene glycol was distilled under reduced pressure and the residue taken up in ether, filtered to remove the sodium chloride, evaporated *in vacuo*, and distilled[3] to give 10.6 g of product, 125° air bath temperature/0.8 mm Hg.

2,2′-Ethylenedioxy-bis(*N,N* - dialkylacetamides)—2,2′- Ethylenedioxy-bis(*N,N*-diisopropylacetamide) was prepared as follows: A 150-ml three-necked flask was fitted with a stirrer, a reflux condenser, and a dropping funnel. Sodium (0.78 g, 0.034 mole) was suspended by vigorous stirring in 20 ml of boiling xylene. Ethylene glycol (1.05 g, 0.017 mole) was dropped slowly into the sodium suspension at reflux temperature, the suspension stirred and refluxed for an additional 7 hr, and then 6 g (0.034 mole) of *N,N*-diisopropyl-chloroacetamide in 15 ml of xylene was dropped into the stirred suspension at reflux temperature during 1 hr. The reaction mixture was refluxed and stirred for an additional hour.

solution of 48 ml (0.35 mole) of dipropylamine in 100 ml of methylene chloride at −40° during 30 min. The mixture was stirred at room temperature for an additional 10 hr. The methylene chloride was evaporated and the residue taken up in 300 ml of ether and filtered to remove the hydrochloride salt of the dipropylamine. The filtrate was extracted with concentrated potassium hydroxide solution. After drying with anhydrous magnesium sulfate and removal of ether *in vacuo*, the residue was distilled with a spin evaporator to yield 24 g of product, 165° air bath temperature/1.0 mm Hg.

Biological Testing—*Rhipicephalus sanguineus*, the brown dog tick, was the test arthropod. The assay was designed to take advantage of the natural inclination of unfed ticks to climb upward.

Test materials were weighed, dissolved in 95% ethanol, and 0.15 ml of the solution was applied to a disk. The disks were cut from filter paper[4] and were 2.9 cm in diameter. One disk was used per compound per treatment level. Treated disks were kept under a hood and allowed to dry for 24 hr before use.

Disks were then inserted in drilled-out vial caps so that the treated sides faced down when the caps were placed on the test chamber. The test chamber was a polystyrene vial (25 × 52 mm) with an untreated disk glued on the drilled out bottom. Fifteen holes were punched in both disks on the chamber with a 23-gauge needle.

Twenty unfed adult brown dog ticks (10 male and 10 female) sorted 24 hr before use, were placed in each test chamber. The chambers were held with the treated end upright under a hood and were slightly elevated on tongue depressors. After four hours, when the ticks had ceased wandering, the chamber was observed and the number of ticks that settled on the treated surface were counted. The results were expressed in the percentage of ticks repelled from the treated surface. The maximum test level was 1.0 mg/cm² and the dose increments were 0.18 log intervals. Nontreated, standard-treated, and solvent-treated disks were included in each test.

The minimum concentration for the standard *N*,*N*-diethyl-*m*-toluamide that gave consistent significant (>80%) repellency was found to be 1.0 mg/cm². Test materials active at levels lower than 1.0 mg/cm² were considered to be more repellent than *N*,*N*-diethyl-*m*-toluamide.

[4] Number 3 Whatman.

RESULTS AND DISCUSSION

For this study, it was necessary to develop a suitable tick repellency assay, and the brown dog tick, *R. sanguineus*, was chosen as the test species. A common behavior of ticks is to crawl upward and this was taken advantage of in the assay used. The apparatus used consisted of a plastic vial with a filter paper impregnated with the test substance in the top. A measurement was made of the number of ticks climbing upward after a set period of time, with varying concentrations of the test chemical on the filter paper.

Chemical data on the compounds synthesized are presented in Tables I–IV.

Repellency data are presented in Table V. With the tick assay used here, *N*,*N*-diethyl-*m*-toluamide and butopyranoxyl both exhibited good repellency at 1 mg/cm² concentration. Since it was the purpose of this study to determine whether these new compounds were better repellents than these standards, they were tested initially at 1-mg/cm² concentration except for Compound II-1.

Compounds described in Table I having a free hydroxy group were poor repellents, as were the compounds from Table II. The volatility of the bis-compounds in Table II probably was too low (bp = 160°/0.5 mm Hg). Also, two of the compounds in Table I were solids.

Compounds from Table III were more repellent, some of them being equivalent to *N*,*N*-diethyl-*m*-toluamide and butopyranoxyl at 1 mg/cm² concentrations. Compound III-3 seems the best of all, with a repellency of 45% at 0.44-mg/cm² concentration, compared to 30% for *N*,*N*-diethyl-*m*-toluamide and butopyranoxyl at that concentration.

Compounds described in Table IV were not very repellent, probably due to their higher boiling points and reduced volatility.

Surgical Catheterization of Hepatic-Portal and Peripheral Circulations and Maintenance in Pharmacokinetic Studies

JAY L. RHEINGOLD [§*], **PAUL PREISSLER** [‡], **PAUL SMITH** [‡], **and PAUL K. WILKINSON** [*¶x]

Received March 30, 1981, from the *School of Pharmacy, University of Connecticut, Storrs, CT 06268 and the ‡Center for Laboratory Animal Care, University of Connecticut Health Center, Farmington, CT 06032. Accepted for publication October 7, 1981. §Present address: American Cyanamid Co., Lederle Laboratories, Pearl River, NY 10965; ¶E. Merck & Co., Rahway, NJ 07065.

Abstract □ A surgical procedure for the chronic catheterization of mongrel dogs was presented with a detailed account of the use and maintenance of these catheters. The methodology allowed for a direct determination of the capacity of the liver to the intact animal to metabolize drugs. The technique permitted the investigator to study the oxidation of drugs by the liver in a specific concentration range and assessment of the first-pass effect of the liver when many drugs are administered *via* the oral route. The dogs were prepared and used in the drug pharmacokinetic studies for periods up to 24 days.

Keyphrases □ Catheterization—hepatic-portal, peripheral circulations, maintenance, pharmacokinetics □ Pharmacokinetics—maintenance of surgical catheterization, hepatic-portal peripheral circulations □ Metabolism—determination of liver capacity in intact dogs, pharmacokinetics, surgical catheterization of hepatic-portal and peripheral circulations and maintenance

Previous investigators (1–17) have reported that following either oral or intravenous administration of ethyl alcohol to humans or animals, there were differences in alcohol distribution in the vascular system. Most authors (1–13) concluded that arterio–venous equilibrium, as defined by zero arterial–venous concentration differences, was attained rapidly in humans. However, previous (14) and more recent studies (15–17) reported distributional trends not seen in the previous work. These results showed, by interpolation, that at only one point in time were equal arterial and venous concentrations attained, and that this time varied with each subject. Increased assay sensitivity and/or longer sampling time perhaps holds the key to the variance in observations.

This methodology permits the direct determination of the capacity of the liver in the intact animal to metabolize drugs. By infusing the liver directly, the blood alcohol concentration entering the liver can be controlled and the oxidation of ethanol in the liver of an intact animal in a specific concentration range under *in vivo* testing conditions can be studied. This technique is useful in assessing the first-pass effect on the liver, observed when many drugs are administered *via* the oral route.

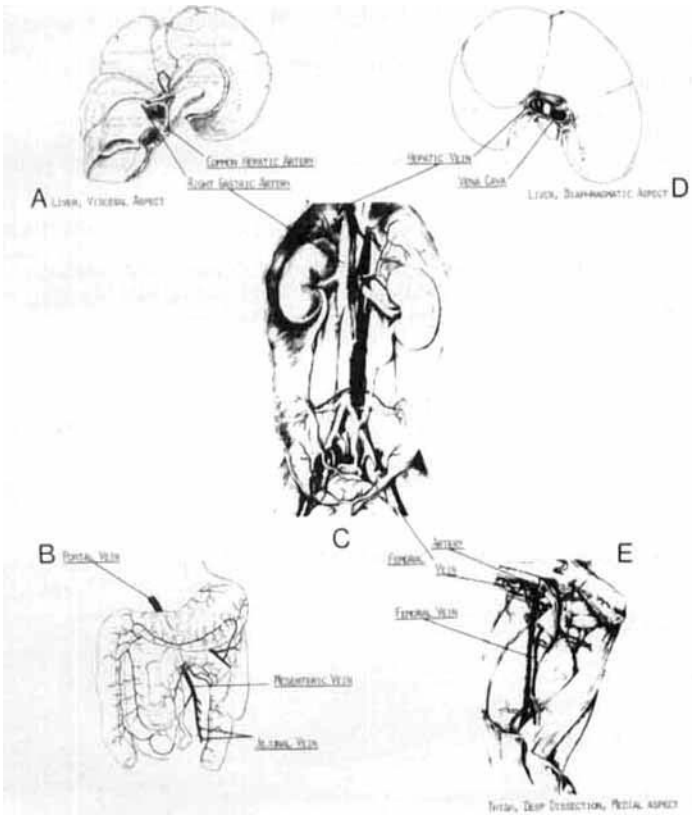

Figure 1—*Diagramatic representation of catheter placements. (Figures from Ref. 18.)*

EXPERIMENTAL

Criteria for Dog Selection—Healthy, full-grown male mongrel dogs (15–31 kg) were selected. The following initial laboratory check-up was performed on each of the dogs: complete blood count (red blood cell count), white blood cell count, differential, hemoglobin, hematocrit, mean corpuscular volume, mean corpuscular hemoglobin, mean corpuscular hemoglobin concentration, red blood cell morphology, sedimentation rate, fecal flotation rate (coccidiosis), creatinine clearance, SGOT, Knott's Test (heartworm), and Brucellosis Screen[1]. Dogs were wormed and vaccinated against rabies[2] and distemper[3].

Dogs selected for the study were quarantined for 1 month and maintained on an adequate diet of regular canine laboratory chow[4]. Prior to their release from quarantine, a similar laboratory check-up, as just described, was performed on each dog to detect any clinical changes and to determine the fitness of each dog for surgery.

Surgical Procedure—Indwelling venous catheters were secured surgically in the hepatic artery, portal vein, hepatic vein, and the femoral artery. An additional catheter was implanted within the saphenous vein.

Prior to surgery, the dogs were fasted (including water) for 6 hr. An enema[5] was administered to each dog 60 min prior to surgery. Acepromazine maleate[6] (0.55–1.10 mg/kg of body weight) was administered intramuscularly as a preanesthetic and/or tranquilizer, and an intravenous injection of sodium pentothal[7] was administered (22 mg/kg of body weight) for induction of anesthesia prior to intubation. With sedation, a 10-mm endotracheal tube[8] was fitted in the dog's throat to facilitate the administration of the anesthetic, methoxyflurane (2,2-dichloro-1,1-difluoroethyl methyl ether[9]) during surgery. A catheter[10] (20 gauge,

15 mm) was inserted in the cephalic vein so that 5% dextrose in Ringer's Irrigation Solution[11] could be infused by intravenous drip during the entire surgical procedure (3–4 hr) and for 1 hr postoperation to prevent fluid loss through dehydration.

Aseptic technique was observed at all times within the surgical bay. Anesthetic intake, temperature, pulse, heart rate, respiratory rate, fluid intake, as well as urine and blood loss were monitored throughout the surgical procedure.

The dog was placed on its back and a catheter[12] was introduced into the urinary bladder. A 12-cm vertical abdominal midline incision was made. Skin, fascia, and muscle were spread laterally until the liver and the greater omentum were exposed. Capillary bleeding was arrested by electrocautery. The liver was deep red in color, firm in consistency, and friable.

Implantation of the first catheter into the hepatic artery required location of the right gastric artery. The right gastric artery leaves the common hepatic artery at nearly a right angle, runs into the lesser omentum at the pylorus, and continues to the lesser curvature of the stomach. The point at which the right gastric artery leaves the common hepatic artery was exposed, and the connective tissue surrounding it and on its surface was removed (Fig. 1A). A 1-mm longitudinal incision was made, and a 60-cm venous catheter[13] was fitted in the artery and advanced into the common hepatic artery. It was secured in the artery by suturing with nonabsorbable silk (000)[14] using a square knot stitch. The catheter was flushed using a 10-U heparin sodium/ml[15] solution *via* a 3-ml plastic syringe[16] attached to the sampling barrel of the catheter, and testing for patency by drawing back until bright red arterial blood appeared in the syringe. The catheter was kept patent by the maintenance of the 10-U heparin sodium/ml solution within the catheter throughout the surgical period. A similar procedure was followed for maintaining patency with the implantation of the three other catheters.

Following the insertion of the hepatic artery catheter, an indwelling catheter was placed in the portal vein. A 90-cm catheter[17] was advanced cranially into the portal vein through one of the mesenteric veins.

A mesenteric vein was isolated by the separation of connective tissue from its surface. With isolation, a 1-mm longitudinal cut was made and the catheter inserted and secured with nonabsorbable surgical silk (000), flushed, and kept patent (Fig. 1B).

With the hepatic artery and portal vein secured and patent, the peritoneum, fascia, and muscle were sutured by a horizontal mattress stitch using surgical chromic gut[18] leaving the skin to be sutured later. The two catheters were set aside for further placement.

A 6-cm cutdown was then made on the left pelvic limb, exposing the femoral artery and femoral vein. A 90-cm indwelling venous catheter was implanted into one of the numerous branches of the femoral vein and fed into the postcava with eventual placement in the hepatic sinus. This served as a site for sampling hepatic vein blood alcohol concentrations. The catheter was flushed and kept patent with heparin.

Nonabsorbable surgical silk (000) was again used for securing the catheter. To ensure proper placement, the distance from the femoral vein to the hepatic sinus was measured and marked on the catheter. When the catheter was secured with the silk, its position within the hepatic sinus was verified by feeling for its tip within the sinus through the wall of the vena cava (Figs. 1C and D). In addition, when the study was complete, a necropsy was performed on each dog revealing the proper position of all catheters.

A fourth catheter was then placed in one of the many branches of the femoral artery. A 1-mm longitudinal cut was made and the indwelling catheter fitted within the femoral artery and secured using nonabsorbable surgical silk (000) (Fig. 1E) and maintained with heparin.

The femoral fascia was sutured with surgical chromic gut and the catheters passed between the medial femoral fascia and the skin to the location of two abdominal catheters. This was done by using a sterile 10-mm endotracheal tube. The tube was inserted between the fascia and the skin after they had been separated by blunt forceps. The syringes were removed from the barrel of each catheter and the catheters advanced through the tube. Once the passage was complete and the endotracheal tube removed over the exposed ends of the catheters, heparin solution was again flushed through each of the catheters.

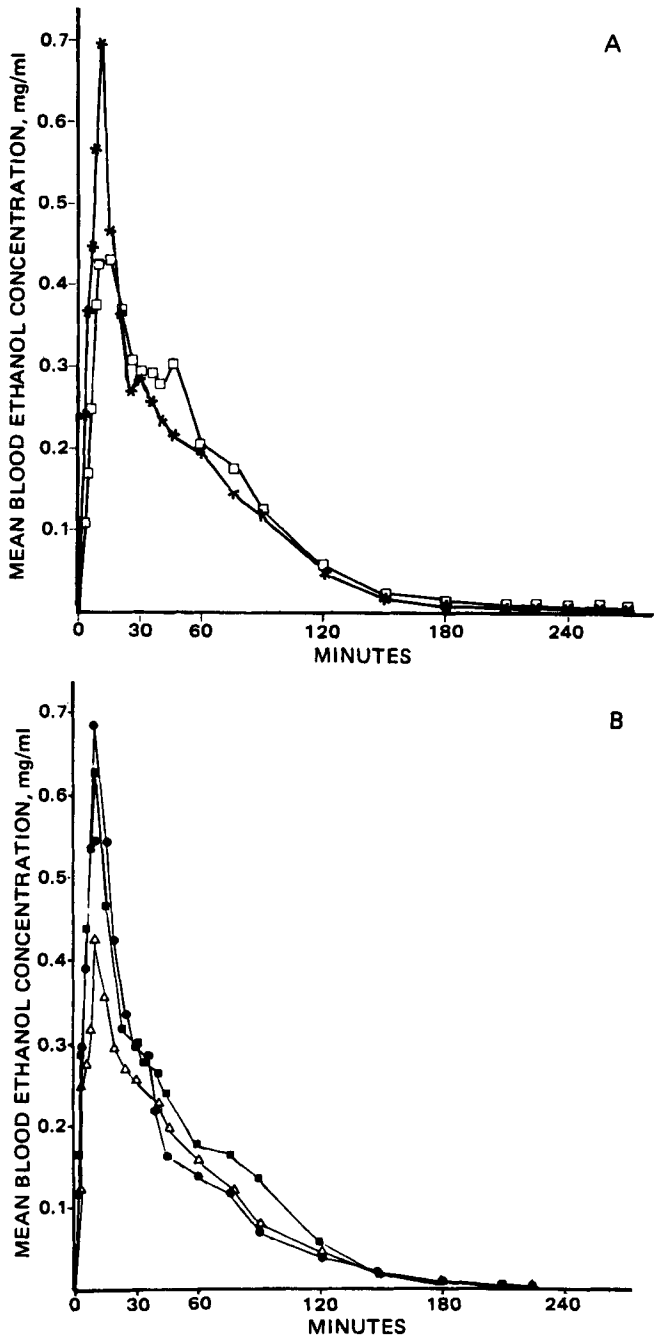

Figure 2—*Typical results of study conducted following surgery. Mean blood–ethyl alcohol concentrations following the 10-min intravenous infusion of 0.26 g/kg of ethyl alcohol* via *the cephalic vein to three dogs. Key: A: (✱) femoral artery; (□) femoral vein; B: (■) hepatic artery, (△) hepatic vein, (●) portal vein.*

The four catheters were placed under the skin to a location behind the dog's neck. This was accomplished by laterally separating (by blunt forceps) the skin and fascia so that the endotracheal tube could be placed between the tissues. A 2-cm incision was made in the dog's skin for the exit of the catheters from the tube. After the tube was positioned, the syringes were removed from the previously labeled catheter barrels and the catheters advanced through the tube. The tube was then removed and a polytef 3-way stopcock[19] was attached to the barrel of each catheter. Each catheter was checked for patency, flushed with 3-ml of the 10-U heparin sodium/ml solution, and the attached stopcock closed off.

The skin at the midline incision and the femoral triangle was then closed using surgical silk (000)[20]. Penicillin G benzathine and penicillin

[19] Model No. K-75, Pharmaseal, Inc., Toa Alta, P.R.
[20] Davis & Geck, Division of American Cyanamid Co., Stamford, Conn.

G procaine[21] (20,000 U/kg, respectively) was administered intravenously to prevent infection.

Following the surgical implantation, there was a need to protect the externalized vascular catheters from the trauma of biting and rubbing. A dog jacket[22], made of durable nylon net, afforded maximal protection and allowed the wound to heal. The jacket was adjustable, so as to fit a range of sizes, and contained two pockets, one on either side of the dog, enabling the housing and protection of the indwelling venous catheters. Clove oil was used as a chewing deterrent. Clove oil was found to be effective and long lasting without ill-effects. In addition, routing the catheters under the skin and through the dermis into an area covered by the jacket's pockets failed to attract the dog's attention and a deterrent from biting was accomplished and proved effective.

Postsurgical Procedure—The dogs were allowed to stabilize postsurgically for a period of 2–3 days. It was found that the heavier dogs required a shorter recovery time. They were permitted their normal diet *ad libitum*. Prior to each animal study the dogs were fasted and water withheld overnight. The four catheters were checked for patency and flushed daily with a 100-U heparin sodium/ml solution in physiological saline.

RESULTS AND DISCUSSION

The experimental design (19, 20), for which the above surgical procedure was developed, entailed the administration of several different doses of ethyl alcohol (8–10% v/v solutions in saline) *via* either the hepatic artery indwelling catheter or a 20-cm catheter[23] inserted at the time of each study into a cephalic vein. Studies were conducted at 2- or 3-day intervals to allow a sufficient wash-out period for the ethyl alcohol. Figures 2A and B show typical results from one such study in which 0.26 g of ethyl alcohol/kg of body weight was administered over 10 min *via* the cephalic vein. Blood samples from all four surgically placed catheters and a fifth catheter (20 cm) inserted at the time of study in the saphenous vein (a branch of the femoral vein) could be collected within a 15–20-sec time period. Thus, simultaneous blood collection at several locations in the vascular system is possible. Simultaneous sampling is essential in order to obtain accurate concentration gradients with time across the liver and within the peripheral circulation. Using the above surgical techniques, mongrel dogs were maintained with patent catheters up to 24 days (postsurgery). The catheters were patent at this time and could have been maintained longer. In this length of time, numerous studies could be conducted.

While the surgical procedure described was for a specific study with ethyl alcohol, it has utility for the study of any drug suspected of liver first-pass metabolism. With appropriate maintenance the catheters could remain patent for extended periods with minimal discomfort to the dog.

Conformation of Some Disubstituted 9-Acridanones

J. BARBE *x, A.-M. GALY *, R. FAURE ‡, A. MAHAMOUD ‡, and J.-P. GALY ‡

Received February 26, 1981, from the **Service de Chimie minérale, Faculté de Pharmacie, 27 Boulevard Jean-Moulin, 13385 Marseille Cedex 5, France*, and the ‡*Service de Chimie organique physique, Faculté des Sciences, rue Henri-Poincaré, 13397 Marseille Cedex 4, France.* Accepted for publication October 27, 1981.

Abstract □ Experimental dipole moments of some disubstituted 9-acridanones were compared to the vectorially and theoretically calculated values using CNDO/2 method. Results supported the existence of a presumed folding of these compounds with the prevalence of a quasi-equatorial conformation.

Keyphrases □ Acridanones—disubstituted, dipole moments, conformation as solutes, □ Conformations—disubstituted acridanones as solutes, dipole moments □ Dipole moments—acridanones, disubstituted, conformation as solutes

The special position of acridanone compounds has frequently been mentioned. Their structure has to be situated between those of acridine and acridane (1), since the former is aromatic while the latter is equivalent to a bridged diphenylamine structure. Acridanone derivatives were identified as metabolites of the acridinic drugs (2–4) as well as metabolites of some dibenzoazepine-like antiepileptic drugs such as carbamazepine (5–7).

These molecular transformations can modify the biological response if it stems from electronic distribution, and they can also induce side effects due to the new geometrical structures which could eventually carry out stereospecific actions.

Crystallographic data presently are the sole source of information about the acridanones structure (8). Because of this, it becomes worthwhile to define the conformation of acridanones as solutes and molecules isolated theoretically.

In this report the dipole moments of some disubstituted 9-acridanones were measured. They were calculated either by means of incremental vectorial addition or by the CNDO/2 method. Calculations and experimental results were compared to portray the molecular structure of the compounds studied.

EXPERIMENTAL

Materials—The following compounds were studied: 1,10-dimethyl-9-acridanone (I); 2,10-dimethyl-9-acridanone (II); 4,10-dimethyl-9-acridanone (III); 1-methyl-10-benzyl-9-acridanone (IV); 2-methyl-10-benzyl-9-acridanone (V); 2-methoxy-10-methyl-9-acridanone (VI); 2-methoxy-10-benzyl-9-acridanone (VII); 4-nitro-10-methyl-9-acridanone (VIII).

These compounds were prepared using phase transfer catalysis according to the process previously worked out with other acridine (9) or acridanone (10) derivatives. The purity of the samples studied was checked by HPLC[1].

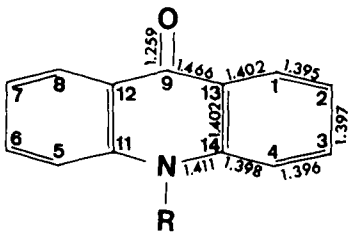

Figure 1—*Molecular geometry of the disubstituted acridanones studied.*

Methods—The dipole moments of the compounds as solutes in anhydrous benzene were measured at 25.00 ± 0.05°. The permittivity[2] and refractive index[3] of the solutions were extrapolated to infinite dilution according to previous reports (11, 12). The quantity $(\epsilon_{12} - n_{12}^2) - (\epsilon_1 - n_1^2)$ was plotted *versus* the molar concentrations, C, of the solute. The slope of the curve at $C = 0$ was then used to calculate the dipole moment, μ:

$$\mu^2 = \frac{9kT}{4\pi N} \frac{3}{(\epsilon_1 + 2)(n_1^2 + 2)} \frac{(\epsilon_{12} - n_{12}^2) - (\epsilon_1 - n_1^2)}{C} \qquad \text{(Eq. 1)}$$

where k is the Boltzmann's constant, N is Avogadro's number, T is the absolute temperature, and ϵ_i and n_i are the permittivities and refraction indexes, respectively, of the solutes (Index 1) and of the solutions (Index 12).

RESULTS AND DISCUSSION

Experimental dipole moments and the theoretical moments, calculated using vectorial incremental addition, are given in Table I. For these calculations, the following molecular increments were used: anisole, 1.25 D; diphenylamine, 1.08 D; nitrobenzene, 3.98 D; toluene, 0.40 D (13); and 4-pyridone, 5.30 D (14).

Molecules were examined as being planar. Nitrogen hybridization was successively considered as sp^2 and sp^3, and in each case a possible conjugation of the nitrogen lone-pair was taken into account. It must be kept in mind that conjugation modifies the value of dipolar increments because of the alteration of the electronic density at the level concerned. The values used are those previously given (15).

The molecules were assumed to be folded, which occurs along a fictitious N—O axis. Calculations were performed for different values of the angle, α, between each benzo ring of the heterocycle. The folding involves two limit-conformers known as R extra (quasi-axial) or R intra (quasi-equatorial) in accordance with the spatial orientation of the N—R bond. The conjugation concerns only the intra structure, because of the electronic hindrances in the extra structure. Four limit structures also were studied in the methoxy substituent: in structures M-1 or M-2, the methyl group is in the benzo plane, while in structures M-3 or M-4 it is out of the

[a] In Debye units, D. [b] For each compound, there are the dipole moments calculated with (first line) and without (second line) conjugation. [c] Nitrogen dioxide and benzo plane are perpendicular. [d] Nitrogen dioxide and benzo ring-carriers are in the same plane.

benzo plane. Free rotation M-5 was also studied for this group. Conversely, free rotation was inconceivable for the benzyl substituent. So, only structure B-1 or B-2 was considered.

The molecular geometry was used for the CNDO/2 calculations (Fig. 1). Substituents are located along the bisector axis.

Bond length and angles are those drawn from the literature (16). Calculations were performed for a planar structure only. Dipole moments are given in Table I while bond indexes of some compounds are collated in Table II. These indexes can be compared to those corresponding to acridine derivatives (17). Average values of bond indexes in each case are summarized in Fig. 2. Comparison shows that the aromatic character of benzo rings is greater in acridanones than in acridines, unlike the aromatic character of the central ring which is lower in acridanones than in acridines. Consequently, the acridanone heterocycle can be assumed to be folded. Moreover, this statement agrees with the result of the comparison between experimental dipole moments and the vectorially calculated ones. There is also an agreement with UV spectra (18).

But, added to this, according to the latter comparison, a particular orientation of the methyl group of the methoxy substituent is involved: lone pairs of the extracyclic oxygen should be conjugated with the π cloud of the ring-carrier. Similarly, the most probable structure for the benzyl substituent seems to be the previously noted structure, B-1. This is in close agreement with the NMR spectra[4] presented in Table III. Indeed, structure B-1 is consistent with the deshielding of the benzylic protons, CH_2, ($5.52 < \delta < 5.57$ ppm) referring to those of the $\varphi—CH_2—NR_2$ like compounds ($3.30 < \delta < 3.96$ ppm) (19).

[a] Solvent, dimethyl sulfoxide; internal standard, tetramethylsilane; temperature, ambient; multiplicity: m, multiplet; s, singlet.

No information is available, however, about the nitro group from the vectorial pattern, because of the supposed free rotation of this substituent. But, inclination of the latter upon the ring-carrier plane is close to 70°, according to the CNDO/2 calculations.

The agreement found between quantum mechanics calculations and incremental vectorial addition must be emphasized. Similar results were previously noted with some other acridine derivatives (17).

As for acridanones, they are presumably slightly folded, the angle of folding being close to 170°. Moreover, the prevailing structure should be the intrastructure.

Cattle and Sheep Skin Permeability: A Comparison of Frozen and Reconstituted Skin with that of Fresh Skin

Keyphrases □ Permeability—cattle and sheep skin, comparison of frozen and reconstituted skin with fresh skin □ Skin—permeability in cattle and sheep, comparison of frozen and reconstituted skin with fresh skin □ Topical drug delivery—cattle and sheep skin permeability, comparison of frozen and reconstituted skin with fresh skin

To the Editor:

It is known that freezing and reconstituting (*i.e.*, thawing) excised human skin does not significantly change the barrier properties it presents to the passive diffusion of drug molecules (1). This knowledge has led to substantial advances in the development of topical drug delivery systems for humans, because potentially useful systems can be identified from the results of *in vitro* screens using frozen and reconstituted human skin (2).

This communication presents data to establish that freezing and reconstituting cattle and sheep skin does not significantly alter their permeability.

It has previously been established (3) that the outer 1 mm of frozen and reconstituted cattle skin (*i.e.*, the stratum corneum, the viable epidermis, the papillary region of the dermis, and a portion of the reticular region of the dermis) acts as an homogeneous barrier to diffusing levamisole molecules. A corollary to this finding is that, for skin samples with thicknesses up to 1 mm, the product of the permeability constant (k_p in centimeters per minute) and the skin thickness (r in centimeters) (*i.e.*, k_pr) is a constant. A similar relationship has been observed for penetration of levamisole through the skins of Merino sheep (4).

To establish the relative permeabilities of fresh and reconstituted cattle and sheep skins, the following experiments were conducted.

Skin was harvested from an 8–9-month Shorthorn-Hereford cross calf in early spring and from a 12–18-month Merino cross ewe in mid-winter. The sheep was shorn and then finely clipped[1] and the calf finely clipped[1] immediately before skin samples were removed with a dermatome[2] set at 1.1 mm.

The permeability of fresh skin and skin that had been stored at −30° for 5–7 days and then thawed to levamisole from a 0.85% solution in an aqueous pH 8.9 buffer was determined using methods identical to those described previously (3).

Values of k_pr for levamisole penetrating through fresh and reconstituted skins are given in Table I.

There was no significant difference (at the 1 or 5% levels) between the values of k_pr for fresh and reconstituted cattle or sheep skin.

Table I—Permeability of Cattle and Sheep Skins to Levamisole[a]

Animal	Skin Thickness, cm	$10^6 k_pr$, $cm^2\ min^{-1}$
	Fresh	
Sheep	0.055	6.0
	0.066	7.7
	0.070	10.7
	0.071	9.2
	Frozen	
Sheep	0.077	7.2
	0.077	6.5
	0.077	8.4
	Fresh	
Calf	0.069	27.7
	0.071	26.8
	0.076	30.9
	0.092	33.7
	0.093	31.7
	Frozen	
Calf	0.065	26.5
	0.069	25.6
	0.071	29.3
	0.082	29.5
	0.086	30.2
	0.091	33.4

[a] From a 0.85% solution in an aqueous pH 8.9 buffer and water-bath temperature of 37°.

Although no relationship has been established between *in vitro* and *in vivo* permeability for cattle and sheep skins, it seems unlikely that live skin, with its blood supply and sweat and sebum secretions, would be appreciably less permeable than excised skin, unless the latter was damaged by the receptor solution.

Consequently, it is concluded that screens for cattle and sheep skin permeability that employ reconstituted skin (5–7) and utilize normal saline as a receptor phase have the potential to provide useful information to developers of veterinary topical dosage forms.

The NIH and Political Pressures

The National Institutes of Health have been in the news even more than usual in recent months. This has been due to a number of factors, including the vacancy in the office of the Director of the overall NIH, the long search for a new director, and the protracted formal approval and appointment process relating to Dr. James B. Wyngaarden once he had been selected. The news interest also has been due to the present vacancy of five of the individual Institute directorships and a sixth that will open up in the next few weeks.

Such "power vacuums" are natural stimuli for gossip and news media speculation—especially when they occur in the political hot-bed that is Washington, D.C.

But lately, the NIH has also been frequently in the news for another reason; namely, the current Congressional efforts to cut federal spending and to reduce the budgetary deficit. Without quoting statistics, it can be simply said that the NIH has not escaped major surgery with respect to its budgetary requests and perceived monetary needs.

All of this serves to remind us of the strong advocacy on the part of many pharmaceutical scientists about 10 to 15 years ago for the creation of a new, separate Institute to be devoted specifically to the pharmaceutical sciences. Presumably, such a new body would concentrate its research efforts and its extramural research funding on such subjects as improved drug delivery systems, pharmacokinetics, bioavailability, and related matters. However, the proposal never "caught fire," and eventually it fell by the wayside.

In retrospect, that may have been fortunate, although no one felt so at the time.

When the separate Institute proposal was first made and championed, federal support for health research generally and for the NIH in particular was flowing like the proverbial waters of Niagara. Today, however, the climate has changed dramatically.

The overall NIH budget and the budgets of the individual Institutes are presently undergoing fierce assaults. The only reason that deeply severe, or perhaps even mortal, fiscal surgery has not occurred is due to the strong support of powerful friends in Congress. When an influential Congressional Committee Chairman takes on a self-appointed and self-assumed role as protector and advocate of one or another of the respective Institutes, it can be safely predicted that the body will fare reasonably well.

And with the various pet diseases of individual Congressional leaders, it is not surprising that the Cancer Institute, or the Heart Institute, or the Aging Institute, or whichever, has managed to avoid wholesale cut-backs. Right or wrong, a fact of life in Washington is that no project, program, cause, or activity will go far or last very long unless it is the beneficiary of a strong lobbying force and potent Congressional allies.

Given the reality that any National Institute of Pharmaceutical Sciences could not begin to command such political support, its budget would immediately become fair game in the fiscal maneuvering. In turn, such ax-wielding would mean that pharmaceutical research and pharmaceutical scientists would take the brunt of eliminated research projects and terminations in employment.

Moreover, given the hindsight of historical experience, it is probably unfortunate that the present individual Institutes were ever created. Less interagency rivalry, less duplication of administrative management, less petty jockeying for resources and publicity, and less wastage in many other areas, would have resulted if there were only a single "National Institute of Health." Experience has shown that independence and strong individual identity among these multiple components are not always conducive to the most efficient and effective operation of our nation's major health research program.

Extended Hildebrand Solubility Approach and the Log Linear Solubility Equation

A. MARTIN *x, P. L. WU *, A. ADJEI *, R. E. LINDSTROM ‡, and P. H. ELWORTHY §

Received July 30, 1981, from the **Drug Dynamics Institute, College of Pharmacy, University of Texas, Austin, TX 78712;* ‡*School of Pharmacy, University of Connecticut, Storrs, CT 06268;* and the §*Department of Pharmacy, The University of Manchester, Manchester M139PL, England.* Accepted for publication November 10, 1981.

Abstract □ The log linear solubility equation, $\log S = \log S_w + \sigma f$, was studied in relationship to the extended Hildebrand solubility approach. It is shown that the log linear form may be derived beginning with the extended Hildebrand approach. The log linear expression gives a good linear fit for semipolar drugs in a number of water–cosolvent mixtures. It is particularly successful when the solubility parameter, δ_1, of the cosolvent is 3 or more solubility parameter units larger than the solubility parameter, δ_2, of the drug. When the cosolvent tends to solvate the drug strongly, the log linear function may even hold where the solubility parameters of the drug and cosolvent are similar. It appears, however, not to be applicable to nonpolar cosolvent systems. An interfacial model for the solubility of drugs in polar mixed solvents is based on σ, a parameter that also figures prominently in the log linear solubility equation. When used to describe mixed solvent systems, the interfacial model applies in the region of the solubility profile (solubility *versus* solvent composition) where the log linear relationships hold. The extended Hildebrand solubility approach is applicable over a wide range of cosolvent composition in mixed systems from nonpolar organic solvents to water.

Keyphrases □ Solubility—extended Hildebrand approach, log linear equation □ Hildebrand equation—extended solubility approach, log linear solubility □ Log linear solubility equation—relationship to the extended Hildebrand solubility approach

Yalkowsky *et al.* (1), introduced a log linear equation:

$$\log S = \log S_w + \sigma f \qquad \text{(Eq. 1)}$$

which describes the solubility of some drugs in binary aqueous systems, where S is the solute solubility in moles per liter in a solvent consisting of water and a nonaqueous cosolvent, S_w is the drug's solubility in water, f is the volume fraction of the cosolvent, and σ is a parameter representing the solubilizing power of the cosolvent for the drug and depends on the polarity of the drug and the cosolvent. Equation 1 was found to be applicable to systems where the polarity of the drug was significantly less than either of the solvents in the binary mixture.

A study (2) on the solubility of *p*-aminoacetophenone in propylene glycol–water mixtures, found it necessary to expand Eq. 1 into a fifth degree polynomial of f to account for nonlinearity across the range of cosolvent (propylene glycol) composition. The linear dependence of logarithmic solubility on volume fraction of the cosolvent (Eq. 1) applied when the Hildebrand solubility parameters of both solvent components were much larger than the solubility parameter of the drug.

THEORETICAL

In the present report, it is shown that the linear relationship of Eq. 1 may be considered in terms of the extended Hildebrand solubility approach (3–5); a model in which the solubility parameter of the solute may be larger or smaller than that of either solvent or lie between the solubility parameters of the two solvents. When the range of solubility parameters of the solvent pair approaches the solubility parameter of the solute, the curve may bow sufficiently that a log linear expression of X_2 on f no longer fits the data satisfactorily. A quadratic or higher polynomial of f must then be used as required by the extended Hildebrand method.

The following derivation shows the relationship of the log linear equation to the extended Hildebrand solubility approach. For the solubility of a drug in pure water:

$$\log X_w = \log X^i - \log \alpha_w \qquad \text{(Eq. 2)}$$

where X_w and X^i are the mole fraction solubility in water and the ideal solubility of the solute, respectively. Log α_w is the logarithm of the solute activity coefficient in water. A general expression for the solubility of a drug in a binary mixture, consisting of water and an organic cosolvent, is:

$$\log X_2 = \log X^i - \log \alpha_2 \qquad \text{(Eq. 3)}$$

where X_2 and α_2 are the mole fraction solubility and activity coefficient, respectively, for the solute in the solvent mixture. Subtracting Eq. 2 from Eq. 3 results in:

$$\log X_2 = \log X_w + \log \alpha_w - \log \alpha_2 \qquad \text{(Eq. 4)}$$

0022-3549/82/0800-0849$01.00/0

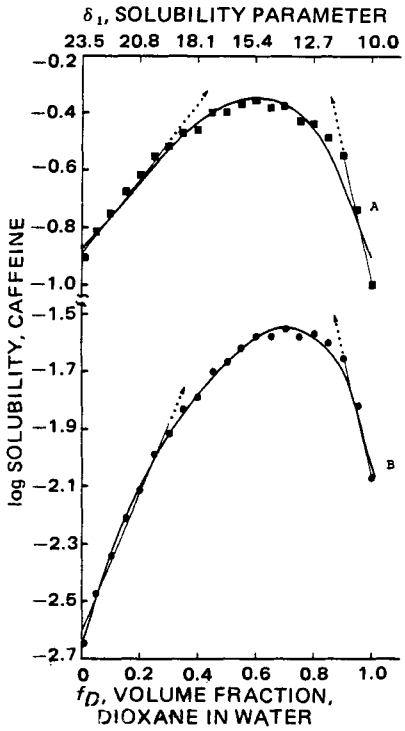

Figure 1—*Solubility of caffeine in dioxane–water mixtures at 25°. The curves were calculated using the extended Hildebrand solubility approach (4, 5). Key:(■) log molarity, Curve A; (●) log mole fraction, Curve B.*

The logarithmic solubility of a drug in water and the drug's log α_w are constants at a definite temperature. For caffeine in water at 25° (4), log $X_w = -2.64111$ and log $\alpha_w = 1.4764$; therefore, log $X^i = -1.1647$.

According to the extended Hildebrand approach (3–5), the activity coefficient of the drug in a mixed solvent is expressed as:

$$\log \alpha_2 = A(\delta_1^2 + \delta_2^2 - 2W) \qquad \text{(Eq. 5)}$$

where δ_1^2 and δ_2^2 are the cohesive energy densities of the solvent and solute, respectively, and W is the interaction energy density of solute and solvent. The term A is obtained from regular solution theory (6):

$$A = \frac{V_2\phi_1^2}{2.303RT} \qquad \text{(Eq. 6)}$$

where V_2 is the solute's liquid molar volume, ϕ_1 is the volume fraction of the pure or binary solvent (total volume fraction of the two solvents in the solution), R is the molar gas constant, and T is the absolute temperature.

Either W or log α_2/A may be regressed in a polynomial on δ_1 to obtain calculated values of log α_2 and mole fraction solubility, X_2 (Eq. 3). Log α_2/A_{calc} may also be obtained by a regression of log α_2/A on f_i, where f_i is the volume fraction of either solvent in a binary mixture (4), for example, water or its cosolvent. For dioxane, D, as the cosolvent:

$$\log \alpha_2/A_{calc} = C_0 + C_1 f_D + C_2 f_D^2 + C_3 f_D^3 + \ldots + C_n f_D^n \qquad \text{(Eq. 7)}$$

For caffeine in dioxane and water at 25°, the extended Hildebrand equation may be expressed as a fourth degree power series in conformity with Eqs. 4 and 7:

$$\log X_{2_{calc}} = \log X_w + \log \alpha_w - C_0A - C_1Af_D - C_2Af_D^2 - C_3Af_D^3 - C_4Af_D^4 \qquad \text{(Eq. 8)}$$

where C_0 is a constant of regression. C_1, C_2, C_3, and C_4 are the coefficients resulting from the regression analysis and remain constant over the range of binary solvent composition for a particular drug at a definite temperature. The value of A varies, although slightly, between 0.093 and 0.103 across the composition of water and dioxane in the caffeine system at 25°.

EXPERIMENTAL

The solubility data in mixed solvents employed in this paper were reported previously (4, 7–9). The drug was brought to equilibrium with the mixed solvent in a constant temperature shaker bath and the drug concentration was determined by spectrophotometric or other convenient analytic procedures. Densities were determined in glass pycnometers under controlled conditions. By obtaining the density of each solution, it was possible to express solubilities in units of molar, molal, or mole fraction concentration.

For calculations involving the extended Hildebrand solubility approach, regression analysis was conducted[1] using multiple linear regression programs (10).

RESULTS AND DISCUSSION

Caffeine in Water–Dioxane Mixtures—Introducing the coefficients of regression analysis into Eq. 8 for caffeine in a mixed solvent system of water and dioxane (4), one obtains:

$$\log X_{2_{calc}} = \log X_w + \log \alpha_w - 14.6274A + 38.4195Af_D - 109.6076Af_D^2 + 114.3535Af_D^3 - 49.3831Af_D^4 \qquad \text{(Eq. 9)}$$

Equation 9 may be simplified by truncating it after the first term in f_D to yield:

$$\log X_{2_{calc}} = \log X_w + (\log \alpha_w - 14.6274A) + 38.4195Af_D \qquad \text{(Eq. 10)}$$

or in general:

$$\log X_{2_{calc}} = \log X_w + (\log \alpha_w - C_0A) + C_1Af_D \qquad \text{(Eq. 11)}$$

The quantity in parentheses is sufficiently small to be neglected since log α_w is equal to 1.4764 and $C_0A \cong 14.627 \times 0.1 = 1.4627$. If the regression procedure yielded log α_2/A with perfect accuracy, C_0 would exactly equal (log α_w)/A. This can be seen by setting f_D equal to zero in Eq. 11, for then the solvent obviously is water, and log α_2/A = log $\alpha_w/A = C_0$. With the quantity within the parentheses, Eq. 11, equal to zero, one arrives at an equation, expressed in mole fraction:

$$\log X_{2_{calc}} = \log X_w + \sigma f_D \qquad \text{(Eq. 12)}$$

analogous to Eq. 1, the log linear expression which, however, has usually been expressed in concentration units of moles per liters or grams per cubic centimeter. The coefficient, $C_1A = 38.4195A$ in Eq. 9, has been obtained by polynomial regression and is equal to σ in Eq. 1 when concentrations are expressed in mole fraction.

One form of the extended Hildebrand expression, Eq. 8, when carried

to the fourth power in f_D, has been shown to reproduce the solubilities of caffeine in dioxane and water within <12% error and for most data points <4% error, a value within the range of experimental accuracy (4)[2].

In Fig. 1, log solubility of caffeine is plotted both in units of moles per liter and mole fraction *versus* volume fraction of the cosolvent, dioxane, as abscissa. Also marked along the horizontal axis (top of Fig. 1) are the solubility parameter values, δ_1, of the mixed solvents, consisting of water and dioxane.

In dealing with caffeine data in earlier reports (4, 5), various polynomial expressions were used. A cubic expression was not as satisfactory as the quartic equation; a quadratic expression yielded poor results; and an equation truncated to the linear term, σf_D, Eq. 12, would be unacceptable as a fit over most of the curve from dioxane (δ_1 = 10.01) to water (δ_1 = 23.45). As observed in Fig. 1, a linear fit is adequate from 0–30% cosolvent composition, although a straight line cannot reproduce exactly the slight curvature of the line. Both the upper and lower curves appear to be parabolic in form, but the curvature is so slight in the 0 to 30% region of dioxane concentration that the data points are adequately fit by a linear function. The intercept is the log solubility in water on a molar (Curve A) or mole fraction (Curve B) scale. In conformity with the criterion for linearity stated earlier, *i.e.*, δ_1 considerably larger than δ_2, the lowest value of δ_1 is 18.4, well above δ_2 = 13.8 of caffeine. It should be noted that the cosolvent of water in this case was not the pure solvent, dioxane, but rather a mixture of 30% dioxane–70% water. Using a log linear equation beyond 30 or 40% as seen in Fig. 1 would not produce meaningful results. Extrapolation into the region of the dashed lines in the direction of the arrows would produce erroneous values of solubility. Accordingly, the log linear technique, although often useful, should be used with caution over a wide range of solvent compositions. A little more effort is required to apply the extended Hildebrand solubility approach, but it usually can be made to reproduce solubility in mixed solvent systems with considerable fidelity across the entire range of binary solvent composition.

Although parts of the curve (0–30% dioxane in Fig. 1) may appear to be approximately linear, log solubility is ordinarily not a linear function of f (except where a strongly solvating cosolvent is present as seen later), and is better fitted with a power series in f or δ_1 rather than with a straight line.

In a manner similar to that discussed above, a 10% water in dioxane mixture could be taken as the cosolvent of dioxane in the region at the far right side of Fig. 1. At this low water concentration side of the figure, segments that are almost linear are observed in Curves A and B. Here, log solubilities *versus* volume fraction of water in the mixture produce linear functions only over a range of 10% water (δ_1 = 10–11.3). The curves begin to bow markedly at 10% water in dioxane because the solvent δ_1 is approaching the δ_2 value, 13.8, of the solute. According to regular solution theory, the solubility of a compound reaches a peak at a solvent composition where $\delta_1 = \delta_2$. The solubility curve approaches a maximum and then begins to decrease across this region and is greatly curved, as seen in the figure.

Results with theophylline, thebromine, and caffeine in other solvent mixtures have been reported (5). They show similar trends described here for caffeine in mixtures of water and dioxane.

The previous example of a log linear approach in relation to the extended Hildebrand model involved a solute with a solubility parameter, 13.8, between that of water, δ_1 = 23.45 and the cosolvent, dioxane, δ_1 = 10.01. By taking this broad view of the subject, one is able to observe more clearly the regions where a log linear equation is applicable and why it fails when the solubility parameter of the mixed solvent approaches the solubility parameter of the solute.

Alkyl *p*-Aminobenzoates in Water–Propylene Glycol Mixtures—The log linear equation, Eq. 1, was originally introduced by Yalkowsky *et al.* (1), to explain the exponential increase in solubility of poorly water soluble compounds upon the addition of an organic cosolvent to water. They found a number of examples from their own work and the literature in which the solubility data was fit by Eq. 1[3]. Unlike the case of caffeine in water and dioxane, Eq. 1 applies particularly well where the solubility parameter of the solute is 3 or 4 units below that of the organic component of the aqueous solvent. The solubility of *n*-alkyl *p*-aminobenzoates in propylene glycol–water mixtures and in several pure solvents has been investigated (9). Figure 2 was prepared using data on the solubility of ethyl *p*-aminobenzoate in binary as well as individual solvents. Mole fraction solubility is plotted against the solvent solubility parameter in Fig. 2 as done in studies involving the extended Hildebrand approach (3–5). The regular solution line is plotted in Fig. 2 to show the curve on which the experimental points would fall if these polar solute–solvent systems followed regular solution behavior at 25°. The regular solution line is calculated using the expression:

$$-\log X_2 = -\log X^i + A(\delta_1 - \delta_2)^2 \qquad \text{(Eq. 13)}$$

where all terms have been defined in earlier equations. The regular solution solubility reaches a peak value at a solubility parameter equal to that of the solute [δ_2 = 12.05 (cal/cm^3)$^{1/2}$]; the mole fraction solubility at this point has the ideal value, X^i = 0.2404, for ethyl *p*-aminobenzoate at 25°. At 37° it is 0.3236 ($-\log X^i_{37°}$ = 0.4900).

It is observed that solutions of ethyl *p*-aminobenzoate in the individual solvents are not regular solutions since they do not lie on the bell-shaped regular solution curve in Fig. 2. The solubility in most of the solvents falls below the ideal solubility line, $X^i_{25°}$ = 0.2404, and this indicates that ethyl

[2] In Ref. 4 the volume fraction of water was referred to as ϕ_w. It was used in place of f_D and this led to a polynomial expression different from Eq. 9, but both expressions result in the same calculated solubilities.

[3] A recent report (11) states that a number of semipolar drugs exhibit parabolic rather than linear log solubility *versus* cosolvent composition curves.

Table I—Regression Equations for Drugs in Binary Solvents Using the Log Linear and The Extended Hildebrand Approaches [a]

[a] Reference 9; solubilities, $X_{2_{calc}}$, obtained with the extended Hildebrand solubility approach, Eqs. 18*a* and *b*; $-\log X_2^1 = 0.49000$, $\delta_2 = 12.05$, $V_2 = 144$. [b] Solvent solubility parameter, $(cal/cm^3)^{1/2}$. [c] Equation 6.

p-aminobenzoate is not highly solvated. By contrast, ethyl *p*-aminobenzoate associates strongly with *N*,*N*-dimethylformamide (Point 2 in Fig. 2), producing a solubility ($X_2 = 0.4260$) above the ideal solubility line. The point for ethyl *p*-aminobenzoate in propylene glycol at 37° (Point 9) lies slightly to the right of the regular solution curve which was drawn for solutions at 25°.

The discussion of the solubility parameter of the compound ($\delta_2 = 12.05$) and the regular solution line is also important for the treatment to follow. However, the current report is a study dealing with mixed solvent systems and attention is drawn to the propylene glycol–water mixtures in Fig. 2. One observes that the data points for the solubility of ethyl *p*-aminobenzoate in mixtures of water and propylene glycol (at 37°) lie alongside the 25° regular solution line. On this scale, solubility in water (Point 10) and in 20% propylene glycol (bottom scale) are imperceptible. The points rise to reasonable solubility values for 30–100% propylene glycol solutions. The line passing through the points in Fig. 2 was calculated using the extended Hildebrand solubility approach, Eq. 18a of Table I:

$$\log \alpha_2/A = -37.7097 + 3.3430\delta_1 - 0.0156\delta_1^2$$

Multiplying both sides by A and adding $-\log X^i$ yields:

$$-\log X_{2_{calc}} = 0.4900 + A(-37.7097 + 3.3430\delta_1 - 0.0156\delta_1^2) \quad \text{(Eq. 22)}$$

from which $X_{2_{calc}}$ is obtained.

Since the solubility parameter of propylene glycol ($\delta_1 = 15$) is sufficiently different from that of ethyl *p*-aminobenzoate ($\delta_2 = 12$), the curve in Fig. 2 may be transformed into a linear form by use of the log linear approach. Figure 3 shows the plots for two esters, ethyl and hexyl *p*-aminobenzoate, in propylene glycol–water mixtures at 37° (9).

The linear least-square line through the data is represented in Table I by Eq. 14*a*, and the linear form is compared with a quadratic expression, Eq. 14*b* for the ethyl ester. Although the coefficient of determination is higher for the quadratic, $R^2 = 0.9964$, than for the linear form, $R^2 = 0.9942$, the Fisher F ratio conversely is greater for the linear (690) than for the quadratic (417) expression. Furthermore, the partial F values for introducing f and then f^2 show that f^2 is not significant when its F value, 1.8, is compared with the table value, 10.1, at the 95% level. The log linear fit is, therefore, considered to be satisfactory.

In Table I (Eqs. 18*a* and *b*), the extended Hildebrand solubility approach is shown for a regression of log α_2/A on δ_1 in both linear and quadratic form for the ethyl ester. Again, the F value is significantly larger for the linear than the quadratic, and the partial F values suggest that the quadratic is not as satisfactory as the linear equation. Although the statistical analysis of the hexyl *p*-aminobenzoate in propylene glycol–water mixtures is not included here, the same conclusion was reached in the case of this ester. The comparison of X_2, observed, with X_2, calculated, for the ethyl ester using both the linear and quadratic forms, Eqs. 18*a* and *b*, is found in Table II. These results show the quadratic equation to yield slightly better solubility predictions. But the curves in Fig. 3 for the ethyl and hexyl esters of *p*-aminobenzoate show that differences between the linear and quadratic approaches are insignificant. Since only six data points are available, further statistical testing would not be fruitful.

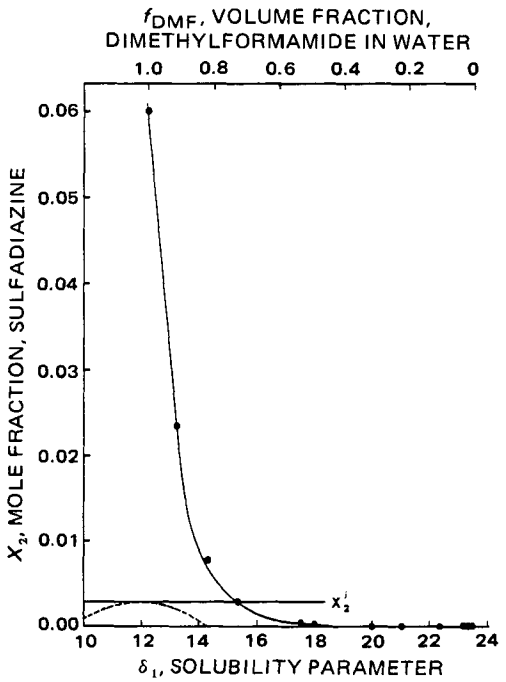

Figure 5—*Mole fraction solubility of sulfadiazine ($X_2^i = 0.0030$) in dimethylformamide–water mixtures at 20° (7). Key: (●) experimental solubility; (---) regular solution curve, Eq. 13; (—) extended Hildebrand line, Eq. 23 (cubic expression).*

Sulfadiazine in Water–Dimethylformamide Mixtures—The solubility of sulfadiazine in mixtures of water ($\delta_1 = 23.45$) and dimethylformamide ($\delta_1 = 12.14$) at 20° has been measured previously (7). The solubility parameter of sulfadiazine is 11.9, as calculated by the Fedors method (12). Yalkowsky *et al.* (1), referred to this study as one which should lend itself to a log linear analysis. The mole fraction solubility and grams of solute per gram of solution at different composition of cosolvent are shown in Fig. 4.

Although the solubility parameter of dimethylformamide is close to that of sulfadiazine, the points do not curve away from linearity as 100% dimethylformamide is approached. Similar results have been found with sulfonamides in dimethylacetamide. Dialkylamides strongly solvate the sulfonamides, and in a series of solvent mixtures, one of which is a dimethylamide, the curve rises to a sharply pointed apex rather than a rounded maximum. This phenomenon may account for the good fit provided by an exponential solubility curve, *i.e.*, a linear fit (Eq. 15*a*, Table I) on a plot of log solubility *versus* volume fraction. Mole fraction solubility is plotted against the solubility parameter, δ_1, of dimethylformamide–water mixtures in Fig. 5, in contrast to the log mole fraction plot of sulfadiazine in Fig. 4. In addition to δ_1, the volume fraction of dimethylformamide (f_{DMF}), in the water–cosolvent mixture is indicated on the horizontal axis (top line of Fig. 5). The extended Hildebrand solubility approach, Eq. 23, was used to plot a curve through the experimental points. The Hildebrand regular solution line, calculated with Eq. 13, is included in the figure to indicate its relationship to the experimental points and the extended Hildebrand line. The regular solution curve is flat rather than peaked as in Fig. 2 because of the scales used in the horizontal and vertical axes. The ideal mole fraction solubility, $X^i = 0.0030$, which corresponds to peak solubility on the regular solution line, is observed to be about one twentieth of the actual solubility of sulfadiazine in dimethylformamide at 20°. The regular solution line does not reproduce the solubility of sulfadiazine in water–dimethylformamide mixtures; whereas the extended Hildebrand solubility equation fits the experimental points well. The regression equation best employed for this purpose is a cubic expression:

$$\log \alpha_2/A_{calc} = -206.441 + 29.7528\delta_1 - 1.45599\delta_1^2 + 0.0258317\delta_1^3 \quad \text{(Eq. 23)}$$

where $n = 14$, $R^2 = 0.9998$, $s = 0.1998$, $F = 18609$, and $F_{(3,10,0.05)} = 3.71$. The linear and quadratic forms, Eq. 19*a* and *b* in Table I, are adequate

Table III—Solubility of Sulfadiazine in Water–Dimethylformamide Mixtures at 20° [a]

[a] Reference 7; back-calculated solubilities $X_{2_{calc}}$ obtained with the extended Hildebrand solubility approach; δ_2 = 11.9 (cal/cm^3)$^{1/2}$; V_2 = 167 cm^3/mole, log X^i_2 = −2.5236. [b] Equation 23, (cubic expression). [c] (log $\alpha_{2_{calc}}$)/A (above) × A (Column 4 above) = log $\alpha_{2_{calc}}$, then log $\alpha_{2_{calc}}$ + 2.5236 = log X_2.

for this purpose but the cubic equation (Eq. 23) is better, as indicated by its R^2, s, and F values. The δ_1 values for the solvent mixtures and the A values are found in Table III together with a comparison of actual solubilities, $X_{2_{obs}}$, and calculated values using the cubic expression, Eq. 23, together with Eq. 3 where log X^i = −2.5236 for sulfadiazine at 20°.

The statistical analyses presented in Table I indicate that the log linear equation (Eq. 19a) provides a satisfactory fit of the data across the range of solvent mixtures from water to pure dimethylformamide. Figure 4 also shows that the linear fit is quite adequate. Therefore, the log linear expression is suitable for sulfadiazine in dimethylformamide–water as well as for ethyl and hexyl p-aminobenzoate in propylene glycol–water mixtures. However, the curve in Fig. 5, where X_2 is plotted against δ_1 (or f_{DMF}), is best fit by a third degree power series (Eq. 23). The residuals (Table III) are surprisingly small when the data is fit with this cubic equation.

Log Linear Equation and Solubilizing Power, σ—In addition to expressing log solubility *versus* volume fraction, Eq. 1, in molar terms (1), Yalkowsky *et al.* (13) used mole fraction concentration:

$$\log X_2 = \log X_w + \sigma f \qquad \text{(Eq. 24)}$$

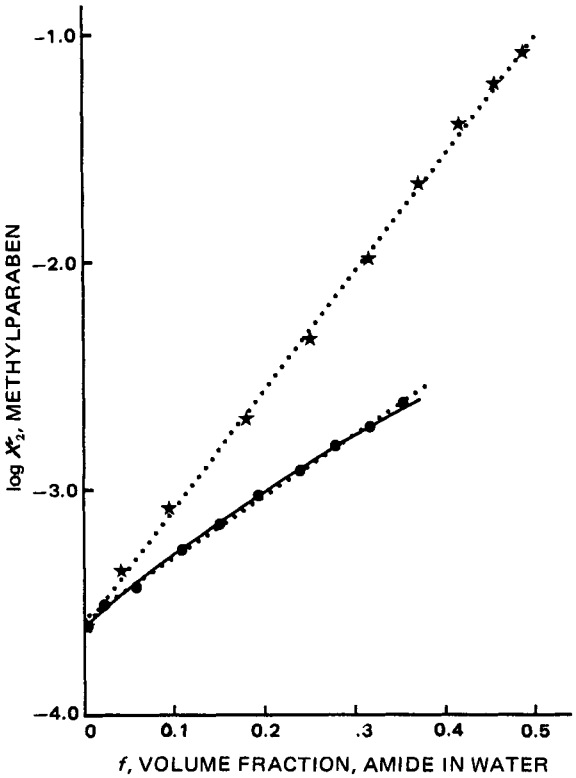

Figure 6—*Log mole fraction solubility of methylparaben in formamide–water (●) and dimethylformamide–water (★) at 25° (8). Key: (—) from Eq. 16b (quadratic); (·····) from Eqs. 16a and 17a using linear regression.*

X_2 is the mole fraction solubility of the solute at a volume fraction f of the cosolvent, X_w is the mole fraction solubility of the solute in water, and σ is a measure of the solubilizing power of the cosolvent for the drug (13). The term σ, which is the slope of the lines represented by Eq. 24, was defined for mixed solvent systems (12) as:

$$\sigma = \frac{C(\gamma_w - \gamma_c)\text{HYSA}}{2.303kT} \qquad \text{(Eq. 25)}$$

where γ_w and γ_c are macroscopic interfacial tensions between a model hydrophobic substance, tetradecane, and water, and between tetradecane and the pure cosolvent, respectively; C is a correction term for the macroscopic surface tensions, accounting for the small radius of curvature at the solute–solvent molecular surface; HYSA is the hydrophobic surface area of the semipolar solute as calculated by a computer program originally written by Hermann (14); k is the Boltzmann constant; and T is the absolute temperature. The value for C should remain relatively constant for various solute-mixed solvent systems, and the value was found to vary within a relatively narrow range, 0.52–0.56, for several systems (13). According to Eq. 25, the value of σ should not change for various compositions of water and cosolvent in a binary solvent mixture, σ being the constant slope of a linear expression, Eq. 24.

According to this interfacial model, it should be possible to calculate solubilities of drugs in polar solvent mixtures using either the linear form of the extended Hildebrand solubility approach:

$$\log X_2 = \log X^i - C_0A + \sigma f \qquad \text{(Eq. 26)}$$

or the log linear expression, Eq. 24, where $\sigma = C_1A$ is defined by Eq. 25.

The interfacial model was tested (8) by determining the solubility of methylparaben (δ_2 = 11) in aqueous systems containing various concentrations of the cosolvents, formamide, methylformamide, and dimethylformamide. Contrary to the requirements of Eq. 25, the σ values were observed to vary in formamide–water from 2.77 to 4.46. For a number of other amide–water cosolvent systems, values for σ varied from 3.40 for acetamide to 6.43 for dimethylpropionamide.

Figure 6 shows the log mole fraction solubility of methylparaben in formamide–water and dimethylformamide–water cosolvent systems. The curve with formamide as the cosolvent is not linear but rather parabolic, and it is well fit by a quadratic expression, Eq. 16b, Table I, of the form:

$$\log X_2 = \log X_w + \sigma f + C_2f^2 \qquad \text{(Eq. 27)}$$

The regression leading to Eq. 16b gives a log mole fraction solubility of methylparaben in water of −3.6009, whereas the experimental value is −3.6091. This is an error of 1.9% in predicting the experimental solubility, X_w = 0.000246, in water, a close estimation using a quadratic expression.

The need for a quadratic equation accounts for a previous inability (8) to obtain a constant value for σ over this range (f = 0.0–0.35) of formamide compositions. Despite the fact that a linear fit of the points produced a regression line with an R^2 of 0.996, visual observation of the curve indicated that σ (Eq. 24) would not be constant over this composition. One would not predict, however, that σ would vary as much as actually found (2.8–4.5). Despite this variability, it is interesting to calculate an average σ, leaving C as an adjustable parameter as suggested previously (13).

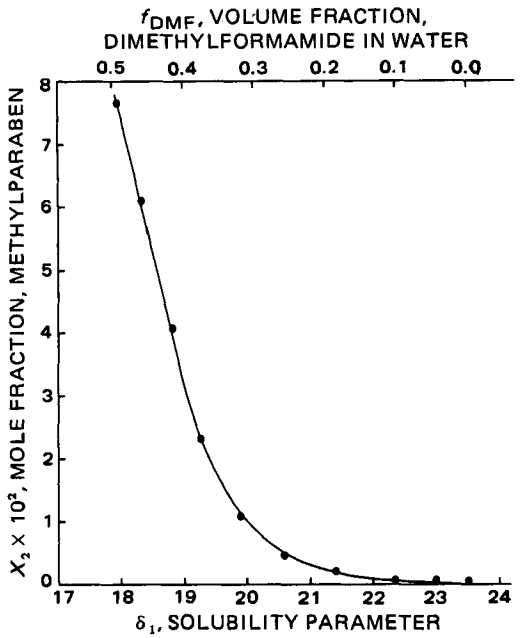

Figure 7—*Mole fraction solubility of methylparaben in dimethylformamide–water at 25° (8). Key: (●) experimental solubility; (—) back calculation curve, Eq. 21b, extended Hildebrand approach.*

The average value of σ in the formamide–water system, obtained from a least-squares linear fit of the curve in Fig. 6 is 2.734 (Eq. 16*a*). Referring to Eq. 25, $\gamma_w = 51.9$ for water–tetradecane and $\gamma_c = 31.2$ for formamide–tetradecane. The hydrophobic surface area of methylparaben is $130A^2$ or 130×10^{-16} cm^2. At 25°, $T = 298.15$°K and the Boltzmann constant equals 1.38×10^{-16} erg molecule^{-1} degree^{-1}. Using Eq. 25, one gets:

$$2.734 = \frac{C(51.9 \text{ erg/cm}^2 - 31.2 \text{ erg/cm}^2)\ 130 \times 10^{-16} \text{ cm}^2}{(2.303)\ (1.38 \times 10^{-16} \text{ erg/molecule deg})\ (298.15 \text{ deg})}$$

$$C \approx 0.9627 \cong 1.0$$

Yalkowsky *et al.*, accepted C values as large as 1.0, but not ordinarily for this kind of system. Considering the approximations, however, this is an acceptable fit.

In Fig. 6, one observes that for methylparaben in dimethylformamide–water, a plot of log X_2 *versus* volume fraction, $f = 0.0$ to $f = 0.5$, of the cosolvent appears to be linear. Here, the R^2 for linear and quadratic functions (Table I, Eqs. 17*a* and *b*) differ little. The partial F values show that the quadratic term is unnecessary. The volume fraction of dimethylformamide has been carried only to $f = 0.5$ in previous work (8) as observed in Fig. 6. However, the line probably becomes markedly curved at higher volume fractions of cosolvent, and Eqs. 17*a* and *b* can no longer be used here. This can be observed by setting $f = 1.0$, *i.e.*, 100% methylformamide, in Eqs. 17*a* and *b*, resulting in X_2 values greater than unity, which is not possible. Therefore the solubility of methylparaben in dimethylformamide–water can be considered log linear only to $f = 0.5$.

Both the linear and quadratic equations (Eqs. 17*a* and *b*, respectively) have a constant, equivalent to log X_w, of ~−3.60 (−3.607 for linear and −3.592 for quadratic) or $X_w = 0.000251$. The slope of the line, identified as σ, is ~5.2 (5.24 for linear and 5.0 for quadratic). Using Eq. 25 to calculate C, with γ_c for dimethylformamide–tetradecane equal to 4.6, one obtains at 25° in the range of $f = 0.0$–0.5:

$$5.2 = \frac{C(51.9 - 4.6)130 \times 10^{-16}}{(2.303)(1.38 \times 10^{-16})(298.15)}$$

$$C = (5.2/6.49) = 0.80$$

Although C is ordinarily considered to have a value of ~0.35–0.55, a value of 0.8 is not unreasonable.

The solubility equation suggested by Yalkowsky *et al.* (13):

$$\log S = \log S_w + \frac{C(\gamma_w - \gamma_c)\text{HYSA}}{2.303kT} \times f \qquad \text{(Eq. 28)}$$

should therefore provide a satisfactory approach for calculating the solubility of relatively hydrophobic drugs in water–cosolvent systems. The interfacial treatment is predicated on this log linear relationship between drug solubility and cosolvent volume fraction. If, however, the solubility parameter of the solute is similar to that of the cosolvent or is between the δ_1 value of the cosolvent and water, the points on the parabolic curve may be in a region of significant curvature; then the log linear equation and the interfacial model, involving σ, will not apply. On the other hand, the extended Hildebrand solubility approach handles drugs in polar and nonpolar solvent systems, whether the drug's solubility parameter is greater than, less than, or lies between the solubility parameters of a solvent pair, such as water and dimethylformamide. The following example demonstrates the use of the linear form of the extended Hildebrand solubility approach.

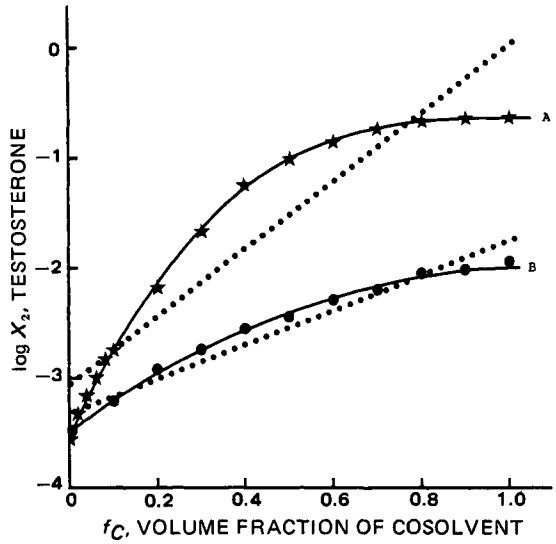

Figure 8—*Log mole fraction solubility of testosterone in chloroform–cyclohexane (★); and in isopropyl myristate–cyclohexane (●) at 25°. Key: (·····) linear regression line; (—) regression lines, (A) cubic, (B) quadratic.*

The solubility X_2 of methylparaben in dimethylformamide–water mixtures $\delta_1 = 18$ ($f = 0.5$) to $\delta_1 = 23.5$ ($f = 0.0$), from previous works (8) is shown in Fig. 7. The extended Hildebrand equation used to obtain the calculated line for these data may be linear, Eq. 21*a*, or quadratic, Eq. 21*b* of Table I. The statistical parameters show these equations to be equivalent. The A values range from 0.058 in pure dimethylformamide to 0.087 in water. The $-\log X^i = 1.0051$. At a volume fraction of dimethylformamide of 0.37, $\delta_1 = 19.28$ and $A = 0.0777$. Equation 21*a* yields log $\alpha_2/A = 8.2894$ and Eq. 21*b* gives log $\alpha_2/A = 8.4131$ for this mixture. When multiplied by A, the results from Eq. 21*a* gives log $\alpha_2 = 0.6441$. This value is added to $-\log X^i$ to obtain 1.6492. Changing the sign and taking the antilog results in $X_{\text{methylparaben}} = 0.0224$. The observed value is 0.0221. The percent error in the back calculation is thus 1.5%.

Nonpolar Cosolvent Systems—In contrast to water–cosolvent systems, it is interesting to consider nonpolar solvent mixtures having solubility parameters lower than the solubility parameters of the solute. An investigation to be published (15) involves a study of the solubility of testosterone ($\delta_2 = 10.9$) and testosterone propionate ($\delta_2 = 9.5$) in cyclohexane ($\delta_1 = 8.2$) with cosolvents such as chloroform ($\delta_1 = 9.1$), ethyl oleate ($\delta_1 = 8.6$), and isopropyl myristate ($\delta_1 = 8.9$). It was found that the log linear relationship did not hold in these systems. Even chloroform, which strongly solvates the steroidal solutes, did not produce a log linear plot. As observed in Fig. 8, the lines are markedly curved when plotted as log X_2 against the volume fraction of the cosolvent. Least-square straight lines are included, but statistical analysis is not needed to show that the experimental data yield nonlinear curves.

A report on benzoic acid in various proportions of hexane and ethyl acetate (16) was also studied for possible log linear characteristics. The solubility parameter of benzoic acid, 11.5, is greater than either hexane, 7.3, or ethyl acetate, 8.9. A plot of log X_2 *versus* volume fraction of the cosolvent, ethyl acetate, in the solvent mixture showed considerable curvature. The line was well fitted by a quadratic equation of the extended Hildebrand approach but not by the log linear form.

Ternary Solvent Systems—In recent work (17), the solubility of four sulfonamides has been determined in a ternary solvent consisting of dimethylacetamide ($\delta_1 = 11.1$), glycerin ($\delta_1 = 17.7$), and water ($\delta_1 = 23.5$). Two compounds of lower solubility in dimethylacetamide, namely sulfadiazine ($\delta_2 = 13.2$) and sulfisomidine ($\delta_2 = 12.6$), produced nearly

straight lines when log X_2 was plotted against the solubility parameter of the ternary solvent[4]. Two compounds of generally greater solubility, sulfathiazole (δ_2 = 13.1) and sulfamethoxazole (δ_2 = 11.6), produced highly curved lines which require quadratic or higher power series equations to fit the points. The solubility parameters of the drug molecules in these systems fall between the δ_1 values of the highly polar solvents, glycerin and water, and the strongly solvating aprotic solvent, dimethylacetamide. The curves show no peaks, but rather rise to a maximum mole fraction solubility in pure dimethylacetamide.

CONCLUSIONS

It may be concluded that the log linear solubility relationship, *i.e.*, log solubility *versus* volume fraction of cosolvent (Eq. 1) as introduced by Yalkowsky *et al.* (1), gives a good linear fit for semipolar drugs in a number of water–cosolvent mixtures, particularly when the solubility parameter of the solute is ~3 solubility parameter units lower than that of the cosolvent of a water–cosolvent mixture. When the cosolvent, such as dimethylformamide, is a strong solvating agent for the solute, sulfadiazine, a straight line function may persist up to 100% cosolvent even though the solubility parameters of drug and cosolvent are quite similar (<2 or 3 δ units apart).

For a system, caffeine, in an ordinary solvent pair, such as water and dioxane, or for theophylline in a moderately solvating mixture, such as water and polyethylene glycol 400 (5), the solubility parameter of the drug lies between the values of water and the cosolvent. Then, the log linear expression may be applied only over a limited range of solvent mixtures on either side of the solubility parameter of the solute. For example, the plot of log solubility *versus* volume fraction in a caffeine solution in water and dioxane was shown to be linear in dioxane from 0 to 30% and nearly linear in water from perhaps 0 to 10%. The log linear expression could not reproduce the solubility data for caffeine over the central range from 30 to 90% dioxane where the curve rises to an apex then falls as the solvent composition approaches pure dioxane.

In some systems, which might be predicted to follow the log linear relationship, a straight line function is not satisfactory but a higher order function, such as a quadratic or cubic in δ_1 or volume fraction provides a fit to the experimental data points. Systems of nonpolar solvents, *e.g.*, cyclohexane, in conjunction with cosolvents such as chloroform, isopropyl myristate, and ethyl acetate have not been found, in limited studies, to yield log linear relationships. These solutions, like more polar ones, are satisfactorily reproduced by use of quadratic, cubic, or quartic equations employed in the extended Hildebrand solubility approach. Ternary solvent systems, both polar and nonpolar, are under study.

It was found possible to derive the log linear equation from the extended Hildebrand solubility approach, thus providing a quasitheoretical foundation for the log linear equation based on solubility parameters.

[4] Volume fraction is not appropriate as the independent variable in a ternary solvent system, but solubility parameter of the solvent mixture may be used instead.

Effects of 3-Chloromethylthiochromone-1,1-dioxide on Nucleic Acid, Protein, and Aerobic and Anaerobic Metabolism of Ehrlich Ascites Tumor Cells

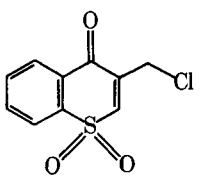
MARK H. HOLSHOUSER *, LARRY J. LOEFFLER, and IRIS H. HALL ˣ

Received April 22, 1981, from the *Division of Medicinal Chemistry, School of Pharmacy, University of North Carolina at Chapel Hill, Chapel Hill, NC 27514.* Accepted for publication October 6, 1981. *Present address: Division of Medicinal Chemistry, School of Pharmacy, Northeast Louisiana University, Monroe, LA 71209.

Abstract □ 3-Chloromethylthiochromone-1,1-dioxide was observed to be a potent inhibitor of Ehrlich ascites carcinoma growth and a moderate inhibitor of P-388 lymphocytic leukemia growth at 10 mg/kg/day. Preliminary *in vitro* studies showed that the agents significantly inhibited RNA and DNA synthesis in Ehrlich ascites cells. *In vivo* studies after dosing on Days 6, 7, and 8 demonstrated the same reductions in nucleic acid synthesis and a moderate reduction in protein synthesis. The primary site of nucleic acid synthesis, which was blocked by 3-chloromethylthiochromone, was at orotidine monophosphate decarboxylase in the primidine pathway. Other enzymes, in anaerobic and aerobic glycolysis, which were blocked include hexokinase, phosphofructokinase, succinic and α-ketoglutarate dehydrogenases, as well as States 3 and 4 of oxidative phosphorylation.

Keyphrases □ 3-Chloromethylthiochromone-1,1-dioxide—effect on nucleic acid, protein, aerobic and anaerobic metabolism of Ehrlich ascites tumor cells □ Metabolism—aerobic and anaerobic, effects of 3-chloromethylthiochromone-1,1-dioxide on nucleic acid, protein, Ehrlich ascites tumor cells □ RNA—effects of 3-chloromethylthiochromone-1,1-dioxide, Ehrlich ascites tumor cells □ DNA—effects of 3-chloromethylthiochromone-1,1-dioxide, Ehrlich ascites tumor cells

The antitumor activity of compounds containing the 1,4-naphthoquinone ring system has been reported previously. For example, dichloroallylawsone is currently in clinical trials in the United States (1–8). An investigation of sulfone analogs of naphthoquinones was undertaken recently (9), resulting in a series of substituted thiochromones and thiochroman-4-ones and their 1,1-dioxides. The synthesis and physical characteristics were reported previously (9). Certain of these agents were found to be active against the growth of Ehrlich ascites carcinoma and moderately active against P-388 lymphocytic leukemia growth in mice (9). The most potent compound, 3-chloromethylthiochromone-1,1-dioxide (I), afforded 100%



I

Scheme I

inhibition of Ehrlich ascites growth at 10-mg/kg/day dose ip (9). Previously, it has been postulated that certain 1,4-naphthoquinones require bioactivation by reduction of the quinone and subsequent displacement of a leaving group to form the potential alkylating agent (10). However, replacement of one of the naphthoquinone carbonyls with a sulfone group would alter the electronic character as well as the reduction potential of the molecules. The mechanism of action on cellular metabolism of the sulfone analogs may be different from the naphthoquinone; thus, a study of the effects of I on Ehrlich ascites cell metabolism was undertaken and those results are reported.

EXPERIMENTAL

Male CF_1 mice (~30 g) were implanted intraperitoneally on day 0 with 2×10^6 Ehrlich ascites tumor cells. For the anticarcinoma screens, animals were dosed intraperitoneally with compounds from Days 1 to 9. Animals were sacrificed on day 10; the volume of ascites fluid and the packed cell volume (ascitocrit) were determined (11). For the P-388 lymphocytic leukemia screen, BDF_1 male mice (~25 g) were implanted with 10^6 P-388 cells on Day 0. Test compounds were administered from Day 1 to 9 intraperitoneally. The day of death was recorded for both control and treated mice (12).

The metabolic *in vivo* studies were performed after inoculating CF_1 mice (~25 g) with 2×10^6 Ehrlich ascites tumor cells on Day 0. On Days 6, 7, and 8, a 10 mg/kg dose ip of I was administered. On Day 9, the mice were sacrificed and the ascites fluid was removed for *in vivo* biochemical assay. The number of tumor cells per milliliter and the 0.4% trypan blue uptake were determined with a hemocytometer. *In vitro* studies were conducted on Day-9 ascites cells with the drug present at 0.036–0.36 m*M* concentrations.

In vivo incorporation of thymidine into DNA was determined by the method of Chae *et al.* (13). One hour prior to the animal sacrifice on Day 9, 10 μCi of [6-^{3}H]thymidine[1] (24.7 Ci/mmole) was injected intraperitoneally. The DNA was isolated and the tritium content was determined in toluene–octoxynol (2:1), 0.4% of 2,5-diphenyloxazole, and 0.01% of 1,4-bis[2-(5-oxazolyl)]benzene scintillation fluid, and corrected for quenching. The DNA concentration was determined by the diphenylamine reaction using calf thymus DNA as a standard (13).

In vivo uridine incorporation of Ehrlich ascites cells into RNA was determined using 10 μCi of [5,6-^{3}H]uridine (24 Ci/mmole) injected into the animal 1 hr prior to sacrifice. The method of Wilson *et al.* (14) was used to extract RNA. Using yeast RNA as a standard, the RNA was quantitated by the orcinol reaction (14). *In vivo* leucine incorporation into protein was determined by the method of Sartorelli (15) using 10 μCi of [4,5-^{3}H]leucine (24.7 Ci/mmole) injected into the animal 1 hr prior to sacrifice. Extracted protein was determined by the Lowry (16) procedure using bovine albumin as the standard.

In vitro incorporation of [^{3}H]thymidine, [^{3}H]uridine, and [^{3}H]leucine[1] was determined using 10^6 Ehrlich ascites day-9 cells, 1 μCi of labeled precursor, 650 μl of minimum essential medium, and 100 ml of drug (0.36 m*M*) (17). The tubes were incubated at 37° for 60 min and inactivated by trichloroacetic acid. The acid insoluble labeled DNA was filtered on glass filter disks[2] and RNA and protein were filtered on nitrocellulose filters[3] by vacuum suction. Results were expressed as disintegrations per minute of incorporated precursor per hour per 10^6 cells.

In vivo nuclear DNA polymerase activity was determined on isolated Ehrlich ascites nuclei (18) after 3 days of dosing. The incubation medium was that of Sawada *et al.* (19) except that [^{3}H]deoxythymidine triphosphate (14 Ci/mmole) was used. The insoluble nucleic acids were collected on glass fiber filters[2] and counted.

In vivo nuclear RNA polymerase activities of Ehrlich ascites cells were determined with isolated nuclei (18). Messenger, ribosomal, and transfer RNA polymerases were isolated by using different concentrations of

Table I—Incorporation of Radiolabeled Precursors into Ehrlich Ascites Cells *In Vitro* During 1-hr Incubation with 3-Chloromethylthiochromone-1,1-dioxide

	Control	Control, %
[^{3}H]Thymidine Incorporation into DNA	100 ± 2[a]	17 ± 2[d]
[^{3}H]Uridine Incorporation into RNA	100 ± 5[b]	22 ± 4[d]
[^{3}H]Leucine Incorporation into Protein	100 ± 9[c]	88 ± 10

[a] 21,052 dpm/mg of DNA. [b] 37,651 dpm/mg of RNA. [c] 18,264 dpm/mg of protein. [d] $p \leq 0.001$.

ammonium sulfate in magnesium chloride (20). The incubation medium was that of Anderson *et al.* (20, 21) using [^{3}H]uridine triphosphate (23.2 Ci/mmole). Insoluble RNA was collected on nitrocellulose filters[3] and counted.

In vivo deoxythymidine and deoxythymidylate monophosphate and diphosphate kinase activities of Ehrlich ascites cells were measured spectrophotometrically at 340 nm for 20 min using 0.1 μmole of reduced nicotinamide adenine dinucleotide (22).

In vivo carbamyl phosphate synthetase activity of Ehrlich ascites cells was determined, using the reaction medium of Kalman *et al.* (23), in the presence of ornithine and ornithine transcarbamylase. Citrulline, formed from ornithine, was measured at 490 nm by the method of Archibald (24). *In vivo* aspartate transcarbamylase activity was assayed using the incubation medium of Kalman *et al.* (23). Colorimetric determination of carbamyl aspartate was carried out by the procedure of Koritz and Cohen (25). *In vivo* orotidine monophosphate decarboxylase activity was assayed by the method of Appel (26) using 0.1 μCi of [^{14}C]orotidine monophosphate (34.9 mCi/mmole). The [^{14}C]carbon dioxide generated in 15 min was trapped in potassium hydroxide[4] and counted. *In vitro* studies of orotidine monophosphate decarboxylase activity were conducted over the range of 0.036–0.36 mmole concentration of drug for 15 min. *In vivo* thymidylate synthetase activity of Ehrlich ascites cells was determined using a postmitochondrial (9000×*g* for 10 min) supernate and 5 μCi of [5-^{3}H]deoxyuridine monophosphate (11 Ci/mmole) according to the method of Kampf *et al.* (27). [^{14}C]Formate incorporation into purine of Ehrlich ascites cells was determined by the method of Spassova *et al.* (28) using 0.5 μCi of [^{14}C]formic acid (4.95 mCi/mmole). Purine was separated on silica gel TLC plates eluted with *n*-butanol–acetic acid–water (4:1:5). After identifying R_f values consistent with the standards, adenine and guanine, the plates were scraped and the radioactive content determined. Phosphoribosyl-1-pyrophosphate amidotransferase activity of Ehrlich ascites cells was determined on a supernate at 600×*g* for 10 min, measuring the reduction of 0.6 μmole of oxidized nicotinamide adenine dinucleotide at 340 nm for 30 min (29).

In vivo inosinic acid dehydrogenase activity of Ehrlich ascites cells was determined spectrophotometrically at 340 nm for 30 min using a supernatant fraction (600×*g* for 10 min). The assay medium was that of Magasanik (30) which contained nicotinamide adenine dinucleotide. *In vivo* dihydrofolate reductase activity of Ehrlich ascites cells was determined at 340 nm for 30 min as the oxidation of reduced nicotinamide adenine dinucleotide phosphate (31).

In vivo ribonucleotide reductase activity of Ehrlich ascites cells was determined by the method of Moore and Hurlbert (32) using [5-^{3}H]cytidine-5′-diphosphate (25 Ci/mmole). Ribose and deoxyribose nucleotides were separated on polyethyleneiminecellulose F plastic precoated TLC plates eluted with 4% boric acid–4 *M* LiCl (4:3) and scraped at the R_f values consistent with the standard deoxycytidine diphosphate.

In vivo phosphorylation of histones of Ehrlich ascites cells was determined by injecting 10 μCi of [γ-^{32}P]ATP (18.8 Ci/mmole) into mice 1 hr prior to sacrifice. The nuclei were isolated (17) and the histone chromatin proteins were extracted by the method of Raineri *et al.* (33). *In vivo* nonhistone protein phosphorylation dependent on nuclear protein kinase was determined using 2 nmoles of [γ-^{32}P]adenosine triphosphate (27 Ci/mmole) and isolated nuclei chromatin protein was collected on nitrocellulose filters (34). *In vivo* cyclic 3′,5′-adenosine monophosphate levels of Ehrlich ascites cells were determined by the radioimmunoassay method of Steiner *et al.* (35) using a commercial kit[5].

In vivo deoxyribonuclease (36), ribonuclease, and cathepsin (37) lysosomal enzymatic activities of Ehrlich ascites cells were determined using DNA, RNA, and azocasein as substrates, respectively. Bound acid hydrolytic enzymes were released using the detergent, octoxynol-100[6], pretreatment. Both free and total enzyme activities were observed by measuring nucleotides and aromatic peptide fragments which were determined at 260 and 280 nm, respectively. UV binding studies (38) were conducted *in vitro* with drug (0.36 m*M*) and DNA (35 μg/ml) in phosphate buffer, pH 7.2, over the 200–340 nm range for 24 hr at room temperature.

Table II—*In Vivo* Effects of 3-Chloromethylthiochromone-1,1-dioxide on Nucleic Acid and Protein Metabolism of Ehrlich Ascites Cells[a]

[a] $n = 6$. [b] $p \leq 0.001$.

An *in vitro* method (39) was used to determine if the drug was an initiation or an elongation protein synthesis inhibitor of Ehrlich ascites cells by comparison with the standards, pyrocatechol violet and emetine, using 1 μCi of [^{3}H]leucine (24.7 Ci/mmole). The reaction medium was spotted on filter paper disks[7], which were treated for 10 min in boiling 5% trichloroacetic, for 10 min in cold 5% trichloroacetic; and washed with cold 5% trichloroacetic acid, ether–ethanol (1:1) ether; and counted (32).

In vitro and *in vivo* oxidative phosphorylation studies (40) were conducted on Ehrlich ascites cells and the liver homogenates[8] of tumor-bearing mice with the substrates, α-ketoglutarate or succinate. Basal oxygen consumption (State 4) was determined with an oxygen electrode connected to an oxygraph. Adenosine diphosphate was then added to obtain State 3 or stimulated respiration. The number of microlites of oxygen per hour per milligram of protein for States 3 and 4 were calculated. The following glycolytic and Krebs cycle enzymatic activities were determined spectrophotometrically: hexokinase (41), phosphofructokinase (42), lactic dehydrogenase (43), succinic dehydrogenase (44), α-ketoglutarate dehydrogenase, and malic dehydrogenase (45). To be consistent in the expression of data for the spectral enzyme studies, a unit of enzyme activity is defined as that quantity of activity giving a change in absorbance of 0.001/min under the condition of the assay. Protein for the enzymatic assay was determined by the Lowry technique (16).

Probable (p) significant differences were determined by Student's t test. Data are expressed in Tables I–VI as percent of the control with standard deviation (n equals the number of animals per group).

RESULTS

Compound I was shown to have 100% inhibition of Ehrlich ascites tumor growth at a 10 mg/kg ip dose. Doses of 20 and 30 mg/kg were found to be less active, *i.e.*, 25 and 18% inhibition, respectively. In the P-388 lymphocytic leukemia screen, I at 10 mg/kg/day intraperitoneally was marginally active at T/C% = 130 (Table VII). After dosing with the agent on days 6, 7, and 8, the cell count per milliliter of Ehrlich ascites fluid was reduced from 226 × 10^6 to 63 × 10^6. The *in vitro* incorporation studies

.180	68 ± 7
.360	44 ± 6

[a] $p \leq 0.001$.

(Table I) demonstrated, using 10^6 cells collected from 9-day Ehrlich ascites animals, that thymidine incorporation into DNA was reduced 83%, and uridine incorporation into RNA was reduced 78%. The *in vivo* thymidine incorporation into DNA for the control was 95,970 dpm/mg, which was reduced 77% by drug administration for 3 days. *In vivo* uridine incorporation into RNA for the untreated animals was 198,200 dpm/mg of RNA, which was reduced 77% by drug therapy. *In vivo* leucine incorporation into protein for the control was 37,946 dpm/mg of protein, which was reduced 50% in the treated animals.

The DNA and RNA polymerase activities were not altered by drug administration. The control values were 45,734 dpm/mg of nuclear protein for DNA polymerase, 6434 dpm/mg for mRNA polymerase, 7340 dpm/mg for rRNA polymerase, and 8254 dpm/mg of nuclear protein for tRNA polymerase. The activity for thymidine kinase was 8.90 enzyme units/mg of protein, thymidine monophosphate kinase was 8.65 enzyme units/mg of protein, and thymidine diphosphate kinase activity was 5.60 enzyme units/mg of protein. Drug treatment did not alter the activities of the kinases except for the diphosphate which was inhibited by 16%. Carbamyl phosphate synthetase activity for the control resulted in the formation of 0.117 mg of citrulline formed/hr/mg of protein, and aspartate transcarbamylase activity resulted in 0.81 mg of carbamyl aspartate formed per hour per milligram of protein. Drug administration resulted in an increase of 45% in carbamyl phosphate synthetase and 16% in aspartate transcarbamylase activities.

In vivo orotidylic monophosphate decarboxylase activity for the control was 26,298 dpm of [^{14}C]carbon dioxide produced/hr/mg of protein, which was reduced 75% by 3 days of drug treatment. *In vitro* orotidylic monophosphate decarboxylase activity was reduced significantly: 56%, by 0.36 m*M* concentration of drug (Table V). *In vivo* thymidylate synthetase activity for normal animals was 103,308 dpm of [^{3}H]thymidine formed hr/mg of protein, which was unchanged by drug therapy. *In vivo* [^{14}C]-formate incorporation into purines for the control was 10,788 dpm of purines/hr/mg of protein. *In vivo* phosphoribosyl pyrophosphate amidotransferase activity for normal cells was 376 enzyme units/mg of protein. *In vivo* inosinic monophosphate dehydrogenase activity resulted in 2.06 enzyme units/mg of protein. Drug treatment resulted in no change in amidotransferase activity but caused a 37% increase in the dehydrogenase activity.

In vivo dihydrofolate reductase activity was 8.56 enzyme units/mg of protein, which was increased 19% by drug treatment. *In vivo* ribonucleotide reductase activity was 155,065 dpm of [^{3}H]deoxycytidine diphosphate formed/hr/mg of protein. This was unaffected by drug treatment. *In vivo* histone phosphorylation for the control was 2954 dpm of [γ-^{32}P]incorporated into histones/hr/mg of nuclear protein, inhibited 18% by drug administration. Nonhistone phosphorylation resulted in 9807 dpm of [γ-^{32}P]incorporated into protein/hr/mg of chromatin protein, elevated 83% by drug therapy. *In vivo* cyclic adenosine monophosphate levels for the control were 3.6 pmole/10^6 cells elevated by 48% after drug administration.

The UV studies with I and DNA demonstrated an elevation of UV peaks at 222 and 240 nm, and a hyperchromic shift at 260 nm, indicating possible binding between the drug and nucleic acids. The effects on glycolytic and Krebs cycle enzymatic activities of I were dramatic. Hexokinase activity for untreated 9-day Ehrlich ascites cells was 195 enzyme units/mg of protein, which was inhibited 84% by drug administration (Table IV). Phosphofructokinase activity was determined for the control as 176 enzyme units/mg of protein, which was reduced 54% by the drug. Malic dehydrogenase activity for the control was 80 enzyme units/mg of protein and lactic dehydrogenase activity was 623 enzyme units/mg of protein. Treatment with I had little effect on these two dehydrogenase activities, causing 14 and 9% inhibition, respectively. Succinic dehydrogenase activity for the control was 69 enzyme units/mg of protein which was reduced 52% by drug treatment. α-Ketoglutarate dehydrogenase activity was measured as 1.68 enzyme units/mg of protein for the control cells, which was reduced 76% by drug therapy for 3 days.

Table IV—*In Vivo* Effects of 3-Chloromethylthiochromone-1,1-dioxide on Glycolytic and Krebs Cycle Enzyme Activities of Ehrlich Ascites Cells of CF_1 Mice [a]

Parameter	Control	Treated
Hexokinase	100 ± 9	14 ± 1[b]

α-Ketoglutarate dehydrogenase	100 ± 11	24 ± 7[b]

[a] $n = 6$. [b] $p \leq 0.001$.

Table V—*In Vitro* Effects of 3-Chloromethylthiochromone-1,1-dioxide on Oxidative Phosphorylation Processes of 9-Day Ehrlich Ascites Cells [a]

Parameter	Control, % Control	Control, % Treated
Succinate —state 4	100 ± 7[b]	70 ± 7[f]
—state 3	100 ± 4[c]	59 ± 5[f]
α-Ketoglutarate—state 4	100 ± 5[d]	57 ± 10[f]
—state 3	100 ± 11[e]	49 ± 7[f]

[a] $n = 6$. [b] 5.27 μl O_2 consumed/hr/mg protein. [c] 8.73 μl O_2 consumed/hr/mg protein. [d] 3.57 μl O_2 consumed/hr/mg protein. [e] 5.16 μl O_2 consumed/hr/mg protein. [f] $p \leq 0.001$.

Both basal and adenosine diphosphate-stimulated respiration rates were reduced 75% by drug therapy *in vivo*, whereas *in vitro* studies at 0.36 m*M* concentration of drug demonstrated 30 and 41% inhibition, respectively, using succinate as substrate (Tables V and VI). The basal- and adenosine diphosphate-stimulated respiration rates using α-ketoglutarate as substrate were inhibited 82 and 86%, respectively. In the *in vitro* studies with α-ketoglutarate as substrate, I demonstrated 43 and 51% inhibition for States 4 and 3, respectively. The *in vivo* effects of the drug on liver respiration rates of tumor-bearing mice were not as severe as those observed in the tumor cells, and only minimal changes were observed (Table VI).

Figure 1 demonstrates that I, when incubated with endogenous mRNA and essential amino acids, follows a pattern of inhibition of protein synthesis, which resembles the initiation inhibitor, pyrocatechol violet, as opposed to the elongation inhibitor, emetine. The degree of inhibition of protein synthesis was relatively moderate.

DISCUSSION

A series of potential bioreductive alkylating agents have been synthesized (7, 8), specifically α-substituted naphthoquinones, quinoline-5,8-quinones, and naphthazarines which contain halomethyl, acetoxymethyl, carbamoylmethyl, and carbophenoxymethyl groups alpha to a carbonyl group as the alkylating moieties. A number of these agents were observed to be active in the sarcoma 180 and adenocarcinoma 755 ascites screens. A rough correlation between antitumor activity in the sarcoma 180 screen and polarographic reduction potential ($E_{1/2}$) of the quinone moiety was demonstrated. Those compounds that possessed the most negative half-wave reduction potential, *i.e.*, those compounds that were difficult to reduce, demonstrated the highest activity against sarcoma 180 tumor growth. Lin *et al.* (7, 8) suggested that those quinone deriva-

tives, when reduced, suffered loss of a leaving group to form a quinone methide, a potential alkylating agent which could alkylate bionucleophiles. It was shown that such an active species could be trapped *in vitro* by an amine function or be allowed to dimerize.

The 3-substituted thiochromone-1,1-dioxides were synthesized as novel analogs of naphthoquinones. Isosteric replacement of one carbonyl with a sulfone group alters the electronic character and ease of reduction. However, preliminary experiments indicated that no apparent correlation existed between half-wave reduction potential and antineoplastic activity in the Ehrlich ascites screen. The thiochromone-1,1-dioxides may be acting as direct alkylating agents *via* a Michael-type addition or a carbamoylation reaction with some biological nucleophile or a direct displacement of the leaving group. For example, high reactivity of I with a variety of alcohols and amines would support this view.

In the naphthoquinone class, lapachol and dichloroallylawsone are the most potent antineoplastic agents (5). Lapachol is currently marketed in Brazil and dichloroallylawsone[9] [2-(3,3-dichloroallyl)-3-hydroxy-1-4-naphthoquinone] is in clinical trials in the United States (15). Bennett *et al.* (46) observed, in cultured L-1210 lymphoid leukemia cells, that dichloroallylawsone interfered with L-1210 cell respiration and inhibited pyrimidine biosynthesis at the dihydro-orotate dehydrogenase step. Thus, it is interesting to observe that the major effect of I is on basal (State 4) and adenosine diphosphate-stimulated (State 3) respiration in Ehrlich ascites cells. Drastic reduction in respiration of Ehrlich ascites cells was observed with succinate as substrate, which requires a flavin adenine nucleotide linked dehydrogenase, as well as α-ketoglutarate, which requires a nicotinamide adenine dinucleotide linked dehydrogenase, both *in vivo* and *in vitro*.

No effects were demonstrated on the respiration of livers of tumor-bearing mice, indicating that the drug has some tissue specificity. However, when the Krebs cycle dehydrogenase activities of Ehrlich ascites cells were measured, it was observed that both succinic dehydrogenase and α-ketoglutarate dehydrogenase activities were inhibited by this agent. Furthermore, activities of the regulatory enzymes of anaerobic glycolysis, hexokinase and phosphofructokinase, were also reduced significantly by I. These studies would indicate that after drug treatment, there existed a reduction in energy available from mitochondrial oxidative phosphorylation, as well as glycolytic substrate phosphorylation, for the synthetic process of rapidly proliferating tumor cells.

Initial studies indicated that I was a moderate inhibitor of protein

[9] NSC 126771.

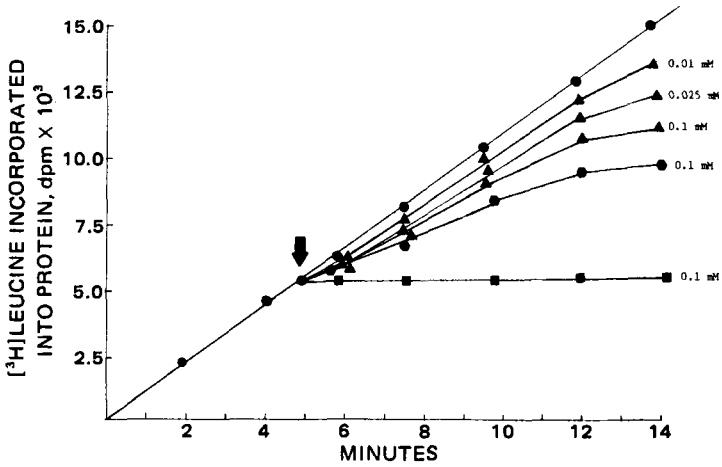

Figure 1—*Effect of 3-chloromethylthiochromone-1,1-dioxide on the initiation and elongation of protein molecular synthesis. Key: (●), control; (▲), drug, 0.01 mM, 0.025 mM, 0.1 mM; (●), pyrocatechol violet, 0.1 mM; (■), emetine, 0.1 mM; ↓, addition of drug.*

synthesis, probably blocking the initiation process of translation. Moderate elevation of cyclic adenosine monophosphate levels of the Ehrlich ascites cells was also observed after drug therapy. Elevated levels are linked with reversal of tumor morphology to a more normal state, reduction of cell proliferation, and enhanced cellular differentiation (47–49).

The inhibition of DNA and RNA synthesis appears to be caused by a lack of pyrimidine due to the fact that I blocks orotidine monophosphate decarboxylase activity, depleting uridylate monophosphate for the conversion to thymidylate monophosphate and cytidylate monophosphate. The decarboxylase enzyme was inhibited both *in vivo* and *in vitro* and is the same site of pyrimidine synthesis inhibition, which has been implicated for the standard clinical antineoplastic agent, azauridine-5′-phosphate (50).

Thus, this sulfone analog of 1,4-naphthoquinones has similar effects on tumor cell metabolism, *i.e.*, inhibition of pyrimidine synthesis and oxidative phosphorylation, as those reported for 1,4-naphthoquinones (46) despite the fact that the sulfone analog does not have the same electronic characteristics or reduction capability as the 1,4-naphthoquinones. Compound I does not suppress the oxidative phosphorylation process exclusively, but its effects are extended to the actual dehydrogenase and kinase enzymes which regulate anaerobic and aerobic glycolysis, indicating that the agent is not simply blocking the electron transport system by acting as an electron acceptor as would be expected for a quinone.

An *In Vitro* Model for the Study of Antibacterial Dosage Regimen Design

ROGER D. TOOTHAKER *§, **PETER G. WELLING** *x, and **WILLIAM A. CRAIG** ‡

Received August 7, 1981, from the *School of Pharmacy, University of Wisconsin, Madison, WI 53706 and the ‡Veterans Administration Hospital, Madison, WI 53705. Accepted for publication November 16, 1981. §Present address: School of Pharmacy, University of Washington, Seattle, WA 98195.

Abstract □ A model was developed that is capable of simulating antibacterial agent concentration *versus* time profiles commonly observed following intravenous and intramuscular bolus injections, intravenous infusions, and oral doses, administered as single or multiple doses. The model consisted of two physical compartments separated by a membrane of a commercial hemodialyzer. The 1.08 m^2 membrane surface area allowed rapid transmembrane passage of drugs and other small molecules, while membrane pore size prevented bacterial passage. These characteristics allowed bacteria in one of the two compartments of the model to be exposed to time-variant drug concentrations without affecting the number or concentration of bacteria. The model was used to study the effects of a multiple intravenous bolus dosage regimen of ampicillin on *Escherichia coli* ATCC 12407.

Keyphrases □ Penicillin—*in vitro* model for the study of antibacterial dosage regimen design □ Models—*in vitro*, study of antibacterial dosage regimen design □ Antibacterials—*in vitro* model, study of dosage regimen design

The antibacterial agent concentration profiles to which bacteria are exposed *in vivo* vary with the method of drug administration. Continuous intravenous infusion yields constant plasma and tissue drug concentrations once steady state is achieved, while the short elimination half-life of most antimicrobial agents results in rapid decreases in plasma and interstitial fluid drug concentrations (1) following bolus intravenous, intramuscular, or oral doses.

Considerable progress has been made during the past 15 years in determining the mechanism of action of β-lactam antibiotics (2, 3). However, the relative therapeutic effectiveness of intermittent and continuous dosage regimens for these compounds is uncertain (4, 5). Attempted correlations of therapeutic effectiveness with various pharmacokinetic parameters, such as maximum plasma concentration (6), the time period during which drug levels exceed the minimum inhibitory concentration (7), area under the plasma level curve (8), intensity factor (9), and the degree of serum protein binding (10), have been difficult due to the many interactions between the drug, bacteria, infection site, and host. Figure 1—*Schematic diagram of model showing sampling ports (A,B,C,D), hemodialysis units (H), reservoirs (R), tubing, main pump, and exchange pump. Arrows indicate direction of broth flow.*

tained from *in vitro* studies of bactericidal kinetics at constant drug concentrations is not directly applicable to the situation *in vivo* where drug concentrations may undergo rapid changes. The importance of phenomena such as the postantibiotic effect in multiple dose antibiotic regimens has also been difficult to assess in animal models and clinical situations due to uncontrollable factors (11).

The present report describes the theory, characterization, and testing of an *in vitro* model which can be used to monitor the antibacterial effect of simulated plasma drug concentration profiles from constant intravenous infusions or from single or multiple intravenous bolus, intramuscular, or oral doses.

EXPERIMENTAL

Drugs—Solutions of anhydrous ampicillin powder[1] in Mueller-Hinton broth[2] were prepared immediately prior to use. Drug concentration was monitored by the inclusion of a trace amount of [^{14}C]penicillin G potassium[3] (16.22 mCi/mmole) in a broth solution of the unlabeled drug. Scintillation counts were obtained on 0.1-ml broth samples in 4.0 ml of a scintillation solution[4].

Bacteria—An overnight culture of *Escherichia coli*, ATCC 12407[5], in Mueller-Hinton broth was serially diluted in broth to ~10^2 colony-forming units/ml (cfu/ml) and allowed to grow to 10^8 cfu/ml. A 1.0-ml aliquot of this solution was used to inoculate the model. Bacterial growth was monitored in 16 × 125-mm glass tubes using optical density measurements obtained spectrophotometrically at 500 nm[6]. Optical density was linearly related to bacterial concentrations between 6×10^5 and 4×10^8 cfu/ml. The minimum inhibitory concentration for ampicillin against the test organism was obtained by the broth dilution method (12) with an initial inoculum size of 5×10^4 cfu/ml and incubation at 37° for 18 hr.

Viable Cell Assay—Viable cell counts were obtained by performing six consecutive serial dilutions of a 0.1-ml broth sample in 0.9 ml of 0.9% sodium chloride solution at 10°. Nutrient agar[2] plates were divided into eight sectors and streaked with duplicative 10-μl aliquots of each dilution. Visual inspection of the number of colonies formed in each sector after incubation at 37° for 12 hr gave the number of colony-forming units per milliliter in the original sample. Colony recounts following an additional 12 hr of incubation failed to show an increase in colony numbers.

Model Description—The model consisted of a closed loop of 0.95-mm i.d. tubing[7] on each side of the membrane of a hemodialyzer[8] (Fig. 1).

Table I—Kinetic Data for Ampicillin in the Experiment [a]

Dose	Time, Above MIC[b], hr	Time, Below MIC, hr	$t_{1/2}$, min	V_{TOT}, ml	C_0[c] MIC	AUC[d], μg min/ml, Above MIC	AUC[d], μg min/ml, $t^{0 \to 6\ hr}$
1	2.6	3.4	75	823	4.12	167	389
2	2.6	3.4	78	824	4.11	172	399
3	2.8	3.2	83	857	3.95	171	407

[a] Data presented in Fig. 5. The three ampicillin doses were administered at 6-hr intervals. [b] Minimum inhibitory concentration. [c] Ratio of drug concentration immediately after injection to the minimum inhibitory concentration for *E. coli*, ATCC 12407. [d] Area under ampicillin concentration *versus* time curve that is above the minimum inhibitory concentration and the area under the total curve during the 6 hr following each dose (minimum inhibitory concentration = 0.9 μg/ml).

Each dialyzer contained a 17-μm thick membrane[9] of 0.54-m^2 surface area. Two dialyzers were connected in series in order to increase membrane surface area and to decrease ultrafiltration of fluid across the membrane. The tubing was gas sterilized, and the model was assembled aseptically and filled with Mueller-Hinton broth. The broth was synchronously pumped through both tubing loops using a dual channel peristaltic pump[10] (main pump) in opposing flows past the membrane. The total volume of broth in the system was ~800 ml (Table I). A 1-liter glass infusion reservoir on each side of the system permitted pressure equalization and allowed the broth volume on each side of the model to be monitored. Access into the closed system was by syringe through injection sleeves from the arterial infusion sets[11]. A broth exchange loop, EXC. IN and EXC. OUT in Fig. 1, was connected to a tubing loop on one side of the model to allow aseptic introduction of fresh broth and removal of a mixture of broth and drug using a dual channel peristaltic pump[10] (exchange pump). The entire system was maintained at 37° in a 0.9-m^3 incubator[12].

Model Theory—The side of the model containing the broth exchange loop was designated the drug compartment; the other side was designated the bacterial compartment. Bacteria in the bacterial compartment could not penetrate the dialysis membrane and, thus, could not enter the drug compartment. Drug introduced into either compartment could rapidly equilibrate across the membrane due to the large membrane surface area, and could be removed from the system through the broth exchange loop on the drug compartment side of the model.

Simulated intravenous infusion concentration profiles in the bacterial compartment were obtained by injecting drug as a bolus into the drug compartment with the broth exchange loop closed (Fig. 2A). Drug concentration in the bacterial compartment C_{Ba} at time t is described as:

$$C_{Ba} = \frac{D}{V_{TOT}}[1 - e^{(k_{12}+k_{21})t}] \qquad \text{(Eq. 1)}$$

where D is the administered dose, V_{TOT} is the total volume of broth in the system, and k_{12} and k_{21} are first-order rate constants for drug movement across the dialysis membrane. Once drug equilibration in the model is achieved, the steady-state drug concentration is given by:

$$C_{Ba}^{ss} = D/V_{TOT} \qquad \text{(Eq. 2)}$$

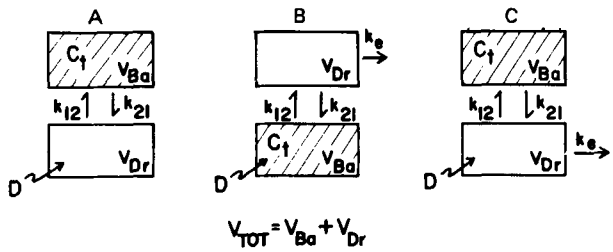

Figure 2—*Schematic representations of drug kinetics in the model during (A) intravenous infusion, (B) intravenous bolus injection, and (C) intramuscular or oral dosage simulations.* V_{Dr} *and* V_{Ba} *are the drug and bacterial compartment volumes, respectively.* C_t *is the concentration of drug in the volume* V_{Ba} *at time t, described in the text as* C_{Ba}. *Other symbols are described in text.*

[11] Travenol Laboratories, Deerfield, Ill.
[12] National Appliance, Hollywood, Fla.

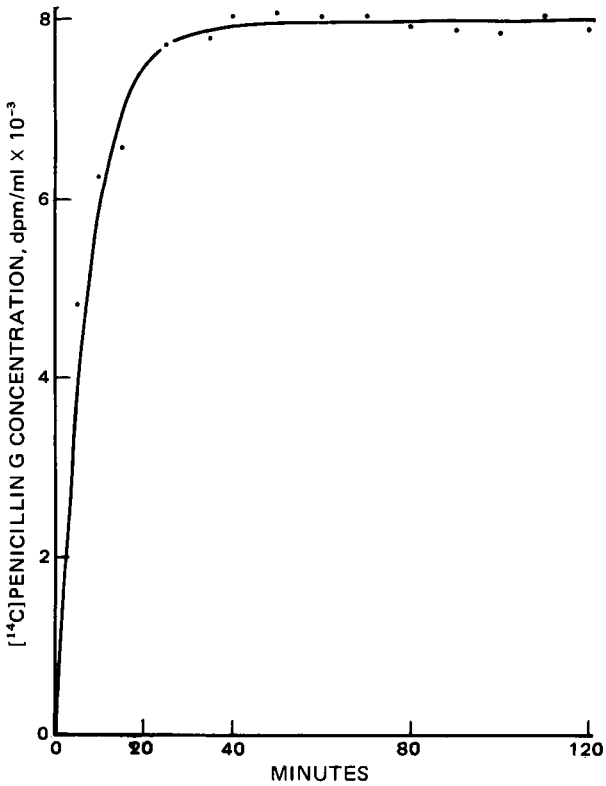

Figure 3—*Intravenous infusion simulation in the model showing experimentally determined drug concentration* versus *time data points.*

The desired C^{ss} value in the bacterial compartment of the model was obtained by selecting the proper dose for the total system volume according to Eq. 2. The time taken for drug levels in the bacterial compartment to reach C^{ss}_{Ba} is a function of the rate of drug passage across the membrane.

Intravenous bolus simulations were achieved by bolus drug injection into the bacterial compartment with the broth exchange loop functioning. The exchange pump speed controlled the rate of drug removal from the model (Fig. 2B). The bacterial compartment drug concentration is described by:

$$C_{Ba} = Ae^{-\alpha t} + Be^{-\beta t} \quad \text{(Eq. 3)}$$

where

$$A = \frac{D(k_{21} + k_e - \alpha)}{V_{Ba}(\beta - \alpha)} \quad \text{(Eq. 4)}$$

$$B = \frac{D(k_{21} + k_e - \beta)}{V_{Ba}(\alpha - \beta)} \quad \text{(Eq. 5)}$$

and

$$\begin{pmatrix}\alpha\\ \beta\end{pmatrix} = \frac{1}{2}\left[(k_{12} + k_{21} + k_e) \pm \sqrt{(k_{12} + k_{21} + k_e)^2 - 4k_{21}k_e}\right] \quad \text{(Eq. 6)}$$

As drug removal by the broth exchange loop was a first-order process, and passage of drug across the membrane was fast compared to drug elimination, a plot of the decrease in the logarithm of the drug concentration with time was linear.

Oral and intramuscular dosage simulations were obtained by injecting a drug bolus into the drug compartment with the broth exchange loop functioning. The membrane passage controlled the rate at which drug concentration increased in the bacterial compartment, while the rate of drug elimination was controlled by the exchange pump rate (Fig. 2C). Equation 7 describes the bacterial compartment drug concentration profile:

$$C_{Ba} = \frac{Dk_{12}}{V_{Ba}(\alpha - \beta)}\left[e^{-\beta t} - e^{-\alpha t}\right] \quad \text{(Eq. 7)}$$

The elimination rates for the intravenous bolus, intramuscular, and oral dose simulations are controlled by the exchange pump speed according to:

$$t_{1/2} = \frac{0.693V_{TOT}}{Q} \quad \text{(Eq. 8)}$$

where Q is the broth exchange loop flow rate.

Use of the Model to Examine the Antibacterial Effect of Ampicillin—The antibacterial effect of a multiple intravenous bolus dosage regimen of ampicillin on *E. coli*, ATCC 12407, was examined. A 1-ml inoculum of 1×10^8 cfu/ml of *E. coli*, which was in logarithmic growth phase, was injected into the bacterial compartment. Logarithmic bacterial growth in the model was monitored by means of optical density. When the bacterial concentration reached 5×10^6 cfu/ml, the first of three 3-mg ampicillin doses was administered as a 1-ml bolus into the bacterial compartment with the broth exchange loop functioning. Similar doses of ampicillin were given at 6 and 12 hr after the initial dose. Drug and viable bacteria concentrations were monitored every 0.5 hr for 18 hr following the first ampicillin dose. The serial dilutions in the bacterial assay served to dilute ampicillin in samples to noninterfering levels.

RESULTS

The kinetics of penicillin G disposition in the model were examined by injecting 0.5 ml of a mixture of 11.2 μg/ml of [^{14}C]penicillin G potassium and 962 μg/ml of unlabeled penicillin G potassium into the system. With the main pump flow rate set at 120 ml/min, circulation time for drug in the model was found to be <3 min. A 0.5-min drug equilibration half-time across the membrane was calculated from an intravenous infusion dose. Observed C^{ss} values under these conditions indicated that the drug did not bind to a significant degree to the dialysis membrane.

Drug concentration profiles in the bacterial compartment during intravenous infusion and oral dosage simulations are shown in Figs. 3 and 4. Multiple bolus intravenous injection simulations are shown in Fig. 5. The residual plot for the absorption phase of the oral simulation was linear, indicating that the approach to steady-state drug concentration in the bacterial compartment can be represented by a first-order process. The absorption and elimination half-lives for the oral dose simulations were ~5 and 53 min, respectively.

The possible effect of changes in the exchange pump flow rate on

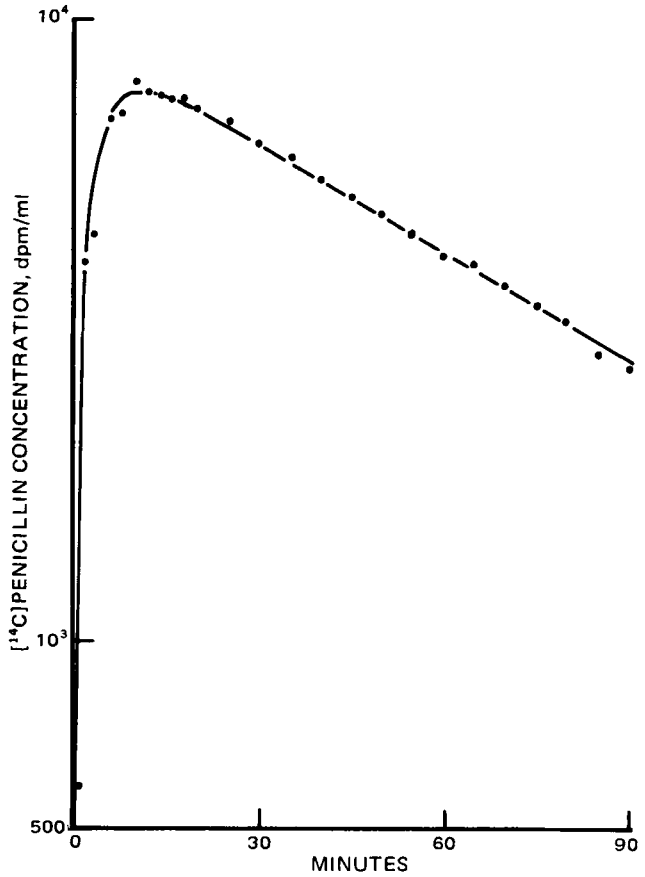

Figure 4—*Intramuscular injection or oral dosage simulation in the model showing experimentally determined bacterial compartment drug concentration* versus *time data points.*

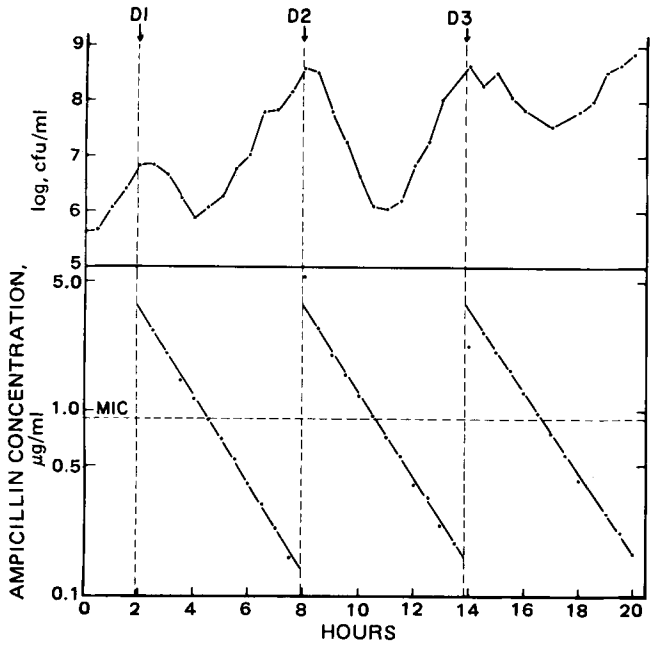

Figure 5—*Plots of the logarithm of the number of colony-forming units per milliliter (cfu/ml) and the log of the drug concentration* versus *time following three (D1,D2,D3) simulated intravenous bolus injections of ampicillin against* E. coli, *ATCC 12407. The minimum inhibitory concentration (0.9 μg/ml) is indicated as a horizontal dotted line.*

bacterial growth in the absence of drug was determined by varying the pump flow rates to yield simulated drug half-lives of infinity (exchange loop closed), 75, and 37 min. The tests were performed on different days using different bacterial inocula. The slopes ($\pm SD$), obtained by linear regression, for the logarithmic bacterial growth curves were 0.72 (±0.05) for $t_{1/2} = \infty$, 0.75 (± 0.02) for $t_{1/2} = 75$ min, and 0.78 (±0.01) for $t_{1/2} = 37$ min. These values were not significantly different from each other and show that bacterial growth rates were unaffected by broth exchange rates within the range of values studied.

The results of the repeated dose intravenous bolus simulation, using ampicillin against *E. coli*, ATCC 12407, are shown in Fig. 5. Pertinent data are presented in Table I. Bacterial kill occurred following each dose of antibiotic, and regrowth resumed shortly after antibiotic levels had fallen below the minimum inhibitory concentration. The time that elapsed between dosing and observed bactericidal effect tended to decrease slightly, but the maximum kill rate and the absolute amount of bacterial kill appeared also to differ with succeeding doses.

DISCUSSION

Antimicrobial therapy is generally administered on an empirical basis and optimization of effect through accurate dosage regimen design has not been accomplished in most cases.

It is difficult to establish accurate relationships between drug kinetics and antibacterial effects *in vivo* because of the contribution of many, often uncontrollable, factors such as tissue penetration, development of bacterial resistance, variable binding of drug to plasma proteins, and interactions of drugs with other substances. Failure to generate useful data in clinical situations, or by the use of animal models, has given rise to an increasing interest in the development of *in vitro* systems which may simulate in an idealistic manner the *in vivo*, clinical situation. While it is recognized that such systems exclude many of the variables that exist *in vivo*, they are nonetheless justified in that they attempt to establish relationships between changing drug concentrations and antibacterial effect in a controlled situation.

Some *in vitro* studies have examined the kinetics of antimicrobial effects using constant drug concentrations (13, 14). However, the results obtained in these studies do not apply to many clinical situations in which drug levels are constantly changing.

Other models have been designed to simulate varying drug levels with respect to time (15–19). In most of these systems, the addition of fresh broth in order to change the concentration of antibiotic results in simultaneous dilution of the organism (15, 16, 18, 19). In some models there is less than optimal control of the drug concentration *versus* time profiles.

The described model has advantages over previous systems in that the addition of fresh growth medium in order to dilute the concentration of antibiotic does not dilute the bacteria, and also the closed, continuously recycling system provides considerable flexibility for the simulation of a variety of single and repeated dosage regimens.

The rapid rate of drug equilibration across the dialyzer membranes observed with the present system can be altered by varying the membrane surface area. This would have the effect of altering the drug absorption rate in oral or intramuscular dose simulations and changing the time for steady-state drug levels to be achieved in the bacterial compartment during infusion simulations.

Tracer quantities of [^{14}C]penicillin G were used in this study to monitor both penicillin G and ampicillin levels, characterize the model, and provide preliminary data on dosage simulation. It is recognized that circulating total radioactivity does not necessarily represent microbiologically active drug, and the preliminary concentration effect relationships described in Fig. 5 must be interpreted in this light. However, the good agreement between drug concentrations relative to the minimum inhibitory concentration and the antibacterial effect serves to illustrate the usefulness of the model for this type of study. To characterize accurately the concentration–effect relationship of any chemically or bacteriologically unstable compound, it will be necessary to measure the concentration of active drug.

Various improvements to the described model are possible and are being investigated. For example, with appropriate engineering, the overall size of the system and the membrane surface area may be reduced to permit greater ease in handling without loss of model flexibility. However, the present model is suitable to study drug antibacterial activity under a variety of dosing conditions. The data in Fig. 5 were generated with the bacteria in logarithmic growth at the time of drug administration. With appropriate adjustment of experimental conditions, drug activity can be determined against bacteria in either logarithmic or stationary growth phases.

Enhanced Rectal Absorption of Theophylline, Lidocaine, Cefmetazole, and Levodopa by Several Adjuvants

TOSHIAKI NISHIHATA, J. HOWARD RYTTING ˣ, and TAKERU HIGUCHI

Received December 18, 1980, from the *Pharmaceutical Chemistry Department, The University of Kansas, Lawrence, KS 66045.* Accepted for publication October 25, 1981.

Abstract □ Ten potential adjuvants for rectal absorption which are structurally similar to salicylate have been examined using an *in situ* perfusion of the rat rectum technique as well as an *in vivo* absorption method from microenemas. All of the adjuvants studied readily disappeared from the perfusate at pH 4.5; however, several were not absorbed well at pH 7.4. Only those that were lost rapidly from the perfusate at pH 7.4 were effective in enhancing the disappearance of the drugs (theophylline, lidocaine, cefmetazole, and levodopa) at either a pH of 4.5 or 7.4. The compounds that were effective in promoting the disappearance of drugs from the rectal perfusate all had hydroxy and carboxy groups. Those substances lacking a hydroxy group were not effective. The binding of these potential adjuvants and salicylates to rat rectum tissue was studied by equilibrium dialysis. Those adjuvants with relatively high binding to rat rectal tissue were better absorbed themselves and promoted the disappearance of drugs more than those substances exhibiting little binding. Thus, adjuvant binding to some feature of the rectal membrane appears to be important in the enhanced absorption of drugs from the rectum under the conditions of this study.

Keyphrases □ Absorption, rectal—enhanced rectal absorption of theophylline, lidocaine, cefmetazole, and levodopa by several adjuvants □ Theophylline—enhanced rectal absorption by several adjuvants □ Lidocaine—enhanced rectal absorption by several adjuvants □ Cefmetazole—enhanced rectal absorption by several adjuvants □ Levodopa—enhanced rectal absorption by several adjuvants

In other papers (1–3), salicylate has been shown to significantly improve the absorption of theophylline, lidocaine, cefmetazole, and levodopa from the rectum, particularly in their ionic forms. The present report describes the effects of several other compounds which are structurally similar to salicylate on the rectal absorption of these drugs. These potential adjuvants include the sodium salts of benzoic acid, *o*-anisic acid, *p*-anisic acid, 3-methoxysalicylic acid, 5-methoxysalicylic acid, 2,4-dihydroxybenzoic acid, 2,5-dihydroxybenzoic acid, 3,5-dihydroxybenzoic acid, 2,4-dimethoxybenzoic acid, and homovanillic acid. The drugs chosen for this study represent several different classes: theophylline is a neutral substance, lidocaine is a base, cefmetazole is an acid, and levodopa exists as a zwitterion in solution.

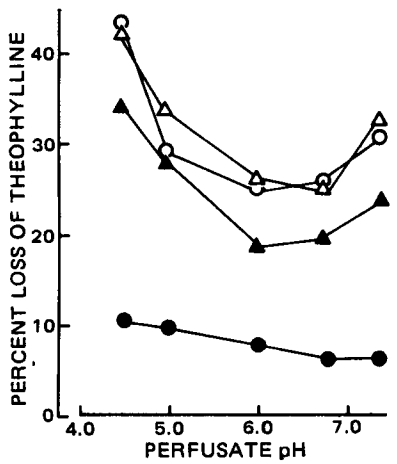

Figure 1—*The percent loss of theophylline from a perfusate of the rat rectum after 1 hr as a function of pH in the presence of 0.5% sodium homovanillate (○); sodium 5-methoxysalicylate (△); sodium 2,4-dihydroxybenzoate (▲); without an adjuvant (●).*

EXPERIMENTAL

Materials—Theophylline[1], sodium cefmetazole[2], and levodopa[2] were used as obtained from the manufacturer. Salicylic acid[3], benzoic acid[3], *o*-anisic acid[3], *p*-anisic acid[3], 3-methoxysalicylic acid[3], 5-methoxysalicylic acid[3], 2,4-dihydroxybenzoic acid[3], 2,5-dihydroxybenzoic acid[3], 3,5-dihydroxybenzoic acid[3], 2,4-dimethoxybenzoic acid[3], and homovanillic acid[3] were converted to the sodium salt by reacting the acid form with either sodium bicarbonate in water followed by recrystallization from ethanol or by reacting the acid with sodium ethoxide in anhydrous ethanol while bubbling nitrogen through the solution. Lidocaine[1] was converted to the hydrochloride salt by mixing with an equimolar solution of hydrochloric acid and evaporating to dryness without heat.

Animals—Sprague-Dawley male rates (200–300 g) were fasted for 16 hr prior to the experiments. During the experiment, the rats were kept on a 38° surface and were anesthetized with pentobarbital (60 mg/kg).

The *in situ* perfusion studies using the rat rectum and the *in vivo* absorption studies were carried out as described previously (2) with an ionic strength of 0.75. The pH of the perfusate was maintained constant by either the addition of 0.1 *N* NaOH or 0.1 *N* HCl, as needed. The analysis of theophylline, lidocaine, cefmetazole, and levodopa were performed by HPLC as described previously (2, 3). The analyses of the adjuvants used in the present study were done using HPLC with a reversed-phase column, 25 cm in length, a flow rate of 1.0 ml/min, and detection at 254 nm. The mobile phases consisted of mixtures of 0.1 *M* acetate buffer–methanol with ratios: 30:70 for benzoate, 2,4-dimethoxybenzoate, *o*-anisate, and *p*-anisate; 60:40 for homovanillate; 3-methoxysalicylate, and 5-methoxysalicylate; and 20:80 for 2,4-dihydroxybenzoate, 2,5-dihy-

droxybenzoate, and 3,5-dihydroxybenzoate. The absolute bioavailabilities were determined as described previously (2).

Binding Study of Adjuvants to Rat Rectal Tissue—The binding of various adjuvants with rat rectal tissue was studied using an equilibrium dialysis method. Dialysis tubing containing 1.4 mg of adjuvant and 200 mg of rectal tissue in 2.0 ml of 0.0667 *M* phosphate buffer at pH 7.4 was suspended in a 10-ml test tube containing 5 ml of the 0.0667 *M* phosphate buffer used earlier. After equilibration for 48 hr at 4°, the concentration of adjuvant in the outside solution was measured. The percent binding of adjuvant to 200 mg of rectal tissue was calculated from the following relationship:

$$\text{Percent Binding} = \{[T - (CV)]/T\}100 \qquad \text{(Eq. 1)}$$

where T, C, and V represent the total amount of adjuvant, the concentration of adjuvant in the outer solution, and the total volume of buffer (7.0 ml), respectively. The amount of adjuvant that is not bound is equal to CV.

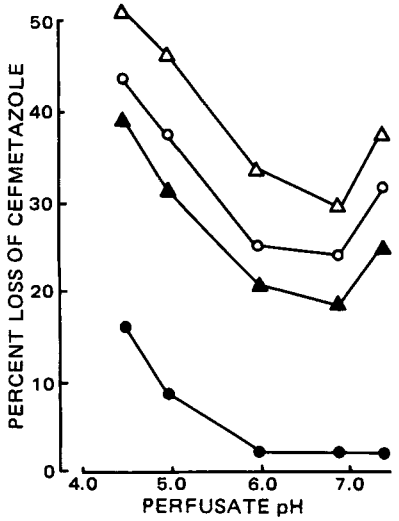

Figure 3—*The percent loss of cefmetazole from a perfusate of the rat rectum after 1 hr as a function of pH in the presence of 0.5% sodium homovanillate (○); sodium 5-methoxysalicylate (△); sodium 2,4-dihydroxybenzoate (▲); without an adjuvant (●).*

RESULTS AND DISCUSSION

Effect of Adjuvants on Drug Disappearance from Perfusate—Ten compounds have been studied regarding their effectiveness in enhancing the loss of theophylline, lidocaine, cefmetazole, and levodopa from a perfusing solution in the rat rectum. The pH profiles of the effects of three of the most potent absorption promoters, *i.e.*, homovanillate, 5-methoxysalicylate, and 3,5-dihydroxybenzoate, on the disappearance of theophylline, lidocaine, cefmetazole, and levodopa from the perfusate after 1 hr are shown in Figs. 1–4.

The disappearance of each of the drugs from the perfusing solution was significantly facilitated by the presence of each of these three adjuvants. The enhancement of loss from the perfusate was particularly evident at pH values >7.4 and <5.0. As shown in Fig. 5, the loss of adjuvant from the perfusate paralleled the extent of disappearance of the drugs studied. Similar results were observed using sodium salicylate as an adjuvant (2). Furthermore, as shown in Fig. 6, the disappearance of these three adjuvants was not affected by the presence or absence of the four drugs studied in the perfusate. This indicates that the enhancement of drug absorption by these adjuvants is not due to the formation of a complex with the drugs.

The effects of the 10 adjuvants studied on the disappearance of theophylline, lidocaine, cefmetazole, and levodopa from a rectal perfusate are summarized in Tables I and II for pH 4.5 and 7.4, respectively. The

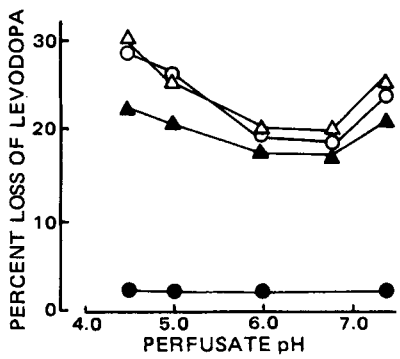

Figure 4—*The percent loss of levodopa from a perfusate of the rat rectum after 1 hr as a function of pH in the presence of 0.5% sodium homovanillate (○); sodium 5-methoxysalicylate (△); sodium 2,4-dihydroxybenzoate (▲); without an adjuvant (●).*

Table III—Absolute Bioavailabilities of a 15-mg/kg Dose of Theophylline and Cefmetazole [a]

Dose of 5-Methoxysalicylate, mg/kg	Bioavailability, % Theophylline	*n*	Cefmetazole	*n*
0	32.5 ± 12.4	4	7.8 ± 1.3	4
10	83.5 ± 9.2	1	18.5	1
15	128.4 ± 32.5	4	38.3 ± 4.2	4

0	32.5 ± 2.4	4	7.8 ± 1.3	4
7.5	69.5 ± 14.8	4		
15	119.7 ± 28.5	4	21.8	1
30			34.7 ± 5.4	4
50			51.2 ± 8.4	4

[a] After rectal administration as a microenema in the presence of 5-methoxysalicylate and homovanillate.

extent of the disappearance of the adjuvants themselves is also shown.

All of the adjuvants studied readily disappeared from the perfusate at pH 4.5. However, at pH 7.4 the disappearance of all the adjuvants was somewhat lower and very low for benzoate, *o*- and *p*-anisate, and 2,4-dimethoxybenzoate. Those adjuvants that were not well absorbed at pH 7.4 did not significantly enhance the disappearance of the drugs at pH 4.5 or 7.4. However, those compounds, which readily disappeared from the perfusate at pH 7.4, facilitated the loss of drugs from the perfusates at pH 4.5 and 7.4.

The disappearance of the adjuvants from the perfusate as reflected by the percent lost after 1 hr did not depend on the initial concentration at pH 4.5. However, the loss of adjuvant at pH 7.4 did depend on the initial concentration with a greater percent loss occurring at the lower concentrations, as shown in the last two columns of Table II.

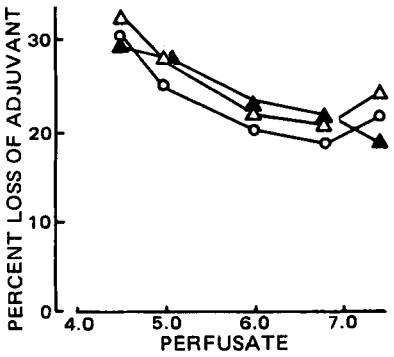

Figure 5—*The percent loss of sodium homovanillate (○), 5-methoxysalicylate (△) and 2,4-dihydroxybenzoate (▲) from a perfusate of the rat rectum after 1 hr as a function of pH. Initial concentration is 0.5%.*

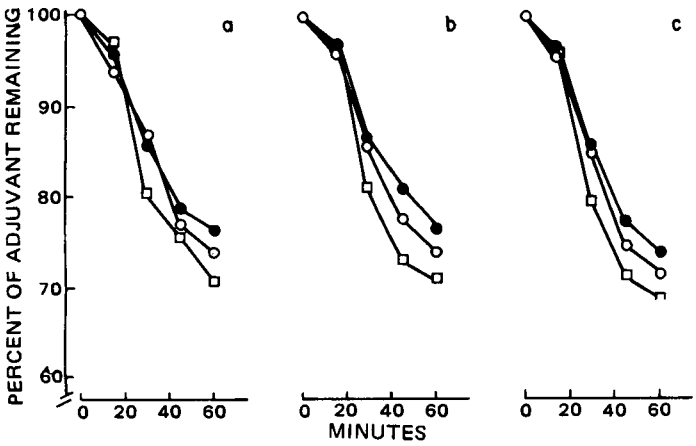

Figure 6—*Percent of homovanillate (●), 5-methoxysalicylate (○), and 2,4-dihydroxybenzoate (□) remaining in the perfusate as a function of time in the presence of (a) theophylline, (b) cefmetazole, or (c) in the absence of drug.*

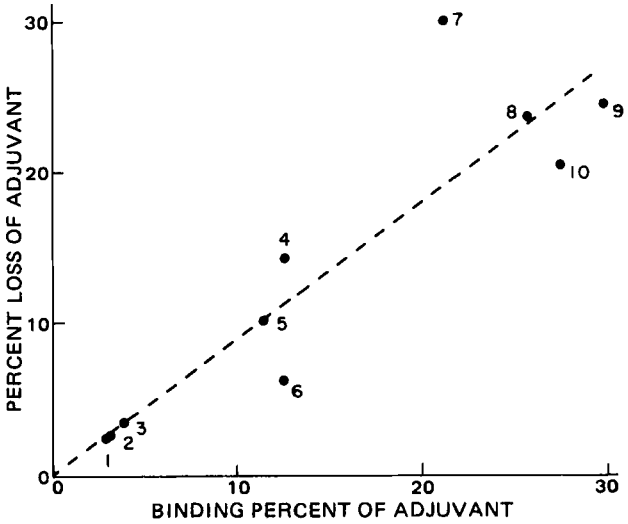

Figure 7—*Percent loss of adjuvant from perfusate at 60 min* versus *the percent binding of adjuvant to rat rectal tissue. Key: 1, benzoate; 2, p-anisate; 3, o-anisate; 4, 2,4-dihydroxybenzoate; 5, 3,5-dihydroxybenzoate; 6, 2,5-dihydroxybenzoate; 7, salicylate; 8, 3-methoxysalicylate; 9, 5-methoxysalicylate; 10, homovanillate.*

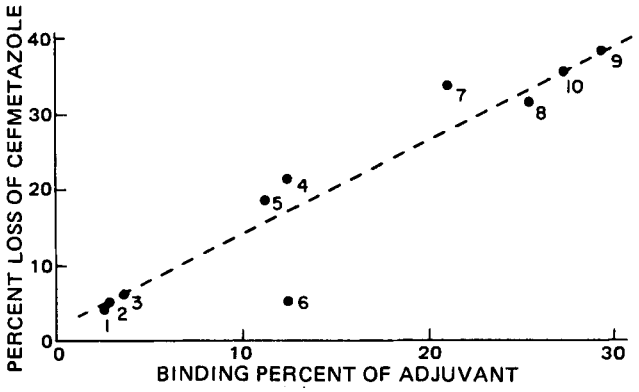

Figure 8—*Percent loss of cefmetazole from perfusate at 60 min* versus *the percent binding of adjuvant to rat rectal tissue. Key: 1, benzoate; 2, p-anisate; 3, o-anisate; 4, 2,4-dihydroxybenzoate; 5, 3,5-dihydroxybenzoate; 6, 2,5-dihydroxybenzoate; 7, salicylate; 8, 3-methoxysalicylate; 9, 5-methoxysalicylate; 10, homovanillate.*

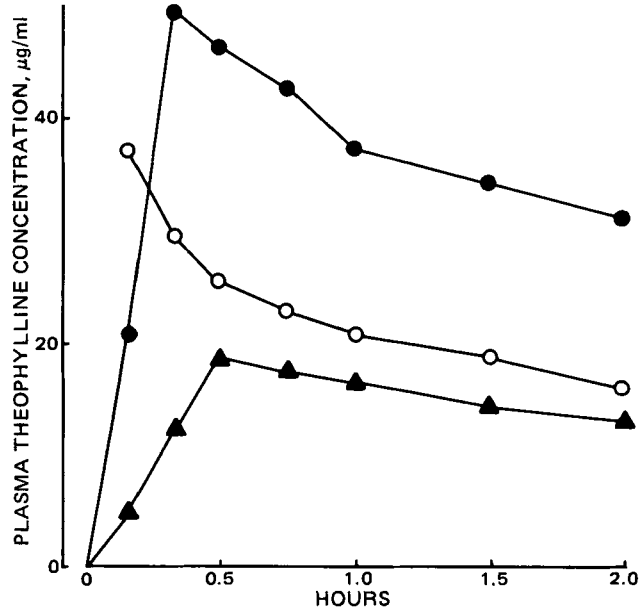

Figure 9—*Theophylline concentration (μg/ml) from an intravenous injection of 10 mg/kg (○) and from a microenema containing 15 mg/kg of theophylline (▲,●) and 15 mg/kg of sodium homovanillate (●).*

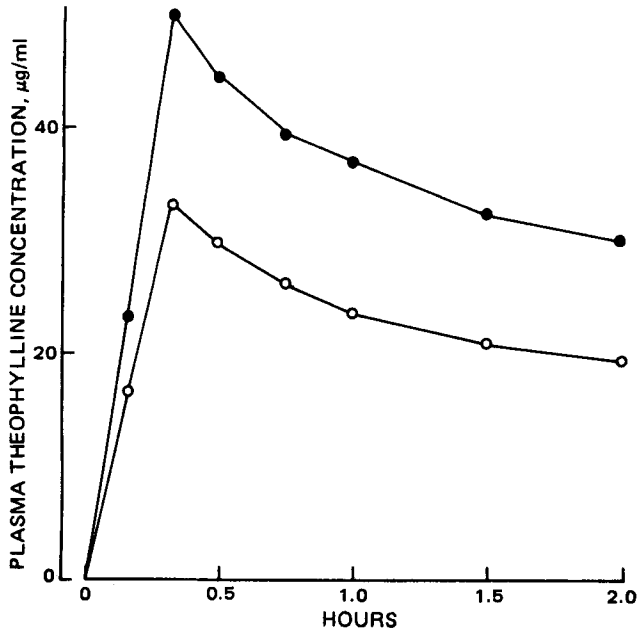

Figure 10—*Plasma theophylline concentration (μg/ml) from a microenema containing 15 mg/kg of theophylline and either 7.5 mg/kg (○) or 15 mg/kg (●) of 5-methoxysalicylate.*

The compounds that were effective in promoting the disappearance of drugs from the rectal perfusate all have hydroxy and carboxy groups. Benzoate, *o*- and *p*-anisate, and 3,5-dimethoxybenzoate do not have hydroxy groups, did not facilitate the disappearance of drugs from the perfusate, and did not disappear from the perfusate themselves at pH 7.4. It appears that for those substances which are chemically similar to salicylate, the presence of both the hydroxy and carboxy groups is important.

Binding of Adjuvants with Rat Rectum Tissue—The facts that those compounds which act as adjuvants for rectal absorption, both in this study and previous studies, disappear from the rectal perfusate even in their ionic form and that disappearance at pH 7.4 depends on their initial concentrations suggests that their potentiating effect may depend on their binding to some feature of the rat rectal tissue. Therefore, a binding study of these potential adjuvants and salicylate with rat rectal tissue was conducted at 4° using equilibrium dialysis.

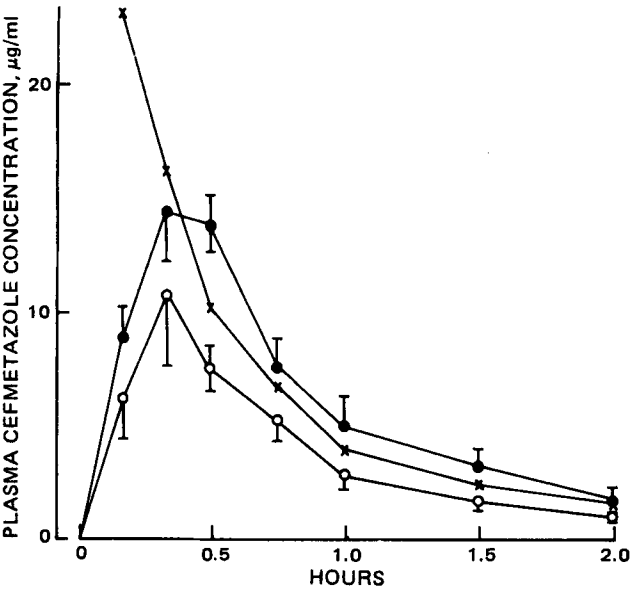

Figure 11—*Plasma cefmetazole concentration (μg/ml) in the rat from an intravenous injection of 10 mg/kg (x) and from a microenema containing 30 mg/kg of cefmetazole (○,●) and 30 mg/kg (○) or 50 mg/kg (●) of sodium homovanillate.*

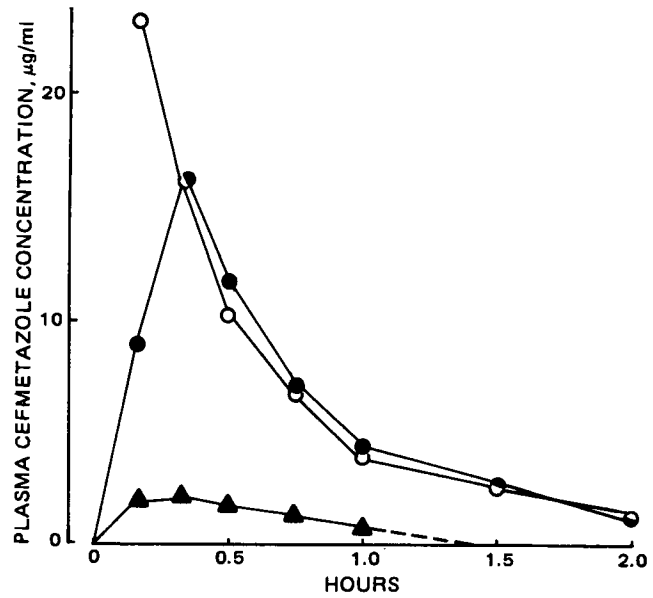

Figure 12—*Plasma cefmetazole concentration (μg/ml) in the rat from an intravenous injection of 10 mg/kg (○) and from a microenema containing 30 mg/kg cefmetazole (▲,●) and 30 mg/kg (●) of 5-methoxysalicylate or no adjuvant (▲).*

The relationship between the percent loss of adjuvant from perfusate at pH 7.4 and the extent of binding of the adjuvant with fat rectal tissue at the same pH is shown in Fig. 7. Figure 8 compares the percent loss of cefmetazole after a 1-hr perfusion in the presence of adjuvant with the percent of binding of the adjuvant. These data show a good correlation between the amount of adjuvant and drug lost and the binding of the adjuvant to rectal tissue. Those adjuvants with relatively high binding to the rectal tissue disappeared to a greater extent and promoted the disappearance of drugs more than those with little binding.

Thus, it appears that binding to some feature of the rectal membrane is necessary for facilitated rectal absorption of drugs and may suggest some type of active transport.

Effects of Adjuvants on Plasma Levels—The effect of homovanillate and 5-methoxysalicylate on the absorption of theophylline and cefmetazole after rectal administration as a microenema at pH 7.4 as reflected in plasma levels of the drug are shown in Figs. 9–12. In each case the absorption was rapid and facilitated by the presence of either homovanillate or 5-methoxysalicylate in the microenema solution and depended on the concentration of the adjuvant. Absolute bioavailabilities of theophylline and cefmetazole as a function of the concentration of homovanillate and 5-methoxysalicylate are shown in Table III.

Effect of Salicylate on the Rectal Absorption of Lidocaine, Levodopa, and Cefmetazole in Rats

TOSHIAKI NISHIHATA, J. HOWARD RYTTING[x], and TAKERU HIGUCHI

Received October 27, 1980, from the *Pharmaceutical Chemistry Department, The University of Kansas, Lawrence, KS 66045.* Accepted for publication November 3, 1981.

Abstract □ Salicylic acid and sodium salicylate have been found to enhance the absorption of lidocaine, levodopa, and cefmetazole after rectal administration to rats. These drugs represent a base (lidocaine), an acid (cefmetazole), and a substance (levodopa) which exists as a zwitterion in solution. The rectal absorption of each type of drug, as well as theophylline, a neutral compound, was enhanced by salicylate, particularly at pH values where the substances exist primarily in their ionic form. A requirement for the observed enhancement is that salicylate be present in the rectal membrane. The loss of drug from the perfusing solution was greater from solutions having an ionic strength of 0.75 than from those with $\mu = 0.15$.

Keyphrases □ Absorption, rectal—effect of salicylate on rectal absorption of lidocaine, levodopa, and cefmetazole, rats □ Salicylate—effect on rectal absorption of lidocaine, levodopa, and cefmetazole, rats □ Lidocaine—effect of salicylate on rectal absorption, rats □ Levodopa—effect of salicylate on rectal absorption, rats □ Cefmetazole—effect of salicylate on rectal absorption, rats

It has been reported (1, 2) that salicylate markedly enhanced the rectal absorption of theophylline. It was suggested that the effect of salicylate depends on its presence in the rectal membrane. It was also observed that the changes in absorption required the presence of salicylate in the formulation and that the mechanism of enhancement is different from that of surfactants.

The present report describes the extension of the use of salicylate to enhance the absorption of lidocaine, levodopa, and cefmetazole after rectal administration to rats. The drugs selected represent four different chemical classes: theophylline is a neutral substance, lidocaine is a basic material, cefmetazole is acidic, and levodopa exists as a zwitterion in solution. Furthermore, each of these drugs exhibits some difficulties in its administration and absorption. For example, it has been reported (3) that levodopa given rectally resulted in no rise in blood levodopa concentrations and no clinical benefit after rectal administration to parkinsonian patients. The purpose of this study was to examine to what extent the effects of salicylate are general and the extent rectal absorption enhancement depends on the specific drugs used. In addition, studies involving intravenous administration of salicylate were included to provide additional information about the mechanism of enhancement.

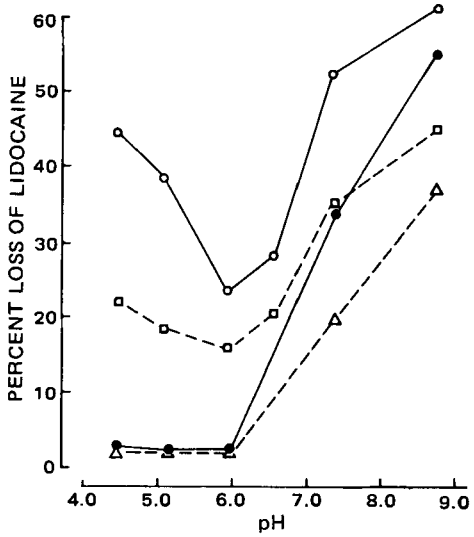

Figure 1—*Effect of pH, ionic strength, and salicylate on the disappearance of lidocaine hydrochloride from a perfusate in the rat rectum after 1 hr. The initial lidocaine hydrochloride concentration was 500 μg/ml, and the sodium salicylate concentration was 0.5 (○ and □) or 0% (● and △). The ionic strength was 0.75 (—) or 0.15 (- - -).*

EXPERIMENTAL

Materials—Sodium salicylate[1], lidocaine[2], sodium cefmetazole[3], and levodopa[3] were used as obtained from the manufacturers.

Animals—Sprague-Dawley male rats (200–300 g) were used in this study and were fasted for 16 hr prior to the experiment. During the experiment, the rats were kept on a 38° surface and were anesthetized with pentobarbital (60 mg/kg).

The *in situ* perfusion of the rat rectum and the *in vivo* absorption studies were carried out as described previously (1, 2) with the following modifications: The pH of the perfusate was maintained constant by either the addition of 0.1 *N* NaOH or 0.1 *N* HCl as needed. Some experiments were also carried out at an ionic strength of 0.15 and 0.75 using sodium chloride to obtain the desired ionic strength. The *in vivo* absorption studies involved administering 0.3 ml of the drug solution into a 2-cm section of the rectum which was isolated by ligation with thread.

Intravenous Infusion Studies—To maintain constant plasma salicylate concentrations, an intravenous infusion method was used for some experiments. After the rats were anesthetized with pentobarbital, a sodium salicylate solution (300 mg/ml), adjusted to pH 7.4 with 0.0114 *M* phosphate buffer, was infused into the leg vein of the rat through a polyethylene canula at a flow rate of 0.05 ml/min during the first 10 min and then at a flow rate of 0.02 ml/min for another 60 min. Beginning 10 min after starting the infusion of the salicylate solution, blood samples

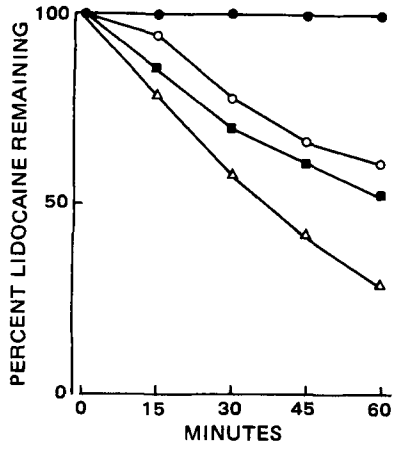

Figure 3—*The percent of lidocaine hydrochloride remaining in perfusate at pH 4.5 and an ionic strength of 0.75 with an initial lidocaine hydrochloride concentration of 500 μg/ml and sodium salicylate concentrations of 0 (●), 0.3 (○), 0.5 (■), and 1% (△).*

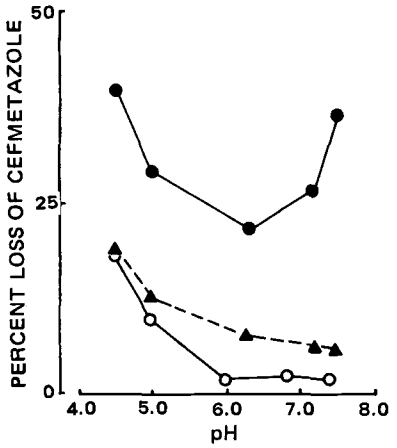

Figure 4—*Effect of pH and salicylate on the disappearance of cefmetazole from a perfusate in the rat rectum after 1 hr. The initial cefmetazole concentration was 200 μg/ml (○, ▲, and ●) and the sodium salicylate concentration was 0.5% (● and ▲). The ionic strength was 0.75 (○ and ●) and 0.15 (▲).*

were taken from the jugular vein at regular intervals to measure the concentration of salicylate in the plasma.

Assay Methods—Salicylate, theophylline, lidocaine, and levodopa were assayed by HPLC as described previously (2). For lidocaine a strong cation exchange column of 25-cm length was used. The mobile phase was 0.1 *M* acetate buffer at pH 3.0. The flow rate was 1 ml/min and a UV detector at 220 nm was used. For levodopa a reversed-phase column with a water–methanol mixture (95:5) as mobile phase was employed. The system was monitored at 254 nm.

The salicylate in the plasma was extracted with ether at a pH <2.0 after deproteinization with a 3.0% trichloroacetic acid solution. Following centrifugation, the ether layer was evaporated and the sediment was dissolved in methanol.

The lidocaine in the plasma was extracted with ether at pH 9.0 after deproteinization with a 3.0% trichloroacetic acid solution. Following centrifugation, the ether layer was evaporated and the sediment was dissolved in methanol.

Table I—Absolute Bioavailability of Cefmetazole as a Function of Initial Salicylate Concentration

Salicylate Dose, mg/kg	Bioavailability, %
0	—
5	22.8 ± 6.5[a]
10	34.5 ± 9.2
15	52.5 ± 7.3
25	91.4 ± 12.3
40	98.6 ± 15.7

[a] Uncertainties are expressed as standard deviations ($n \geq 4$).

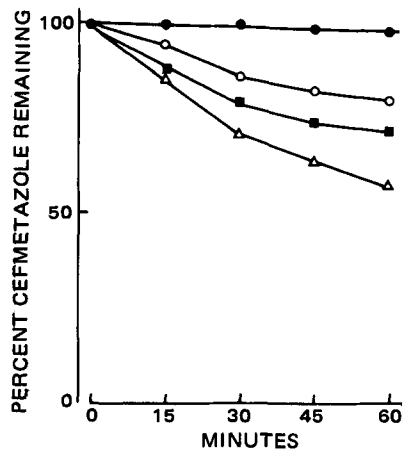

Figure 5—*The percent of cefmetazole remaining in perfusate at a pH of 7.4 and an ionic strength of 0.75 with an initial cefmetazole concentration of 200 μg/ml and sodium salicylate concentrations of 0 (●), 0.3 (○), 0.5 (■), and 1% (△).*

The levodopa in the plasma was extracted with acetone (5 times the sample volume). Following centrifugation, the supernate was evaporated and the sediment was dissolved in water.

Cefmetazole was also assayed by liquid chromatography using a high resolution reversed-phase column and an ion-pairing technique. The mobile phase consisted of a mixture of 77.5% (v/v) 0.025 *M* citrate buffer at pH 5.0 containing 0.005 *M* tetrabutylammonium (ion-pairing agent) and 22.5% (v/v) acetonitrile. The column effluent was monitored by UV absorption at 254 nm and peak height measurements were used for quantitation. The column was maintained at room temperature.

One-milliliter cefmetazole plasma samples were mixed with 0.1 ml of 0.01 *M* phosphoric acid and 0.6 ml of acetonitrile for 20–30 sec and then centrifuged at ~2000 rpm for 5 min. The supernate was then evaporated to dryness under nitrogen and the residue dissolved in 0.1 ml of water just prior to assay. Blank plasma samples containing drug concentrations up to 30 μg/ml were also measured to establish a calibration curve.

RESULTS AND DISCUSSION

Drug Disappearance from Perfusate—The pH profile of the effect of salicylate on the disappearance of lidocaine from a perfusate in the rat rectum is shown in Fig. 1. At pH values >6 and in the absence of salicylate, lidocaine disappeared readily from the perfusate and the presence of salicylate enhanced absorption only moderately. However, lidocaine loss was very small from acidic solutions in the absence of salicylate. At pH values <6, the presence of salicylate markedly enhanced the loss of lidocaine from perfusate solutions.

It is also apparent from Fig. 1 that the loss of lidocaine from the perfusate is greater with an ionic strength of 0.75 than at 0.15 using sodium chloride to adjust the ionic strength. As shown in Fig. 2, the loss of sali-

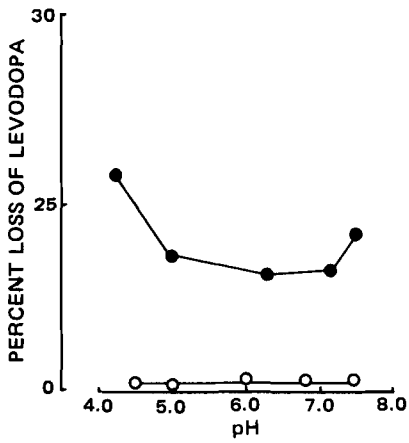

Figure 6—*Effect of pH and salicylate on the disappearance of levodopa from a perfusate in the rat rectum after 1 hr. The initial levodopa concentration was 200 μg/ml (○ and ●) and the sodium salicylate concentration was 0.5% (●).*

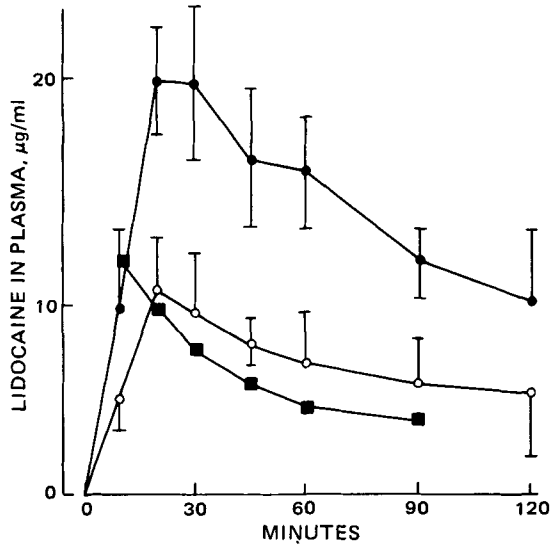

Figure 7—*Concentration of lidocaine in the plasma as a function of time after rectal administration of a microenema at pH 4.5 and a lidocaine hydrochloride dose of 60 mg/kg (● and ○) and sodium salicylate doses of 7.5 (○) and 15 mg/kg (●). Uncertainties are expressed as standard deviations by the error bars with* n = 6. *Lidocaine hydrochloride was also given intravenously (■) with a dose of 20 mg/kg.*

cylate is also greater at $\mu = 0.75$ than 0.15 from the perfusate at all pH values studied.

It appears that lidocaine is well absorbed from the rat rectum in the nonionic form which would predominate at basic pH values, but is not well absorbed from acidic solutions in which lidocaine exists as the protonated species. The presence of salicylate in the perfusate significantly increases the absorption of the water soluble form which is not absorbed effectively in the absence of salicylate.

As shown in Fig. 3, increasing the initial concentration of salicylate results in more rapid loss of lidocaine from the perfusate at pH 4.5. However, as reported previously (2), the disappearance rate constant of salicylate from the perfusate does not depend on the initial concentration of salicylate in the perfusate at a pH of 4.5, indicating that the disappearance of lidocaine from perfusate at a pH of 4.5 may depend on the amount of salicylate in the rectal membrane.

The loss of cefmetazole from perfusate in the rat rectum in the absence of salicylate was small as illustrated in Figs. 4 and 5. The addition of salicylate to the perfusate facilitated the disappearance of cefmetazole at all pH values. Again, the greatest enhancement was found at pH values at which the drug existed in the ionized state and at the higher ionic strength ($\mu = 0.75$). In fact, the effect of ionic strength is more pronounced for cefmetazole than for lidocaine. Furthermore, it was again observed that increasing concentrations of salicylate resulted in a more rapid disappearance of cefmetazole from the perfusing solution.

The presence of salicylate in the perfusate also promoted the disappearance of levodopa which was not absorbed significantly in the absence of salicylate at any pH (Fig. 6). The greatest enhancement occurred at

Table II—The Effect of Salicylate Given Intravenously on the Loss of Cefmetazole and Theophylline from Perfusate [a]

Minutes	Plasma Salicylate Concentration, mg/ml	Percent Remaining in Perfusate	Percent Remaining with no Salicylate (intravenous)

60	2.21 ± 0.31	95.8 ± 1.1	95.4 ± 2.1

[a] Uncertainties are expressed as standard deviations ($n \geq 4$).

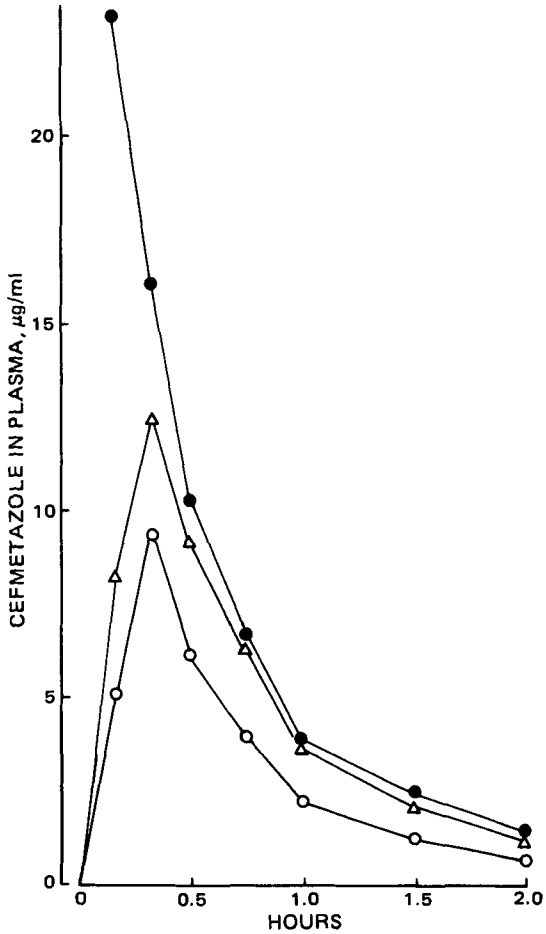

Figure 8—*Concentration of cefmetazole in the plasma as a function of time following rectal administration of a microenema at pH 7.4 and a cefmetazole dose of 15 mg/kg and 25 (○) or 40 mg (△) of sodium salicylate. Cefmetazole (10 mg/kg) was also given intravenously (●).*

pH values <5 and >7. Loss of levodopa was also more rapid with increasing concentrations of salicylate in the perfusate.

It was previously reported (1, 2) that salicylate itself was well absorbed at pH values <5 and >7.4. Thus, the disappearance rates of lidocaine, cefmetazole, and levodopa appear to depend on the effective disappearance of salicylate.

Plasma Levels Obtained from Microenemas—Lidocaine was administered as a solution at pH 4.5 because the perfusate studies indicated that it was absorbed at pH 7.4 in the absence of salicylate. Cefmetazole and levodopa were administered in solutions having pH values of 7.4.

As shown in Fig. 7, the plasma levels of lidocaine increased rapidly after rectal administration in the presence of salicylate. However, in the absence of salicylate, no lidocaine was found in the plasma. The detection limit for lidocaine was 2.5 μg/ml. Figure 6 also indicates that a higher dose of salicylate resulted in a higher blood level of lidocaine. As reported earlier (2), upon addition of salicylate at doses >15 mg/kg, the absolute bioavailability of lidocaine was nearly 100%.

Salicylate also markedly increased the blood levels of cefmetazole as illustrated in Fig. 8. Without the presence of salicylate, no cefmetazole was detected in the plasma. The minimum assay sensitivity was 0.1 μg/ml; however, in the presence of salicylate in solution, the plasma cefmetazole levels increased rapidly with maximum levels being reached 30 min after rectal administration. The absolute bioavailability as a function of salicylate concentration is shown in Table I.

As shown in Fig. 9, similar results were obtained for levodopa. In the absence of salicylate, levodopa was not found in the plasma. The sensitivity of the assay was 0.25 μg/ml. The absolute bioavailability of levodopa was ~75% in the presence of 15 mg of salicylate/kg.

These results indicate that salicylate may facilitate the rectal absorption of many types of drug substances, particularly in their ionic form.

Requirement of Salicylate in the Rectal Membrane—The disappearance of drug from the rectum appears to depend on the concurrent

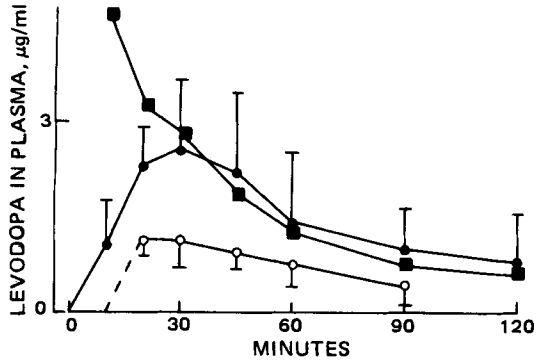

Figure 9—*Concentrations of levodopa in the plasma as a function of time following rectal administration of a microenema at pH 7.4 and a levodopa dose of 15 (● and ○), 7.5 (○), and 15 mg/kg (●) of sodium salicylate. Levodopa (10 mg/kg) was also given intravenously (■).*

rise in the plasma salicylate concentration after the simultaneous rectal administration of both salicylate and drug as shown in Fig. 10 for cefmetazole and levodopa. To examine the effect of salicylate levels independent of rectal absorption, the effect of salicylate given intravenously on the rectal absorption of cefmetazole and theophylline was studied. In this study, sodium salicylate was given by an intravenous infusion to maintain a relatively high plasma salicylate concentration of ~2 mg/ml. As shown in Table II and Fig. 10, salicylate in the plasma alone did not affect the loss of cefmetazole or theophylline from the solution perfusing the rat rectum. Furthermore, no salicylate was found in the perfusate, indicating that little if any salicylate was present in the rectal membranes after intraveous infusion of salicylate. Although salicylate is readily absorbed from the rectum to the plasma, the reverse does not occur under these conditions. It also appears that salicylate does not promote rectal drug absorption except when it is present in the rectal tissue. This is supported by the observation (2) that the enhancement of theophylline absorption from the rectum by salicylate was eliminated by washing the rectum with a buffer solution after pretreatment with salicylate. This is in contrast to the effect of sodium lauryl sulfate which continued after washing the rectum following pretreatment with sodium lauryl sulfate.

It appears that salicylate interacts with some feature of the rectal membrane facilitating the transport of drug substances from the rectum

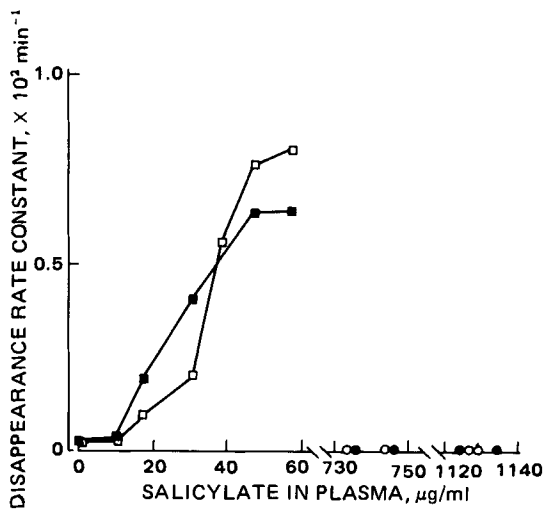

Figure 10—*Disappearance rate constant (× 10^2 min^{-1}) of cefmetazole (■) and levodopa (□) from perfusate as a function of salicylate concentration in the plasma following rectal administration. Analysis of Iodochlorhydroxyquin in Cream Formulations and Bulk Drugs by High-Performance Liquid Chromatography

E. J. KUBIAK and J. W. MUNSON ˣ

Received June 6, 1981, from the *Quality Control Division, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication October 23, 1981.

Abstract □ A high-performance liquid chromatographic method for the analysis of iodochlorhydroxyquin in creams and as bulk drugs has been developed. Iodochlorhydroxyquin was acetylated in the 8-position by reaction with acetic anhydride in pyridine. The resulting ester was mixed with the internal standard and chromatographed on a microparticulate silica column. Recovery was quantitative and the method was shown to be applicable to cream formulations from several manufacturers.

I as bulk drug, cream, ointment, compound powder, and tablets appear in USP XX.

The USP XX assay for I in cream formulations involves extraction of the drug into carbon disulfide and quantitation by IR spectroscopy. The sample preparation in this assay is cumbersome in that it requires multiple extractions and one back-extraction step. Also, the use of quantitation by IR spectroscopy limits the extent to which the assay can be automated.

In this study a chromatographic method was developed with high specificity and an experimentally simple sample preparation. An approach utilizing acetylation of the 8-hydroxy group of I and normal-phase high-performance liquid chromatography (HPLC) was found to satisfy these conditions.

BACKGROUND

The analysis of I in dosage forms and biological samples has been accomplished by TLC, GC, and HPLC. Compound I has been analyzed using silica gel plates with a methanol–methoxyethanol–hydrochloric acid (88:10:2) developing solvent (1). Three unidimensional developments of the plate were required to completely isolate I from frequently encountered impurities. The following compounds were observed as impurities in samples of I: 5,7-dichloro-8-hydroxyquinoline (II); 5,7-diiodo-8-hydroxyquinoline (III); 5-chloro-8-hydroxyquinoline (IV); and 8-hydroxyquinoline (V). In a previous study (2), I was reacted with *N*-trimethylsilylimidazole to form the silyl ether in the 8-position. Silylated I and related compounds were separated and quantitated by GC using a methylsilicone column. The silyl ether was formed by reacting I with *N*-methyl-*N*-silyltrifluoroacetamide, and I was analyzed in several dosage forms by GC (3).

Table I—Relative Retention Times and Relative Responses for Related Compounds

Compound	Relative Retention[a]	Relative Response[b]
5-chloro-7-iodo-8-hydroxyquinoline (I)	1.00	1.00
5,7-dichloro-8-hydroxyquinoline (II)	1.08	0.07
5,7-diiodo-8-hydroxyquinoline (III)	0.94	0.64
5-chloro-8-hydroxyquinoline (IV)	1.45	0.04
8-hydroxyquinoline (V)	Not Detected	

[a] All compounds chromatographed as the 8-acetate ester. [b] Peak height response at 254 nm.

Extractive alkylation has also been used as a derivatizing procedure for I prior to GC analysis. Compound I is extracted into methylene chloride using tetraalkylammonium salts as ion pairing agents. Methyl iodide in the methylene chloride solution then reacts with I to form the 8-methyl ether which is then analyzed by GC. Tetrapentyl- and tetrahexylammonium hydroxide have been used as ion-pairing reagents (4). To avoid problems associated with the hydroxide portion of the ion-pairing reagent, tetrabutylammonium hydrogen sulfate has been employed as the pairing ion in the analysis of I in urine and plasma (5). Acetate ester formation has been used in the GC analysis of I in serum, urine, and milk (6). Compound I is extracted into pyridine–benzene (1:9) and then derivatized with acetic anhydride.

Iodochlorhydroxyquin has also been analyzed in urine by HPLC (7). This method used an anionic exchange resin and gradient elution to achieve satisfactory chromatography.

EXPERIMENTAL

Materials—Testosterone acetate[1], iodochlorhydroxyquin[2], 5,7-diiodo-8-hydroxyquinoline[3], 5,7-dichloro-8-hydroxyquinoline[3], 5-chloro-8-hydroxyquinoline[3], and 8-hydroxyquinoline[3] were used as received. Pyridine[4], glacial acetic acid[4], and acetic anhydride[4] were analytical reagent grade. Butyl chloride[5] and tetrahydrofuran[5] were distilled in glass. Water used in preparation of the mobile phase was deionized.

Mobile Phase—All mobile phases were prepared by mixing water-saturated butyl chloride with butyl chloride at a ratio of 1:1 and then adding the appropriate amounts of tetrahydrofuran and glacial acetic acid. The mobile phase used for analysis of I was butyl chloride–water-saturated butyl chloride–tetrahydrofuran–glacial acetic acid(55:55:3:2). All mobile phases were filtered before use.

Instrumentation—The HPLC system has been described previously (8). The column used contained microparticulate silica[6] (10 μm, 30 cm × 4 mm).

Quantitative Procedure for I in Creams—An accurately weighed quantity of cream equivalent to 30 mg of I was transferred to a 100-ml volumetric flask. Tetrahydrofuran (~70 ml) was added, shaken vigorously until the sample was completely dissolved, and tetrahydrofuran was added to volume. A standard preparation was prepared by dissolving an accurately weighed quantity of I (~30 mg) in 100.0 ml of tetrahydrofuran. The standard and sample preparations (5.0 ml) were transferred into suitable vials. Two milliliters of a pyridine–acetic anhydride mixture (1:1) were added to the sample and each vial was heated for 15 min at 60°. After the samples returned to ambient temperature, 15.0 ml of the internal standard solution, prepared by dissolving 450 mg of testosterone acetate in 60 ml of tetrahydrofuran and then diluting to 1000 ml with butyl chloride, was added and mixed thoroughly. A 3-ml portion of each sample

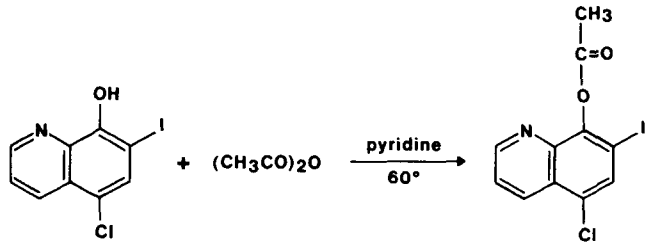
was transferred to a second vial and evaporated to dryness under a gentle nitrogen flow at 40°. Residue was reconstituted in ~15 ml of mobile phase. (Gentle warming and/or vigorous shaking may be necessary to ensure reconstitution.) Aliquots of the final solution were chromatographed and quantitated using peak height or peak area ratios.

Quantitative Procedure for I Bulk Drug—An accurately weighed quantity of I (~30 mg) was transferred to a 100-ml volumetric flask. The same procedure was followed as with cream.

RESULTS AND DISCUSSION

Initial attempts to develop a direct liquid chromatographic assay for I were unsuccessful. Using silica columns, the retention times were excessive. Using reversed-phase chromatography (octadecylsilane, 10 μm), reasonable elution times were obtained but the peaks exhibited unacceptable tailing in most cases. The observed behavior suggested that I was binding strongly to silanol groups on both types of column packings. To avoid this problem, the approach of acetylating the highly polar 8-hydroxy group was undertaken. The resulting 8-acetate ester was much less polar and could be chromatographed easily using a silica column and a modified butyl chloride mobile phase.

The derivatization reaction (Scheme I) is rapid under the chosen conditions. It was determined experimentally that one-half the amount of acetylating reagent (pyridine–acetic anhydride mixture) called for in the procedure would give quantitative conversion to the ester in 15 min at 60°. It was also found that the reaction gives essentially 100% recovery in 5 min at 60°. The amount of acetylating reagent and the length of reaction time used in the final analytical procedure, therefore, represent excess quantities.



Scheme I

The effects of tetrahydrofuran and acetic acid on the capacity factors for the 8-acetate ester of I and testosterone acetate were studied by varying the amounts added to the mobile phase. The amount of butyl chloride in the mobile phase was kept constant; however, the ratios changed slightly. The effects of varying the amount of acetic acid were minimal. However, small changes in the tetrahydrofuran concentrations caused dramatic shifts in the capacity factors for both compounds as shown in Fig. 1. Therefore, the concentration of tetrahydrofuran must be carefully controlled to obtain reproducible results.

To evaluate the specificity of the chromatographic system, several related compounds were derivatized by acetylation and examined for chromatographic retention and response. Of the compounds tested (Table I), 5,7-diiodo-8-hydroxyquinoline (III) showed the greatest potential for interference. Figure 2 showed the chromatographic tracings

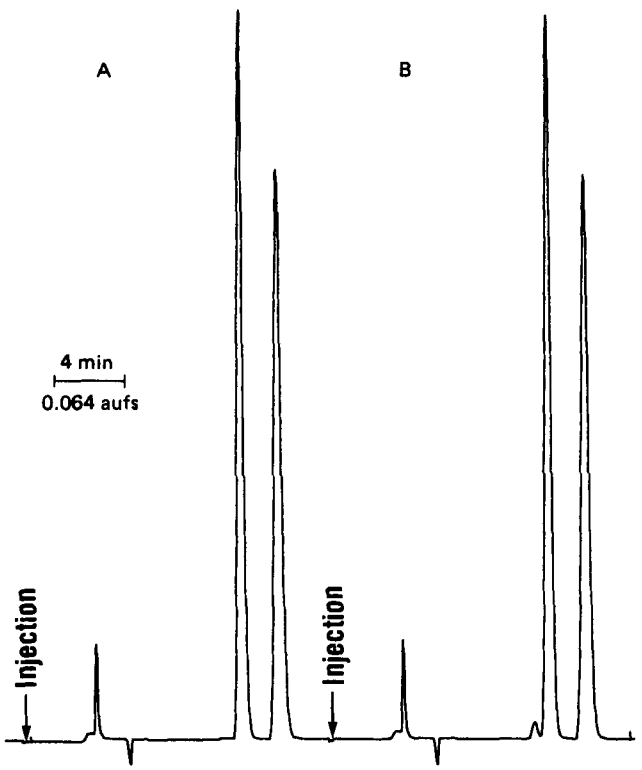


Figure 2—*Chromatographic tracings of a standard preparation before (A) and after (B) adding 3% 5,7-diiodo-8-hydroxyquinoline prior to derivatization step.*

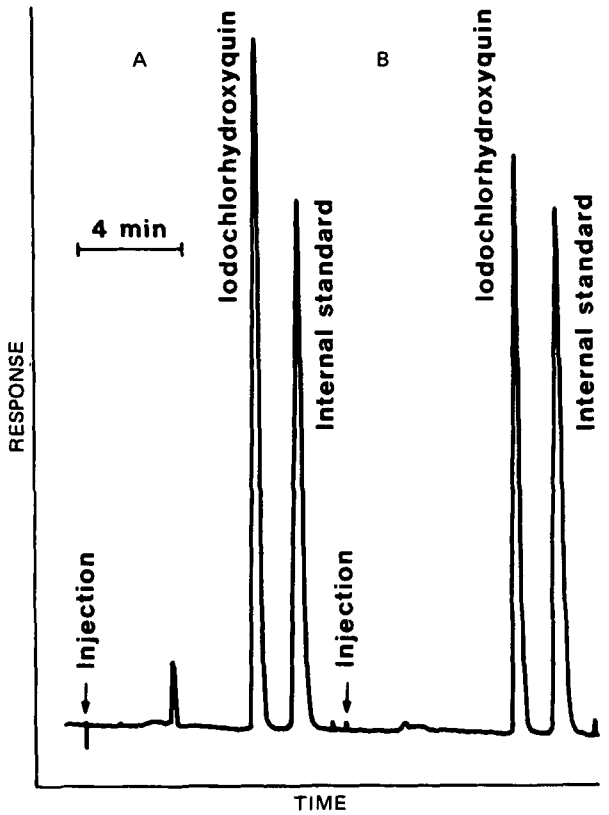

Figure 3—*Typical chromatographic tracings of sample preparation (A) and standard preparation (B). See text for details.*

Table IV—Analysis of Iodochlorhydroxyquin Bulk Drug

Lot	Purity, %	
	Peak Area Calc.	Peak Height Calc.
A	98.9, 98.3	99.4, 98.9
B	99.2, 99.9	99.5, 99.1
C	97.4, 98.7	98.9, 99.4
D	98.5, 98.4	98.3, 98.9
E	99.9, 99.4	99.2, 98.7
F	98.3, 98.9	98.2, 99.2

of a standard preparation before and after the addition of III in an amount equivalent to 3% of I. Baseline resolution was achieved and recovery of III was quantitative over the range of 1.5–5.0% expressed on the basis of I. While 5,7-dichloro-8-hydroxyquinoline elutes near the peak for I, its relative response at 254 nm is very low and should not interfere at low concentrations. Furthermore, no changes in assay results for I were observed with samples spiked with as much as 6% of III.

Typical chromatographic tracings for standard and sample preparations are shown in Fig. 3. No interferences were observed from formulation excipients, even though no sample clean-up steps were employed. No late eluting peaks were observed over an 8-hr period.

Placebo samples with added I were analyzed by this method to determine recovery efficiency. The recovery data (Table II) indicate that the procedure is quantitative for I over the range of 22–37 mg/g. This range corresponds roughly to 75–125% of label for the typical 3% cream formulations (30 mg/g). Replicate analysis of a single lot (n = 8) at 30 mg/g gave a 1.1% *RSD*. Results from the analyses of several lots of cream formulations from five manufacturers are shown in Table III. Good agreement with label content was observed in all cases.

A slightly modified procedure was used to analyze samples of bulk drug. Five samples of I (18–43 mg) were analyzed according to this procedure. The weight of I found was plotted against the weight of I added. The resulting linear regression equation had a slope of 1.00, an intercept of −0.02, and a correlation coefficient of 0.999. One lot of bulk drug was analyzed 10 times to determine the precision of the bulk drug assay. Using peak area ratios as the basis for calculation, the average value was 99.12% purity with a 1.1% *RSD*. Using peak height ratios, the mean was 99.21% purity with a 0.6% *RSD*. Six additional lots of iodochlorhydroxyquin bulk drug were analyzed in duplicate. The results of these assays are shown in Table IV.

Distribution of Bile Salts Between 1-Octanol and Aqueous Buffer

MADHU VADNERE and SIEGFRIED LINDENBAUM ˣ

Received June 15, 1981, from the *Department of Pharmaceutical Chemistry, The University of Kansas, Lawrence, KS 66045.* Accepted for publication October 13, 1981.

Abstract □ The distribution of four bile salts: sodium cholate (I), sodium deoxycholate (II), sodium chenodeoxycholate (III), and sodium ursodeoxycholate (IV), between aqueous buffer and 1-octanol has been measured as a function of temperature between 25 and 55° and as a function of bile salt concentration at concentrations <0.1 mole/liter in the aqueous phase. The distribution isotherms obtained have been explained on the basis of reversible association in the aqueous phase. The treatment assumes that the bile acid exists as a monomer in the organic phase, which is verified by vapor pressure osmometry. A graphical method has been employed to estimate the association constants in the aqueous phase for the various equilibria encountered. An aggregation number of four for IV and 12 for I, II, and III has been estimated. From the results, thermodynamic functions associated with the transfer of each of the bile salts from water to octanol and those associated with association processes in the aqueous phase were calculated. These results are consistent with previous findings that the premicellar association of bile salts occurs by hydrophobic interaction. The thermodynamics of transfer of bile salts revealed an unfavorable enthalpic and favorable entropic contribution for all four bile salts. However, for IV, which is an epimer of III, both enthalpic and entropic contributions are reduced, compared to III, suggesting a pronounced effect of stereochemical orientation on hydrophobic interaction.

increased by the presence of bile salts. Recently, it was reported (10) that the solubility of diazepam increased in bile salt solutions. This ability of bile salts to dissolve water-insoluble material has been attributed to the presence of micelles (2). A knowledge of factors that govern the micellization, therefore, is of great importance in understanding the role of these biological surfactants in the dissolution of poorly water-soluble substances.

As a part of the program to study the aggregation pattern of bile salts in aqueous solution, the partition method offered an interesting tool. The partition method has been used (11–13) to determine the critical micelle concentration of the quaternary ammonium salts. The distribution of four bile salts[1]: sodium cholate (I), sodium deoxycholate (II), sodium deoxychenocholate (III), and sodium ursodeoxycholate (IV) between 1-octanol and aqueous buffer was measured, and the results of these studies have been used to give information on the state of aggregation of bile salts in aqueous solution and the thermodynamics of the transfer process.

EXPERIMENTAL

Materials—The sources of bile acids and their purification are given elsewhere (14). [2,4-^{3}H]Cholic acid in ethanol[2], specific activity 1 mCi/6.7 × 10^{-4} mmoles; [^{3}H,(G)]deoxycholic acid in ethanol[2], specific activity 4 Ci/mmole; and [11,12(H)-^{3}H]chenodeoxycholic acid[3] in toluene–ethanol, specific activity 10.4 Ci/mmole were used without further purification. A sample of [^{14}C(G)]ursodeoxycholic acid[4] was purified by TLC (purity >99%). Benzil[5] was recrystallized several times from methanol, giving a melting point of 95.0 ± 0.5°. 1-Octanol[6] was used as obtained. The water was double deionized. The same liquid scintillation cocktail[7] was used for both aqueous and organic samples.

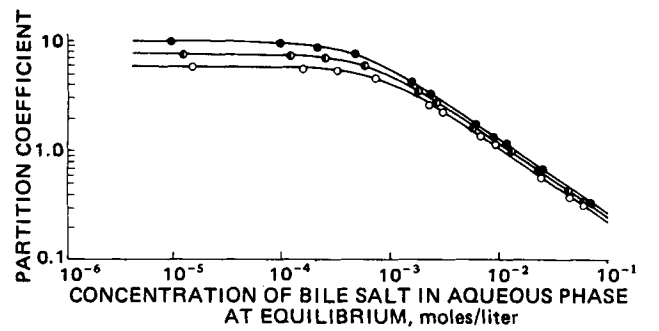

Figure 3—*Distribution isotherms for sodium ursodeoxycholate at 25° (○), 40° (◐), and 55° (●) between 1-octanol and 0.02 M tromethamine buffer (pH 8). The solid line is calculated according to Eqs. 15a and b.*

[1] These compounds exist largely as the free acids in 1-octanol.
[2] New England Nuclear Corp., Boston, Mass.; radiochemical purity was guaranteed to be >98%.
[3] Amersham, Arlington Heights, Ill.; purity >98%.

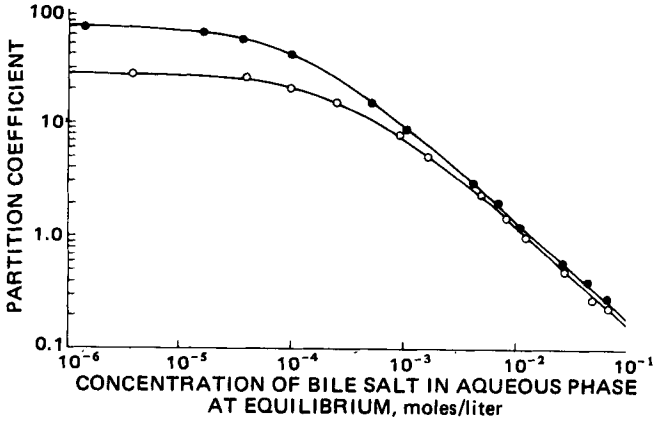

Figure 4—*Distribution isotherms for sodium chenodeoxycholate at 25° (○) and 55° (◐) between 1-octanol and 0.02 M tromethamine buffer (pH 8). The solid line is calculated according to Eqs. 15a and b.*

Partition Coefficient Measurements—The aqueous phase was 0.02 *M* tromethamine buffer (pH 8) and the organic phase was 1-octanol. To minimize volume changes due to mutual solubility, the aqueous and organic phases were presaturated with each other. The aqueous solutions of various concentrations of bile salt were prepared by dilution using a stock solution. ^{3}H-Labeled bile salt was incorporated for analytical determination.

Vials containing 4 ml of octanol and 4 ml of aqueous phase with various amounts of bile salt were shaken for 12 hr in a thermostated water bath. The temperature of the water bath was controlled to ±0.4°. Two samples of 1 ml each from both phases were withdrawn for analysis while keeping the vials thermostated. Scintillation cocktail[7] (10 ml) was added to each sample and mixed thoroughly. Count rates were measured on a liquid scintillation system[8]. The mass balance in the two phases was accounted for within ±2%. The maximum estimated error in the partition coefficient measurements was within ±5%.

Vapor Pressure Osmometry—Vapor pressure osmometry was used to determine the state of association of the bile acids in the organic phase. In this method (15), a steady-state temperature difference between a reference solution and a test solution and the pure solvent was determined. Thermistors were employed as temperature sensors and their electric resistance measured with an osmometer[9]. A solid-state null detector[10] was substituted to improve stability and sensitivity, and the temperature was controlled with a proportional thermistor temperature controller.

RESULTS AND DISCUSSION

The experimental results for the partition of the sodium salts of the bile acids between 0.02 *M* tromethamine buffer (pH 8) and 1-octanol are summarized in Figs. 1–4. Here the partition coefficient, defined as the ratio of the bile salt concentration in the organic phase to the concentration of bile salt in the aqueous phase, is plotted as a function of the equilibrium bile salt concentration (moles/liter) in the aqueous phase. It can be shown that if a solute exhibits ideal behavior in each of two liquids in contact, and in equilibrium, then the partition coefficient is constant, independent of the concentration. It can be seen from Figs. 1–4 that the partition coefficient of all four bile salts studied varies with the concentration. At higher concentrations of bile salt much more solute is found in the aqueous phase than would be expected from a consideration of the partition behavior at lower concentrations.

A sharp break at the critical micelle concentration (CMC) in a plot of C_{org} *versus* C_{aq} was observed (11–13) for quaternary ammonium compounds. A phase separation model for the quaternary ammonium compounds based on the partition behavior was proposed. Unlike quaternary ammonium compounds, bile salts do not exhibit a sharp break in the C_{org} *versus* C_{aq} plot; instead the change in the slope is gradual. This behavior can be explained on the basis of the reversible association of bile salts in the aqueous phase.

Theoretical Considerations—The following treatment of the experimental data can be made by assuming that, although the bile salt present in the aqueous phase is composed of monomers and aggregates of bile salt, only monomeric bile salt is distributed between the two solvents. The hypothetical equilibria involved are presented in Scheme I.

It is conceivable that the monomeric form is partitioned as one or more of three species: free acid; sodium–bile salt ion pair; and tromethamine–bile salt ion pair.

Figure 5 shows the independence of partition coefficient on the tromethamine buffer concentration, indicating that bile salt is not partitioned as tromethamine–bile salt ion pair at pH 8. Figure 6 shows the effect of sodium ion concentration at pH 8 and 9.2. It is evident that at higher pH values, where the bile acid exists mostly in the ionized form, there is a linear dependence of the partition coefficient on the sodium ion concentration; whereas, at pH 8 there is virtually no sodium ion concentration dependence indicating negligible partitioning of bile salt

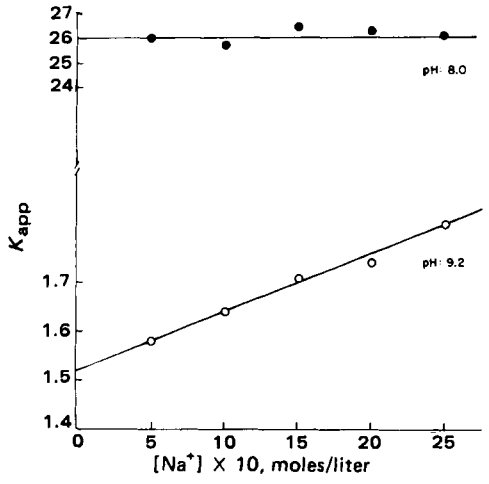

Figure 6—*Effect of sodium ion concentration on partition coefficient of sodium chenodeoxycholate at pH 8.0 (●) and pH 9.2 (○), 25°; organic phase: 1-octanol, aqueous phase: 0.02 M tromethamine buffer.*

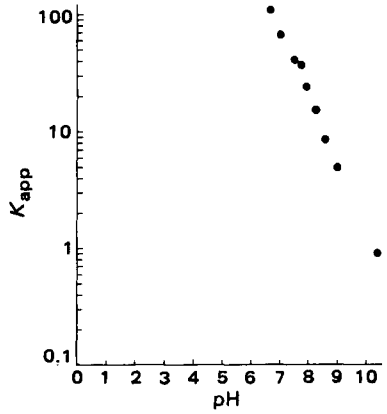

Figure 7—*Effect of hydrogen ion concentration on partition coefficient of sodium chenodeoxycholate at 25°; organic phase: 1-octanol, aqueous phase: 0.02 M tromethamine buffer.*

as the sodium salt ion pair compared to free acid. The marked dependence of partition coefficient on hydrogen ion concentration is seen in Fig. 7.

The concentration in the aqueous phase may be written as[11]:

$$[C]_{aq} = [\text{Monomer}] + 2[\text{Dimer}] + 3[\text{Trimer}] + \ldots \quad \text{(Eq. 1)}$$

where, $[C]_{aq}$ represents the total equilibrium molar concentration of bile salt in the aqueous phase.

Assuming that the association equilibria follow the mass law, the equilibria in the aqueous layer can be described in terms of association constants. Thus:

$$2\ \text{Monomer} \overset{K'_2}{\rightleftharpoons} \text{Dimer}$$

$$3\ \text{Monomer} \overset{K'_3}{\rightleftharpoons} \text{Trimer}$$

Therefore, Eq. 1 may be written as:

$$[C]_{aq} = [M]_{aq} + 2K'_2[M]^2_{aq} + 3K'_3[M]^3_{aq} + \ldots \quad \text{(Eq. 2)}$$

where, $[M]_{aq}$ is the monomer concentration in the aqueous phase. The concentration in the organic phase can be described by the following relationship:

$$[C]_{org} = K\frac{[H^+]}{[H^+] + K_a}[M]_{aq} \quad \text{(Eq. 3)}$$

where K is the intrinsic or true partition coefficient of the acid form, and K_a is the dissociation constant of the bile acid. Let:

$$K\frac{[H^+]}{[H^+] + K_a} = K^0_{app} \quad \text{(Eq. 4)}$$

where K^0_{app} is the apparent partition coefficient at a given pH in the infinitely dilute solution. Then Eq. 3 may be written as:

$$[C]_{org} = K^0_{app}[M]_{aq} \quad \text{(Eq. 5)}$$

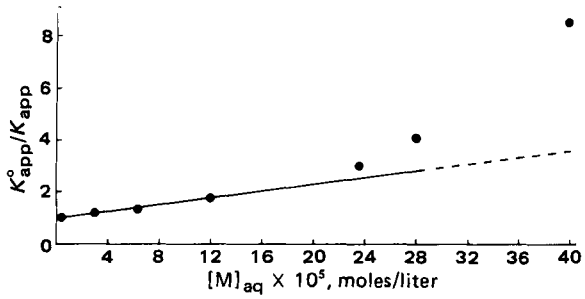

Figure 8—*A plot testing the possible occurrence of dimers in aqueous solutions of sodium deoxycholate at 25° according to Eq. 7.*

[11] The different forms identified as monomer, dimer, trimer, *etc.*, may consist of the free acids, charged anions, or mixtures of the two.

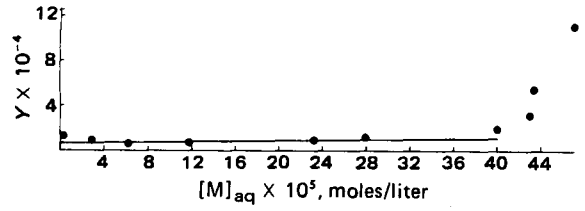

Figure 9—*A plot testing the possible occurrence of dimers and trimers in aqueous solutions of sodium deoxycholate at 25° according to Eq. 10.*

from Eqs. 2 and 5 the following can be written:

$$\frac{[C]_{aq}}{[C]_{org}} = \frac{1 + 2K'_2[M]_{aq} + 3K'_3[M]^2_{aq} + \ldots}{K^0_{app}}$$

or:

$$\frac{K^0_{app}}{K_{app}} = 1 + 2K'_2[M]_{aq} + 3K'_3[M]^2_{aq} + \ldots \quad \text{(Eq. 6)}$$

where $K_{app} = [C]_{org}/[C]_{aq}$ is the partition coefficient at the same given pH but at some finite concentration.

Proposed Testing of Assumptions—Since reversible associations of the type discussed are markedly dependent on the concentration of associating solute, it would be expected that in relatively dilute solutions, dimerization would be the primary equilibrium.

As the concentration of bile acid is increased, the tendency to form higher aggregates would be expected to be more pronounced. With this consideration, a simple test of the proposed relationship can be made.

If, at lower concentration of bile salt, the formation of dimers is the primary equilibrium, then to a first approximation, Eq. 6 can be reduced to:

$$K^0_{app}/K_{app} = 1 + 2K'_2[M]_{aq} \quad \text{(Eq. 7)}$$

From Eqs. 3 and 4, $[M]_{aq}$ can be obtained:

$$\frac{[C]_{org}}{K^0_{app}} = [M]_{aq} \quad \text{(Eq. 8)}$$

Figure 8 summarizes the results obtained when Eq. 7 was tested. The straight line relationship expressed by Eq. 7 is found to exist at lower concentration of II. The curvature apparent at higher concentration is due to the formation of higher polymeric species. The same trend is found for all four bile salts studied.

The proposition that higher polymeric species are found at higher concentration can be tested in a similar manner, for if the bile acid found in the aqueous phase is primarily present as monomer, dimer, and trimer, then Eq. 6 can be approximated by:

$$K^0_{app}/K_{app} = 1 + 2K'_2[M]_{aq} + 3K'_3[M]^2_{aq} \quad \text{(Eq. 9)}$$

or:

$$\frac{(K^0_{app}/K_{app}) - 1}{[M]_{aq}} = Y = 2K'_2 + 3K'_3[M]_{aq} \quad \text{(Eq. 10)}$$

The linearity expressed by this equation is tested in Fig. 9. Here, Y is plotted as a function of monomeric bile salt concentration in the aqueous phase. The expected intercept $2K'_2$ agrees within 5% with the value obtained from Fig. 8. A slope of 2.17×10^7 with correlation coefficient of 0.86 is obtained for this relationship.

By assuming that dimerization and tetramerization are the important equilibria, Eq. 6 may be reduced to:

$$K^0_{app}/K_{app} = 1 + 2K'_2[M]_{aq} + 4K'_4[M]^3_{aq} \quad \text{(Eq. 11)}$$

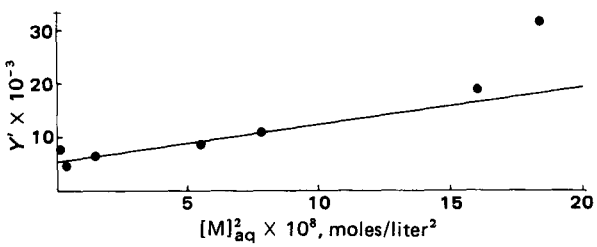

Figure 10—*A plot testing the possible occurrence of dimers and tetramers in aqueous solutions of sodium deoxycholate at 25° according to Eq. 12.*

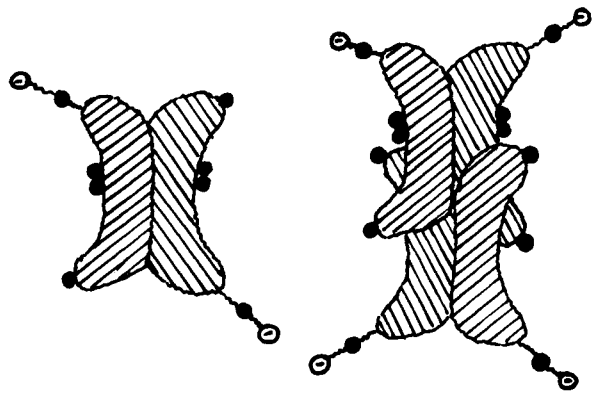

Figure 11—*Longitudual sections of dimers and tetramers; (●) OH groups; (⊖) negatively charged ionic group of bile salt.*

or:

$$\frac{(K^0_{app}/K_{app}) - 1}{[M]_{aq}} = 2K'_2 + 4K'_4[M]^2_{aq} \quad \text{(Eq. 12)}$$

Figure 10 illustrates a plot of this relationship. The theoretically expected straight line relationship is found to exist, with a correlation coefficient of 0.97. The linear relationship for 1-2-3 and 1-2-4 model extends over to the same concentration range with a somewhat better correlation for the latter one, however. Therefore, a monomer–dimer–tetramer species was considered to be prominent in this region. However, the existence of the trimer cannot be ruled out. A preponderance of tetramer over trimer is expected since a pair of dimers can come together with back-to-back hydrophobic interaction to form a tetramer with wide separation of charges (Fig. 11) (16), whereas in the trimer, charges would be expected to be closer, thus rendering it relatively less stable.

A curvature at higher concentration once again indicates that aggregates greater than tetramer are very likely. If it is assumed that, at higher concentration only monomer, dimer, tetramer, and 'n'mer are predominant species, then Eq. 2 reduces to:

$$[C]_{aq} = [M]_{aq} + 2K'_2[M]^2_{aq} + 4K'_4[M]^4_{aq} + nK'_n[M]^n_{aq} \quad \text{(Eq. 13)}$$

Rearranging and taking logs:

$$\log Y'' = \log nK'_n + n \log [M]_{aq} \quad \text{(Eq. 14)}$$

where:

$$Y'' = [C]_{aq} - [M]_{aq} - 2K'_2[M]^2_{aq} - 4K'_4[M]^4_{aq}$$

Thus, a plot of log Y'' *versus* log $[M]_{aq}$ should yield a straight line with slope equal to n, the aggregation number. The linearity of this double log

(12)	35°	3.60	10.54	37.92
	45°	3.72	10.78	39.04
	55°	3.88	11.04	40.08
Ursodeoxycholate	25°	2.35	8.15	—
(4)	40°	2.51	8.45	—
	55°	2.65	8.78	—
Chenodeoxycholate	25°	3.43	10.30	36.78
(12)	55°	3.85	11.60	40.78

plot is tested in Fig. 12. The aggregation number and all the association constants are summarized in Table I. The aggregation number of 12 for II obtained in this study is in close agreement with the value 13 reported previously (17). However, the association constant value, log K'_{13} = 27.4, differs from log K'_{12} = 36.78, obtained in the present study. This discrepancy may be due to the octanol dissolved in the aqueous phase in this study.

It is recognized that the distribution of water and octanol in the equilibrium phases might change with the concentration of bile salt, in which case K^0_{app} would no longer be constant. In this treatment, it is assumed for the sake of simplicity that the composition of the equilibrium phases is unchanged by the presence of bile salt. This assumption may have a small effect on the values of the association constants derived in the treatment.

The partition isotherms were generated using the following:

$$K_{app} = [C]_{org}/[C]_{aq} \qquad \text{(Eq. 15}a\text{)}$$

and:

$$[C]_{aq} = \left(\frac{[C]_{org}}{K^0_{app}}\right) + 2K'_2\left(\frac{[C]_{org}}{K^0_{app}}\right)^2 + 4K'_4\left(\frac{[C]_{org}}{K^0_{app}}\right)^4 + 12K'_{12}\left(\frac{[C]_{org}}{K^0_{app}}\right)^{12} \qquad \text{(Eq. 15}b\text{)}$$

and association constants from Table I. Figures 1–4 show that there is good agreement between the calculated and experimental values.

On the basis of the preceding discussion, it is also possible to calculate the distribution of bile salt/acid in its various forms in aqueous solution. The results of such calculations are illustrated in Fig. 13. Here, the concentration of bile salt as a particular species has been plotted as a function of total concentration of bile salt in solution. The concentration of bile salt as monomers and dimers reaches a plateau, whereas dodecamer is seen to increase as the concentration of total bile salt in the system increases.

All the association constants, K'_2, K'_4, K'_{12}, follow a Van't Hoff type relationship which is seen in Fig. 14. From the slope of these lines it is possible to estimate ΔH^0 for association. The results of such calculations are listed in Table II. These results are in agreement with the expectations that hydrophobic interactions lead to a positive enthalpy change (18).

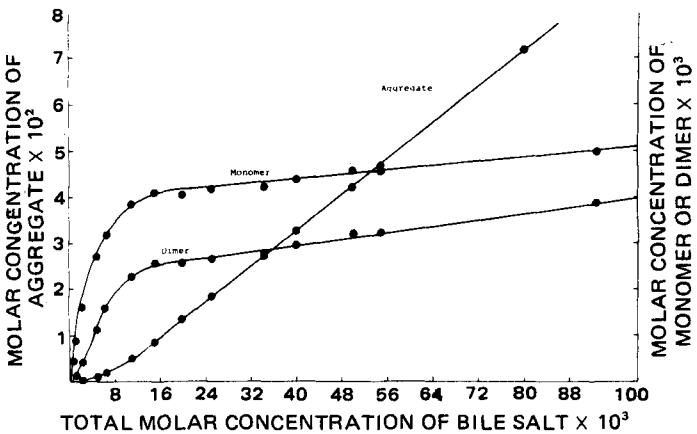

Figure 13—*A plot showing the distribution of sodium cholate among its various forms in aqueous solution at 25°.*

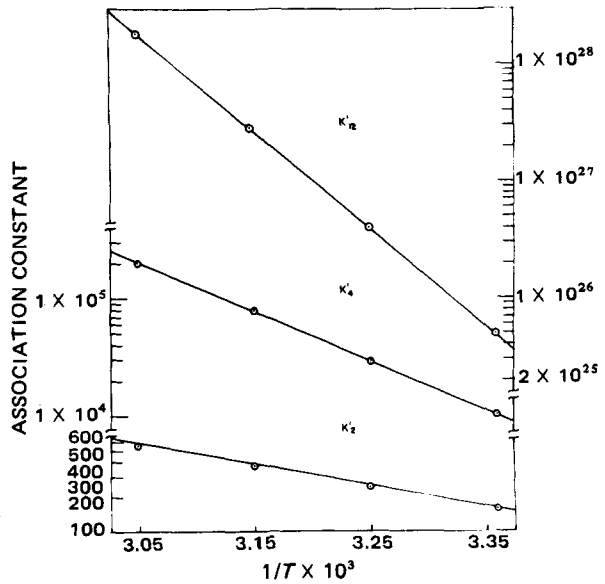

Figure 14—*A plot showing Van't Hoff type relationship for the association constants of sodium cholate.*

Figure 15 shows plots of log K^0_{app} *versus* $1/T$ for all the bile salts studied. If the activity coefficients in the two phases are assumed to be unity in very dilute solution, then from the slope of the plot log K^0_{app} *versus* $1/T$, estimates of ΔH^0 can be obtained. Also by using:

$$-\Delta G^0 = RT \ln K^0_{app}$$

and

$$\Delta G^0 = H^0 - T\Delta S^0$$

all of the thermodynamic functions for the transfer process can be obtained. Table III lists these thermodynamic transfer functions.

The values for the enthalpy of transfer of bile salt from the aqueous to the organic phase are all positive (unfavorable) (Table III). Positive values for ΔH^0 of transfer of hydrocarbon and aliphatic alcohols are also obtained (18). Positive values of ΔH^0 for this process are expected on the basis of the hydrophobic properties of these solutes. In aqueous solution the water molecules in the vicinity of these nonpolar molecules or moieties are more strongly hydrogen bonded so that a region of higher local order exists than in pure water. In partitioning out of the aqueous phase, the normal hydrogen bonded structure resumes, accompanied by a decrease in the amount of hydrogen bonding and a less ordered state. These processes are accompanied by an increase in enthalpy (the energy required to break hydrogen bonds) and an increase in entropy as expected for a loss in order. The data show that the entropy gain is greater for the more hydrophobic molecules. The dihydroxy bile salts, II and III, show a larger entropy change than I: the more polar tri-hydroxy bile salt. The data for IV demonstrate that it is not only the number of hydroxyl groups on the molecule that determine its hydrophobic character, but the orientation is also important. In IV, the —OH groups are no longer all in the α configuration, the —OH group in the 7 position is oriented toward the back of the molecule so that there is no longer a clearly hydrophobic side to the structure. As a consequence, even though it is a dihydroxy bile salt, IV shows a smaller positive change in entropy for the aqueous–organic transfer process than either of the other dihydroxy salts (II and III) or even the trihydroxy salt (I). Even for IV, however, hydrophobic forces appear to predominate since positive values of ΔH^0 and ΔS^0 are still obtained for the transfer process.

One of the assumptions in the foregoing model was that the bile acids do not associate in octanol. This was verified by using vapor pressure osmometry.

Table II—ΔH^0 for Association Process [a]

Bile salt	ΔH^0_{dimer}	$\Delta H^0_{tetramer}$	$\Delta H^0_{dodecamer}$
Cholate	4.0	4.8	3.2
Deoxycholate	3.0	2.8	4.0
Ursodeoxycholate	2.2	2.3	—
Chenodeoxycholate	3.1	4.8	4.9

[a] Kilocalories per mole of bile salt in the aggregate.

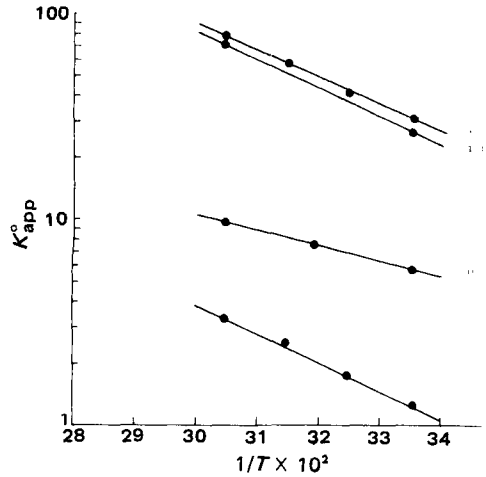

Figure 15—*A plot showing Van't Hoff type relationship for the* K^0_{app}, *sodium deoxycholate (II), sodium cholate (I), sodium ursodeoxycholate (IV), and sodium chenodeoxycholate (III).*

The osmolality of the test solution ($m_x\phi_x$), the reference solution ($m_r\phi_r$) and the measured resistance ratio ($\Delta R_x/\Delta R_r$) are related by:

$$\frac{m_x\phi_x}{m_r\phi_r} = \frac{\Delta R_x}{\Delta R_r}$$

where m is the molality, ϕ is the osmotic coefficient, ΔR is the change in resistance, and x and r refer to test and reference solutions, respectively.

If a nonassociating solute such as benzil is used as a reference, then the deviation of the ratio (ϕ_x/ϕ_r) from unity is related to the extent of association.

Table IV shows the ratio (ϕ_x/ϕ_r) for cholic and deoxycholic acids at 25°. It is seen that the ratio is ~0.8 and above in all cases, suggesting that under the conditions of the partition studies, the bile acid exists mainly as the monomer in the organic phase. It is likely that there is some association in the organic phase. However, for simplicity of calculation, this was assumed to be zero. This approximation may have an effect on the magnitude of the association constants.

Bile Acid–Octanol Complex—Figure 16 shows the effect of varying the ratio of octanol to isooctane in the organic phase, and it can be seen that octanol complexes with bile acid. A quantitative treatment may be obtained by considering that each mole of bile acid $(BA)_{aq}$ complexes with n moles of octanol (X) to give a complex $(BA\ X_n)_{org}$. Thus:

$$(BA)_{aq} + n\ X \overset{K_{eq}}{\rightleftharpoons} (BA\ X_n)_{org} \qquad \text{(Eq. 16)}$$

Accordingly:

$$K_{eq} = \frac{[(BA\ X_n)_{org}]}{[(BA)_{aq}][X]^n} \qquad \text{(Eq. 17)}$$

From Eqs. 15*a* and 17 it follows:

$$\log K_{app} = \log K_{eq} + n \log [M] \qquad \text{(Eq. 18)}$$

Table III—Thermodynamic Transfer Functions

Bile Salt	K^0_{app} 25°	ΔG^0 25°	ΔH^0 Kcal/mole	$T\Delta S^0$

[a] cholic acid. [b] benzil. [c] deoxycholic acid.

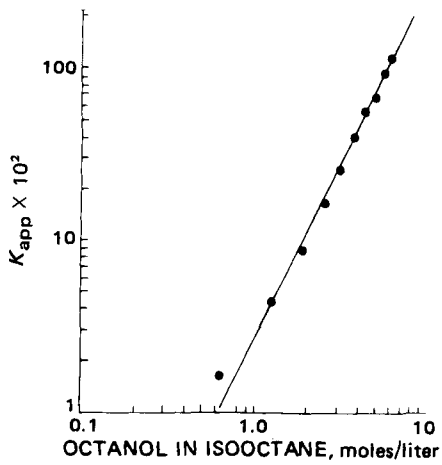

Figure 16—*A plot testing the possible complexation of sodium cholate with octanol according to Eq. 18.*

The linearity predicted in this double log plot is realized in Fig. 16. Binding numbers of 2, 1.7, and 1.8 are found for I, II, and III, respectively, suggesting that each mole of bile acid is solvated or complexed by 2 moles of octanol.

Since the solvation is the same in the organic phase for all bile acids studied, the differences in the free energy of partitioning results entirely from the differences in their interactions with water. The solvation of bile acids by octanol provides further support for the finding that bile acids are monomeric in the organic phase. There is evidence which suggests (19, 20) that in nonhydrogen bonding solvents, bile acids and their esters tend to form dimers and higher aggregates. Studies to determine the nature of the aggregates in nonhydrogen bonding solvents are presented in the following report (21).

Association of Deoxycholic Acid in Organic Solvents

MADHU VADNERE and SIEGFRIED LINDENBAUM[x]

Received August 27, 1981, from the *Department of Pharmaceutical Chemistry, The University of Kansas, Lawrence, KS 66045.* Accepted for publication October 27, 1981.

Abstract □ The distribution of deoxycholic acid (I) between aqueous buffer and an organic phase consisting of isooctane–1-octanol (70:30, v/v) (System A) or isooctane–chloroform (80:20, v/v) (System B) was studied. The distribution isotherms suggested that I associates strongly in the organic Systems A and B unlike in pure 1-octanol. Therefore, a previous model, describing distribution of bile salts between 1-octanol and aqueous buffer, was modified to include association of I in the organic phases to describe distribution behavior. The treatment suggested that I exists as monomer and dimer in System A with a dimerization constant of 820 M^{-1}. A model consisting of monomer–tetramer–hexamer in the organic phase best describes the data for System B. The data support the view that association in the organic phase is due to hydrogen bonding between bile acid molecules.

Keyphrases □ Deoxycholic acid—association in organic solvents □ Bile salts—association of deoxycholic acid in organic solvents □ Partition coefficient—association of deoxycholic acid in organic solvents

In the preceding paper (1), the distribution behavior of bile salts between aqueous buffer and 1-octanol was reported. By vapor pressure osmometry data, it was shown that bile acids exist primarily as monomers in 1-octanol[1]. A recent paper (2) reported strong association of bile acid esters in nonaqueous solvents such as carbon tetrachloride and chloroform using vapor pressure osmometry. The association in carbon tetrachloride is much stronger than in chloroform. The relatively low association in chloroform was attributed to the hydrogen bonding ability of chloroform. This probably also explains the monomeric state of bile acids in 1-octanol. If this were true, then modifying the hydrogen bonding solvent (*e.g.*, 1-octanol or chloroform) by addition of a nonhydrogen bonding nonpolar solvent like isooctane should result in an increased association of bile acid in such organic systems. In the present report the state of association of deoxycholic acid (I) is examined in two such modified solvent systems: isooctane–1-octanol (70:30) (System A) and isooctane–chloroform (80:20) (System B) using the distribution behavior of I between the organic phase and aqueous buffer. Partition equilibria were used to study the association of solutes in the organic phase on the basis of the previously determined association pattern in the aqueous phase.

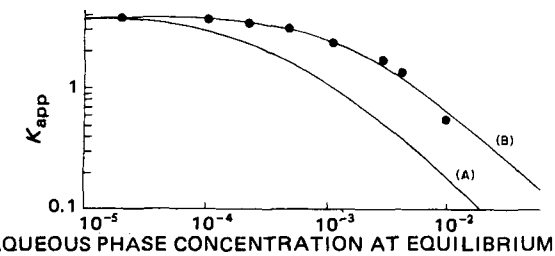

Figure 1—*Distribution isotherm for sodium deoxycholate at 25°. Curve A is based on the model in Scheme IA. Curve B is calculated on the basis of the model in Scheme IB. Key: (●) experimental data.*

[1] It was found that bile salts exist primarily in the acidic form in 1-octanol and in the anionic form in the aqueous phase under the experimental conditions of this investigation.

EXPERIMENTAL

Materials—The purity of sodium deoxycholate[2] (>99%) was confirmed by TLC and titration with perchloric acid in glacial acetic acid [^{3}H,(G)]deoxycholic acid in ethanol, specific activity 4 Ci/mmole[3], radiochemical purity 98%; 1-octanol[4]; 2,2,4-trimethylpentane (isooctane)[5] were used as obtained. The same scintillation cocktail[6] was used for both aqueous and organic samples.

Experimental details of partition coefficient measurements are given in the preceding paper (1).

RESULTS AND DISCUSSION

The experimental results obtained for the partition of I between 0.02 *M* tromethamine buffer (pH 8) and two mixed organic phases are summarized in Figs. 1 and 2. Here, the partition coefficient defined as the ratio of the bile salt (and acid) concentration in the organic phase to the concentration of bile salt (and acid) in the aqueous phase, is plotted as a function of the equilibrium total bile salt and acid concentration (moles/liter) in the aqueous phase.

The nature of the distribution isotherm obtained for System A is similar to one obtained for 1-octanol in the previous study (1). The distribution of I between 1-octanol and aqueous buffer was explained on the basis of reversible association of I in the aqueous phase and no association in the organic phase as shown in Scheme IA. In the present case, since

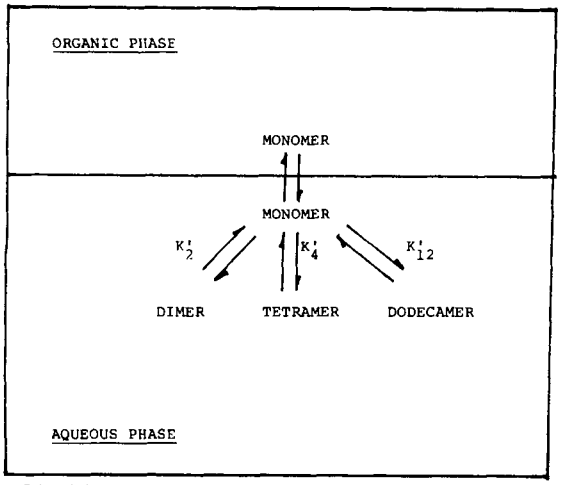


Scheme IA—The possible equilibria involved in the partitioning of bile salts between 1-octanol and aqueous solution.

the aqueous phase is not changed[7], association constants obtained previously are expected to remain constant and should describe the total concentration of I in the aqueous phase according to:

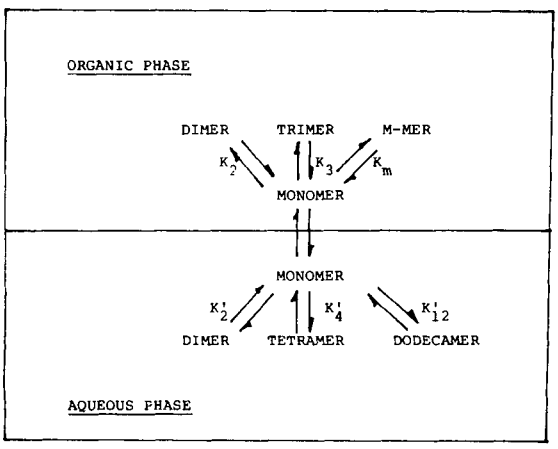
$$[C]_{aq} = [M]_{aq} + 2K'_2[M]^2_{aq} + 4K'_4[M]^4_{aq} + 12K'_{12}[M]^{12}_{aq} \quad \text{(Eq. 1)}$$

where, $[C]_{aq}$ is the total concentration of bile salt in the aqueous phase in moles per liter, $[M]_{aq}$ is the monomer concentration of bile salt in the aqueous phase[8] in moles per liter, and K'_2, K'_4, and K'_{12} represent association constants in the aqueous phase where subscripts refer to association numbers.

If the assumption that I does not associate in the organic solvent is true for System A, then the model shown in Scheme IA with the above association constants should describe the distribution isotherm. Calculations based on this model generated Curve A in Fig. 1. It is apparent from Fig. 1 that experimental points have significant positive deviation from Curve A. This positive deviation of partition coefficients from expected values based on the previous model suggests that there is much more solute in the organic phase than expected by assuming only monomers. This may be explained by considering reversible association of solute in the organic phase as shown in Scheme IB. This model assumes that only the monomer is transported from one phase to another, and higher aggregates are formed by the association of monomers in both phases. Thus, it can be shown that the concentration of bile salt and acid in the organic phase may be written as:

$$[C]_{org} = [M]_{org} + 2K_2[M]^2_{org} + 3K_3[M]^3_{org} + \ldots \quad \text{(Eq. 2)}$$

where, $[C]_{org}$ is the total concentration of I in the organic phase in moles per liter, $[M]_{org}$ is the monomer concentration of I in the organic phase



Scheme IB—The possible equilibria involved in the partitioning of bile salts between aqueous solution and Solvent Systems A or B.

[7] This assumes that the two organic phases either do not modify the aqueous phase or modify it to the same extent.

[8] This may be acid, anion, or a mixture of both.

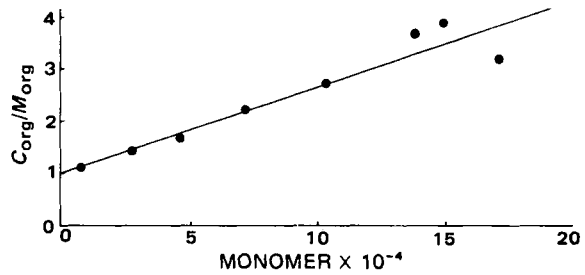


Figure 3—*A plot testing the possible occurrence of dimers in organic phase System A according to Eq. 6.*

in moles per liter, and K_2, K_3 . . . are association constants for I in the organic phase. Also:

$$K_{app} = [C]_{org}/[C]_{aq} \quad \text{(Eq. 3)}$$

$$K^0_{app} = [M]_{org}/[M]_{aq} = \lim_{c \to 0} K_{app} \quad \text{(Eq. 4)}$$

where, K_{app} is the apparent partition coefficient at any given concentration, and K^0_{app} is the apparent partition coefficient at infinite dilution.

By using carrier-free radiolabeled samples, K^0_{app} was obtained at concentration $<10^{-10}$ *M*. From Eq. 1 $[M]_{aq}$ was computed where $[C]_{aq}$ was known experimentally and aqueous association constants were used from previous studies (1). Using this computed value of $[M]_{aq}$ in Eq. 4, $[M]_{org}$ was calculated.

If the monomer and dimer are the primary species in the organic system, then Eq. 2 reduces to:

$$[C]_{org} = [M]_{org} + 2K_2[M]^2_{org} \quad \text{(Eq. 5)}$$

Rearranging gives:

$$([C]_{org}/[M]_{org}) = 1 + 2K_2[M]_{org} \quad \text{(Eq. 6)}$$

Thus, a plot of $([C]_{org}/[M]_{org})$ *versus* $[M]_{org}$ should give a straight line with unit intercept and slope = $2K_2$. This relationship can be seen in Fig. 3 for System A. It gives the estimate of $K_2 = 820\ M^{-1}$. Using this value of K_2 and Eqs. 1, 3, and 5, the distribution isotherm was generated as shown by Curve B in Fig. 1. It is seen that the curve calculated on the basis of the proposed model is in close agreement with the experimental data.

The distribution isotherm for System B exhibits a maximum (Fig. 2). This may be anticipated if the association in the organic phase is stronger than that in the aqueous phase until the CMC (critical micelle concentration) in the aqueous phase (CMC_{aq}) is reached. Under this circumstance the partition coefficient will increase until the CMC_{aq} is reached, the association in the aqueous phase being greater, the partition coefficient would be expected to decrease. Thus, a maximum in the isotherm may occur approximately in the concentration region corresponding to the CMC_{aq}. The value of the CMC thus estimated from this study is $\sim 7 \times 10^{-3}$ *M*, which compares reasonably well with literature values of 5–6 $\times 10^{-3}$ *M* (3–6).

A monomer–dimer treatment similar to the one used for System A did not yield a straight line relationship for System B. Instead, a positive

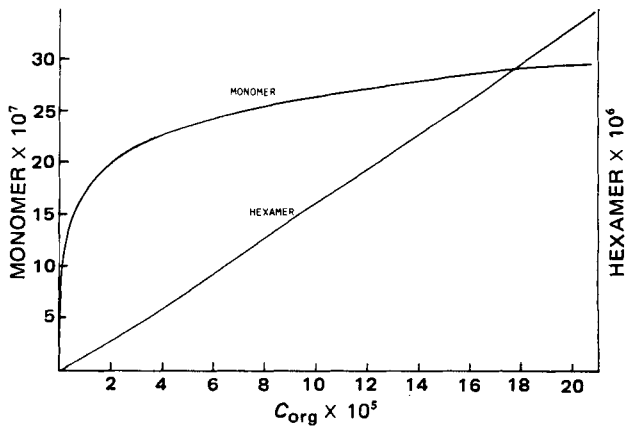

Figure 4—*A plot showing the distribution of deoxycholic acid among its various forms in Solvent System B.*

deviation was observed suggesting that higher aggregates exist in System B. The data for the system, therefore, were treated by a nonlinear least-squares fit to Eq. 2. The best fit was obtained for the monomer–tetramer–hexamer model in the organic phase. The estimated association constants were $K'_4 = 9.96 \times 10^2\ M^{-3}$, $K'_6 = 4.79 \times 10^{28}\ M^{-5}$. The distribution isotherm based on these constants is in good agreement with the experimental data (Fig. 2). Figure 4 shows the distribution of deoxycholic acid among its various forms in Solvent System B.

In studies with the methylester of deoxycholic acid (2), it was found that the methylester exists as monomers and dimers in chloroform ($K_2 \approx 14.0\ M^{-1}$) and monomers and tetramers in carbon tetrachloride ($K_4 \approx 2.8 \times 10^5\ M^{-3}$). Although no report was found in the literature for comparison with the present observations, a qualitative comparison can be made with the data derived previously (2). In pure octanol, hydrogen bonding interactions between solvent molecules and the hydroxyl and carboxyl groups of the bile acid are considerable. Consequently, this interaction precludes any appreciable self association of steroidal monomers. Solvent System A is a solvent of low polarity. Octanol is, therefore, expected to self associate to a significant extent in this solvent system (7). Thus, there is likely to be only weak interaction between 1-octanol and bile acid molecules. This leads to self association of solute molecules either between hydroxyl groups, carboxylic acid groups, or both. It was found in the preceding study (1) that under the condition of the experiment it is the free acid form that is partitioned in the organic phase. An acid form, because of its relatively more polar nature compared to the ester form, is expected to associate more strongly.

Even higher aggregation is expected, therefore, in Solvent System B, since this solvent is even less polar than Solvent System I. The organic phase has been rendered less polar, by increasing the isooctane concentration and by substituting 1-octanol (dielectric constant 10.34) with chloroform (dielectric constant 4.81).

These results have important significance in terms of mixed micelles of bile salts with lecithin (8). In a low dielectric inert medium such as the interior of a lecithin bilayer or liposome, pairwise association of bile salt molecules hydrogen-bonded to each other through their hydroxyl and/or carboxylic acid groups is plausible. Such a mixed disk model for bile salt lecithin micelles in which hydrogen bonded bile salt anion pairs are found within the interior of the micelle has been proposed previously (9). It cannot be decided on the basis of the present or previous (9) work whether the associated species are bile salt anions or free acid molecules. Molecular models suggest that the hydroxyl groups on the trihydroxy bile acids and dihydroxy bile acids can align to form hydrogen bonded pairs. It was suggested (10) that this hydrogen-bonded pairing occurs in aqueous solvents. However, it has been shown (1, 11) that in aqueous solution, bile salts are associated by hydrophobic forces. The previous hydrogen-bonded pairing model (10) appears to be the most likely structure in a low dielectric, nonhydrogen-bonded medium. The partition of bile salts from an aqueous to a lipid membrane phase would thus involve an inversion from hydrophobic back-to-back association in the aqueous phase, to hydrogen-bonded association in the lipid phase.

Abstract □ Two pilot studies were performed to determine if oral phenothiazine products could generate a significant increase in serum levels of the hormone prolactin. The two studies employed three and four healthy normal male subjects, respectively. In the first study the subjects received a screening dose, a placebo, one 8-mg perphenazine tablet, and two 8-mg perphenazine tablets. In the second study, the subjects were dosed with two 10-mg amitriptyline tablets, one 10-mg amitriptyline tablet with one combination tablet containing 10 mg of amitriptyline and 4 mg of perphenazine, and two combination tablets, each containing 10 mg of amitriptyline and 4 mg of perphenazine. In both cases the drug treatments produced a significant rise in the serum prolactin levels *versus* a placebo or control. This increase was defined as a prolactin response. The possible utility of this response in bioavailability testing is discussed.

Keyphrases □ Prolactin—serum prolactin level increase following administration of perphenazine oral dosage forms, application to bioavailability testing □ Bioavailability—application to testing, serum prolactin level increase following administration of perphenazine □ Perphenazine—oral dosage forms, serum prolactin level increase following administration, application to bioavailability testing

An adequate methodology for determining the bioavailability and bioequivalence of phenothiazine dosage forms has been sought for some time. The phenothiazines are a vital psychopharmaceutic tool in combating mental and emotional illnesses. In addition, these drugs are produced and marketed in a very large number of dosage

deviation was observed suggesting that higher aggregates exist in System B. The data for the system, therefore, were treated by a nonlinear least-squares fit to Eq. 2. The best fit was obtained for the monomer–tetramer–hexamer model in the organic phase. The estimated association constants were $K'_4 = 9.96 \times 10^2\ M^{-3}$, $K'_6 = 4.79 \times 10^{28}\ M^{-5}$. The distribution isotherm based on these constants is in good agreement with the experimental data (Fig. 2). Figure 4 shows the distribution of deoxycholic acid among its various forms in Solvent System B.

In studies with the methylester of deoxycholic acid (2), it was found that the methylester exists as monomers and dimers in chloroform ($K_2 \approx 14.0\ M^{-1}$) and monomers and tetramers in carbon tetrachloride ($K_4 \approx 2.8 \times 10^5\ M^{-3}$). Although no report was found in the literature for comparison with the present observations, a qualitative comparison can be made with the data derived previously (2). In pure octanol, hydrogen bonding interactions between solvent molecules and the hydroxyl and carboxyl groups of the bile acid are considerable. Consequently, this interaction precludes any appreciable self association of steroidal monomers. Solvent System A is a solvent of low polarity. Octanol is, therefore, expected to self associate to a significant extent in this solvent system (7). Thus, there is likely to be only weak interaction between 1-octanol and bile acid molecules. This leads to self association of solute molecules either between hydroxyl groups, carboxylic acid groups, or both. It was found in the preceding study (1) that under the condition of the experiment it is the free acid form that is partitioned in the organic phase. An acid form, because of its relatively more polar nature compared to the ester form, is expected to associate more strongly.

Even higher aggregation is expected, therefore, in Solvent System B, since this solvent is even less polar than Solvent System I. The organic phase has been rendered less polar, by increasing the isooctane concentration and by substituting 1-octanol (dielectric constant 10.34) with chloroform (dielectric constant 4.81).

These results have important significance in terms of mixed micelles of bile salts with lecithin (8). In a low dielectric inert medium such as the interior of a lecithin bilayer or liposome, pairwise association of bile salt molecules hydrogen-bonded to each other through their hydroxyl and/or carboxylic acid groups is plausible. Such a mixed disk model for bile salt lecithin micelles in which hydrogen bonded bile salt anion pairs are found within the interior of the micelle has been proposed previously (9). It cannot be decided on the basis of the present or previous (9) work whether the associated species are bile salt anions or free acid molecules. Molecular models suggest that the hydroxyl groups on the trihydroxy bile acids and dihydroxy bile acids can align to form hydrogen bonded pairs. It was suggested (10) that this hydrogen-bonded pairing occurs in aqueous solvents. However, it has been shown (1, 11) that in aqueous solution, bile salts are associated by hydrophobic forces. The previous hydrogen-bonded pairing model (10) appears to be the most likely structure in a low dielectric, nonhydrogen-bonded medium. The partition of bile salts from an aqueous to a lipid membrane phase would thus involve an inversion from hydrophobic back-to-back association in the aqueous phase, to hydrogen-bonded association in the lipid phase.

Serum Prolactin Level Increase in Normal Subjects Following Administration of Perphenazine Oral Dosage Forms: Possible Application to Bioavailability Testing

RANDALL J. ERB ˣ and WILLIAM P. STOLTMAN

Received August 21, 1981, from the *Pharmadynamics Research, Inc., West Lafayette, IN 47906.* Accepted for publication November 3, 1981.

Abstract □ Two pilot studies were performed to determine if oral phenothiazine products could generate a significant increase in serum levels of the hormone prolactin. The two studies employed three and four healthy normal male subjects, respectively. In the first study the subjects received a screening dose, a placebo, one 8-mg perphenazine tablet, and two 8-mg perphenazine tablets. In the second study, the subjects were dosed with two 10-mg amitriptyline tablets, one 10-mg amitriptyline tablet with one combination tablet containing 10 mg of amitriptyline and 4 mg of perphenazine, and two combination tablets, each containing 10 mg of amitriptyline and 4 mg of perphenazine. In both cases the drug treatments produced a significant rise in the serum prolactin levels *versus* a placebo or control. This increase was defined as a prolactin response. The possible utility of this response in bioavailability testing is discussed.

forms. Also, several of the most frequently prescribed phenothiazines recently have lost patent protection or shall lose this protection in the near future. Hence, an adequate testing methodology for the phenothiazines is of critical importance. The present report presents data that should lead to the establishment of a meaningful, reliable, reproducible methodology of phenothiazine bioavailability and bioequivalence evaluations.

Traditionally, methods of assessing the major tranquilizers have centered around detection of the parent drug and metabolites in plasma by chemical assay. This approach has been based on the assumption that detectable plasma drug levels are adequately reflective of drug concentrations at critical sites in the central nervous system. There has been work published that suggests that this assumption may be incorrect (1, 2).

The mechanism of action of the phenothiazines has received considerable attention. There is much evidence that the phenothiazines act through a blockade of dopaminergic and noradrenergic receptors (3–9). Blockade of dopaminergic receptors with phenothiazines has been positively

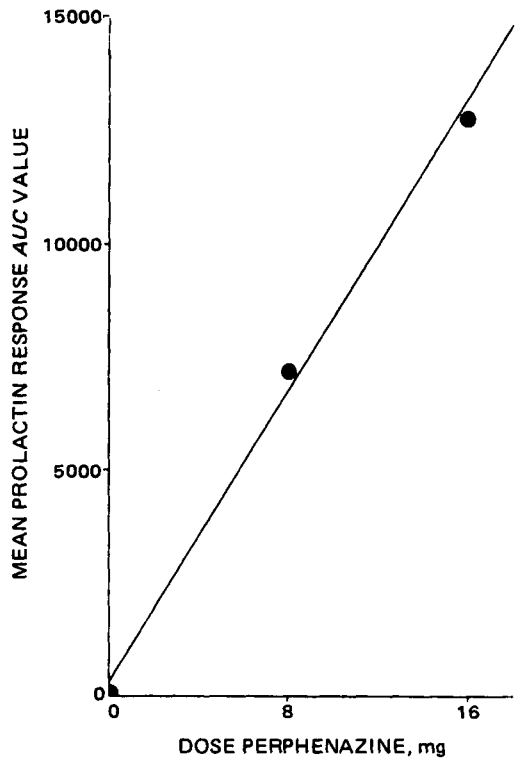

Figure 2—*The mean 60–480 min* AUC's *for the prolactin response for three healthy normal male subjects dosed with a placebo, one 8-mg perphenazine tablet, and two 8-mg perphenazine tablets* ($y = a_1x + a_0$; $y = 792.94x + 374.17$; $r^2 = 0.996$).

correlated with the antipsychotic effect of the phenothiazines (10–14).

Dopaminergic neurons also tonically inhibit the release of prolactin from the pituitary gland (15, 16). Intramuscular and intravenous administration of various phenothiazine products has generated a reproducible, dose-dependent response: an increase in serum prolactin level (17, 18). This increase has been attributed to the blockade of dopaminergic neurons (19). The change in plasma prolactin concentration to these neuroleptic agents correlates with their clinically observed antischizophrenic potency (13).

The present study was initiated to determine whether oral phenothiazine dosage forms also generate a prolactin response, and to preliminarily assess this response as a bioavailability/bioequivalence test procedure for phenothiazine dosage forms.

The results indicated that the oral phenothiazine doses dependably generated a prolactin response that was significantly greater than a placebo generated response. The method has much potential for bioavailability testing.

EXPERIMENTAL

Two studies were conducted to investigate changes in serum prolactin levels after administration of several oral phenothiazine dosage forms.

The first study investigated the changes in serum prolactin after the administration of tablet perphenazine to healthy normal subjects.

Subjects—Males (18–35 years of age) were employed as experimental subjects. All were classified as healthy and normal on the basis of the following: interview, physical examination, electrocardiograph, exercise stress test, chest X-ray, intraocular pressure measurement, microscopic urinalysis, hematology, and blood chemistry. Hematology included the following: red blood cell count, hemoglobin, hematocrit, mean corpuscular volume, mean corpuscular hemoglobin, and white blood cell count with differential. Blood chemistry included the following: triglycerides, serum

[a] 60–480 min for three healthy normal male subjects dosed with a placebo, 8 mg, and 16 mg of perphenazine.

glutamic oxalacetic transaminase, serum glutamic-pyruvic transaminase, phosphorus, alkaline phosphatase, uric acid, albumin, blood urea nitrogen, chloride, potassium, lactic dehydrogenase, calcium, bilirubin, total protein, glucose, sodium, albumin–globulin ratio, and creatinine. Each test value had to fall within the acceptable limits for the test for the subject to be accepted in the study. Each subject also signed an informed consent form prior to first participation in the study. Subjects abstained from any drug or drug product for the entire study. Each subject agreed to abstain from alcohol for 48 hr prior to each experiment. Subjects were not permitted tobacco for 12 hr prior to each experiment. Also, subjects were not to take anything orally, except water, for 10 hr prior to each experiment.

The subjects reported to the facility once a week for 4 consecutive weeks. They arrived at the facility at ~8 am. Each subject was briefly examined. The oral temperature, pulse, respiration, and blood pressure of each subject was determined and recorded. The predrug blood sample then was drawn.

Doses and Experimental Design—All three subjects received the doses in the same order. The doses were as follows: (*a*) one milligram of perphenazine as a liquid concentrate[1], (*b*) one 8-mg perphenazine tablet[2], (*c*) one placebo capsule, (*d*) two 8-mg perphenazine tablets. The first dose was used as a screening dose to prevent any hypersensitive individuals from receiving a larger dose. The perphenazine concentrate was administered mixed in ~175 ml of orange juice. No blood samples were taken from the subjects before or after the administration of this screening dose. The subjects were observed for any reaction that might constitute evidence of an allergic or hypersensitive response to the perphenazine. All of the subjects received all of the doses.

Blood Samples—Blood samples were obtained periodically from the volunteers during each of the other three experiments. Prior to each dose administration, a predrug blood sample was obtained. Five postdrug samples were obtained during each experiment at 1, 2, 3, 6, and 8 hr postdose.

Each blood sample was obtained from a vein in the antecubital space

[a] Prolactin response = [prolactin in sample] − [predrug prolactin sample]. [b] *AUC* values (60–480 min) for four healthy male subjects given two 10-mg amitriptyline tablets, one 10-mg amitriptyline tablet, one 10-mg amitriptyline and 4-mg perphenazine combination tablet, and two combination tablets. [c] Sample used for prolactin response calculation.

using a 21-gauge thin-wall needle[3] inserted into a 10-ml plain, silicone-coated vacuum blood collection tube[4], 16 × 100 mm. Each sample tube was placed upright in a rack for ~15 min then centrifuged[5] for ~15 min at 3250 rpm. The serum was filtered[6] and transferred to a storage tube[7]. The storage tubes were sealed, placed in a rack, and stored in an upright position in a freezer at −15°.

Assay—The samples were assayed for their prolactin level using a prolactin radioimmunoassay[8] that had a sensitivity of ±2–3 ng/ml of prolactin/sample. The samples were prepared for assay[9] and the prolactin concentration was determined in a gamma well scintillation counter[10].

Calculations and Data Analysis—Several calculations were made once the serum prolactin was determined for each blood sample. First, the mean placebo prolactin concentration over time (60–480 min) for each of the three subjects was determined. Normally, data 0–480 min would have been analyzed. After the blood samples were analyzed it was discovered that the predrug prolactin levels were somewhat elevated. This was attributed to predrug anxiety; therefore, for this study, the predrug (zero) reading was ignored. Data analysis started with the 60-min sample. The second study employed two predrug samples. The prolactin level decreased in every case for the second sample verifying the earlier observation. The appropriate subject placebo mean value was subtracted from each serum prolactin concentration. The resulting value was defined as the prolactin response for each sample. The area under the prolactin response curve (*AUC*) was calculated for the 60–480-min postdrug period. These *AUC* data were used in a statistical analysis of the experiments.

Statistical Analysis—An ANOVA was performed on the prolactin response *AUC*'s. Pairwise comparisons were made between the treatments employing a least significant difference analysis. Using a method described previously (20), an adequate sample size estimate was calculated for future bioequivalence studies. This estimate was set to determine a sample size large enough to detect a difference of 20% between *AUC*'s, with $\alpha = 0.05$ and $\beta = 0.20$. Also calculated were the best-fitting regression line values for the mean *AUC*'s, and the r^2 value, which expressed the amount of variation in one variable, which could be attributed to the second variable.

A second study was conducted, with several differences in procedures. First, four subjects were employed instead of three. The criteria and methods used to select subjects were not changed.

Second, different dose treatments were selected for study. Again, each subject received the doses in the same order: (*a*) two 10-mg amitriptyline tablets[10], (*b*) one 10-mg amitriptyline tablet and one combination tablet containing 10 mg of amitriptyline and 4 mg of perphenazine[11], (*c*) two tablets each containing 10 mg of amitriptyline and 4 mg of perphenazine.

This dosing provided for a constant level (20 mg) of amitriptyline with increasing doses (0, 4, and 8 mg) of perphenazine.

Third, the prolactin response was defined differently. The prolactin response was defined as the serum prolactin concentration for any sampling time minus the serum prolactin concentration from the second predrug sample.

The data were treated in a manner similar to the data obtained from the first study, but with 0–480 min *AUC*'s being calculated.

RESULTS AND DISCUSSION

The serum prolactin levels, prolactin response values, and the 60–480 min *AUC*'s for the first experiment are presented in Table I. Examination of this table reveals that for each subject the *AUC* value for each experiment increased with the size of the perphenazine dose. The *F* value for the treatment variable was significant in the ANOVA. The least significant difference results indicated that a significantly larger prolactin response ($p < 0.05$) was generated by both the perphenazine dosage forms *versus* the prolactin response produced by the placebo (Table II). There was not a significant difference between the prolactin responses produced by the two perphenazine dosage forms. Given the small sample size, this was not surprising. The mean prolactin response values for the three doses are illustrated in Fig. 1. Despite the lack of a statistically significant

[a] Analysis of variance for the 0–480 min postdrug *AUC* values for four healthy normal male subjects dosed with (*a*) two 10-mg amitriptyline tablets, (*b*) one 10-mg amitriptyline tablet and one combination tablet containing 10 mg of amitriptyline and 4 mg of perphenazine, and (*c*) two combination tablets, a dose of 20 mg of amitriptyline and 8 mg of perphenazine.

difference between the prolactin responses to the 8- and 16-mg perphenazine doses, the figure demonstrates that an increase in the prolactin response accompanied each increase in the perphenazine dosage level. The best fitting linear regression equation and the mean 60–480-min *AUC*'s are assembled in the dose–effect curve (Fig. 2). More than 99% of the prolactin response (variation) can be explained by the changes in the dose of perphenazine (*i.e.*, $r^2 \geq 0.99$). The subject sample size estimate (20) calculated using these data was 24.

Tables III and IV contain the data and the statistical analysis for the second pilot study using amitriptyline tablets and amitriptyline–perphenazine combination tablets. Again, each increase in the dose level of perphenazine was accompanied by an increase in the size of the 0–480-min *AUC*. Also, the *AUC*'s for both perphenazine treatments were significantly larger than the *AUC*'s calculated for the experiments where amitriptyline alone was given. Figure 3 portrays the mean prolactin response values over time for the three dose treatments. Figure 4 illustrates the mean 0–480 dose–effect curve minute *AUC* values for the three doses. Also, the best fitting linear regression equation is listed. A 93% variation in the *AUC* values can be accounted for by the changes in the perphenazine dosage levels. The subject sample size estimate calculated using these data was 30.

The results of these two studies support the findings of previous investigations demonstrating increased serum prolactin following the administration of various phenothiazine dosage forms. The present studies, however, employed oral phenothiazine dosage forms, in contrast with the parenteral dosage forms used earlier. This is an important addition, since the solid oral dosage forms are generally the least bioavailable but most heavily used in treatment. The present studies demonstrated that these oral dosage forms generated a statistically significant prolactin response.

It can be assumed that the mechanism by which the perphenazine generated the increase in serum prolactin is the same as proposed earlier, *i.e.*, a blockade of the dopaminergic pathways tonically inhibiting prolactin release. In this regard, less concern need be given to the active *versus* inactive metabolites of the drug. If a product of the metabolic breakdown of perphenazine also blockades the prolactin inhibitory pathway, it should also exert an antipsychotic action and contribute to the overall clinical effect.

Meaningful comparisons between the two studies are difficult to make. On the average, the 60–480 postdose *AUC*'s for the amitriptyline–perphenazine study were larger. Amitriptyline, however, should not have a significant effect on dopaminergic pathways (21). A *t* test was performed between the placebo *AUC*'s and the *AUC*'s calculated from the amitriptyline tablet dose treatment experiments. No significant difference was found between these data sets. Hence, the presence of the amitriptyline appears not to add to or detract from the prolactin response produced by the perphenazine, despite possible effect on noradrenergic sites.

The data obtained in these studies have implications for screening and bioavailability testing of phenothiazine products. Certainly any potential

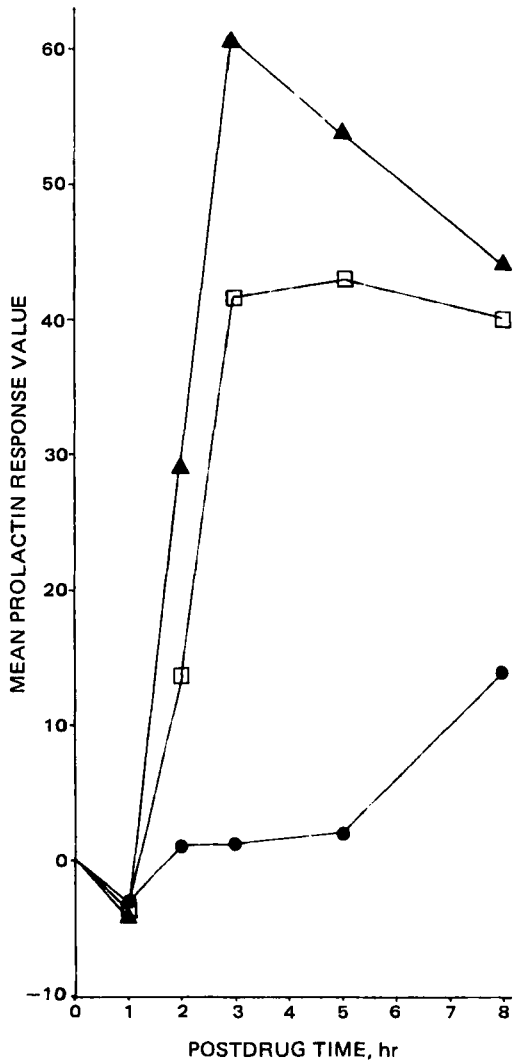

Figure 3—*The mean prolactin response* versus *time over an 8-hr postdrug period for four healthy, normal male subjects dosed with two 10-mg amitriptyline tablets (●); one 10-mg amitriptyline tablet and one 10-mg amitriptyline–4-mg perphenazine combination tablet (□); two combination 10-mg amitriptyline–4-mg perphenazine tablets (▲).*

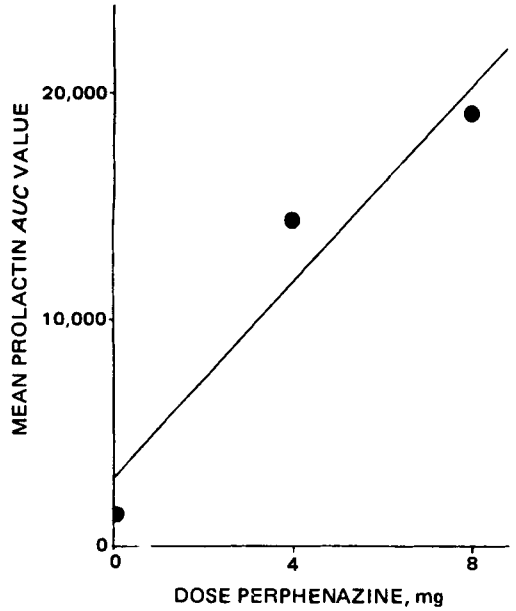

Figure 4—*The mean 60–480 min* AUC's *for the prolactin response for four healthy, normal male subjects dosed with two 10-mg amitriptyline tablets (0 mg of perphenazine); one 10-mg amitriptyline tablet and one combination tablet (4-mg perphenazine and 20-mg amitriptyline); and two combination tablets (total of 8-mg perphenazine and 20-mg amitriptyline) (*$y = a_1x + a_0$; $y = 2167.03x + 3061.13$; $r^2 = 0.931$*).*

phenothiazine product could be screened using the prolactin response. The prolactin response methodology is simpler, more economical, and more sensible; it reflects the proposed clinical effect at a site contiguous with the central nervous system. Therefore, expanded studies of this type, employing a larger subject sample size, could provide the basis for a bioavailability and bioequivalence testing methodology for all phenothiazine dosage forms. These studies could compare the prolactin response to a given product *versus* a placebo and a standard, or one standard product *versus* another, presumably equivalent, product. Some further quantification of the response will be necessary prior to applications of this methodology. It is the prolactin response, not prolactin blood levels, *per se*, that is dose-dependent for the phenothiazines, since intra- and intersubject variability in baseline serum prolactin levels are considerable. The prolactin response, however, is both reproducible and consistent.

Determination of Mianserin and Metabolites in Plasma by Liquid Chromatography with Electrochemical Detection

RAYMOND F. SUCKOW *x, THOMAS B. COOPER *, FREDERIC M. QUITKIN ‡, and JONATHAN W. STEWART ‡

Received July 21, 1981, from the **Analytical Psychopharmacology Laboratory, Rockland Research Institute, Orangeburg, NY 10962* and the ‡ *Depression Evaluation Service, New York State Psychiatric Institute, New York, NY.* Accepted for publication October 20, 1981.

Abstract □ A procedure for the determination of mianserin, desmethylmianserin, and 8-hydroxymianserin in plasma at therapeutic concentrations by liquid chromatography with electrochemical detection is described. Following a multiple-step extraction from alkaline plasma into methyl-*tert*-butyl ether, the reconstituted extract was injected onto a reversed-phase trimethylsilyl-packed column and eluted with an acetate–acetonitrile mobile phase containing an ion-paired reagent. The method provides an absolute recovery of 71–76% and a day-to-day precision of 5.4–9.1% for each compound at 25 ng/ml. The minimum quantifiable level for all three compounds was 5 ng/ml (*RSD* > 11%), and the detector response was linear up to 500 ng/ml. Fixed-dose steady-state plasma level data for 34 patients are reported.

Keyphrases □ Mianserin—determination in plasma, liquid chromatography, electrochemical detection, metabolites □ Liquid chromatography—determination of mianserin in plasma, electrochemical detection, metabolites □ Electrochemical detection—determination of mianserin in plasma by liquid chromatography, metabolites

High-pressure liquid chromatography (HPLC) with electrochemical detection is becoming an increasingly popular and useful combination for the quantitation of a wide variety of biologically important compounds (1). The sensitivity and selectivity of this detector makes it an important alternative tool to UV and fluorescence detection in biological science. The use of reversed-phase columns and ion-pairing reagents facilitate the examination of metabolite profiles in that rapid and efficient separation can be achieved in relatively short time periods. A method was recently described using ion-pair reversed-phase electrochemical detection for the determination of imipramine as well as its metabolites in plasma (2).

Mianserin hydrochloride (1,2,3,4,10,14b-hexahydro-2-methyldibenzo[*c*,*f*]pyrazino[1,2-*a*]azepine monohydrochloride) is a new tetracyclic antidepressant currently undergoing clinical evaluation in the United States. The chemical structures of this compound and known pharmacologically active metabolites are shown in Structure I. The pharmacology and therapeutic efficacy of mianserin in depressive illness have been reviewed (3) and the identification of its major urinary metabolites in various species including humans have been reported (4). The determination of mianserin in biofluids has been performed using GC with nitrogen detection (5) and by mass fragmentography (6). Neither assay included the simultaneous determinations of the metabolites found in plasma. To date HPLC has only been used for sample clean-up prior to mass fragmentography (7) and not for quantitation of mianserin.

In the present report, a liquid chromatographic method using electrochemical detection is described, which simultaneously quantitates mianserin, desmethylmianserin, and 8-hydroxymianserin in plasma. In addition, results of actual patient samples are reported.

EXPERIMENTAL

Apparatus—Chromatography was performed by a dual piston solvent delivery pump[1] connected to an automatic sampler[2]. Separations were achieved with either a 15-cm × 4.6-mm i.d. trimethylsilyl 5-μm particle size column[3] or a 25-cm × 4.6-mm i.d. octadecylsilyl 10-μm particle size column[4]. The detector system consisted of a thin-layer flow-through electrochemical cell[5] with glassy carbon as the working and auxiliary electrodes and a silver–silver chloride reference electrode. The potential and current response was monitored by an amperometric controller[6] and

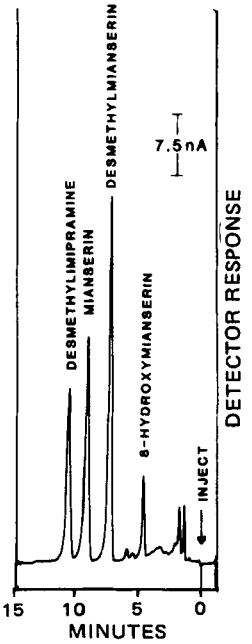

Figure 1—*Sample chromatogram of a 1-ml spiked plasma extract containing 25 ng of 8-hydroxymianserin and 100 ng each of mianserin and desmethylmianserin. One-half (50 μl) of the reconstituted extract was injected.*

Table I—Summary of the Linear Regression Data for the Standard Curve [a]

Compound	Slope ±*SD*, ng/ml	*x* Intercept ±*SD*, ng/ml	Correlation coefficient ±*SD*	Standard error of the estimate ±*SD*
Mianserin	76.28 ± 1.52	−0.41 ± 1.74	0.9999 ± 0.0001	1.93 ± 0.90
Desmethylmianserin	47.96 ± 1.29	0.99 ± 2.68	0.9999 ± 0.0002	1.72 ± 1.27
8-Hydroxymianserin	44.78 ± 4.16	4.10 ± 1.09	0.9986 ± 0.0012	1.50 ± 0.62

[a] Data computed from five consecutive standard curves.

recorder[7] and interfaced with a laboratory data acquisition system[8]. Aluminum column temperature control blocks were devised to fit columns of either size, and the temperature was controlled by a circulating water bath[9].

Reagents—Acetic acid[10], sodium acetate[10], sodium carbonate[10], and sodium bicarbonate[10] were all analytical reagent grade. Sodium heptane sulfonate[11] was used as received. Acetonitrile-UV[12] and methyl-*tert*-butyl ether[12] were used without further purification. Distilled water was passed through a water purification system[13] before use.

Standards—One milligram (free base) per milliliter of stock solution of mianserin hydrochloride[14], desmethylmianserin maleate[14], 8-hydroxymianserin maleate[14], and desmethylimipramine hydrochloride[15] were prepared in 0.1 *N* HCl. A stock solution of 1 mg/ml of 2-hydroxyimipramine[16] was prepared in methanol. For spiking plasma, the mianserin and desmethylmianserin stock solutions were diluted with 0.01 *N* HCl to give a working solution of 2 ng/μl of each. The stock solution of 8-hydroxymianserin was diluted with 0.1 *N* HCl to give working solutions of 1 ng/μl and 0.1 ng/μl. Desmethylimipramine was diluted with 0.01 *N* HCl to 2 ng/μl and 2-hydroxyimipramine was diluted with 0.1 *N* HCl to give 1 ng/μl to provide working solutions for the internal standard.

Standard curves were prepared containing five levels of spiked samples: 25, 50, 100, 200, and 400 ng/ml of mianserin and desmethylmianserin and 5, 10, 25, 50, and 100 ng/ml of 8-hydroxymianserin. Each set of standards included a blank.

Extraction—Internal standard, desmethylimipramine (25 μl, 50 ng), and 1.0 ml of 0.6 *M* carbonate buffer (pH 9.7) were added to 1.0 ml of plasma standard or unknown sample in specially washed glassware[17]. Eight milliliters of methyl-*tert*-butyl ether was added and the mixture was shaken for 15 min and centrifuged at 1500×*g* for 10 min. The organic layer was then transferred to a 15-ml tapered centrifuge tube containing 1.2 ml of 0.1 *N* HCl. After mixing for 10 min and centrifuging at 1500×*g* for 10 min, the organic layer was aspirated, the aqueous portion transferred to a 3-ml tapered glass-stoppered minicentrifuge tube, and neutralized with 0.5 ml of 0.6 *M* carbonate buffer (pH 9.7). Methyl-*tert*-butyl ether (0.5 ml) was added and the tube was stoppered, shaken, and centrifuged for 5 min at 1500×*g*. The lower aqueous layer was discarded and the organic layer transferred to a small glass vial[18].

The vial was placed within a 4-ml vial assembly (containing the adapter spring) and placed in a vacuum centrifuge[19]. The ether was evaporated under vacuum at 45°. The extract was then reconstituted with 100 μl of mobile phase, capped, and mixed.

Chromatographic Conditions—The mobile phase consisted of 0.1 *M* acetate buffer (pH 4.2)–acetonitrile (67:33) with 0.005 *M* sodium heptane sulfonate. The mixture was filtered and degassed prior to use.

Table II—Reproducibilty of Assays for Mianserin, Desmethylmianserin, and 8-Hydroxymianserin

Within Run [a] Concentration in Plasma, ng/ml	*RSD*,% Mianserin	Desmethylmianserin	8-Hydroxymianserin
100	3.3	2.9	7.2
50	6.9	5.9	8.5
10	4.7	4.3	11.8
5	8.1	10.4	8.2
Day-to-day [b]			
25	6.6	5.4	9.1

[a] $n = 6$. [b] $n = 5$.

Table III—Recovery of Mianserin, Desmethylmianserin, and 8-Hydroxymianserin from 1 ml of Plasma [a]

Compound	Recovery, %	*SD*, %	*RSD*, %
Mianserin, 50 ng	76	4.9	5.4
Desmethylmianserin, 50 ng	71	4.9	7.0
8-Hydroxymianserin, 25 ng	72	2.5	3.4

[a] $n = 6$.

The flow rate was 1.5 ml/min and temperature set at 30° resulting in an inlet pressure of ~1000 psi. The effluent was monitored through the detector cell at a potential of +1.05 V *versus* silver–silver chloride reference electrode.

Quantitation—All determinations were performed by calculating the peak height and/or area ratios of each compound to the internal standard. A linear regression analysis for each of the standard curves was performed by a computer program resulting in the calculation of slope, *x* intercept, correlation coefficient, and standard error.

RESULTS AND DISCUSSION

Mianserin, desmethylmianserin, and 8-hydroxymianserin were separated in a single chromatogram within 12 min. A typical chromatogram of spiked plasma is shown in Fig. 1. A blank plasma extract showed no endogenous interfering peaks (Fig. 2).

The absolute sensitivity (S/N ~3) of this method was checked by injecting a standard solution containing 1 ng of all three compounds. In practical terms the minimum quantifiable levels were 5 ng/ml of plasma. The electrochemical detector cell with glassy carbon as the working and auxilliary electrodes opposite each other permitted a linear detector response over a range from 5 to at least 500 ng. A summary of the data for the regression curves appears in Table I.

The precision of this method was determined by spiking six 1.0-ml aliquots of drug-free plasma with various levels of drug and metabolites. After the addition of 50 ng of internal standard, the sample was processed as described. The percent relative standard deviation for various levels are reported in Table II.

The absolute recovery was checked by preparing a solution of 50 ng of mianserin and desmethylmianserin, and 25 ng of 8-hydroxymianserin. The internal standard was added to each solution and the sample injected into the chromatograph. One milliliter of plasma was added to each of

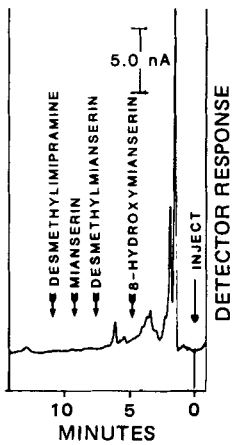

Figure 2—*Sample chromatogram of a 1-ml blank sample extract. The entire reconstituted extract (100 μl) was injected.*

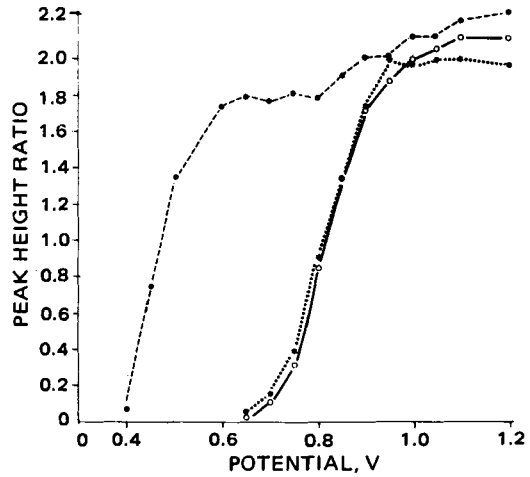

Figure 3—*A plot of the peak height ratio* (i.e., *detector response*) *against the oxidation potential* (versus *silver–silver chloride reference electrode*) *under the same chromatographic conditions described in the text:* (--●--) *8-hydroxymianserin,* (···*···) *desmethylmianserin,* (—o—) *mianserin.*

the same number of aliquots and processed routinely except for the internal standard. When the final extract was dried down, the internal standard was added (50 ng) with mobile phase and injected. The difference between the ratios of standards to internal standard in the processed samples *versus* direct injection samples gave a measure of the overall recovery (Table III).

The determination of the optimum oxidation potential for these compounds was done by injecting a standard solution of these compounds in methanol into the chromatograph at various potentials. A fixed wavelength UV detector[20] at 254 nm connected in series preceding the electrochemical cell, was used as an internal standard.

The ratios of the peak heights from the electrochemical and UV detectors were plotted against the various potentials. Figure 3 shows that the 8-hydroxymianserin undergoes oxidation at a more negative potential than either mianserin or its desmethyl metabolite. The lower oxidation potential of this metabolite is due to the presence of the ring hydroxyl group. A possible mechanism of electrochemical oxidation of hydroxylated derivatives could be explained by the formation of a quinone imine (8). Similar current–potential curves were observed with imipramine,

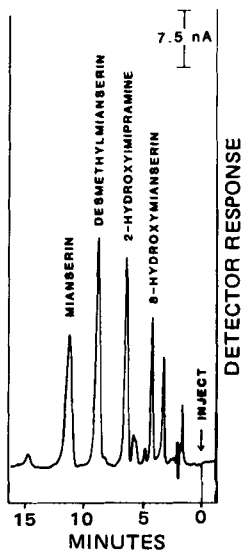

Figure 4—*Sample chromatogram of a 1-ml spiked plasma extract containing 50 ng each of mianserin and desmethylmianserin and 25 ng of 8-hydroxymianserin with 50 ng of 2-hydroxyimipramine as the internal standard. The column was octadecylsilane and the mobile phase was 0.1* M *acetate buffer (pH 4.2)–acetonitrile (65:35) with 0.005* M *heptane sulfonate. The flow rate was 1.3 ml/min.*

[20] Model 440, Waters Associates, Milford, Mass.

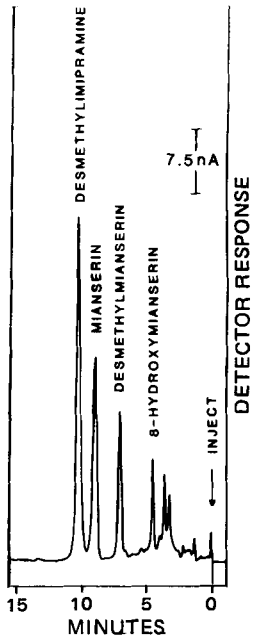

Figure 5—*Sample chromatogram of 1 ml of plasma sample from a patient receiving 120 mg/day of mianserin. Seventy percent reconstituted extract was injected. The plasma levels were calculated to be 13 ng of 8-hydroxymianserin, 21 ng of desmethylmianserin, and 45 ng of mianserin.*

desmethylimipramine, and their 2-hydroxy metabolites under similar experimental conditions (2). A mechanism of electrochemical oxidation of imipramine and chemically related dibenzazepines was recently described by a two-step three-electron ECE process[21] (9). Mianserin and its metabolites, which contain the dibenzazepine nucleus, may undergo similar mechanisms. The optimum potential found for electrochemical detection of mianserin and metabolites was +1.05 V *versus* silver–silver chloride which was compatible with that found previously for the internal standard, desmethylimipramine.

Interfering peaks from other pharmacologic agents, that may be administered concomitantly with this antidepressant, appeared from chlorpromazine and its metabolites and the hydroxylated metabolites of loxapine. Other low dose phenothiazine major tranquilizers such as fluphenazine, perphenazine, and haloperidol are generally found in much lower quantities in plasma and are not detected or elute beyond 12 min. Some commonly used benzodiazepines (flurazepam, chlordiazepoxide, and diazepam) are frequently administered anxiolytic and hypnotic adjuvants. These compounds, as well as their metabolites, would interfere

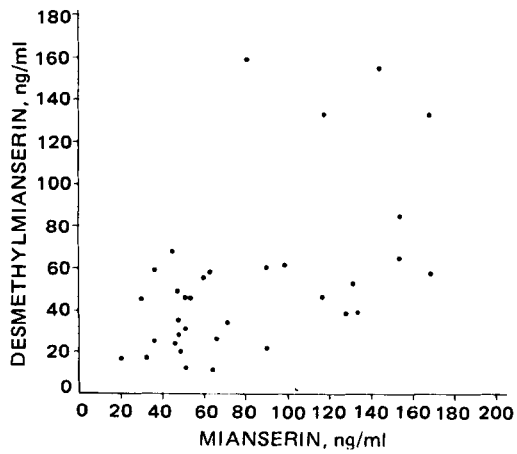

Figure 6—*Relationship between steady-state plasma mianserin and desmethylmianserin level in 34 patients on a fixed dose of 150 mg/day* (r = *0.54*).

[21] An electron-transfer step followed by a chemical reaction and a second electron-transfer step.

if a UV detector (at 254 nm) was used. However none of these drugs or metabolites were electrochemically responsive under the described conditions. A knowledge of the patient drug profile can be very helpful in the identification of interfering peaks.

The multistep extraction procedure used in this method was developed for the recovery of mianserin and its desmethylated and 8-hydroxy metabolites from plasma. A relatively clean chromatogram resulted with no endogenous interfering peaks but with an acceptable recovery of all compounds. Ether may be used in place of methyl-*tert*-butyl ether with a similar rate of recovery. However, it was found that methyl-*tert*-butyl ether required no prior distillation, was less likely to form peroxides, and was easier to handle in the laboratory. Mianserin and desmethylmianserin may also be extracted from plasma by either increasing the plasma pH to 12 and/or using a more nonpolar solvent such as *n*-heptane with 1.5% isoamyl alcohol thus eliminating the 8-hydroxymianserin from the assay. The other major metabolite found in human urine was mianserin-*N*-oxide. This metabolite may be present in plasma but is not extracted from a basic plasma medium.

This method was suitable for automatic sample processing. The use of the automatic injector was compatible with the electrochemical detector and the data acquisition systems. The primary concern in automating this system was the stability of the baseline with respect to drift. It was found that at a detector attenuation of 30 nA full scale or higher, the baseline remained virtually drift-free during a typical 6–8-hr run. In addition, there was no evidence of electrode contamination due to the possible oxidation products forming at the electrode during continuous operation.

If necessary, chromatography can be performed with an octadecylsilyl reversed-phase column with only a minor modification in mobile phase and a change in internal standard. However, several interfering endogenous plasma peaks were present in some samples, which may prove troublesome when low levels of drug are encountered. A spiked plasma sample using this column appears in Fig. 4.

Plasma samples from 34 different patients on a 150-mg/day fixed dose were analyzed for mianserin, desmethylmianserin and its 8-hydroxy metabolite. A representative chromatogram of a patient plasma sample appears in Fig. 5. The mean mianserin plasma level was found to be 81 ng/ml with a range of 20–169 ng/ml. The mean desmethyl metabolite was found to be 53 ng/ml with a range of 11–150 ng/ml. Of these samples, only four had measurable levels (5 ng/ml) of the 8-hydroxy metabolite and the remainder had traces (<5 ng) or none detected. Two patients receiving <150 mg/day (one 120 mg/day, and another 90 mg/day) were found to have 12 and 13 ng/ml of the 8-hydroxy metabolite, respectively. There was no apparent correlation between the plasma level of the nonconjugated 8-hydroxymianserin and the plasma levels of mianserin or desmethylmianserin. Figure 6 demonstrates the relatively weak correlation between mianserin and its desmethyl metabolite.

In three studies, where patients received 60 mg/day of mianserin, steady-state blood levels of mianserin were found in a 6–120-ng/ml range (10), 4–98 ng/ml (mean 36 ng/ml) (6), and a mean of 50 ng/ml (11). The presence of a significant amount of 8-hydroxymianserin as well as the parent compound has been reported (4), although desmethylmianserin could not be detected in the urine of two female volunteers. This was in contrast to earlier findings and rather unusual.

This method provides a means for the simultaneous determination of mianserin, desmethylmianserin, and 8-hydroxymianserin in plasma. The procedure is reliable and sensitive enough for routine plasma monitoring and single dose pharmacokinetic studies. In the single-dose studies, larger volumes of plasma (~3 ml) will be required to determine time points late in the pharmacokinetic curve.

2-^{14}C-1-Allyl-3,5-diethyl-6-chlorouracil I: Synthesis, Absorption in Human Skin, Excretion, Distribution, and Metabolism in Rats and Rabbits

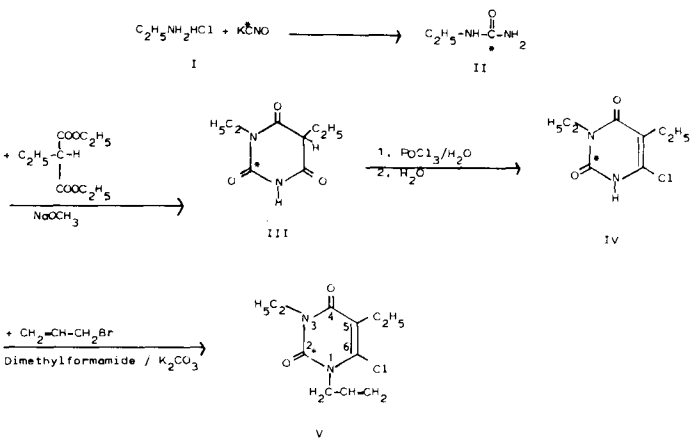
RAVINDER KAUL ˣ, BERND HEMPEL, and GEBHARD KIEFER

Received August 10, 1981, from the *Research Laboratories, Pharmaceuticals Robugen GmbH, Postfach 266, D-7300 Esslingen, West Germany.* Accepted for publication November 3, 1981.

Abstract □ With ^{14}C-potassium cyanate as the starting material, 2-^{14}C-1-allyl-3,5-diethyl-6-chlorouracil was synthesized for *in vitro* and *in vivo* absorption studies in human skin and for metabolic studies in rats and rabbits. The radioactivity in the horny layer, epidermis, and dermis of the human skin was determined after different intervals of time, and the radioactivity excreted in the urine was measured by collecting samples for 5 days from a patient and also under occlusion conditions. Almost 90% of the radioactivity remained on the surface and ~6.28% penetrated and was systemically absorbed. Over a 5-day period, a total of 3.25% was excreted. Almost 3% was systemically absorbed and cumulated in the system. After intraperitoneal application in male and female rats, most of the radioactivity was excreted in the feces and urine, with female rats excreting more in the urine than male rats. The radioactivity rose in the organs in the first 3 hr and then decreased. At the end of 144 hr, no appreciable radioactivity could be found in the organs and tissues, except in the carcass where the cumulation was maximum (1%). After intravenous injection in rabbits, most of the radioactivity (80%) was excreted in the urine and only 4% in the feces. At the end of 96 hr, ~3% was cumulated in the body. The drug was quantitatively metabolized in both rats and rabbits: Metabolite 1 (70–85%), Metabolite 2 (10–15%), Metabolite 3 (5–10%), and Metabolite 4 (0.3%).

Keyphrases □ 2-^{14}C - 1 - Allyl-3,5-diethyl-6-chlorouracil—synthesis, absorption in human skin, excretion, distribution and metabolism, rats, rabbits □ Excretion—2-^{14}C-1-allyl-3,5-diethyl-6-chlorouracil, synthesis, absorption in human skin, distribution and metabolism, rats, rabbits □ Metabolism—2-^{14}C-1-allyl-3,5-diethyl-6-chlorouracil, synthesis, absorption in human skin, excretion, distribution, rats, rabbits □ Absorption—2-^{14}C-1-allyl-3,5-diethyl-6-chlorouracil, synthesis, human skin, excretion, distribution, metabolism, rats, rabbits

1-Allyl-3,5-diethyl-6-chlorouracil[1] (V) has shown promising therapeutic activity against herpes simplex and vaccinia virus (1, 2). It is used for the external treatment of herpes and other viral infections of the skin and mucous membranes. Its absorption in human skin and excretion, distribution, and metabolism in rats and rabbits were studied using ^{14}C-V.



Scheme I

EXPERIMENTAL[2]

Synthesis—For absorption studies in human skin and for metabolism studies, ^{14}C-V, specific activity 0.073 mCi/mmole was synthesized (Scheme I). The starting material was ^{14}C-potassium cyanate[3], specific activity 0.082 mCi/mmole.

^{14}C-N-Ethylurea (II)—A solution of ^{14}C-potassium cyanate (1.0 g, 12.33 mmoles) in 2 ml of water was added to ethylaminehydrochloride (I) (0.95 g, 11.77 mmoles) in water (1 ml) at 80° with constant stirring. The water was completely removed and the residue dried to give 1.72 g of ^{14}C-II (90.0% yield), mp 91–92° [lit. (3) mp 90–93°].

2-^{14}C-3,5-Diethylbarbituric Acid (III)—Diethyl ethylmalonate (2.17 g, 11.72 mmoles) was added dropwise to 5 ml of a 30% methanolic sodium methoxide solution. The reaction mixture was refluxed for 30 min with constant stirring. The methanolic solution (3 ml) of ^{14}C-II (1.72 g, 19.52 mmoles) was then added. The reaction mixture was refluxed for 5 hr at 100° with constant stirring under anhydrous conditions. After cooling, the solvent was evaporated to dryness and the residue was dissolved in 10 ml of hot water. The solution was acidified to pH 1–2 with 2.2 ml of concentrated hydrochloric acid and extracted with chloroform (5 × 15 ml). The solvent was removed and the residue crystallized from ether to give 2.16 g of 2-^{14}C-III (47.6% yield), mp 92–93° [lit. (4) mp 93–94°].

2-^{14}C-3,5-Diethyl-6-chlorouracil (IV)—Phosphorus oxychloride (2 ml) was added dropwise to a mixture of III (2.16 g, 11.73 mmoles) and water (0.1 ml). The reaction temperature was slowly raised to 100° with constant stirring, and after heating for 90 min it was cooled. The remaining phosphoryl chloride was decomposed carefully with 6 ml of water. The cooled mixture was stirred for 1 hr and allowed to stand in the refrigerator overnight. The white crystalline precipitate was filtered off, washed with ice cold water, and dried to give 1.23 g of 2-^{14}C-IV (52.1% yield), mp 168° [lit. (5) mp 167–169°].

2-^{14}C-1-Allyl-3,5-diethyl-6-chlorouracil (V)—Potassium carbonate (2.235 g), allyl bromide (0.68 ml), and dimethylformamide (12.5 ml) were added to 2-^{14}C-IV (1.23 g, 6.07 mmoles) under anhydrous conditions. The mixture was refluxed with stirring for 2 hr at 90–100° and filtered. The residue was washed with chloroform and the filtrate concentrated. The oily liquid was distilled *in vacuo* (bp 119–120°/0.1 mm) to give 1.17 g of 2-^{14}C-V (79.5% yield), specific activity 0.073 mCi/mmole [lit. (5) bp 118–120°/0.1 mm]. ^{1}H-NMR and mass spectra obtained were consistent with structure V. Radiochemical purity was checked by radioscanning of the TLC plates.

Radioactivity Measurements—The radioactive zones on TLC plates were located with a thin-layer scanner[4]. The radioassay in the solution was carried out in a two-canal liquid scintillation counter[5], using a scintillation solution of 1000 ml of dioxane, 180 g of naphthalene, 8 g of 2,5-diphenyloxazole, and 0.1 g of 1,4-bis[2-(4-methyl-5-phenyl-oxazolyl)] benzene. The external standardization technique was employed.

Application—*Human Skin*—A 0.4% solution of ^{14}C-V was made in water using 3% of a solubilizing agent[6]. For *in vitro* studies, 20 μl = 4.9 mg was applied on an area of 7 cm^2. For *in vivo* studies, 50 μl = 4.9 mg of a 0.1% solution of ^{14}C-V was applied on an area of 28 cm^2.

Rats and Rabbits—A 0.15% solution of ^{14}C-V was made in sterile water with 3% of a solubilizing agent[6]. Male and female Wistar rats (200–220 g) were given 7.5 mg/kg body weight of ^{14}C-V solution by intraperitoneal injection. The animals were kept in metabolic cages which enabled the collection of feces and urine separately. They were given free access to

food[7] and water and were kept at 22° and 55% humidity. The feces and urine were collected daily over a period of 144 hr. For studying the distribution, the rats were killed at different time intervals and all organs and tissues were removed separately. All samples were frozen at −20° and taken out before use. New Zealand male rabbits (2 kg each) were given a dose of 15 mg/kg body weight by intravenous injection into the ear vein. Feces and urine were collected daily over a 96-hr period. At the end of this period they were killed and organs and tissues removed and frozen.

Preparation of the Skin—In Vitro *Investigation*—The subcutaneous fat was carefully removed from skin mammary ablations shortly after surgery. Three different specimens of appropriate size were obtained. For each penetration period one specimen was used. The skin was gently cleaned and subcutaneous fat was removed. An area of 7 cm^2 was marked out. The solution of ^{14}C-V was applied for 90 sec by gently rubbing with a glass spatula. Subsequently, the specimen was stretched in a draft-free penetration chamber according to published procedures (6, 7). The subcutaneous side was in contact with gently agitated saline. The glass chamber was kept at a constant temperature of 32° for the indicated time period (penetration time).

In Vivo *Investigations*—Two patients were included in this study. A solution of ^{14}C-V was applied gently to a 28-cm^2 area of healthy skin, and the treated area was protected against unintentional abrasion by a wire cage under free access of air.

Processing of the Skin and Urine—In Vitro—After 100-, 300-, and 1000-min penetration time, the surplus of ^{14}C-V on the surface was removed gently with dry cotton. The specimens were then fastened on a rubber stopper and the horny layer removed by repeated stripping with adhesive tape[8] until a polished shining layer was visible, indicating that all horny skin was removed. Each of the ~20 strips was placed in a separate vial. After removal of the horny layer, a 28-mm^2 sample was punched out and cut horizontally on a freeze microtome[9]. The 16 slices of 10-μm thickness first-sectioned represented the epidermis. The remaining part representing the dermis was cut into 40-μm slices. Thus, ~70 samples were obtained in each experiment with one penetration time and were counted separately. Each sample was placed in a scintillation glass and 0.3 ml of 0.5 *N* NaOH was added. The closed glasses were kept

[a] Average of three animals; administration of 15.0 mg of 2-^{14}C-V.

for 6 hr in an incubator at 75°. Scintillation solution then was added to each sample and the radioactivity measured.

In Vivo—Two penetration times (100 and 1000 min) were selected. The surplus ^{14}C-V was removed and the horny layer sampled as indicated above. A specimen of 28 mm^2 was punched out from the excised area and sliced in the same manner as described for *in vitro* experiments. By day urine was sampled over a 4-hr period and during the night over an 8-hr period; each volume was measured. Samples of 0.3 ml were taken and after addition of hyamine, added directly to the scintillation cocktail.

Penetration Under Occlusion—In a third patient, the pathological skin condition was simulated by occlusion technique, which causes hydration of the horny layer and thus facilitates the penetration. The horny skin was completely removed and 50 μl/28 cm^2 of 0.10% ^{14}C-V was applied and covered with occlusive film[10] for 1000 min, which helped the maximum penetration.

Calculation for Absorption in Human Skin—Subsequent calculations of disintegrations per minute of the percentage of the applied quantity and absolute quantities per layer of skin were performed using a computer program. Absolute quantities are given in micrograms within the respective layer calculated for a 1-cm^2 surface, in micrograms per milliliter of volume of the layer, and in millimoles (calculated on the basis of 1 liter of skin volume). The following tissue thicknesses were taken in calculation: horny layer, 20 μm; epidermis, 160 μm; and dermis, 1.5 mm.

Animal Sample Preparation—*Feces, Organs, and Tissues*—For qualitative and quantitative determination of the radioactivity, the feces samples were dried at 60°, powdered, homogenized[11], and extracted with methanol in a soxhlet apparatus for 48 hr. The organs and tissues were cut into fine pieces and extracted with methanol for 72 hr according to procedures described previously (8, 9). An aliquot (0.1 ml) of the samples was taken up for required measurements.

Urine—An aliquot (0.1–0.2 ml) was mixed directly into the scintillation solution and measured for radioactivity (10).

Chromatography—Analytical TLC was performed on 20 × 5-cm (0.25 mm) silica gel plates[12]. Solvent systems were (v/v): (*a*) petroleum ether–ethyl acetate (8:2); (*b*) petroleum ether–ethyl acetate (5:5); (*c*) cyclohexane–acetone (7:3); (*d*) chloroform–ether (6:4).

Gas Chromatography—Analytical GLC determinations were performed on a gas chromatograph[13] equipped with a flame-ionization detector. The chromatographic column was glass tubing (1.5 m × 0.4-mm i.d.) packed with 3% SE-30 on 100–120 mesh Varaport 30. The operating conditions were: injection port temperature, 230°; oven temperature, 200°; detector temperature, 250°; nitrogen (carrier gas) flow rate, 20 ml/min.

Enzymatic Hydrolysis of the Urine—The rabbit urine was adjusted to pH 7 with acetic acid and then extracted with ether for 96 hr in a liquid–liquid extractor, removing ~90% of the radioactivity (Extract A). The rest of the radioactivity could not be removed with organic solvents and was probably due to conjugates. The urine after ether extraction was concentrated to half of its volume and adjusted to pH 5.5 with concentrated acetic acid. It was diluted to half of its volume with acetate buffer. The enzymatic hydrolysis was done with 0.01 ml of β-glucuronidase and arylsulfatase[14]/ml of urine at 37° for 72 hr and extracted with ether for 96 hr (Extract B).

RESULTS AND DISCUSSION

Absorption in Human Skin—*In Vitro*—Table I shows that most of the applied ^{14}C-V (85–90%) remained on the skin surface or was washed

Table VIII—Ratio in Percent of Various Metabolites of V in Feces [a] and Urine [b] of Male and Female Rats

Sample	Sex	Percent Metabolite 1	Metabolite 2	Metabolite 3
Feces	Male	68	20	12
	Female	65	22	13
Urine	Male	85	10	5
	Female	88	8	4

[a] The feces of various time intervals were mixed together. [b] The urine of various time intervals were pooled together.

in the penetration chamber. Over a 1000-min period, however, ~8% penetrated into the dermis, which acted as a further transport system in the body. The absolute quantity within the respective layers calculated for a 1-cm^2 surface area showed the accumulation of the radioactivity in the dermis, the thickest tissue. The absolute values calculated with an equal tissue volume, however, showed a surprisingly higher molar concentration after a 1000-min period in all tissues. The rejection rate included the percentage of the radioactivity in the saline of the penetration chamber and on the surface of the skin which was wiped off with cotton.

In Vivo—The results are shown in Table II. Here also it is evident that most of the ^{14}C-V remained on the skin surface. The concentration in the horny layers was somewhat higher than *in vitro* studies; in the epidermis it was almost the same. However, the concentration in the dermis *in vivo* was much less than *in vitro* after a penetration time of 1000 min. This is because the circulation system does not play a role *in vitro*, and the drug accumulated in the excised skin. The difference (6.28%) between these *in vivo* and *in vitro* dermal concentrations after a penetration time of 1000 min could be considered as resorption of the drug through the circulatory system. It was more clear when the absolute concentration *in vitro* and *in vivo* was compared. The fact that ^{14}C-V was systemically absorbed in the system was also confirmed by the excretion of the radioactivity in the urine. Over a 5-day period, 3.24% of the activity was excreted after which it was negligible or had completely stopped showing that at least 3% of ^{14}C-V accumulated in the body. The difference between 100- and 1000-min studies showed that a steady state of penetration (*i.e.*, equilibrium between the passage of the substance from the horny skin and its further transport in the circulatory system) relatively soon had reached a standstill; probably it required <100 min. Because of the importance of absorption and excretion of ^{14}C-V, occlusion conditions were employed in a third patient to allow maximum penetration for a period of 1000 min. Similarly, 9.4% of the radioactivity (Table II) could be detected in the urine.

Animal Excretion—*Rats*—Table III shows the excretion of the radioactivity in feces and urine of male and female rats up to 144 hr. A total of 66.1% of the activity was excreted by the male rats in the feces and 28.5% in the urine. On the other hand, the female rats excreted ~52.9% in the feces and 43.8% in the urine. These different excretion rates in the feces and urine could be due to different physiological conditions in both sexes and the female rats excreted a greater quantity of urine than male rats. However, both male and female rats excreted >95% of the radioactivity (male 94.6%, female 96.7%) in the feces and the urine.

Rabbits—Table IV shows the excretion of the radioactivity in the feces and urine of male rabbits up to 96 hr. Most of the radioactivity (88.1% in urine and 3.6% in feces) was excreted after 24 hr. Excretion was slow and at the end of 96 hr, a total of 93% of the activity was excreted in the feces and the urine. This showed that in both rats and rabbits, the kidneys are one of the main elimination organs in the excretion of V and its metabolites.

Animal Distributions—*Rats*—Table V gives the values for male and female rats as percentages of applied dose. The radioactivity increased in all organs and tissues in the first 3 hr and then decreased. In blood the fall of the activity was slow and remained at a constant level between 16 and 72 hr. This was in agreement with urine where maximum excretion took place between these periods. This shows that metabolism of ^{14}C-V was complete after 16 hr and the maximum blood concentration was reached. However, some differences in values in male and female rats were recorded, showing the different metabolism rates in the two sexes. In the kidneys, the main organ of excretion, the radioactivity rose and decreased during various time intervals which can be explained due to throwback mechanisms. In all organs and tissues, however, the radioactivity decreased smoothly, except for a slight rise between 48 and 72 hr, which was due to redistribution phenomenon of these organs. In the liver, the main organ of biotransformation, no concentration of the radioactivity was observed after 5 hr. The high concentration of the activity in the intestine was due to feces that contained high activity and was subsequently excreted. This was further confirmed by contents of the intestinal tract which contained high activity and was ultimately excreted with feces. This shows that the liver plays an important part in the biotransformation and the activity in the feces originated mainly from the activity *via* the bile. At the end of 144 hr, <0.1% of the activity was found in all the organs and tissues of both male and female rats, except in the carcass, where values between 1.02 and 1.21% were recorded. In the carcass of both male and female rats, high radioactivity was accumulated even after 1 hr of application of ^{14}C-V and then decreased.

Rabbits—Table VI gives the values in the organs and tissues at the end of 96 hr. Except in the bones and carcass, very little activity could be found in the other organs and tissues. A total of 3.7% was found in the body after 96 hr.

Metabolism—*Rats*—The feces and the urine of rats showed on the TLC scanner Metabolites 1, 2, and 3 but no unchanged ^{14}C-V. Table VII gives the R_f values of the metabolites compared with ^{14}C-V.

The ratio of these metabolites in feces and urine of both male and female rats is given in Table VIII. Metabolite 1 is the major metabolite in the feces and urine of both male and female rats. The GLC investigations of the prepurified feces and urine showed the presence of another metabolite, 4, in 0.2% concentration. In the increasing order of their retention time in GLC, the metabolites were classified as follows: Metabolite 4 > Metabolite 1 > Metabolite 2 > Metabolite 3.

Rabbits—The combined rabbit urine after extraction with ether (Extract A) showed the presence of Metabolites 1, 2, and 3 in the ratio of 8.5:1.0:0.5. GLC showed the presence of Metabolite 4 in 0.3% concentration. The urine of the rabbits after enzymatic hydrolysis (Extract B) gave Metabolite 1 in 3% yield which showed that it occurred partially as a conjugate. Because of less radioactivity in the feces and many impurities, it could not be investigated properly.

2-^{14}C-1-Allyl-3,5-diethyl-6-chlorouracil II: Isolation and Structures of the Major Sulfur-Free and Three Minor Sulfur-Containing Metabolites and Mechanism of Biotransformation

RAVINDER KAUL ˣ, BERND HEMPEL, and GEBHARD KIEFER

Received August 10, 1981, from the *Research Laboratories, Pharmaceuticals Robugen GmbH, Postfach 266, D-7300 Esslingen, West Germany.* Accepted for publication November 3, 1981.

Abstract □ The metabolites of 1-allyl-3,5-diethyl-6-chlorouracil in rabbit urine were isolated by preparative thick-layer, liquid-column, and gas chromatography. With the aid of mass and ^{1}H-NMR spectra, and by comparison with an authentic sample, the major metabolite, 1, was identified as 6,8-diethyl-2-hydroxymethyl-tetrahydrooxazolo-[3,2-*c*]-pyrimidine-5,7(4H,6H)-dione, Metabolite 2 as 1-allyl-3-ethyl-5-(1-hydroxyethyl)-6-methylthiouracil, Metabolite 3 as 1-allyl-3,5-diethyl-6-methylthiouracil, and Metabolite 4 as 6,8-diethyl-2-hydroxymethyl-tetrahydrothiazolo-[3,2-*c*]pyrimidine-5,7(4H,6H)-dione. The mechanism of the formation of sulfur-containing metabolites is discussed, and a new metabolic pathway for the formation of methylthio compounds is proposed.

1-Allyl-3,5-diethyl-6-chlorouracil[1] (I) has shown promising therapeutic activity against herpes simplex and vaccinia virus (1, 2) and is used for the external treatment of herpes and other viral infections of the skin and mucous membranes. Its absorption in human skin and excretion, distribution, and metabolism in rats and rabbits using ^{14}C-I were reported previously (3). The isolation and structure determination of the major and three minor metabolites are reported in this study.

EXPERIMENTAL[2]

Application—For the isolation of the metabolites, four male rabbits, each 2–2.5 kg, were kept in metabolism cages. Each rabbit was given 5 mg of ^{14}C-I daily [specific activity 0.073 mCi/mmole (3)] mixed in the food over a period of 3 months. They were given dry food[3] and water and kept under normal laboratory conditions. The urine samples were collected daily and frozen to avoid any decomposition.

Radioactivity Measurements—The radioactive zones on TLC plates were located with a thin-layer scanner[4]. The radioassay in the solution was carried out in a two-canal scintillation counter[5], using a scintillation solution of 1000 ml of dioxane, 180 g of naphthalene, 8 g of 2,5-diphenyl-oxazole, and 0.1 g of 1,4-bis[2-(4-methyl-5-phenyl-oxazolyl)] benzene. The external standardization technique was employed. An aliquot (0.1 ml) of the sample solution was directly mixed into the scintillation solution and measured for radioactivity.

Chromatography—Analytical TLC was performed on 20 × 5-cm (0.25 mm) silica gel plates[6]. The solvent system was petroleum ether–ethyl acetate (1:1, v/v). Preparative TLC was performed on 20 × 20-cm (2 mm) silica gel plates with the described solvent system. Column chromatography was carried out on 0.05–0.2-mm silica gel with increasing proportions of ethyl acetate in petroleum ether.

Gas Chromatography—Analytical GLC determinations were performed on a gas chromatograph[7] equipped with a flame-ionization detector. The chromatographic column was glass tubing (1.5 m × 0.4-mm i.d.) packed with 3% SE-30 on 100–120 mesh Varaport 30. The operating conditions were: injection port temperature, 230°; oven temperature, 200°; detector temperature, 250°; and nitrogen (carrier gas) flow rate, 20 ml/min.

Preparative gas chromatography was performed on a gas chromatograph[8] with a flame-ionization detector. The chromatographic column was aluminum tubing (4 m × 6-mm i.d.) packed with 3% SE-30 on 100–120 mesh Varaport 30. The operating conditions were: detector/injector temperature, 225°; exit tip temperature, 200°; column oven temperature, 200°, isotherm; split 1:14; and nitrogen (carrier gas) flow rate, 350 ml/min.

Metabolite Isolation—The urine was adjusted to pH 7 and extracted in a liquid–liquid extractor with ether for 96 hr yielding ~90% of the radioactivity (Extract A), which on TLC showed Metabolites 1, 2, and 3 in the ratio 8.5:1.0:0.5 (3). GLC also showed Metabolite 4 (0.3%) but no unchanged I. For the isolation of the metabolites, Extract A was first purified to remove major impurities. It was applied on preparative TLC plates in a linear form and developed in the solvent system. The silica gel beyond the start line was removed, extracted with methanol in a soxhlet apparatus, solvent removed, and concentrated nearly to 5 ml. The process was repeated again. Purified Extract A (30 μCi or 100 mg of total metabolites) was concentrated to dryness and taken up in petroleum ether. It was loaded on a glass column (80 × 3 cm), filled with silica gel and eluted with increasing proportions of ethyl acetate in petroleum ether using an automatic fraction collector. Eight hundred 20-ml fractions were collected. A radioassay was carried out with each fraction. The loaded radioactivity was recovered fully. The following eluates were pooled together and concentrated after analysis in GLC:

100–150 (25% ethyl acetate in petroleum ether)—Metabolite 3
151–250 (30% ethyl acetate in petroleum ether)—Metabolite 2
450–650 (65% ethyl acetate in petroleum ether)—Metabolite 1
651–800 (70% ethyl acetate in petroleum ether)—Metabolite 4

The concentrated eluate of Metabolite 1 was brown-colored. It was loaded on a silica gel column and eluted with 60% ethyl acetate in petroleum ether. The solvent was removed and the residue was twice crystallized from methanol to yield 45 mg of Metabolite 1, mp 163–164°. Metabolites 2–4 could not be further purified by column chromatography. GLC showed the presence of a number of impurities. The substance was therefore purified by preparative GLC, to yield 20 mg of Metabolite 2 and 8 mg of Metabolite 3. Attempts to isolate and purify Metabolite 4 failed due to the minimal amount.

Synthesis—*Metabolite 1 (6,8-Diethyl-2-hydroxymethyl-tetrahydrooxazolo-[3,2-c]pyrimidine-5,7(4H,6H)-dione)* — 6,8-Diethyl-2-bromomethyl-tetrahydrooxazolo[3,2-*c*]pyrimidine-5,7(4H,6H)dione (1.5 g, 5 mmoles), prepared according to the literature method (4), was dissolved in 10 ml of dimethylformamide and heated under reflux for 10 hr with silver acetate (20 mmoles), which was obtained by heating 2.8 g of silver carbonate and 20 ml of acetic acid. After cooling, the insoluble

material was filtered off and the solvent evaporated. The residue was dissolved in chloroform and washed with a saturated solution of sodium bicarbonate followed by water. The organic layer was dried over sodium sulfate and filtered through active charcoal and the solvent was removed *in vacuo*. The residue was dissolved in methanol (10 ml). A solution of 0.6 g of sodium hydroxide in 3 ml of water was added and the reaction mixture kept for 16 hr at room temperature. The solvent was removed *in vacuo* and the residue dissolved in methanol–water (1:1) and loaded on an ion-exchange resin[9] (H^+) column and eluted with methanol–water (1:1). The eluates were pooled together and evaporated *in vacuo* and the residue crystallized from ethyl acetate–petroleum ether mixture to give Metabolite 1, mp 162.5–163.5°, in a 40% yield.

Anal.—Calc. for $C_{11}H_{16}N_2O_4$: C, 55.01; H, 6.71; N, 11.65. Found: C, 55.52; H, 6.28; N, 11.08.

Metabolite 3 (1-Allyl-3,5-diethyl-6-methylthiouracil)—Methyl mercaptan (10 g, 0.2 mole) in methanol was added to 50 ml of a 30% methanolic sodium methoxide solution. Compound I (36.4 g, 0.15 mole) was added with stirring. The reaction mixture was refluxed with stirring for 24 hr and poured into water. It was extracted with chloroform, the solvent evaporated, and the residue distilled *in vacuo* to give Metabolite 3, bp 109°/0.02 mm, in 36% yield.

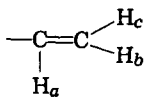
Anal.—Calc. for $C_{12}H_{18}N_2O_2S$: C, 56.67; H, 7.13; N, 11.01; S, 12.61. Found: C, 56.70; H, 7.35; N, 11.31; S, 12.52.

Metabolite 4 (6,8-Diethyl-2-hydroxymethyl-tetrahydrothiazolo-[3,2-c]pyrimidine-5,7(4H,6H)-dione) — 1-(2′,3′-Epoxypropyl)-3,5-diethyl-6-chlorouracil (2.6 g, 10 mmoles), prepared according to the described method (5), was dissolved in dry dimethyl sulfoxide (20 ml) and sodium hydrogen sulfide (1.1 g, 20 mmoles) was added. The reaction mixture was then concentrated *in vacuo* and the residue poured into water. After it was extracted twice with methylene chloride, the organic layer was dried over sodium sulfate. The solvent was removed and the milky viscous liquid was purified by column chromatography using silica gel (0.05–2 mm) with methylene chloride as elution solvent to give Metabolite 4, mp 83°, in 40% yield.

Anal.—Calc. for $C_{11}H_{16}N_2O_3S$: C, 51.54; H, 6.25; N, 10.93; S, 12.54. Found: C, 50.86; H, 6.55; N, 10.44; S, 12.12.

RESULTS AND DISCUSSION

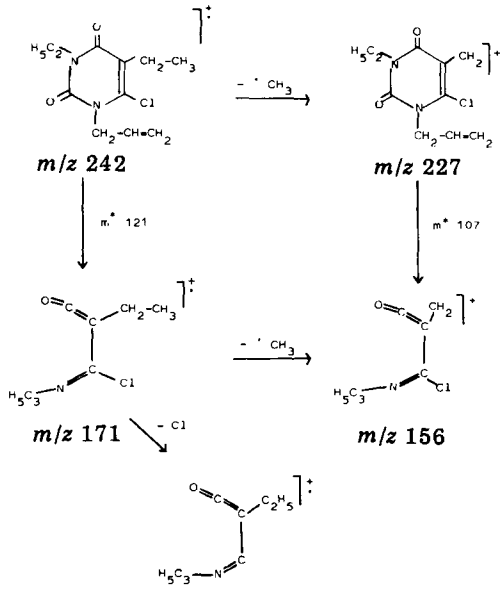
Mass and ^{1}H-NMR Spectrum of I—In the ^{1}H-NMR spectrum of I, both methyl groups appeared as triplets at δ 1.08 and 1.20 ppm. The methylene group at N-3 appeared as a quartet at δ 3.93, and the methylene group at N-1 appeared as a doublet at δ 4.65 ppm. In the allylic protons of



H_a appeared at δ 5.94 ppm as a multiplet, H_b at δ 5.22 ppm as a doublet, and H_c at δ 5.17 ppm as a doublet (J_{ab} = 12 Hz, J_{ac} = 17 Hz).

In the mass spectrum, the intensity ratio of the signals at *m/z* 242/244, 227/229, 201/203, 171/173, and 156/158 showed the presence of chlorine. The loss of ethyl isocyanate, C_2H_5CNO (242 → 171 or 227 → 156) supported by metastable peaks m* in the final sequence is characteristic of uracil and barbituric acid derivatives in a retro-Diels-Alder fragmentation (6–8). The fragmentation of I can be formulated according to Scheme I.

Structure of Metabolite 1—In the mass spectrum of the metabolite, the major fragmentation is formulated according to Scheme II, the formula of each fragment being established by high resolution mass spectrometry. Direct correlation between the fragments is demonstrated by the appearance of the metastable peaks m*. The mass spectrum of the metabolite showed the absence of chlorine in the molecule. First, the β-methyl group at C-8 was cleaved off the molecular ion leaving a highly stabilized cation. Next, the substituent at N-4 was removed: the expulsion of C_3H_4O showed one oxygen having been incorporated into the allylic side chain, while the other oxygen was bonded to the pyrimidine ring system. The loss of ethyl isocyanate (C_2H_5CNO) in the final sequence was similar to that of I. In the ^{1}H-NMR spectrum ($CDCl_3$), a signal appeared at δ 2.80 ppm (1 H) which, being exchangeable with deuterium oxide and also rather susceptible in position and line shape to both temperature and concentration, must be attributed to an hydroxide group. Since it was split into a triplet (J = 6.0 Hz), the metabolite must



Scheme I

contain a —CH_2OH moiety. The lone C-2 proton appeared at the lowest field, split into seven lines (not a heptuplet). The methylene proton at both C-3 and exocyclic carbon were nonequivalent, however, rendering the spectrum unsusceptible to first-order analysis. The theoretical spectra for Metabolite 1 and for closely related compounds prepared by independent synthesis were calculated and fitted to the experimental data within ±0.01 Hz. Table I lists the data thus obtained which confirm the heterobicyclic structure for the metabolite. In each case, the less shielded C-3 protons were assigned to H^A by virtue of the larger coupling to H^C (J *cis* > J *trans* for five-membered ring) (9). Spectral analysis of all compounds listed in Table I additionally was complicated by the N—CH_2 quartet being superimposed upon the partial spectra of H^A, H^B, and $H^{D,E}$. By changing the solvent from $CDCl_3$ to C_6D_6, however, all protons situated on the fused five-membered ring appeared better shielded by 0.8–1.3 ppm, while signals of the N-6 and C-8 substituent protons were shifted slightly to lower field. Apparently, the benzene molecules orient themselves in a manner known from other amide spectra (10): farthest away from the negative end of the N—C—O dipole, thus, placing substituents at N-4 and C-9 directly within the diamagnetic shielding cone due to arene ring current. If spectra accumulation was possible, the rather low solubility of these compounds in benzene (<5 × 10^{-2} mole/liter) was more than offset by the well separated partial spectra[10]. These data establish Metabolite 1 as 6,8-diethyl-2-hydroxymethyl-tetrahydrooxazolo-[3,2-c]pyrimidine-5,7(4H,6H)-dione. The metabolite structure was confirmed by its independent synthesis; the synthetic Metabolite 1 mass spectrum and ^{1}H-NMR, GLC, and TLC data were identical with those of the isolated product.

Structure of Metabolite 3—The mass spectrum of Metabolite 3 showed the absence of chlorine in the molecule. The methyl group was also cleaved off here (254 → 239) and in a retro-Diels-Alder reaction supported by metastable peaks, the loss of ethyl isocyanate (239 → 168) subsequently took place. In this respect, the fragmentation was similar

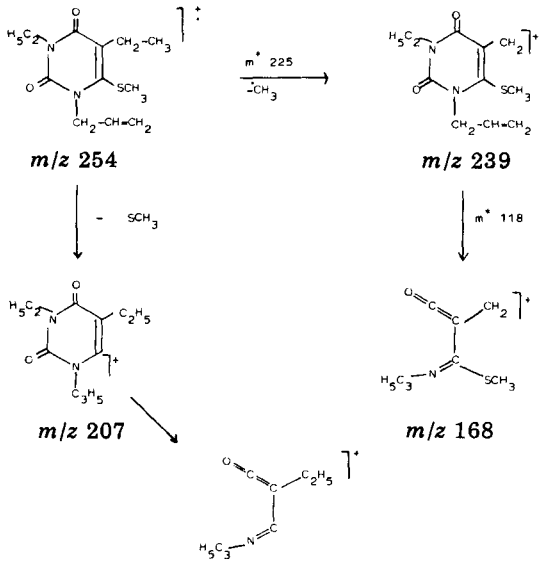
[a] δ (ppm) relative to tetramethylsilane as internal standard; *J* (Hz); 30°. All spectra were measured at 90 MHz by Pulse-Fourier-Transform technique (8k interferogram, dwell time 560 or 840 μsec); number of scans varied between 1000 and 20,000, depending on concentration. [b] Values of δ and *J* given for H^A–H^F were obtained from theoretical spectra calculated with programs ITRCL1 and ITRCL2 (NICOLET users society) on a NICOLET BNC-12. [c] Spectra show some evidence of H^D,H^E-nonequivalence. [d] $\delta_{OH}F$ 2.797 ppm, J_{df} = 5.48 Hz, J_{ef} = 6.52 Hz.

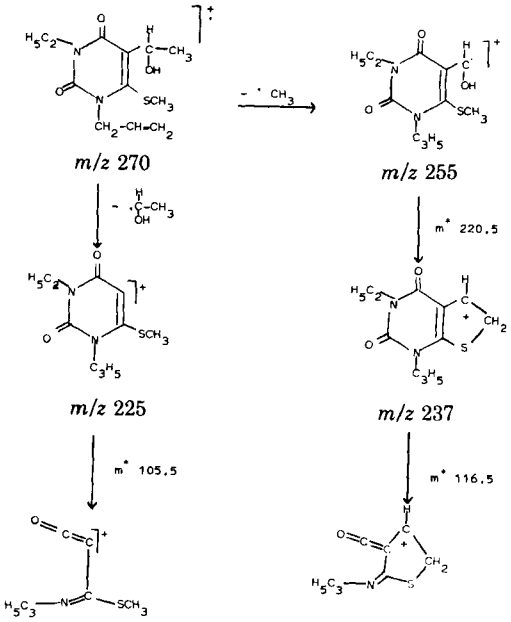
to that of I, as also the fragment at *m/z* 136 appeared in both the spectra. The intensity of ions at m + 2 with 5.1% relative intensity and the loss of 47 mass units showed the presence of an SCH_3 group. The fragmentation of Metabolite 3 can be formulated according to Scheme III. In the ^{1}H-NMR spectrum ($CDCl_3$), near the signals of unchanged allyl and alkyl groups, a singlet appeared at δ 2.44 (3 protons) showing the presence of an SCH_3 group. These data establish Metabolite 3 as 1-allyl-3,5-diethyl-6-methylthiouracil, which was further confirmed by an independent synthesis. The synthetic Metabolite 3 mass spectrum, ^{1}H-NMR, GLC, and TLC data were identical with those of the isolated product.

Structure of Metabolite 2—In the mass spectrum the intensity ratio of the ions at *m/z* 272/270 and 257/255 with 6.5% relative intensity showed the presence of sulfur. The fragmentation pattern of Metabolite 2 (Scheme IV) was identical with I and Metabolite 3. The behavior of certain ions showed the presence of a hydroxyethyl group. The methyl group at C-5 was knocked off (270 → 255) and then a water molecule was eliminated (255 → 237), and in a retro-Diels-Alder reaction, the ion at *m/z* 166 was formed. By loss of a hydroxyethyl group, the ion at *m/z* 225 was formed and subsequently by retro-Diels-Alder reaction the ion at *m/z* 154 also formed. The loss of an allyl group with 41 mass units was also similar to the fragmentation of I and Metabolite 3. ^{1}H-NMR showed the protons of allylic and *N*-ethyl groups. The singlet at δ 2.43 ppm (3 protons) was assigned to an SCH_3— group. A doublet at δ 1.55 ppm (3 protons) was assigned to an hydroxide group. Due to nonavailability of the synthetic product, a comparison could not be made but these data confirm the Metabolite 2 as 1-allyl-3-ethyl-5-(1-hydroxyethyl)-6-methylthiouracil.

Structure of Metabolite 4—As Metabolite 4 could not be isolated, its structure, 6,8-diethyl-2-hydroxymethyl-tetrahydrothiazolo-[3,2-*c*]-pyrimidine-5,7(4H,6H)-dione, was based on mass spectra obtained by



Scheme III

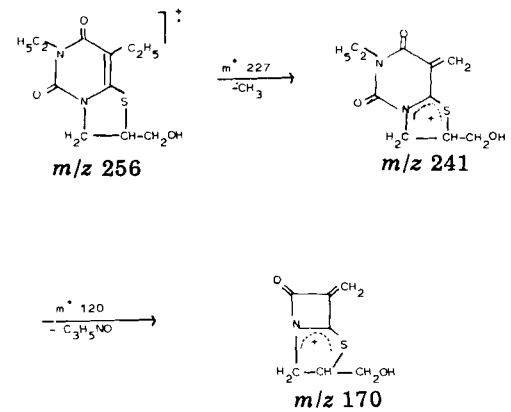


Scheme IV

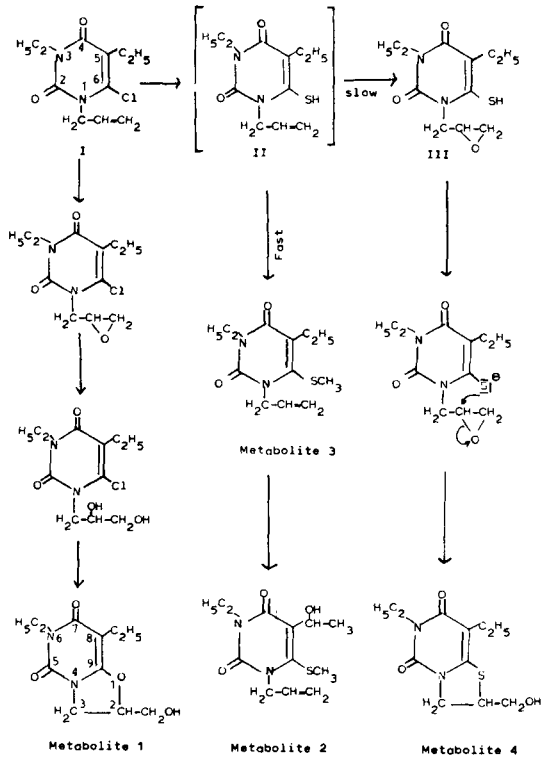
the combination of GLC–mass spectrometry. In the mass spectrum of the metabolite, the metastable peaks establish the following major fragmentation:

$$m/z\ 256 \xrightarrow{m^*\ 227} m/z\ 241 \xrightarrow{m^*\ 120} m/z\ 170$$

The intensity of the ions at m + 2 with 5.1% relative intensity showed the presence of sulfur. First, the β-methyl group at C-8 was cleaved off the molecular ion (256 → 241) leaving a highly stabilized cation. The loss of ethyl isocyanate (241 → 170) by a retro-Diels-Alder fragmentation sup-



Scheme V



Scheme VI

ported by a metastable peak in the final sequence is characteristic of uracil and barbituric acid derivatives. The structure of the metabolite was confirmed by its independent synthesis. The synthetic Metabolite 4 showed the fragmentation pattern as shown in Scheme V, the molecular formula of each fragment was established by high resolution mass spectrometry. The mass spectrum of Metabolite 4 was identical in all respects with the synthetic product, and thus established its structure as 6,8-diethyl - 2 - hydroxymethyl-tetrahydrothiazolo-[3,2-*c*]pyrimidine-5,7-(4H,6H)-dione.

Mechanism of Biotransformation—*Metabolite 1*—In the formation of Metabolite 1, the first step is epoxidation of the allylic double bond of I followed by hydrolysis to propane-2,3-diol as described for analogous compounds (11). Subsequently, the β-hydroxy group substitutes the heterocyclic chlorine, thus forming the fused bicyclic Metabolite I *via* an intramolecular S_N reaction.

Metabolites 2–4—Recently, the formation of sulfur-containing metabolites from sulfur-free drugs has developed increasing interest. The methylthio (—SCH_3) metabolites have been reported in a number of drugs (12–18). The origin and the mechanism of formation of these methylthio metabolites is not known so far. Two pathways have been proposed: direct attachment of a methylthio group and transformation of mercapturic acids or glutathione conjugates (19, 20). Metabolite 4, due to its unique structure, supports the mechanism of the formation of methylthio metabolites *via* the formation of an intermediate thiol (—SH). A bicyclic sulfur-containing barbituric acid derivative of this type as a product of biochemical degradation has not yet been reported in the literature. A new metabolic pathway for the formation of this sulfur-containing Metabolite 4 and for the methylthio metabolites, 2 and 3, is proposed according to Scheme VI. In the formation of Metabolite 4, the first step is the substitution of chlorine by a thiol group forming an intermediate compound (II). This reaction may be enzymatic. The epoxidation of the double bond takes place giving Compound III. Subsequently, the sulfur atom attacks the β-carbon atom of the epoxide ring thus forming the fused bicyclic Metabolite 4 *via* an intramolecular S_N-reaction. The formation of methylthio Metabolites 2 and 3 may take place through this intermediate (II), as the enzymatic methylation of the thiols is reported *in vitro* and *in vivo* (21). It seems that the methylation of the intermediate (II) is a fast preferential reaction, therefore, larger amounts of Metabolites 2 and 3 are formed. The epoxidation of II is a slow specific reaction. The epoxide (III) is unstable. It has a pronounced tendency to ring closure leading to the stable Metabolite 4.

Study of the Metabolic Conversion of Imipramine and Desipramine to *N*-Nitrosodesipramine by Bacteria Using a Nitrogen-Selective GC Analysis

JOHN K. BAKER *x, ALICE M. CLARK ‡, and CHARLES D. HUFFORD ‡

Received September 9, 1981, from the **Department of Medicinal Chemistry and the* ‡*Department of Pharmacognosy, School of Pharmacy, University of Mississippi, University, MS 38677.* Accepted for publication November 12, 1981.

Abstract □ A GC method using dual nitrogen selective and flame ionization detectors was developed for the determination of *N*-nitrosodesipramine using *N*-butyryldesipramine as the internal standard. The precision of the method was found to be ±5.0% and the accuracy was ±4.9%. The method could be used to detect 10 ng/ml of *N*-nitrosodesipramine in bacterial cultures. When desipramine and sodium nitrite were incubated with aerobic or anaerobic bacteria, the nitrosamine level was found to be 10–300 times higher than the controls. When imipramine and potassium nitrate were incubated with a mixed anaerobic culture, the level of *N*-nitrosodesipramine was found to be 4.5 times higher than the control.

Keyphrases □ Imipramine—metabolic conversion to *N*-nitrosodesipramine by bacteria, nitrogen-selective GC, desipramine □ *N*-nitrosodesipramine—metabolic conversion of imipramine and desipramine by bacteria, nitrogen-selective GC □ Desipramine—metabolic conversion to *N*-nitrosodesipramine by bacteria, nitrogen-selective GC, imipramine □ Metabolic conversion—imipramine and desipramine to *N*-nitrosodesipramine by bacteria, nitrogen-selective GC

Previous studies have shown that secondary amines can be converted to carcinogenic *N*-nitroso amines when incubated with bacteria found in the intestine or bladder (1–4). It has also been demonstrated that bacteria can convert trimethylamine to dimethylamine and produce *N*-nitrosodimethylamine (3, 5). Though the conversion of these simple amines to *N*-nitroso compounds may have an impact on public health, the level of exposure to these compounds would be fairly low. The exposure to maintenance drugs such as desipramine and imipramine would be considerably higher, however, and these drugs might be converted to the *N*-nitroso derivatives in the intestine or bladder by bacteria. Recent studies in these laboratories with fungi have shown that these microorganisms *N*-demethylate imipramine in yields of 2–11% depending on the organism studied (6). Work presently in progress with aerobic and anaerobic bacteria has shown that many of the organisms give a 1–3% conversion from imipramine to desipramine. The objective of the present study was to develop an analytical method for *N*-nitrosodesipramine suitable for complex matrixes and to determine if either desipramine or imipramine would be converted to the nitrosamine in the presence of the bacteria.

EXPERIMENTAL

Synthesis of *N*-Nitrosodesipramine—Though there are references to *N*-nitrosodesipramine in the literature (7, 8), no synthetic information has been given nor have any of the spectral properties of the alleged compound been reported.

In the present study, 200 mg of the desipramine hydrochloride (0.66 mmole) was dissolved in 10 ml of water, made basic with 4 drops of concentrated ammonium hydroxide, then extracted with 15 ml of methylene chloride. The extract was dried with anhydrous sodium sulfate, then the extract was added to a solution containing 115 mg of nitrosonium tetrafluoroborate (0.66 mmole $NOBF_4$) in 5 ml of methylene chloride at room temperature. Over a 15-min period, 100 mg of pyridine in 2 ml of methylene chloride was added to the well-stirred suspension. After 1.5 hr the mixture was washed with 10 ml of 2 *N* HCl, 15 ml of 10% Na_2CO_3, then dried with anhydrous sodium sulfate. The solvent was evaporated to give 165 mg (85% yield) of the nitrosamine as a thick oil (IR: 1445 cm^{-1}, N=O). The mass spectrum of the nitrosamine obtained using the solid probe showed a fairly intense molecular ion at 295 (12%) and a peak at 265 characteristic of the loss of the nitrosyl group. The nitrosamine was also observed to produce peaks at 193 (100%), 208 (96%), 220 (50%), and 234 (32%) which were similar to those observed for the fragmentation of desipramine. The mass spectrum obtained by the GC mode (Fig. 1) was observed to be essentially the same.

Synthesis of *N*-Butyryldesipramine—Using 15 ml of toluene as the solvent, 200 mg of desipramine hydrochloride (0.55 mmole), 200 mg of butyric anhydride (1.3 mmoles), and 200 mg of pyridine were heated on a steam bath for 1 hr. The mixture was washed with 20 ml of aqueous 10% Na_2CO_3, the toluene layer was dried, then the solvent was evaporated under vacuum to give a 270-mg residue. The IR spectrum of this material indicated that the desired product was contaminated with a small amount of butyric anhydride. The residue was then sonicated with 10% Na_2CO_3 for 30 min, then extracted with methylene chloride, dried with anhydrous sodium sulfate, and evaporated to give 230 mg (95%) of the final product as an oil; IR (thin film): 2950, 1637, 1483, 1227, and 750 cm^{-1}; mass spectrum (GC mode): 336 (M^+, 7%), 234 (9%), 222 (13%), 208 (100%), 193 (45%), and 142 (89%).

Determination of *N*-Nitrosodesipramine—Sulfamic acid (30 mg) was added to a 10.0-ml sample of the bacterial culture to remove residual nitrite. Then, 20.0 μg of *N*-nitrosodesipramine (internal standard) in ethyl acetate was added, and the sample was extracted with 5 ml of isooctane. The isooctane layer was transferred to a conical evaporation tube[1],

Table I—Recovery of *N*-Nitrosodesipramine and *N*-Butyryldesipramine

Sample Medium	Extraction Recovery	
	N-Nitroso-desipramine, %[a]	Internal Standard, %[b]
Water	103.6	105.2
	96.6	101.4
	101.4	102.3
Mean ± *SD*	100.5 ± 3.6	103.0 ± 2.0
Sterilized Bacterial Culture	81.4	73.5
	96.3	90.9
	86.7	83.3
	93.0	94.3
Mean ± *SD*	89.4 ± 6.6	85.5 ± 9.2

[a] The sample was spiked with 1.0 μg/ml of *N*-nitrosodesipramine and the percent recovery was determined by comparison to the peak height obtained for 10 μg/50 μl of the nitrosamine in ethyl acetate. [b] The sample was spiked with 2.0 μg/ml of the internal standard and the percent recovery was determined by comparison to the peak height obtained for 20 μg/50 μl of the internal standard in ethyl acetate.

then evaporated at 80° under a stream of nitrogen. When the samples were almost dry, the walls of the evaporation tubes were washed down with 500 μl of methanol, then the samples were evaporated to dryness. The residue was taken up in 50 μl of ethyl acetate and 1.0 μl was used for the GC analysis.

The GC analysis[2] was conducted using dual nitrogen selective and flame ionization detectors with a dual pen recorder. The column (2 mm × 183 cm) was operated at 260° with helium as the carrier gas (30 ml/min) and with a packing of 3.0% methyl–phenyl silicone polymer[3] on a 110–120 mesh silanized support[4]. The carrier gas coming from the column was split equally between the flame ionization detector (H_2 = 19 ml/min) and rubidium bead nitrogen selective detector (H_2 = 2.3 ml/min), and each detector received 300 ml/min of air. Using these conditions, the retention time for *N*-nitrosodesipramine was 9.2 min and 14.9 min for *N*-butyryldesipramine. The nitrogen detector response index of the nitrosamine (response index = 0.155) was measured relative to caffeine as described previously (9).

In the analysis of the bacterial cultures, the presence of the nitrosamine was ascertained through the use of the retention times of the components

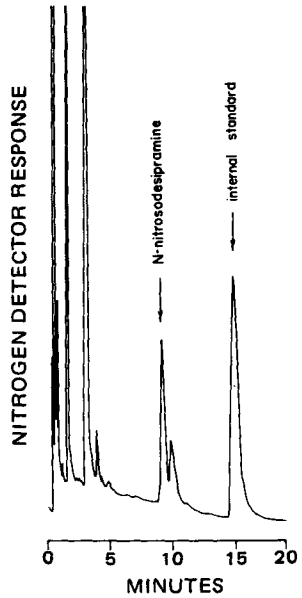

Figure 2—*Nitrogen-selective GC of bacterial cultures. The chromatogram was obtained from the extract of a culture of* Enterobacter aerogenes *containing desipramine and sodium nitrite. Though a dual flame ionization detector–nitrogen detector system was used for all samples, the flame ionization detector response has been omitted from the figure for simplicity.*

Table II—Accuracy and Precision of the Analytical Method

Bacterial Culture	*N*-Nitrosodesipramine, μg/ml[a]
1	1.108
2	1.060
3	1.042
4	0.987
Mean ± *SD*	1.049 ± 0.050

[a] A full-term Stage II culture not containing any drug or nitrite was sterilized, then spiked with 1.0 μg/ml of the nitrosamine. A 10-ml sample was then taken for analysis.

and the response index (9) of each component. Electron impact mass spectra[5] of the GC peaks were used as a secondary means of peak identification for some of the samples. Quantitations were based on the nitrogen-selective detector peak heights of the nitrosamine relative to the internal standard (*N*-butyryldesipramine). The method was calibrated using a simple solution containing a known quantity of the nitrosamine and the internal standard.

Incubation of Bacterial Cultures—Aerobic bacteria were grown according to a two-stage fermentation procedure using a defined medium (10) supplemented with either 25 m*M* $NaNO_2$ or 25 m*M* KNO_3. The Stage II cultures were incubated (37°, 250 rpm) with either 100 μg/ml of desipramine hydrochloride or 100 μg/ml of imipramine hydrochloride for 48 hr.

The anaerobic bacteria used in the study were isolated as pure cultures from the intestinal contents of a naive male Wistar rat. Mixed cultures of anaerobic bacteria from the large intestine and small intestine were also used.

Stage I cultures of the anaerobes were grown (24 hr, 37°) in 10 ml of the defined medium supplemented with either 25 m*M* $NaNO_2$ or 25 m*M* KNO_3 using an anaerobic chamber[6] for the culture tubes. Then 0.5 ml of the Stage I culture was transferred to the Stage II tubes containing 10 ml of the defined medium and 25 m*M* $NaNO_2$ or KNO_3 and 100 μg/ml of desipramine hydrochloride or imipramine hydrochloride. The Stage II cultures were incubated for 48 hr (37°) in fresh anaerobic chambers.

Control studies were conducted in which the defined sterile medium containing 25 m*M* $NaNO_2$ and 100 μg/ml of desipramine hydrochloride was adjusted to pH 5.0, 6.0, 7.0, and 8.0, then incubated with the same method for the Stage II aerobic cultures or the Stage II anaerobic cultures.

RESULTS AND DISCUSSION

Initial attempts to prepare *N*-nitrosodesipramine using desipramine, aqueous sodium nitrite, and hydrochloric acid (pH ≅ 3 maintained) were not successful. Even after 24 hr, the reaction mixture did not show significant amounts of the nitrosamine, but a large amount of another product that gave a GC–mass spectrum [*m/z* 240 (M^+, 100%), 193 (74%), 179 (15%), 167 (25%), and 83 (79%)] that would be consistent with a *C*-nitro derivative of iminodibenzyl. Due to a lack of pure reference standards of the four possible isomers of nitroiminodibenzyl, no attempts were made to establish the identity of the product.

Recently, it has been shown that nitrosonium tetrafluoroborate with pyridine can be used to produce nitrosamines of much higher purity (11). In particular, it was anticipated that the reagent would avoid the acidic conditions that are associated with *C*-nitrosation of aniline-like compounds. Indeed, it was found that this reagent gave an 85% yield of a high-purity product in 1.5 hr at room temperature. The mass spectrum of the product (Fig. 1) showed a molecular ion (295), a loss of the *N*-nitrosyl fragment (265), and the loss of the iminodibenzyl fragment (194) which would be characteristic of the *N*-nitroso compound as compared to the *C*-nitroso compound. The IR spectrum of the product was also characteristic of a nitrosamine.

In selecting an internal standard for the analysis of *N*-nitrosodesipramine, it was desirable to use a compound that was extremely lipophilic, like the nitrosamine and that had the same acid–base properties as the nitrosamine. The acetyl, propionyl, and butyryl amide derivatives of desipramine were investigated as potential internal standards and they were found to have retention times of 12.0, 13.0, and 14.9 min on the same GC system that gave a retention time of 9.3 min for the nitrosamine. Preliminary studies with bacterial cultures, to which no internal standard had been added, showed that cultures often produced small GC peaks

at 10.1 and 11.0 min that would have caused some minor problems if the acetyl or propionyl amides had been used as the internal standard.

Though isooctane is too nonpolar to be ideal for the extraction of most drugs, this property proved to be critical in obtaining extracts that gave high-quality chromatograms. Solvents such as methylene chloride were found to give good recoveries of the nitrosamine, but the chromatograms gave an off-scale response for the nitrogen-selective detector for the first 3–4 min and several large peaks that eluted after the nitrosamine. When isooctane was used for the extraction, high-quality chromatograms were obtained for the bacterial cultures (Fig. 2) and quantitative recoveries of the nitrosamine and the internal standard were obtained from aqueous model systems (Table I). A bacterial culture not containing any drug or *N*-nitrosodesipramine was harvested at the end of the Stage II fermentation, then the culture was sterilized and spiked with the nitrosamine and internal standard. Though the recoveries from this matrix were not quantitative (Table I), the recoveries were very high, and the recoveries of the nitrosamine and the internal standard were the same.

When a set of four sterilized bacterial cultures was spiked with a known quantity of the nitrosamine and then analyzed with the internal standard method, it was found that the average value for the determination was 4.9% higher than the true value (Table II), however, this error was within the ±5.0% variance for the method. Using the sample sizes as described in the experimental section, the detection limit was ~0.010 μg/ml. This detection limit was not due to signal–noise limitations, but because of the presence of a peak on the shoulder of the nitrosamine that was detectable at only these very low levels.

The analysis of the aerobic bacterial cultures (Table III) showed that the amount of desipramine converted to *N*-nitrosodesipramine was 10–300 times higher in the cultures than in the controls. The identity of the nitrosamine in each of the cultures was verified by a comparison of the retention time and nitrogen detector response index (9) of the unknown and the reference standard. The GC–mass spectra of some of the extracts were examined and found to be identical to the reference standard (Fig. 1).

The chemical *N*-nitrosation of simple secondary amines increases as the pH decreases, and the rate reaches a maximum at pH 3 for most aliphatic amines. Though a buffer system was used with the bacterial cultures, the pH of several of the cultures dropped during the fermentation. However, when desipramine and sodium nitrite were incubated under identical conditions in sterile media, only trace quantities of the nitrosamine was formed even at the lower pH range (Table III). After a consideration of all of these factors, the production of the nitrosamine in the cultures of *Enterobacter aerogenes*, *Klebsiella pneumoniae*, *Proteus mirabilus*, and *Proteus vulgaris* was considerably above the control values and above that which would be expected of any simple chemical model.

Preliminary studies with imipramine, potassium nitrate, and mixed aerobic cultures (Table III) indicated that *N*-nitrosodesipramine was not formed. Though a wide variety of aerobes have been previously demonstrated to convert nitrate to nitrite (4, 12), this conversion was not monitored in the present study. Thus, the absence of the nitrosamine could be the result of a low conversion of nitrate to nitrite or a result of a slow rate of *N*-demethylation.

Of the anaerobic cultures (Table IV), isolate LI-B2 was found to produce considerably higher levels of *N*-nitrosodesipramine than the control incubations. The isolates obtained from the small intestines produced nitrosamine levels above the control values, but the concentration was nearly an order of magnitude lower than for the large intestine isolate.

A mixed culture of large intestine anaerobes (Table IV) was found to produce a concentration of *N*-nitrosodesipramine 4.5 times higher than the control incubation of imipramine and potassium nitrate alone. Though the concentration of the nitrosamine formed in the mixed culture seemed low, it was 500–1000 times greater than the simple nitrosamines commonly found in food samples (13) or human feces (14).

CONCLUSIONS

The analytical method developed for the determination of *N*-nitrosodesipramine in bacterial cultures was found to give accurate and precise (±5.0%) results with good sensitivity (0.01 μg/ml). Using the nitrogen detector response index as an additional identification aid, the nitrosamine was easily quantitated in the complex bacterial culture matrix.

[7] API 20E System, Analytab Products, Plainview, N.Y.

Several of the aerobic and anaerobic cultures were found to give high levels of *N*-nitrosodesipramine when incubated with desipramine and sodium nitrite. Though it cannot be stated that the transformation was an entirely enzymatic reaction, the yield of the nitrosamine was far higher than could be obtained by the acid catalyzed reaction between nitrite and desipramine.

Preliminary studies with mixed anaerobic cultures with imipramine and nitrate showed that the nitrosamine was formed more rapidly than the control, but the yield was very low. Additional studies with pure cultures will be needed to determine if the low yield was due to a low rate of *N*-demethylation.

Blood Level Studies of All-*trans*- and 13-*cis*-Retinoic Acids in Rats Using Different Formulations

R. S. SHELLEY, H. W. JUN ˣ, J. C. PRICE, and D. E. CADWALLADER

Received July 31, 1981, from the *Department of Pharmaceutics, School of Pharmacy, University of Georgia, Athens, GA 30602.* Accepted for publication November 12, 1981.

Abstract □ Studies to determine the bioavailability of all-*trans*-retinoic acid from a microencapsulated product were carried out using rats as test animals. The microcapsules were tableted in rat food and individual rats given a tablet containing the equivalent of 10 mg of all-*trans*-retinoic acid. Comparisons were made with bioavailability data obtained after intravenous and oral administrations of a solution and a suspension. The elimination of all-*trans*-retinoic acid following intravenous administration of 1- to 5-mg doses occurred by dose-dependent kinetics. The half-lives for the terminal linear portion of the elimination phase after the plateau level were 0.78, 0.74, and 0.93 hr for the 1-, 2.5-, and 5-mg doses, respectively. Based on the doses administered and the relative area under the serum level curves, the all-*trans*-retinoic acid microcapsules were found to be ~34% as bioavailable as the solution dosage form and the microfine suspension 93% as bioavailable. The bioavailability of all-*trans*-retinoic acid in oral solution was ~40% of the intravenous dose. For comparison, rats were also dosed intravenously with 13-*cis*-retinoic acid, and this compound was found not to follow dose-dependent kinetics at similar dosage levels used for all-*trans*-retinoic acid.

Keyphrases □ Bioavailability—Blood level studies of all-*trans*- and 13-*cis*-retinoic acids using different formulations, rats □ Microencapsulation—blood level studies of all-*trans*- and 13-*cis*-retinoic acids using different microencapsulated formulations, rats □ Blood level studies—all-*trans*- and 13-*cis*-retinoic acids using different formulations, rats □ Retinoic acids, all-*trans*- and 13-*cis*- —blood level studies using different formulations, rats

A number of retinoids have been shown to prevent or inhibit the growth of epithelial tumors. The use of these compounds for chemoprevention of tumors has been reviewed previously (1, 2). Although a long-term study with a synthetic retinoid was reported (3), most studies have been relatively short term with manual dosing of the retinoids. For long-term efficacy studies, a more economical and less troublesome mode of drug administration is through the diet of the test animals. However, simple mixing of retinoids with feed is precluded because of the unstable nature of the compounds toward air, light, and moisture. Earlier studies with vitamin A compounds have shown that these chemicals can be protected from environmental hazards by microencapsulation (4, 5).

Requirements of a microcapsule product are that first it must be readily miscible with the feed of the test animals, and second, it must be soluble or digestible in the GI tracts of the animals so that the retinoid is biologically available. In the present study, all-*trans*-retinoic acid was microencapsulated, and the bioavailability of the compound from the finished product was determined and compared with intravenously and orally administered retinoid using rats as test animals. Also, for comparison, rats were dosed intravenously with 13-*cis*-retinoic acid.

EXPERIMENTAL

Chemicals—All-*trans*-retinoic acid[1], 13-*cis*-retinoic acid[2], and all-*trans*-retinol acetate[3] were used as received. All other chemicals and reagents were the highest grade commercially available.

Microcapsules—All-*trans*-retinoic acid was encapsulated in gelatin–dextrose microcapsules by a process similar to that reported for the encapsulation of vitamin A derivatives (6) using a three-phase suspension

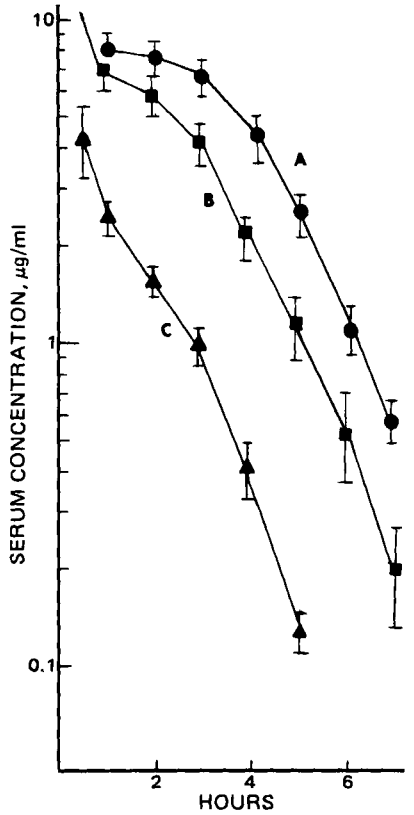

Figure 1—*Average serum concentrations of all-*trans*-retinoic acid following rapid intravenous administration in saline solution. Key: (▲) 1.0-mg dose, six rats; (■) 2.5-mg dose, six rats; (●) 5.0-mg dose, five rats.*

method. Gelatin was chosen as the major encapsulating material because it offers adequate bioavailability and good stability under various storage conditions (5, 7). The geometric mean diameter of the microcapsules was 0.19 mm with a geometric standard deviation of 1.81. The microcapsules were stored at −10° until needed for testing.

The microcapsules were assayed to determine content uniformity and stability using spectrophotometric analysis[4] after dissolution of the microcapsules in water at 65° and extraction with chloroform. The all-*trans*-retinoic acid content determined by assay of 12 samples (50 mg) of microcapsules from a homogenized mixture was found to be 2.83 ± 0.05 mg with a coefficient of variation of 1.77% indicating good uniformity of the formulation. The concentration of all-*trans*-retinoic acid in the microcapsules was 6.03% of the total weight.

Animal Dosing—Adult Sprague-Dawley rats (~360 g) were used. All dosed rats were fasted ~24 hr prior to dosing with retinoid. Water was available *ad libitum*. Orally dosed rats received 5- to 10-mg doses of all-*trans*-retinoic acid. Rats given intravenous injections were dosed with 1–5 mg of either all-*trans*-retinoic acid or 13-*cis*-retinoic acid. Oral and intravenous dosing was staggered ~5–10 min so that blood samples could be collected from each of the rats at approximately the same time intervals after dosing.

Oral doses of all-*trans*-retinoic acid were given in 0.5 ml of 0.3% NaOH–0.9% saline solution and in microfine suspension (<3-μm particles) *via* gastric intubation to lightly anesthetized rats. Intravenous injections for both all-*trans*- and 13-*cis*-retinoic acids were given in a 0.3% NaOH–0.9% saline solution and injected into the tail vein of lightly anesthetized rats.

All-*trans*-retinoic acid microcapsules were fed to fasted rats in the following manner. Ground-up rat food–microcystalline cellulose (2:1) was mixed with all-*trans*-retinoic acid microcapsules and tableted by compression into 12.5-mm disks at 2724 kg for 20 sec. Each tablet contained the equivalent of 10 mg of all-*trans*-retinoic acid. Ten rats were put in individual cages, and each rat was given one food tablet containing the all-*trans*-retinoic acid. Six or more of the rats consumed the tablets completely within 10 min.

Serum Collection—Multiple blood samples were collected from each rat using a modification of a previous method (8). Blood samples of 250–300 μl were collected under reduced pressure from an incision made at the distal end of the tail of unanesthetized rats and collected in serum separation tubes. Immediately following centrifugation, the serum samples were transferred to 15-ml screw-capped test tubes and stored at −10° where they remained for 20–60 hr before they were assayed. Because of the small amount of blood collected per sample, eight or nine blood samples could be taken from each rat over the time-course of 7–10 hr.

Microfine Suspension[d], 5 mg	12.8 ± 1.4	93	36.9
Microcapsules[e] tableted in rat food, 10 mg	4.6 ± 6[b]	33.5	13.3

[a] Corrected for the body weight. [b] Adjusted to 5 mg by dose ratios. [c] Average 9 rats. [d] Average 11 rats. [e] Average 12 rats.

Serum Assay—Serum samples were assayed by a reversed-phase high-pressure liquid chromatographic method reported previously (9).

A standard curve was obtained by comparing the peak height ratio of all-*trans*-retinoic acid or 13-*cis*-retinoic acid to all-*trans*-retinol acetate and the spiked serum all-*trans*-retinoic acid or 13-*cis*-retinoic acid concentration. Unknown serum sample concentrations were calculated by comparing the peak height ratios of the samples to the processed standards. The lower working limit for the assay was 100 ng/ml of serum

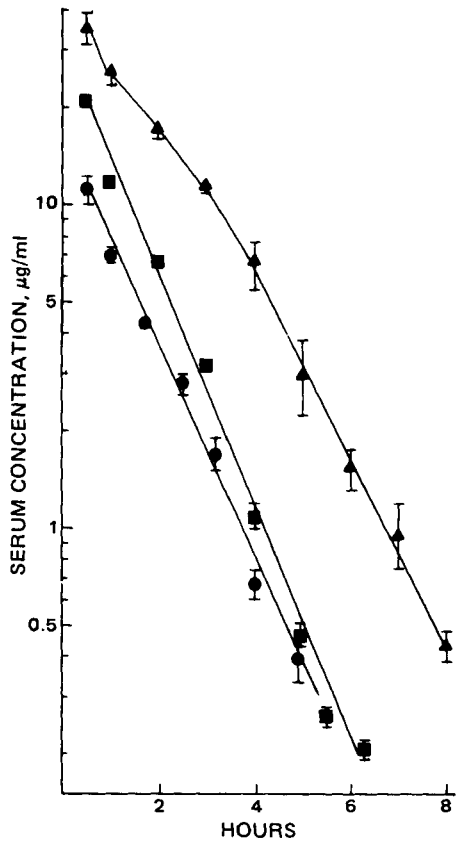

Figure 2—*Average serum concentrations of 13-*cis*-retinoic acid following rapid intravenous administration in saline solution. Key: (●) 1.25-mg dose, eight rats; (■) 2.5-mg dose, six rats; (▲) 5.0-mg dose, eight rats.*

and the recovery of all-*trans*-retinoic acid and 13-*cis*-retinoic acid was 102.9 ± 5.6 and 91.7 ± 5%, respectively. The areas under the serum level *versus* time curves were determined by the trapezoidal rule. The elimination half-lives were determined from the slope of the elimination curves by using a linear regression program with a programmable calculator.

RESULTS AND DISCUSSION

Serum levels *versus* time profiles following a 1-, 2.5-, and 5-mg iv dose of all-*trans*-retinoic acid were shown in Fig. 1. Serum concentrations showed a rapid decline immediately after injection as the retinoid was distributed into tissues. However, serum levels rapidly reached a plateau and remained stable for several hours before returning to the linear elimination phase. Increasing the dose of all-*trans*-retinoic acid to 2.5 and 5 mg, respectively, resulted in a more pronounced and longer plateau (Figs. 1A and 1B), indicating a possible saturation of elimination pathways at higher doses. The time required for the serum levels to return to the linear elimination phase after the plateau began was ~94, 135, and 190 min for the 1-, 2.5-, and 5-mg doses, respectively. The half-life for the linear elimination phase after the plateau was 0.78, 0.74, and 0.93 hr for the 1-, 2.5-, and 5-mg doses, respectively, and these values were not significantly different ($p > 0.05$).

Recently, after observing nonlinear declining of serum levels of all-*trans*-retinoic acid in the rat, several potential causes for the nonlinear kinetics were investigated (10). Dose-dependent elimination due to the saturation of biliary excretion was ruled out since the same nonlinear behavior in rats with biliary fistulas was observed. It was found that interrupting the enterohepatic recirculation system had no effect on the nonlinear elimination phenomenon. Also discovered was a greater conversion of all-*trans*-retinoic acid to all-*trans*-retinoyl-β-glucuronide, supposedly a minor metabolite, as the intravenous dose was increased. Both results indicated that the dose-dependent elimination was due to saturation of major metabolic pathways instead of saturation of biliary excretion. However, at the present time there is some disagreement as to what the major metabolic pathways might be in the biotransformation of all-*trans*-retinoic acid in rats (11–13).

For comparison, 13-*cis*-retinoic acid was intravenously administered in rats in 1.25-, 2.5-, and 5-mg doses and the results obtained summarized in Fig. 2. The saturation phenomenon was completely absent at lower doses and only a brief nonlinear phase was observed at the 5-mg dosage level. Also, the half-lives of the linear elimination phase were slightly longer than those of all-*trans*-retinoic acid, averaging 0.8–0.9 hr. Similar results were observed (14) when the disposition of all-*trans*- and 13-*cis*-retinoic acids in mice was studied. A plateau phenomenon was found in the serum level *versus* time curve following an intravenous injection of all-*trans*-retinoic acid but not for 13-*cis*-retinoic acid. Since dose-dependent kinetics were observed with all-*trans*-retinoic acid but not with 13-*cis*-retinoic acid, these results would indicate that the metabolic enzymes for these chemicals are probably different. However, currently there is little data available as to the enzymatic reactions of 13-*cis*-retinoic acid in rats.

Since the intravenous dose of all-*trans*-retinoic acid produced dose-dependent kinetics, it was not possible to accurately determine the area under the curve (*AUC*). However, an approximate *AUC* was obtained by using the trapezoidal rule and found to be 6.94 ± 0.8 μg hr/ml for the 1-mg iv dose. After adjusting and comparing the 1-mg dose to the 5-mg dose, the oral solution dosage form was found to be only 40% as bioavailable as the intravenous dose. The low bioavailability of the oral solution could be the result of either a first-pass effect occurring or from the inaccuracy of the *AUC* calculation due to the dose-dependent kinetics. For these reasons, all-*trans*-retinoic acid in oral solution was used as a standard for bioavailability comparisons to the other formulations.

Shown in Fig. 3 are the average serum levels after dosing nine rats orally with saline solutions containing 5 mg of all-*trans*-retinoic acid. Peak serum levels occurred after 2.5 hr with an elimination half-life of 0.69 hr and an *AUC* of 13.74 ± 1.6 μg hr/ml. Average peak serum level was 3.2 μg/ml. Results after oral administration of microcapsules in laboratory animal feed are shown in Fig. 4. The curve represents data averaged from 12 rats each dosed with the equivalent of 10 mg of all-*trans*-retinoic acid. Peak serum concentration occurred at ~3 hr and the *AUC* was 9.21 ± 1.2 μg hr/ml with an elimination half-life of 1.02 hr.

Figure 5 shows the average serum levels achieved when 11 rats were dosed orally with the microfine suspension dosage form. A 5-mg dose was administered which resulted in an average peak serum level time of 3 hr and an *AUC* of 12.8 ± 1.4 μg hr/ml with an elimination half-life of 0.65 hr.

Based on the doses administered and the relative area under the serum level curves (Table I), the all-*trans*-retinoic acid microcapsules were ~34% as bioavailable as the solution dosage form, and the microfine suspension was 93% bioavailable. The low bioavailability of the microcapsules is possible because all-*trans*-retinoic acid was not completely released from the microcapsules in the digestive tract of the rat. The half-life of the elimination phase was 1.5 times greater than that of the solution, indicating that absorption was probably still occurring after the

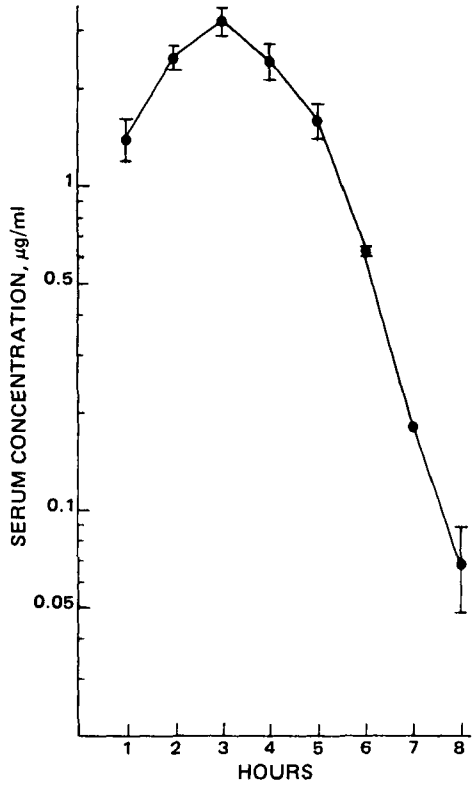

Figure 5—*Average serum concentrations of all-*trans*-retinoic acid following a 5.0-mg dose of a microfine suspension to 11 rats.*

peak concentration thus producing the slowly declining serum concentrations. Another possible cause of the slow release of the chemical from the microcapsules was interaction with the rat food in which the microcapsules were tableted. In a preliminary study, it was found that all-*trans*-retinoic acid crystals tableted in rat food were only 73% bioavailable as the solution, possibly indicating that the rat food in which the crystals were tableted was interfering with absorption.

The microfine suspension was formulated as a possible alternative to microencapsulation. It has the advantage of a greater bioavailability, but the disadvantages of being a less stable formulation and less readily miscible with the rat food as compared to the solid microcapsules. The primary purpose of microencapsulation was to stabilize the retinoids for feeding to rats in their laboratory diets for long-term testing of the compounds for chemo-prevention of tumors.

All-*trans*-retinoic acid was successfully microencapsulated and the bioavailability of the encapsulated and liquid dosage forms compared. Although the microcapsules were only 34% bioavailable as the solution dosage form, this is a good compromise because of the increased stability and ease of handling. Also, all-*trans*-retinoic acid was found to follow dose-dependent kinetics at the doses studied; whereas, 13-*cis*-retinoic acid did not follow dose-dependent kinetics when given at the same dosage levels as the all-*trans*-retinoic acid.

Tack Behavior of Coating Solutions I

S. K. CHOPRA * and R. TAWASHI ˣ

Received June 8, 1981, from the *Faculty of Pharmacy, University of Montreal, Montreal, Quebec, Canada H3C 3J7*, and the **Schering Canada, Inc., Pointe Claire, Quebec, Canada, H9R 1B4.* Accepted for publication November 3, 1981.

Abstract □ The tackiness of various tablet coating solutions was determined using a parallel plate technique with a tensile testing machine in conjunction with an oscilloscope where the separation force was displayed as a function of time. Measurements were made at various rates of separation on liquid films of constant thickness. Results showed that the force required to split a liquid film increases with an increase in rate of separation, and that tackiness increases with an increase in viscosity. The relation between tack and viscosity was not linear, and a modified Stefan equation was proposed.

Keyphrases □ Tablet coating solutions—tack behavior, viscosity □ Viscosity—tack behavior of tablet coating solutions □ Tackiness—tack behavior of tablet coating solutions

The effect of coating formulations and coating process variables on the appearance of a coated tablet has been the subject of various investigations (1–3). Much effort has been devoted to the study of the theory of adhesion of film-forming materials to the surface of a tablet (4–6). However, very little is known about the tackiness of coating solutions and its effect on the coating process. Studies on the evaluation of coating formulations have made some reference to the problem of tackiness of hydroxypropyl cellulose solutions during the coating process (7). However,

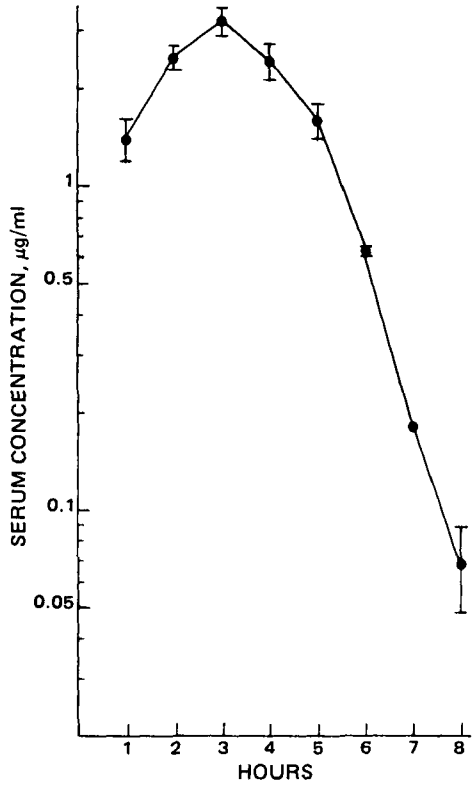

Figure 5—*Average serum concentrations of all-*trans*-retinoic acid following a 5.0-mg dose of a microfine suspension to 11 rats.*

peak concentration thus producing the slowly declining serum concentrations. Another possible cause of the slow release of the chemical from the microcapsules was interaction with the rat food in which the microcapsules were tableted. In a preliminary study, it was found that all-*trans*-retinoic acid crystals tableted in rat food were only 73% bioavailable as the solution, possibly indicating that the rat food in which the crystals were tableted was interfering with absorption.

The microfine suspension was formulated as a possible alternative to microencapsulation. It has the advantage of a greater bioavailability, but the disadvantages of being a less stable formulation and less readily miscible with the rat food as compared to the solid microcapsules. The primary purpose of microencapsulation was to stabilize the retinoids for feeding to rats in their laboratory diets for long-term testing of the compounds for chemo-prevention of tumors.

All-*trans*-retinoic acid was successfully microencapsulated and the bioavailability of the encapsulated and liquid dosage forms compared. Although the microcapsules were only 34% bioavailable as the solution dosage form, this is a good compromise because of the increased stability and ease of handling. Also, all-*trans*-retinoic acid was found to follow dose-dependent kinetics at the doses studied; whereas, 13-*cis*-retinoic acid did not follow dose-dependent kinetics when given at the same dosage levels as the all-*trans*-retinoic acid.

Tack Behavior of Coating Solutions I

S. K. CHOPRA * and R. TAWASHI ˣ

Received June 8, 1981, from the *Faculty of Pharmacy, University of Montreal, Montreal, Quebec, Canada H3C 3J7*, and the **Schering Canada, Inc., Pointe Claire, Quebec, Canada, H9R 1B4.* Accepted for publication November 3, 1981.

Abstract □ The tackiness of various tablet coating solutions was determined using a parallel plate technique with a tensile testing machine in conjunction with an oscilloscope where the separation force was displayed as a function of time. Measurements were made at various rates of separation on liquid films of constant thickness. Results showed that the force required to split a liquid film increases with an increase in rate of separation, and that tackiness increases with an increase in viscosity. The relation between tack and viscosity was not linear, and a modified Stefan equation was proposed.

Keyphrases □ Tablet coating solutions—tack behavior, viscosity □ Viscosity—tack behavior of tablet coating solutions □ Tackiness—tack behavior of tablet coating solutions

The effect of coating formulations and coating process variables on the appearance of a coated tablet has been the subject of various investigations (1–3). Much effort has been devoted to the study of the theory of adhesion of film-forming materials to the surface of a tablet (4–6). However, very little is known about the tackiness of coating solutions and its effect on the coating process. Studies on the evaluation of coating formulations have made some reference to the problem of tackiness of hydroxypropyl cellulose solutions during the coating process (7). However,

to our knowledge, no systematic, quantitative study on the tackiness of tablet coating solutions has been reported.

The objective of this study was to assess the tackiness of some polymer solutions used in tablet coating. Knowledge about the tacky behavior of coating formulations is a prerequisite for solving some of the technical problems encountered in tablet coating.

BACKGROUND

Tack is defined as the impulse per unit area (ft) necessary to separate two planes, initially in contact, through an intervening liquid (8). The basic expression for the separation of two flat circular plates in a viscous Newtonian liquid was given by Stefan (9) as follows:

$$F = \frac{3\pi\eta r^4}{4t}\left(\frac{1}{h_1^2} - \frac{1}{h_2^2}\right) \quad \text{(Eq. 1)}$$

Where F is the force (dynes) of separation, η is the viscosity (poise) of the liquid, r is the radius (centimeters) of the plates, h_1 and h_2 are the initial and final thicknesses (centimeters) of the liquid film, and t is the time (seconds) required for separation. The force of separation per square centimeter (f) is equal to $F/\pi r^2$, where πr^2 is the surface area of the plates. Therefore, tack can be expressed as:

$$ft = \frac{3\eta r^2}{4}\left(\frac{1}{h_1^2} - \frac{1}{h_2^2}\right) \quad \text{(Eq. 2)}$$

If the final thickness $h_2 \gg h_1$, then:

$$ft = \frac{3\eta r^2}{4h_1^2} \quad \text{(Eq. 3)}$$

The validity of the relation described by Eq. 3 has been questioned by various investigators because the experimental confirmation of the proposed equality was not satisfactory. Some of the experiments on tack appear to be inadequately designed due to the lack of suitable instrumentation. The deviation of other experimental results from Eq. 3 has been attributed to a variety of factors such as the effect of high rates of separation (10), onset of cavitation and formation of multiple filaments (11, 12), flow properties of highly viscous materials (13), surface roughness, and wettability of the solid surfaces (14).

Based on these considerations, studies were designed to evaluate and quantitate the various physicochemical parameters influencing the tackiness of tablet coating solutions.

EXPERIMENTAL

Materials—Polymers used in this study were hydroxypropyl methylcellulose[1] (5 cps), hydroxypropyl methylcellulose (15 cps), hydroxypropyl methylcellulose[1] (50 cps), hydroxypropyl cellulose[2], and povidone[3]. Solvents used for making coating solutions were distilled water, ethanol[4] (95%), and methylene chloride[5]. Newtonian liquids used were glycerin[6] (97%) and white mineral oil[7].

Measurement of Viscosity—All measurements were made on a rotational cup and bob viscometer[8] in conjunction with a strip chart recorder[9]. Temperature was held constant at 25° for aqueous test solutions

and at 15° for polymer solutions in organic solvents. The cup and bob geometry was varied according to the viscosity of the sample.

Tack Measurement Assembly—Tack measurements were made using a tensile testing machine[10]. A schematic diagram of the assembly used is shown in Fig. 1.

The probe (Fig. 1c) and plate (Fig. 1f) are of stainless steel, type 302. The end of the probe was machined and lapped. The working area of the probe and plate were polished using techniques similar to that described previously (14).

The horizontal position of the bottom plate (Fig. 1f) was checked using a spirit level. Prior to the measurement of tack, it was ascertained that the probe was perfectly parallel to the plate.

Measurement of Film Thickness—The bottom plate (Fig. 1f) was brought into contact with the probe by raising the vertically moving stage (Fig. 1h). The pointed end of the pin (Fig. 1g) was then aligned with the crosshair line of the ocular micrometer attached to the telemicroscope[11] to mark the zero clearance between the probe and the plate.

The bottom plate was then lowered and the circular space (Fig. 1e) within the ring (Fig. 1d) was filled with ~0.5 ml of the test liquid. Utmost care was taken to avoid the introduction of air into the liquid during this transfer.

The bottom plate was then brought closer to the probe leaving a desired gap and any excess liquid was squeezed out. The difference in number of divisions between the new position and the zero position of the pointed end of the pin was used to calculate the film thickness of the liquid.

The resistance to necking-down takes place under the probe and not around it; therefore, the size of the reservoir is not of serious importance. The amount of the liquid should not be so small that the reservoir is

completely used up at the very start of the necking-down process. When the volume of the test liquid is properly adjusted, a variation in volume of as much as 50% does not affect the tack measurement.

Measurement of Tack—After adjustment of the thickness of the test liquid, the crosshead bar (Fig. 1b) was allowed to move upwards at a specified speed. The test liquid first formed a column, necked-down, and then finally separated. The separation process was photographed and is shown in Fig. 2.

The events were recorded on a storage type oscilloscope[12] where the separation force (F) was displayed as a function of time. The measurements were made at 25° for aqueous test solutions and at 15° for polymer solutions prepared in organic solvents.

A minimum of six measurements were taken for every test solution at each separation rate. The test solution was changed if the presence of air bubbles was noticed.

RESULTS AND DISCUSSION

Effect of Rate of Separation on Force of Splitting Liquid Film—Figure 3 shows the force–time oscillograms obtained for a 10% aqueous solution of hydroxypropyl methylcellulose (5 cps) at various rates of separation. The traces show that as the time of separation decreases, the peak force increases.

The relation between peak force and the rate of separation for 5, 10, and 15% (w/w) aqueous solutions of hydroxypropyl methylcellulose (5 cps) is shown in Fig. 4. These plots demonstrate that the force required to split a liquid film increases with an increase in the rate of separation. The plots obtained are not linear and results are consistent with the experimental data presented in the study of tackiness of inks by Strasburger (15). Nevertheless, that author tried to fit the experimental data points to a theoretical straight line based on a modified Stefan equation derived previously (12):

$$F = \frac{3}{2}\pi\eta u\frac{r^4}{h_2{}^3} \qquad \text{(Eq. 4)}$$

where u is the rate of separation.

Effect of Rate of Separation on Tack—The plots of rate of separation *versus* tack of aqueous solutions of hydroxypropyl methylcellulose (5 cps) for concentrations ranging from 5 to 20% are shown in Fig. 5. The tack was calculated by dividing the area under the curves of the force–time oscillograms by the surface area of the probe.

Figure 5 illustrates that the tack is independent of the rate of separation for 5, 7.5, and 10% (w/w) aqueous solutions of hydroxypropyl methylcellulose (5 cps) solutions. These results are in agreement with Eq. 3. The tack values of 15 and 20% (w/w) solutions for rates of separation, $\geq 1.677 \times 10^{-1}$ cm/sec, fell below the average tack values obtained at lower rates of separation.

[12] Model 5113 with 5B12N time base and two 5A26 dual differential amplifiers, Tektronix, Inc., Beaverton, Ore.

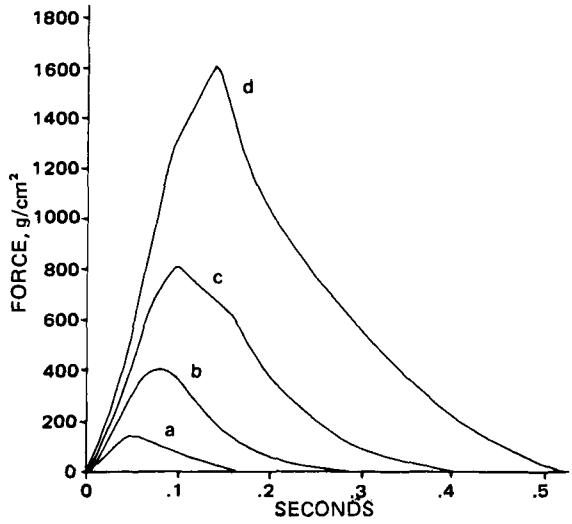

Figure 8—*Force–time oscillograms at rate of separation of 8.33×10^{-2} cm/sec for aqueous solutions of hydroxypropyl methylcellulose (5 cps). Key: a, η = 0.29 poise; b, η = 2.44 poise; c, η = 9.5 poise; d, η = 41 poise.*

A similar behavior was also noticed for pure liquids such as glycerin and liquid paraffin, where the tack values at the rate of separation of 3.33×10^{-1} cm/sec are lower than those obtained at a lower rate of separation (Table I). Thus, for a liquid of given viscosity, there is an upper limit of the rate of separation beyond which the equation described by Stefan is not applicable.

The reason for obtaining low tack values at higher rates of separation may be due to viscoelastic effects (9, 16). When the probe is pulled away from the plate, the liquid flows towards the axis of the plate at the rate governed by h_1, t, and η. When stress is applied slowly, *i.e.*, when t is long, the liquid responds by flow. If t is too short, the mechanism of rupture of the liquid film is quite different from that envisaged by Stefan. The liquid gets no chance to flow and the elastic forces become more important for the breakdown of the film. Under such circumstances, the tack values obtained are lower than that predicted by Eq. 3.

Effect of Viscosity on Tack—The relation between tack and viscosity is shown in Fig. 6. The theoretical ft was calculated by substituting the values of r, h, and η in Eq. 3. The experimental curve was plotted using the average of tack values obtained at various rates of separation for a number of solutions of hydroxypropyl methylcellulose (5 cps) in varying concentrations and hence viscosities.

Figure 6 shows that the experimental curve falls below the theoretical curve and also deviates from linearity as the viscosity of the test solution increases. The same experimental data plotted on a log–log scale is shown in Fig. 7 with a correlation coefficient of 0.9994, indicating the validity of the relationship $ft = k\,\eta^c$; k and c are constants with respective values of 24,862 and 0.6737. The value of k depends on the instrumental factor, k' and $3r^2/4h_1{}^2$. The value of k' was found to be 1.215×10^{-1}. The equation for the experimental conditions described then becomes:

$$ft = \frac{3}{4}r^2 k'\eta^{0.67}\frac{1}{h_1{}^2} \qquad \text{(Eq. 5)}$$

To confirm the relationship described in Eq. 5, aqueous solutions of three different molecular weight grades of hydroxypropyl methylcellu-

	43.5	Water	5.97	8.23	7.95
Hydroxypropyl methylcellulose (5 cps)	5	Ethanol–Methylene Chloride (50:50, w/w)	0.41	1.37	1.41
Hydroxypropyl methylcellulose (5 cps)	5	Ethanol–Methylene Chloride (75:25, w/w)	0.95	2.4	2.51
Hydroxypropyl methylcellulose (5 cps)	5	Ethanol–Water (50:50, w/w)	0.68	1.92	2.01
Hydroxypropyl methylcellulose (5 cps)	5	Ethanol–Water (75:25, w/w)	0.84	2.21	2.13

lose, a single grade of hydroxypropyl cellulose and of povidone, all in varying concentrations, were prepared. Solutions of hydroxypropyl methylcellulose (5 cps) were also prepared in mixtures of varying proportions of ethanol and methylene chloride, and ethanol and water.

The viscosities and the corresponding tack values of the above solutions were determined and the results are presented in Table II. This table illustrates that the experimental tack values, within a margin of error of ±5%, match the predicted tack values calculated using Eq. 5.

In the present study, the experimental tack values obtained for various coating solutions were lower than those predicted by Stefan's equation. Also, the relationship obtained between tack and viscosity was not linear. The low experimental tack values obtained in Fig. 6 could be attributed to the instrumental factors such as the surface roughness of the probe and plate. The nonlinearity of the relationship between the tackiness and viscosity cannot be attributed to the experimental conditions, as these were kept constant throughout the study.

One of the factors that can influence the values of tack is the initial lag in force. This is due to the finite time of acceleration of the crosshead bar before it attains a constant speed. The force–time oscillograms in Fig. 8 were obtained at the same rate of separation. The shape of the traces obtained for lower viscosity solutions (Fig. 8, Curves a and b) are different than those for higher viscosity solutions (Fig. 8, Curves c and d). This suggests that the mode of liquid film separation is different for the higher viscosity solutions. It has been suggested (9) that when the ratio η/t increases to a point where the flow pattern of the liquid towards the axis of the plate is not uniform, the resulting ft is a fraction of that calculated by Eq. 3. This may account for the nonlinearity between tack and viscosity.

Tack Effects in Tablet Coating—The fact that a force is required to separate two objects joined by a thin liquid film (Fig. 4) could explain the phenomenon of picking and sticking in the pan-coating process.

At any given moment during the process of pan coating, a thin film of coating solution is present between two tablets, or between a tablet and the wall of a coating pan. When the pan is allowed to rotate, the tablets are carried upwards by the combined effects of centrifugal and frictional forces until gravity overcomes the effects and the tablets cascade down. The force exerted by these moving tablets splits the liquid film before the complete evaporation of solvent occurs.

If the force required to split the liquid film is greater than the forces of adhesion between the polymer film and the tablets, then picking may occur. The picking here is defined as the transference of portions of polymer film from the weakly adhered parts of one tablet to another or to the wall of a coating pan. However, if the force exerted by the moving tablets is not sufficient to split the liquid film present between the wet tablets, then sticking may occur.

The fact that the resistance of the liquid film to splitting increases with the rate of separation may further explain why the picking is more pronounced in a larger pan than in a smaller one. In the larger coating pan, the tablets cascade down at higher velocity than in a small coating pan, and therefore, the stress exerted on the polymer film during the separation of wet tablets will be higher in the former than in the latter.

In the tablet coating process, coating solutions when applied are dilute solutions of high polymers. As the polymer solution dries during the coating process, the concentration of the polymer increases from ~5% to nearly 100%. Consequently, the flow behavior of the polymer solution changes from Newtonian to non-Newtonian and finally to an elastic solid. The tacky behavior of these solutions during the coating process is a target for future investigation.

Stereochemical Studies of Demethylated Ketamine Enantiomers

SUK CHANG HONG and JOHN N. DAVISSON ˣ

Received July 13, 1981, from the *Division of Medicinal Chemistry and Pharmaceutics, College of Pharmacy and Health Sciences, Northeast Louisiana University, Monroe, LA 71209.* Accepted for publication November 3, 1981.

Abstract □ The enantiomorphs of norketamine, 2-(*o*-chlorophenyl)-2-aminocyclohexanone, were synthesized and screened for biological activity. Resolution was achieved by fractional crystallization of the tartrate salts. Stereochemical purity was determined using standard GC or GC–MS analysis. Preliminary pharmacological evaluations revealed that intraperitoneally injected dextrorotatory norketamine caused a greater duration of loss of righting reflex in mice than the levorotatory isomer.

Keyphrases □ Ketamine—stereochemical studies of demethylated ketamine enantiomers □ Enantiomers—stereochemical studies of demethylated ketamine enantiomers □ Stereochemistry—studies of demethylated ketamine enantiomers

Ketamine, 2-(*o*-chlorophenyl)-2-(methylamino)cyclohexanone (I), is rapidly and extensively metabolized (1, 2). The parent compound is demethylated to norketamine (II), which is believed to undergo further oxidation and conjugation reactions. Numerous investigations concerning the pharmacological properties and metabolism of ketamine have been conducted during the past several years (1–5). More recently, the pharmacological actions of the enantiomers of ketamine also have been evaluated (3, 6). Human studies have resulted in the suggestion that dextrorotatory ketamine hydrochloride may be more acceptable as an anesthetic agent when compared to the racemic or levorotatory drug (6). Additionally, levorotatory ketamine hydrochloride was shown to cause significantly higher incidences of unusual dreaming and posthypnotic phenomena than the dextrorotatory isomer. Norketamine resulting from the administration of levorotatory ketamine hydrochloride showed higher plasma levels than that derived from the dextrorotatory enantiomer, especially in the postanesthetic period. Animal experiments have revealed similar patterns of pharmacological activities for the ketamine enantiomers. Stereochemical differences in metabolism and the possibility of certain metabolites having prolonged biological half-lives have been offered as possible explanations for posthypnotic phenomena (3).

Pharmacological data have been reported for racemic norketamine, but no information is available for the purified enantiomers (5). As part of an investigation to determine stereochemical and pharmacological relationships between enantiomers of ketamine and those of metabolites, the synthesis, resolution, and preliminary pharmacological studies of enantiomerically purified norketamine have been completed and are described in this report.

EXPERIMENTAL

Instrumentation—Melting points are reported as corrected values[1]. UV[2] and IR[3] spectra were recorded with double-beam spectrometers. NMR[4] spectra were recorded on a 60-MHz apparatus with tetramethylsilane as an internal reference. Optical rotation was measured with an automatic polarimeter[5]. GLC[6] conditions were as follows: glass column, 1.8 m × 2-mm i.d. packed with 3% SP2300 or 3% SP2401 on 100/120 mesh Supelcoport; carrier gas was nitrogen at 30 ml/min; the injector, column, and detector temperatures were 250, 210, and 275°, respectively. GC–MS[7] conditions were as follows: glass column, 1.8 m × 2-mm i.d. packed with 3% SP2300 or 3% SP2401 on 100/120 mesh Supelcoport; carrier gas was helium at 30 ml/min; injector, column, and source temperatures were 270, 230, and 225°, respectively. Ionization was at 75 eV.

Synthesis of Norketamine (II)—1-Bromocyclopentyl(o-chlorophenyl)ketone (III), 50 g (0.18 mole) (7, 8) was placed in a 500-ml round bottom flask containing 300 ml of 28% ammonium hydroxide solution which had been saturated with anhydrous ammonia. The mixture was agitated vigorously for 7 days at room temperature using a mechanical shaker. The dark brown bottom layer was separated, dissolved in 500 ml of cyclohexane–petroleum ether (5:1) solution, and placed in a refrigerator. After 2 days, 24 g (60% yield) of a white solid (mp 90.5–91.5°) was obtained. The IR spectrum revealed strong combined NH—OH stretching at 3225 cm^{-1} and C=N absorption at 1645 cm^{-1} consistent with the iminoalcohol intermediate (7). Without further purification, an isopropyl alcohol solution (200 ml) of 20 g (0.09 mole) of this solid was refluxed for 5 days. Crude norketamine was obtained by evaporation of the solvent under reduced pressure. The residue was dissolved in absolute ether and saturated with dry hydrogen chloride gas. The solid was filtered and dissolved in 50 ml of distilled water. The solution was neutralized with 10% sodium carbonate–ammonium hydroxide solution (1:1) and extracted with methylene chloride (3 × 200 ml). Evaporation of the solvent left a tan oily product (16 g) whose spectral data were identical to those of an analytical reference sample of racemic norketamine[8].

Resolution of Norketamine—A 20-g solution (0.09 mole) of racemic norketamine in 50 ml of methanol was mixed with a methanol solution (200 ml) of (+)-tartaric acid (15.1 g, 0.1 mole). The mixture was stirred overnight at room temperature and filtered. The solvent was evaporated at reduced pressure. The resulting crude solid was washed with 400 ml of 2-butanone and then dissolved in 5.4 liters of refluxing acetone. Fine needle-like crystals (7.5 g) were collected after storing the solution for 2 days at room temperature. The filtrate was saved for later isolation of the other enantiomer.

The bitartrate salt was recrystallized three additional times from acetone resulting in 4.8 g of fine needle-like crystals (mp 181–182°). The free base was obtained with 0.5 *N* NaOH solution and converted into the hydrochloride or bisuccinate salt using standard procedures. The hydrochloride salt was recrystallized from ethanol yielding a fine white solid, mp 175–177°; $[\alpha]_D^{25}$ −96.4° (*C* = 1.0, water). The bisuccinate salt was recrystallized from acetone yielding white platelets, mp 139–140°; $[\alpha]_D^{25}$ −66.2° (*C* = 1.0, water).

Anal.—Calc. for $C_{16}H_{20}ClNO_7$: C, 51.41; H, 5.39; N, 3.75; Cl, 9.48 O, 29.97. Found: C, 51.41; H, 5.39; N, 3.72; Cl, 9.43 O, 30.05. The combined filtrates remaining from the above procedures were evaporated to dryness. The remaining solid was dissolved in water, neutralized with 0.5 *N* NaOH, and extracted with methylene chloride. Following evaporation

of the solvent, the residue was treated with (−)-tartaric acid in the same manner as described for (+)-tartaric acid. The resulting hydrochloride salt was recrystallized from ethanol yielding a fine white solid, mp 176–178°; $[\alpha]_D^{25}$ +95.0° (*C* = 1.0, *water*). The bisuccinate salt (mp 138–140°) was recrystallized from acetone; $[\alpha]_D^{25}$ +66.3° (*C* = 1.0, water).

Anal.—Calc. for $C_{16}H_{20}ClNO_7$: C, 51.41; H, 5.39; N, 3.75; Cl, 9.48 O, 29.97. Found: C, 51.43; H, 5.42; N, 3.73; Cl, 9.45 O, 30.05.

Determination of Stereochemical Purity—(+)-Norketamine bisuccinate, 2 mg (5.3 μmoles), was basified with 0.1 *N* NaOH and extracted with 3.0 ml of methylene chloride. The methylene chloride solution was separated and dried over anhydrous sodium sulfate. A 2-ml aliquot of this solution was mixed with 10 μl of a 0.5-*M* methylene chloride solution of (−)-α-methoxy-α-trifluoromethylphenylacetyl chloride (V) (9). The mixture was heated to 60° for 2 hr, cooled to room temperature and washed with 3 ml of 0.5 *N* HCl, 3 ml of 0.5 *N* NaOH, and 5 ml of distilled water. After drying over anhydrous sodium sulfate, the methylene chloride was evaporated under nitrogen, and the residue was dissolved in 25 μl of methanol. This solution (1–2 μl) was used for GLC and GC–MS analysis. (−)-Norketamine bisuccinate and racemic norketamine bisuccinate were derivatized in the same manner.

Animal Experiments—Male Swiss-Webster mice (25–32 g), provided with rodent laboratory chow[9] and water *ad libitum*, were housed in wire meshed cages (16 × 18 × 24 cm) suspended above indirect bedding. The temperature was maintained at 20–24° and the photoperiod was controlled to provide light from 6 am to 6 pm. Drugs were dissolved in distilled water and all injections were made intraperitoneally. Judgment of loss of righting reflex was made on an all-or-none basis after termination of drug injection. Mice that lost righting reflex were then placed on their backs in individual plastic cages and observed. Righting reflex was judged to be regained when an animal turned to a prone position

twice within a 10-sec period. All animal experiments were performed between 1 and 6 pm.

RESULTS AND DISCUSSION

The synthesis of norketamine was accomplished by utilizing an aminoketone synthesis introduced previously (7, 8) (Scheme I). The product was obtained directly from the thermal rearrangement of the intermediate Schiff base (IV) in a two-step sequence. This was accomplished in refluxing solvents ranging from methanol (bp 65°) to naphthalane[10] (bp 190°). Lower boiling alcohols produced greater yields with less decomposition than higher boiling solvents. In these studies refluxing IV in isopropyl alcohol resulted in an 80% yield of product after 5 days. Spectral data (IR, NMR) were consistent with the structure of norketamine, and the GLC retention time and mass spectrum were identical to those of an analytical reference sample.

Resolution of norketamine proved to be tedious. Formation of the diastereomeric bitartrate salts and subsequent recrystallization from acetone was found to be the most efficient method of resolution attempted. One major drawback was the large volumes of acetone needed to accomplish the purification.

Progress of the resolution was followed either by measuring optical activity or by GLC analysis. For the latter, diastereomers, formed by reacting the enantiomers with (−)-α-methoxy-α-trifluoromethylphen-

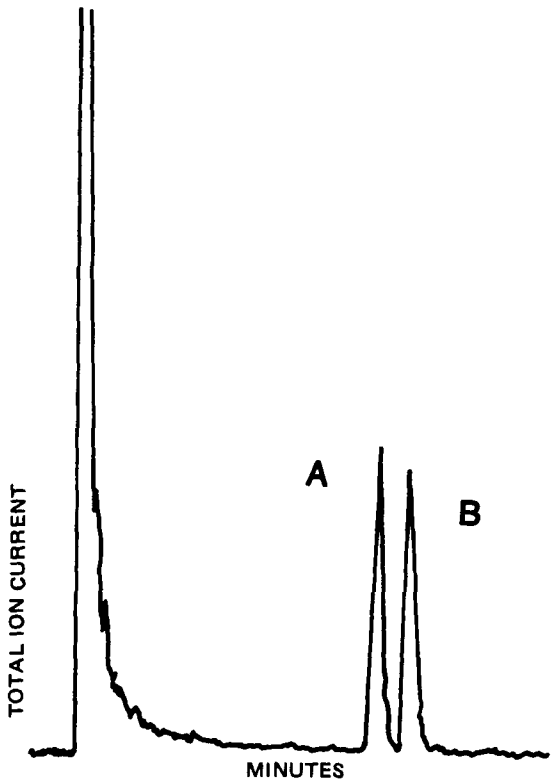

Figure 1—*Reconstructed gas chromatogram of the (−)-α-methoxy-α-trifluoromethylphenylacetamide analogs of (+)-norketamine (A) and (−)-norketamine (B).*

[10] Decalin.

ylacetyl chloride, were chromatographed over 3% SP2401 (9) (Scheme II). Using this system good separation of diastereomers was achieved (Fig. 1). Retention times of derivatized (+)-norketamine and (−)-norketamine were 13.5 and 14.9 min, respectively. These compounds failed to show a parent ion (m/z = 439) using electron impact mass spectroscopy, but when subjected to chemical ionization conditions, both displayed significant M + 1 ions. Fragmentation patterns also were consistent with the structures. When purified enantiomers were derivatized and subjected individually to GLC analysis, no contamination from the other stereoisomer could be detected, indicating that the resolution procedure had resulted in highly stereochemically pure norketamine.

The enantiomers were converted into either hydrochloride or bisuccinate salts. The former proved to be quite hygroscopic making the bisuccinate salts more convenient for subsequent studies. The signs of optical rotation were the same for both salts. The free bases were not highly purified to permit accurate measurements of their optical rotations, but using partially purified samples, it was determined that the signs of rotation for the free bases and the salts were the same. This observation is in contrast to reported optical rotations of ketamine (10). The free bases and hydrochloride salts for this compound show opposite signs of rotation.

Initial pharmacological evaluation revealed that intraperitoneally injected dextrorotatory norketamine bisuccinate caused a greater duration of loss of righting reflex in mice than the levorotatory isomer (Table I). At doses of 100 mg/kg (calculated on free base content) the levorotatory isomer failed to induce loss of righting reflex, whereas this same dose appeared to be near the ED_{50} value for the dextrorotatory form. At 200 mg/kg all animals lost righting reflex with the dextrorotatory compound, producing a significantly greater duration of loss (Table I). These preliminary studies also suggested that levorotatory norketamine bisuccinate may cause greater amounts of central excitation than the dextrorotatory form. This is based on the observation that animals receiving the levorotatory drug appeared to show greater amounts of spontaneous locomotor activity than those receiving the dextrorotatory isomer.

Similar actions as to loss of righting reflex and central excitation have been reported for the ketamine enantiomers (3). Also, it has been shown that racemic norketamine and ketamine are qualitatively similar with regard to central nervous system depressant effects and posthypnotic excitation (5). Because of the these findings, it is tempting to speculate that the levorotatory salts of ketamine and norketamine have identical stereochemical configurations; the same being true for the dextrorotatory forms. However, additional studies will be needed to establish the exact stereochemical relationships between these compounds as well as the pharmacological significance of the norketamine enantiomers.

Preparations of Solid Particulates of Theophylline–Ethylenediamine Complex by a Spray-Drying Technique

H. TAKENAKA *, Y. KAWASHIMA *ˣ, S. Y. LIN *, and Y. ANDO ‡

Received May 27, 1981, from the **Gifu College of Pharmacy, Mitahora, Gifu 502, Japan* and the ‡*Ichimaru Company, Matsuhora, Takatomi, Gifu 502-21, Japan.* Accepted for publication November 3, 1981.

Abstract □ Aqueous solutions of ethylenediamine and theophylline were spray dried to obtain solid particulates of theophylline–ethylenediamine complex to improve solubility of theophylline. Packing and flow properties of the spray-dried products were much improved when compared with those of original theophylline particles, due to their spherical shapes which were confirmed by a scanning electron microscope. The solubility of theophylline in the resultant products was found to be three to five times higher than that of original theophylline. The solubilities of the products decreased with increasing drying temperature and rotation speed of the atomizer, which was interpreted in terms of the contents of ethylenediamine in the products. The products were confirmed to be a mixture of aminophylline, α-aminophylline, and theophylline by X-ray analysis and NMR spectroscopy. The logarithm of the relative intensity of the X-ray diffraction peak of α-aminophylline to that of theophylline decreased linearly with drying temperature and rotation speed of the atomizer. Thermal decomposition of the spray-dried products involved liberations of crystal water at 100° and ethylenediamine between 110 and 127°. Liberation of ethylenediamine occurred *via* three steps for aminophylline, but with different steps for the spray-dried products.

Keyphrases □ Complexation—theophylline–ethylenediamine, preparations, spray-drying technique, solid particulates □ Theophylline—complexation with ethylenediamine, preparations, solid particulates, spray-drying technique □ Ethylenediamine—complexation with theophylline, preparations, solid particulates, spray-drying technique

The spray-drying technique has been accepted as a favorable method for drying a variety of heat-sensitive materials, such as foods, pharmaceuticals, enzymes, *etc.* The preparation of particulate solids from liquid droplets by chemical reaction during drying is one of the recent uses of this technique. Microcapsules of barbituric acid and phenobarbital with a tensioactive precondensate of the hexamethylolmelamine type, which form macromolecules under the influence of heat, have been prepared previously (1, 2). An ammonium sulfate sphere has been produced by the reaction of a single drop of phosphoric acid with gaseous ammonia (3).

The objective of the present study was to prepare solid particulates of the theophylline–ethylenediamine complex (*e.g.*, aminophylline) by a spray-drying technique. The manufacturing method of aminophylline referred to in the

0022-3549/82/0800-0914$01.00/0

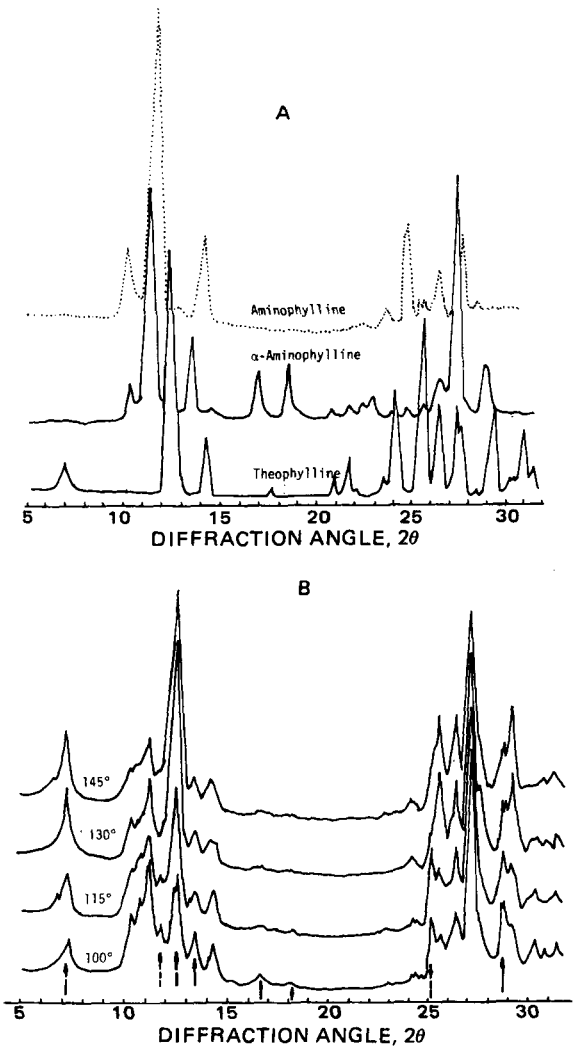

Figure 1—*(A) X-ray diffraction patterns of references; (B) the spray-dried products prepared at various spray-drying temperatures.*

Japanese Pharmacopeia (JP) involves a multistage process including reaction, filtration, drying, *etc.* In addition, the reaction takes several hours. The process of the present study offers the advantage of reducing the preparation steps, which can save time and cost. Another objective was to investigate the spray-drying conditions affecting the composition of the products. Thermal decomposition of spray-dried products by thermal analysis was also investigated.

EXPERIMENTAL

Materials—Theophylline[1] and ethylenediamine[1] used were chemical reagent grade. Aminophylline[1] (JP) and another theophylline–ethylenediamine complex, α-aminophylline, were used as a reference for identifying the spray-dried products. α-Aminophylline was produced by a method (JP) modified previously (4). Ethylenediamine purified by distillation (11.47 ml) was dissolved in 100 ml of absolute alcohol. Theophylline (30.82 g) was stirred into the resulting solutions. After agitation for several hours, the resultant precipitates were filtered and dried at 5–7° immediately after filtration without washing. The X-ray diffraction pattern of the products, *i.e.*, α-aminophylline, was different from that of aminophylline (JP) as shown in Fig. 1A. α-Aminophylline contained 13.9% ethylenediamine, 85.9% theophylline, and 0.2% water, which suggested the composition of α-aminophylline with 2 moles of theophylline, 1 mole of ethylenediamine, and small amounts of water.

115	10,000	14.2	1.48	1.37	40.4
115	20,000[e]	10.1	1.57	1.32	40.0
115	40,000	9.8	1.34	1.39	29.0

[a] Geometric mean diameter. [b] Geometric standard deviation. [c] Particle density, the particle density of aminophylline is 1.43. [d] The solubilities of theophylline and aminophylline (JP) in water are 8.74 and 49.4 mg/ml, respectively, at 30°. [e] The parameters (*a*,*b*) in Eq. 1 of spray-dried products, original theophylline, and spray-dried theophylline are (0.16, 0.064), (0.23, 0.062), and (0.31, 0.036), respectively.

Spray-Drying Technique—Theophylline (53.5 g) and ethylenediamine (23.0 ml) were dissolved in 500 ml of water. The solutions were atomized in a drying chamber by a centrifugal wheel atomizer at rotations of 10,000, 20,000, or 40,000 rpm. The drying chamber was maintained at 100, 115, 130, or 145 ± 5°. The dried products were collected by a cyclone. As a reference, 500 ml of aqueous suspensions containing 53.5 g of theophylline was spray dried at 115° with an atomizer rotation speed of 20,000 rpm.

Measurement of Micromeritic Properties—The sizes of the spray-dried products were measured by a photographic counting method using a particle size analyzer[2]. The packing properties of the products were investigated by a tapping method. The true densities of the products were measured with a helium–air comparison pycnometer[3]. The surface topographs of the products coated with gold were investigated by a scanning electron microscope[4]. The solubilities of the products were measured in water at 30°.

Measurement of Physicochemical Properties—The contents of ethylenediamine and theophylline in the products were measured by a neutralization titration method with 0.1 *N* HCl and spectrophotometrically at 270 nm, respectively. Water contents were measured by the Karl Fischer method[5]. To analyze the crystalline form of the products, X-ray diffraction patterns were obtained by an X-ray diffractometer[6]. Thermal decomposition of the products was examined using a differential scanning calorimeter[7] with heating rate at 10°/min. Thermal analysis of the products treated with heating at 110 or 120° for 30 min was also carried out in a muffle to investigate the process of the thermal decomposition. NMR spectra of ethylenediamine, aminophylline, α-aminophylline, theophylline, and the spray-dried products were obtained in dimethyl sulfoxide using an NMR spectrometer[8].

RESULTS AND DISCUSSION

Micromeritic Properties of Spray-Dried Products—Size distribution of the spray-dried products was described in log-normal form. The geometric mean diameters of the products varied from 9.8 to 14.2 μm, and were independent of the drying temperature, but dependent on the rotation speed of the atomizer. The sizes of products decreased with an increase of the rotation speed, since the diameters of the spray droplets were reduced by enhancing the rotation speed. The geometric standard deviations of diameters of the products were 1.31–1.57 (Table I).

The scanning electron photographs of the original and the spray-dried theophylline and spray-dried products with ethylenediamine are exhibited in Fig. 2. The surface of the spray-dried theophylline was rough compared with that of the original crystal. A number of small spherical-sized products, which adhered to the crystals, yielded from the atomized solution of theophylline, are shown in Fig. 2B. Spray-dried products prepared from the formulation containing ethylenediamine yielded spheres covered with thin flake crusts, as shown in Figs. 2C and D. Loose internal texture of the products could be predicted from the characteristic surface topography. This was confirmed by the lower particle densities of the spray-dried products than original theophylline and aminophylline (JP) as tabulated in Table I.

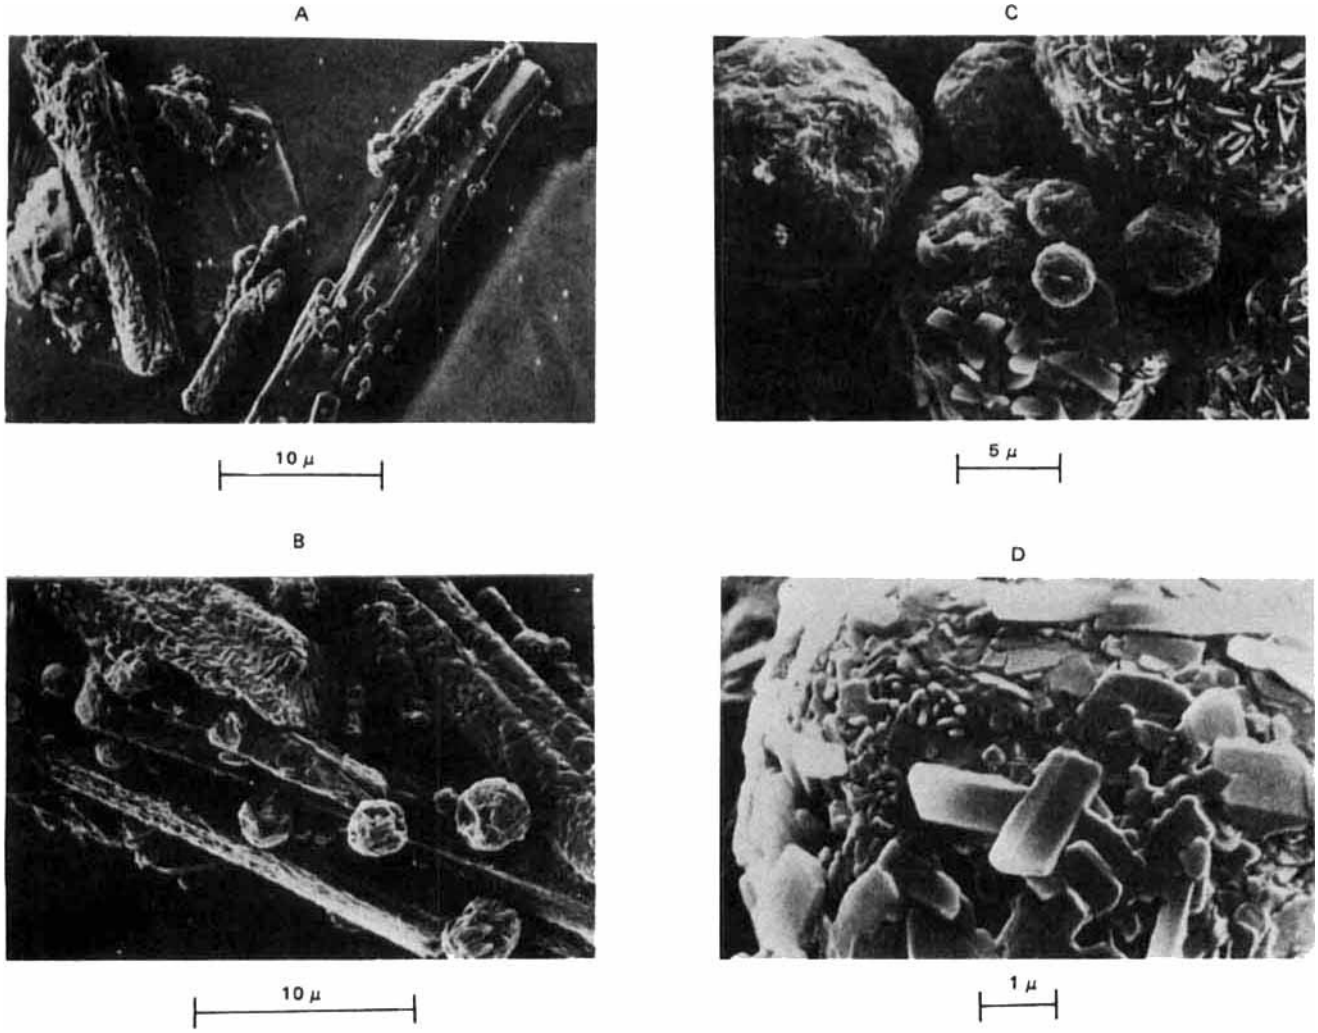

Figure 2—*Scanning electron microscopic photographs of spray-dried products. Key: (A) original theophylline; (B) spray-dried theophylline; (C) and (D) spray-dried products prepared at 115°, 20,000 rpm with the formulation containing ethylenediamine (20 ml) and theophylline (53.5 g).*

Packing and flow properties of the spray-dried products were much improved compared with those of original theophylline particles due to their spherical shapes. The packing process by tapping was described by the Kawakita equations (5, 6):

$$n/C = 1/ab + n/a \quad \text{(Eq. 1)}$$

$$C = (V_0 - V_n)/V_0 \quad \text{(Eq. 2)}$$

where a and b are constants representing the proportion of consolidation at the closest packing attained and packing velocity index, respectively, n is the number of taps, V_0 is the volume of powder in a measuring cylinder at the loosest packing, and V_n is the volume after the nth tapping. Parameter a in Eq. 1 for the spray-dried products was found to be smaller than that of original theophylline (Table I), which indicated that packing properties of the spray-dried products were improved.

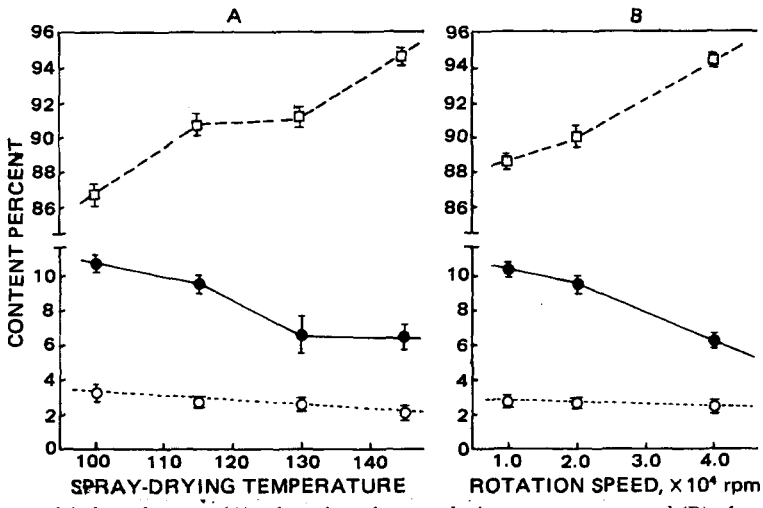

Figure 3—*Composition of the spray-dried products as (A) a function of spray-drying temperature and (B) of rotation speed of the atomizer. Key: (□) theophylline; (●) ethylenediamine; and (○) water.*

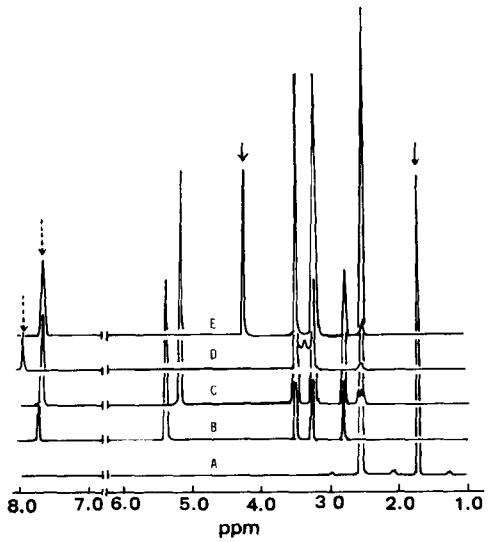

Figure 4—*NMR spectra of (A) ethylenediamine, (B) aminophylline, (C) α-aminophylline, (D) theophylline, and (E) the spray-dried products prepared at 115°, 20,000 rpm with the formulation containing ethylenediamine (20 ml) and theophylline (53.5 g). Key: (→) amino group protons of ethylenediamine; (- - -→) proton at position 8 of theophylline.*

The solubility of the spray-dried products with ethylenediamine was found to be three to five times higher than that of original theophylline, but lower than that of aminophylline (JP). However, no improvement in the solubility of the spray-dried theophylline without ethylenediamine was found. The solubilities of the products with ethylenediamine decreased with increase of both the drying temperature and the rotation speed of the atomizer. This finding could be interpreted in terms of the contents of ethylenediamine in the products, which decreased with an increase in the drying temperature and the rotation speed of the atomizer.

Physicochemical Properties of the Spray-Dried Products—The contents of theophylline in the products increased with increasing temperature of the drying chamber, whereas ethylenediamine contained in the products decreased with the temperature, as shown in Fig. 3. The ethylenediamine content in the products dropped sharply by raising the drying temperature higher than the boiling point of ethylenediamine (117°) but >6% ethylenediamine still remained. This finding suggested that ethylenediamine contained in the products did not exist as a free form adsorbed on the surface of the products but as a chemically bonded form, which resulted in preventing evaporation of ethylenediamine. This speculation was proven by NMR spectra of the spray-dried products in Fig. 4, which almost coincided with those of aminophylline and α-aminophylline. The signal of amino group protons of ethylenediamine in the product shifted to lower field (chemical shift, δ = 4.3 ppm) compared with that of ethylenediamine (δ = 1.7 ppm), which might be due to intermolecular hydrogen bondings. The hydrogen bondings might be attained by the interaction between the hydrogens of NH_3^+ of ethylenediamine formed by a proton migration from =NH of theophylline, and C=O at position 6 and $=N^-$ of theophylline (4, 7). The signal of the proton at position 8 of aminophylline and the spray-dried products shifted to a higher field compared with that of theophylline, as shown in Fig. 4, which support the migration of a proton from =NH of theophylline to NH_2 of ethylenediamine. Water content of the products decreased gradually with increased temperature.

Theophylline contents in the products increased with increased rotation speed of the atomizer, while the contents of ethylenediamine and water decreased with rotation speed (Fig. 3). An increase in the rotation speed of the atomizer reduced the diameters of resultant spray droplets by which evaporation speed was accelerated (Table I); therefore, this action was equivalent to raising drying temperature.

The X-ray diffraction patterns of the products prepared at various drying temperatures are exhibited in Fig. 1B. In the pattern of the spray-dried products, the characteristic peaks of theophylline appeared at 7.2 and 12.5°, of aminophylline at 11.8 and 25.2°, and of α-aminophylline at 11.2, 13.5, 16.7, 18.1, and 28.8°. These were confirmed by the references in Fig. 1A. The described X-ray diffraction analysis suggested that the spray-dried products were a mixture of these three compounds. The X-ray diffraction pattern varied with the drying temperature. The

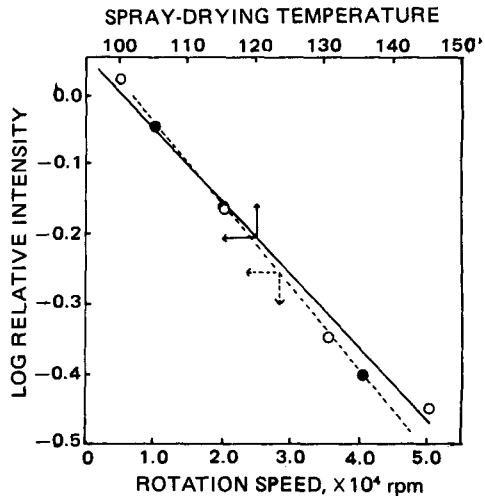

Figure 5—*Relative intensities of X-ray diffraction peak of α-aminophylline to theophylline as a function of spray-drying temperature (○) and of rotation speed of the atomizer (●).*

intensities of characteristic diffraction peaks of aminophylline at 25.2° and of α-aminophylline at 11.2, 16.7, and 18.1° decreased with the increasing drying temperature, whereas those of theophylline at 7.2, 12.5, and 29.3° increased strongly (Figs. 1A and B).

This relation can be described quantitatively in Fig. 5. The relative intensities (*RI*) of α-aminophylline to theophylline defined by Eq. 3 are plotted against drying temperature on a semilogarithmic graph:

$$RI = \frac{I(11.2°) - I(20.0°)}{I(12.5°) - I(20.0°)} \qquad \text{(Eq. 3)}$$

where I(11.2°) and I(12.5°) are the relative intensities of diffraction peaks of α-aminophylline and theophylline to that of sodium chloride at 31.7° used as an internal standard material, respectively, and I(20.0°) is the relative intensity of the base line to that of sodium chloride. The logarithm of the relative intensity correlated improportionately to the drying temperature. A similar correlation was found between the rotation speed of the atomizer and the logarithm of the relative intensity (Fig. 5).

Thermal Decomposition of the Spray-Dried Products—Differential scanning calorimetry and thermogravimetric thermograms of the references of aminophylline, α-aminophylline, and theophylline are exhibited in Fig. 6A by solid and dotted lines, respectively. On the differential scanning calorimetric curve of aminophylline, endothermic peaks at 100–103, 110, 120, 127, and 271° appeared. The endothermic peak at 100° was caused by releasing water, where the weight loss (4%) detected by thermogravimetric analysis corresponded to 1 mole of water. The endothermic peaks which appeared in the 110–127° range might have been caused by liberation of ethylenediamine, since the thermogravimetric curve revealed the weight loss corresponding to 1 mole of ethylenediamine. These findings indicate that ethylenediamine of aminophylline may be liberated by heating *via* three stages. The endothermic peak at 271° corresponds to the melting point of theophylline. The differential scanning calorimetric thermogram of α-aminophylline revealed two endothermic peaks at 116 and 271°. No endothermic peak at 100° caused by releasing water appeared on the thermogram, which was predicted by the Karl Fischer analysis described in the experimental section. The decomposition of α-aminophylline was completed up to 125°, at which point the weight loss reached 12%, equivalent to ~1 mole of ethylenediamine.

The differential scanning calorimetric thermograms of the spray-dried products are displayed as a function of drying temperature and of rotation speed of atomizer in Figs. 6B and C, respectively. On the differential scanning calorimetric curve of the product prepared at the relatively low drying temperature (*e.g.*, 100°), endothermic peaks appeared at 100, 116, and 271°. Liberation of ethylenediamine from the product was assumed to occur at 116°, because the endothermic peaks at 100 and 271° correspond to the releasing point of water and the melting point of theophylline, respectively. When the drying temperature was increased, the endothermic peak at 116° became weak, while another peak appeared at 127°, as seen on the thermogram of the products prepared at 115°. This finding indicates that the bond strength of ethylenediamine with theophylline in the products was affected by the drying temperature employed for spray drying. The latter peak became intense, whereas the former

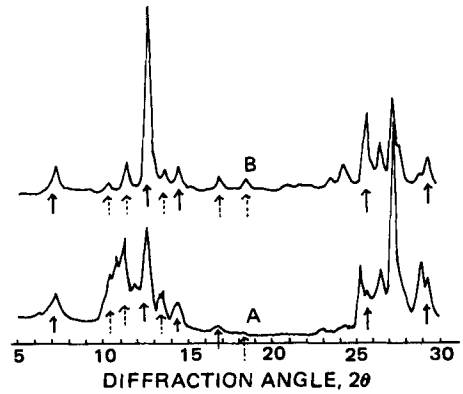

Figure 8—*Changes in X-ray diffraction patterns of the spray-dried products caused by heat-treatment. Key: (A) spray-dried products prepared at 115°, 10,000 rpm; (B) products treated at 110°, 30 min; (→) theophylline; (- - -→) α-aminophylline.*

peak disappeared when the drying temperature was >130°. The weight loss indicated by thermogravimetric curves in Fig. 6B corresponded approximately to the contents of water and ethylenediamine contained in the products as indicated in Fig. 3. The weight loss detected by thermogravimetric analysis decreased with an increase in the drying temperature as shown in Fig. 6B, as predicted from the findings in Fig. 3.

The changes in differential scanning calorimetry and thermogravimetric thermograms, with the rotation speed of the atomizer, are displayed in Fig. 6C. The thermal behaviors of the product prepared with high (low) rotational speed of the atomizer resembled those of the products prepared at high (low) drying temperature. As expected, the weight loss which appeared on the thermogravimetric curve decreased with increasing rotation speed of the atomizer.

Differential scanning calorimetric and thermogravimetric thermograms of the products treated with heating were compared with those of the products prior to the treatment in Fig. 7. After treatment by heating, the endothermic peak at 100° for water releasing disappeared from the thermogram. No weight loss on the thermogravimetric curve at 100° also indicated that the products treated by heating contained no crystalline water. However, an endothermic peak at 127° of the products prepared by spray drying at high temperature or with high rotation speed of the atomizer still remained even after heat treatment at 120°. The products prepared at low drying temperature or at low atomizing speed revealed an endothermic peak at 120° on the thermograph after heat treatment at 110°. The weight loss detected at 127 or 120° by thermogravimetric analysis suggested that some ethylenediamine still remained in the products even after heat treatment.

The X-ray diffraction pattern of the products treated with heating revealed characteristic peaks of theophylline and α-aminophylline at 7.2, 12.5, 14.2, 25.7, 29.3° and 10.2, 11.2, 13.5, 16.7, 18.1°, respectively. The peaks for theophylline strengthened, but no diffraction peaks for aminophylline appeared on the pattern in Fig. 8. These findings proved that the endothermic peak at 116 or 127°, that appeared on the thermogram of the spray-dried products, was caused by the liberation of ethylenediamine contained in a theophylline–ethylenediamine complex.

Bioavailability of Regular and Controlled-Release Chlorpheniramine Products

J. A. KOTZAN *, J. J. VALLNER *x, J. T. STEWART *, W. J. BROWN *, C. T. VISWANATHAN ‡, T. E. NEEDHAM §, S. V. DIGHE ‡, and R. MALINOWSKI ‡

Received May 8, 1979, from the **Biological Availability Group Studies Laboratory, School of Pharmacy, University of Georgia, Athens, GA 30602*, the ‡*Food and Drug Administration, Rockville, MD*, and the §*Baxter Travenol Laboratories, Morton Grove, Ill.* Accepted for publication November 3, 1981.

Abstract □ The bioavailability of chlorpheniramine regular-release *versus* controlled-release products was compared using 15 human subjects. The dosage forms evaluated were an 8-mg barrier coated-bead capsule, an 8-mg repeat action tablet, two 4-mg tablets, and 4- and 8-mg syrups. Single doses of each product were administered orally in a 5-way crossover study, plasma samples were collected at specific time intervals, and chlorpheniramine levels assayed by HPLC. Pharmacokinetic analysis was based on a two-compartment open model. The average plasma elimination half-life of chlorpheniramine was calculated to be ~18.3 hr. The controlled-release products gave a higher C_{max} than the 4-mg syrup, but <two 4-mg tablets. The controlled-release products also extended the time necessary to attain peak drug levels compared to the 4- and 8-mg syrups. The area under the curve (*AUC*) data for the controlled-release products was not equivalent to equal amounts of the regular-release products. The study indicated that while the controlled-release chlorpheniramine products were successful in prolonging the time course of absorption, this was at the expense of incomplete bioavailability of the drug.

Keyphrases □ Chlorpheniramine—bioavailability of regular and controlled-release products □ Bioavailability—regular and controlled-release chlorpheniramine products □ Controlled-release products—bioavailability of chlorpheniramine

Chlorpheniramine maleate is commonly used in the treatment of various allergic conditions. The different dosage forms of chlorpheniramine maleate marketed include regular- (or immediate) release and controlled- (or sustained) release products.

Keyphrases □ Chlorpheniramine—bioavailability of regular and controlled-release products □ Bioavailability—regular and controlled-release chlorpheniramine products □ Controlled-release products—bioavailability of chlorpheniramine

Chlorpheniramine maleate is commonly used in the treatment of various allergic conditions. The different dosage forms of chlorpheniramine maleate marketed include regular- (or immediate) release and controlled- (or sustained) release products.

Little comparative information is currently available

0022-3549/82/0800-0919$01.00/0

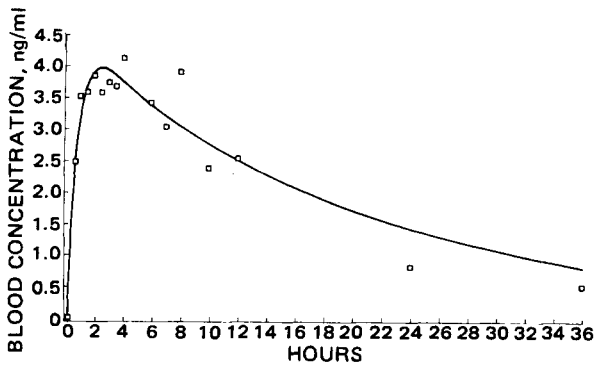

Figure 1—*A comparison of computer predicted (—)* versus *observed (□) chlorpheniramine plasma concentrations* versus *time following administration of the 4-mg syrup.*

concerning the bioavailability of regular-release *versus* controlled-release products or on comparisons among the various controlled-release products themselves. It is generally assumed that the controlled-release products prepared by different methods are bioequivalent. Chlorpheniramine maleate is commercially available as a coated slow-release bead, a repeat-action tablet, a single-dose tablet, and a syrup. *In vivo* comparison of these different dosage forms as well as differently designed products is not currently available.

The present study compares two different controlled-release products of chlorpheniramine maleate to equivalent doses of immediate-release tablets and an equivalent dose and single dose of the drug in solution. In addition, the study provides information regarding the bioequivalency of two sustained-release products formulated by different methods.

EXPERIMENTAL

Subjects—Fifteen healthy male volunteers [18–27 years old (mean 21), 66–80 kg (mean 74), and within ±10% of ideal weight for their height and age (1)] were selected for the study. All subjects were shown by medical examination to be in good physical condition with normal blood and urine chemistry. Informed consent was obtained from all subjects. Each volunteer was instructed to refrain from taking any medication for 1 week prior to and during the study.

The subjects fasted for 8 hr prior to the drug administration. Each subject received 200 ml of water at the time of dosing and at ~1.5 hr postdose. The same low-fat meal was provided for all subjects 3 hr after administration of the dose. A second meal was given to all subjects ~10 hr after initial drug administration. Throughout the study the subjects were ambulatory and proceeded with their normal daily routine. The dose was administered and blood samples (5 ml) were collected immediately before dosing and at 0.3, 0.7, 1, 1.5, 2, 2.5, 3, 3.5, 4, 6, 7, 8, 10, 12, 24, 36, 48, 72, 96, and 144 hr. Samples were drawn from a forearm vein into heparinized vacuum tubes using indwelling needles from 0 to 4 hr and by venipuncture thereafter. The plasma was separated and frozen until assayed.

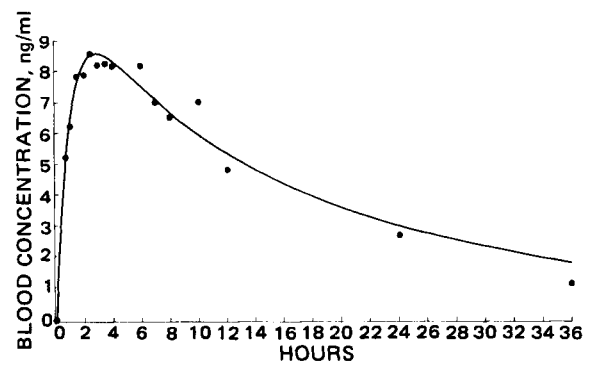

Figure 2—*A comparison of computer predicted (—)* versus *observed (●) chlorpheniramine plasma concentrations* versus *time following administration of the 8-mg syrup.*

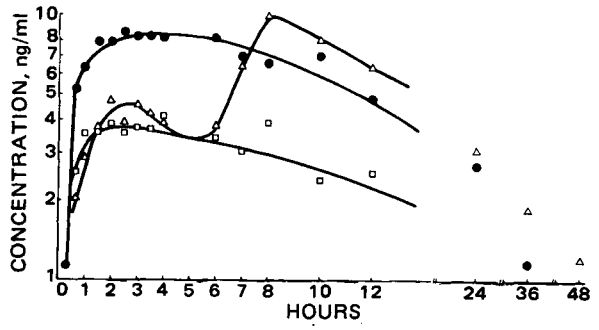

Figure 3—*A comparison of mean plasma concentration–time profiles for the 4- and 8-mg syrups of chlorpheniramine to the 4-mg tablet, administered at 0 and 6 hr. Key: 4-mg syrup (□), 8-mg syrup (●), 4-mg tablet (△).*

Study Design—The drugs as listed in the table below were administered using a five-way crossover design with all subjects receiving each dose.

	Strength	Dose
Drug 1[1]	4 mg	4 mg (0, 6 hr)
Drug 2[2]	8 mg	8 mg
Drug 3[3]	2 mg/5 ml	4 mg
Drug 4[4]	8 mg	8 mg
Drug 5[3]	2 mg/5 ml	8 mg

The subjects were formed into five groups of three subjects each, such that the total body weights of the five groups were essentially the same. The following scheme was used with 2 weeks between each study period:

	Study Period				
	1	2	3	4	5
Group A (Subjects 1–3)	Drug 1	Drug 2	Drug 3	Drug 4	Drug 5
Group B (Subjects 4–6)	Drug 2	Drug 5	Drug 4	Drug 3	Drug 1
Group C (Subjects 7–9)	Drug 3	Drug 1	Drug 5	Drug 2	Drug 4
Group D (Subjects 10–12)	Drug 4	Drug 3	Drug 1	Drug 5	Drug 2
Group E (Subjects 13–15)	Drug 5	Drug 4	Drug 2	Drug 1	Drug 3

Analysis—The HPLC analyses were performed on a liquid chromatograph[5]. The column contained a packing material consisting of an octadecylsilane material bonded to a microparticulate silica gel[6] (<10 μm) for reversed-phase chromatography. The mobile phase consisted of 1:4 acetonitrile–0.075 *M* monobasic ammonium phosphate whose pH was adjusted to 2.6 with concentrated phosphoric acid. The flow rate was set at 1.0 ml/min, the peaks were monitored at 254 nm, and the recorder sensitivity was set at 0.005 aufs.

Stock solutions of chlorpheniramine base (1.5 μg/ml) and brompheniramine base (2.5 μg/ml) were prepared by dissolving equivalent amounts of chlorpheniramine maleate and brompheniramine maleate in distilled water.

Plasma chlorpheniramine levels were determined by a modification of the HPLC procedure reported previously (2). To 1.5 ml of plasma in a 15-ml centrifuge tube were added 75 μl of brompheniramine (internal standard) and 1 ml of 5% aqueous potassium hydroxide. Ether (3 ml) was then added followed by shaking (15 min) and centrifugation (3000 rpm, 15 min). The aqueous layer was then frozen with the aid of a dry ice–acetone bath and the ether decanted into a clean 15-ml centrifuge tube. To this was added 0.1 ml of 0.5% phosphoric acid, the mixture shaken for 10 min, centrifuged, and refrozen. The ether layer was discarded, and the remaining aqueous portion was placed under a nitrogen stream for 5 min

[a] Mean of 15 values ± *SD*. [b] Fraction of the dose absorbed expressed as concentration in its distribution volume in the body calculated from $FD/V_c\beta = AUC_{0\to\infty}$. [c] Administered twice as single 4-mg doses at 0- and 6- hr intervals. [d] Obtained by trapezoidal rule technique. The last measured plasma concentration was divided by the least squares slope value for the β phase, indicating log–trapezoidal extrapolation to zero concentration (*i.e.*, $AUC_{0\to\infty}$).

to rid of residual ether. A 60- to 80-μl portion of the aqueous phase was then injected into the liquid chromatograph.

Calibration curves were constructed by adding 3.5-, 5.0-, 10-, and 20-μl quantities of the chlorpheniramine stock solution into individual 15-ml centrifuge tubes containing 1.5 ml of blank human plasma to give the equivalent of 3.5, 5.0, 10.0, and 20.0 ng of chlorpheniramine/ml. To each tube was then added 75 μl of brompheniramine stock solution (internal standard) and each tube assayed according to the procedure described above.

Ratios of chlorpheniramine peak heights to those of the internal standard (*D/IS*) were calculated for each chromatogram. Regression analysis of these data at the various concentrations of chlorpheniramine gave typical results: slope, 0.0403; intercept, 0.0212; and correlation coefficient, 0.9967 (n = 16). The standard error of estimate of $Y(D/IS)$ on X (chlorpheniramine concentration) was ±0.0122. The minimum detectable quantity of chlorpheniramine that can be measured using the procedure is 1 ng/ml (S/N = 2). The slope and intercept data from regression analysis for chlorpheniramine were then used to solve for drug concentration in the human plasma samples: D/IS = (slope X concentration) + intercept.

Interassay reproducibility of chlorpheniramine determined by the assay of spiked plasma samples containing 3.5, 5.0, 10.0, and 20.0 ng/ml gave percent relative standard deviations (*RSD*) of 9.7, 7.9, 5.4, and 5.0%, respectively (n = 10). Interassay reproducibility of the drug at the 2.5-ng/ml level was 15% (n = 10). Linearity of the calibration curve <2.5 ng/ml was assumed using the linear regression calculation for the standard curve data. Interassay accuracy data at the 3.5-, 5.0-, 10.0-, and 20.0-ng/ml levels gave the following typical results (n = 3): 6.6, 4.4, 0.7, and 0.15%, respectively.

Pharmacokinetic Analysis—Individual curves following administration of syrup dosage forms, that is, immediately available drug not having to undergo disintegration or dissolution, were graphed and the data analyzed *via* NLIN[7] or SAS[8]. Both one- and two-compartment open models with first-order absorption and elimination were examined. Although both models are indistinguishable if one only looks at the residual sum of squares of the model fit, the two-compartment model gives better results (Figs. 1 and 2).

All pharmacokinetic parameters reported here are the results of using the above computer program and the two-compartment model. For a particular dosage form, plasma half-lives for each subject were calculated from least-square fits of the terminal slope of the log plasma chlorpheniramine concentration *versus* time curve. The individual subject half-life data was then used to calculate the mean plasma half-life for the particular dosage form. The *AUC* data were calculated by computer using the trapezoidal rule technique. The last measured plasma concentration

was divided by the least-squares slope value for the β-phase, indicating log-trapezoidal extrapolation to zero concentration (*i.e.*, $AUC_{0\to\infty}$). Other bioavailability parameters were calculated following the usual methods (4).

RESULTS AND DISCUSSION

In examining controlled-release dosage forms, consideration of drug plasma levels is integral to ensuring that such dosage forms adhere to the release characteristics claimed. The barrier-coated bead product (Drug 4) is designed such that, "a therapeutic dose of antihistamine is released promptly and the remaining medication, released gradually, sustains the effect for a prolonged period" (5). The chlorpheniramine repeat action tablet (Drug 2) contains 8 mg of drug such that the "dosage is divided equally between an outer layer for rapid absorption and an inner core protected by special timed barrier for release 3–6 hr after ingestion" (6). In this study, three additional doses were administered: the 4- and 8-mg syrups to provide a comparison of plasma levels (if these quantities of drug were immediately released from an oral dose) and 4-mg tablet given at 0 and 6 hr to provide comparative repeat action plasma concentrations of two single doses.

The equation for an open two-compartment model with first-order absorption is (7):

$$C = Le^{-\alpha t} + Me^{-\beta t} + Ne^{-k_a t} \qquad \text{(Eq. 1)}$$

Using this equation, parameters fitting the model were derived for 4- and 8-mg syrups:

4-mg Syrup: $C = 2.8e^{-0.61t} + 4.4e^{-0.047t} - 7.2e^{-1.03t}$ residual sums of square = 1.87;

8-mg Syrup: $C = 4.0e^{-0.13t} + 7.3e^{-0.040t} - 11.3e^{-0.98t}$ residual sums of square = 2.66.

Only the data from the 4- and 8-mg syrups have been applied to the model since the other dosage forms or administrations were of a controlled form and, thus, not theoretically able to be fit to such a model. It should be noted that the one-compartment model was also examined. The criteria for choosing the two-compartment model to describe the data include lower sum of square, more valid plasma elimination half-life [considering recent literature information of 20–30 hr (8–11)], and curvature of the blood level–time curve data after C_{max}.

Figures 1 and 2 show plots of mean plasma chlorpheniramine levels *versus* time following oral administration of 4- and 8-mg syrups, respectively. The smooth curve in each figure is a computer prediction using the mathematical models derived for the respective syrups. Both figures show that a reasonable prediction of the data results when using the two-compartment model.

Table I shows the average plasma chlorpheniramine levels and standard deviation for each of the five different doses (dosage forms) as a function of time. Due to drug already in solution, the plasma levels for the two syrup treatments were detectable at 0.7 hr. The remaining dosage forms could only be detected 1 hr after administration. None of the five different doses were analytically detectable at 0.3 hr or >36 hr in plasma.

Figure 3 illustrates a plasma level–time profile for the 4- and 8-mg syrups and the 4-mg tablet (administered at 0 and 6 hr). The similarity of the blood levels of drug for the two 4-mg doses can be seen up to the 7-hr sample when the second 4-mg tablet, administered at 6 hr, began to show an increased chlorpheniramine concentration.

Plasma level profiles for the 8-mg syrup, Drug 4, and Drug 2 are shown in Fig. 4. It can be seen that Drug 4 and Drug 2 produce plasma levels which are essentially equivalent, while the peak level of the 8-mg syrup is definitely higher than the other two dosage forms. The similarity in plasma level profiles of Drug 2 and the two single administered 4-mg tablets is illustrated in Fig. 5.

The mean pharmacokinetic parameters for the various dosage forms of chlorpheniramine are shown in Table II. The average plasma elimination half-life ranges from 14.6 hr for the 4-mg syrup to 21.2 hr for Drug 4. An ANOVA of the $t_{1/2}$ of the five dosage forms of drug in each of the 15 subjects produced a calculated F value of 4.48 which, when compared to the $F_{0.99}$ (4, 56) of 3.65, indicates a significant difference in the half-life. The plasma elimination $t_{1/2}$ of the 4-mg syrup was significantly lower than Drug 4 and two 4-mg dosage forms as measured by the Duncan's Multiple Range Test (12). It is believed that the difference is attributable to the intersubject variability and the relatively low terminal phase levels of the 4-mg syrup which approached the limits of the assay sensitivity. The ~18.3-hr average half-life for all dosage forms studied is longer than that found previously (2), but is comparable to the reported 20–30 hr data (8–11).

The mean fraction of dose absorbed expressed as concentration in the distribution volume of the body (FD/V_c) ranged from 3.1 ng/ml after the 4-mg syrup to 6.3 ng/ml following the 8-mg syrup (Table II). As can be seen in Table III, three different categories of degrees of absorption are present with respect to the 8-mg syrup as the reference standard. The two 4-mg tablets are grouped with the 8-mg syrup, while the repeat action tablets and the two 4-mg tablets are members of both the reference standard and the second group. The coated slow-release beads and the 4-mg syrup dosage forms formed the last groups demonstrating significantly less absorption than the reference 8-mg syrup dosage form.

The peak concentration (C_{max}) of chlorpheniramine varied widely among the five different doses. However, the level of peak concentration increased as expected in the order of the 4-mg syrup, Drug 4, Drug 2, tablets, and 8-mg syrup. The calculated F value of 8.70, when compared to the $F_{0.99}$ (4, 56) of 3.65, showed that there is a significant difference between the highest plasma concentrations reached for each dose. In Table III, a Duncan's Multiple Range Test of these data indicates that the peak concentration produced by the 8-mg syrup is different from those peak concentrations found for Drug 4 and the 4-mg syrup in all 15 subjects. This shows that the controlled-release Drug 4 dosage form was apparently not releasing a large quantity of its dose immediately.

An ANOVA of the time to peak concentration produced a calculated F of 9.22, which is significantly different when compared to $F_{.99}$ (4, 56) of 3.65. Tables II and III show that the average t_{pk} of the 4- and 8-mg syrups are statistically similar. The t_{pk} of Drug 4 (6.1 hr) is not significantly different from Drug 2 (7.6 hr), even though the release mechanisms are not the same. Dissolution studies of these two dosage forms, currently underway in these laboratories, should provide additional drug release information.

An examination of the plasma half-life multiple range data reveals that Drug 2 and the 8-mg syrup displayed half-lives which could be considered in either the high or low groups (Table III). However, Drug 4 clearly had a statistically longer plasma half-life when compared to that of the 4- and 8-mg syrups. Of the four pharmacokinetic parameters evaluated, the plasma half-life measures displayed the lowest F value among the five dosage forms. It follows that the plasma half-life was the single parameter which displayed overlap between the dosage form groups. Thus, the sustained-release dosage forms have the least impact on the plasma half-lives of the chlorpheniramine blood levels when compared to their impact on peak time, peak height, and AUC.

There is a strong relationship between the type of chlorpheniramine dosage form and the AUC data from 0 hr to infinity. The AUC parameter

was the only pharmacokinetic measure which was separated into three distinct subgroups without any overlap. As expected, the 4-mg syrup delivered the least amount of drug over the duration of the blood sampling. This is because the amount of actual drug present is one-half the amount in all other administrations, and with the small dose administered, the blood levels of drug at early and late sampling times could not be determined by the analytical method. The *AUC* computed for a 4-mg tablet (by using the data from 0 to 6 hr and extrapolating to infinity) compared well with recent published data (11). The sustained dosage forms of Drugs 4 and 2 were not able to deliver the quantity of drug delivered by two of the 4-mg tablets or the single dose of 8-mg syrup. The sustained dosage forms comprised the intermediate Group B (Table III).

Table IV presents individual *AUC* data along with ratios of the individual *AUC* data per 8-mg syrup *AUC*. The mean *AUC* ratios for each dose and dosage form were approximately that of the predicted values. On an individual basis, however, the results show considerable deviation from the mean. Using these data, only a few individuals would pass the 75/75 test (13) because of the large intra- and intersubject variation.

Are the controlled-release dosage forms of chlorpheniramine successful? The most successful controlled-release dosage form should increase to the same peak concentration and at the same rate, when compared to the immediate release (noncontrolled) drug product. The dosage form should also increase the time the drug remains at the peak concentration and, in addition, have about twice the area under the blood level–time curve (assuming that the controlled-release dosage form contains twice the amount of drug contained in a normal, single oral dose). With these criteria, examination of Figs. 3–5 and Tables I–III would indicate that neither the coated slow-release bead product nor the tablet within a tablet product meet all of these conditions. Both of the controlled-release dosage forms give a higher peak concentration than the single 4-mg syrup, but both provided less drug concentration at the C_{max} than two 4-mg tablets. As expected, the time the peak levels occurred was extended over the immediately available syrups and was about the same time as the two 4-mg tablets. The *AUC* of the controlled-release formulations was not equivalent to the same amounts of noncontrolled release products, nor were they equal to two times the *AUC* of the 4-mg syrup (realizing the difficulties involved in obtaining an exact *AUC* for this small dose). Neither the coated bead nor tablet within a tablet was completely successful; however, more valid conclusions can be made following data reduction of a recently completed multiple-dose study of these same dosage forms.

Quantification of the Effect of Excipients on Bioavailability by Means of Response Surfaces I: Amoxicillin in Fat Matrix

MATÍAS LLABRÉS, JOSÉ L. VILA ˣ, and RAMÓN MARTÍNEZ-PACHECO

Received April 11, 1980, from the *Departamento de Farmacia Galénica, Facultad de Farmacia, Universidad de Santiago de Compostela, Spain.* Accepted for publication November 17, 1981.

Abstract □ A study was carried out to determine the effect of a fat excipient on the bioavailability of amoxicillin tablets. Three formulations with a fat excipient content of 10, 20, and 30%, respectively, were administered to 15 healthy volunteers according to a Latin-square design. The excretion curves were characterized with the help of two parameters, namely, the quantity of drug excreted between 0–2 and 0–12 hr postadministration, respectively. The effect of the fat excipient content was quantified with the use of polynomials whose corresponding orders were given by the ANOVA. In the case of both parameters, a quadratic response to the fat excipient content was found. At the same time, a dissolution study was carried out using a previously established method. Here, the parameters used to characterize the dissolution curves were the quantities of dissolved drug in 30 and 180 min, respectively. Again, a quadratic response to the fat excipient content was observed in the case of both parameters.

Keyphrases □ Amoxicillin—quantification of the effect of excipients on bioavailability by means of response surfaces, fat matrix □ Bioavailability—quantification of the effect of excipients by means of response surfaces, amoxicillin in fat matrix □ Excipients—quantification of the effect on bioavailability by means of response surfaces, amoxicillin in fat matrix

The quantification of the effect that certain excipients and technological procedures have on drug bioavailability is an interesting aspect of the field of pharmaceutical technology. Most of the investigations carried out with human subjects have used commercial formulations, that is, formulations whose composition and elaboration process are unknown (1–3). Therefore, only the bioequivalence or bioinequivalence of these formulations can be established. *In vitro* studies of drug release and drug dissolution, although more numerous, have failed to reflect the biopharmaceutical or clinical consequences of drug–technological factor interaction (4, 5).

BACKGROUND

Bioequivalence studies are usually based on the general linear model of ANOVA. This model, when applied to a three-way crossover design (formulation, subject, and period), takes the following form:

$$y_{ijk} = \mu + F_k + S_i + W_j + e_{ijk} \qquad \text{(Eq. 1)}$$

where y_{ijk} denotes the observation on the ith subject with the kth formulation on the jth period; μ represents the general mean; F_k, S_i, and W_j represent the effects produced by subject, formulation, and period, respectively; and e_{ijk} is the error associated with observation y_{ijk} and is assumed to have normal distribution with the mean zero and variance constant for all observations, σ^2. If this study were not confined only to establishing the bioequivalence or bioinequivalence between two formulations, but extended to include the quantification of the effects of excipients and technological factors on bioavailability, then the term F_k would have to be subdivided to meet these new demands. For example, if the study were to englobe factors A and B, and if the effect of each of these factors and of their mutual interaction were desired, then the term F_k would have to be replaced by the term:

$$A_m + B_n + AB_{mn} \qquad \text{(Eq. 2)}$$

where A_m represents the effect of factor A at level m, B_n the effect of factor B at level n, and AB_{mn} the effect of their interaction. Thus, the ANOVA could indicate the way in which these factors modify bioavailability and help establish not only the optimum formulation but also the *in vivo–in vitro* correlations.

Table I—Percent Composition and Mean Weight [a] of Formulations A, B, and C

Formulation	Amoxicillin Trihydrate	Fat, %	Talc, %	Mean Weight
A	85%	10	5	514
B	75%	20	5	582
C	65%	30	5	672

[a] Mean weight in kilograms.

The object of this study, which comprises three separate studies, is to quantify the effects which two excipients (a synthetic fat and a silica colloid) have on the bioavailability of amoxicillin tablets. Quantification was obtained by means of response surfaces expressed as low-order polynomials, a technique used to quantify the effects of excipients on some physicochemical properties of different dosage forms (6, 7). At the same time, a study was carried out to determine the effect of the above excipients on the dissolution rate of amoxicillin in formulations tested *in vivo*. Finally, the correlation between both series of data was also studied.

The present report studies the effect of a synthetic fat excipient at three equally spaced levels.

EXPERIMENTAL

Assayed Formulations and Analytical Method—Three formulations of amoxicillin trihydrate[1] tablets, containing 375 mg of anhydrous amoxicillin, were manufactured and studied. The percent composition of the three formulations, A, B, and C, is shown in Table I. The three formulations differed only in their synthetic fat[2] (mono-, di-, tripalmitate estearate of glycerin) content. In each case the hardness was 4 kg on the hardness tester scale[3].

Table II—Mean Values and Variances [a] for the *In Vivo* Parameters Employed

Formulation	E_2	E_{12}
A	143.4 (4129.2)	369.8 (4248.7)
B	45.8 (1433.4)	329.8 (14349.2)
C	17.4 (136.9)	102.4 (2416.3)

[a] Variances in parentheses.

The *in vivo* and *in vitro* samples were assayed by means of a spectrophotometric method which was specific for intact drug (8).

Clinical Protocol—Urine analysis of the unchanged drug was carried out in 15 healthy volunteers of both sexes, whose ages ranged from 20 to 32. The subjects, tested for renal insufficiency, gave a negative response. A written consent was obtained from each subject. Subjects were divided at random into three equal groups. A Latin-square 3 × 3 design with five replicates was used, and the washing period between successive administrations was 5 days. Immediately before a standard breakfast, the fasted subjects were given two tablets equivalent to 750 mg of anhydrous amoxicillin. Urine samples were collected 1, 2, 3, 4, 5, 6, 8, 10, and 12 hr postadministration.

Pharmacokinetic Analysis—The effect of fat content on the quantity of drug absorbed and on the absorption rate were the two parameters used to characterize the urinary excretion curves. These parameters can be characterized by E_{12} the total quantity of drug, expressed in milligrams, excreted in the 12 hr following administration; and E_2 the quantity of drug, expressed in milligrams, excreted in the first 2 hr postadministration (during which time the maximum urinary excretion rate of the free drug was observed).

Characterization of the formulations by means of pharmacokinetic parameters was ruled out for two reasons. First, the absorption processes observed in Formulations B and C were too complex; second, to avoid the introduction of estimation error, which would have been confused with the experimental error and would have entailed the use of nonparametric tests and, consequently, the loss of information about the assay in question.

Dissolution Rate Studies—Dissolution rate studies were carried out using the apparatus described previously (9). This apparatus was the flowthrough type without an accumulating reservoir. To calculate the quantity of dissolved drug at different times, the method proposed previously (10) was used. The following conditions were employed: angle agitation, 180; intensity of agitation, 6 oscillations/min; dissolution cell volume, 47.5 ml; flow rate, 1 ml/min. Enzyme-free juices, gastric and enteric, were the dissolution media employed. Three dissolution tests were carried out on each formulation using a tablet in each test, although the results refer to a 750-mg dose. The following parameters were employed to characterize the dissolution curves obtained: D_{180} was the quantity of drug, in milligrams, dissolved in 180 min, and D_{30} was the quantity of drug, in milligrams, dissolved in 30 min.

Statistical Analysis—Prior to the establishment of the ANOVA for the Latin-square design, the model was submitted to an additive test and to a variance homogeneity test in order to confirm its validity. Tukey's test (11) confirmed the additivity of the model. Nevertheless, Cochran's test (12) confirmed the existence of heterogeneous variances among the treatments for the two parameters under study. Therefore, the use of the three-way ANOVA in the Latin square lacked validity on account of power deficiency. To overcome this problem, and because the logarithmic transformation of data failed to stabilize the variances, the generalization of Scheffé's test proposed by Brown and Forsythe (13) was used. Although the latter test is a one-way ANOVA, in the presence of heterogeneous variances, it is a valid solution. According to Brown and Forsythe, the modification of Scheffé's probability is:

$$P_r\{(H - O)^2/(\sum Z_i^2 S_i^2/n_i) < (g - 1) F_{1-\alpha,g-1,f}\} \geq 1 - \alpha \quad \text{(Eq. 3)}$$

where $H = \Sigma Z_i \overline{X}_i$ is an estimation of $O = Z_i \mu_i$, f is defined by:

$$\frac{1}{f} = \sum \frac{C_i^2}{(n_i - 1)} \text{ and } C_i = \frac{(\sum Z_{ik}^2)\, S_i^2/n_i}{\sum_i \left(\sum_k Z_{ik}^2\right) S_i^2/n_i} \quad \text{(Eq. 4)}$$

where $\overline{X}_i$ is the mean of the treatments, S_i^2 is the variance, and g is the number of treatments.

For the *in vitro* parameters chosen, the corresponding one-way ANOVA was employed.

The study of response surfaces was achieved by subdividing the sum of squares for the term treatments of the ANOVA by means of a series of orthogonal polynomials which are defined by the number of factors studied as well as by the number of their levels (14). Therefore, such a study presupposes the use of an adequate experimental design. The subdivision in this study is achieved by means of the following polynomials (Z):

Treatments	Z_1	Z_2
T_1	−1	1
T_2	0	−2
T_3	1	1
Component	Linear	Quadratic

which subdivide the sum of squares for treatments in linear and quadratic responses. The levels of the factors studied must be equally spaced; if not, it would be impossible to carry out the orthogonal comparisons offered.

Once the type of response has been inferred, a polynomial function with the correspondent degree is adjusted to mean values by means of the least-square method.

RESULTS AND DISCUSSION

A quantitative study of bioavailability requires a grasp of two basic concepts. First, the concept of bioavailability includes the quantity of drug absorbed and the rate of absorption (15). Second, bioavailability is a random variable and, therefore, its interval (*i.e.*, a parameter which can measure interindividual variability) has to be estimated. The choice of the E_{12} parameter is clearcut, since it reflects the total quantity of drug absorbed, as the half-life of amoxicillin in ~1 hr. The E_2 parameter is mainly controlled by the rate of absorption, while depending to a certain degree on the total quantity of drug absorbed. There are two reasons for studying the variability of these parameters in the light of their respective variances: from a statistical point of view, variance gives a good idea of the interval; and variance homogeneity is a prequisite for the study of the ANOVA. Therefore, there is a combination of statistical and biopharmaceutical criteria.

Table III—Results of ANOVA for E_{12} [a]

i	H_i	$V(H)$	$g-1$	f	F	A	Results
1	−267.41	444.34	2	21	3.47	55.53	Significant linear response
2	−187.49	4270.80	2	21	3.47	172.16	Significant quadratic response
3	−39.96	1239.86	2	21	3.47	92.76	No significant contrast A *versus* B
4	−267.41	444.34	2	21	3.47	55.53	Significant contrast A *versus* C
5	−227.45	1117.71	2	21	3.47	88.07	Significant contrast B *versus* C

[a] $\alpha = 0.05$. The minimum value necessary for rejecting the null hypothesis is $A = \sqrt{(g-1)FV(H_i)}$ (Ref. 13).

Table IV—Results of ANOVA for E_2 [a]

i	H_i	$V(H)$	$g-1$	f	F	A	Results
1	−125.96	284.41	2	21	3.47	44.03	Significant linear response
2	69.26	666.67	2	21	3.47	68.02	Significant quadratic response
3	−97.61	370.85	2	21	3.47	50.73	Significant contrast A *versus* B
4	−125.96	284.41	2	21	3.47	44.03	Significant contrast A *versus* C
5	−28.35	104.69	2	21	3.47	26.95	Significant contrast B *versus* C

[a] $\alpha = 0.05$ (see Table III).

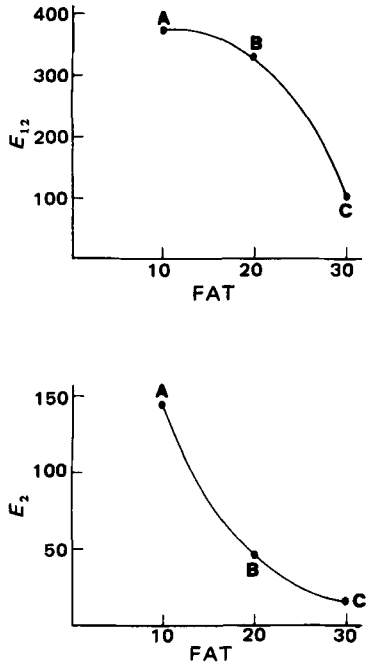

Figure 2—*Response curves for* E_{12} *and* E_2 *in function of fat content.*

Figure 1 shows the mean urine excretion accumulative curves of the three formulations studied. The mean values and the variances of the respective parameters are shown in Table II. The respective ANOVA results appear in Tables III and IV. The contrasts between pairs of formulations and the orthogonal contrasts used to study the influence of the excipient must be distinguished. From the contrasts between formulations, it can be inferred that A and B are bioequivalent using the mean value of the E_{12} parameter, the total quantity absorbed, but not so using the E_2 parameter, the rate of absorption. On the other hand, and in the case of both parameters, the variability of Formulation B is statistically greater than that of Formulation A. This means that Formulation B not only is absorbed more slowly but also its variability is much greater, two reasons for considering them to be bioinequivalent. Formulation C shows much lower values for both parameters.

With respect to the influence of the synthetic fat content on bioavailability, the ANOVA results imply a quadratic response for both parameters. Therefore, the following second-degree polynomials indicate a quantitative relationship between bioavailability and synthetic fat content in those formulations whose fat content lies within the limits of this study:

$$E_{12} = 222.320 + 24.138\,x - 0.938\,x^2 \qquad \text{(Eq. 5)}$$

$$E_2 = 310.280 - 20.150\,x + 0.346\,x^2 \qquad \text{(Eq. 6)}$$

in which x is the fat content expressed in percent. These polynomials are shown in Fig. 2. It can be seen that when the fat content is increased from 10 to 20%, there are no observable changes of importance, at first, in the mean quantity of drug absorbed; nevertheless, there is a marked decrease

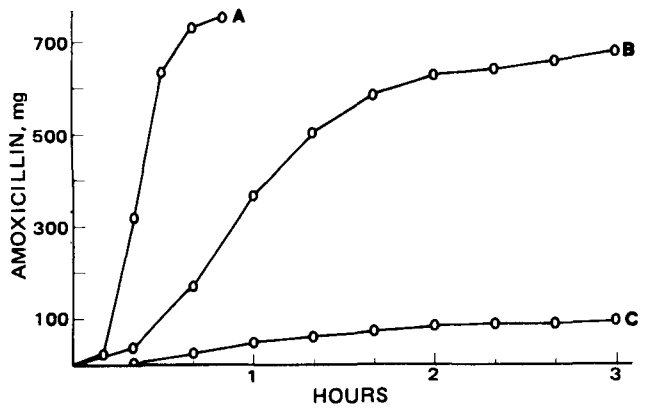

Figure 3—*Cumulative dissolution curves.*

Table V—Mean values of Three Dissolution Tests for the Chosen *In vitro* Parameters

Formulation	D_{30}	D_{180}
A	577.8	750.6
B	71.3	681.0
C	16.5	91.9

Table VI—Results of ANOVA for D_{180}

Source of Variation	Sum of Squares	Degrees of Freedom	F	α
Treatments	780,319.56	2	4013.14	<0.01
Linear	645,818.92	1	6642.83	<0.01
Quadratic	134,500.64	1	1383.46	<0.01
Residual	583.32	6		
Total	780,902.88	8		

Table VII—Results of ANOVA for D_{30}

Source of Variation	Sum of Squares	Degrees of Freedom	F	α
Treatments	632,495.56	2	176.25	<0.01
Linear	548,208.96	1	352.50	<0.01
Quadratic	84,286.60	1	46.97	<0.01
Residual	10,765.79	6		
Total	643,261.35	8		

in the rate of absorption. It can also be seen that when the fat content is increased from 20 to 30%, there are noticeable decreases in both E_2 and E_{12}. However, it can be seen that the variation coefficients obtained with the data listed in Table II increase when the fat content increases. In the case of the E_{12} parameter, these are 18, 36, and 48% for Formulations A, B, and C, respectively.

The use of these second-degree polynomials obtained from the mean values might lead to certain criticism. The ANOVA only indicates the existence of a statistically significant deviation in the linear relationship between the parameters and the synthetic fat content. This does not mean that the second-degree polynomial is the optimum function or that there is some physical–chemical basis for justifying its use. The fact is that it is the simplest linear function application to the statistical model used. With respect to the utility of these functions for determining the type of effect produced by the excipient, this depends on whether the function used can be said to be equivalent to the hypothetical function

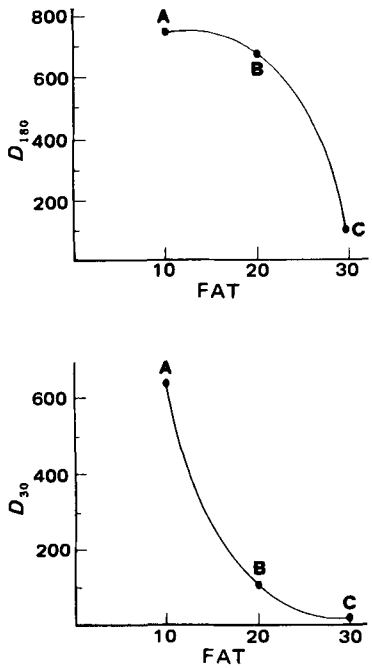

Figure 4—*Response curves for* D_{180} *and* D_{30} *in function of fat content.*

derived from those physical-chemical properties responsible for the modification involved and for the interaction between the dosage form and the physiological surroundings where drug release and drug absorption takes place. The best way to avoid any possible discrepancy between real behavior and that inferred from the ANOVA is to carefully choose the interval and the number of levels necessary for the study. The cost of the *in vivo* experiment necessarily limits the number of levels studied.

The dissolution accumulative curves obtained are shown in Fig. 3, while the mean values of the chosen parameters, D_{30} and D_{180}, are listed in Table V. A quadratic response for both parameters, with respect to the fat content, can be inferred from the one-way ANOVAs shown in Tables VI and VII. The polynomials, after least-squares adjustment, were:

$$D_{180} = 300.090 + 70.924\,x - 2.593\,x^2 \qquad \text{(Eq. 7)}$$

$$D_{30} = 1549.010 - 112.343\,x + 2.053\,x^2 \qquad \text{(Eq. 8)}$$

They are shown in Fig. 4. It is worth noting that this excipient exercises the same influence *in vitro* as it does *in vivo*.

Bioequivalence studies carried out on formulations whose composition is defined by an appropriate experimental design afford the opportunity of studying the effect of the different excipients on bioavailability; that is, the effect of these excipients on the quantity of drug absorbed and on the rate of absorption. The effect the excipients have on interindividual variability must also be considered. As has been pointed out previously (16, 17), it is not sufficient just to accept the null hypothesis for the parameters employed as an indication of bioequivalence between two formulations; the variability must also be similar.

Quantification of the Effect of Excipients on Bioavailability by Means of Response Surfaces II: Amoxicillin in Fat–Silica Matrix

MATÍAS LLABRÉS, JOSÉ L. VILA ˣ, and RAMÓN MARTÍNEZ-PACHECO

Received April 11, 1980, from the *Departamento de Farmacia Galénica, Facultad de Farmacia, Universidad de Santiago de Compostela, Spain.* Accepted for publication November 17, 1981.

Abstract □ This report studies the bioavailability of amoxicillin in different fat–silica matrixes. A urinary excretion study was carried out on four formulations containing fat and silica excipients. The formulations were administered to 24 healthy volunteers according to a Latin-square design. The following percent proportions of fat–silica were used: 15:3.75, 15:7.50, 30:3.75, and 30:7.50. The urinary excretion curves were characterized using the quantity of unchanged drug excreted between 0–2 and 0–12 hr postadministration, respectively as parameters. The ANOVA results showed that both excipients had an additive effect on the quantity of drug excreted between 0 and 2 hr, whereas the effect on the quantity of drug excreted between 0 and 12 hr was also one of interaction between both excipients. Quantification of the ANOVA results in terms of excipient content was conducted by means of the adequate linear functions. At the same time, a dissolution study was carried out using the quantity of drug dissolved in 30 and 180 min as parameters. The behavior was similar to that encountered for the *in vivo* parameters.

Keyphrases □ Amoxicillin—effect of excipients on bioavailability by means of response surfaces, fat–silica matrix □ Bioavailability—effect of excipients by means of response surfaces, amoxicillin in fat–silica matrix □ Excipients—effect on bioavailability by means of response surfaces, amoxicillin in fat–silica matrix

The aim of the present study is to determine the effect which the combination of two excipients, a synthetic fat[1] and a silica colloid[2], has on the bioavailability of amoxicillin tablets.

EXPERIMENTAL

Assayed Formulations—Four formulations of amoxicillin trihydrate[3] tablets were manufacturerd and studied. Formulations, D, E, F, and G, contained 375 mg of anhydrous amoxicillin, and their percent composition is shown in Table I. Hardness, in each case, was 5 kg on the hardness tester scale[4].

Clinical Protocol—The urinary excretion of unchanged drug was studied in 24 healthy volunteers whose ages ranged from 20 to 30 years and who showed no evidence of renal insufficiency. The subjects were randomly divided into four equal groups. A Latin-square 4 × 4 design with 6 replicates was used, and the washing period was 5 days. Immediately before a standard breakfast, fasted subjects were given two tablets equivalent to 750 mg of anhydrous amoxicillin. Urine samples were collected at 1, 2, 3, 4, 5, 6, 8, 10, and 12 hr postadministration.

Pharmacokinetic Analysis—Characterization of the urinary excretion curves was achieved by means of the parameters mentioned in the previous report (1).

Dissolution Rate Studies—The apparatus and methodology used were both described in the previous report (1).

Statistical Analysis—Heterogeneous variances for the treatments

Table I—Percent Composition of Formulations

Formulation	Amoxicillin Trihydrate, %	Fat, %	Silica, %	Talc, %
D	77.25	15	3.75	5
E	72.50	15	7.50	5
F	62.25	30	3.75	5
G	57.50	30	7.50	5

Table II—Mean Values and Variances [a] for the Excretion Parameters

Formulation	E_2	E_{12}
D	36.2 (763.3)	237.6 (11,322.6)
E	84.2 (4,407.8)	352.9 (16,708.0)
F	16.9 (113.7)	112.8 (3,366.3)
G	52.5 (1,982.4)	353.4 (7,306.9)

[a] Variances in parentheses.

were observed and exposed by means of Barlett's test (2). Once again, logarithmic transformation of data failed to stabilize the variances; therefore, Scheffé's test, modified by Brown and Forsythe (3), was again employed.

The study was carried out on four formulations combining two equally spaced levels of each of the excipients. Therefore, the subdivision of the sum of squares for the term treatments of the ANOVA, to obtain the response surfaces, was achieved by means of the following polynomials (Z):

Treatment	Z_1	Z_2	Z_3
T_1	−1	−1	1
T_2	1	−1	−1
T_3	−1	1	−1
T_4	1	1	1
Component	Fat mean response	Silica mean response	Interaction

These polynomials subdivide the sum of the squares in mean response for each excipient and interaction between the two excipients (4).

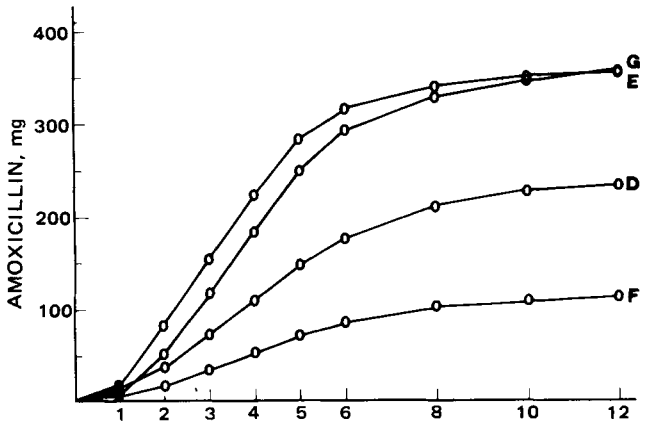

Figure 1—*Cumulative curves for urinary excretion of unchanged amoxicillin.*

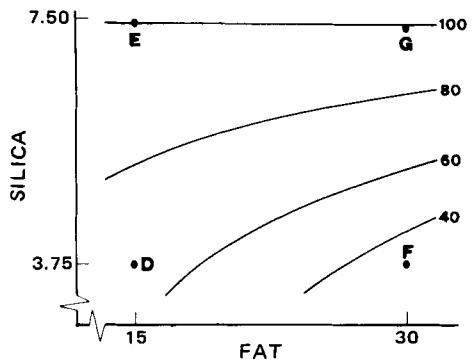

Figure 2—*Contour curves for* E_{12} *as function of fat and silica contents.*

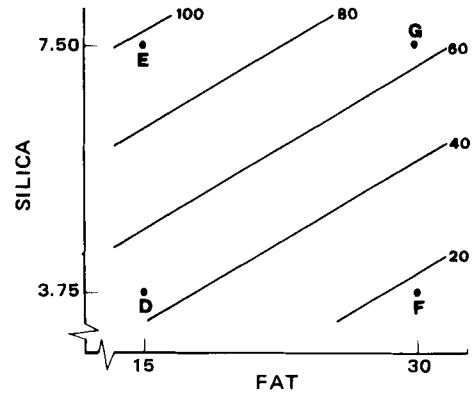

Figure 3—*Contour curves for* E_2 *as function of fat and silica contents.*

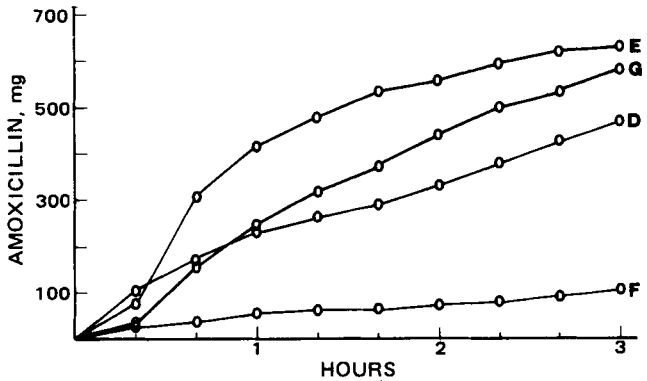

Figure 4—*Cumulative dissolution curves.*

Having inferred the factors that affect absorption, and the existence or nonexistence of interaction, the corresponding polynomial functions were then adjusted to the mean experimental values by means of the least-squares method. The results are shown graphically by means of the contour lines generated by these equations.

RESULTS AND DISCUSSION

The mean urine excretion curves are depicted in Fig. 1, whereas the mean values of the parameters used for their characterization, E_2 and E_{12}, and the respective variances, are shown in Table II. The ANOVA results appear in Tables III and IV. As mentioned previously (1), two parts must be distinguished, namely, the contrasts between pairs of formulations and the orthogonal contrasts used to monitor the effect of the excipients on bioavailability. The latter contrast shows that both excipients have a significant effect on the two parameters. With respect to the E_{12} parameter, significant interaction between both excipients is also observed. According to this, the following functions indicate the quantitative correlation between the bioavailability parameters and the fat (x_1) and (x_2) content, expressed as percent, for those formulations

whose composition lie within the limits of the experiment:

$$E_{12} = 372.17 - 16.66\,x_1 - 2.63\,x_2 + 2.22\,x_1x_2 \qquad \text{(Eq. 1)}$$

$$E_2 = 22.90 - 1.70\,x_1 + 11.15\,x_2 \qquad \text{(Eq. 2)}$$

The response surfaces obtained are shown in Figs. 2 and 3. A value of 100% is assigned to Formulation E, to which the other formulations are referred. Observation of Fig. 2 leads to the conclusion that, in order to obtain acceptable physiological availabilities within the limits of the experiment, a silica content close to 7.5% should be used, no matter what the fat content may be; because at this level, the silica practically cancels out the effect of the fat on the E_{12} parameter. For this reason, Formulations E and G present equivalent absorption. Nevertheless, with low silica concentration (3.75%), the fat content produces a marked effect as can be seen by the differences observed between Formulations D and F. The response surface obtained for the E_2 parameter plane surface in this case, due to the nonexistence of interaction between excipients, is shown in Fig. 3. The observed response corresponds to the sum of the effects produced by both excipients: negative with regard to the fat content and positive in the case of silica. For this reason, Formulation E, with low content in fat and high content in silica, gives the highest value for the E_2 parameter and also shows significant differences with regard to the other formulations. It is also seen that those formulations characterized by incomplete absorption show higher variation coefficients, as pointed out previously (5).

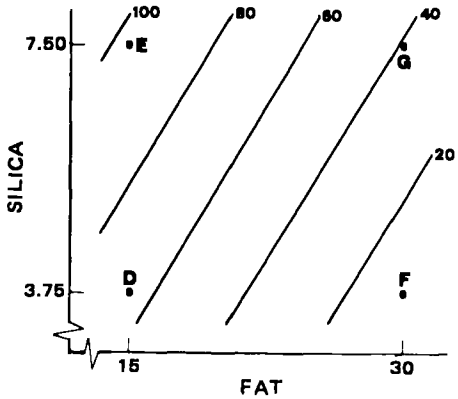

Figure 6—*Contour curves for* D_{30} *as function of fat and silica contents.*

With respect to the dissolution tests, the mean accumulative curves appear in Fig. 4, while the mean values of the chosen parameters are shown in Table V. The respective ANOVAs are shown in Tables VI and VII. It can inferred from Table VII that the two excipients have a significant effect on both parameters, whereas in the case of the D_{180} parameter, there is also significant interaction between both excipients. According to this, the following functions indicate the quantitative correlation between the dissolution parameters and the fat (x_1) and silica (x_2) content, expressed as a percent, for those formulations whose composition lie within the bounds of this study:

$$D_{180} = 964.39 - 42.06\,x_1 - 29.16\,x_2 + 4.66\,x_1x_2 \qquad \text{(Eq. 3)}$$

$$D_{30} = 267.20 - 10.25\,x_1 + 18.34\,x_2 \qquad \text{(Eq. 4)}$$

Commentaries similar to those made about the *in vivo* response may also be made about the response surfaces obtained *in vitro* which are depicted in Figs. 5 and 6. Nevertheless, with the conditions used in the dissolution studies, the order relationship *in vivo* (G, E, D, F, for E_{12} and E, G, D, F, for E_2) is not the same as *in vitro* (E, G, D, F for D_{180} and E, D, G, F for D_{30}).

Quantification of the Effect of Excipients on Bioavailability by Means of Response Surfaces III: *In Vivo–In Vitro* Correlations

MATÍAS LLABRÉS, JOSÉ L. VILA ˣ, and RAMÓN MARTÍNEZ-PACHECO

Received April 11, 1980, from the *Departamento de Farmacia Galénica, Facultad de Farmacia, Universidad de Santiago de Compostela, Spain.* Accepted for publication November 17, 1981.

Abstract □ This study compares one of the previously studied formulations with commercial amoxicillin capsules. The results indicate that the percentage of the dose absorbed is similar in both formulations; nevertheless, the amoxicillin capsules present a higher absorption rate. The *in vivo–in vitro* correlations in terms of response surfaces, and the general correlation among all the formulations studied in the three articles of this series is discussed. The quantity of drug excreted in 2 hr and the quantity of drug dissolved in 30 min presents a correlation coefficient $r = 0.9458$ ($p < 0.01$) and the quantity of amoxicillin excreted in 12 hr and the quantity dissolved in 180 min presents a correlation coefficient $r = 0.9761$ ($p < 0.01$).

Keyphrases □ Amoxicillin—effect of excipients on bioavailability by means of response surfaces, *in vivo–in vitro* correlations □ Bioavailability—effect of excipients by means of response surfaces, amoxicillin, *in vivo–in vitro* correlations □ Excipients—effect on bioavailability by means of response surfaces, amoxicillin, *in vivo–in vitro* correlations

The comparison between Formulation E (1), previously studied, and a commercial amoxicillin capsule (Formulation S) was carried out. This study has a double purpose: first, to determine whether the absorption of the drug in Formulation E (which showed good absorption in previous studies) is equivalent to the absorption shown by the conventional formulations; second, to determine the degree of the individual variation for both types of formulations.

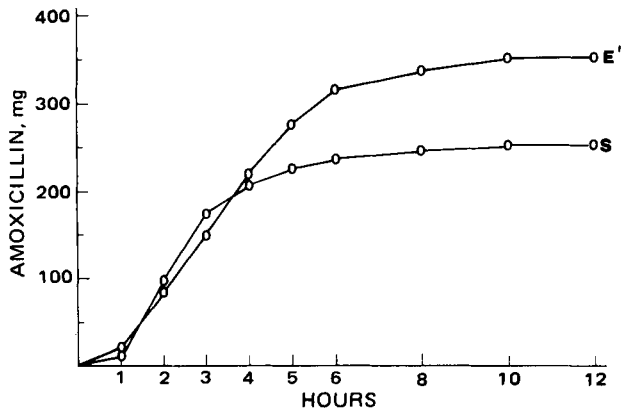

Figure 1—*Mean cumulative curves for urinary excretion of unchanged amoxicillin.*

EXPERIMENTAL

Assayed Formulations—A comparison is made between Formulation E, whose composition has been described (1) and commercial capsules[1] containing 500 mg of anhydrous amoxicillin. To differentiate the results of the present study from those obtained previously (1), Formulation E is termed E′ in the present report.

Clinical Protocol—Urinary excretion of unchanged drug was studied in 12 healthy volunteers of both sexes, whose ages ranged from 20 to 30 years and who showed no evidence of renal insufficiency. Subjects were divided at random into two equal groups of six. A Latin-square 2 × 2 design with 6 replicates was used, and the washing period was 5 days. The conditions of administration and sample times are the same as those described in the previous two reports (1, 2).

Pharmacokinetic Analysis—The parameters employed to characterize the excretion curves obtained are the same as those described previously (1, 2), E_2 and E_{12}.

Dissolution Rate Studies—The apparatus and methodology used were both described in Part I (2).

Statistical Analysis—Cochran's test (3) confirmed the existence of heterogeneous variances for the treatments. Therefore, Scheffé's test modified by Brown and Forsythe (4) was employed (even though the logarithmic transformation of data stabilized the variances) in order to maintain homogeneity in the statistical treatment of data.

RESULTS AND DISCUSSION

A commercial formulation of 500 mg was chosen because the urinary excretion curves obtained for Formulation E in the previous study indicated the possibility of obtaining peaks similar to those obtained with 500-mg doses in conventional formulations. This approach, together with the comparison of the parameters E_2 and E_{12}, permits the possibility of determining whether or not there is a prolongation in the release–absorption process with respect to Formulation E′. This would explain the large individual variations observed in previous studies.

Figures 1 and 2 show the excretion and dissolution mean cumulative curves for both formulations. With respect to the E_2 parameter, the mean values and variances (in parentheses) obtained for Formulations E′ and S were 85.3 (2824.2) and 98.1 (2188.9), respectively. The corresponding figures for the E_{12} parameter were 354.4 (9003.6) and 253.6 (1895.9). The dissolution parameter D_{30} yielded mean values of 204.8 and 404.0 for Formulations E′ and S, respectively, whereas the D_{180} parameter yielded mean values of 634.0 and 471.5 for the respective formulations. The ANOVA results, using the method of Brown and Forsythe (4), show that both formulations are equivalent with regards to the E_2 parameter ($F_{1,22} = 0.392$) but differ significantly (0.01) with regards to the E_{12} parameter ($F_{1,22} = 11.190$). The quantity of intact drug excreted in urine was ~50% of the administered dose in the case of each formulation, which has been

Therefore, Scheffé's test modified by Brown and Forsythe (4) was employed (even though the logarithmic transformation of data stabilized the variances) in order to maintain homogeneity in the statistical treatment of data.

RESULTS AND DISCUSSION

A commercial formulation of 500 mg was chosen because the urinary excretion curves obtained for Formulation E in the previous study indicated the possibility of obtaining peaks similar to those obtained with 500-mg doses in conventional formulations. This approach, together with the comparison of the parameters E_2 and E_{12}, permits the possibility of determining whether or not there is a prolongation in the release–absorption process with respect to Formulation E′. This would explain the large individual variations observed in previous studies.

Figures 1 and 2 show the excretion and dissolution mean cumulative curves for both formulations. With respect to the E_2 parameter, the mean values and variances (in parentheses) obtained for Formulations E′ and S were 85.3 (2824.2) and 98.1 (2188.9), respectively. The corresponding figures for the E_{12} parameter were 354.4 (9003.6) and 253.6 (1895.9). The dissolution parameter D_{30} yielded mean values of 204.8 and 404.0 for Formulations E′ and S, respectively, whereas the D_{180} parameter yielded mean values of 634.0 and 471.5 for the respective formulations. The ANOVA results, using the method of Brown and Forsythe (4), show that both formulations are equivalent with regards to the E_2 parameter ($F_{1,22} = 0.392$) but differ significantly (0.01) with regards to the E_{12} parameter ($F_{1,22} = 11.190$). The quantity of intact drug excreted in urine was ~50% of the administered dose in the case of each formulation, which has been

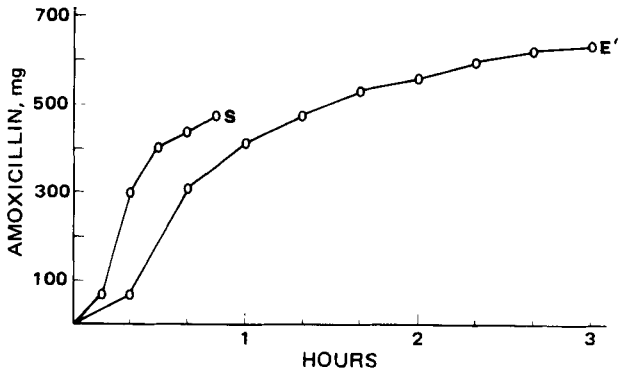

Figure 2—*Mean cumulative dissolution curves.*

discussed previously (5). The ratio between the observed values for the E_{12} parameter, in the case of each of the formulations, is the same as the ratio between doses, thus indicating equal absorption extent for both formulations. With respect to the E_2 parameter, statistically the ratio is equal to unity. This indicates a reduction in the absorption rate of Formulation E′ compared with Formulation S. Furthermore, there is a greater variation between subjects for Formulation E′, with respect to both parameters, which is why there are heterogeneous variances.

Response surfaces are not only useful for quantifying the effect of the different factors on bioavailability, but also serve as a basis for establishing the possible *in vivo–in vitro* correlations. Furthermore, this latter aspect is an important problem facing biopharmaceutics in the field of dosage form control. This importance is underlined by the numerous methods proposed for the study of such correlations (6, 7). Nevertheless, the fact that these methods are mainly empirical is not desirable. For this reason, some authors (6) point out that quantitative-type correlations, at least, "should probably be derived only when there is a theoretical reason for relating the variables."

Although the conditions found in the GI tract are difficult to simulate, it is possible to study a series of factors which presumably affect the processes of release–dissolution of the drug in a biological medium, assuming that these processes are the limiting steps in absorption. The rate with which a drug is liberated from the dosage form is conditioned by two types of factors: the effect of the different excipients and technological factors and their possible interaction with the drug and the interactions between the dosage form and the GI environment. Some kind of physicochemical model is necessary so that the interaction between the technological factors of the dosage form and the physiological environment can be simulated *in vitro*. However, no such model is readily available. However, statistical models can be used, as is the case here, to see if the effects of the technological factors studied *in vitro* by means of certain parameters are comparable to the effects produced *in vivo*. Furthermore, this approach affords the possibility of obtaining the optimum conditions for *in vitro* testing.

Obtaining a correlation between the *in vivo* and *in vitro* response surfaces implies that the polynomials obtained from both series of data are related by means of any one operator; nevertheless, from a practical

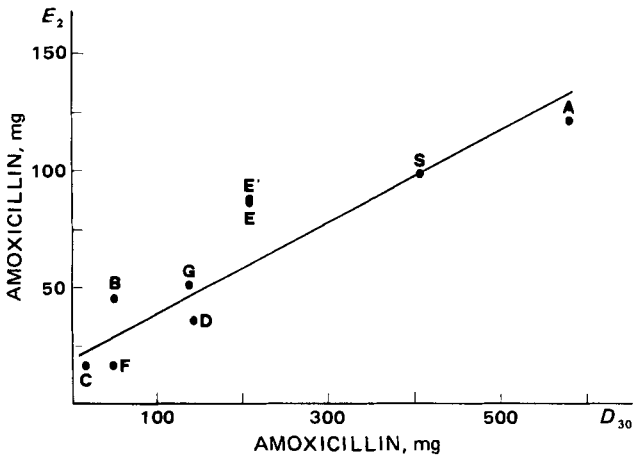

Figure 3—*Linear relationship between the amount of unchanged amoxicillin excreted in 2 hr and the amount dissolved in 30 min [y = 20.90 + 0.2169 x (r = 0.9458; F = 59.48; $\alpha < 0.01$)].*

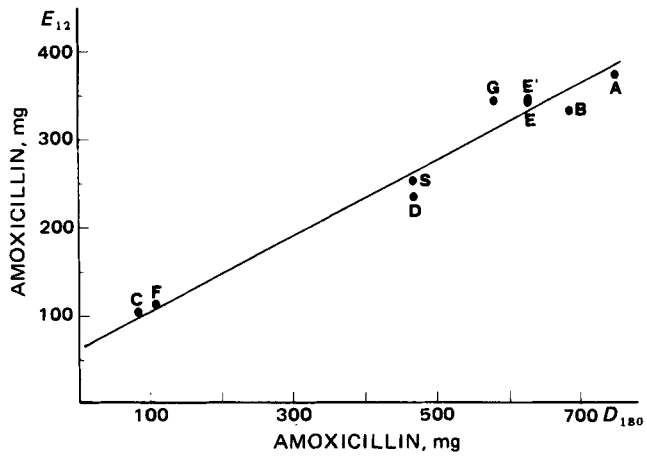

Figure 4—*Linear relationship between the amount of unchanged amoxicillin excreted in 12 hr and the amount dissolved in 180 min [y = 64.01 + 0.4278 x (r = 0.9761; F = 141.30; $\alpha < 0.01$)].*

point of view, it is desirable to have a linear relationship between both, that is, the polynomials obtained should have linear combination. Furthermore, the use of linear relations makes the predictions more plausible. Due to the nature of the experimental data, obtaining linear combinations, is not expected; nevertheless, the approximation to this situation can be tested by means of the linear regression of the polynomial coefficients obtained *in vivo versus* those obtained *in vitro*. If both polynomial functions are a linear combination, then a linear relationship with the ordinate at the origin, statistically equal to zero, will be obtained. This situation is analyzed by means of the ANOVA of the regression among coefficients, using as index the F value obtained for the regression term b_0. To establish precisely the coefficients of the polynomial function used *in vivo*, taking as a basis the *in vitro* counterparts, it is desirable to meet Wetz's criterion (8). According to Wetz, the minimum value of F necessary for equating prediction errors with experimental errors is four times the tabulated value. Another necessary condition is that the ordinate in the origin should be statistically equal to zero. It should also be noticed that the proportion constant for the polynomial coefficients is the same as one obtained by means of the regression between the *in vivo* and *in vitro* parameters.

The regression obtained among the polynomial coefficients corresponding to the E_2 and D_{30} parameters, for Formulations A, B, and C is:

$$y = 1.1419 + 0.1995\,x \quad (r = 0.9999;\ F = 25{,}200.8) \qquad \text{(Eq. 1)}$$

in which the ordinate in origin is statistically equal to zero; the F value is superior to the quadruple of the value tabulated (645.6). Thus, both polynomials must be considered a linear combination within the experimental limits. From this the relationship between the E_2 and D_{30} parameters is as follows:

$$E_2 = 16.04 + 0.200\,D_{30} \quad (r = 0.9977;\ F = 226.5) \qquad \text{(Eq. 2)}$$

in which the y intercept is statistically equal to zero and the slope is almost equal to that obtained in the regression among polynomial coefficients. This coincidence confirms the existence of a linear combination between the response surfaces *in vivo* and *in vitro*.

Nevertheless, the regression obtained between the polynomial coefficients corresponding to E_{12} and D_{180} is:

$$y = -12.473 + 0.768\,x \quad (r = 0.9912;\ F = 56.47) \qquad \text{(Eq. 3)}$$

where the F value is smaller than the critical value tabulated for $\alpha = 0.05$. For this reason, the existence of a linear combination between sets of coefficients cannot be considered. Nevertheless, the relation between the parameters E_{12} and D_{180}:

$$E_{12} = 64.227 + 0.400\,D_{180} \quad (r = 0.990;\ F = 549.19) \qquad \text{(Eq. 4)}$$

presents an excellent linear correlation, even though there is no relationship between the *in vivo* and *in vitro* response curves; the relation, in fact, is exclusively empirical.

The existence of a linear combination between the polynomials obtained for E_2 and D_{30}, but not for E_{12} and D_{180}, suggests an alteration of the intensity factor (7), since the times corresponding to the *in vivo* and *in vitro* parameters chosen are multiples in both cases.

In the second study carried out on Formulations D, E, F, and G, it was pointed out that the two systems do not arrange the different formulations in the same way, and therefore, the existence of response surfaces proportional for the chosen parameters must be ruled out.

With regards to the general correlations, Figs. 3 and 4 show the regression of E_2 against D_{30} and E_{12} against D_{180}, respectively, for all the formulations studied. In spite of the large differences existing between the various formulations, a significant linear regression is obtained, especially in the case of E_{12} against D_{180}. Even the F value obtained for the regression term, b_0, of the ANOVA of the regression was higher than the quadruple of the critical value tabulated. The high F values indicate the capability of the apparatus employed for the *in vitro* studies.

A study of response surfaces is not necessary for establishing a routine control. Nevertheless, in biopharmaceutics, a knowledge of the technological factors which can interact with drugs, as well as of the physicochemical properties responsible for this interaction, is essential. A mechanistic model which would include all variables, both technologically and physiologically dependent, is not feasible, therefore, the use of response surfaces to quantify the effect produced by the factor studied is necessary. This quantification should be independent of therapeutic implications and should insist on establishing the necessary guidelines for obtaining an exact formulation of the dosage forms.

Determination of Isoetharine in Plasma by Reversed-Phase Chromatography with Amperometric Detection

GEORGE B. PARK *, RAYMOND F. KOSS *, JULIE UTTER *, BRIAN A. MAYES ‡, and JEROME EDELSON *x

Received August 26, 1981, from the **Department of Drug Metabolism and Disposition* and the ‡*Department of Toxicology, Sterling-Winthrop Research Institute, Rensselaer, NY 12144.* Accepted for publication November 12, 1981.

Abstract □ A reversed-phase liquid chromatographic method for the determination of isoetharine in blood plasma, utilizing amperometric detection, is described. Plasma samples were extracted utilizing an ion-pair reagent, di-(2-ethylhexyl)phosphoric acid, to concentrate the catecholamine. Only minor differences were observed in the relative bioavailability of isoetharine hydrochloride and isoetharine mesylate after oral administration to rats. Observed plasma levels, at 1 hr after oral medication, were highly variable in dose-ranging studies at doses of 800–2500 mg/kg/day for 2 weeks.

Keyphrases □ Bioavailability—determination of isoetharine in plasma by reversed-phase chromatography with amperometric detection □ Reversed-phase chromatography—determination of isoetharine in plasma with amperometric detection □ Isoetharine—determination in plasma by reversed-phase chromatography with amperometric detection

Isoetharine (4-[1-hydroxy-2-[(1-methylethyl)-amino]-butyl]-1,2-benzenediol) (I) is a β-agonist which is widely

	R_1	R_2
I	CH_2CH_3	$-CH(CH_3)_2$
II	H	$-C(CH_3)_3$

used as a bronchodilator in inhalation therapy. Reversed-phase liquid chromatography with amperometric detection has been used extensively for the determination of endogenous and exogenous biogenic amines in various biological media (1). The most common methods for sample preparation include various modifications of the method of Anton and Sayre (2) in which the compound of interest is adsorbed to alumina through the catechol moiety. In addition, ion exchange resins (3) and boric acid gels (4) have been used to concentrate the analyte and separate it from interfering substances. In the present study, the catecholamine was extracted into an organic solvent through the formation of an ion-pair with di-(2-ethylhexyl)phosphoric acid (5).

The present report describes an analytical method developed for the determination of isoetharine in blood plasma, and the application of the method to the analysis of rat plasma in studies comparing the oral bioavailability of the hydrochloride and mesylate salts (the two marketed salt forms of isoetharine) and in dose-ranging toxicity studies.

EXPERIMENTAL

Reagents—Isoetharine[1] (hydrochloride and mesylate salts) (I), colterol[2] (mesylate salt, internal standard) (4-[2-[1,1-dimethylethyl)-amino]-1-hydroxyethyl]-1,2-benzenediol) (II), methanol[3], benzene[4], di-(2-ethylhexyl)phosphoric acid[5], were used as received. Water was deionized, distilled, and treated with high-intensity UV radiation[6]. All other chemicals were reagent grade or better and used without further purification.

A 1.5% (or 0.5%) solution of di-(2-ethylhexyl)phosphoric acid in ben-

Determination of Isoetharine in Plasma by Reversed-Phase Chromatography with Amperometric Detection

GEORGE B. PARK *, RAYMOND F. KOSS *, JULIE UTTER *, BRIAN A. MAYES ‡, and JEROME EDELSON *x

Received August 26, 1981, from the **Department of Drug Metabolism and Disposition* and the ‡*Department of Toxicology, Sterling-Winthrop Research Institute, Rensselaer, NY 12144.* Accepted for publication November 12, 1981.

Abstract □ A reversed-phase liquid chromatographic method for the determination of isoetharine in blood plasma, utilizing amperometric detection, is described. Plasma samples were extracted utilizing an ion-pair reagent, di-(2-ethylhexyl)phosphoric acid, to concentrate the catecholamine. Only minor differences were observed in the relative bioavailability of isoetharine hydrochloride and isoetharine mesylate after oral administration to rats. Observed plasma levels, at 1 hr after oral medication, were highly variable in dose-ranging studies at doses of 800–2500 mg/kg/day for 2 weeks.

Keyphrases □ Bioavailability—determination of isoetharine in plasma by reversed-phase chromatography with amperometric detection □ Reversed-phase chromatography—determination of isoetharine in plasma with amperometric detection □ Isoetharine—determination in plasma by reversed-phase chromatography with amperometric detection

Isoetharine (4-[1-hydroxy-2-[(1-methylethyl)-amino]-butyl]-1,2-benzenediol) (I) is a β-agonist which is widely

	R_1	R_2
I	CH_2CH_3	$-CH(CH_3)_2$
II	H	$-C(CH_3)_3$

used as a bronchodilator in inhalation therapy. Reversed-phase liquid chromatography with amperometric detection has been used extensively for the determination of endogenous and exogenous biogenic amines in various biological media (1). The most common methods for sample preparation include various modifications of the method of Anton and Sayre (2) in which the compound of interest is adsorbed to alumina through the catechol moiety. In addition, ion exchange resins (3) and boric acid gels (4) have been used to concentrate the analyte and separate it from interfering substances. In the present study, the catecholamine was extracted into an organic solvent through the formation of an ion-pair with di-(2-ethylhexyl)phosphoric acid (5).

The present report describes an analytical method developed for the determination of isoetharine in blood plasma, and the application of the method to the analysis of rat plasma in studies comparing the oral bioavailability of the hydrochloride and mesylate salts (the two marketed salt forms of isoetharine) and in dose-ranging toxicity studies.

EXPERIMENTAL

Reagents—Isoetharine[1] (hydrochloride and mesylate salts) (I), colterol[2] (mesylate salt, internal standard) (4-[2-[1,1-dimethylethyl)-amino]-1-hydroxyethyl]-1,2-benzenediol) (II), methanol[3], benzene[4], di-(2-ethylhexyl)phosphoric acid[5], were used as received. Water was deionized, distilled, and treated with high-intensity UV radiation[6]. All other chemicals were reagent grade or better and used without further purification.

A 1.5% (or 0.5%) solution of di-(2-ethylhexyl)phosphoric acid in ben-

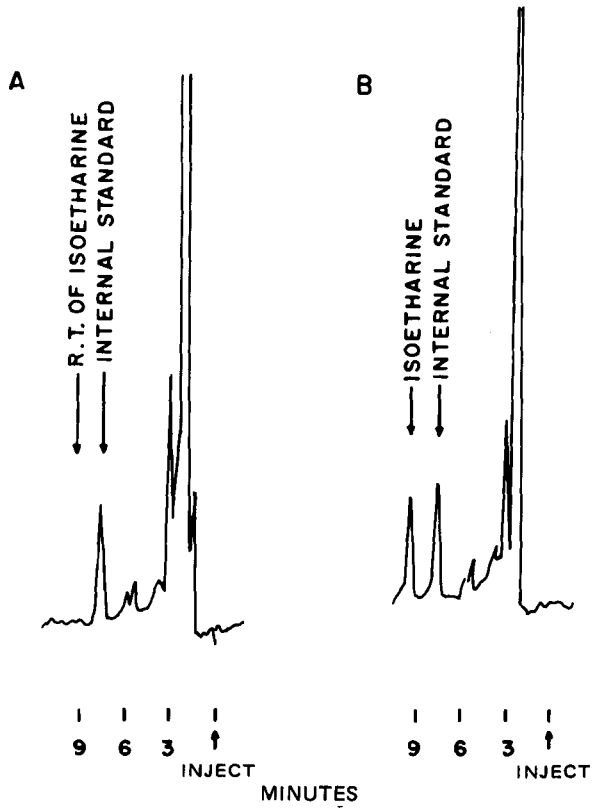

Figure 1—*Representative chromatograms of processed rat plasma: (A) control plasma containing only internal standard; (B) 4 ng/100μl standard. See text for chromatographic conditions. Attenuation 10 nA/V (full scale).*

zene was prepared by diluting 0.6 ml of reagent to 40.0 ml (or 0.5 ml of reagent to 100 ml) with benzene. Phosphate buffer, pH 6.9 (0.2 *M*), was prepared by dissolving 13.6 g of KH_2PO_4 in 300 ml of water, adding 50 ml of 1 *N* NaOH, diluting to 0.5 liter, and adjusting the pH to 6.9 with 1 *N* HCl. Fresh stock standard solutions of isoetharine and colterol were prepared in 0.05 *N* H_2SO_4 at concentrations of 100 μg/ml. All glassware was silanized before use.

Preparation of Standards—The chromatographic system was calibrated by analyzing duplicate plasma standards containing 0, 2.5, 5, 10, 20, 40, 60, 80, and 100 ng/ml of free base. The standards were prepared by adding 100-μl aliquots of isoetharine stock standards (made by serial dilution of the 100 μg/ml stock standard solution with 0.05 *N* H_2SO_4) to 1.0 ml of control human plasma (oxalate anticoagulant). Fresh standards were prepared for each analysis set and analyzed with the prepared samples. Values are reported as isoetharine.

Preparation of Spiked Plasma Samples—Two sets of samples, to be analyzed under single-blind conditions, were prepared in triplicate by adding appropriate volumes of isoetharine stock standard solutions to 1.0 ml of human control plasma. One set was analyzed upon preparation; the other set was frozen for 7 days at −70° before analysis.

Analytical Procedure for Spiked Samples—To each tube containing a sample or standard were added 50 ng of internal standard (100 μl of a 500-ng/ml solution in 0.05 *N* H_2SO_4), 2.0 ml of phosphate buffer (pH 6.9) and 10 ml of 1.5% di-(2-ethylhexyl)phosphoric acid in benzene solution. The tube was shaken and centrifuged. The organic phase was transferred, with methanol-washed disposable pipets, to a tube containing 130 μl of 0.2 *N* H_2SO_4. The tube was shaken and centrifuged, and the organic phase was discarded. The tube was placed in the laboratory freezer (−4°) until chromatographic analysis (usually the next day), at which time the aqueous phase was thawed, and a 100-μl aliquot was injected into the chromatograph.

Chromatography—The HPLC was a modular system constructed of commercially available components: a reciprocating pump[7], syringe-loaded injection valve[8], a 5-μm ODS (25 cm × 4.6-mm i.d.) column[9], and an amperometric (electrochemical) detector with a glassy carbon electrode[10]. The chromatographic conditions were as follows: mobile phase, 0.1 *M* Na_2SO_4 (adjusted to pH 2.8 with phosphoric acid and then adjusted to pH 3.0 with NaOH)–methanol (87.5:12.5, v/v); flow rate, 1.2 ml/min (~150 bar); applied potential, +0.60 V *versus* Ag/AgCl (3 *M* NaCl); at ambient temperature; an injection volume of 100 μl; and approximate retention times of 7.5 min for colterol (internal standard) and 9.3 min for isoetharine.

[a] $n = 6$. [b] Mean minimum quantifiable level = 0.92 ng/ml, $n = 2$. [c] Coefficient of variation.

Animal Dosing and Sample Collection—Two groups of six Sprague-Dawley rats[11] each were medicated orally with isoetharine hydrochloride or mesylate. Each animal received the equivalent of 120 mg of isoetharine base *via* a stomach tube as a solution in distilled water. A minimum of 0.2 ml of blood was collected from the orbital sinus in microcentrifuge tubes containing oxalate anticoagulant. Samples were collected prior to medication and at 1, 2, 4, 6, 8, and 10 hr after medication. At 12 hr after medication, blood was collected from the abdominal aorta. The blood was centrifuged and the plasma was separated. The plasma samples were stored in a low-temperature freezer (−70°) until analysis.

In a separate exploratory dose-ranging study, 10 rats/group were medicated orally with isoetharine hydrochloride for 2 weeks at doses of 0, 800, 1400, 2000, and 2500 mg/kg/day. At the end of two weeks, blood samples were obtained from the orbital sinus 1 hr after medication. Plasma was separated and frozen until analysis for isoetharine levels. One rat in the 2500-mg/kg group died during the study.

Sample Preparation—The plasma samples were analyzed by the procedure described for spiked samples with several modifications required because of the small sample volumes. Aliquots of the plasma samples (25–150 μl) were transferred to screw-cap tubes, and 100 μl (5.0 ng) of a solution of colterol (50 ng/ml in 0.05 *N* H_2SO_4) was added as internal standard. Two milliliters of 2% boric acid, 2 g of ammonium sulfate, and 10 ml of 0.5% di-(2-ethylhexyl)phosphoric acid in benzene solution were added. Each tube was shaken and centrifuged, and the organic phase was transferred into a conical tube containing 130 μl of 0.05 *N* H_2SO_4. The tube was shaken and centrifuged; the organic phase was aspirated and discarded. The aqueous phase was frozen until liquid chromatographic analysis on the following day. Duplicate standards containing 0, 0.5, 1, 2, 4, 6, 8, 10, and 15 ng of isoetharine (free base) in 100 μl of control plasma were used for calibration of the chromatograph. Fresh standards were prepared and extracted with each analysis set.

Statistical Analysis—A regression analysis of the peak height ratios (isoetharine/internal standard) obtained for the standards was performed to determine the linearity of the response with respect to concentration. The resulting linear regression was used to estimate the concentrations of isoetharine in the plasma samples. The minimum quantifiable level of the assay was estimated as the concentration whose 80% confidence limit just encompassed zero[12].

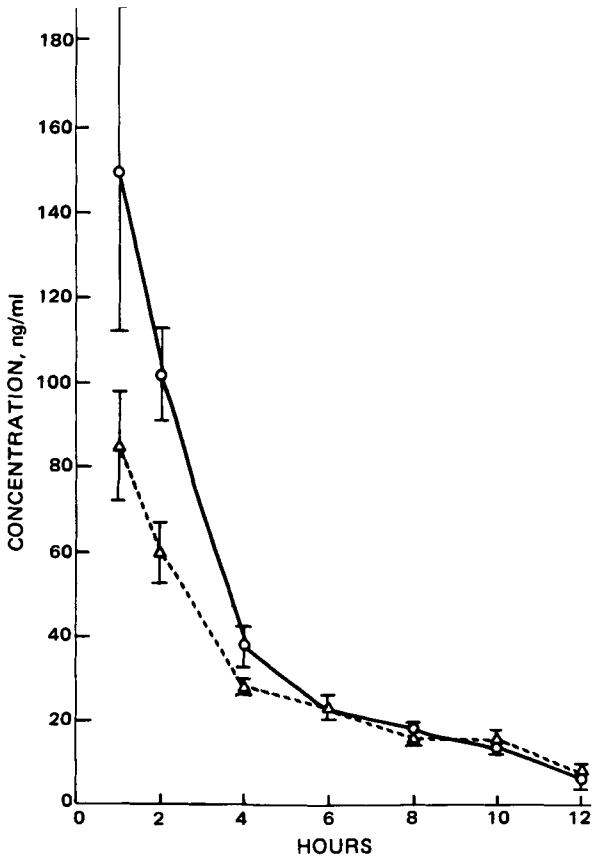

Figure 2—*Plot of mean isoetharine plasma concentration after oral administration of isoetharine hydrochloride or isoetharine mesylate. Key: (○) hydrochloride salt administered; (△) mesylate salt administered. Vertical bars represent the standard error of the mean.*

The assayed levels for the spiked samples were expressed as the percent differences from the nominal values, and a two-way ANOVA with replication was carried out to determine if there was a concentration effect, a time (fresh *versus* frozen) effect, or a concentration times time interaction.

An ANOVA was carried out to determine differences between the two salt forms in terms of maximum observed concentration (C_{max}), the time of the maximum observed concentration (t_{max}), apparent first-order elimination rate constant (K), and the area under the plasma concentration *versus* time curve (AUC). C_{max} and t_{max} were determined by direct observation; the elimination half-life for each rat was determined from a least-squares regression on the logarithm of the 4–12-hr plasma concentration data with time. This assumes first-order elimination kinetics. The AUC was determined from the plasma data by the trapezoidal rule. The data from the dose-ranging study were analyzed by a least-squares regression to determine if observed plasma levels were dose related.

RESULTS AND DISCUSSION

Representative chromatograms of extracted rat plasma standards are shown in Fig. 1. Linear least-squares analysis indicated that peak height ratio (isoetharine/internal standard) *versus* concentration was linear over a range of at least 0 and 0.5–100 ng/ml.

The results of the single-blind analysis of the spiked plasma samples are summarized in Table I. The accuracy of the assay, defined as the mean percent difference from the nominal level was >5%. The estimated assay precision, calculated from the overall mean square error term of the two-way ANOVA, was ±1.9%. The mean (±SE) minimum quantifiable level of the assay was 0.92 (±0.20) ng/ml, n = 2. The mean (±SE) percent recovery of the assay, determined by comparison with unextracted standards, at concentrations of 10, 50, and 100 ng of isoetharine/ml and 50 ng of internal standard/ml, was 78.4 (±2.31%) for isoetharine and 79.1 (±3.6%) for the internal standard.

The two-way ANOVA with replication on the percent differences for the samples indicate neither a concentration effect nor a concentration times time interaction. A highly significant time (fresh *versus* frozen) effect was indicated; however, the trend was to a higher concentration upon freezing. The observed differences were due to a slight difference in the slopes derived from the regression analysis on the standards for the two days, and the difference was statistically significant because of the good precision at each concentration. The observed time effect is considered of little practical significance. The stability of isoetharine and the internal standard in the final acid extract was shown by chromatographing the final acid extract for a set of standards twice, separated by 8 weeks of storage at −4°. The chromatograms obtained on the two days indicated no apparent decomposition of either isoetharine or the internal standard.

The results of the analysis of rat plasma samples, taken after the oral administration of isoetharine hydrochloride and isoetharine mesylate are plotted as means *versus* time of collection in Fig. 2. The mean (±SE) maximum observed plasma concentrations (C_{max}) for the hydrochloride and mesylate salts were 162 (±32) and 92.0 (±9.8) ng/ml, respectively. The mean (±SE) times to C_{max} (t_{max}) were 1.2 (±0.2) and 1.3 (±0.2) hr for the hydrochloride and mesylate salts, respectively.

The area under the plasma concentration *versus* time (AUC) plot was calculated for each rat by the trapezoidal rule using the experimental data. The mean (±SE) AUC was 498 (±56) ng hr/ml for the hydrochloride salt and 344 (±16) ng hr/ml for the mesylate salt.

The apparent first-order elimination rate constant, K, was determined for each animal using the 4- to 12-hr data. The mean (±SE) values of K were 0.21 (±0.04) hr^{-1} for the hydrochloride salt and 0.17 (±0.03) hr^{-1} for the mesylate salt. The corresponding half-lives are 3.3 and 4.1 hr, respectively. It should be emphasized that these are crude estimates of the rate constants since they were determined from data collected over a time period of approximately two half-lives.

ANOVA on the means of C_{max}, t_{max}, and K for the two salts indicated that the differences were not statistically significant ($p \geq 0.05$). The difference between the AUC means for the two salts was significant at the 5% level but not at the 1% level. The hydrochloride salt had the larger AUC (498 ng hr/ml *versus* 344 ng hr/ml).

The observed isoetharine concentrations in rats medicated orally for 2 weeks were highly variable. A least-squares analysis of the data was inconclusive in determining whether the observed plasma levels were proportional to dose in the range of 800–2500 mg/kg.

The formation of an ion-pair with di-(2-ethylhexyl)phosphoric acid provided a simple, rapid means of isolating two exogenous catecholamines from plasma for subsequent quantitation by reversed-phase liquid chromatography. The method is applicable to small (<100 μl) samples and samples up to 2 ml. In this study, the described extraction procedure proved more reliable and gave cleaner chromatograms than adsorption to either alumina or boric acid gels. The usefulness of the assay is demonstrated in that small samples could be analyzed, allowing serial samples to be taken from individual rats, and in the analysis of samples from rats medicated over a 20-fold range of doses.

N-Alkylated Derivatives of 5-Fluorouracil

NITYA G. KUNDU ˣ **and SCOTT A. SCHMITZ**

Received August 24, 1981, from the *School of Pharmacy and LAC-USC Cancer Center, Research Laboratory, University of Southern California, Los Angeles, CA 90033.* Accepted for publication November 16, 1981.

Abstract □ Some *N*-alkyl derivatives of 5-fluorouracil were designed to act as latent depot forms of 5-fluorouracil. A general and efficient method for the syntheses of the alkylated derivatives is described. As expected, the alkylated derivatives of 5-fluorouracil did not show any cytotoxicity in cell culture systems even up to 10^{-4} *M* concentration. The synthesis of 1,3-dimethyl-5-fluoro-5,6-dihydrouracil is also described.

5-Fluorouracil (I) and its deoxyribonucleoside derivative, flouridine (II), have been found to be highly effective compounds for the treatment of various solid tumors (1–3). The tetrahydrofuryl derivative (III) of 5-fluorouracil has also been found to be clinically active (4). Efforts have been made to improve upon the efficacy of these drugs (5–11).

III, R = 

Recently, 1-alkyl carbamoyl derivatives (IV) of 5-fluorouracil have been tested as masked forms of 5-fluorouracil and several of them have been found to be promising (12, 13). The synthesis and antitumor properties of various *N*-acyl and *N*-(alkoxycarbonyl)-5-fluorouracil derivatives (V) which probably act as depot forms of 5-fluorouracil have been reported (14). 5′-*O*-Glucuronide of 5-fluorouridine (VI) has been described recently (15). This is expected to be activated by the β-glucuronidase activity in tumor cells.

VI

In view of the success of the various acyl, alkoxycarbonyl, and carbamoyl derivatives of 5-fluorouracil, the authors became interested in suitable *N*-alkyl derivatives of 5-fluorouracil in which an activated methylene group is attached to the nitrogen atom of the fluorouracil ring. These compounds could act as latent depot forms of 5-fluorouracil (Scheme I). In this report, a general method for the syntheses of various N_1, N_3-dialkyl (VII–X) and N_1-monoalkyl (XI and XII) derivatives of 5-fluorouracil and the study of their toxicities in cell culture systems are reported. In addition, the synthesis of N_1, N_3-dimethyl-5-fluoro-5,6-dihydrouracil (XIII), a model for 5-fluoro-5,6-dihydrouracil, which is an intermediate in the catabolism of 5-fluorouracil, is also described.

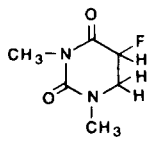
XI, R = $CH_2C_6H_5$

XII, R = $CH_2-CH=CH_2$



XIII

RESULTS

Chemistry—The direct *N*-alkylation of 5-fluorouracil has been studied previously (16). It was observed that by using dimethyl sulfoxide as solvent and potassium carbonate as base, alkylation of 5-fluorouracil with unreactive halides led to N_3-alkylation, whereas with reactive halides, alkylation was found to be N_1-alkylation. However, formation of N_1, N_3-dialkyl derivatives was not described. Since among the acyl derivatives of 5-fluorouracil, the diacylated derivative, N_1-acetyl-N_3-*O*-toluyl-5-fluorouracil was found to be the most promising (14), there has been a greater interest in studying the dialkylated species of 5-fluorouracil. Preformation of the potassium salts[1] of 5-fluorouracil and subsequent reaction of the potassium salts with different alkylating agents led to excellent yields of the alkylated species. The formation of the potassium salts of 5-fluorouracil was accomplished in dimethylformamide as a solvent in the presence of potassium carbonate as a base. The process was found to be relatively slow at room temperature and was completed by overnight stirring when a thick gel of the potassium salts of 5-fluorouracil was formed. Reaction of the gel with different alkylating agents yielded either a mixture of monoalkyl and dialkyl products or, exclusively, the dialkyl products dependent upon the amount of the alkylating agents used. However, in all cases the total yields of the alkylated species (as shown in Table I) were very high compared with the other reported methods (16–18) of alkylation. In Table II are shown the different proportions of mono- and dialkylated species which could be obtained by using different amounts of the alkylating agents.

[1] Probably a mixture of N_1-mono, N_3-mono, and N_1, N_3-dipotassium salts is formed.

The structures of the alkylated species were established by elemental analyses and by spectroscopic methods. The compounds gave satisfactory carbon, hydrogen, nitrogen, and fluorine analyses (Table I). In mass spectral measurements (see Experimental) all the compounds showed the molecular ions, and their fragmentation patterns confirmed their structures. The UV absorption spectra (Table III) of the dialkylated species showed them to be the N_1, N_3-dialkylated species. The monoalkylated species were found to be the N_1-alkylated derivatives by comparison of their melting points with those reported in the literature (16, 17) and also from the independence of their UV absorptions in neutral, acidic, and basic media (Table III). No N_3-alkylated compounds were isolated under the reaction conditions. A comparison of the PMR spectra of the mono- and dialkylated derivatives (Table IV) showed that N_1-CH_3 and N_1-CH_2- groups have higher field chemical shifts than the corresponding N_3-CH_3 and N_3-CH_2-groups. This provides an independent method for the identification of N_1- and N_3-substituted alkyl derivatives of 5-fluorouracil.

5-Fluoro-5,6-dihydrouracil is an intermediate in the catabolic degradation of 5-fluorouracil, and has been synthesized (2) in an extremely small yield by the catalytic hydrogenation of 5-fluorouracil. Lithium tri-*sec*-butyl borohydride has been used for the reduction of α,β-unsaturated ketones and esters to the corresponding saturated ketones and esters (19, 20). Recently, this reagent has been used successfully for the reduction of the 5,6-double bond of uracil and 5-fluorouracil derivatives (21). When 1,3-dimethyl-5-fluorouracil was reduced with lithium tri-*sec*-butyl borohydride, a quantitative yield of crystalline 1,3-dimethyl-5-fluoro-5,6-dihydrouracil (XIII) was obtained. Its structure was established by elemental analysis, lack of UV absorption, and its PMR spectrum. In the mass spectrum, a very strong peak due to the parent molecular ion was seen, confirming the structure of the compound.

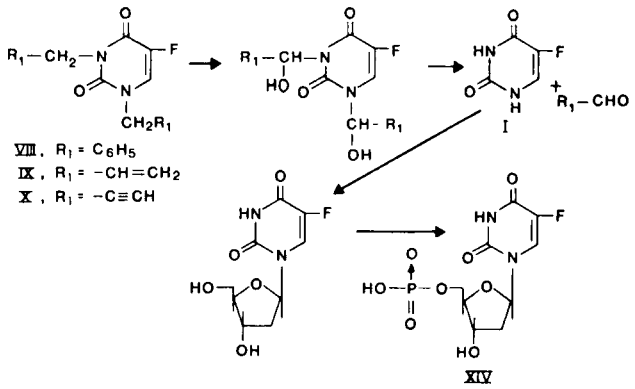
[a] The absorptions could not be determined due to a solubility problem.



Scheme I

Growth Inhibition Studies—The growth inhibitory effects of the compounds (VII–XII) were studied against L-1210 (22) and CCRF-CEM leukemic cells in culture (23). As expected, none of the compounds showed any significant cell inhibitory effects even at concentrations up to 10^{-4} *M*.

DISCUSSION

N_1, N_3-Dialkylated (VII–X) and N_1-monoalkylated (XI and XII) derivatives of 5-fluorouracil were synthesized by a simple and highly efficient method. These compounds were chosen since they either have a small alkyl group (*e.g.*, methyl) or an active methylene group (attached to an unsaturated center) on nitrogen. These compounds, as expected, were found to have very little toxicity against leukemic cells in culture. However, like many anticancer agents (24, 25), these compounds could be activated by an oxidative mechanism (26, 27) in the whole animal as shown in Scheme I[2]. A slow formation of 5-fluorouracil (I) could provide the active compound (XIV) in a small steady state. Also, since the alkylated derivatives are much more soluble in nonpolar solvents in contrast to 5-fluorouracil, they are expected to have different pharmacological characteristics compared with 5-fluorouracil. Further biological studies of these compounds are in progress.

[2] Alternative metabolic transformation leading probably to inactive products are not ruled out by Scheme I.

5-Fluoro-5,6-dihydrouracil is an intermediate in the catabolism of 5-fluorouracil. There is no convenient method available for the synthesis of this compound. A highly efficient method for the synthesis of 1,3-dimethyl-5-fluoro-5,6-dihydrouracil has been developed. This compound in combination with 5-fluorouracil may show different toxicities to tumor systems. This aspect is also under extensive study.

EXPERIMENTAL[3]

***N_1, N_3*-Dimethyl 5-Fluorouracil (VII)**—5-Fluorouracil (2.0 g, 15.4 mmoles) was dissolved in dimethylformamide (50 ml) when a clear solution was formed. To this solution powdered anhydrous potassium carbonate (4.2 g, 30.4 mmoles) was added, and the mixture was stirred overnight at room temperature when a thick white gel of the potassium salts of 5-fluorouracil was formed. Methyl iodide (4.2 g, 29.6 mmoles) was added and the mixture was stirred for 3 days at room temperature. Dimethylformamide was removed under high vacuum and the residue was partitioned between chloroform (200 ml) and water (100 ml). The aqueous layer was again extracted with chloroform (2 × 100 ml). The combined chloroform extract was dried over anhydrous magnesium sulfate, filtered, and solvent was removed to yield a crystalline white solid (2.2 g, 13.9 mmoles, 90%), single spot on TLC, R_f = 0.12, 0.25, and 0.91 in Solvents A, B, and C, respectively. On crystallization from absolute ethanol this yields long white needles, mp 130–131° [lit. (18) mp 128–130°]; ν_{max} 3070, 1702, and 1650 cm^{-1}; MS m/z 158 (M^+, 100%).

***N_1,N_3*-Dibenzyl-5-fluorouracil (VIII) and *N_1*-Benzyl-5-fluorouracil (XI)**—Benzyl bromide (7.8 g, 45.6 mmoles) was added to the potassium salts of 5-fluorouracil made by stirring 5-fluorouracil (3 g, 23 mmoles) and anhydrous potassium carbonate (6.3 g, 45.6 mmoles) in dimethylformamide (80 ml). The mixture was stirred at room temperature for 6 days. Dimethylformamide was removed and the residue partitioned between chloroform and water. The chloroform extracts on removal of solvent yielded an oil which was chromatographed on silica gel. The column was washed with petroleum ether (bp 35–60°, 300 ml) and then the dibenzyl derivative (VIII) was eluted with chloroform–ethyl acetate (15:1 Fractions 2–4, total volume 250 ml) and was obtained on removal of solvent as a gum (6 g, 19.4 mmoles, 84%); TLC, R_f = 0.38, 0.90, and 0.95 in Solvents A, B, and C respectively; IR ν_{max} 3040, 3080, 1710, 1720, 1660, 1650 cm^{-1}; MS m/z 310 (M^+, 51.7%), 219 (M^+ − 91, 19.3%), 91 ($C_6H_7^+$, 100%).

***N_1*-Benzyl-5-fluorouracil (XI)**—N_1-Benzyl-5-fluorouracil was eluted with chloroform–methanol (10:1 fractions 6–7). On removal of solvent, a white solid (300 mg, 1.4 mmoles, 6%) was obtained. This was crystallized from absolute ethanol as white plates, mp 170° [lit. (16) mp 170–171°]; TLC R_f 0.06, 0.08, and 0.81 in solvents A, B, and C, respectively; IR ν_{max} 3070, 1720, 1665 cm^{-1}; MS m/z 220 (M^+), 91 ($C_7H_7^+$, 100%).

***N_1, N_3*-Diallyl-5-fluorouracil (IX) and *N_1*-Allyl-5-fluorouracil (XII)**—The potassium salts of 5-fluorouracil (10 g, 76.6 mmoles) were made by stirring with anhydrous potassium carbonate (11 g, 79.7 mmoles) in dimethyformamide (50 ml). Allyl bromide (12 g, 100 mmoles) was added and the mixture was stirred for 1 week at room temperature. Dimethylformamide was removed under vacuum and the residue was treated with water (100 ml) and 6 *N* HCl to pH 4. The mixture was extracted with methylene chloride. The methylene chloride layer was washed with water, dried over anhydrous magnesium sulfate, and solvent was removed yielding a gummy semisolid residue which was chromatographed on silica gel (40–140 mesh). The column was washed with petroleum ether (bp 40–60°) and then diallyl-5-fluorouracil (IX, 6.7 g, 31.9 mmoles, 41.5%) was eluted with methylene chloride. The monoallyl-5-fluorouracil (XII, 4.24 g, 24.9 mmoles, 32.4%) was eluted with methylene chloride–ethyl acetate (15:1) and chloroform–methanol (10:1). N_1, N_3-Diallyl-5-fluorouracil was crystallized from absolute ethanol in the cold as long white needles, mp 38°; TLC, R_f = 0.27, 0.69, and 0.98 in solvents A, B, and C, respectively; IR ν_{max} 1650, 1680 cm^{-1}; MS m/z 210 (M^+, 26.5%). N_1-Monoallyl-5-fluorouracil was crystallized from absolute ethanol in small white needles, mp 125–126°; TLC, R_f = 0.07, 0.08, and 0.71 in Solvents A, B, and C, respectively; IR ν_{max} 1650, 1680 cm^{-1}; MS m/z 170 (M^+).

***N_1,N_3*-Dipropargyl-5-fluorouracil (X)**—To the potassium salts made from 5-fluorouracil (5 g, 38.5 mmoles) and anhydrous potassium carbonate (8.0 g, 57.9 mmoles) in dimethylformamide (160 ml), propargyl bromide (9.5 ml of 80% solution in toluene) was added and stirred at room temperature for 4 days. Dimethylformamide was removed under high vacuum and the residue was partitioned between water (10 ml) and methylene chloride (300 ml). The methylene chloride layer was washed with water, dried over anhydrous magnesium sulfate, and solvent removed to obtain a residue (7.3 g, 35.42 mmoles, 92%) which crystallized readily at room temperature. The material was crystallized from methylene chloride into long colorless needles, mp 98°; TLC, R_f 0.23, 0.67, and 0.98 in solvents A, B, and C, respectively; IR ν_{max} 3280 (≡CH), 1655, 1670, 1718 cm^{-1}; MS m/z 206 (M^+), 167 (M^+—CH_2—C≡CH).

***N_1,N_3*-Dimethyl-5-fluoro-5,6-dihydrouracil (XIII)**—N_1, N_3-Dimethyl-5-fluorouracil (316 mg, 2 mmoles) was dissolved in dry tetrahydrofuran (10 ml) and cooled in a dry ice–acetone bath under argon atmosphere. Lithium tri-*sec*-butyl borohydride (2.2 ml of 1 *M* solution in tetrahydrofuran) was injected and the mixture was stirred in a dry ice–acetone bath for 10 min. The mixture was decomposed with saturated ammonium chloride solution which was injected and stirred in the cold bath for another 10 min. Tetrahydrofuran was removed under aspirator and the residue was extracted with methylene chloride. The methylene chloride layer was washed with water, dried over anhydrous magnesium sulfate, and solvent was removed to obtain a thick liquid which was chromatographed over silica gel. Compound XIII was eluted with methylene chloride–ethyl acetate (15:1). On removal of solvent, a thick colorless liquid (315 mg, 1.97 mmoles, 98.5%) was obtained which crystallized from ethanol, mp 51°; TLC, R_f = 0.15, 0.33, and 0.94 in Solvents A, B, and C, respectively; IR ν_{max} 1728, 1690 cm^{-1}; MS m/z 160 (M^+, 100%).

Growth Inhibition Assay—L-1210 cells and CCRF-CEM cells were grown in medium[4] supplemented with 10% dialyzed fetal calf serum with

[3] Melting points were determined on a Thomas-Hoover melting point apparatus and are uncorrected. The UV spectra were recorded on a Beckman model 25. Spectra were taken in 95% ethanol unless otherwise mentioned. The IR spectra were done on a Beckman 4210 in a fluorinated hydrocarbon. PMR spectra (δ) were recorded on a Varian EM-390 90-MHz NMR spectrometer in deuterated chloroform, using tetramethylsilane as internal reference. Elemental analyses were performed by Galbraith Laboratories, Inc., Knoxville, Tenn., or Spang Microanalytical Laboratory, Ann Arbor, Mich. Mass spectra were taken on a Hewlett-Packard, model 5985 spectrophotometer. TLC was performed on an Eastman Chromagram sheet (6060 silica gel with fluorescent indicator) in the indicated solvents: Solvent A, chloroform; Solvent B, methylene chloride–ethyl acetate (15:1); Solvent C, chloroform–methanol (10:1); R_f's for 5-fluorouracil are 00.0, 00.0, and 0.26 in Solvents A, B, and C, respectively.

[4] Roswell Park Memorial Institute (RPMI) 1640.

a doubling time of 10–12 and 18–24 hr, respectively. The solutions were diluted to a stock solution of 10^{-3} *M* with phosphate-buffered saline, sterilely filtered, and aseptically diluted by half-log increments. Each concentration (0.7 ml) was added to duplicate 13- × 75-mm test tubes. Cells from logarithmically growing stock culture were suspended in prewarmed medium[4] supplemented with 10% dialyzed fetal calf serum, 10 m*M* (morpholine-propanesulfonic acid, and 20 m*M* [*N*-(2-hydroxyethyl)piperazine-*N'*-2-ethanesulfonic acid]. Cell suspension (1.8 ml) was added to each tube. The tubes were incubated upright at 37° in a warm room or dry incubator. Under these conditions, L-1210 cells grew exponentially 15- to 25-fold from an initial density of 2–2.5 × 10^4/cm^3; CCRF-CEM cells grew exponentially 8- to 10-fold. After 48 hr (for L-1210 cells), or 72 hr (for CCRF-CEM cells), the incubation was terminated and the cell densities were determined[5]. The degree of proliferation of each 2-ml culture was expressed as the ratio of the final cell density to the initial cell density; this index was plotted against the drug concentration employed. The concentration of drug which depresses the ratio to 50% of control (the IC_{50}) was graphically determined. For the clinically effective drug, 5-fluorouracil, IC_{50} = 1.9 × 10^{-6} *M* for CCRF-CEM cells in culture.

High-Pressure Liquid Chromatographic Assay of Cloxacillin in Serum and Urine

F. W. TEARE *x, R. H. KWAN, M. SPINO, and S. M. MacLEOD

Received April 6, 1981, from the * *Faculty of Pharmacy, University of Toronto, Toronto, Canada, M5S 1A1* and the *Department of Clinical Pharmacology, The Hospital for Sick Children, Toronto, Canada.* Accepted for publication September 2, 1981.

Abstract □ Two rapid, specific, and sensitive high-pressure liquid chromatographic (HPLC) assays were developed for cloxacillin in serum and urine. A reversed-phase column (RP-8) was selected for use with two different sets of HPLC conditions and sample pretreatment procedures. Cloxacillin extraction efficiencies are reported from serum and urine. Equations are presented for linear relationships between peak height or peak area ratios of cloxacillin to nafcillin (internal standard) and the cloxacillin concentration over a range of 0–80 μg/ml. The sensitivity limit of these assays was ~0.3 μg/ml of a standard solution for one method and 0.05 μg/ml for the other HPLC assay.

Keyphrases □ Cloxacillin—high-pressure liquid chromatographic assay, serum, urine, nafcillin □ Nafcillin—cloxacillin, high-pressure liquid chromatographic assay, serum, urine □ High-pressure liquid chromatography—cloxacillin in serum and urine □ Penicillins—high-pressure liquid chromatography of cloxacillin

Cloxacillin sodium (I), [3-(*o*-chlorophenyl)-5-methyl-4-isoxazoyl] penicillin sodium, is a semisynthetic penicillin synthesized in 1962 (1). It can be administered both parenterally and orally. Like other penicillins, I is sensitive to nucleophilic and electrophilic attack catalysed by general bases and acids, respectively. Maximum stability of

High-Pressure Liquid Chromatographic Assay of Cloxacillin in Serum and Urine

F. W. TEARE *x, R. H. KWAN, M. SPINO, and S. M. MacLEOD

Received April 6, 1981, from the * *Faculty of Pharmacy, University of Toronto, Toronto, Canada, M5S 1A1* and the *Department of Clinical Pharmacology, The Hospital for Sick Children, Toronto, Canada.* Accepted for publication September 2, 1981.

Abstract □ Two rapid, specific, and sensitive high-pressure liquid chromatographic (HPLC) assays were developed for cloxacillin in serum and urine. A reversed-phase column (RP-8) was selected for use with two different sets of HPLC conditions and sample pretreatment procedures. Cloxacillin extraction efficiencies are reported from serum and urine. Equations are presented for linear relationships between peak height or peak area ratios of cloxacillin to nafcillin (internal standard) and the cloxacillin concentration over a range of 0–80 μg/ml. The sensitivity limit of these assays was ~0.3 μg/ml of a standard solution for one method and 0.05 μg/ml for the other HPLC assay.

Keyphrases □ Cloxacillin—high-pressure liquid chromatographic assay, serum, urine, nafcillin □ Nafcillin—cloxacillin, high-pressure liquid chromatographic assay, serum, urine □ High-pressure liquid chromatography—cloxacillin in serum and urine □ Penicillins—high-pressure liquid chromatography of cloxacillin

Cloxacillin sodium (I), [3-(*o*-chlorophenyl)-5-methyl-4-isoxazoyl] penicillin sodium, is a semisynthetic penicillin synthesized in 1962 (1). It can be administered both parenterally and orally. Like other penicillins, I is sensitive to nucleophilic and electrophilic attack catalysed by general bases and acids, respectively. Maximum stability of

0022-3549/82/0800-0938$01.00/0

I occurs at pH 6.3 (2). The pKa of the carboxylic hydrogen is reported as 2.70–2.73 in water at 25° (3). Cloxacillin is 94–96% bound to serum proteins (4).

Previously reported assays for I include those based on spectrophotometry (5–10), titrimetric methods (6), microbiological methods (6, 7), an electrophoretic method (11), a polarimetric procedure (12), and an HPLC method for aqueous solutions (13).

Paper chromatograms of urine and serum samples following oral administration of I showed a similar ratio of unchanged I and a metabolite (14). Intramuscular injection of I is reported to give rise to metabolite formation as well. Cole *et al.* (15) reported that 21.6% of I appeared as the penicilloic acid metabolite in urine collected within 12 hr of a 500-mg oral dose but that none was found at half this dose.

Prompted by the apparent absence of any reported HPLC assay for cloxacillin in human serum or urine, two such methods were developed and are reported in this paper. These methods were developed for clinical studies and preliminary pharmacokinetic evaluation of I (16).

EXPERIMENTAL

The two distinct sets of HPLC assay conditions reported here will be referred to as HPLC Systems I and II. System I: RP-8 column; mobile phase, methanol–aqueous 0.04 *M* NaH_2PO_4 (4.1:5.9), pH 4.5; flow rate, 1.1 ml/min; detection wavelength, 225 nm; chart speed, 0.508 cm/min; retention time, cloxacillin, 8.75 min and nafcillin, 15.80 min. System II: RP-8 column; mobile phase, acetonitrile–aqueous 0.04 *M* NaH_2PO_4 (6.2:20), pH 4.5; flow rate, 1.6 ml/min; detection wavelength, 210 nm; chart speed, 0.508 cm/min; retention time, cloxacillin, 5.10 min and nafcillin, 6.60 min. Likewise, two different sample pretreatment procedures were used and are referred to as Procedures A and B.

Materials—A 10-cm × 4.6-mm i.d. stainless steel column[1] containing a chemical bonded reversed-phase (C_8) on 10-μM silica was selected. The modular HPLC system was comprised of a pump[2], an injection valve[3], a guard column[4], a variable wavelength UV-detector[5], and an integrator-plotter[6]. Other equipment used included a centrifuge[7] and mechanical mixer[8]. All inorganic buffer salts and acids were analytical grade and were dissolved in reagent grade water[9]. Organic solvents were acetonitrile[10] and methanol[10].

Mobile Phases I and II were deaerated and filtered through 1.0-μM pore membranes[11] under reduced pressure.

Standard Solutions—Cloxacillin sodium[12] (I) and nafcillin sodium[13] (II) were used as received for weekly preparation of stock standard and stock internal standard solutions, respectively. Human control serum[14] and control urine were used in the daily preparation of working standard solutions as well as simulated samples. Standard solutions of I were prepared in water, control serum, and control urine as follows: to each of seven appropriately labeled tubes[15] was added in succession 0.5 ml of water (or urine or serum), 0.01 ml of one of the working standards of I in the 0–54.3-μg range, and 0.05 ml (equivalent to 12.0 μg of II) of internal standard solution. The contents of each tube were thoroughly mixed by the mechanical mixer. These standards and similar simulated samples were subjected to one or the other of the pretreatment Procedures A or B, to compensate for recovery losses and other systematic errors.

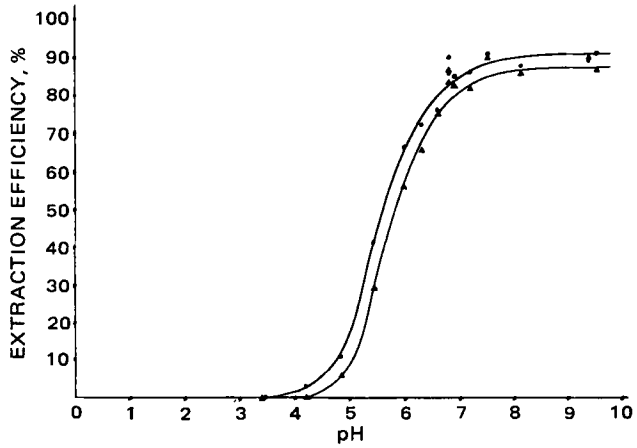

Figure 1—*Extraction efficiency of cloxacillin (●) and nafcillin (▲) from urine as a function of pH of the 0.04-*M *sodium dihydrogen phosphate buffer.*

Standard and Sample Pretreatment Procedures—*Procedure A*—Protein precipitation was performed by adding dropwise 0.5 ml of acetonitrile to a 0.5-ml sample of serum (or urine) in a small tube. This was followed by agitation for 20 sec by the mixer and centrifugation at 3000 rpm for 1 min. The clear supernate was filtered[16], and 10 μl of the filtrate was injected onto the column.

Procedure B—A drug extraction and back extraction procedure was performed as follows: to 0.5 ml of serum (or urine), in a small test tube, was added 0.05 ml of internal standard solution, equivalent to 12.0 μg of II. Then 0.05 ml of 1 *M* H_2SO_4 was added and the tube was mixed for 5 sec. Two milliliters of methylene chloride[17] was added and the tube was shaken for 2 min prior to centrifugation at 2000 rpm for 2 min. The organic layer was transferred to a second tube containing 1.0 ml of aqueous 0.04 *M* NaH_2PO_4, pH 6.80. This tube was stoppered and the shaking and centrifugation steps were repeated. An aliquot equivalent to ~75% of the aqueous layer containing the penicillins was transferred to a third tube, which was agitated vigorously on the mixer for 20 sec to dispel the volatile methylene chloride carried over in the aqueous layer. Injections (10 μl) of the final assay solution were used. Either integrated peak area ratios or peak height ratios of I–II were calculated and referred to a standard curve similarly constructed with standard solutions of I in accordance with the internal standard assay method. The sample concentrations were reported as micrograms of I per milliliter of serum or urine.

Precision and sensitivity limits were estimated for these assays.

RESULTS AND DISCUSSION

Preliminary trials were made using three reversed-phase columns[18] and mobile phases consisting of various ratios of aqueous buffers and either methanol or acetonitrile. Simple mixtures of water and methanol or acetonitrile proved inadequate for these assays. The effect of buffer pH was studied (16). The best results were obtained with an RP-8 column using aqueous 0.04 *M* NaH_2PO_4, pH 4.5, blended with methanol or acetonitrile in HPLC Systems I and II, respectively. These systems provided adequate resolution at desirable retention times. The wavelength of detection was selected to give maximum sensitivity consistent with minimum interference from trace endogenous biological materials. The method of sample pretreatment was developed to minimize interferences arising from the biological fluids.

Pretreatment Procedure A involving a simple protein precipitation step produced good results when HPLC System I was used. However, the addition of acetonitrile diluted the sample and, hence, decreased the level of sensitivity for I in the method. Procedure B involved the extraction of the undissociated acid forms of penicillins I and II with methylene chloride, followed by back-extraction of the ionized forms into aqueous phosphate buffer, pH 6.8. This procedure reduced the level of endogenous

material interference and enhanced the sensitivity of the assay for I and II through the use of a detection wavelength of 210 nm.

Figure 1 shows the pronounced effect of buffer pH on the extraction efficiency of penicillins I and II in pretreatment Procedure B. A pH of 6.80 gave near optimal recovery and remains within the pH range of compatibility for these reversed-phase columns. A greater level of interference by endogenous biological materials occurs as the buffer pH becomes >pH 7.0 (16). The methylene chloride volume used in Procedure B also markedly affects the overall extraction efficiency of I and II. A 1:1 volume ratio of methylene chloride–serum produced a troublesome gelatinous globule due to proteins present. Although volume ratios of 4:1 or 5:1 gave similar and good drug recoveries, 6:1 or larger ratios caused lower recoveries of these drugs (16). The 4:1 volume ratio of methylene chloride–serum was selected for the sample (or standard) serum pretreatment Procedure B. The length of exposure of drugs I and II to sulfuric acid (Procedure B) is critical. This exposure to acid must be minimized and fixed at a value of <5 min. It has been found that ~1.5% of cloxacillin and 6.4% of nafcillin are degraded during 5 min when exposed to this strong mineral acid. Fortunately, this exposure to acid can easily be reduced if only a few serum samples are extracted at one time. The absence of degraded I and II peaks on HPLC chromatograms of samples pretreated by Procedure B indicates that insignificant, if any, degradation occurred during this short extraction period.

Figure 2 shows a representative chromatogram of cloxacillin and internal standard, nafcillin, extracted by Procedure B and chromatographed by System II, except that a longer column[19] of the same type packing was used. Figure 2 also shows the influence of the guard column. Figure 3 shows a typical chromatogram obtained with the shorter RP-8 column[18], using otherwise identical conditions. Note the small peak at 3.70 min due to residual methylene chloride, which was not adequately removed from this sample as it was in the normal procedure for Procedure B. This shorter RP-8 column had an advantage in that time and solvents were saved due to the shorter retention times for penicillins I and II.

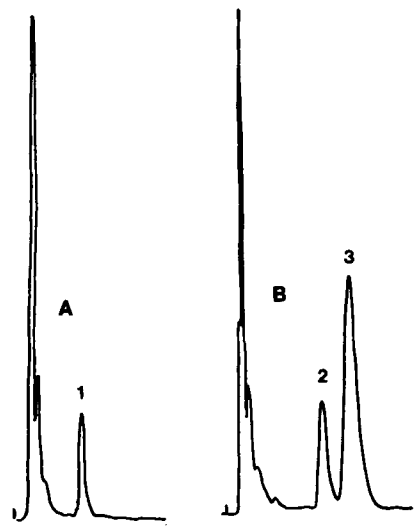

Figure 3—*Cloxacillin extracted from serum and chromatographed on a 10-cm × 4.6-mm i.d. RP-8 column. (A) Blank serum extract showing Peak 1 due to unremoved methylene chloride (3.70 min); (B) serum extracted cloxacillin (Peak 2, 5.3 min) and nafcillin (Peak 3, 6.85 min).*

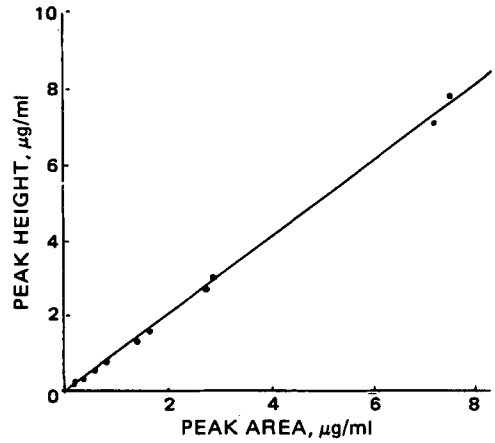

Figure 4—*Comparison of the serum cloxacillin concentrations from two human males as assayed by the internal standard method using peak height ratio and peak area ratio of cloxacillin to nafcillin. Linear regression analysis of this plot yields the equation* $y = 1.0117x - 0.0452$, *with a coefficient of correlation,* $r = 0.9990$. *A 250-mg iv dose of cloxacillin was given to each volunteer.*

The mean absolute extraction efficiencies for six replicate cloxacillin standards using Procedure B were 83.4 ± 1.4% *SD*, coefficient of variation (*CV*) = 1.6 and 91.4 ± 3.5%, *CV* = 3.8%, from serum and urine standards, respectively (16). Similarly determined mean extraction efficiencies for nafcillin (internal standard) were 78.9 ± 1.4%, *CV* = 1.8% and 84.5 ± 2.8%, *CV* = 3.3% for serum and urine standards, respectively. Neither serum nor urine standards containing both penicillins I and II gave rise to any extra peaks which could not be accounted for when the assay involved the pretreatment Procedure B with HPLC System II. This suggests the absence of any significant *in vitro* acid degradation of I and II. These reproducible high recoveries from both biological fluids ensure rather acceptable sensitivity for these assays of cloxacillin.

The precision of the HPLC System II was determined using a simulated serum sample containing 5 μg of I and 1.5 μg of II as well as 0.5 ml of control human serum. Sample pretreatment Procedure B was used and six replicate 10-μl injections of the final assay solution were assayed according to HPLC System II in which peak height ratios were calculated. The mean peak height ratio of I–II was 3.273 ± 0.032, *CV* = 1.0%.

The minimum quantitative limit, defined here as a signal–noise ratio of 3, for cloxacillin in an aqueous standard was ~0.3 μg/ml using HPLC System I and 0.05 μg/ml using HPLC System II. These do not represent overall assay sensitivity limits, since no pretreatment procedures were employed.

In the assay of cloxacillin using sample pretreatment Procedure B and HPLC System II, either peak height ratios or integrated peak area ratios of I–II can be used. Twelve serum samples were obtained from two male humans after different times following infusion of 250 mg iv of cloxacillin. Duplicate aliquots of each sample were extracted using Procedure B and assayed with HPLC System II. Figure 4 shows a comparison of the two methods of plotting, through regression analysis[20], in which the coefficient of correlation ($r = 0.9990$) indicates excellent agreement. Therefore, either I–II ratio can be used in the preparation of the internal standard method calibration curve for I. Figure 4 also confirms the excellent reproducibility of this assay over the concentration range used. The equation obtained by regressional analysis of the serum calibration curve, using peak height ratios of I–II *versus* concentration of I in six cloxacillin serum standards assayed by the same procedure, was $y = 0.591x + 0.0162$, ($r = 0.9976$).

Since both penicillins were somewhat more efficiently extracted

[19] Lichrosorb RP-8 packing in a HiBar II column, 25-cm × 4.6-mm i.d., EM Lab Inc., E. Merck, Darmstadt, W. Germany.

[20] Hewlett-Packard calculator model 9100A; Plotter, model 9125B; and program cards, model 9100.

(Procedure B) from urine than from serum, the calibration curves for I in these two biological fluids differed slightly. These calibration curves can be represented by equations obtained through linear regressional analysis: $y = 0.0437x + 0.0070$, ($r = 0.9991$) and $y = 0.0462x + 0.0270$, ($r = 0.9985$) for serum and urine cloxacillin standards, respectively. In these equations, y equals the integrated peak area ratio of I–II, and x equals the cloxacillin standard concentration in the serum or urine. HPLC System II was used to obtain these calibrations. The cloxacillin concentration covered the 0–80 μg/ml range of biological fluid.

The specificity of either HPLC System I or II is indicated by the fact that no endogenous material, metabolite of I, or degradation product of I or II gave peaks having the same retention times of I or II in chromatograms of *in vivo* serum or urine or of simulated *in vitro* serum or urine samples. The same was true for aqueous solutions of I or II deliberately degraded under acidic or alkaline conditions (16). No interfering peaks were detected in HPLC System II from extracts of human or rabbit serum or of human urine following intravenous administration of cloxacillin. Many other drugs which might be administered during cloxacillin therapy failed to interfere with this HPLC assay. The specific drugs tested for interference were penicillin G, amoxicillin, ticarcillin, carbenicillin, cephalexin, ampicillin, theophylline, acetaminophen, hydrocortisone acetate, vitamins A, C, D and E, and chloramphenicol (16). While this is not an exhaustive list, it represents many drugs that might be found in conjunction with I in urine or serum. Diazepam might partially interfere with this HPLC assay if its serum level is high (16).

The assay method involving pretreatment Procedure A and HPLC System I was initially developed to assay cloxacillin in human serum and urine but has also been used to determine I in rabbit plasma and serum. The same assay was used to establish that 51.35% of an intravenous dose of cloxacillin was excreted unchanged in the urine of one 75-kg human male volunteer within 24 hr. An extra peak was observed not previously seen in *in vitro* urine samples of cloxacillin. The peak may represent a metabolite, since it is not identical to any acidic or alkaline-degraded I peak. Cloxacillin had half-life values ($t_{1/2}$) of 26.9 and 26.5 min in two healthy human male volunteers who received intravenous doses of I (16). These values are in reasonable agreement with a reported value of 33 min in normal human adults (17). The overall elimination rate constants determined in the same two persons were 0.0258 min^{-1} and 0.0262 min^{-1} (16) and compare favorably with a reported value of 0.021 ± 0.003 min^{-1} (17).

In summary, two successful HPLC assays, together with serum and urine sample pretreatment procedures, have been developed. Pretreatment Procedure A used with HPLC System I, while slower, is superior for the resolution of peaks for I and II from each other and all biological endogenous materials or degradation compounds of I or II. The assay including pretreatment Procedure B and HPLC System II is preferred for the rapid assay of unchanged cloxacillin in urine and serum. This assay is specific, sensitive, rapid, precise, and has sufficient accuracy for the intended purposes.

Prolongation of Drug Half-Life due to Obesity: Studies of Desmethyldiazepam (Clorazepate)

DARRELL R. ABERNETHY [x], DAVID J. GREENBLATT, MARCIA DIVOLL, and RICHARD I. SHADER

Received August 17, 1981, from the *Division of Clinical Pharmacology, Departments of Psychiatry and Medicine, Tufts University School of Medicine and New England Medical Center Hospital, Boston, MA 02111.* Accepted for publication November 20, 1981.

Abstract □ Desmethyldiazepam pharmacokinetics were determined after oral administration of its precursor, clorazepate, to 12 obese subjects (mean weight: 105.4 kg; mean percent ideal body weight: 170%) who were matched for age, sex, and smoking habits with 12 normal controls (66.5 kg; percent ideal body weight: 103.3%). After an overnight fast, a single 15-mg clorazepate capsule, equivalent to 10.3 mg of desmethyldiazepam, was administered. Multiple plasma samples drawn 10–42 days postdose were analyzed for desmethyldiazepam by electron-capture GLC. Obese subjects compared to controls had a prolonged desmethyldiazepam elimination half-life ($t_{1/2}$) (154.1 hr *versus* 57.1 hr; $p < 0.005$). Assuming quantitative conversion of clorazepate to desmethyldiazepam and 100% systemic availability, volume of distribution (V_d) was greatly increased in the obese (158.8 liters *versus* 63.3 liters; $p < 0.001$). The value of V_d remained greater even after correction for body weight (1.52 liter/kg *versus* 0.94 liter/kg; $p < 0.005$). However, clearance of desmethyldiazepam was not different between groups (13.2 ml/min in obese *versus* 13.4 ml/min in controls). The percent ideal body weight was highly correlated with V_d ($r = 0.82$), as was total body weight ($r = 0.86$). The value of $t_{1/2}$ was correlated highly with V_d ($r = 0.89$) but only weakly with clearance ($r = -0.38$). Therefore, the large increase in the desmethyldiazepam $t_{1/2}$ value seen in obese subjects is predominantly due to the disproportionate distribution of this lipid-soluble drug into body fat as opposed to lean tissue. The contribution of clearance to desmethyldiazepam $t_{1/2}$ was of much less importance than was V_d in this obese study population.

Keyphrases □ Desmethyldiazepam—prolongation of drug half-life due to obesity □ Pharmacokinetics—prolongation of drug half-life due to obesity, desmethyldiazepam □ Obesity—prolongation of drug half-life, desmethyldiazepam

The elimination half-life ($t_{1/2}$) of drugs has often been equated with the rate of biotransformation and clearance (1). However, principles of pharmacokinetics indicate that half-life is a hybrid variable, depending upon both drug distribution and clearance (2):

$$t_{1/2} = \frac{0.693 \times \text{Volume of Distribution } (V_d)}{\text{Clearance}} \quad \text{(Eq. 1)}$$

To date only a few experimental circumstances have been described in which a high inverse correlation between clearance and elimination half-life did not exist, with a significant contribution to variability in elimination half-life being attributable instead to changes in the volume of distribution (3, 4). Clorazepate, a prodrug which is converted to desmethyldiazepam after oral administration (5), has been used in this laboratory and by others as a means of evaluating desmethyldiazepam pharmacokinetics (6, 7). The present study demonstrates that in obese individuals, comprising perhaps 20% of the population of the United States (8), a potentially serious misinterpretation of drug metabolizing capacity may occur with some lipid-soluble drugs when elimination half-life is used as a measure of drug metabolism.

EXPERIMENTAL

Subjects—Twelve obese (>133% ideal body weight) and 12 control (<125% ideal body weight) subjects participated in the study (Table I).

Table I—Subject Characteristics and Kinetic Variables for Diazepam

	Mean (with range) Values[a]	
	Obese ($n = 12$)	Control ($n = 12$)
Subject Characteristics		
Age, years	33(23–61)	33(24–74)
Sex, F/M	8/4	7/5
Total body weight, kg	105(77–197)	67(51–91)[b]
Ideal body weight, kg	62(41–77)	65(50–82)
Percent ideal body weight	170(134–257)	103(86–125)[c]
Smoking, no/yes	9/3	9/3
Kinetic Variables of Absorption		
Absorption lag time, hr	0.20(0.06–0.25)	0.40(0.18–0.73)[c]
Half-Time for absorption, hr	0.94(0.25–2.03)	0.48(0.02–1.85)
Time to peak plasma concentration, hr	1.3(0.5–2.5)	1.5(0.5–3.0)
Peak plasma concentration, ng/ml	149(90–239)	249(89–590)[d]
Kinetic Variables of Elimination		
Elimination half-life, hr	154(64–369)	57(30–77)[b]
V_d, liter	159(91–340)	63(38–119)[c]
V_d/kg total body weight, liter/kg	1.52(1.00–2.51)	0.94(0.63–1.30)[b]
V_d/kg ideal body weight, liter/kg	2.58(1.49–4.43)	0.98(0.60–1.45)[c]
Clearance, ml/min	13.2(7.4–18.2)	13.4(5.7–21.8)
Clearance/kg total body weight, ml/min/kg	0.14(0.05–0.23)	0.20(0.10–0.31)
Free fraction, percent	2.4(1.5–3.1)	2.5(1.8–3.7)

[a] Student t test for difference between control and obese groups; [b] $p < 0.005$. [c] $p < 0.001$. [d] $p < 0.02$.

The ideal body weight was defined from life insurance tables as follows (9):

Ideal body weight (males) = 50 kg ± 0.9 kg/cm above or below 150-cm height.

Ideal body weight (females) = 45 kg ± 0.9 kg/cm above or below 150-cm height.

The percent ideal body weight was calculated as the ratio of actual or total body weight to ideal body weight. Other measures of adiposity such as weight/height and weight/height^2 (10) have been evaluated in such populations, but it was found that none of these other indexes provides more information than dose comparison of total body weight and ideal body weight.

Obese and control subjects were matched for age, sex, and cigarette smoking habits. No subjects were on a special diet designed for weight loss and all remained at the same weight during the study.

Procedure—After an overnight fast, all subjects received a capsule containing 15 mg of clorazepate dipotassium[1] with 75 ml of water. Subjects remained fasting for 3 hr after drug ingestion. Venous blood samples were drawn into heparinized tubes before the dose, at 5, 15, 30, and 45 min, and 1, 1.5, 2.0, 2.5, 3, 4, 6, 8, 12, and 24 hr, and every 1 to 2 days for 10–42 days. An indwelling butterfly cannula, kept patent by a slow infusion (20 ml/hr) of physiologic saline, was used to obtain blood samples during the first 8 hr postdosing. All other samples were drawn by separate venipuncture. Samples on subsequent days were drawn in the nonfasting state. Blood specimens were centrifuged, and the plasma was separated and stored at −20° until assayed.

Analysis of Samples—Plasma desmethyldiazepam concentrations were determined by electron-capture GLC (6). The extent of diazepam binding to plasma protein for each subject was determined from pooled samples drawn in the nonfasting state at least 72 hr postdose. Binding

[1] Tranxene, Abbott Laboratories, North Chicago, Ill.

0022-3549/82/0800-0942$01.00/0

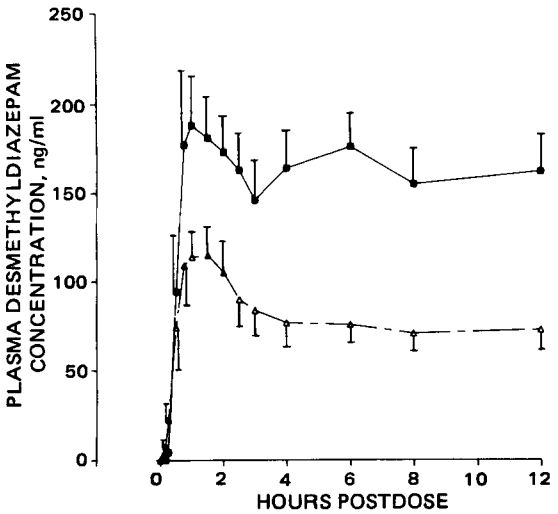

Figure 1—*Mean plasma desmethyldiazepam concentrations over the initial 12 hr after drug administration. Each value is the mean (±SE) for the 12 subjects in obese and control groups at the corresponding time. Pharmacokinetic variables of absorption are listed in Table I. Key: (■) control; (△) obese.*

was determined by equilibrium dialysis using duplicate 2-ml samples spiked to contain 500 ng of desmethyldiazepam/ml. Recovery of desmethyldiazepam from the dialysis system was 100% and the variation for replicate samples was <10%. Binding was independent of the total desmethyldiazepam plasma concentration up to levels of 5000 ng/ml (11, 12).

Data Analysis—Plasma desmethyldiazepam concentrations were analyzed by weighted iterative nonlinear least-squares regression techniques as described previously (13–15). Since desmethyldiazepam derived from orally ingested clorazepate is 100% bioavailable[2], coefficients and exponents from the function of best fit were used to calculate the following kinetic variables: lag time prior to the start of absorption, absorption half-life, total volume of distribution (V_d) using the area method, elimination half-life, and total clearance (16, 17). The data were further analyzed by determination of kinetic parameters for the fraction not bound to plasma protein (18, 19). Assuming that protein binding of desmethyldiazepam for a given subject was constant over time and independent of total concentration, values for V_d and clearance were divided by the subject's unbound fraction yielding values of unbound V_d and unbound (intrinsic) clearance.

Differences in kinetic variables between obese and control groups were

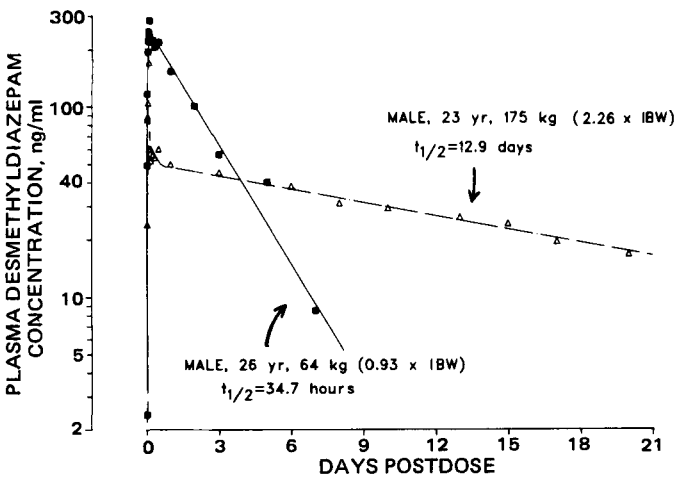

Figure 2—*Plasma desmethyldiazepam concentrations and pharmacokinetic functions following oral chlorazepate administration to a representative obese male [(△); 23 years; 175 kg (2.26 × IBW); $t_{1/2}$ = 12.9 days] and to a matched control male of normal weight [(■); 26 years; 64 kg (0.93 × IBW); $t_{1/2}$ = 34.7 hr].*

[2] Unpublished observation.

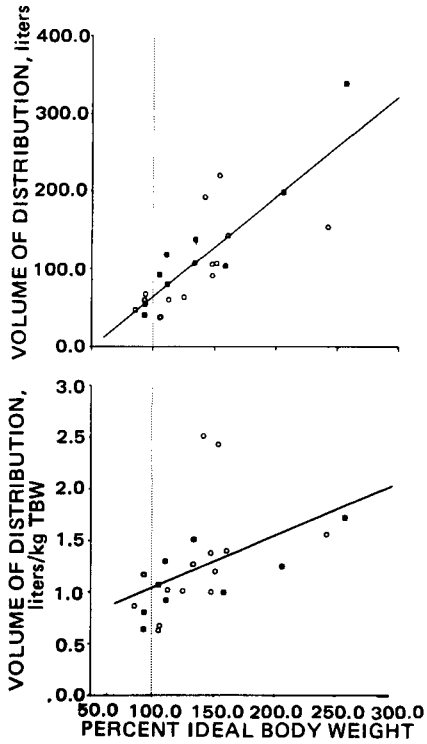

Figure 3—*Relation of percent ideal body weight (abscissa) to desmethyldiazepam absolute volume of distribution (top) and corrected for total body weight (r = 0.82) (bottom). Solid lines were determined by least-squares regression analysis. Key: (■) male; (○) female.*

assessed by Student t test. Relationships among kinetic variables and subject characteristics were evaluated by linear regression analysis.

RESULTS

Lag time elapsing prior to the appearance of desmethyldiazepam in plasma after clorazepate was significantly shorter in the obese than in the control subjects ($p < 0.001$). However, absorption half-life and the time to peak plasma concentration did not differ significantly between groups (Table I). Peak plasma concentrations were much lower in the obese subjects ($p < 0.02$), presumably reflecting the much more extensive distribution of desmethyldiazepam in obesity (Fig. 1, Table I).

Elimination of desmethyldiazepam from plasma after ingestion of clorazepate was adequately described in all subjects by a linear sum of exponential terms (Fig. 2). Pharmacokinetic variables (Table I) reveal a significantly prolonged elimination half-life ($p < 0.001$) in obese as compared to control subjects. This is not explained by a change in clearance, as total metabolic clearance was nearly identical in the two groups (Table I). Since the extent of protein binding was similar in obese and control groups (Table I), intrinsic (unbound) clearance was also similar in the two groups.

The V_d value, in liters, as well as V_d corrected for total body weight (V_d/kg of total body weight) and V_d corrected for ideal body weight (V_d/kg of ideal body weight), were significantly larger in obese subjects than controls (Table I). Represented as a continuous function among all subjects, there was a highly significant ($r = 0.82$; $p < 0.001$) positive correlation between percent ideal body weight and absolute V_d, as well as V_d/kg total body weight ($r = 0.49$, $p < 0.05$) (Fig. 3). This indicates disproportionate distribution of desmethyldiazepam into excess body weight over ideal body weight that is greater than distribution into ideal body weight. Using mean values for total body weight and V_d, distribution of desmethyldiazepam into excess body weight over ideal body weight is approximately twice as extensive as distribution into ideal body weight.

The difference in elimination half-life between groups is the result of the marked increase in V_d in the obese group. This is demonstrated by the highly significant correlation between elimination half-life and V_d ($r = 0.89$; $p < 0.001$) and the nonsignificant correlation between elimination half-life and clearance ($r = -0.38$; *NS*) (Fig. 4).

DISCUSSION

Many drugs are administered on the basis of dose per unit body weight. This assumes that drug clearance is proportional to weight, and that drug

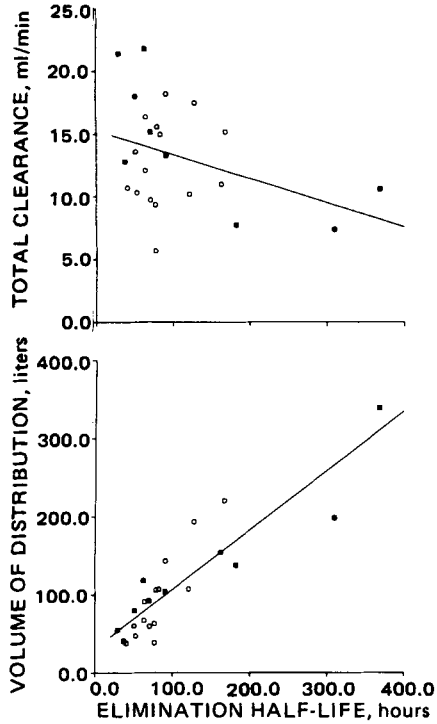

Figure 4—*Relation of desmethyldiazepam volume of distribution (top) and total clearance (bottom) to desmethyldiazepam elimination half-life (abscissa). Volume of distribution was highly correlated with half-life (r = 0.89), but clearance is not significantly related to half-life (r = −0.38). Key: (■) male; (○) female.*

distribution per unit weight is unchanged with large variations in body weight. However, such assumptions may not be warranted since obese individuals may have a significant incidence of hepatocellular disease (20), changes in renal blood flow (21), and marked deviation in body composition from normal (8). A recent report demonstrates a marked increase in tissue enflurane uptake and an increase in the rate and amount of metabolite appearing in peripheral blood in the obese state in the absence of other pathological processes (22). In addition, drug distribution may be quite different in the obese individual as compared to one of normal body weight. Evaluation of the kinetics of digoxin (23), gentamicin (24), tobramycin (24, 25), and amikacin (26) in obesity suggest that distribution of these drugs is mainly into lean body mass, such that an incorrect drug dosage may result from calculation based on total body weight. Similar results are reported for theophylline (27). In contrast, fat-soluble drugs such as diazepam may be much more extensively distributed into body weight in excess of ideal body weight than into ideal body weight (3). Again, this may result in incorrect drug dosage and/or prolongation of time to steady-state plasma concentration if loading and maintenance doses do not take the degree of obesity into consideration.

The present study assessed the effect of obesity on the absorption, distribution, and clearance of desmethyldiazepam, a lipid-soluble benzodiazepine antianxiety agent. Subjects in both obese and control groups varied in age, sex, and cigarette smoking habits, all of which can influence drug disposition. However, these factors are unlikely to have influenced the results, since control and obese subjects were matched for these characteristics. The findings indicate that distributional changes in obesity can remarkably alter the apparent half-life of elimination despite no change in metabolic clearance. Furthermore, the extent of distribution into excess body weight over ideal body weight is even more extensive than into ideal body weight. This is presumably due to the lipophilic character of desmethyldiazepam.

Thus, elimination half-life of lipid-soluble drugs changes greatly in obese patients in the absence of change in total metabolic clearance. Total clearance is the appropriate pharmacokinetic parameter to use for evaluation of the rate of biologic drug removal, as drug dose required to achieve a given steady-state plasma level is a function of this independent variable, not the dependent variable elimination half-life.

Medicament Release from Suppository Bases I: Physicochemical Characteristics and Bioavailability of Indomethacin in Rabbits

NICHOLAS J. VIDRAS *, VINCENT E. REID *, N. R. BOHIDAR ‡, and FOTIOS M. PLAKOGIANNIS *x

Received August 2, 1979, from the *Division of Pharmaceutics, Arnold and Marie Schwartz College of Pharmacy and Health Sciences, Long Island University, Brooklyn, NY 11201 and ‡Merck, Sharp and Dohme Research Laboratories, West Point, PA 19486. Accepted for publication November 3, 1981.

Abstract □ This investigation was designed to determine the *in vitro* release of indomethacin from suppository bases and the *in vivo* bioavailability in rabbits. Suppositories containing 25 mg of indomethacin were made by the fusion method with theobroma oil, esterified fatty acids (C_{10}–C_{18}), and polyethylene glycol 1000. To produce an exact dosage form, a formula for the determination of the displacement value was derived, and it was found that theobroma oil > esterified fatty acids (C_{10}–C_{18}) > polyethylene glycol 1000. The suppository hardness was determined by using appropriate apparatus and it was found that the esterified fatty acids (C_{10}–C_{18}) allowed the formation of more brittle suppositories. The release rates were determined with the USP dissolution apparatus, with or without cellophane membrane, and it was found that polyethylene glycol 1000 > esterified fatty acids (C_{10}–C_{18}) > theobroma oil. The bioavailability of indomethacin after rectal administration was greater with polyethylene glycol base. Significant correlation was obtained during the first 45 min between the *in vitro* release (dialyzing tubing) and the *in vivo* bioavailability.

Keyphrases □ Indomethacin—physicochemical characteristics, bioavailability, rabbits, suppository bases □ Bioavailability—indomethacin physicochemical characteristics, rabbits, suppository bases □ Suppositories—bases, indomethacin, physicochemical characteristics, bioavailability, rabbits

Indomethacin, a nonsteroid drug, was first synthesized in 1961 (1). It has been proven to have anti-inflammatory and analgesic effects in rheumatoid arthritis (2–6), gout (7), osteoarthritis (8–10), ankylosing spondylitis (11), glomerulonephritis (12), and acute musculoskeletal disorders (13). Unfortunately, like other analgesic and anti-inflammatory agents, it carries the risk of GI irritation. The tablets and capsules, which are presently used, have led to peptic ulceration and anorexia (14, 15), nausea, vomiting, dyspepsia, and diarrhea (16). Other side-effects have involved the central nervous system, including headache, giddiness, mental changes, faintness, drowsiness, and blurring of vision. An attractive route of administration for patients with peptic ulcers and for those who are unable to tolerate the drug could be the rectal route.

Previous studies on the rectal administration of indomethacin (17–20) have given little information regarding the suppository bases used, the influence of the suppository base on the release of the drug, or the effects of the physicochemical properties such as hardness or melting range on *in vitro* and *in vivo* drug release. In this study, indomethacin suppositories in three different bases, polyethylene glycol 1000, esterified fatty acids (C_{10}–C_{18}), and theobroma oil were used to evaluate their physicochemical properties, to examine the *in vitro* release of indomethacin, its *in vivo* release in rabbits, and to correlate if possible the *in vitro* with *in vivo* data.

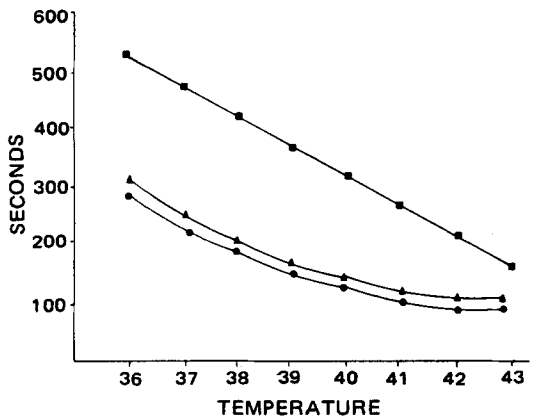

Figure 1—*Time interval for complete melting of indomethacin suppositories as a function of temperature using the USP disintegration apparatus. Key: (■) polyethylene glycol; (▲) esterified fatty acids (C_{10}–C_{18}); (●) theobroma oil.*

EXPERIMENTAL

Chemicals—Indomethacin[1], polyethelene glycol 1000[2], esterified fatty acids (C_{10}–C_{18})[3], theobroma oil[4], heptane[4], phosphate buffer[4] solutions, (pH 7–9), sodium hydroxide[4], and hydrochloric acid[4]. All reagents were analytical or reagent grade purity.

Preparation of Suppositories—All suppositories were prepared by the fusion method using a metal mold with 12 cavities (10). Drug displacement (3) in polyethylene glycol 1000, esterified fatty acids (C_{10}–C_{18}),

and theobroma oil was first determined, and then the amount of indomethacin required was calculated.

Weight Variation—Twenty suppositories from each base were weighed, and the average weight and percent deviation for each suppository was calculated.

Content Uniformity Test—Although the USP does not specify a content uniformity for suppositories, the relative potency of the suppositories was determined. Thirty suppositories were randomly selected from each base, 10 of which were assayed individually. A preweighed suppository was melted and dissolved in 15 ml of phosphate buffer solution (pH 8). The buffer solution was added to a final yield of 1 liter. The adsorbance was measured on a spectrophotometer[5] at 318 nm. Blank suppositories were tested, and it was determined that the suppository vehicles had no effect on the UV absorbance at 318 nm. The concentration of indomethacin in the samples was determined from a standard curve.

Melting Range Test (Macro-Melting Range Test)—It has been shown (4, 5) that a narrow melting range is important in maintaining the shape of the suppository in ambient temperatures and in controlling the melting time of the suppository after insertion. The melting range test is a time measure for complete melting or dispersal of the suppository when immersed in a constant temperature water bath. Two apparatuses were used for the determination of the melting range. The USP tablet disintegration apparatus[6] was set as required in USP XIX, using water as the immersion fluid. A suppository, stored for at least 24 hr at room temperature, was placed in each tube of the basket, and each tube was covered with a disk. The time required for each suppository to completely melt at a specific temperature was determined. The temperature for this study ranged from 36 to 43°. The melting point testing apparatus for suppositories[7] was also used.

Breaking Test (Hardness)—The breaking test was designed to measure the brittleness and fragility of suppositories (1). This was measured by the weight in kilograms under which a suppository collapses at a specific temperature. The hardness of each suppository was determined by utilizing the fracture point testing apparatus for suppositories[7].

Release of Indomethacin from Suppository Bases—Three different methods were used for the determination of the release rates:

Method A—The USP rotating basket dissolution apparatus was used for the determination of release rates by this method. Each suppository was placed in the wire basket, which was lined from the inside with filter paper, and lowered into a flask containing 600 ml of phosphate buffer solution (pH 8). (The filter paper was used as a barrier for the diffusion of the suppository base.) The basket was rotated at 100 rpm at a constant temperature (37 ± 0.5°). Five-milliliter samples were withdrawn at appropriate time intervals and assayed to obtain a dissolution profile. Five milliliters of phosphate buffer was added to the dissolution medium to compensate for sampling. The absorbances of these solutions were measured at 318 nm on a spectrophotometer and the concentrations were determined from the standard curve.

Method B—The same apparatus and the conditions as previously described were employed. The modification was to place the suppository in a cellophane membrane[8] before exposure to the buffer solution.

Method C—This method employed dialysis. The dialyzing bags were prepared from dialysis tubing tied with plastic cord and soaked overnight in the phosphate buffer solution (pH 8). After rinsing the bags twice, 20 ml of phosphate buffer (pH 8) and one suppository were placed in each bag and suspended in a 500-ml wide-mouth bottle containing 400 ml of the phosphate buffer solution. The bottle was placed in a water bath at a constant temperature[9] of 39 ± 0.5° and agitated with a magnetic stirrer. At constant time intervals, a 5-ml sample was removed from the bottle and assayed to obtain a dissolution profile. Five milliliters of phosphate

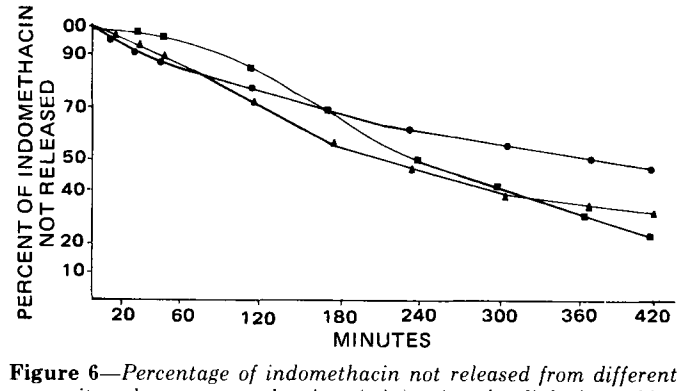

Figure 6—*Percentage of indomethacin not released from different suppository bases* versus *the time (min) using the dialyzing tubing method. Key: (■) polyethylene glycol; (▲) esterified fatty acids (C_{10}–C_{18}); (●) theobroma oil.*

[8] Dupont Co.
[9] The temperature, 39°, was chosen in order to initiate the *in vivo* conditions as closely as possible (the temperature of the rectum of the rabbits was 39°) and ensure complete melting of the suppositories.

Table I—Related Bioavailability Parameters from Serum Level Data

Parameter	Treatment A: Polyethylene Glycol 1000 Suppositories	Treatment B: Esterified Fatty Acids (C_{10}–C_{18}) Suppositories	Treatment C: Theobroma Oil Suppositories	Treatment D: Powder Suspension
Average of Peaks of Individual Serum Concentrations (Time Curve), μg/ml	1.35	1.12	1.17	1.64
Time of Peak Value of Individual Serum Concentration–Time Curves, min	60	90	90	90
Average of Area under Individual Serum Concentration–Time Curves, μg/ml min	178.53	182.42	177.92	215.10

buffer (pH 8) was added to the dissolution medium to compensate for sampling. The absorbances were measured at 318 nm in a spectrophotometer and the concentrations of indomethacin were obtained from the standard curve.

***In Vivo* Studies**—Twelve healthy white New Zealand male rabbits (3–4.5 kg) were randomly divided into four groups of three animals each. Four different dosage forms of indomethacin were administered, and each dosage form provided 25 mg of indomethacin.

At time zero, each rabbit received indomethacin as follows: Group A, one polyethylene glycol 1000 suppository; Group B, one esterified fatty acids (C_{10}–C_{18}) suppository; Group C, one theobroma oil suppository; and Group D, 25 mg of indomethacin suspended in ~100 ml of water administered orally. Retention of the suppositories by the rabbits was ensured by the use of an appropriately sized styrofoam disk taped to the rectum after insertion. Blood (2–5 ml) was taken by cardiac puncture from each rabbit at different time intervals up to 4 hr.

Assay of Serum—The serum samples were assayed by modifying a method described previously (17). One milliliter of serum was pipeted into a glass stoppered centrifuge tube containing 2 ml of a 1 *M* citrate buffer and 25 ml of heptane containing 5% isoamyl alcohol. The test tube was mechanically agitated for 30 min and then centrifuged. Twenty milliliters of the heptane phase was pipeted into a second centrifuge tube containing 5 ml of a 0.2 *M* citrate buffer. This was agitated for 25 min and then centrifuged. Ten milliliters of the organic phase was pipeted into a third centrifuge tube containing 3 ml of 0.1 *N* NaOH and shaken for 5 min. The organic phase was removed by aspiration and 2 ml of the aqueous phase transferred to a quartz cell for immediate spectrofluorophotometric determination (activation maximum, 305 nm; fluorescence maximum, 400 nm)[10,11].

RESULTS AND DISCUSSION

In the preparation of suppositories some difficulty is experienced in achieving the exact dosage. This is because the volume of suppositories from a particular mold is uniform, but its weight will vary because the density of the drug usually differs from the density of the base with which the mold is calibrated. Each mold should be calibrated before use by preparing suppositories using the base alone, weighing the blank suppositories, and taking the mean weight as the calibration factor. Therefore, to prepare accurate suppositories, it is essential to derive a general expression (Eq. 1) to account for the displacement value of a drug, which is defined as the number of parts by weight of the drug that displaces one part by weight of the base:

$$F = \frac{XB}{100\,(A - B) + XB} \qquad \text{(Eq. 1)}$$

where F is the displacement value of a drug; X is the percentage of drug used; B is the weight of n suppositories containing X% of a drug; and A is the calibration factor, *i.e.*, weight of unmedicated n suppositories.

According to the definition, the displacement value of a drug is:

$$F = \frac{\text{Amount of the drug in each suppository}}{\text{Amount of base displaced in each suppository}} \qquad \text{(Eq. 2)}$$

Since the amount of drug in each suppository is $X/100\,B$, and the amount of base displaced by the above amount of drug is $(A - (100 - X)/100\,B)$, Eq. 2 becomes:

$$F = \frac{\frac{X}{100}B}{A - \frac{100 - X}{100}B} = \frac{XB}{100\,(A - B) + XB} \qquad \text{(Eq. 3)}$$

Therefore, the quantity of base required is calculated using the following equation:

$$P = (N \times S) - \frac{D}{F} \qquad \text{(Eq. 4)}$$

where P is the amount of base required (in grams); N is the number of the prepared suppositories; S is the size of the mold used (in grams); and D is the amount of drug (in grams) that is required.

The displacement values of indomethacin were calculated in the polyethylene glycol 1000, esterified fatty acids (C_{10}–C_{18}), and theobroma oil suppository bases, and were found to be 1.72 ± 0.21, 2.06 ± 0.14, and 2.44 ± 0.39, respectively.

The weight variation of 20 randomly selected indomethacin suppositories containing 25 mg of the drug in the three bases was determined and found to be from 1.71 to 1.84 g for polyethylene glycol 1000, 1.38 to 1.48 g for esterified fatty acids (C_{10}–C_{18}), and 1.09 to 1.17 g for theobroma oil. All the suppositories prepared met the acceptable limits of the German, Russian, and Nordica pharmacopeias (21), which state that individual weight variations of rectal suppositories can vary by ±5, ±5, and ±10% of their average weight, respectively. The USP does not have any limits for acceptable weight variation of rectal suppositories. Although the USP does not specify content uniformity standards, the content uniformity of indomethacin suppositories in polyethylene glycol 1000, esterified fatty acids (C_{10}–C_{18}), and theobroma oil was determined and found to be within −5.2 to +12.2, −8.2 to +9.8, and −8.2 to +12.2 of the labeled amounts, respectively.

The definitions of rectal suppositories as reported in different pharmacopeias, specifically state the "suppositories should soften, melt, or dissolve at body temperature." However, these are of little value, as pointed out previously (22), unless the method of determining these characteristics is given. This is because different methods give different results and, consequently, suppositories may be accepted as satisfactory, although they do not melt, soften, or dissolve in the rectal environment. Furthermore, if a uniform method for determining the melting range could be developed, it would be quite useful in deciding if a suppository is sufficiently firm to be introduced into the rectum or handled and stored at ordinary room temperature or in warm environments. The melting range was determined by using the USP disintegration apparatus and a commercial disintegration apparatus[6]. Figure 1 shows the time for

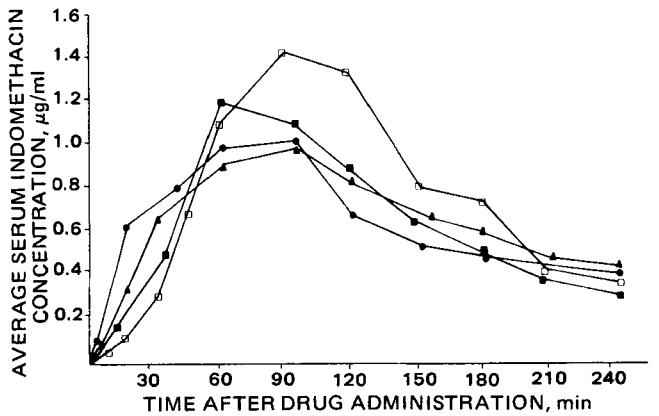

Figure 7—*Average serum indomethacin concentrations (μg/ml) obtained for three rabbits after receiving 25 mg of indomethacin given as: (■) polyethylene glycol; (▲) esterified fatty acids (C_{10}–C_{18}); (●) theobroma oil; (□) oral dose.*

complete melting of indomethacin suppositories as a function of temperature. It is apparent from Fig. 1 that the polyethylene glycol 1000 indomethacin suppositories require a longer time for complete dissolution than that of esterified fatty acids (C_{10}–C_{18}) and theobroma oil in the USP disintegration apparatus. Figure 2 shows the time that is required to dissolve the polyethylene glycol 1000 indomethacin suppository as a function of temperature in the commercial disintegration apparatus[6]. This apparatus can be used for bases having densities >1 g/cm^{-3}. Polyethylene glycol 1000 can be measured in the apparatus but esterified fatty acids (C_{10}–C_{18}) (0.97 g/cm^{-3}) and theobroma oil (0.86 g/cm^{-3}) cannot.

The breaking load of the indomethacin suppositories in the three bases as a function of temperature is shown in Fig. 3. As can be seen from these curves, it is possible to determine the degree of deformation. A steep curve (esterified fatty acids, C_{10}–C_{18}) indicates a brittle base, whereas a flat curve (theobroma oil) indicates greater elasticity of the suppository base and a longer softening interval. A large number of methods are available for determination of the release of medicament from suppository bases (23–30); however, to our knowledge none have been proven to be totally satisfactory in correlating *in vitro* release with *in vivo* bioavailability. The release of indomethacin from the three suppository bases was determined by using three methods: two existing methods and a new, modified method.

Using the USP dissolution apparatus, the percent of indomethacin released is shown in Fig. 4. The data indicate that the time required to release the total amount of indomethacin from the polyethylene glycol 1000 suppository base was ~10 times less than that of the other two bases due to the water solubility of polyethylene glycol 1000 base. Therefore, the USP dissolution apparatus cannot be used for the determination of the medicament release from water soluble suppository bases without the use of membranes or filters. The inability of the USP dissolution method to be used with water soluble bases led to the use of membranes to hinder the erosion process.

The plot of indomethacin released using Method B is shown in Fig. 5. The data indicate that in the first hour the order of release was theobroma oil > esterified fatty acids (C_{10}–C_{18}) > polyethylene glycol 1000, but after the first hour, the order changed to polyethylene glycol 1000 > esterified fatty acids (C_{10}–C_{18}) > theobroma oil. The use of cellophane membranes and the dialysis technique, Methods B and C (Fig. 6), may represent an additional slow step in the overall release of indomethacin from suppositories, which may prevent a comparison of the methods. Therefore, an investigation is under way to determine and calculate the possible lag time in the methods.

[a] Highly significant ($p < 0.01$).

25-mg doses of indomethacin are shown in Table I and Fig. 7. As can be seen from the data, the peak levels obtained were 1.35 μg/ml for Treatment A, 1.12 μg/ml for Treatment B, 1.17 μg/ml for Treatment C, and 1.64 μg/ml for Treatment D. Furthermore, the average peak of indomethacin concentration obtained after rectal administration of 25 mg of indomethacin was 82.31, 68.29, and 71.34% for Treatments A, B, and C, respectively, of that when given orally.

The absorption of indomethacin from all suppository bases, as well as from those administered orally, was rapid, as reflected by the relatively short time to attain the peak plasma indomethacin level (Fig. 7 and Table I). The time of occurrence of the maximum peak level was considerably less after Treatment A (60 min) than that after Treatments B, C, and D (90 min).

The area under the plasma concentration–time curve (AUC) was calculated by the trapezoidal rule. The values of AUC measurements, as well as the average of peaks of individual serum concentration–time curves and the time of peak value of individual serum concentration–time curves, are given in Table I.

Statistical Analysis—The mean plasma concentration of indomethacin associated with polyethylene glycol 1000, esterified fatty acids (C_{10}–C_{18}), theobroma oil, and suspension was statistically compared, based on three rabbits per each treatment and 11 sampling time periods. The ANOVA for a split-strip-plot (31–32) design suitable for time-dependent responses was conducted and the results presented in Table II.

The ANOVA indicated that there is an interaction between treatment and time periods. The interpretation of the significant interaction indicates that there exists one or more time periods in which the mean plasma concentration of the treatments are significantly different. This information led to the second set of analyses in which an ANOVA was conducted for each time period to identify the time period in which the treatments were significantly different. These results are provided in Table III. Some of the collection times in Table III show a range of time periods and not a specific collection time, because the ANOVA is used to identify the time period in which the treatments are significantly different. Therefore, the exact collection time should be used. The 12–15 min time period indicates that some blood samples at the third collection time were collected at 12 min, while others at 15 min. Specifically, the collection time for the indomethacin–polyethylene glycol 1000 suppositories was 12 min, while for the other treatments it was 15 min.

It can be seen that there is a significant difference among the treatments in the 12–15-min time period. This is the most critical information of the experiment. The ANOVA for this period is given in Table IV. A Duncan's Multiple Range Test was conducted, and the results (Table V) revealed that Treatment C ($\bar{C} = 0.70$) was significantly higher) ($p > 0.05$) than that of Treatment A ($A = 0.18$) and Treatment D ($\bar{D} = 0.12$). There was no significant difference between Treatments B and C. As time increased, the variability of the plasma concentration increased, and thus, no significant differences among the treatments were detected (31, 32).

The present results indicate that the indomethacin is well absorbed from the rectum, although the peak serum concentration and AUC were less than after an equivalent oral dose, which is in accordance with previous experiments (17).

Table V—Analysis of Variance According To Duncan's Multiple Range Test

	Significance Triangle			
	D	A	B	C
0.6967 C	—[a]	—[a]	0[b]	
0.400 B	0			
0.1800 A	0			
0.1200 D				

[a] Implies significant difference between C and D and between C and A ($p < 0.05$). [b] 0 implies no significant difference at $p = 0.05$.

An attempt to correlate the *in vivo* with the *in vitro* release of the indomethacin proved to be unsatisfactory because of the wide variance in the results from three *in vivo* treatments and three dissolution methods. However, the dialyzing tubing method gave the best correlation with the *in vivo* data in three suppository bases, whereas the USP dissolution method gave the best correlation only with the use of fatty suppository bases (esterified fatty acids (C_{10}–C_{18}) and theobroma oil). Attempts to use a sequential order correlation between the three dissolution methods and the *in vivo* results show that the best correlation was found during the first 45 min of the experiment.

High-Performance Liquid Chromatographic Determination of Proglumide in Plasma

TERUYOSHI MARUNAKA ˣ, YOSHINORI MINAMI, YUKIHIKO UMENO, and EIJI MATSUSHIMA

Received May 22, 1981, from the *Research Laboratory, Taiho Pharmaceutical Co., Ltd., Kawauchi-cho, Tokushima, 771-01, Japan.* Accepted for publication October 7, 1981.

Abstract □ A rapid and sensitive method for determining the anticholinergic agent, proglumide, in plasma by high-performance liquid chromatography is described. Samples were acidified with hydrochloric acid and extracted with chloroform. The dried extract was resolved in chloroform and chromatographed on an adsorption chromatographic column using a mobile phase of chloroform–methanol (24:1) on a high-performance liquid chromatograph equipped with a UV absorbance detector (240 nm). The detection limit for proglumide was 0.05 μg/ml.

Keyphrases □ Proglumide—high-performance liquid chromatographic determination in plasma □ High-performance liquid chromatography—analysis, proglumide in plasma □ Anticholinergic agent—proglumide, high-performance liquid chromatographic determination in plasma

Proglumide (xylamide, DL-4-benzamido-*N*,*N*-dipropylglutaramic acid) is a derivative of the amino acid that was developed as an anticholinergic agent (1–7). The GLC methods have been reported for the assay of proglumide in plasma (8–10). Proglumide has been assayed for its methyl derivative (8, 9), and its trimethylsilyl derivative determined (10).

The present report describes a rapid, precise, and sen-

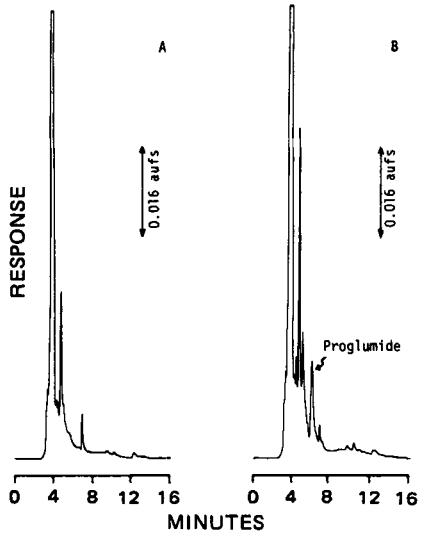

Figure 1—*High-performance liquid chromatograms of human control plasma (A) and human plasma extracts following addition of proglumide at 0.5 μg/ml (B). The conditions were: column (25-cm × 6.2-mm i.d.); mobile phase, chloroform–methanol (24:1); flow rate, 1.5 ml/min; and UV detector, 240 nm (room temperature).*

sitive high-performance liquid chromatographic (HPLC) method using an adsorption chromatographic column for determination of proglumide in plasma.

EXPERIMENTAL

Materials—Proglumide[1] was used as received. Chloroform and methanol were liquid chromatographic grade[2], and the other chemicals[2] were analytical reagent grade.

HPLC Conditions—The high-performance liquid chromatograph[3] was equipped with a high-pressure injection valve[4] and a variable-wavelength (240 nm) UV absorbance detector[5].

An adsorption chromatographic column[6] (25-cm × 6.2-mm i.d.) was used for the separation and maintained at room temperature. The mobile phase was chloroform–methanol (24:1) at a flow rate of 1.5 ml/min. A gradienter[7] was used for controlling the mobile phase concentration. A computer system[8] was employed for quantitative calculations.

Analytical Procedure—Blood samples were collected in heparinized containers and centrifuged to separate the plasma.

A sample of 1.0 ml of plasma was diluted to 2.0 ml with distilled water, adjusted to pH 3.0 with 1 *N* HCl, and then shaken vigorously with 20 ml of chloroform at room temperature for 10 min. This extraction was repeated once. The combined chloroform layer was evaporated to a suitable volume under reduced pressure at water temperature, then transferred to a test tube (5-ml capacity) by washing with chloroform, and dried under nitrogen. The residue was dissolved in 100 μl of chloroform, and 30-μl portions of this solution were injected into the liquid chromatograph with a 100-μl syringe[9].

Calibration curve for the determination of proglumide by HPLC was prepared by plotting the peak area against the concentration of this compound. This calibration curve was linear.

RESULTS AND DISCUSSION

The HPLC separation of proglumide extracted from plasma was first examined using a reversed-phase column[10]. When a linear gradient system with methanol–5 m*M* KH_2PO_4 (0–100% methanol, 6%/min) was used as the mobile phase, proglumide was well separated from plasma constituents.

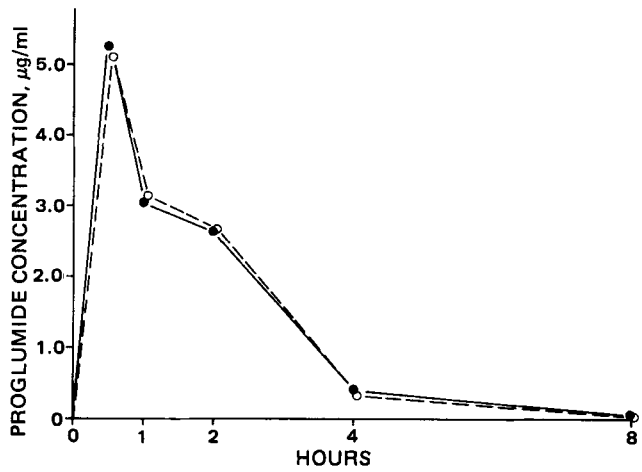

Figure 2—*Comparison of plasma levels of proglumide determined by HPLC (●) and GLC (○) methods after a single oral dose of 400 mg of proglumide to a healthy human.*

An adsorption chromatographic column[6] was used next for the separation of proglumide extracted from plasma. A mixture of a nonpolar solvent (*e.g.*, chloroform, methylene chloride, or ethylene chloride), containing 4–6% alcohol (*e.g.*, methanol or ethanol) as the mobile phase, gave a good separation of proglumide from plasma components. Of these columns and mobile phases tested, a column[6] and chloroform–methanol (24:1) as the mobile phase showed the most suitable chromatographic separation and analysis time and was chosen for the present experiments.

The HPLC separation pattern of proglumide extracted from human plasma following addition of 0.5 μg/ml of this compound and that of a control plasma extract are shown in Fig. 1. The retention time of proglumide was 6.0 min, and the time required for the assay was 15 min. The detection limit for proglumide under the present HPLC condition was 0.05 μg/ml of plasma. The present method had a precision of ±2.8% and good reproducibility.

Known amounts (0.1, 0.5, 1.0, 5.0, and 10.0 μg/ml) of proglumide were added to human plasma (1.0 ml) and the recovery of proglumide was examined five times at each concentration. The overall recovery of proglumide was 93.1 ± 3.2%.

A 400-mg dose of proglumide was administered orally to a healthy male, and the time course of change in concentration of proglumide in plasma was measured by the present HPLC method. The results were compared with those by the GLC method (8, 9). As shown in Fig. 2, the overall difference between the value obtained by the two methods was ± 3.7%.

The present HPLC method is simple and rapid since it does not require the preparation of derivatives and has high accuracy and sensitivity.

Belladonna Alkaloids and Phenobarbital Combination Pharmaceuticals Analysis I: High-Performance Liquid Chromatographic Determinations of Hyoscyamine–Atropine and Scopolamine

LINDA J. PENNINGTON ˣ and WALTER F. SCHMIDT

Received March 3, 1981, from the *Food and Drug Administration, Atlanta, GA 30309.* Accepted for publication November 16, 1981.

Abstract □ High-performance liquid chromatographic separations are described for the analysis of hyoscyamine–atropine and scopolamine in combination pharmaceutical dosage forms containing phenobarbital. A mobile phase containing 0.034 *M* tetramethylammonium phosphate in water–methanol (21:10, pH 2.0) separated hyoscyamine or atropine from scopolamine on an octadecylsilane column in <9 min. Monitoring of the column effluent at 220 nm gave a detection limit of 0.02 μg for each alkaloid. Hyoscyamine sulfate and/or atropine sulfate were determined as total equivalent hyoscyamine sulfate, and scopolamine hydrobromide was determined as a separate entity. Data from the application of the method to commercial pharmaceutical products are also presented.

Keyphrases □ High-performance liquid chromatography—belladonna alkaloids and phenobarbital combination pharmaceuticals, determination of hyoscyamine–atropine and scopolamine □ Combination drugs—belladonna alkaloids, high-performance liquid chromatographic determination of hyoscyamine–atropine and scopolamine □ Alkaloids—belladonna, combination pharmaceuticals, high-performance liquid chromatographic determination of hyoscyamine–atropine and scopolamine

Microgram quantities of the belladonna alkaloids, hyoscyamine, atropine, and scopolamine, are widely used in combination with phenobarbital in pharmaceutical dosage forms for antispasmodic, anticholinergic, and sedative effects, especially in the treatment of functional GI disorders. Methodology was developed in this laboratory which would allow for the analysis of the belladonna alkaloids and for phenobarbital in such products. The present report presents the method, procedures, and data obtained on the determination of hyoscyamine–atropine and scopolamine.

The detection and quantitation of individual tablet levels of belladonna alkaloids in the common combination dosage forms is difficult for the following reasons: (*a*) low concentrations, (*b*) low UV absorptivity, (*c*) instability to the heat and pH ranges normally encountered in suitable sample analysis extraction procedures, and (*d*) interference from the large concentration and high UV absorptivity of phenobarbital. Currently available methodology for detection and quantitation of belladonna alkaloids includes colorimetry (1), fluorometry (2), GC (3–5), and HPLC (6, 7). The colorimetric procedure uses an ion-pair extraction with bromothymol blue at pH 5.6 for a total alkaloid determination and an ion-pair extraction with bromocresol purple at pH 6.6 for a hyoscyamine–atropine determination; scopolamine is estimated by the difference between the two assays (1). The fluorometric procedure consists of an extraction followed by ion-pair reaction with eosine yellow and determines only hyoscyamine and atropine (2). The simultaneous analysis of scopolamine and hyoscyamine–atropine can be achieved with GC but requires extensive column preparation and conditioning (3–5). Adsorption effects hamper especially the quantitation of scopolamine due to its low concentration in dosage forms as well as the peak broadening, which occurs due to its longer GC retention time. Loss of the alkaloids by adsorption on the sodium sulfate used to dry solvent extracts prior to GLC injection has also been noted (5). Due to the instability of the alkaloids' free bases, sample solutions must be injected on the day of extraction. The two HPLC (6, 7) procedures utilize reversed-phase ion-pairing chromatography with UV detection at 254 and 230 nm, respectively, to quantitate atropine and/or scopolamine. However, because of excessive background absorbance of the mobile phase, these methods lack sufficient sensitivity to quantitate the alkaloids at the microgram levels present in the common combination dosage forms.

Improved HPLC procedures are reported for the analysis of hyoscyamine, atropine, and scopolamine in combination pharmaceutical dosage forms containing phenobarbital. The method is applicable to a wide range of elixirs, tablets, and capsules for individual tablet assays (content uniformity test), as well as composite assays. In addition, the analysis of 22 commercial products using the described HPLC methods is presented.

EXPERIMENTAL

Apparatus—A liquid chromatograph[1] equipped with a 20-μl loop injector[2], a variable wavelength UV detector[3], and a recorder-integrator[4] were used. A 25 cm × 4-mm stainless steel column containing octadecylsilane chemically bonded to 5 μm silica[5] was employed.

Reagents—Methylene chloride[6] was passed through a 10 × 3-cm glass column containing 75 g of basic aluminum oxide[7] and stored over basic aluminum oxide (25 g/4 liters of solvent) in a light resistant glass container.

A carbonate buffer (pH 9.4) was prepared by mixing 5.3 g of anhydrous sodium carbonate and 4.2 g of sodium bicarbonate in 100 ml of distilled water.

A solution containing 1% concentrated HCl in methanol was prepared fresh daily.

A 0.05 *M* tetramethylammonium phosphate buffer was prepared by mixing 23 ml of 20% tetramethylammonium hydroxide in methanol[8] and 10 ml of concentrated phosphoric acid in 500 ml of distilled water, adjusting to pH 2.0 with concentrated phosphoric acid, and diluting to 1 liter with distilled water.

Preparation of Internal Standard Solutions—An internal standard solution was prepared for use in the drug standard solution by dissolving anhydrous theophylline[9] in methanol (300 μg/ml). The theophylline

Range	94.7–105.1	93.0–106.1		94.4–103.0	93.6–105.2

[a] Portions of sample spiked with standard solution containing hyoscyamine sulfate and scopolamine hydrobromide and analyzed according to procedure. [b] Product did not contain scopolamine hydrobromide. [c] Value obtained by second analyst. Value not included in statistics.

solution was then diluted with methylene chloride (2.25 μg/ml) for use in the assay procedure.

Preparation of Drug Standard Solutions—A standard solution of scopolamine hydrobromide[10] in distilled water (500 μg/ml) was prepared and stored in low-actinic glassware.

A mixed standard solution was prepared by weighing hyoscyamine sulfate[11] (16 mg) into a 50-ml low-actinic volumetric flask, adding 3.0 ml of the methanolic theophylline internal standard solution (300 μg/ml) and 2.0 ml of scopolamine hydrobromide standard solution, and diluting to ~40 ml with distilled water.

Preparation of Mobile Phase—The mobile phase was prepared by mixing 525 ml of 0.05 *M* tetramethylammonium phosphate buffer with 250 ml of methanol.

HPLC Conditions—A flow rate of 0.8 ml/min was used with UV detection set at 220 nm and the sensitivity set at 0.02 aufs.

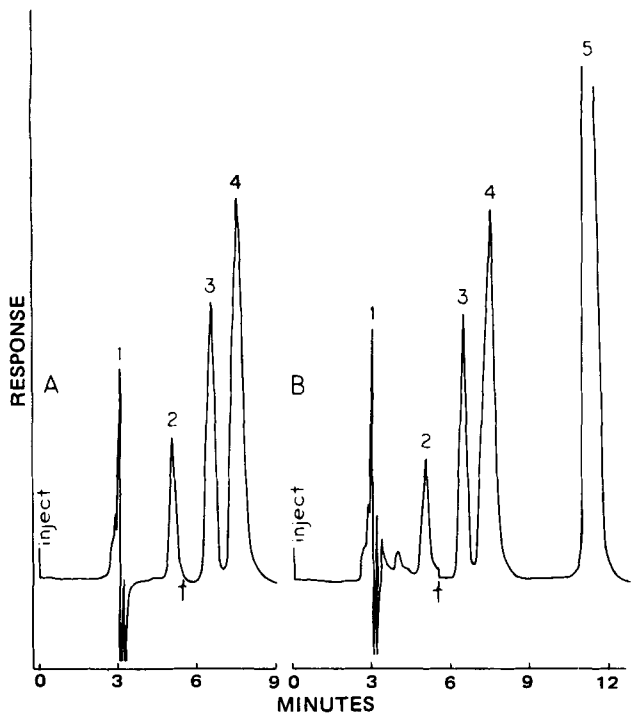

Figure 1—*Typical chromatograms of HPLC separations of A, the standard solution and B, the tablet sample. Key: 1, solvent; 2, scopolamine; 3, theophylline (internal standard); 4, hyoscyamine–atropine; 5, phenobarbital. Attenuation change of 4× after each scopolamine peak at the arrow.*

[10] USP Reference Standard.
[11] NF Reference Standard.

Assay for Tablets and Capsules—Twenty tablets were weighed and finely powdered, or the contents of 20 capsules were weighed and composited. A sample portion equivalent to ~0.6 mg of combined hyoscyamine sulfate–atropine sulfate was accurately weighed and quantitatively transferred to a 50-ml centrifuge tube; 25 ml of 0.05 *N* sulfuric acid then was added and the tube shaken for 15 min. The mixture was then centrifuged for 5 min at 3000 rpm. A 5.0-ml aliquot of the supernate was pipeted into a 125-ml separatory funnel where it was extracted with two 30-ml portions of methylene chloride. The organic phase was then discarded. Two milliliters of carbonate buffer (pH 9.4) was added to the aqueous phase remaining in the separatory funnel and the mixture was extracted with four 30-ml portions of methylene chloride. Each extract was filtered through a methylene chloride-rinsed glass wool plug into a flash evaporator[12] fitted with a concentrator tube[13]. Exactly 3 ml of theophylline internal standard solution (2.25 μg/ml) and 9–10/50 grit boiling chips[14] were added to the concentrator. A distilling column[15] was added to the concentrator and the methylene chloride evaporated on a steam bath to ~10 ml. The distilling column was then rinsed with 1–2 ml of methylene chloride and the solvent evaporated to 0.5–1 ml. The distilling column was removed and the column-concentrator junction rinsed with ~1 ml of methylene chloride into the concentrator tube. The concentrator tube was placed in a beaker of warm water (40 ± 5°) and the solvent evaporated to ~1 ml with the aid of a current of dry air. Next, 0.1 ml of acidic methanol was added, mixed, and the solution evaporated to dryness using the conditions described previously. The sides of the concentrator tube were rinsed with 0.5 ml of methanol and the solution again evaporated to dryness. The extract was then dissolved in 300 μl of distilled water and a 20-μl sample was injected onto a liquid chromatograph.

Content Uniformity Test—One tablet or the contents of one capsule were transferred to a 125-ml separatory funnel and 7 ml of 0.05 *N* sulfuric acid added. The funnel was shaken until the tablet disintegrated and then shaken for an additional 5 min. Thereafter, the "Assay for Tablets and Capsules" was followed beginning with, " . . . it was extracted with two 30-ml portions of methylene chloride . . .."

Assay for Elixirs—A sample equivalent to ~0.6 mg of combined hyoscyamine sulfate–atropine sulfate was pipeted into a 150-ml beaker. The solution was warmed in a 40 ± 5° water bath with a current of air for 30 min to remove alcohol. After cooling to room temperature, the sample was quantitatively transferred to a 25-ml volumetric flask and adjusted to volume with distilled water. Exactly 5 ml of this solution was pipeted into a 125-ml separatory funnel, 2 ml of 0.2 *N* sulfuric acid added, and the "Assay for Tablets and Capsules" was followed thereafter beginning with, " . . . it was extracted with two 30-ml portions of methylene chloride . . .."

Calculations—After obtaining the chromatograms, each peak response was determined by measurement of peak height or peak area. The quantity, in milligrams, of hyoscyamine sulfate–atropine sulfate and scopolamine hydrobromide in the portion of sample taken was calculated

[a] Label claim range from 0.1205–0.217 mg/unit dose. [b] Label claim range from 0.0060–0.0284 mg/unit dose; 0.006–0.0075 most common. [c] Product did not contain scopolamine hydrobromide. [d] Values in parentheses are the average of 10 individual tablet assays (content uniformity). [e] Value obtained by second analyst.

by the formula $0.3C \times (Ru/Rs)$. The values Ru and Rs are the ratios of the hyoscyamine sulfate (or scopolamine hydrobromide) response to the internal standard response for sample (u) and standard (s), respectively, and C is the concentration of hyoscyamine sulfate (or scopolamine hydrobromide) (milligrams per milliliter) in the standard solution.

RESULTS AND DISCUSSION

Mobile Phase Selection—The presence of tetramethylammonium ions at pH 2 in the methanol–water mobile phase was found to minimize column adsorption of the alkaloids resulting in decreased retention time. Their presence also provided a high resolution separation of scopolamine and hyoscyamine–atropine, as shown in Fig. 1. The mobile phase was sufficiently UV-transparent for the detector to be set at 220 nm where alkaloid absorptivity is considerably higher. Three octadecylsilane columns were used, and the separation of component peaks on each column was as good as or better than that shown.

Even though the pH of the mobile phase buffer was at the lower extreme of the range normally considered advisable for column stability, the columns maintained separation and reproducibility for 5 months with daily use. At the end of each day's use, the column was rinsed with water and then methanol and stored in methanol overnight to avoid column deterioration from prolonged contact with the low pH buffer in the mobile phase.

Interferences—Considerable interference in the area of the hyoscyamine–atropine peak was encountered when first testing the procedure. Upon checking the reagent blank, the interference was attributed to impurities in commercially available methylene chloride. Passing the methylene chloride through basic alumina eliminated the interference. Each commercial product analyzed was carried through the procedure without addition of internal standard to check for interference of excipients in the area of the internal standard peak. A synthetic preparation of excipients representative of those encountered in the commercial products analyzed was also prepared and carried through the procedure to test for interference in the areas of the scopolamine peak and hyoscyamine–atropine peak. No significant interferences were detected. Phenobarbital was not entirely removed by the extraction procedure but did not interfere with the HPLC determination because it was well separated from the peaks of interest, as shown in Fig. 1.

Stability of Standard Preparation and Sample Solutions—A standard solution was prepared and its peak areas checked each day against a freshly prepared standard solution for 1 week. No deterioration in standard peak responses was noted. A sample solution was treated in a similar manner and sample peak responses also did not deteriorate. When standards or samples were dissolved in 0.05 N sulfuric acid or mobile phase instead of water, peak responses deteriorated.

Validation Tests—Twenty microliters of each of a series of five standard solutions containing 0–0.5 mg of hyoscyamine sulfate/ml and 0–0.032 mg of scopolamine hydrobromide/ml were injected onto the HPLC. Linear responses were obtained for each drug in its respective range by both peak height and peak area. Six replicate injections of the procedural standard solution gave a coefficient of variation of 1.4% for scopolamine hydrobromide and 0.5% for hyoscyamine sulfate.

Precautions in Sample Extraction—To minimize decomposition of the alkaloids due to heat, acids, and bases, the sample was carried through the entire extraction procedure to final dilution without stopping. The evaporation of solvent was found to be the most critical step. Since the alkaloid free bases decompose above 45°, methylene chloride (bp 38°) was chosen as the extracting solvent. Use of the flash evaporator allowed for rapid evaporation without bumping and splattering of the solvent. During the evaporation, the sample was not allowed to go to dryness before addition of methanolic hydrochloric acid to prevent possible loss of the alkaloids' free bases. The final methanol rinse was added to drive off residual hydrochloric acid which would decompose scopolamine salt. Because the alkaloid concentrations are in the microgram range, and thus subject to minute interferences, all glassware was thoroughly rinsed with distilled water and methylene chloride to ensure cleanliness.

Recovery of Standards—An aliquot of each commercial formulation assay composite was spiked with a standard solution of scopolamine hydrobromide and hyoscyamine sulfate, extracted and assayed according to the procedure, and the percentage of standard recovered calculated. Recovery of alkaloid standards was also checked by a second analyst for Formulations 14 and 21. The recovery results for each product and the statistical evaluation of the recovery data are summarized in Table 1.

Analysis of Commercial Formulations—Twenty-two commercial formulations consisting of elixirs, tablets, and capsules were assayed. Tablets and capsules were also analyzed for content uniformity. Results of the analyses are summarized in Table II. The average content uniformity values generally agreed with the assay values, but individual tablet values often varied ±10% of the average value. This variation coupled with the low concentration of alkaloids caused difficulty in preparing a uniform assay composite for tablets and capsules. Assays on Formulations 14 and 21 were checked by a second analyst, and the results compared favorably with those of the first analyst.

Belladonna Alkaloids and Phenobarbital Combination Pharmaceuticals Analysis II: High-Performance Liquid Chromatographic Determination of Phenobarbital

WALTER F. SCHMIDT ˣ **and LINDA J. PENNINGTON**

Received March 9, 1981, from the *Food and Drug Administration, Atlanta, GA 30309.* Accepted for publication November 16, 1981.

Abstract □ A high-performance liquid chromatographic separation is described for the analysis of phenobarbital in combination pharmaceutical dosage forms containing belladonna alkaloids. A mobile phase of 0.003 *M* tetramethylammonium chloride in water–methanol (3:2, pH 7.4) was used to separate phenobarbital from belladonna alkaloids on an octadecylsilane column in <7 min. The column effluent was monitored at 240 nm, which resulted in a detection limit of 6 ng of phenobarbital. The method is applicable to elixirs, tablets, and capsules with no preliminary extraction procedure. Data from the application of the method to commercial products is also presented.

Keyphrases □ High-performance liquid chromatography—belladonna alkaloids and phenobarbital combination pharmaceuticals, determination of phenobarbital □ Phenobarbital—belladonna alkaloids, combination pharmaceuticals, high-performance liquid chromatographic determination □ Combination drugs—belladonna alkaloids, high-performance liquid chromatographic determination of phenobarbital

Phenobarbital is present in elixirs, tablets, and capsules with belladonna alkaloids for its sedative effects. It has been previously analyzed by such procedures as extraction with UV detection (1), partition chromatography with UV detection (2), derivative formation with gas chromatography (3–5), normal-phase high-performance liquid chromatography (HPLC) (6, 7), and reversed-phase HPLC (8–10). Since an assay was desired which would work as rapidly and as effectively with elixirs as with tablets and capsules with minimum sample preparation, reversed-phase HPLC was investigated.

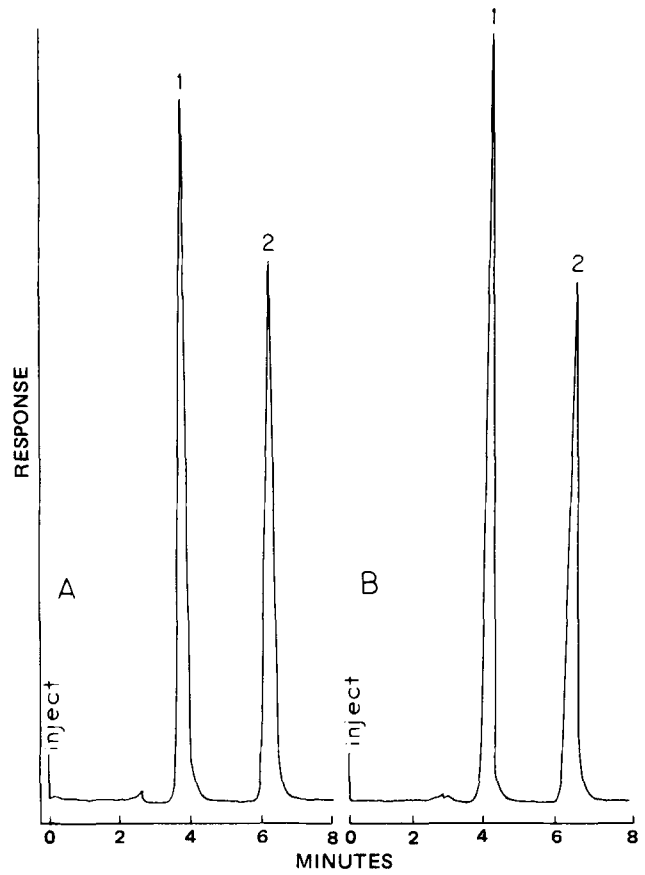

Figure 1—*Typical HPLC chromatograms showing separations of A, the standard solution and B, the sample solution. Key: 1, phenobarbital; 2, guaifenesin (internal standard).*

The HPLC retention properties of phenobarbital at different pH values of the mobile phase using ammonium phosphate and ammonium carbonate buffers was investigated previously (8). It was found that phenobarbital could not be resolved from the solvent front on 37–40-μm commercially packed reversed-phase columns, and that the phenobarbital peak resolution was not improved by variations in either pH or the methanol–water ratio. Others, also investigating the reversed-phase retention properties of phenobarbital at different pH values of the mobile phase (9) found, using sodium phosphate buffers, that retention volumes would change with the pH of the mobile phase on a 10-μm commercially packed reversed-phase column. However, no optimization of analytical conditions was attempted. Reversed-phase HPLC was used also for the analysis of phenobarbital in animal feeds with an unbuffered methanol–water mobile phase (10). However, the mobile phase was selected to minimize animal feed interferences.

A reversed-phase HPLC procedure was developed in this laboratory which is rapid, specific, and stability indicating for the analysis of phenobarbital in the presence of belladonna alkaloids in commercial elixirs, tablets, and capsules. Analytical data for selected commercial products using the proposed method are reported.

EXPERIMENTAL

Apparatus—A liquid chromatograph[1], equipped with a 20-μl loop injector[2], a variable wavelength UV detector[3], and a recorder-integrator[4], was used. A 25 cm × 4-mm i.d. stainless steel column containing octadecylsilane chemically bonded to 5-μm silica[5] was employed.

Reagents—A 0.01 *M* tetramethylammonium chloride solution was prepared by mixing 1.1 g of tetramethylammonium chloride[6] in 1 liter of distilled water. A 0.02 *M* phosphate buffer (pH 7.4) was prepared by dissolving 6.80 g of monobasic potassium phosphate in ~250 ml of distilled water, adjusting to pH 7.4 with ~39 ml of 1 *N* NaOH, and diluting to 1 liter.

Preparation of Internal Standard Solution—A guaifenesin[7] internal standard solution in methanol (3.2 mg/ml) was prepared (Fig. 1).

Table I—Recovery Data for Spiked Sample Determinations of Commercial Formulations for Phenobarbital [a]

Elixirs		Tablets and Capsules	
Formulation [b]	Percent Recovery	Formulation [b]	Percent Recovery
2	100.0	10	99.2
5	98.0	15	101.4
9	99.9	19	101.8
		20	100.8
Mean Recovery	99.3		100.8
SD	1.1		1.1
RSD	±1.1		±1.1
Range	98.0–100.0		99.2–101.8

[a] Portion of sample spiked with standard solution containing phenobarbital and analyzed according to procedure. [b] Numbering corresponds to formulations in Table II.

Preparation of Drug Standard Solution—A phenobarbital[8] standard solution was prepared in absolute methanol (260 μg/ml). Five milliliters of this solution was added to 4.0 ml of guaifenesin internal standard solution and 30 ml of 0.02 *M* phosphate buffer (pH 7.4), cooled to room temperature, and the volume adjusted to 50.0 ml with absolute methanol.

Preparation of Mobile Phase—A mobile phase was prepared by mixing 150 ml of 0.02 *M* phosphate buffer (pH 7.4), 150 ml of 0.01 *M* tetramethylammonium chloride solution, and 200 ml of absolute methanol.

HPLC Conditions—A flow rate of 1.0 ml/min was used with the UV detector set at 240 nm and the detector sensitivity set at 0.04 aufs.

Assay for Phenobarbital in Elixirs—A quantity of elixir equivalent to ~16 mg of phenobarbital was pipeted into a 50-ml volumetric flask. Thirty milliliters of methanol was added to the flask, the contents shaken for 4 min, and made to volume with methanol. About 5 ml of the solution was passed through a 0.5-μm filter. Aliquots of 2.0 ml of the filtrate and 2.0 ml of guaifenesin internal standard solution were combined with 15 ml of 0.02 *M* phosphate buffer (pH 7.4) into a 25-ml volumetric flask. The solution was mixed and made to volume with methanol. A 20-μl portion of the solution was injected into a liquid chromatograph. The peak response was compared with the peak response by peak height or peak area of 20 μl of phenobarbital standard solution. The quantity of phenobarbital in the portion of sample taken was calculated by the formula $(Ru/Rs) \times C$ in which Ru and Rs were the ratios of phenobarbital to guaifenesin peak response for sample (u) and standard (s), respectively, and C was the concentration of phenobarbital in the standard solution.

Assay for Phenobarbital in Tablets and Capsules—Twenty tablets or the contents of 20 capsules were weighed and finely powdered. A portion of sample composite equivalent to ~16 mg of phenobarbital was accurately weighed and transferred to a 50-ml volumetric flask. Five milliliters of distilled water was added and the contents of the flask shaken for 1 min. The procedure for "Assay for Phenobarbital in Elixirs" was then followed beginning with, "Thirty milliliters of methanol was added . . .."

Content Uniformity in Tablets and Capsules—A tablet or the contents of one capsule were quantitatively transferred to a volumetric flask which would yield a concentration of ~0.32 mg/ml of phenobarbital. Five milliliters of distilled water was added and the contents of the flask were mixed for 1 min. The "Assay for Phenobarbital in Elixirs" was then followed beginning with, "Thirty milliliters of methanol was added . . .."

RESULTS AND DISCUSSION

A slightly basic mobile phase (pH 7.4) was used to increase the UV absorptivity of phenobarbital, while avoiding the considerable column degradation normally observed with a mobile phase at a more basic pH. The addition of tetramethylammonium cations to the mobile phase resulted in selective increased retention of anionic compounds (*i.e.*, phenobarbital) through the formation of a tetramethylammonium ion-pair (11). Increased peak broadening with a resulting loss in peak resolution occurred when samples or standards were dissolved in methanol instead of in the mobile phase.

No intefering peaks were detected with 20 min of injection in any of the commercial products analyzed. The belladonna alkaloids did not interfere because of their separate retention times, lower absorptivities, and smaller sample concentrations. The column was found to be stable with daily usage for more than 1 month with no apparent loss in resolution of phenobarbital and guaifenesin internal standard.

[8] USP reference standard.

Table II—HPLC Analysis Results for Commercial Formulations

Formulation	Dosage Form	Percent of Label Claim [a]
1	Elixir	101.9
2	Elixir	102.2
3	Elixir	102.5
4	Elixir	98.8
5	Elixir	99.7
6	Elixir	98.1
7	Elixir	108.6
8	Elixir	101.2
9	Elixir	95.6

20	Capsule	106.8, 106.8 [c], (109.2)
21	Capsule	105.0 (101.9)

[a] Label claim range 15–32 mg/unit dose. [b] Values in parentheses are the average of 10 individual tablet assays (content-uniformity). [c] Value obtained by second analyst.

Six replicate injections of a standard solution containing 0.026 mg/ml of phenobarbital gave a coefficient of variation of 0.5% for the ratio of the peak response of phenobarbital to that of internal standard. Linear response was obtained in the 0–0.055 mg/ml range for a series of five phenobarbital standards.

Seven commercial formulations were each spiked with a standard solution of phenobarbital, extracted and assayed, and the percentage of standard recovery calculated. The recovery results and the statistical evaluation of the recovery data are summarized in Table I.

Twenty-one commercial formulations consisting of elixirs, tablets, and capsules were assayed. Tablets and capsules were also analyzed for content uniformity. Results of the content uniformity analyses are summarized in Table II. The average content uniformity values agreed with the composite assay values. Composite assays on Formulations 16, 17, 19, and 20, listed in Table II, were performed by another analyst. These results compared favorably with the original findings.

Ion-Pair High-Performance Liquid Chromatography of Terbutaline and Catecholamines with Aminophylline in Intravenous Solutions

DAVID A. WILLIAMS *x, **ESTHER Y. Y. FUNG** ‡, and **DAVID W. NEWTON** §

Received June 15, 1981, from the *Department of Chemistry, Massachusetts College of Pharmacy and Allied Health Sciences, Boston, MA 02115, the ‡Tiers Drug Store, Uxbridge, Ontario, Canada LOC 1 KO, and the §Department of Pharmaceutics, College of Pharmacy, University of Nebraska Medical Center, Omaha, NE 68105. Accepted for publication November 12, 1981.

Abstract □ A stability-indicating ion-pair high-performance liquid chromatographic (HPLC) assay that is rapid and specific for epinephrine, isoproterenol, dopamine, norepinephrine, methyldopate, or terbutaline in intravenous solutions with aminophylline has been developed using a spectrofluorometric detector. A HPLC method for the analysis of terbutaline and methyldopate is introduced, and the superiority of fluorometric over UV detection of terbutaline and the catecholamines is illustrated.

Keyphrases □ High-performance liquid chromatography—ion-pair, terbutaline and catecholamines with aminophylline in intravenous solutions □ Fluorescence detector—high-performance liquid chromatographic analysis of catecholamines in presence of aminophylline □ Catecholamines—ion-pair high-performance liquid chromatography with aminophylline in intravenous solutions

Dopamine (I), epinephrine (II), isoproterenol (III), methyldopate (IV), norepinephrine (V), or terbutaline (VI) may be combined with aminophylline (VII) in intravenous admixtures prior to patient administration. Catecholamines and other phenolic sympathomimetic amines are reportedly more unstable in an alkaline media and can undergo rapid autoxidation to biologically inactive quinoid products (1). Thus, the therapeutic efficacy of these sympathomimetic amines is directly related to their stability in an alkaline aminophylline solution (pH 8.6–9.0) for injection. Little information has appeared regarding the stability of these sympathomimetic amines (I–VI) when combined with aminophylline solutions. This may be due in part to the lack of a rapid, specific, stability-indicating assay for I–VI in the presence of their degradation products and theophylline.

Over the years, catecholamines (I–V) have been assayed using UV or spectrofluorometric methods. However, the poor specificity of these commonly employed methods for I–V in the presence of quinone degradation products raises doubts about their validity.

One significant advantage of chromatographic assays is that they are stability-indicating (2, 3). This is of importance when determining the rate and extent of degradation of potent, potentially lifesaving pharmacologic agents such as sympathomimetic drugs which are diluted in parenteral solutions for clinical administration, sometimes in combination with other drugs.

Several HPLC procedures for the assay of catecholamines and related drugs or metabolites have employed UV detection (4–7), fluorescence detection with precolumn derivatization (8), or electrochemical detection (9–11). Finally, other less expedient chromatographic procedures have been applied to the analysis of some of these drugs (12, 13). Apparently, neither the HPLC assay for terbutaline and methyldopate, nor the use of fluorometric detection requiring no derivatization has been reported for the HPLC analysis of VI or the catecholamines (I–V) in solutions intended clinically for injection. The present report describes a rapid, sensitive, and stability-indicating method for I–VI in the presence of aminophylline and the superiority of fluorometric over UV detection.

Table I—Conditions for the High-Performance Liquid Chromatographic Assay of Terbutaline and Five Catecholamines in 5% Dextrose in Water Injection in the Absence and Presence of Aminophylline

Drug	Methanol in Eluant, % (v/v)	Fluorometer Sensitivity[a]	Volume Injected, μl
Dopamine Hydrochloride (I)	25	2 × 0.3	20
Epinephrine Hydrochloride (II)	25	4 × 3	20
Isoproterenol Hydrochloride (III)	35	4 × 10	20
Methyldopate Hydrochloride (IV)	35	4 × 1	15
Norepinephrine Bitartrate (V)	15	4 × 10	15
Terbutaline Sulfate (VI)	35	4 × 10	40
Aminophylline (VII)	—	—	—

[a] Fluorescence detector P.M. gain × sensitivity range. Maximum sensitivity = 4 × 10.

EXPERIMENTAL

Apparatus—A high-pressure liquid chromatograph[1] equipped with a septumless injector[2] and a variable wavelength spectrofluorometric[3] or a variable wavelength UV detector[4] was employed in conjunction with a microparticulate C_{18} column[5] for separation.

Reagents—All chemicals and reagents were analytical grade unless otherwise indicated. Dopamine hydrochloride[6], epinephrine hydrochloride[7], isoproterenol hydrochloride[8], methyldopate hydrochloride[9], norepinephrine bitartrate[7,8], terbutaline sulfate[10], aminophylline[7], and glass-distilled HPLC grade methanol[11] were used without further purification. Sodium heptanesulfonate[12] was recrystallized from an acetone–water mixture.

Table II—Retention Time and Analysis of the Catecholamines and Terbutaline in Known Mixtures

Drug		t_R[a] min	t_R, min[a] aminophylline	Concentration, mg/liter Added	Concentration, mg/liter Found ± CL[b]	Error, %
I	(80–900)[c]	4.08	ND[d]	800.0	802.53 ± 7.09	0.32
II	(0.4–4.2)[c]	4.13	3.50	4.0	3.98 ± 0.02	0.50
III	(0.2–2.4)[c]	4.33	3.17	2.0	2.02 ± 0.06	1.0
IV	(120–1100)[c]	4.50	2.75	1000.0	996.92 ± 5.30	0.31
V	(0.8–8.5)[c]	4.75	5.33	8.0	8.05 ± 0.09	0.63
VI	(0.4–4.2)[c]	5.33	2.75	4.0	3.96 ± 0.05	1.0

[a] Flow rate = 1.6 ml/min. t_R for aminophylline is for theophylline. [b] 95% confidence limits. [c] Concentration range (μg/ml) used for preparing standard curves. [d] Not detected, sensitivity too low.

Analytical Procedure—Standard solutions (Table I) of each drug were freshly prepared by diluting a stock solution with 5% dextrose in water for injection, USP[13]. The mobile phase was 0.35 *M* acetic acid and 0.005 *M* sodium heptanesulfonate in different concentrations of methanol (Table II). The flow rate was 1.6–2.0 ml/min at ambient temperature. The injection volumes for the standard or sample solution are reported in Table II. The catecholamines (I–V) were detected using an excitation wavelength (λ_{ex}) of 285 nm and an emission wavelength (λ_{em}) of 315 nm. The values of λ_{ex} and λ_{em} for terbutaline were 280 and 310 nm, respectively. The UV detector was operated at 280 nm. The concentrations of I–VI were determined from their respective peak areas by comparison to a standard curve. Peak areas were calculated from the product of peak height times half-height peak widths. Good reproducibility was obtained without the use of an internal standard.

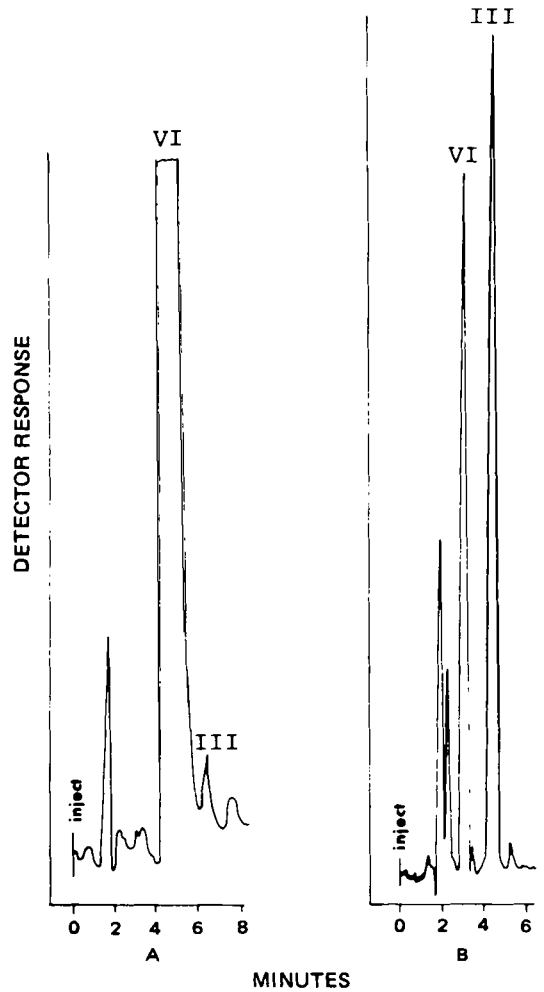

Figure 1—*(A) Chromatogram of isoproterenol hydrochloride (III), 2 μg/ml and aminophylline (VII), 500 μg/ml. UV detector = 280 nm, flow rate = 1.6 ml/min, 0.005* M *1-heptanesulfonate sodium and 0.35* M *acetic acid in 20% (v/v) methanol. The recorder was set at 1 mV; detector response = 0.004 aufs, and injection volume = 20 μl. (B) Chromatogram of isoproterenol hydrochloride (III), 2 μg/ml and aminophylline (VII), 500 μg/ml. Fluorometric detector (λ_{ex} = 285 nm, λ_{em} = 315 nm), flow rate = 1.6 ml/min, 0.005* M *1-heptanesulfonate sodium and 0.35* M *acetic acid in 35% (v/v) methanol. The recorder was set at 10 mV, and a chart speed of 0.5 cm/min; detector sensitivity and injection volume are given in Table I.*

RESULTS

The chromatogram peaks attributed to aminophylline actually represent theophylline, because at pH 2.4–3.0 of the mobile phase, aminophylline dissociates into theophylline and the ethylenediammonium ion. The high concentration and strong UV absorbance of theophylline makes the accurate HPLC analysis for dilute solutions of II, III, V, and VI difficult and poorly reproducible with a UV detector. Increasing the injection volume and/or retention time produced unsatisfactory results. The advantage of fluorescence detection in this study was to provide decreased response to theophylline concurrently with increased sensitivity and selectivity towards II, III, V, and VI without pre- or postcolumn derivatization. A typical chromatogram illustrating the advantage of using fluorescence detection is shown for III in Fig. 1. For I and IV, fluorescence detection offered no advantage over UV detection because of their much higher concentrations, relative to II, III, V, and VI (Table III). Theophylline may not be detectable when using the fluorescence detector at its lower sensitivity, which was the case for dopamine. The sensitivity of the fluorescent method permits quantitation of II, III, V, and VI to <0.1 μg/ml. The methanol concentration in the mobile phase needed to achieve the desired separation for I–VI from aminophylline is given in Table I, and their respective retention times, which are the mean of four replicate determinations, are reported in Table II. Standard curves of eight drug concentrations *versus* their peak height areas were constructed from triplicate injections for each drug in Table I. The linear plots showed that the peak height area of each drug was directly related to its concentration.

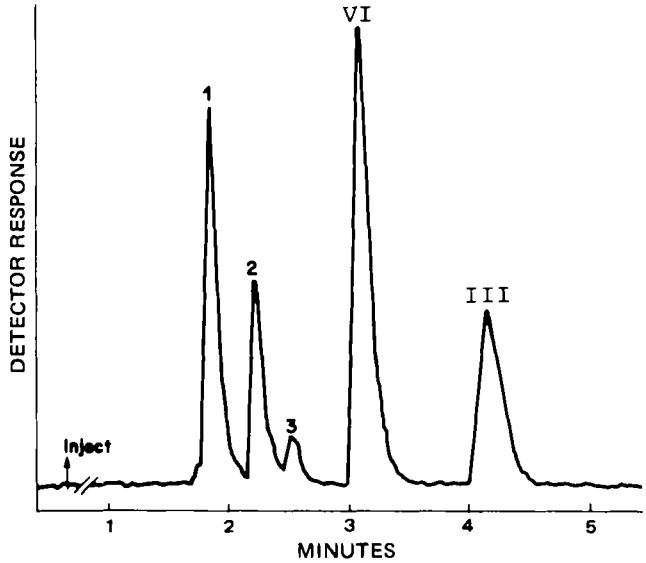

Figure 2—*Chromatogram of isoproterenol hydrochloride (III), 2 μg/ml and aminophylline (VII), 500 μg/ml, after 17 hr of exposure to fluorescent light. Fluorometric detector (λ_{ex} = 285 nm, λ_{em} = 315 nm), flow rate 1.6 ml/min 0.005* M *1-heptanesulfonate sodium and 0.35* M *acetic acid in 35% (v/v) methanol. The recorder was set at 10 mV and a chart speed of 4 cm/min; detector sensitivity and injection volume are given in Table I. Peaks 1 and 3 are degradation products, and Peak 2 is unidentified.*

The correlation coefficient for the standard curves over the concentration range used in this study was >0.997 (n = 22 or 25). The analysis of the concentrations of I–VI in the experimental samples compared favorably with the theoretical values of the drug formulations (Table II) with <1% error.

The described HPLC assay has been successfully applied as a stability-indicating method for determining the rate and percentage of autoxidation of commercially supplied injectable solutions of I–VI which had been diluted in 5% dextrose in water injection, with and without aminophylline (500 μg/ml) (14). The chromatographic separation of I–VI from their autoxidation products is illustrated in Fig. 2, with III, which has undergone 70% decomposition after being exposed to 17 hr of fluorescent light. Peak 1 represents the principal degradation product and Peak 3 a minor product. The unidentified Peak 2 is present in unexposed samples and does not appear to change after exposure to light. Similarly, the degradation products of I, II, and IV–VI elude within 2–3 min following injection. Figure 1B represents III before exposure to fluorescent light and decomposition has already commenced. This method has demonstrated the capability of separating degradation products from the analysis of pure I–VI.

The application of ion-pair HPLC for the analysis of formulations containing VI or IV has not been previously described. This reported method is applicable for the accurate determination of these drugs, using either UV or fluorescence detectors.

DISCUSSION

Various analytical methods have been used in stability studies for catecholamines but suffered from their inability to quantitate or separate degradation products from the parent substance. The combination of fluorescence detection with reversed-phase ion-pair HPLC yields a rapid and selective method for the quantitative separation and determination of I–VI in the presence of their autoxidation products and pharmaceutical adjuvants. The lowest concentration at which the sympathomimetic amines used in this study could be detected was 0.1 μg/ml.

The described method is applicable for the content uniformity and quality control of products containing VI and IV.

Despite the widespread use of UV detection in HPLC assays, the sensitive fluorescence measurement for low concentrations of sympathomimetic amines in pharmaceutical preparations has not been extensively reported except for their clinical analysis in biological fluids. The sensitive measurement of I–VI will allow studies of the purity of dosage forms and investigation of their degradation kinetics and pharmacokinetics. Without the use of a fluorescence detector, II, III, V, or VI could not be quantitatively measured in the presence of aminophylline. Also, the presence of pharmaceutical adjuvants should not interfere, because of their poor fluorescent properties.

Enhanced Entrapment of a Quaternary Ammonium Compound in Liposomes by Ion-Pairing

MICHAEL JAY ˣ and GEORGE A. DIGENIS

Received September 9, 1981, from the *Division of Medicinal Chemistry and Pharmacognosy, College of Pharmacy, University of Kentucky, Lexington, KY 40536.* Accepted for publication November 10, 1981.

Abstract □ The encapsulation of a quaternary ammonium compound by multilamellar liposomes was enhanced by formation of ion-pairs with a counterion. Thus, [^{14}C]methantheline bromide was synthesized and paired with a 25 M excess of trichloroacetate. Under these conditions, the amount of radioactivity entrapped by phosphatidylcholine liposomes was three times greater than when no trichloroacetate was present. The increased liposomal loading was probably due to the solubilization of the ion-pair in the lipid membrane of the liposome.

Keyphrases □ Liposomes—quaternary ammonium compound, entrapment, ion pairing □ Ion-pairing—quaternary ammonium compound, entrapment, liposomes □ Ammonium—quaternary compound, entrapment in liposomes, ion-pairing

Liposomes are microscopic lipid vesicles originally used to study the structure and function of biological membranes (1). In recent years, liposomes have demonstrated potential as carriers and transporters of biologically active compounds (2). A wide variety of compounds have been encapsulated in liposomes, ranging from RNA (3) and insulin (4) to small molecules like histamine (5). Liposomes have been administered intravenously and orally (6), and a recent report describes the delivery of drugs *via* liposomes by the topical route (7). Liposomes elicit no immunological or toxicological responses and are completely biodegradable. For these reasons, liposomes have been viewed as an attractive mechanism for drug delivery, especially for biologically unstable compounds, but not without certain drawbacks. Special techniques have been developed in an attempt to direct liposomes to specific targets or organ systems by immunological methods (8) and by producing pH-sensitive liposomes (9). Polymerized

III

R = C_2H_5

vesicles have been produced to increase their stability (10), but one major problem still exists, *i.e.*, many drugs are very poorly encapsulated by lipsomes, especially water-soluble compounds (11).

Some progress in this case has been reported. The degree of encapsulation of the chemotherapeutic agents 6-mercaptopurine and 8-azaguanine in single compartment liposomes has been improved by the formation of charge-transfer complexes with chloranil (2,3,5,6-tetrachloro-*p*-benzoquinone) and cyanocobalamin (12, 13). In this report, the enhanced entrapment of a quaternary ammonium compound in multilamellar liposomes by the formation of ion-pairs is described. More specifically the entrapment of the antimuscarinic drug, methantheline bromide, in the presence and absence of trichloroacetate was compared. A relatively simple procedure for the synthesis of [^{14}C]methantheline bromide, based on the method of Cusic and Robinson (14) is reported. This differs from the product synthesized in a previous study in the position of the carbon 14 label (15).

EXPERIMENTAL[1]

***N,N*-Diethylaminoethyl Xanthene-9-carboxylate (II)**—2-Diethylaminoethyl chloride hydrochloride[2] (3.0 g, 0.017 mole) was added to 30 ml of 1.0 *N* NaOH and extracted three times with 30 ml of ether. The combined ether extracts were dried over sodium sulfate, filtered, and evaporated under reduced pressure yielding a viscous oil. To this oil was added 4.0 g (0.019 mole) of xanthene-9-carboxylic acid[3] (I) in 15 ml of isopropyl alcohol and the mixture was refluxed overnight. After filtering, the solvent was evaporated, yielding an oily residue which crystallized upon further drying. Recrystallization from ethyl acetate afforded 4.277 g (0.012 mole) of analytically pure material which melted at 145–147° [lit. (15) 143–145°], IR (KBr): 1735 (C=O) cm^{-1}, with a 68% yield.

[^{14}C]Methantheline Bromide (*N,N*-Diethylaminoethyl xanthene-9-carboxylate[^{14}C]methobromide) (III)—A 0.3-g aliquot of II was made alkaline and extracted into ether as described previously. After drying, the solvent was evaporated and the resultant oily residue was dissolved in 4 ml of absolute ethanol. The solution was transferred to a vial containing 0.25 mCi (4.75 mg) of [^{14}C]methyl bromide[4] (5 mCi/mmole) which was cooled to 0–4° in an ice bath. The vial was sealed and allowed to stand for 48 hr at room temperature. The addition of dry ether to the ethanolic solution resulted in the formation of a precipitate which, upon recrystallization from benzene, gave 12.1 mg (0.029 mmole, 0.144 mCi) of fine, white needles (58% yield). The product had an IR spectrum identical to the authentic material[5] and melted at 173–175° in close agreement with the literature value of 175° (6). A radiochromatogram of the product [(silica gel) ethanol–water–acetic acid (3:2:1), R_f = 0.56] verified its radiochemical purity.

For the experiments with liposome entrapment of III, unlabeled methantheline bromide was added to III resulting in a final specific activity of 1 μCi/μmole.

Preparation of Multilamellar Liposomes—Unsonicated multilamellar liposomes were prepared according to the method of Maghew *et al.* (16). Phosphatidylcholine[6] (10 μmoles) and cholesterol[6] (3 μmoles) were dissolved in 2 ml of chloroform and placed in a cylindrical test tube. The chloroform was evaporated leaving a thin film in the bottom of the tube. To this was added the aqueous phase which consisted of 1 μmole of III (1 μCi in 2 ml of phosphate buffer at pH 7.4). In the ion-pairing experiments, 25 μmoles of trichloroacetate[7] was added as well. The mixture was mechanically agitated for 10 min after which time the liposome-entrapped radioactivity (arising from III) was separated from the free radioactivity (*i.e.*, nonliposome-bound activity) by molecular sieves[8]. The extent of entrapment by liposomes of III in the presence and absence of trichloroacetate was calculated by comparing the total number of counts arising from liposome-bound radioactivity with the free radioactivity.

RESULTS AND DISCUSSION

The partitioning of charged species into a nonaqueous medium results from the masking of the hydrophilic site by a counterion. Some counterions are more effective than others in increasing the lipophilicity of the charged species. The use of ion-pairing techniques has been utilized to enhance the lipid solubility of certain ionic compounds (17) and, in this connection, has improved the GI absorption of large cationic drugs (18). The chloroform–water partition coefficient of methantheline bromide was shown to increase over 200-fold when ion-paired with a 25 *M* excess of trichloroacetate (19). Higher concentrations of trichloroacetate did not improve the partitioning of methantheline into the chloroform layer (20). The entrapment of this drug by multilamellar liposomes would presumably be enhanced by the formation of ion-pairs with trichloroacetate, which would allow methantheline to be solubilized in the lipid membrane of the liposome. Multilamellar liposomes have a high lipid content relative to the aqueous phase compared to sonicated unilamellar liposomes. As a result, the effects of ion pairing on increasing lipid solubility should be most pronounced in the multilamellar liposomes. Solubilization of methantheline in the liposomal membrane should significantly increase the total amount of drug carried by the liposome. In the absence of trichloroacetate, the drug would only be carried in the small aqueous core of the liposome and the thin aqueous layers between the lipid bilayers of the multilamellar liposome. In the presence of trichloroacetate, the drug would be carried in these aqueous compartments as well as in the membrane itself.

The addition of a 25 *M* excess of trichloroacetate (with respect to III) in the aqueous phase during liposome production resulted in a threefold increase in the amount of radioactivity, which was entrapped by the multilamellar liposomes (1005–3027 dpm). Varying the cholesterol content of the liposomal membrane from 0 to 5 μmoles per 10 μmoles of phosphatidylcholine, did not significantly alter the entrapment of III. The increase of entrapped radioactivity arising from [^{14}C]methantheline from 0.44–1.2% by ion-pairing could be increased further by utilizing phospholipid membranes with physical properties differing from phos-

[1] Infrared spectra (KBr) were recorded on a Perkin-Elmer 567 spectrophotometer. Melting points were determined using a Thomas-Hoover capillary apparatus and are uncorrected. Radiochemical purity was determined with a Packard 7201 radiochromatogram scanner. Radioactive samples were counted in a Packard 3375 Tri-Carb Liquid Scintillation Spectrometer. ACS (Amersham) was the cocktail used for radioactive samples.

phatidylcholine. The use of a charged membrane as well as the addition of other membrane adjuvants may affect the entrapment of methantheline and other compounds by liposomes.

These ion-pairing techniques can be used to increase liposomal loading of a large number of ionic compounds. The liposome-entrapped compounds can be used to overcome some traditional problems in the oral administration of drugs such as acid lability, inadequate intestinal absorption, and poor palatability.

The administration of methantheline bromide *via* liposomes is particularly desirable considering the poor absorption observed for quaternary ammonium compounds. In addition, ion-pairing of quaternary ammonium compounds increases the loading of these poorly entrapped drugs in liposomal membranes.

pH-Sensitive Microcapsules for Drug Release

KIRAN BALA * and PADMA VASUDEVAN ‡x

Received July 24, 1981, from the **Centre for Biomedical Engineering, All India Institute of Medical Sciences*, and the *‡Centre for Rural Development and Appropriate Technology, Indian Institute of Technology, Hauz Khas, New Delhi-110 016 India.* Accepted for publication November 3, 1981.

Abstract □ Microcapsules were designed for a sustained drug release, where the external medium controls the rate of release of the drug. As a model, secretin was encapsulated in acryloyl chloride–lysine capsules, and the conditions of formation are described. The scanning electron micrographs show the formation of good spherical microcapsules in the size range of 5–10 μm. The release of secretin was studied in four media having different pH. Polymer dissolution was pH sensitive, and the capsules placed in different media eroded at a constant rate, depending on the pH of the medium. Dissolution of the microcapsules was limited to the polymer buffer media and the drug was released by zero-order kinetics. The possible use of such a system is in the treatment of duodenal ulcers and the diagnosis of pancreatic diseases.

Keyphrases □ Microcapsules—pH sensitive, drug release □ Drug release—pH sensitive microcapsules, polymerization □ Polymerization—pH sensitive microcapsules for drug release □ Dosage forms—pH-sensitive microcapsules for drug release

Microencapsulation is a process by which individual entities of a solid, liquid, or gas are discretely enclosed in a shell of inert polymeric materials. These inert shells may be designed to release their ingredients at a specific rate and/or under a specific set of conditions. Microencapsulation of a material may permit the alteration of its physical properties so that the desired availability is achieved and at the same time the encapsulated material is protected from its environment. Release of drug may be achieved *via* erosion, dissociation, or diffusion. Dosage forms have become more complex and now include such forms as sustained release, prolonged action, and repeat action. The technique of microencapsulation is one of the newer methods for sustained delivery which is receiving increasing attention (1, 2).

Precisely controlled sustained delivery does not always correspond to the optimum therapeutic regimen, however. In many applications a better delivery system is the one that delivers the active agent only when needed. In the present study secretin was microencapsulated in acryloyl chloride–lysine microcapsules, and the rate of release was studied in different media of varying pH.

BACKGROUND

Secretin (3), a small polypeptide (molecular weight ~3400), is present in the mucosa of the upper small intestine in the inactive form of prosecretin. When chyme enters the intestine, it causes the release and activation of secretin, which is subsequently absorbed into the blood. The constituent that causes greatest secretin release is hydrochloric acid, although almost any type of food will cause at least some release. Secretin is released any time the pH of the duodenal contents falls below ~4.0. This immediately causes large quantities of pancreatic juice containing abundant amounts of sodium bicarbonate to be secreted. Carbonic acid is formed by reaction of sodium bicarbonate with hydrogen chloride. The carbonic acid is immediately dissociated into carbon dioxide and water, and the carbon dioxide is absorbed into the body fluids, thus, leaving a neutral solution of sodium chloride in the duodenum. In this way, the acid contents emptied into the duodenum from the stomach become neutralized and the peptic activity of the gastric juices is immediately blocked. Since the mucosa of the small intestine cannot withstand the intense digestive properties of gastric juice, this is a highly important protective mechanism against the development of duodenal ulcers (4). A second function of hydrolytic secretin by the pancreas is to provide an appropriate pH for action of pancreatic enzymes. All such enzymes

function optimally in a slightly alkaline or neutral medium. The pH of the hydrolytic secretion averages 8.0.

Secretin release *in vivo* is pH-sensitive. To simulate this system, it was proposed to design a secretin microcapsule that would become more permeable at low pH. The acryloyl chloride–lysine encapsulation system was chosen as the wall material, since it was anticipated that the presence of unreacted amino groups in the capsule wall would likely cause the erodibility of the polymer to become pH dependent.

EXPERIMENTAL

Microcapsules were prepared by interfacial polymerization as described previously (5). Acrylic acid distilled under reduced pressure was polymerized under vacuum by gamma radiation from a cobalt 60 source. The polyacrylic acid was dissolved in distilled 1,6-dioxane and then converted into the acid chloride with thionyl chloride. The polyacryloyl chloride that precipitated out was dissolved in dimethylformamide.

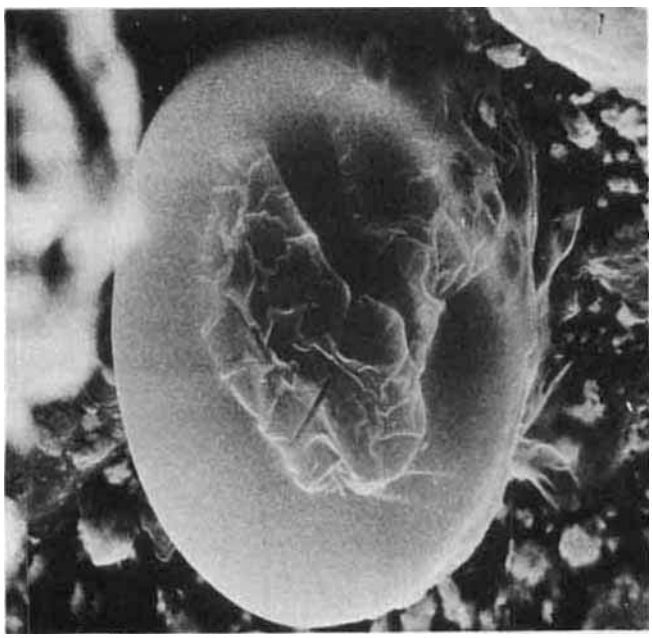

Figure 2—*Scanning electron micrograph of polyacryloyl chloride–lysine microcapsules containing secretin (5000× 2.5).*

Table I—Cumulative Release of Secretin at Different pH

Time, days	I pH 2 Amount, mg	I pH 2 Secretin, %	II pH 4 Amount, mg	II pH 4 Secretin, %	III pH 7 Amount, mg	III pH 7 Secretin, %

7	—	—	35.0	70	18.0	36
8	—	—	40.0	80	20.0	40
9	—	—	42.5	85	22.5	45
10	—	—	44.0	88	26.0	52
12	—	—	47.0	94	30.0	60
14	—	—	—	—	35.0	70
16	—	—	—	—	40.0	80
18	—	—	—	—	44.0	88
20	—	—	—	—	47.0	94
22	—	—	—	—	48.0	96

Secretin (50 mg) was mixed with an equal volume of 0.8 *M* lysine dissolved in a tromethamine buffer (pH 7.4), containing 2 ml of 0.45 *M* sodium bicarbonate solution. This mixture was freshly prepared and stirred in a 100-ml beaker at room temperature. The organic phase [a 15-ml mixture of chloroform–cyclohexane (1:4)] was added with stirring to the beaker. Stirring was continued for 45–60 sec at the maximum speed to disperse the aqueous droplets and to reduce their size, and polyacryloyl chloride solution in dimethylformamide was added. The amount of polyacryloyl chloride used was approximately equivalent to lysine. In this way polyacryloyl chloride–lysine microcapsules containing secretin were prepared.

The microcapsules were separated from the organic phase by centrifugation and transferred to the aqueous phase with the aid of polyoxyethylene sorbitol washed repeatedly with saline solution and dispersed in isotonic buffer. Scanning electron micrographs of the capsules were taken[1]. Release of encapsulated drug was studied by following its elution in buffer solutions of different pH. For a typical experiment the microcapsules were equilibrated with 15 ml of buffer for 24 hr. The supernate was separated by centrifugation and its optical density was determined at 245 nm. A fresh buffer (5 ml) was equilibrated until no more elution of the drug occurred.

RESULTS AND DISCUSSION

To check the reproducibility of the method of encapsulation and release, three sets of samples (labeled I, II, and III) were prepared under the same conditions just described. The electron micrograph of each sample was taken separately. In all cases, the capsules were 5–10 μm in diameter (Figs. 1 and 2).

The release rates of secretin at different pH values are given in Table I. Figure 3 shows the cumulative release of secretin as a function of time for all samples. In all cases, at least up to 80% of the drug was released by a zero-order mechanism; however, the rate of release was fastest at pH

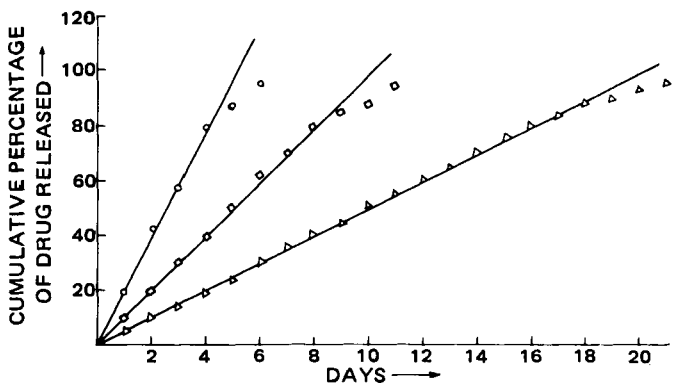

Figure 3—*Cumulative percentage of secretin released from acryloyl chloride–lysine microcapsules. Key: (○) pH 2, (□) pH 4, (△) pH 7.*

[1] Micrographs taken by a Cambridge Steroscan S_4-10 instrument.

2, and was prolonged for up to 6 days. At pH 4, the release sustained for up to 12 days, and on increasing the pH to 7, the duration of the release increased to 22 days. Thus, it was also observed that as the pH increased, the solubility of the wall material decreased and the quantity of drug released per day decreased. When the pH was raised to 10, no dissolution of the polymer wall occurred and no release of secretin was observed for several days.

The data indicated that the drug was perhaps released by polymer dissolution at the polymer–water interface by a mechanism similar to that discussed previously (6, 7). Detailed study of this polymer will be necessary before the complete mechanism for erosion can be understood; the mechanism of release is the subject of further study. However, in the present study the interest was more on controlled release of the drug at low pH, which has been achieved. The above type of capsules would be suitable for sustained drug release at low pH. Further, since the polymer was erodible up to pH 8, it can form a suitable biosoluble wall material for encapsulating other drugs. The biocompatibility of this material is being studied.

Notable features of the microcapsules described in this report are: their ability to undergo surface erosion and, hence, release of the core material by zero-order kinetics, and sensitivity of the erosion rate to the surrounding aqueous environment (pH). A pH environment has a major effect on the erosion rate and, thus, controls the drug release which is increased by decreasing the pH.

Reaction of Phenobarbital with Diphenhydramine

MELVIN F. W. DUNKER[x] and LAURENCE M. SIROIS

Received June 8, 1981, from the *College of Pharmacy and Allied Health Professions, Wayne State University, Detroit, MI 48202.* Accepted for Publication November 3, 1981.

Abstract □ A compound of low water solubility, consisting of phenobarbital–diphenhydramine in a 1:1 ratio and mp 109.5–110.5° was isolated from a prescription which had been dispensed as a clear solution and later returned with a white sediment. The information obtained suggested that it was either an easily dissociated complex or a salt.

Keyphrases □ Phenobarbital—reaction with diphenhydramine, complexation, salts □ Diphenhydramine—reaction with phenobarbital, complexation, salts □ Complexation—phenobarbital and diphenhydramine, salts

A number of salts, complexes, or addition compounds formed by barbiturates, particularly by phenobarbital, have been recorded previously (1–6). Similarly, there are recorded complexes and salts for diphenhydramine, the best known being dimenhydrinate, USP (7). The products formed by heating diphenhydramine and barbital or allobarbital in alcohol at 100–120° are reported to be 1:1 salts melting at 86 and 102–103°, respectively (8).

Literature pertaining to intravenous admixtures refers to diphenhydramine hydrochloride as being incompatible with phenobarbital sodium (9–11) as well as several other barbiturate salts; forming particulate matter (12, 13), forming a precipitate (14), or as not remaining clear for 24 hr after mixing (15). The only explanation provided is that solutions of sodium barbiturates and sodium diphenylhydantoin are alkaline and may lead to the formation of precipitates from solutions of acid salts. A previous study (16) pointed out that aqueous solutions of diphenhydramine hydrochloride and phenobarbital sodium will form a precipitate when mixed in low concentrations, even at pH values at which phenobarbital would be soluble. It was assumed that the precipitate was an undissociated, less soluble diphenhydramine–phenobarbital complex. No characteristics for this substance were reported.

The reported compound was first obtained from the crystalline settlement in a compounded prescription consisting of 250 ml of diphenhydramine hydrochloride elixir in which 750 mg of phenobarbital sodium had been dissolved in accordance with physician's instructions. When prepared, the mixture slowly became cloudy and then deposited crystals over several days. Upon filtration and recrystallization of the solid from ~75% alcohol, the hard, colorless crystals melted at 109.5–110.5° (uncorrected). The product was found to be composed of phenobarbital–diphenhydramine (1:1).

The formation of the crystals could be avoided by dissolving the equivalent amount of phenobarbital in 10 ml of alcohol and mixing it into the elixir. Such a sample was still free of crystals after 1 year. Since the crystals are very soluble in alcohol, somewhat soluble in water, and the pH of the elixir results in only a low concentration of diphenhydramine base, the product probably does not form in an amount sufficient to exceed its solubility in the hydroalcoholic medium.

EXPERIMENTAL

Diphenhydramine hydrochloride elixir[1], diphenhydramine[1], diphenhydramine hydrochloride[1], phenobarbital[2], and phenobarbital sodium[2] were obtained as indicated. The various solvents were USP or reagent grade.

[1] Elixir Benadryl, Parke-Davis & Co.; the diphenhydramine and its hydrochloride were provided by Parke-Davis & Co.

It was assumed that the precipitate was an undissociated, less soluble diphenhydramine–phenobarbital complex. No characteristics for this substance were reported.

The reported compound was first obtained from the crystalline settlement in a compounded prescription consisting of 250 ml of diphenhydramine hydrochloride elixir in which 750 mg of phenobarbital sodium had been dissolved in accordance with physician's instructions. When prepared, the mixture slowly became cloudy and then deposited crystals over several days. Upon filtration and recrystallization of the solid from ~75% alcohol, the hard, colorless crystals melted at 109.5–110.5° (uncorrected). The product was found to be composed of phenobarbital–diphenhydramine (1:1).

The formation of the crystals could be avoided by dissolving the equivalent amount of phenobarbital in 10 ml of alcohol and mixing it into the elixir. Such a sample was still free of crystals after 1 year. Since the crystals are very soluble in alcohol, somewhat soluble in water, and the pH of the elixir results in only a low concentration of diphenhydramine base, the product probably does not form in an amount sufficient to exceed its solubility in the hydroalcoholic medium.

EXPERIMENTAL

Diphenhydramine hydrochloride elixir[1], diphenhydramine[1], diphenhydramine hydrochloride[1], phenobarbital[2], and phenobarbital sodium[2] were obtained as indicated. The various solvents were USP or reagent grade.

[1] Elixir Benadryl, Parke-Davis & Co.; the diphenhydramine and its hydrochloride were provided by Parke-Davis & Co.

[2] Merck & Co., Rahway, N.J., commercial packages.

0022-3549/82/0800-0962$01.00/0

The sample of diphenhydramine hydrochloride elixir had a pH of 6.8, which changed to 8.35 when 750 mg of phenobarbital sodium was dissolved in 250 ml of the sample. The mixture slowly became turbid, cleared as some oily droplets formed, and eventually crystallized over a period of several days. A crop of 833 mg of slightly pink crystals was collected. After treatment with charcoal and several crystallizations from ~30% alcohol, long, colorless needles, mp 109.5–110.5° (uncorrected)[3], were obtained. From 75–95% alcohol, clear, dense prisms of the same melting point were obtained. The crystals were dried *in vacuo* over phosphorus pentoxide at 80°.

Anal.—Calc. for $C_{29}H_{33}N_3O_4$: C, 71.45; H, 6.82; N, 8.62. Found[4]: C, 71.22; H, 6.77; N, 8.73.

After removal of the first crop of crystals, the filtrate was concentrated on a steam bath and then allowed to stand in open air. Large crystals formed (probably some sucrose since the elixir contains considerable syrup) and the mixture was extracted with three portions of ether. After removal of the ether the residue was taken up in 95% alcohol, treated with charcoal, and filtered. An additional 168 mg (mp 108–110° and giving no depression of melting point with previous crystals) of clear prisms was obtained, representing an overall yield of 95.9% based on the diphenhydramine hydrochloride present.

RESULTS AND DISCUSSION

The crystalline product from diphenhydramine hydrochloride elixir is easily soluble in 95% alcohol and is soluble in ether, acetone, chloroform, hot benzene, and somewhat soluble in water.

The same crystalline product could be obtained by dissolving phenobarbital in diphenhydramine with warming, followed by solution of the clear viscous material in alcohol. On cooling, prisms formed with mp 108–109°.

When a solution of 714 mg of phenobarbital in 10 ml of 95% alcohol was added to 240 ml of diphenhydramine hydrochloride elixir, the mixture remained clear and free of crystals for 1 year. There was no change in pH when the solution of phenobarbital was mixed with the elixir. It is probable that the small increase in alcohol concentration coupled with the low dissociation of the diphenhydramine hydrochloride in acid medium may not allow enough compound to form to exceed the solubility.

A solution of 300 mg of diphenhydramine hydrochloride in 30 ml of water had a pH of 5.5. When 261 mg of phenobarbital sodium was added with stirring, the mixture immediately became turbid. Droplets settled out, which quickly crystallized, and the pH changed to 7.5. After chilling, filtrating, washing, and drying, a crop of 425 mg (84.8%) of white crystals was obtained. The product melted sharply at 108–109° and gave no depression of melting point when mixed with material obtained from the prescription.

The UV spectra of phenobarbital, its sodium salt, diphenhydramine, its hydrochloride, and the product were compared, but no characteristics allowing distinction between a salt or a simple mixture could be observed. This agrees with observations reported for the phenobarbital–quinine complex (17).

A comparison of the IR spectra of potassium bromide pellets of phenobarbital, its sodium salt, diphenhydramine hydrochloride, and of the product indicated that the typical tertiary amine salt absorption at 2400–2700 cm^{-1} had disappeared in the product and the typical enolization band of phenobarbital (1620 cm^{-1}) is weak and shifted to ~1670 cm^{-1}. When the IR spectra of the product and of an equimolar mixture of phenobarbital and diphenydramine in chloroform were compared, no differences could be observed.

The NMR spectra of the product and an equimolar mixture of phenobarbital and diphenhydramine were run in deuterochloroform and compared. Most peaks were identical and could be assigned easily by comparison with spectra of the individual components. The only exception was a downfield signal (broad singlet accounting for two protons) which appeared at 10.9 ppm in the spectrum of the product and shifted upfield to 10.4 ppm in the spectrum of the mixture.

The sharp melting point of the product and the broad melting of mixtures [(102–147°) mixed with diphenhydramine hydrochloride and (106–155°) when mixed with phenobarbital] suggest that a new substance exists in the crystalline state. The evidence from the spectral measurements in solution indicates extensive dissociation.

[3] The melting points were obtained on a Hoover Melting Point Apparatus in open capillaries and are uncorrected. UV spectra were determined in 95% ethanol on a Beckman model DK-2A recording spectrophotometer. IR spectra were recorded either as potassium bromide pellets on a Beckman model 8 Infrared Spectrometer or in chloroform solution on Beckman model IR-33 Spectrometer. NMR spectra were recorded in deuterochloroform in a Varian model EM-360 Spectrometer using 1% tetramethylsilane as an internal reference standard.

Effect of a Major Metabolite on the Plasma Protein Binding of Tolmetin

Keyphrases □ Tolmetin—effect of a major metabolite on plasma protein binding □ Metabolites—effect on the plasma protein binding of tolmetin □ Plasma protein binding—effect of a major metabolite, tolmetin

To the Editor:

The nonsteroidal anti-inflammatory agent, tolmetin, is highly bound (>99%) to plasma proteins (1). Recently, Selley *et al.* (2) reported that 3 μg/ml (10.4 μ*M*) of 1-methyl-5-(4-carboxybenzoyl)-1*H*-pyrrole-2-acetic acid (I), a major metabolite of tolmetin (3), caused a marked (245%) increase in tolmetin free fraction when dialyzed until equilibrium against 4% human serum albumin containing 26.4 μg/ml (84 μ*M*) of tolmetin. Such a result is unusual since these investigators also observed that I was bound only 72% to human serum albumin. This implies that the metabolite may have less affinity for albumin binding sites than tolmetin; yet, small concentrations of I were capable of displacing the extensively bound parent drug. We decided to investigate further the effect of I on tolmetin binding.

Plasma was obtained from three healthy volunteers and was seeded with 0 (control sample), 0.8 (0.23 μg/ml), 8 (2.3 μg/ml), 80 (23 μg/ml), and 800 μ*M* (230 μg/ml) concentrations of I[1] and dialyzed against 0.125 *M* Sørenson's sodium–potassium phosphate buffer (pH 7.4) containing 80 μ*M* (25.2 μg/ml) of [^{14}C]tolmetin (14.8 μCi/mg)[1]. Equilibrium was achieved after 4 hr of dialysis using an equilibrium dialysis system[2] equipped with a microcell accessory and cellulose dialysis membranes (MW cutoff, 6000–8000)[3]. This experiment was also performed using human serum albumin[4] instead of human plasma. Aliquots (100 or 150 μl) of dialysate and dialyzed plasma were assayed for radioactivity in 10 ml of scintillation cocktail[5] using a liquid scintillation spectrometer[6] and external standard quench correction.

In a second series of experiments, plasma aliquots (0.2 ml each) from 10 healthy volunteers were dialyzed against Sørenson's buffer (0.2 ml) containing 0.5, 5, and 50 μg/ml of [^{14}C]tolmetin, and the tolmetin free fraction was determined at each concentration. In addition, samples (1.0 ml) of pooled human plasma were seeded with 2, 20, and 200 μg/ml of I and dialyzed against 1.0-ml aliquots of 0.067 *M* Sørenson's buffer. Buffer and plasma samples (0.5 ml) were assayed for I using a sensitive HPLC procedure[7]. The percentage of free (unbound) I or tolmetin was calculated using:

$$\frac{C_d}{C_p} \times 100 = \% \text{ free} \qquad \text{(Eq. 1)}$$

where C_d is the concentration of ligand in the dialysate (unbound) and C_p is the concentration of ligand in dialyzed plasma (bound and unbound).

Table I lists the results obtained when 80 μ*M* [^{14}C]tolmetin was dialyzed in the presence of increasing concentrations of I in both plasma and 4% human serum albumin. The metabolite produced no effect on tolmetin protein binding when added at equimolar concentrations or less. In contrast, tolmetin free fraction increased when I was added in 10-fold molar excess over tolmetin. These results are consistent with the observation that tolmetin was much more highly bound to plasma proteins than I over the broad range of concentrations studied (Table II). The metabolite may have less affinity for binding sites shared with tolmetin on plasma proteins (probably albumin). Under these conditions I would not be expected to displace any protein-bound tolmetin except when added in great excess. These data differ from the study by Selley *et al.* (2), who reported that addition of 3 μg/ml of I yielded an in-

crease in free fraction of tolmetin (present at 26.7 μg/ml) from 0.29 ± 0.02% (Mean ± *SD*) to 1.0 ± 0.12%. It appears that factors other than the metabolite itself must have contributed to the increase in tolmetin free fraction observed by these investigators.

The fact that I does not readily displace tolmetin from plasma protein binding sites has important implications in the understanding of tolmetin disposition. Since the metabolite circulates at concentrations lower than those of tolmetin in healthy subjects (1, 4) and arthritic patients (5), no effect of I on tolmetin disposition would be anticipated based on the data presented in Table I. In anephric patients receiving tolmetin, I accumulates in plasma to concentrations often >10-fold those of tolmetin[8]. Some displacement of tolmetin by the metabolite in these patients might be expected. However, since uremic plasma has reduced binding affinity for tolmetin (6), it is difficult to assess the additional influence of high circulating metabolite concentrations on tolmetin disposition in the uremic patient.

Hydroxyisolongifolaldehyde: A New Metabolite of (+)-Longifolene in Rabbits

Keyphrases □ Longifolene—hydroxyisolongifolaldehyde, a new metabolite in rabbits □ Metabolites—hydroxyisolongifolaldehyde from longifolene in rabbits □ Hydroxyisolongifolaldehyde—a new metabolite of longifolene in rabbits

To the Editor:

In spite of daily usage of terpenoid-containing plant products such as fruits, drinks, tobacco, *etc.*, the metabolic fate of terpenoids is essentially unknown. The aim of this study is to clarify terpenoid biotransformation in mammalian biochemistry from the toxicological point of view. This will provide guidance for the effective usage of natural products and for preparation of starting materials for organic synthesis.

Wild rabbits damage the forests in Japan by feeding on the artificially planted young *Chamaecyparis obtusa*, an important tree used commercially in Japan. This Japanese cypress contains longifolene (I) as a major sesquiterpene hydrocarbon. The metabolism of α-pinene, camphene, and other related terpenoids in rabbits was studied previously (1–7).

Longifolene (36 g), $[\alpha]_D$ = +39.3°, in chloroform, was administered to rabbits and the metabolites were isolated according to the method described previously. The neutral crude alcohols (3.7 g), were acetylated and purified to afford the main acetate (II) (17% for total acetates), which gave the following spectral data: mass spectrum: *m/z* 278 ($C_{17}H_{26}O_3$); 2700 and 1710 cm^{-1}; and a small doublet (J = 1.5 Hz) at 9.88 ppm of an aldehyde group. It was hydrolyzed by potassium carbonate in methanol and on silica gel chromatography gave pure metabolic alcohol (III). The parent ion of III, *m/z* 236, means a molecular formula $C_{15}H_{24}O_2$ showing that two oxygen atoms were introduced into longifolene. These oxygen atoms are based on a hydroxyl group (3450 cm^{-1}) and an aldehyde group (2700 and 1720 cm^{-1}; 9.87 ppm). The signals at 3.46 and 3.31 ppm (AB quartet) of this alcohol shifted 0.5 ppm upfield compared with those of acetate, suggesting the presence of a primary hydroxyl group. The olefin group of longifolene was lost in this alcohol. Thus, the change of this *exo*-methylene group to an aldehyde or primary alcohol was expected. The positions of newly introduced groups were determined on the basis of IR, ^{1}H-NMR, and ^{13}C-NMR spectra.

First, the aldehyde proton signal of III split into a doublet (J = 2.0 Hz) indicating the presence of an adjacent 7-H proton. By this splitting, it was concluded that the position of the aldehyde group is not at C-12, C-14, and C-15 but at C-7. The 7-H configuration was determined on the basis of a coupling constant. Provided that 7-H is in an α-configuration, the coupling constants of this proton would be anticipated to be $J_{7,1}$ = 1.3–2.6 Hz and $J_{7,8}$ = ~0.5 Hz. However, if 7-H is in a β-configuration, these values would be expected to be: $J_{7,8}$ = 3.6–5.0 Hz, $J_{7,9}$ ~1.2 Hz, and $J_{7,11}$ = 0.5 Hz. In fact, $J_{7,8}$ in III was observed as 3.5 Hz meaning 7-H has the β-configuration. Thus, the configuration of this aldehyde group was determined to be in the C-7-*endo*-form, which is stable in isolongifolaldehyde (8).

Second, in the IR spectra of the metabolized alcohol and

Scheme I

its acetate, the absorption of the *gem*-dimethyl group, which appeared at 1355 and 1370 cm^{-1} in longifolene, was lost and instead a new single absorption (1360 cm^{-1}) appeared in this region. This suggests that one of the *gem*-dimethyl groups at C-2 was hydroxylated producing a primary alcohol. Furthermore, in the ^{13}C-NMR of III, the downfield shift of the C-2 carbon and the upfield shifts at C-1, C-3, and C-14 or C-15 were observed when compared with longifolene (Table I)[1].

The determination of which methyl (C-14 or C-15) was hydroxylated remains to be established. It is well known that the orientation of the C-7 substituent group in longifolene changes easily from the *exo*- to *endo*-form. However, such isomerization of the C-7 aldehyde during isolation processes was not found by TLC, GLC, or IR. Therefore, longifolene would be metabolized in rabbits as follows: (*a*) attack on the *exo*-methylene group from the *endo*-face to form its epoxide; and (*b*) isomerization of the epoxide to a stable *endo*-aldehyde. Thus, the metabolic route of longifolene would be written as in Scheme I.

In the metabolism of compounds having *exo*-methylene groups such as myrcene (2), camphene (3), and camphene epoxide (4), their glycols were obtained and their formation can be explained through epoxides. The reason for not finding longifolene-7,13-glycol can be attributed to the less stable longifolene-7,13-epoxide.

Terpenic aldehydes are biotransformed from camphor (dog) (9) and fenchone (rabbit) (10). Introduction of an aldehyde group in biotransformation is remarkable, and this isolongifolaldehyde may have some biological activity which is found in other sesquiterpene aldehydes such as polygodial. The hydroxylation of *gem*-dimethyl groups producing a primary alcohol has been reported on the compounds having three- (1, 2), four- (7), five- (10), and six- (11) membered rings in mammals. In this study, hydroxylation of the *gem*-dimethyl group on the seven-membered ring was newly added.

[1] The complete analysis of ^{13}C-NMR spectrum of longifolene was based on the comparison with that of longifolol, which was kindly furnished by Dr. K. Tori, Shionogi Research Laboratory, Shionogi & Co., Ltd., Japan.

ACPE: Education's Measuring Stick

American drug products have long been regarded as meeting a level of quality and excellence generally unsurpassed throughout the world. In turn, the reasons often attributed to this phenomenon—in addition to the obvious capabilities and performance of the drug industry itself—are the elements of effective standards establishment and effective standards enforcement. In other words, the track record of drug quality is due, in large measure, to the impact or contribution made by the official compendia (*i.e.*, the USP/NF) and by the federal Food and Drug Administration.

Similarly, the graduates of American pharmacy schools have also been highly regarded worldwide as being uniformly well grounded in the art and science of the profession they have chosen. And, as in the case of American drug products, such consistency of quality and overall level of excellence is no accident.

Pharmacy education in the United States is blessed with a competent, effective, and efficient body that sets standards and accredits professional programs of the colleges and schools of pharmacy as well as the providers of continuing pharmaceutical education. The group responsible for these activities is the American Council on Pharmaceutical Education.

This national agency is not a government body. As in the case of the USP/NF, the ACPE represents the volunteer effort of the private sector to meet a perceived need and to establish a suitable level of performance that will give both the public and the health care community reasonable assurance of the quality of the products involved—in the former case high-quality pharmaceuticals and in the latter case high-quality pharmacy practitioners.

The Council is sponsored by three national groups in pharmacy: The American Association of Colleges of Pharmacy to represent academia and pharmacy educators; the American Pharmaceutical Association to represent the pharmacy profession and its practitioners; and the National Association of Boards of Pharmacy to represent governmental bodies responsible for the examination and licensure of pharmacy practitioners. Each of these three groups appoints three individual representatives to sit on the Council.

In addition, the public interest is represented on the ACPE through the participation of the American Council on Education, and that body appoints the tenth member to serve on the Council.

The ACPE is served by a very small but competent staff operating on a rather meager annual budget. This constitutes a dramatic illustration that big is not necessarily better, that empire building may not be beneficial for a particular agency, and that a key virtue of a lean operation often is maximum efficiency through minimum red tape.

Indeed, despite its very limited staff and resources, the ACPE has been very active in evaluating the professional degree programs of colleges and schools of pharmacy. Such evaluations and accreditations are made against standards of curriculum, of facilities, of staff, and of related considerations which the Council has developed and instituted over the years.

Similarly, evaluations are made of the providers of continuing pharmaceutical education, again judging such providers and their programs against criteria developed and adopted by the ACPE. Furthermore, the standards or criteria utilized are not static: they regularly undergo review and revision to ensure that they are meeting contemporary needs of the profession and of the public.

Our reason for choosing this particular time to comment on the ACPE and its work is due to the fact that the agency just celebrated its 50th Anniversary since its founding on August 26, 1932, by the above named sponsoring organizations.

Unquestionably, the ACPE has served well both pharmacy and the public. The uniformly high quality of the American network of higher education in pharmacy is a clear testimonial to that fact.

We take this opportunity to salute the Council, its members, its staff, its sponsors, and all those who now have, or who formerly had, a role in its successful operation. Its composition, structure, and operation make it unique among the accrediting agencies for the professions. Moreover, from our personal observation, it also appears to us to be the best and the most credible such accrediting agency.

RESEARCH ARTICLES

Estimation of All Parameters from Nonisothermal Kinetic Data

IAN G. TUCKER and W. R. OWEN †

Received March 3, 1981, from the *Pharmacy Department, University of Queensland, St. Lucia, Australia 4067.* Accepted for publication August 3, 1981. † Deceased.

Abstract □ A method is described which estimates (using least-squares analysis) all parameters (kinetic parameters and also zero and infinite time assays) from nonisothermal kinetic data. This method overcomes the time delays required for infinite time assays and biased estimates caused by the use of those assay results. Flexible temperature and data collection programs can be used. The mathematical models account for thermal volume expansion and the appropriate model is selected by statistical tests (provided the reaction is studied over ~90% decomposition). The models use a reparameterized Arrhenius equation in which the frequency factor is replaced by k_a, the rate constant at a specified temperature. This improves the numerical procedure and allows room temperature stability to be estimated directly.

Keyphrases □ Kinetics—estimation of all parameters from nonisothermal data □ Models, mathematical—estimation of all parameters from nonisothermal kinetic data □ Drug stability—estimation from nonisothermal kinetic data

Nonisothermal kinetic methods enable drug stability to be estimated at any temperature from a single test rather than multiple experiments as required by the traditional isothermal approach.

A logarithmic nonisothermal method has been proposed (1) as well as reciprocal (2), linear (3), polynomial (4), and stepped (5) temperature programs. Most methods have used manual and/or approximate procedures to estimate the kinetic parameters. One method (6) employed numerical integration (trapezoidal method) within a nonlinear, least-squares regression; however, this is only applicable where dependent (concentration) and independent (time) variables can be separated in the model.

All methods thus far have treated time zero and time infinity concentrations as known. When these parameters are not known to a precision greatly exceeding that of the data, then they should be estimated from the data (7). This also avoids the lengthy time delays necessary to determine values at infinity. Treating them as constants may lead to biased kinetic parameter estimates as in isothermal experiments (8) and confidence limits might be falsely reduced (9).

In addition to these limitations of current methods, the effect of thermal volume expansion has not been considered.

The present report develops a nonrestrictive, numerical treatment which allows flexible temperature and data collection programs, estimates of all parameters, and accounts for thermal volume expansion in nonisothermal solution kinetics.

THEORY

The general form of the rate equation for a nonisochoric system (10) is:

$$-dM_1/dt = (1/V')^{\upsilon-1}\, k \prod_{i=1}^{i=j} M_i^{\upsilon_i} \qquad \text{(Eq. 1)}$$

where υ_i is the exponent of the ith reactant, υ is the reaction order ($= \upsilon_1 + \upsilon_2 + \ldots + \upsilon_j$), M_i is the number of moles of the ith reactant, V' is the solution volume which is a function of time, and k is the rate constant.

For a nonisothermal, nonisochoric system:

$$-dM_1/dt = (1/V')^{\upsilon-1}\, Ae^{-E/(RT)} \prod_{i=1}^{i=j} M_i^{\upsilon_i} \qquad \text{(Eq. 2)}$$

where A is the frequency factor, E is the apparent activation energy, R is the gas constant, and T is the absolute temperature.

From Eq. 2 the following apply:

$$-dM_1/dt = Ae^{-E/(RT)}\, V' \qquad \text{zero-order} \qquad \text{(Eq. 3)}$$

$$-dM_1/dt = Ae^{-E/(RT)}\, M_1 \qquad \text{first-order} \qquad \text{(Eq. 4)}$$

$$-dM_1/dt = Ae^{-E/(RT)}\, M_1\, M_2/V' \qquad \text{second-order} \qquad \text{(Eq. 5)}$$

It has been pointed out for isothermal kinetics (11) that if a reactant solution is prepared at room temperature and used at a different temperature, allowance should be made for thermal volume change. It is clear from Eq. 4 that first-order reactions are exempt from this requirement,

0022-3549/82/0900-0969$01.00/0

Table I—Convergence Rate of MARQDT when Minimizing on k_a and E, or A and E, for Typical First-Order Simulated Nonisothermal Data [a]

Initial Parameter Estimates[b]			Iterations Required	
k_a, min^{-1}	E, kcal mole^{-1}	$10^{-10}A$, min^{-1}	k_a/E	A/E
0.20	14.0	0.37	5	>20
0.20	16.0	10.70	6	>20
0.10	14.9	0.84	2	5
0.33	14.0	0.60	8	9
0.06	16.0	3.20	5	>15
0.06	14.0	0.11	5	>20
0.12	14.9	1.01	4	9

[a] Parametric values are E = 15.0 kcal/mole, $A = 1.0 \times 10^{10}$ min^{-1}, k_a = 0.10096 min^{-1}, where k_a is the rate constant at 25° and the linear temperature program range is 25–45°. [b] For each test, the two models have the same initial sum of squares.

since a volume term does not appear in the equation; however, pseudo first-order reactions for which Eq. 5, with M_2 constant, is applicable, are not exempt.

For nonisothermal experiments, the change in molar concentration, C', ($C' = M/V'$) of a reactant is due to reaction and thermal volume change. For the case where all samples are cooled to the same temperature (T_s) before analysis, the measured concentration (C) is independent of thermal volume change, and $C = M/V$ where V is the volume at T_s.

Since temperature and volume are functionally related to time [$T = f_1(t)$; $V' = V/f_2(t)$], Eqs. 3–5 can be rewritten as:

$$-dC_1/dt = Ae^{-E/[Rf_1(t)]}/f_2(t) \quad \text{zero-order} \quad \text{(Eq. 6)}$$

$$-dC_1/dt = Ae^{-E/[Rf_1(t)]}C_1 \quad \text{first-order} \quad \text{(Eq. 7)}$$

$$-dC_1/dt = Ae^{-E/[Rf_1(t)]}C_1C_2f_2(t) \quad \text{second-order} \quad \text{(Eq. 8)}$$

where C_2 is the concentration of Reactant 2 at volume V or the constant catalyst concentration at V in the pseudo first-order case.

Model for Absorbance Measurement—If change in absorbance (D) is used to follow the reaction and the following assumptions are made: (a) the reaction goes to completion; (b) the absorbance is the sum of component absorbances due to reactant, product, and constant background; (c) all component absorbances obey the Beer-Lambert law; and (d) the sum of the moles of reactant and moles of product is constant, then:

$$C_1 = (D - D_\infty)/[(a_r - a_p)b] \quad \text{(Eq. 9)}$$

$$C_{10} = (D_0 - D_\infty)/[(a_r - a_p)b] \quad \text{(Eq. 10)}$$

where D_0 and D_∞ are the absorbances at zero and infinite times, respectively, and are constant, a_r and a_p are the absorptivities of reactant and product, respectively, b the cell path length, and C_{10} is the concentration of reactant 1 at time zero and T_s.

Recalling that for pseudo first-order reactions, Eq. 8 with C_2 constant is applicable, then substituting Eq. 9 into Eqs. 6–8 yields:

$$-dD/dt = Ae^{-E/[Rf_1(t)]}(a_r - a_p)\,b/f_2(t) \quad \text{zero-order} \quad \text{(Eq. 11)}$$

$$-dD/dt = Ae^{-E/[Rf_1(t)]}(D - D_\infty) \quad \text{first-order} \quad \text{(Eq. 12)}$$

$$-dD/dt = Ae^{-E/[Rf_1(t)]}(D - D_\infty)\,C_2\,f_2(t) \quad \text{pseudo first-order} \quad \text{(Eq. 13)}$$

$$-dD/dt = Ae^{-E/[Rf_1(t)]}(D - D_\infty)^2\,f_2(t)/[(a_r - a_p)\,b] \quad \text{second-order} \quad \text{(Eq. 14)}$$

Similar equations can be derived for other situations where the sum of moles of reactant and moles of product is not constant.

Equations 11–14 cannot be integrated analytically. However, they can be solved numerically (*i.e.*, D values calculated at specified times) when initial values are supplied (*i.e.*, $D = D_0$ at $t = 0$).

For isothermal kinetics where $f_1(t)$ is constant, these equations can be integrated to give the familiar forms. For example, Eq. 12 yields:

$$D = D_\infty + (D_0 - D_\infty)e^{-kt} \quad \text{(Eq. 15)}$$

The parameters (D_0, D_∞, A, and E for nonisothermal; D_0, D_∞, and k for isothermal) are chosen so as to minimize Eq. 16:

$$SS = \sum_{i=1}^{i=N}(D_i - \hat{D}_i)^2 \quad \text{(Eq. 16)}$$

[a] Parameters and constants used to generate the first-order data were k_a = 0.1 hr^{-1}, E = 15 kcal/mole, D_o = 1.0, D_∞ = 0.05 with a linear temperature program over the range 25–45° in all cases. Also a_r = 1, a_p = 0, b = 1, with the random error variance of 0.56×10^{-6}. [b] The zero-order model has no D_∞ term.

where D_i and $\hat{D}_i$ are observed and calculated absorbances, respectively, at the ith datum, and N is the number of data.

Computational Procedures—*Temperature–Time Relationship* $f_1(t)$—For each data set, an orthogonal polynomial regression program, ORTHO (12), was used to establish the polynomial of lowest order which adequately described the temperature–time data. This enables flexible temperature programs to be employed. ORTHO uses the Gram–Schmidt orthonormalization procedure with an iterative straightening refinement (13).

Volume–Time Relationship $f_2(t)$—Data for the specific volume (V'_{sp}) of water at various temperatures are available (14). ORTHO was used to establish a polynomial relationship for this data over the experimental temperature range (30–92°),

$$V'_{sp} = 0.99992806 - 0.35791641 \times 10^{-4}\,T + 0.72094751 \times 10^{-5}\,T^2 - 0.42243321 \times 10^{-7}\,T^3 + 0.21949816 \times 10^{-9}\,T^4 - 0.47002556 \times 10^{-12}\,T^5 \quad \text{(Eq. 17)}$$

where T is degrees centrigrade for this equation only. All residuals about this regression were less than 7×10^{-7} ml/g and were randomly distributed.

Since the relationship $f_1(t)$ was established for each data set, and the general relationship $V'_{sp} = f(T)$ (Eq. 17) is available, the volume–time relationship $f_2(t)$ was established for each set.

Relationships $T = f_1(t)$ and $V'_{sp} = f(T)$ were used in the nonlinear regression program, MARQDT.

Optimization Routine—The function to be minimized (Eq. 16) contains nonlinear parameters so an iterative least-squares regression is required. A nonlinear regression program (MARQDT) was developed for this purpose. The program uses the Marquardt algorithm (15) with minor modifications (12). The advantages of this method have been described previously (16).

Initial estimates are required for the parameters. When these are not available from prior knowledge, satisfactory values can be obtained by one of the differential nonisothermal methods (17), provided thermal volume effects are neglected. These estimates are improved iteratively until the convergence test (the relative change in parametic estimates in consecutive iterations is less than 1 in 10^4) is satisfied.

Numerical Differentiation—The Marquardt algorithm requires partial derivatives with respect to each parameter at each datum. Since integrated functional equations are not available for nonisothermal kinetics, the partial derivatives were estimated numerically. These were computed using the two-point central difference method. Choice of the step length has been discussed previously (18).

Table III—Goodness of Fit Statistics for Various Models Fitted to Nonisothermal First-Order Simulated Data [a]

Percent Reacted	Model: First-Order	Pseudo First-Order	Second-Order	Zero-Order
		$10^6 V_r$ [b]		
18	0.56	0.56	0.56	0.55
54	0.56	0.56	0.59	5.5
71	0.56	0.56	0.72	21
87	0.56	0.56	1.6	73
99	0.56	0.56	13	279
		Probability[c]		
18	NS	NS	NS	NS
54	NS	NS	NS	S
71	NS	NS	NS	S
87	NS	NS	S	S
99	NS	NS	S	S

[a] See Table II. [b] V_r is the residual variance (*i.e.*, residual SS/df) and should be compared with the error variance of 0.56×10^{-6}. [c] Probabilities (NS = not significant at $p = 0.01$ level) for runs, mean square successive difference, and F tests were similar.

Numerical Integration—A fourth-order Runge–Kutta method with error estimation and step size control was used in MARQDT for the solution of Eqs. 11–14 (19). The method has been tested extensively on a number of derivative functions and found to perform excellently provided relative rather than absolute truncation errors are used to control step size.

In this work, a relative truncation error of 10^{-5} was used for sum of squares (SS) calculations, and 10^{-4} for partial derivative evaluations. This error in $\hat{D}_i$ for SS calculations was about one-fiftieth of the random error in the data and so did not contribute significantly to the calculated SS value. Further decrease in the truncation error did not lead to significant changes in the parameter estimates but only increased computational time.

Initial values are required for a particular solution of a differential equation. In the present work these were $D = D_0$ at $t = 0$ with D_0 being treated as a parameter.

Statistical Aspects—*Goodness of Fit*—The adequacy of the kinetic model was judged in two ways. First, the residuals were examined for nonrandomness or trends. If the model is adequate or the fit is good, the residuals should be randomly distributed in time. They were examined visually and by the runs (20) and mean square successive difference (21) statistical tests. Second, the residual variance about the regression was compared with the error variance of the experimental system (F-test) a knowledge of which was available from prior testing. However, in nonlinear regressions the residual variance is not an unbiased estimate of the pure error even when the model is correct, so this F-test is only approximate (16).

Confidence Limits—In nonlinear regressions, exact confidence limits for the parameters are not available; however, the linear estimates calculated from the variance–covariance matrix and residual variance are often adequate approximations (16). A Monte Carlo method has been described (22) to test the accuracy of these linear approximations. This test involves the following steps:

1. Estimate best-fit parameters and their approximate confidence limits;
2. Generate data using the best-fit estimates and add normally distributed random error with a variance equal to that of the original data set;
3. Estimate best-fit parameters for the data set;
4. Repeat steps 2 and 3 a number of times (15 has been used) and determine the confidence limits for the distribution of best-fit estimates.

This analysis need not be carried out every time a particular model is run, but should be used to check the linear approximations at least once for each model.

EXPERIMENTAL

Materials—p-Nitrophenyl acetate (I) was prepared by acetylation of p-nitrophenol (23) and recrystallized from fractionated benzene and petroleum ether (40–60° fraction) mixed solvent to a constant melting point (77.6°). p-Nitrophenol was recrystallized to constant melting point (115°) from fractionated benzene, and both materials were stored in vacuum desiccators in the dark until required for use. Thermal analysis indicated these samples to be greater than 99.9% pure.

Table IV—Parameter Estimates and Goodness of Fit Statistics for Various Models Fitted to Nonisothermal Second-Order Data [a]

Pseudo first	0.0737	−15.64	0.989	−0.1287	S
Zero	0.0711	−30.57	0.968	—	S

[a] See Table II for parameter and constant values used to generate data over 90% reacted. [b] $p = 0.001$, S = significant, NS = not significant.

Concentrated hydrochloric acid[1] was diluted with glass distilled water to produce sufficient dilute acid for all experiments. This acid was standardized against freshly dried sodium carbonate (analytical reagent grade) using methyl orange indigo carmine indicator (24). Replicate analyses ($n = 4$) indicated the acid to be 0.2396 M (SE mean = ±0.0003 M).

Equipment—A 1-liter, closed, stirred, glass reaction vessel was immersed in a 60 liter polyethylene glycol 600 bath. In isothermal experiments the temperature was controlled by a circulating heater[2], while a variable speed programmer[3] was used for nonisothermal tests.

Temperatures inside the reaction vessel were monitored with a four-lead platinum resistance thermometer[4].

Samples were withdrawn automatically *via* polytef tubing, cooled to 32° in a jacketed coil, then passed into a 2-mm quartz flow-cell for spectrophotometric[5] analysis.

Analysis—The rate of hydrolysis was followed spectrophotometrically at 318 nm (2). Spectra recorded during the reaction showed a single iso-

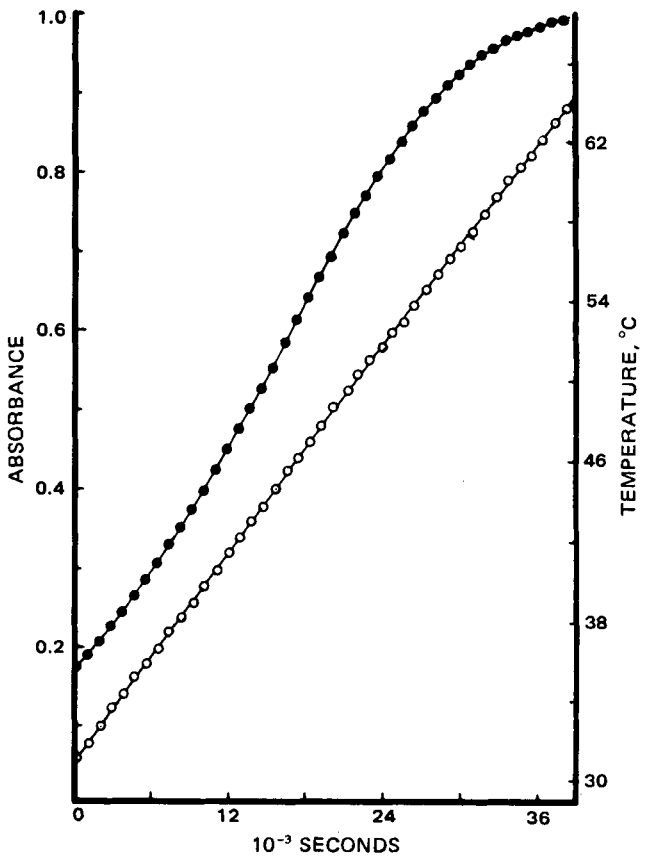

Figure 1—*Typical temperature program* (○) *and reaction data* (●) *with fitted curves for the nonisothermal acid catalysed (0.2396* M *HCl) hydrolysis of I. The temperature time relationship determined by ORTHO was* T(K) $303.911 + 0.904339 \times 10^{-3}\,t - 0.105973 \times 10^{-8}\,t^2$.

bestic point (292 nm) indicating a one-to-one reaction and stability of the absorbing product, *p*-nitrophenol. The final spectrum was identical with that of *p*-nitrophenol.

A Beer–Lambert calibration, using replicate samples, confirmed linear concentration–absorbance relationships for I and *p*-nitrophenol, and that the component absorbances were additive. Since it was shown that spectra in acid and water were identical, this calibration was performed in distilled water, thereby minimizing decomposition problems.

Procedure—One liter of acid was allowed to equilibrate thermally in the closed reaction vessel. About 80 mg of I dissolved in 2 ml of fractionated ethanol was added to produce an ~0.0004 *M* solution which was bubbled with high purity nitrogen. The temperature programmer was started when I was added and the first sample withdrawn 2 min later. Samples were withdrawn automatically, cooled to 32°, and assayed directly, the concentrations used being such that the infinite time absorbance was ~1. At each sampling, reaction vessel temperature, sample absorbance, and time data were automatically recorded.

Design—About 30 data were collected during each experimental run. Triplicate isothermal tests were performed at 39.26, 49.03, 58.68, and 68.24°. Triplicate nonisothermal tests at each of four different approximately linear heating rates (~3, 6, 12, and 18°/hr) were used. These all started at about 30° and continued until decomposition exceeded 90% giving a maximum temperature of about 76° (for 18°/hr).

RESULTS AND DISCUSSION

Reparameterization of the Model—For first-order nonisothermal kinetics with a linear temperature program, exact simulated data were generated using parameter values of $A = 1 \times 10^{10}$ min^{-1}, $E = 15$ kcal/mole, $D_0 = 1$, $D_\infty = 0$, and $T = 298.15 + t$. D_0 and D_∞ were then held constant at their parametric values, while A and E were estimated. Convergence of the program was very slow, even for initial estimates close to the true values.

Sum of squares contours for the data in question were generated and found to be very elongated in the direction of the A parameter. It has been pointed out (16) that in such cases, slow convergence of any iterative estimation procedure is likely. Clearly, A is an ill-determined parameter; that is, large changes in A cause small changes in SS. In retrospect, it is apparent why A is ill-determined. It is the rate constant at infinite temperature. Since data are usually collected in the range 25–90°, estimation of A involves an extrapolation outside the data, and such estimates are poorly determined.

Conditioning can often be improved by reparameterizing the model. In the present study, this was done by replacing A with $k_a\, e^{E/(RT_a)}$ in Eqs. 11–14, where the new parameter k_a is the rate constant at T_a, a temperature within the experimental range. Sum of squares contours for various T_a values were found to be well-rounded ellipses, *i.e.*, the parameters were well-conditioned. Since little change occurs in the conditioning with changes in T_a, provided it is within or near the experimental range, it may be advantageous to choose $T_a = 25°$. This would allow the room temperature rate constant to be estimated directly, and approximate confidence limits would also be immediately available.

[d] Their nonisothermal estimates, k_a being calculated from their second-order rate constant at 25° using $[H^+] = 0.2396\ M$ and $E = 17.0$ kcal/mole. [e] Their isothermal estimate. [f] Determined from their second-order rate constant as above. [g] For phenyl acetate.

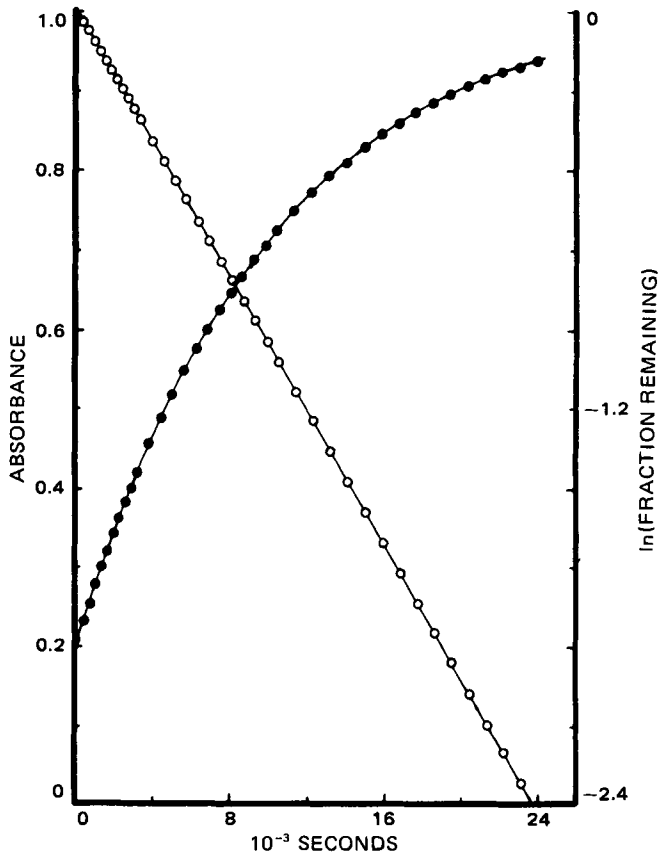

Figure 2—*Typical data for the isothermal acid catalysed (0.2396 M HCl) hydrolysis of I showing the first-order, nonlinear, least-squares curve (●) and the more usual linearized logarithmic plot (○). D_∞ from the nonlinear regression was used to calculate the fraction remaining.*

The new model was tried on the same first-order simulated data and convergence was rapid. A comparison of the new and old models for this typical data set, for differing initial estimates, is shown in Table I. In all cases the program converged to the parametric values and the new model was superior. Convergence was acceptable, since the initial estimates were far worse than normally would be expected.

It is clear that A may be of theoretical interest, but k_a is of greater interest in practical stability studies and its use facilitates the numerical procedure. In all subsequent computations, the reparameterized models were used.

Goodness of Fit—To test the ability to select the appropriate kinetic model, simulated data (40 pairs) were generated and normally distributed random error was added. The variance of the random error was that of the experimental system. The parameter estimates for zero-, first-, pseudo first-, and second-order fits to first-order data are given in Table II while the statistics for judging the goodness of fit are in Table III.

In all cases, ~95% confidence limits of the first-order estimates bracketed the parametric values. This, along with the excellent agreement between the residual variances (about the regression) and error variance (Table III), indicated the program was functioning correctly.

With the reaction 18% complete, the 95% confidence limits (−0.087–0.194) for the first-order estimate of k_a bracketed the parametric value, but the point estimate is about half the parametric value. This shows the danger of estimating rate constants from data covering a low percentage reacted, and of the need to compute confidence limits.

At high percentages reacted, the estimated E values for the zero-order model were negative. These values were expected, since the decrease in concentration causes a decrease in reaction rate for first-order kinetics; this is not accounted for in the zero-order model. Consequently, the reaction rate apparently decreased with temperature rise.

From Table III, it is clear that at the added random error level the various kinetic models could not be distinguished below 18% decomposition. At 54% reacted the zero-order model was inadequate, at 87% the second-order was inadequate, but the first- and pseudo first-order models

[a] I and II are Row 1 estimates of D_∞ and D_0. I − CL means D_∞ was treated as a constant with value I minus the 95% confidence limit of a reading (0.0008 absorbance unit).

remained indistinguishable, even at 99% decomposition. When the error variance was reduced by a factor of 10, the second-order model was then inadequate at 71% reacted, but the first- and pseudo first-order models were adequate. Attempts to separate these two models by increasing the temperature range to 60° while maintaining 90% reacted were unsuccessful.

Second-order and zero-order data were generated using parameter and constant values given previously (Table II) and covering 90% reacted with a temperature range of 20°. The parameter estimates and probabilities for second-order data are given in Table IV and for zero-order data in Table V.

At 90% decomposition and at the random error level used, the second-order equation was the only adequate model (Table IV). The other models were shown to be inadequate by the statistical tests and the meaningless E estimates.

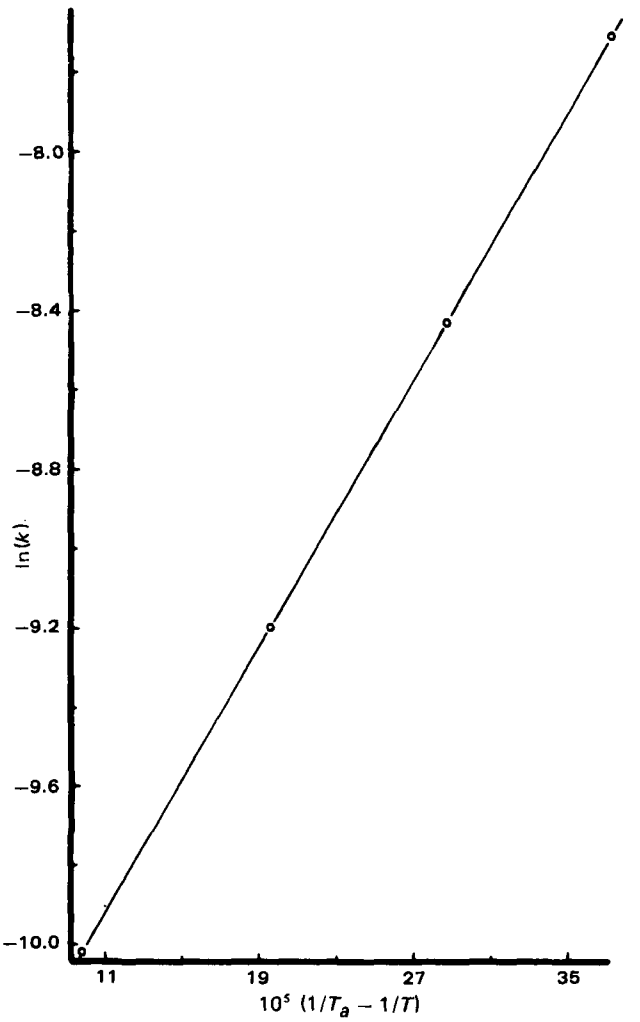

Figure 3—*Arrhenius plot for the acid catalysed (0.2396 M HCl) hydrolysis of I, T_a = 30°. Points cover the range of the experimental rate constants.*

The probabilities in Table V indicate that zero-order data can be described equally well by all models. Additionally, the kinetic parameter estimates (k_a,E) were reasonable for all models (although if prior stability information were available, the k_a estimates from the incorrect models would be suspect). However, the D_∞ estimates for the incorrect models were unacceptable, since absorbances of −50 and −252 are meaningless. Therefore, the first-, pseudo first-, and second-order models were rejected because of their D_∞ estimates and the zero-order model was accepted by default and because it was not rejected by the statistical tests.

For zero-order reactions, the rate increases continuously with time due to temperature rise and comes to an abrupt halt at zero concentration. For first-order, the rate increases initially but then decreases when the effect of lowered concentration exceeds that due to the increased k value. In second-order reactions, the decrease in rate occurs at a lower percentage reacted since rate is proportional to concentration squared. Therefore, all models appear similar before the inflection points and, consequently, zero-order reactions covering a high percentage decomposition appear like first- and second-order reactions covering a small percentage reacted. From Table V, the 90% reacted zero-order model was adequately fitted by first- and pseudo first-order models covering ~2% ($D_\infty \sim -50$) or a second-order model with ~0.5% decomposition ($D_\infty = -252$).

Data from the nonisothermal hydrolysis of I, over ~90% decomposition, were treated similarly. Graphs for a typical temperature program and reaction together with the ORTHO and MARQDT (pseudo first-order) fits are shown in Fig. 1. In all cases, zero- and second-order models were inadequate but the first- and pseudo first-order nonisothermal models were adequate. Pseudo first-order rate constants were estimated from isothermal data using nonlinear least-squares regression (Eq. 15). Plots of a typical data set and the fitted curve are shown in Fig. 2 along with the usual linearized graph. The rate constants were corrected for thermal volume expansion and then k_a and E were estimated by linear least-squares regression using the logarithmic form of the reparameterized Arrhenius equation (Fig. 3). Nonisothermal parameter estimates were in good agreement with isothermally determined values. These estimates are shown in Table VI with literature values.

Confidence Limits—In all cases tested, the approximate confidence limits did not greatly exceed the Monte Carlo limits (usually only by a factor of <1.5). This indicates that the approximate error estimates cause less confident parameter estimates than is justified. However, in a

Table VIII—Variations in Parameter Estimates when Thermal Volume Expansion is Neglected[a]

Temperature Range	Model: Zero-Order	Pseudo First-Order	Second-Order
		k_0	
20	0.09973	0.1002	0.1002
40	0.09949	0.1004	0.1003
60	0.09900	0.1007	0.1004
		E	
20	15.07	14.94	14.96
40	15.09	14.92	14.94
60	15.13	14.90	14.93

[a] Exact nonisothermal simulated data were generated using: $k_a = 0.1$, $E = 15.0$, $D_0 = 1.0$, $D_\infty = 0.05$, $a_r = 1$, $a_p = 0$, $b = 1$, $T = 298.15 + t$, and $T_a = 25°$ for various models incorporating the volume correction term.

practical sense, the differences were not large and errors caused by accepting the approximate values would be safe.

D_0 and D_∞ as Constants—The errors resulting from treating D_0 and D_∞ as constants were investigated using a typical set of I data. Initially, all parameters (k_a, E, D_0, and D_∞) were estimated (row 1, Table VII) and the residual variance from this fit was used to obtain the 95% confidence limits of a reading. Variables D_0 and/or D_∞ were then treated as constants and the remaining parameters were re-estimated from the data. Constant values for D_0 and D_∞ were best estimates from the four parameter fit ±95% confidence limits of a reading (0.0008 absorbance unit). It is acceptable that D_0 be determined to this precision, since for nonisothermal kinetics, the reaction initially proceeds slowly. However, determination of D_∞ may involve time delays with instrument drift, mechanism changes, *etc.*, so an uncertainty of 0.01 absorbance unit would not seem unreasonable. Table VII shows the results of these refits.

It is apparent that fixing D_0 and D_∞ reduces the 95% confidence limits of E as expected, while those of k_a are reduced except where the increase in residual variance outweighs the decrease caused by fixing D_0 and D_∞ (Table VII). In a practical sense it is unlikely that the decreases in 95% confidence limits would cause serious errors, but the inflated residual variances make the model suspect, making the choice of the appropriate reaction order difficult.

Errors in k_a and E estimates were quite small (0.16 and 0.23% range, respectively) when D_∞ was treated as a constant in error by the 95% confidence limit of a reading (Rows 2 and 3 in Table VII), but similar errors in D_0 caused considerable biases in the estimates (1.6 and 1.2% ranges for k_a and E, respectively). When the error in D_∞ was increased to 0.01 absorbance unit, k_a and E ranges were 2.1 and 3.4% in the worst case. These errors must be seen in light of the experimental precision and, hence, the approximate confidence limits. The 95% confidence limits for k_a and 99% limits for E for Rows 4 and 5 and 8 and 9 in Table VII do not bracket the best (Row 1) estimates. That is, biased estimates resulted from using constant (incorrect) values for D_0 and D_∞.

Thermal Volume Expansion—Comparison of the first- and pseudo first-order estimates in Table II indicates that errors caused by neglecting thermal volume expansion are small for this model. However, to ascertain the magnitude of expected biases for all models, exact simulated data (no added random error) were generated. Data (40 pairs) covering 90% decomposition and temperature ranges of 20, 40, and 60° were produced using reparameterized Eqs. 11, 13, and 14. Parameters were re-estimated using these equations and again without the volume correction term [$f_2(t)$]. In all cases where the complete equations were used, the estimates agreed (to 6 correct digits) with the parametric values. Errors caused by neglecting the volume correction are shown in Table VIII.

The biases observed are quite small (*e.g.*, pseudo first-order, 40° range, biases are +0.4% in k_a and −0.53% in E). These percentages varied little with parameter values (*e.g.*, with $k_a = 0.01$ and $E = 30$, the errors were +0.4% in k_a and −0.3% in E). Assuming an error variance of 0.56×10^{-6}, the 95% confidence limits for the 40° pseudo first-order range are ±0.61% for k_a and ±0.64% for E. These limits bracket the parametric values.

The bias in k_a depended on the T_a chosen. For $T_a = 90°$, the error was −1.9% but this increased error must be compared with the wider 95% confidence limits of ±2.5%. Thus, the bias errors are relatively small. As seen previously, fits with and without volume correction terms (first- and pseudo first-order, Table III) are equally good. Therefore, the need for a volume correction term was not evident from the experimental system, and justification for the term is theoretical (10).

From a practical viewpoint it appears that failure to correct for volume expansion has a negligible effect on kinetic parameter estimates from a single data set; however, in the long term, slightly biased estimates will result and the inclusion of the term is warranted.

Development of a Method for Study of the Tendency of Drug Products to Adhere to the Esophagus

MARTTI MARVOLA *x, KARI VAHERVUO, ASLAK SOTHMANN, ESKO MARTTILA, and MARKKU RAJANIEMI

Received June 29, 1981, from the *Pharmaceutical Research Laboratories, Orion Pharmaceutical Co., Espoo, Finland*, and the **School of Pharmacy, University of Helsinki, Helsinki, Finland.* Accepted for publication November 9, 1981.

Abstract □ A method to determine the adherence of drugs to the esophagus was developed using isolated swine esophagi. A number of types of tablets and capsules (*e.g.*, of doxycycline) were tested. The results showed that the tendency of products to adhere to the esophagus can be regulated by pharmaceutical properties. It was concluded that the method described is simple, inexpensive, and accurate.

Keyphrases □ Esophagus—study of drug product adherence, doxycycline, swine esophagus □ Adherence—study of drug products in esophagus, doxycycline, swine esophagus

In recent years, many case reports concerning drug-induced esophageal ulceration or stricture in humans have been published. Serious damage has been caused by doxycycline (1–3), emepronium bromide (4–6), potassium chloride (7–9), alprenolol (3), and iron salts (3, 10). The mechanism of injury is not yet well understood, although it is obvious that the lesions were caused by drug substances. The primary reason has apparently been adherence of the drug product to the esophageal wall, allowing high local drug concentrations to be formed. The tendency to adhere is obviously greatest for hard gelatin capsules, but differences between various tablet formulations are also evident. The risk of esophageal lodging can generally be avoided by taking dosage forms with water and, if possible, in an upright position. Despite this, there is a great need for development of new drug products and product coatings with less tendency to adhere to the esophageal mucosa. However, no adequate and simple method for measuring adherence has been available.

The aim of the present investigation was to develop a method for study of the tendency of products to adhere to the esophageal wall, using the isolated swine esophagus. Our results on the effects of various pharmaceutical properties of products on adhesion will be published later.

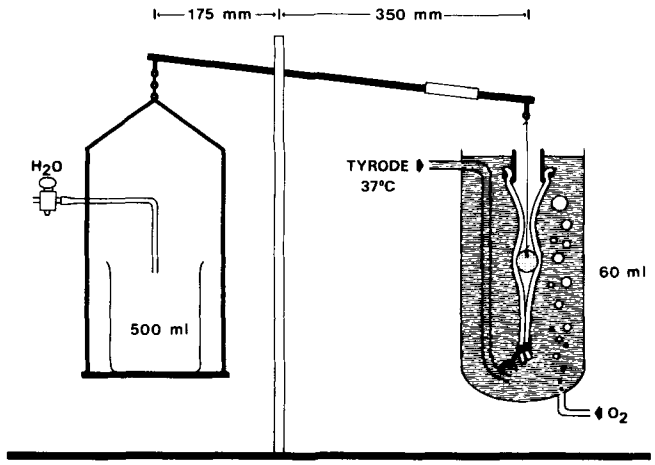

Figure 1—*Measurement system for force needed to detach product from the esophagus and organ bath I.*

EXPERIMENTAL

Isolated Esophagus Preparation—Pigs of both sexes of Landrace and Yorkshire breeds, weighing 90–100 kg were used. Immediately after slaughter, the esophagi were removed and transported to the laboratory in Tyrode solution, kept at ~4°. The composition of the Tyrode solution was (g liter^{-1}): sodium chloride 8.0, potassium chloride 0.2, calcium chloride · $2H_2O$ 0.134, sodium bicarbonate 1.0, sodium dihydrogen phosphate 0.05, and glucose · $1H_2O$ 1.0. During experiments the solution was aerated with pure oxygen and kept at 37°. Segments 6–7 cm long were cut from the esophagus. The segments were mounted in two kinds of organ baths. Organ bath I: The volume of the classic organ bath for isolated preparations was 60 ml (Fig. 1). The lower end of the esophageal segment was tied off and the upper end was attached around a glass tube (diameter 15 mm). The solution in the organ bath was changed at intervals of about 30 min. Organ bath II: The volume of the second organ bath was 2000 ml (Fig. 2). In this preparation, the lower end of the esophageal segment was also attached around a glass tube (diameter 8 mm). There was, therefore, free passage through the preparation, which allowed washing of the mucosa. The Tyrode solution in this organ bath was not changed during the 6-hr experiments.

Recording of Adherence—A hole (diameter of 1 mm) was drilled in the products to be tested. The product was attached to a copper wire (diameter of 0.25 mm) and placed, using a plastic tube as an applicator, in the esophageal preparation for a fixed time. The force needed to detach the product was measured using a modified prescription balance (maximum load 500 g; see Fig. 1). This force was used as a parameter for adherence. The force (F) in newtons was calculated by the equation:

$$F = \frac{0.00981W}{2}$$

where W = amount of water in the beaker in grams. The water flow rate was 280 g min^{-1} (corresponding to 1.37 N min^{-1}).

Characteristics Studied—To discover the usefulness of the preparation the following characteristics were studied: (*a*) the effect of the time for which the product remains in the esophagus upon the force needed to detach it; (*b*) the effect of the surface areas of different products on the force needed for detachment; (*c*) differences between the results obtained using the two different organ baths; (*d*) the effect of washing of the mucosa on adherence; and (*e*) differences in adherence to the esophagus of some commercially available doxycycline preparations.

Drug Products—Hard gelatin capsules[1], sizes 0, 1, 2, 3, 4, and 5, were filled with lactose. Placebo tablets were compressed from a mixture of basic granules (96%), talcum (3%), and magnesium stearate (1%). The

4	0.35	10	0.25	10	0.062
5	0.40	11	0.24	11	0.058
		12	0.24	12	0.056

basic granules contained lactose (78%), corn starch (19%), and gelatin (3%). Potassium chloride tablets were compressed from pure potassium chloride. The diameters of the placebo and potassium chloride tablets were 7, 9, 10, 11, or 12 mm. The shape of all tablets was biconvex. The surface areas of the capsules and tablets were calculated according to geometrical principles and are given in Table I.

As sugar-coated tablets, a commercial product[2] of 11-mm diameter was used. The diameter of the film-coated tablets[3] was also 11 mm. The film-forming material was hydroxypropylmethylcellulose.

In the final part of the present study, six commercially available doxycycline (100–150 mg) products (A–F) and two test formulations (G, H) were studied using the method developed. Products B–E were film-coated tablets. Product F was a capsule formulation (size 3). Products A, G, and H were uncoated tablets.

RESULTS AND DISCUSSION

Initially, the effect of the time interval between administration of the drug and commencement of detachment on the force needed for detachment was studied with four different products. As can be seen from

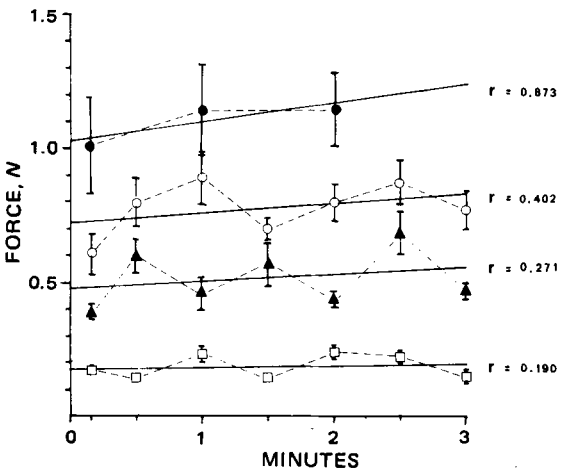

Figure 3—*Effect of the time interval between administration of the drug and commencement of detachment on force needed for detachment of drug. Key: (●) hard gelatin capsule size 2; (○) placebo tablet, diameter 11 mm; (▲) hydroxypropylmethylcellulose film-coated tablet, diameter 11 mm; (□) sugar-coated tablet, diameter 11 mm. Each point represents mean* ±SEM, n = *10.*

[2] Sembrina, Orion Pharmaceutical Co, Finland.
[3] Kaliduron, Orion Pharmaceutical Co, Finland.

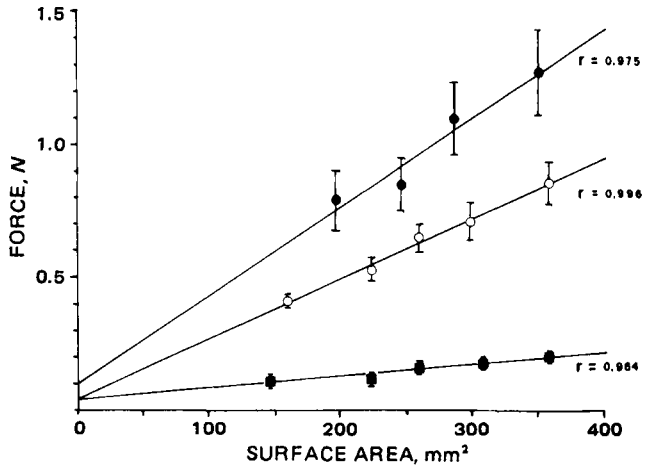

Figure 4—*Effect of surface area of product on the force needed for detachment. Key: (●) hard gelatin capsules, sizes 2, 3, 4, and 5: (○) placebo tablets, diameter 7, 9, 10, 11, and 12 mm; (■) potassium chloride tablets, diameter 7, 9, 10, 11, and 12 mm. Each point represents mean* ±SEM, n = *20.*

Fig. 3, no clear linear or exponential correlation between force and time was noted. In subsequent experiments, an interval of 2 min was usually used. Because of disintegration, hard gelatin capsules could not be left in the esophagus for longer than 2 min. For the same reason, the longest time in experiments using tablets was 3 min.

The results pertaining to the effect of surface area of product on the force exerted for detachment are shown in Fig. 4 and Table II. The forces for gelatin capsules larger than size 2 could not be measured, because the esophageal mucosa became detached from the preparation if forces greater than 1.5 N had to be used. As can be seen from Fig. 4, a significant (p = 0.05–0.001) linear correlation between force and area exists for every product. The force per unit of surface area appears independent of product size (Table II). The intercepts from extrapolation of the lines in Fig. 4 were 0.04–0.1 N. These can be regarded as the magnitudes of force needed to pull the products out of the esophagus, even though they are not adhering.

Three different sizes of placebo tablets (diameters 9, 11, and 12 mm), identical sizes of potassium chloride tablets, two different capsule sizes (2 and 4) and sugar-coated tablets were tested using identical procedures and organ baths I and II (n = 20). No statistically significant differences in results were observed. However, the classic organ bath for isolated preparations (I) was a little easier to handle. This is why most results in the present study were obtained with organ bath I.

Table III—Effect of Washing on Force Needed to Detach the Placebo Tablets from the Isolated Esophagus [a]

Diameter, mm	Force Without Washing, N, mean ± *SD* n = 20	Force after Washing with 5 ml Water, N, mean ± *SD* n = 10
10	0.65 ± 0.23	0.19 ± 0.07
11	0.71 ± 0.30	0.20 ± 0.04
12	0.86 ± 0.34	0.33 ± 0.09

[a] Student's t test; $p < 0.001$.

Table IV—Force Needed to Detach Doxycycline Products from the Isolated Swine Esophagus [a]

Product	Diameter, mm	Force, N, mean ± *SD*	n	t test[b]
Tablet A	9	0.29 ± 0.07	12	
Tablet B	9	0.27 ± 0.05	6	NS
Tablet C	9	0.30 ± 0.08	6	NS
Tablet D	10	0.58 ± 0.15	6	b
Tablet E	10	0.78 ± 0.22	6	b
Capsule F	(size 3)	1.21 ± 0.25	8	b
Tablet G	9	0.17 ± 0.04	8	b
Tablet H	10	0.16 ± 0.05	8	b

[a] Interval between administration and start of detachment was 2 min. [b] Student's t test comparison with Tablet A; $p < 0.001$. NS = not significant.

The effect of washing on adherence was tested using organ bath II. The preparation was washed with 5 ml of water immediately after administration of the drug. The results are shown in Table III. After washing, the force needed for detachment was only about 30% of that without washing.

Doxycycline has caused most of the reported drug-induced injuries to the esophagus (3, 11). The adherence properties of all doxycycline products at present being marketed in Finland were therfore studied. In addition, two experimental formulations of doxycycline were included in the study. As can be seen from Table IV, there were significant differences between the products. Hard gelatin capsules required the most force to dislodge. In addition, the forces for detachment of experimental formulations G and H were significantly lower than those for the best commercially available products.

In the present study about 60 esophageal preparations from 30 different pigs were used, but no marked interindividual variation was observed. The same preparation could be used for 20–30 consecutive measurements without excessive variation in results. If the mucosa was washed, 50–60 measurements with the same preparation were possible. In the experiments, esophagi stored at 4° in Tyrode solution for 24 hr as well as fresh esophagi were used, but no significant differences between the two were noted. The effect of possible spontaneous esophageal contractions on the detaching force was eliminated by using a large number of n-values (usually $n = 20$).

As can be seen from Figs. 3–4 and Table IV there were significant differences in the tendency for adherence, as between pharmaceutical formulations. The adherent tendency of uncoated potassium chloride tablets and sugar-coated tablets was only about 15–20% that of gelatin capsules. Thus, it is reasonable to try to develop drug products with less tendency to adhere. Large sizes should be avoided, especially in the case of drugs that are known to cause esophageal stricture or ulceration.

Erythrocyte Changes in Aqueous Polyethylene Glycol Solutions Containing Sodium Chloride

TOMIKAZU NISHIO *x, SUMIKO HIROTA ‡, JUNKO YAMASHITA ‡, KIKUE KOBAYASHI ‡, YUKARI MOTOHASHI ‡, and YURIKO KATO ‡

Received November 17, 1980, from the **Research Laboratories, Ohta Pharmaceutical Co., Ltd., 21-25 Namiki 1-chome, Kawaguchishi, Saitama 332, Japan*, and the ‡*Faculty of Pharmaceutical Sciences, Science University of Tokyo, Ichigaya Funagawara-machi, Shinjukuku, Tokyo 162, Japan.* Accepted for publication November 19, 1981.

Abstract □ The behavior of rabbit erythrocytes in aqueous solutions of polyethylene glycol 300 (I) and polyethylene glycol 400 (II) containing sodium chloride was investigated during 2–120 min incubation at 37°. No hemolysis was found in I (0–10.1%) and II (0–12.9%) solutions in the presence of sodium chloride (0.45–1.35%), but prelytic potassium ion loss and changes in the appearance of the erythrocytes proceeded with the passage of time. The potassium ion loss increased with increasing concentration of polyethylene glycol and/or sodium chloride. The mean cellular volume of erythrocytes decreased temporarily (during the first 2 min) in both I (6.7%) and II (8.6%) solutions containing sodium chloride (0.68–1.35%), and then increased progressively to the same value as that determined by solution of sodium chloride at the same concentration but without polyethylene glycol (~30 and 120 min in I and II solutions, respectively). Both I (10.1%) and II (12.9%) induced a stomatocytic transformation of erythrocytes, but at the higher concentrations (0.9–1.35%) of sodium chloride, II accelerated the progress of spontaneous transformation to echinocytes. The results indicate that these solutions were not isotonic with rabbit erythrocytes.

Keyphrases □ Erythrocytes—changes in aqueous polyethylene glycol solutions, sodium chloride □ Sodium chloride—erythrocyte changes in aqueous polyethylene glycol solutions □ Polyethylene glycol—aqueous solutions containing sodium chloride, erythrocyte changes

The hemolysis of rabbit and human erythrocytes occurs in polyethylene glycol even at iso-osmotic concentrations, while the hemolysis is almost completely inhibited in the presence of a suitable amount of sodium chloride (1, 2). However, little is known about the retention of the normal characteristics of erythrocytes in polyethylene glycol solutions containing sodium chloride.

The experiments described deal with the quantitative variations of hemolysis, potassium ion loss, mean cellular volume, and shape of rabbit erythrocytes produced in aqueous polyethylene glycol 300 (I) and polyethylene glycol 400 (II) solutions with reduced sodium chloride content.

EXPERIMENTAL

Materials—Polyethylene glycol 300[1] and 400[1] in reagent grade were used without further purification. All other reagents and chemicals used were reagent grade or high purity.

Preparation of Solutions—The polyethylene glycol and sodium chloride solutions were weight-in-volume percentage preparations, and were adjusted to pH 7.4 by addition of 3 N HCl. Iso-osmotic concentration of polyethylene glycol was estimated by the freezing point depression data.

Preparation of Erythrocyte Suspension—Fresh rabbit (albino) erythrocytes, using heparin (100 U/ml of blood) as an anticoagulant re-

agent, were washed three times with a chilled 0.9% NaCl solution to remove plasma and the buffy coat and resuspended at 80% hematocrit in the same solution.

Erythrocyte Incubation—To a mixture of 1 ml of polyethylene glycol solution (0–10.1% for I and 0–12.9% for II in the final medium) and 1 ml of NaCl solution (0–1.35% in the final medium), 0.5 ml of erythrocyte suspension (hematocrit value 80%) was added and mixed immediately. The mixture was incubated for a certain period (up to 120 min) at 37°, and an aliquot was withdrawn from the suspension and analyzed for the mean cellular volume and morphology of erythrocytes. The remaining suspension was centrifuged at 2000×*g* for 3 min, and both hemoglobin and potassium ion in the supernate were quantitatively determined. The degree of hemoglobin loss (hemolysis) and potassium ion loss were expressed as a percentage of their total losses induced by an aqueous saponin solution (100 mg/liter).

Estimation of Mean Cellular Volume—The mean volume of erythrocytes was calculated from the total cell volume, which was determined by the microhematocrit method and from the number of erythrocytes determined with a micro cell counter[2].

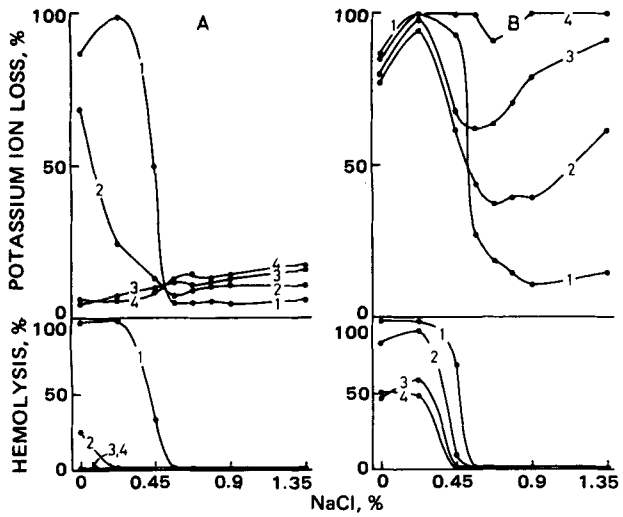

Figure 2—*The release percentage of potassium ion (A, B upper) and hemoglobin (A, B lower) from rabbit erythrocytes in II–sodium chloride solutions in various proportions after incubation for 2 min (A) and 120 min (B) at 37°. Curves 1–4 represent the percent release in II (0, 4.3, 8.6, and 12.9%, respectively) solutions. Each point is the mean value of three observations.*

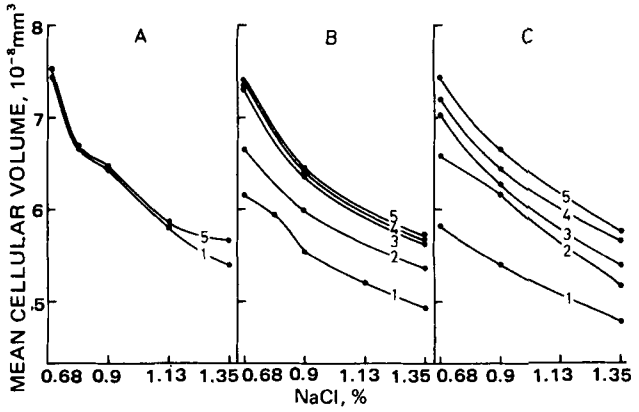

Figure 3—*The mean cellular volume of rabbit erythrocytes in the aqueous solutions of sodium chloride (A), 6.7% I–sodium chloride (B), and 8.6% II–sodium chloride (C) at 37°. Curves 1–5 represent the mean cellular volume after incubation for 2, 10, 30, 60, and 120 min, respectively. Each point is the mean value of three observations.*

Morphological Study of Erythrocytes with Scanning Electron Microscopy—Erythrocytes were fixed in 2.5% glutaraldehyde by standing overnight, followed by treatment in 2% osmium tetroxide for 2 hr in an isotonic phosphate-buffered saline solution (pH 7.4). The erythrocytes were dehydrated in a graded series of ethanol and air dried, followed by coating with gold–palladium alloy with an ion coater[3]. The erythrocytes were observed and photographed with a scanning electron microscope[4]. Morphology was defined according to Bessis' classification (3).

Determination of Hemoglobin (4)—The hemolyzates were added to ferricyanide–cyanide reagent, and the pigments were converted to cyanomethemoglobin. Their optical densities were analyzed with a spectrophotometer[5] at 540 nm.

Determination of Potassium Ion—Before measurements, proteins present in the hemolyzates were precipitated by boiling for 10 min and centrifuged. Potassium ion in the supernate was determined with an atomic absorption spectrophotometer[6] (air acetylene flame).

Measurement of Freezing Point Depression—The freezing point depression measurement was made on aqueous solutions of I and II by means of an osmometer[7].

RESULTS

Hemolysis and Potassium Ion Loss—Figures 1 and 2 show the release percentage of hemoglobin (hemolysis) and potassium ion from rabbit erythrocytes in various I and II solutions, respectively, with reduced content of sodium chloride at 37°.

After 2 min of incubation in I (Fig. 1A) and II (Fig. 2A) solutions with 0–0.45% NaCl, the percentage of hemolysis and potassium ion loss decreased with increased concentration of polyethylene glycol, and no loss occurred at iso- (I: 6.7%; II: 8.6%) or hyperosmotic concentration of polyethylene glycol. This finding was similar to that obtained for sodium chloride. Sodium chloride (>0.45%) prevented both the hemolysis and the potassium ion loss, regardless of the concentration of polyethylene glycol.

During a period from 2 to 120 min (I: Fig. 1B; II: Fig. 2B) at 0–0.45% NaCl, both hemolysis and potassium ion loss proceeded even at iso- or hyperosmotic concentration of polyethylene glycol (more rapidly in I than II solution) in contrast to the degree of hemolysis remaining unchanged for sodium chloride. At 0.45–1.35% NaCl, no hemolysis occurred, but potassium ion loss occurred depending upon the concentration of polyethylene glycol (remarkably in II solution). Furthermore the loss increased with increase of the concentration of sodium chloride. A minimal loss occurred at 0.6% NaCl.

Mean Cellular Volume of Erythrocytes—Figure 3 shows the mean cellular volumes of erythrocytes in solutions of I (6.7%) and II (8.6%) containing various concentrations of sodium chloride at 37°. Erythrocyte occupied a mean cellular volume of 6.4×10^{-8} mm^3 in 0.9% NaCl solution.

Table I—The Distribution of Rabbit Erythrocyte Shapes[a] in Polyethylene Glycol–Sodium Chloride Solutions

Medium Composition, %	After 2-min Incubation, %			After 120-min Incubation, %		
	Stomatocyte	Discocyte	Echinocyte	Stomatocyte	Discocyte	Echinocyte
0.6 NaCl	3.3	82.6	14.1	2.0	64.8	33.2
0.9 NaCl	2.3	75.8	21.9	1.0	60.9	38.0
1.35 NaCl	8.5	79.2	12.4	0.5	37.6	62.0
10.1 I + 0.6 NaCl	4.4	91.2	4.4	6.4	86.6	7.0
10.1 I + 0.9 NaCl	7.6	90.7	1.7	8.6	70.4	21.0
10.1 I + 1.35 NaCl	24.8	65.2	9.9	11.0	38.2	50.9
12.9 II + 0.6 NaCl	39.5	60.1	0.4	5.4	89.8	4.8
12.9 II + 0.9 NaCl	29.1	69.6	1.4	11.7	44.5	43.8
12.9 II + 1.35 NaCl	31.2	62.8	6.0	3.5	21.5	75.0

[a] The percentage of each cell type (stomatocyte, discocyte, and echinocyte) was estimated in three fields of scanning electron micrograph each containing between 100 and 200 cells/field.

The value increased to 7.53×10^{-8} mm^3 in 0.68% NaCl solution or decreased to 5.39×10^{-8} mm^3 in 1.35% NaCl solution within 2 min. After that, each value remained unchanged. In polyethylene glycol–sodium chloride solutions, the mean cellular volume decreased temporarily and then increased progressively to the same value as that determined by solution of sodium chloride at the same concentration but without polyethylene glycol. It took ~30 and 120 min in I and II, respectively, to reach this stage.

Shape of Erythrocytes—Table I shows the distribution of erythrocyte shapes after a certain period of incubation at 37° in I (10.1%)–, or II (12.9%)–sodium chloride solutions. Both I and II slightly induced cup-formed erythrocytes (stomatocytic transformation) on 2-min incubation. On prolonged incubation the progressive echinocytic transformation was observed with all the solutions examined. After 120 min of incubation, the presence of I retarded the echinocytic transformation regardless of sodium chloride content. II also retarded the transformation at a low concentration (0.6%) of sodium chloride, whereas it accelerated it at a high concentration (0.9–1.35%) of sodium chloride.

DISCUSSION

A previous study (1) reported that sodium chloride prevented hemolysis in polyethylene glycol 200 (≤25%) or I (≤40%) solutions. The present investigation also indicates that ≥0.45% concentration of sodium chloride prevented almost completely the hemolysis of rabbit erythrocyte in I or II solutions, but did not prevent prelytic potassium ion loss, mean cellular volume change, and shape change. In addition, the present experimental data showed that the time course of these erythrocyte changes could be divided into the first phase which occurred during the first 2 min, and the second phase which occurred during further incubation. For example, as shown in Fig. 1 (Curves 2 and 3) and Fig. 2 (Curves 2–4), hemolysis and potassium ion loss in the first phase were prevented in the polyethylene glycol solutions with a small amount of sodium chloride (0–0.45%), while in the second phase it proceeded gradually. Similarly, it was reported (5, 6) that red cells were hemolyzed in hypotonic electrolyte solutions in two phases: an early fast phase due to rapid water entry followed by a slow phase. The time course of hemolysis in the polyethylene glycol solutions was approximately the same as that for the hypotonic electrolyte solutions except that the reaction (for the polyethylene glycol solutions) proceeded more rapidly in the second phase. The process of cellular volume change was also divided into two phases in the polyethylene glycol solutions containing sodium chloride (Fig. 3). In the first phase the mean cellular volume decreased temporarily, as if erythrocytes were placed in the solution in which polyethylene glycol exerted osmotic pressure as well as sodium chloride (Curve 1, Fig. 3). In the second phase the mean cellular volume increased progressively to the same value as that determined by solution of sodium chloride, at the same concentration but without polyethylene glycol (Curves 2–5, Fig. 3). This may be explained from the viewpoint of osmotic support. In the first phase polyethylene glycol acts as an osmotic particle, since most polyethylene glycol molecules remain outside the erythrocyte membrane, while in the second phase the osmotic pressure decreases gradually as they penetrate the membrane.

The potassium ion loss occurred at both hypo- and hypertonic concentration of polyethylene glycol and sodium chloride, and increased with increase in the concentration of polyethylene glycol and/or sodium chloride. This result suggests that polyethylene glycol disturbs the erythrocyte membranes and produces the prelytic potassium ion loss. Discoloration of rabbit erythrocytes has previously occurred at high concentration (>15%) of polyethylene glycol (1). The discoloration also indicates the damage of the cell membranes by polyethylene glycol. Both polyethylene glycol and sodium chloride exert osmotic pressure in the first phase, and such a high osmotic pressure may accelerate the potassium ion loss.

Polyethylene glycol exerted an influence upon the spontaneous transformation of erythrocyte shape to echinocyte, which was said to result from ATP depletion of erythrocytes by incubation (7). This mechanism, however, is yet unclear.

Observation of the behavior of erthrocytes that are suspended in a solution is the direct procedure for determining whether the solution is isotonic, hypotonic, or hypertonic. If the cells retain their normal characteristics, the solution is isotonic (8). The present investigation evaluates the tonicity of polyethylene glycol–sodium chloride solutions. The I and II solutions containing 0.6% NaCl are the most isotonic, because both the prelytic potassium ion loss and the transformation of erythrocyte shape (discocyte: 86.6% in I; 89.9% in II) were relatively inhibited by addition of 0.6% NaCl. Whereas, on the basis of mean cellular volume data (9), the I or II solution containing 0.9% NaCl is the most isotonic, because the mean cellular volume in this solution was the same as in 0.9% NaCl (after incubation for 120 min). An isotonic solution consisting of polyethylene glycol and sodium chloride was not obtained at any concentration of sodium chloride.

Because rabbit erythrocytes were employed in the present investigation, a quantitative transfer of the experimental data to a human erythrocyte system is not possible, however it may be expected that the data apply qualitatively.

A conclusion drawn from this experiment for rabbit erythrocytes was that hemolysis did not occur in I and II solutions with ≥0.45% NaCl, but prelytic potassium ion loss, mean cellular volume change, and shape transformation were observed. Therefore, these solutions were not isotonic.

Anthralin: Chemical Instability and Glucose-6-phosphate Dehydrogenase Inhibition

DANIEL CAVEY ˣ, JEAN-CLAUDE CARON, and BRAHAM SHROOT

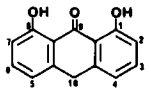
Received June 19, 1981, from the *Centre International de Recherches Dermatologiques, Sophia-Antipolis, F-06565 VALBONNE Cédex, France.* Accepted for publication November 20, 1981.

Abstract □ The chemical stability of the antipsoriatic drug, anthralin (1,8-dihydroxy-9-anthrone), in solution has been studied using high-performance liquid chromatographic analysis. The time course for decomposition in solution has been correlated with that of the inhibition of glucose-6-phosphate dehydrogenase, one of the most widely documented biochemical properties associated with anthralin. Solutions of anthralin in aqueous buffer (37°, pH 7.5, under light protection) decomposed completely within 4 hr giving the 10,10′-dimer (40%), no detectable 1,8-dihydroxy-9,10-anthraquinone, and a greatly increased potency of inhibition of glucose-6-phosphate dehydrogenase. This increased inhibitory potency could not be explained by formation of the dimer which, like anthralin and its quinone, were shown to be only weak inhibitors of the enzyme. In acetone solution exposed to light and air, anthralin decomposed completely within 4 days, in part *via* the dimer as intermediate. The final solution had the characteristic color of anthralin-brown, contained the quinone (20%), and like decomposed aqueous solutions of anthralin, completely inhibited glucose-6-phosphate dehydrogenase. The results show that neither anthralin, nor either of its two identified decomposition products, is the potent toxic species against glucose-6-phosphate dehydrogenase.

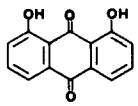
Keyphrases □ Anthralin—chemical instability and glucose-6-phosphate dehydrogenase inhibition □ High-performance liquid chromatography—chemical instability and glucose-6-phosphate dehydrogenase inhibition of anthralin □ Decomposition—anthralin, chemical instability and glucose-6-phosphate dehydrogenase inhibition

Anthralin (1,8-dihydroxy-9-anthrone, I) has been used successfully for over 60 years in the topical treatment of psoriasis (1–3). However, this treatment suffers from two main disadvantages: staining and irritation of the skin (4). It is well known that anthralin is unstable in solution and, depending on the conditions, can present a complex mixture of products and colors which have as their endpoint anthralin-brown (4, 5).

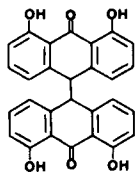
In view of this chemical instability, the *in vitro* biological properties which have been attributed to anthralin itself might, in fact, be related to some of its decomposition products. Furthermore, the therapeutic action and side effects following topical application of anthralin might result from the decomposition of this molecule into other chemical species having in turn antipsoriatic, irritating, and staining properties. Several attempts have been made to study the behavior of some known breakdown products in test systems which are claimed to give some indication of antipsoriatic or potentially toxic properties (6–8). Despite interest in the subject, little is known about which compounds play a major role in the action of this drug.



I



II



III

In a reinvestigation of anthralin, the first objective was to evaluate the stability of the molecule, particularly in a physiological buffer, using high-performance liquid chromatography (HPLC), and to relate the findings to one of the most widely documented biochemical properties attributed to anthralin itself: the inhibition of glucose-6-phosphate dehydrogenase (9, 10, and references therein)[1].

EXPERIMENTAL

Chemicals—The following chemicals were analytical grade reagents[2]: 2-[4-(2-hydroxyethyl)-1-piperazinyl]ethanesulfonic acid, iso-octane, diisopropyl ether, methanol, ethanol, 1-butanol, 1,3-butanediol, acetone, acetonitrile, 2-butanone, dimethylformamide, 1-propanol, 2-propanol, and acetic acid. 2-Butanol, tetrahydrofuran, and 1,4-dioxane were chromatographic grade[3]. 1,8-Dihydroxy-9-anthrone (anthralin/dithranol, I)[4] was purified by column chromatography (6). 1,8-Dihydroxy-9,10-anthraquinone (quinone, II) and bi(1,8-dihydroxy-9-anthron-10-yl) (dimer, III) were synthesized[5] following published procedures (7).

Enzymological studies were performed using pure yeast glucose-6-phosphate dehydrogenase[6], with glucose-6-phosphate and nicotinamide adenine dinucleotide phosphate as substrate and coenzyme, respectively[7]. All other chemicals were pure grade reagents[8].

High-Performance Liquid Chromatography—Analysis of anthralin and its derivatives was performed on an HPLC system[9] set at 254 nm (reference at 500 nm), and equipped with a reversed-phase 25-cm column[10], following the analytical conditions developed in this laboratory (11). In all experiments, samples (15 μl, either aqueous or organic solutions) were injected directly into the chromatographic system without previous solvent extraction.

Measurements of Glucose-6-phosphate Dehydrogenase Activity—All incubation experiments of glucose-6-phosphate dehydrogenase with anthralin and its derivatives were performed in a Ringer buffer composed of 140 m*M* NaCl, 5.2 m*M* KCl, 2.8 m*M* $CaCl_2$, 1.3 m*M* $MgSO_4$, and 20 m*M* 2-[4-(2-hydroxyethyl)-1-piperazinyl]ethanesulfonic acid at pH 7.5. In this buffer, the enzymatic activity remained almost constant over a 2-hr period at 37°. Before starting the experiments, the commercial enzyme suspension was diluted 300-fold in cold Ringer buffer and kept at 0°.

Time Course of the Influence of Anthralin, Dimer, and Quinone on

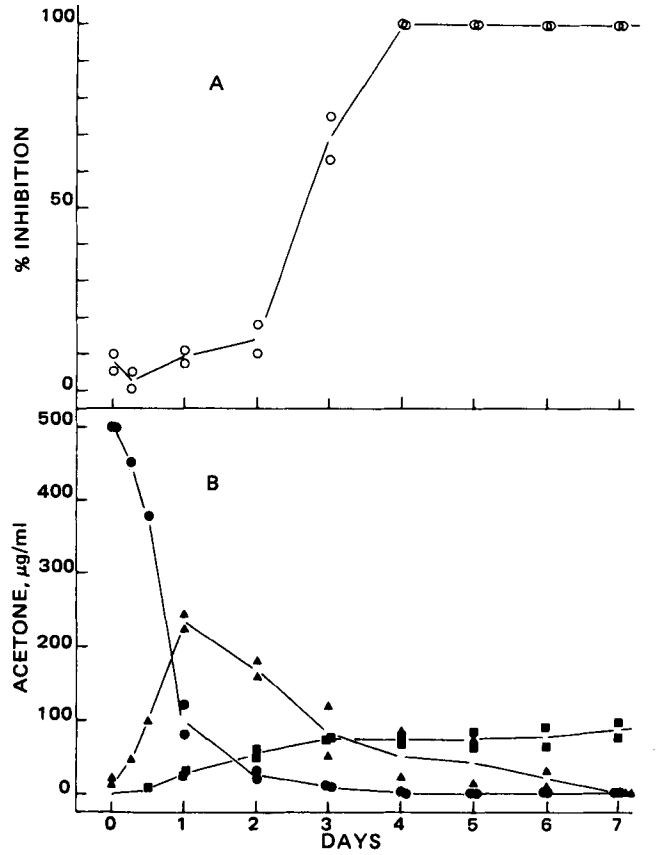

Figure 1—*Time course of the decomposition of anthralin in acetone (initial concentration = 0.5 mg/ml = 2.2 mM, 25°, continuous exposure to artificial light): inhibitory potency against glucose-6-phosphate dehydrogenase (A) and chemical composition of the medium as assayed by HPLC (B). Key: (○) percent of inhibition obtained by incubating the enzyme with 1% of the acetone solution for 5 min; (●) concentration of anthralin; (▲) concentration of dimer; (■) concentration of quinone.*

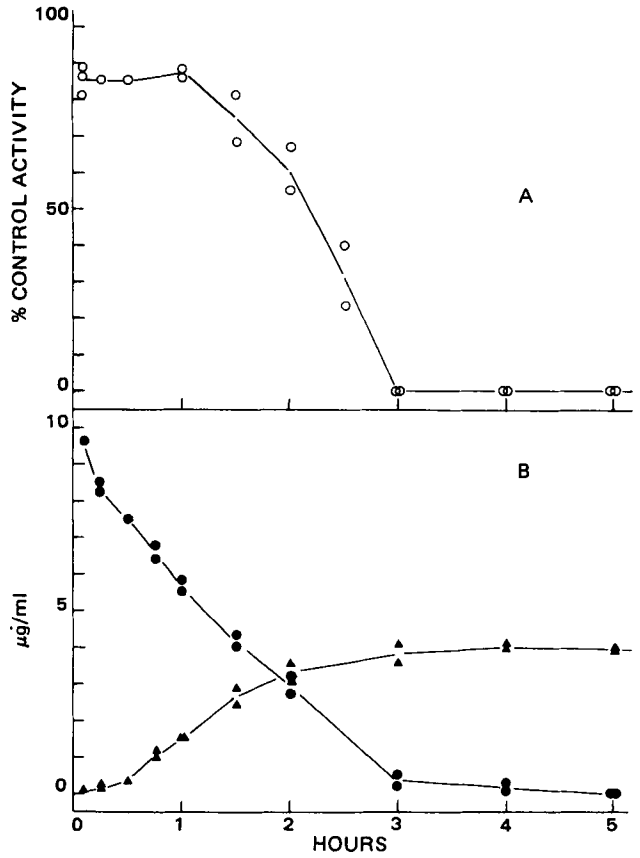

Figure 2—*Activity of glucose-6-phosphate dehydrogenase as a function of time of incubation with a solution of anthralin (A) (10 μg/ml in 1% acetone–Ringer buffer, pH 7.5, 37°, light protection), and the concurrent chemical composition of the medium, as determined by HPLC (B). Key: (○) percent of control enzymatic activity (the enzyme and anthralin were added at time zero); (●) concentration of anthralin; (▲) concentration of dimer.*

the Activity of Glucose-6-phosphate Dehydrogenase—The incubation medium (final volume = 3 ml) consisted of 2.92 ml of Ringer buffer, 50 μl of enzyme solution, and 30 μl of a 1 mg/ml solution of anthralin, dimer, or quinone in acetone to give a final concentration of 10 μg/ml in the incubation medium. Two test solutions and one control solution (to which acetone alone had been added) were kept for each specified time period at 37° in a water bath under light protection. The first test solution was then immediately analyzed by HPLC. To the second test solution and its control was added 50 μl of 10 m*M* nicotinamide adenine dinucleotide phosphate (final concentration 0.17 m*M* = 3 K_m under the present conditions)[11] and 50 μl of 18.6 m*M* glucose-6-phosphate (final concentration 0.31 m*M* = 3 K_m)[11], and the appearance of reduced nicotinamide adenine dinucleotide phosphate was immediately measured by its optical density at 340 nm at 37°[12].

At time zero of incubation, the control activity in the incubation medium (expressed as the variation of optical density per minute) was 0.21–0.23 ΔOD/min. Due to the presence of 1% acetone, this control activity decreased with increasing incubation time (to 50% of initial activity after 5 hr of incubation). To eliminate this unspecific solvent effect, each determination of the activity in the presence of anthralin or derivatives was corrected using the control activity in the presence of acetone alone at the same incubation time.

Time Course of Decomposition in Ringer Buffer and Inhibition of Glucose-6-phosphate Dehydrogenase—Duplicate solutions (30 μl of 1 mg anthralin/ml of acetone added to 2.92 ml of Ringer buffer) were kept for each selected time period at 37° in a water bath under light protection. To one solution, 50 μl of enzyme solution was then added and the solution (final volume = 3 ml, theoretical anthralin concentration 10 μg/ml = 44.2 μ*M*) maintained under light protection at 37° for an additional 5-min period. Enzymatic activity was measured as described earlier. To the second solution, 50 μl of enzyme solution was added and the mixture immediately analyzed by HPLC as described previously.

Time Course of Decomposition in Acetone and Inhibition of Glucose-6-phosphate Dehydrogenase—Anthralin was dissolved in acetone to a final concentration of 0.5 mg/ml. The solution was continuously exposed to air and artificial light[13] at 25° for a period of up to 1 week. At selected times the chemical composition of the medium was analyzed by HPLC, and its inhibitory potency against the enzyme was assessed by adding 30 μl of the acetone solution to a mixture of 2.92 ml of Ringer buffer and 50 μl of enzyme solution. The medium (final volume = 3 ml, theoretical anthralin concentration 5 μg/ml = 22.1 μ*M*) was maintained in a water bath at 37° for 5 min, and the enzymatic activity determined as described earlier.

RESULTS AND DISCUSSION

Selection of a Ringer Buffer–Solvent System—Despite the presence of the polar groups at C-1, C-8, and C-9, the anthralin molecule is quite lipophilic in nature. Consequently, an aqueous solution of anthralin (suitable for enzymological studies) must be prepared by adding a small volume of a concentrated solution of anthralin in an organic solvent to the aqueous medium. The criteria for a suitable organic solvent were solubility and relative stability of anthralin, water miscibility, and compatibility with the enzyme. Acetone was selected as the most suitable solvent (Table I). Stock solutions of anthralin (0.5 mg/ml or 1 mg/ml) in acetone could be used within 3 hr following the preparation.

The chemical decomposition of anthralin in acetone (0.5 mg/ml) was investigated over a 1-week period (Fig. 1B)[14]. At 25°, continuous exposure

[11] Under the present conditions (*i.e.*, Ringer buffer at pH 7.5 and 37°), the apparent Michaelis constants of glucose-6-phosphate and nicotinamide adenine dinucleotide phosphate were determined and found to be 0.1 m*M* and 0.05 m*M*, respectively.

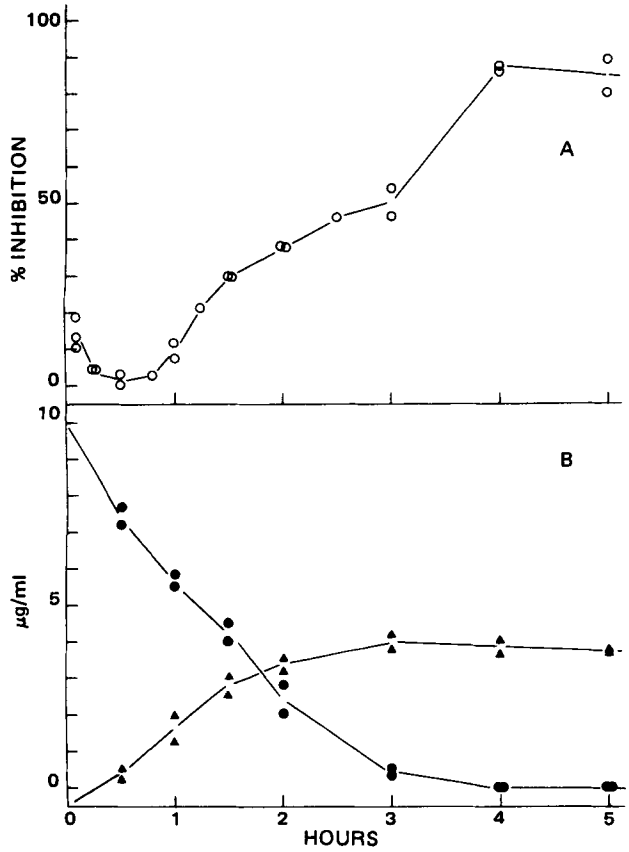

Figure 3—*Time course of the decomposition of anthralin in aqueous buffer (initial concentration = 10 µg/ml in 1% acetone–Ringer buffer, pH 7.5, 37°, light protection): inhibitory potency against glucose-6-phosphate dehydrogenase (A) and chemical composition of the medium as assayed by HPLC (B). Key: (○) percent of inhibition obtained by incubating the enzyme with the medium for 5 min; (●) concentration of anthralin; (▲) concentration of dimer.*

of the solution to light led to the decomposition of anthralin, in part *via* the dimer, and gave a final solution containing 20% quinone and having the characteristic color of anthralin-brown. For the studies in aqueous buffer, a 1% acetone–Ringer buffer system, in which the enzyme compatibility was even better than at 2% (Table I), was finally selected.

Time Dependence of Decomposition of Anthralin with Enzyme—The time dependence of the decomposition of anthralin in Ringer buffer and of the inhibition of glucose-6-phosphate dehydrogenase with enzyme present in the medium is as follows: Anthralin is unstable in aqueous solution at pH 7.5, irrespective of the organic solvent vehicle. When kept in 1% acetone–Ringer buffer at 37° under light protection, anthralin completely decomposed within 4 hr (Fig. 2B), undergoing, in part, oxidation to the dimer (40%), but not to detectable quantities of its quinone. The presence of glucose-6-phosphate dehydrogenase did not influence this process, since very similar results were obtained either in the presence (Fig. 2B) or in the absence (Fig. 3B) of enzyme in the Ringer buffer solution.

The corresponding time course of inhibition of glucose-6-phosphate dehydrogenase by anthralin (at its upper limit of solubility of 10 µg/ml) showed an initial slight inhibition (~15%) (Fig. 2A) which was rapidly established and lasted for ~1 hr, followed by an increasing inhibition, which was complete after 3 hr of incubation. Therefore, it was intriguing to speculate why enzyme inhibition should be initially maintained and then increased to reach its maximum over a 3-hr period, since HPLC analysis showed that anthralin was 25% degraded even after 30 min. The maintenance of the level of enzyme inhibition during the first phase could indicate that anthralin interacted slightly but irreversibly with the enzyme.

The second, slowly rising phase could be explained by the breakdown of anthralin into highly toxic species, which were responsible for the total destruction of enzymatic activity. Since the dimer was formed, it could have been suspected as being the highly toxic anthralin derivative. A solution of pure dimer (10 µg/ml = 22.1 µ*M*) was prepared in 1% acetone–Ringer buffer, at pH 7.5 and kept at 37° under light protection in the presence of the enzyme. At selected intervals, the composition of the medium was determined and the enzymatic activity was measured. The dimer was essentially stable over 2 hr (Fig. 4B) and caused only a modest, stable inhibition (10–20%) of glucose-6-phosphate dehydrogenase (Fig. 4A). Similar results were obtained with pure quinone (10 µg/ml, not shown).

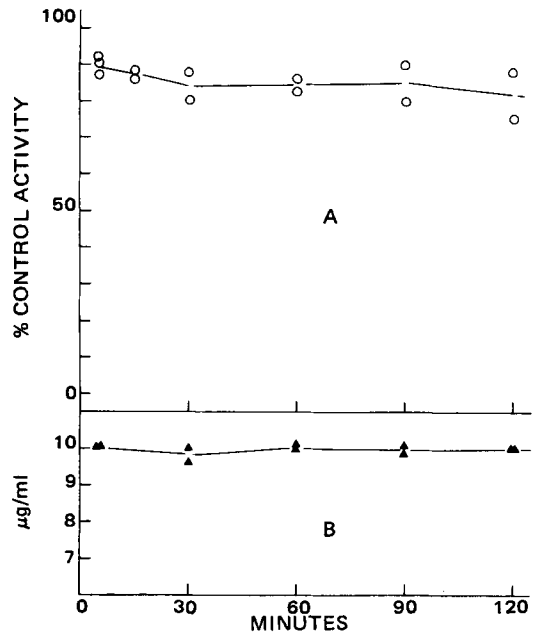

Figure 4—*Activity of glucose-6-phosphate dehydrogenase as a function of time of incubation with a solution of dimer (A) (10 µg/ml in 1% acetone–Ringer buffer, pH 7.5, 37°, light protection), and the concurrent chemical composition of the medium, as assayed by HPLC (B). Key: (○) percent of control enzymatic activity (the enzyme and dimer were added at time zero); (▲) concentration of dimer.*

These results demonstrate that the dramatic inhibition of glucose-6-phosphate dehydrogenase by anthralin solutions cannot be explained by the formation of dimer (40%), and suggest that one (or more) other unidentified breakdown products must be the toxic species. These breakdown products could not be detected under the present analytical conditions.

Time Dependence of Decomposition of Anthralin without Enzyme—The time dependence of the decomposition of anthralin in Ringer buffer, without enzyme and the inhibitory potency of the medium against glucose-6-phosphate dehydrogenase is as follows: Solutions of anthralin

Table I—Stability Properties of Anthralin in Pure Solvents and Compatibility of Solvent with Glucose-6-phosphate Dehydrogenase

Solvent	Stability[a]	Enzyme Compatibility[b] (percent solvent)
Methanol	– –	
1-Propanol	– –	ND[c]
1,3-Butanediol	– –	
Dimethylformamide	– –	
Ethanol	–	2
2-Propanol	–	1
1-Butanol	–	0
Tetrahydrofuran	–	0
2-Butanol	+	0

Acetic acid	++	0

[a] After 3 hr of exposure to day light at room temperature, the percentage of initial anthralin (0.5 mg/ml solvent) which has decomposed is >15% (– –), between 5 and 15% (–), between 1 and 5% (+), <1% (++). [b] Enzyme compatibility with solvent is expressed as the maximum percentage of solvent in the incubation medium, for which <10% of initial enzymatic activity is lost after 30 min of incubation at 37°. [c] Not done.

in 1% acetone–Ringer buffer (10 μg/ml) were left for appropriate periods at 37° under light protection in the absence of enzyme. The enzyme inhibitory potency of the aged solutions was assayed by adding glucose-6-phosphate dehydrogenase for an additional incubation period of 5 min.

The results shown in Fig. 3 indicate that the gradual disappearance of anthralin during the first 30 min was responsible for the concomitant decrease in the enzyme inhibitory potency of the solution. The reappearance of a stronger inhibitory activity, however, is in striking contrast with the complete degradation of anthralin which occurred during the following 2–3 hr and, as already noted, could not be attributed to the formation of the dimer.

Similarly, when anthralin was left in acetone (0.5 mg/ml) for several days under continuous exposure to light (Fig. 1), the final dark brown solution, which was totally devoid of anthralin or dimer, showed a strong toxicity against glucose-6-phosphate dehydrogenase (Fig. 1A). Incubation of 1% of the acetone solution with the enzyme in Ringer buffer (5 min) resulted in a total destruction of enzymatic activity, which could not be explained by the presence of quinone.

CONCLUSION

Using a highly sensitive and reproducible HPLC assay, additional evidence has been given for the chemical instability of anthralin in solution, particularly aqueous media. In acetone solution over long periods, anthralin decomposes, in part *via* the dimer, to give a final solution containing 20% quinone. In aqueous media at pH 7.5, 37°, and under light protection, the corresponding dimer (but not quinone) is formed. Near their upper limit of solubility in Ringer buffer, anthralin, dimer, and quinone interact with glucose-6-phosphate dehydrogenase, but this interaction leads to a fairly modest decrease of enzymatic activity. The dramatic changes regarding inhibition of the enzyme cannot be explained by the formation of dimer from anthralin and suggest that other breakdown products, unidentified as yet, must be the most active derivatives against glucose-6-phosphate dehydrogenase. Thus, if neutral aqueous buffers are used for the investigation of the mode of action of anthralin, the chemical instability of this molecule and the possible interference of highly active breakdown products should be kept in mind. Therefore, both *in vitro* and *in vivo* data should be interpreted cautiously.

Steroidal Oxazoline Derivatives: Synthesis and *In Vitro* Effect on Bovine Pancreatic Ribonuclease Activity

A.-MOHSEN M. E. OMAR ˣ and OMAIMA M. ABOULWAFA

Received October 14, 1981, from the *Pharmaceutical Chemistry Department, Faculty of Pharmacy, University of Alexandria, Egypt.* Accepted for publication November 19, 1981.

Abstract □ A series of steroidal oxazoline derivatives, containing different chains attached to the heterocyclic ring, were synthesized and examined for *in vitro* effect on bovine pancreatic ribonuclease activity. The results indicated weak anabolic properties for all products except Compounds III and XII which showed mild catabolic activities.

Keyphrases □ Oxazoline—steroidal derivatives, synthesis and *in vitro* effect on bovine pancreatic ribonuclease activity □ Derivatives—steroidal oxazoline, synthesis and *in vitro* effect on bovine pancreatic ribonuclease activity □ Ribonuclease activity—bovine, pancreatic, steroidal oxazoline derivatives, synthesis and *in vitro* effects

In connection with a program studying modified steroids, a variety of *N,N*-disubstituted aminoethyl ethers of 6-phenyl, benzyl, or thiazolidinyl-17β-estradiol were synthesized and tested for antiestrogenic properties (1). In addition, various androgenic and estrogenic keto-steroids were converted into the corresponding 4-substituted-3-thiosemicarbazone (2) and acylhydrazone (3–5) derivatives, and the products evaluated for anticancer (2, 4) and endocrinological (2, 3, 5) activities.

Extending the studies to steroids containing fused heterocyclic systems, the synthesis of a series of 2′-thio-17-oxoestra-1(10),4-dieno[2,3-*d*]oxazolines (V, VII, IX, and XI) and the corresponding estra-1,5(10)-dieno[4,3-*d*]oxazolines (VI, VIII, X, and XII), possessing methyl or *N,N*-disubstituted aminoethyl moieties in the heterocyclic ring, was undertaken[1]. The *in vitro* effect of the product on the activity of the bovine pancreatic ribonuclease was evaluated as a preliminary measure for their anabolic and catabolic properties (6) (Scheme I).

RESULTS AND DISCUSSION

Chemistry—The 2- (I) and 4-aminoestrones (II), prepared by reduction of the 2- and 4-nitroestrones (7) with sodium dithionite in alkaline medium (8), were treated with carbon disulfide and potassium hydroxide in boiling ethanol to produce 2′-thio-17-oxoestra-1(10),4-dieno[2,3-*d*]oxazoline (III), and 2′-thio-17-oxoestra-1,5(10)-dieno[4,3-

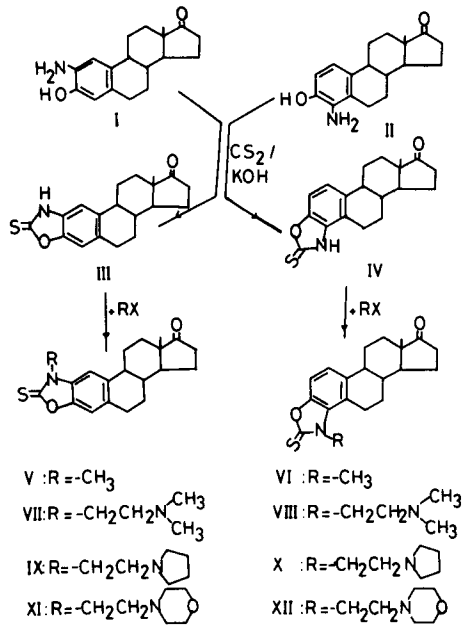
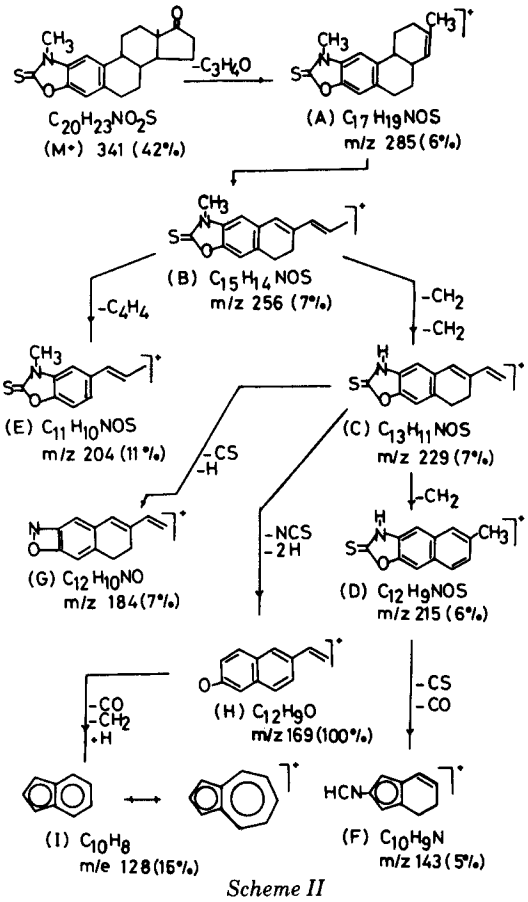


Scheme I

d]oxazoline (IV), respectively. The reaction of Compound III with methyl iodide in cold aqueous sodium hydroxide solution yielded the corresponding *N*-methylsteroidal oxazoline derivative (V). The application of the same procedure to synthesize the other required compounds (VI–XII) was fruitless. The preparation of the 3′-[2-(*N*-pyrrolidinyl)-ethyl] derivative (IX) necessitated the reaction of 2′-thioxazoline (III) with 2-(*N*-pyrrolidinyl)ethyl chloride hydrochloride salt in refluxing sodium ethoxide solution, while for compounds VI–VIII and X–XII, the use of potassium hydroxide in boiling acetone was the most effective in conducting the reaction to completion. The products (Table I) were identified by IR, UV, PMR, and, for one representative example, by mass spectra. The IR spectra of the products lacked the C=N absorption bands and exhibited a band at 930 cm^{-1} for the C=S absorption (9).

In the PMR spectra (Table II), the steroidal[2,3-*d*]oxazolines (V, VII, IX, and XI) showed two singlets at 7.08–7.20 and 7.27–7.59 ppm for the C_4 and C_1 protons of the steroidal skeleton. The analogous steroidal[4,3-*d*]oxazolines (VI, VIII, X, and XII) showed the C_1 and C_2 protons as a singlet at 7.20 ppm. The C_{18}—CH_3 of all products as well as the N—CH_3 of Compounds V and VI resonated as two singlets at 0.91–0.92 and 2.71–2.75 ppm, respectively. The protons of the 2-methylene chain of Compounds VII–XII were identified as two triplets resonating at



Scheme II

different chemical shifts. The first, appearing at 2.21–2.88 ppm, was assigned to the more shielded methylene protons adjacent to the *N*-dimethyl, pyrrolidino, or morpholino function. The other triplet, resonating at 3.42–3.49 ppm, was assigned to the relatively less shielded methylene protons attached to the oxazoline ring. The spectra also showed the signals for the pyrrolidine and morpholine protons at the expected chemical shift in the high field region.

The mass spectrum of Compound V showed a molecular ion peak at *m/z* 341. Its fragmentation as demonstrated in Scheme II involved the cleavage of Ring D to give Ion A at *m/z* 285 which after cleavage of Ring

[a] All products were crystallized from ethanol except compounds VII and X, which were crystallized from aqueous ethanol.

C produced Ion B at *m/z* 256. Successive elimination of methylene groups from Ion B gave Ions C, D, and E at *m/z* 229, 215, and 204, respectively. Ion D then lost a carbon monosulfide and a carbon monoxide function, and produced the isocyanide Ion F at *m/z* 143. Ion C either eliminated carbon monosulfide and a hydrogen to give Ion G at *m/z* 184 or underwent cleavage of an isothiocyanate ion and two hydrogens to yield Ion H as the base peak at *m/z* 169. This in turn eliminated carbon monoxide and a methylene ion and accepted a hydrogen giving Ion I at m/z 128. The spectrum has also shown the various ions reported for the normal fragmentation of estrone (10) and oxazole (11, 12).

Biological Screening—Compounds III–V, VII–IX, XI, and XII were *in vitro* tested for possible anabolic–catabolic activity by measuring their effects on the activity of the bovine pancreatic ribonuclease. The applied method, as reported (6), involved the utilization of four sets of incubation media: the medium containing the steroidal derivative and the enzyme, the blank lacking the enzyme, the control devoid of the steroidal derivative, and the control blank containing the enzyme and the phosphate buffer solution. After mixing the components of each set, the tubes were incubated at 37° for 15 min, and treated with an ethanol–glacial acetic acid mixture to terminate the reaction. They were stored for 1 hr in the refrigerator, centrifuged for 15 min, and the supernates were spectrophotometrically measured at 260 nm. The activity of the ribonuclease was calculated according to a previous report (13) and the data expressed as the mean values of five experiments ± standard deviation in units per milliliter.

In accordance with the results obtained (Table III), the majority of products caused a weak percentage inhibition of ribonuclease indicating mild anabolic properties. Compounds III and XII, induced a weak percentage activation of ribonuclease and hence proved to be of mild catabolic nature. In contrast to such findings, a variety of compounds having a heterocyclic ring fused to the 2,3- or 3,4-positions of various steroids have been reported to possess more potent endocrinological activity than the parent steroidal nuclei (14–19).

EXPERIMENTAL[2]

2′-Thiosteroidal-oxazolines III and IV—A mixture of the aminosterone (I or II) (8) (150 mg, 0.52 mmole), carbon disulfide (3.5 ml), and potassium hydroxide (30 mg) in ethanol (20 ml) was heated under reflux for 6 hr. The final solution was concentrated, cooled to room temperature, acidified with glacial acetic acid, treated with enough water until permanent turbidity, and left overnight in the refrigerator. The deposited white solid was filtered, washed with water, and crystallized from ethanol giving the required products. Compound III was obtained as white shiny scales darkening at 280°, mp 310°, yield: 87%. Compound IV was produced as white prisms, mp 188–192°, yield: 99%. IR (mineral oil): 1730 (C=O), 1510, 1495, 1140, and 930 cm^{-1} (H—N—C=S amide I, II, III, and IV bands, respectively) (9). UV of Compound IV, λ_{max} (ethanol) (log ϵ): 225 (4.477), 265 (4.202), 270 (4.180), 300 (sh) (4.503), and 310 nm (4.982). The products give microanalytical data within ±0.4% for C, H, and N.

2′-Thio-3′-methyl-17-oxoestra-1(10),4-dieno[2,3-*d*]oxazoline (V)—Methyl iodide (90 mg, 0.63 mmole) was added dropwise to an ice-cooled solution of 2′-thio-17-oxoestra-1(10),4-dieno[2,3-*d*]oxazoline (III) (200 mg, 0.61 mmole) in a mixture of ethanol (10 ml) and 10% aqueous potassium hydroxide solution (10 ml). The mixture was stirred for 1 hr, while being cooled in ice, and for an additional hour at room temperature. The final solution, containing some deposited products, was left overnight in the refrigerator, filtered, and the product crystallized from ethanol to give white shiny scales of the required Compound V. IR (mineral oil): 1720 (C=O) and 920 cm^{-1} (C=S). The yield and physical constants of the product are recorded in Table I. Mass spectrum of V showed *m/z* (relative abundance %) M^+ at 341 (42), 285 (6), 284 (6), 257 (4), 256 (7), 243 (8), 242 (4), 231 (9), 230 (13), 229 (7), 228 (11), 218 (5), 217 (18), 216 (13), 215 (6), 204 (11), 191 (11), 184 (7), 183 (11), 182 (9), 180 (3), 179 (5), 178 (26), 172 (5), 170 (9), 169 (100), 167 (5), 166 (4), 165 (6), 164 (6), 158 (7), 157 (15), 156 (5), 155 (7), 154 (6), 153 (8), 152 (5), 145 (4), 144 (4), 143 (5), 142 (6), 141 (11), 140 (5), 131 (8), 130 (6), 129 (15), 128 (15), 127 (6), 117 (5), 116 (15), 115 (22), 103 (15), 91 (6), 79 (4), 77 (6), 67 (6), 55 (6), and 41 (6).

2′-Thio-3′[2-(*N*-pyrrolidino)ethyl]-17-oxoestra-1(10),4-dieno-[2,3-*d*]oxazoline (IX)—2-(*N*-Pyrrolidinyl)ethyl chloride hydrochloride (110 mg, 0.6 mmole) was added to a solution of the thione derivative III (200 mg, 0.61 mmole) in sodium ethoxide (prepared from 30 mg of sodium metal and 10 ml of absolute ethanol) and the mixture was heated under reflux for 1 hr. The formed inorganic salt was filtered from the hot mixture and the filtrate concentrated to give, after cooling, the required product IX (Table I). IR (mineral oil): 1720 (C=O) and 920 cm^{-1} (C=S).

2′-Thio-3′-substituted-17-oxoestra-1(10),4-dieno[2,3-*d*]-and-1,5(10)-dieno[4,3-*d*]oxazolines (VI–VIII and X–XII)—A mixture of the steroidal 2′- (III) or 4′-thione (IV) derivative (200 mg, 0.61 mmole), potassium hydroxide (70 mg, 1.25 mmoles), and one molar equivalent of the selected alkyl, dialkylaminoalkyl, or *N*-heteroalkyl halide in acetone (15 ml) was heated under reflux for 2.5–12 hr (TLC). Filtration while hot, to remove the inorganic salt, and concentration of the acetone solution followed by treatment with water gave the required products identified as shown in Tables I and II. IR (mineral oil): 1730–1725 (C=O) and 965–920 cm^{-1} (C=S). UV of Compound VIII λ_{max} (ethanol) (log ϵ): 220 (4.449), 258 (4.303), 280 (4.181), and 290 nm (4.142).

Materials and Methods for the *In Vitro* Anabolic–Catabolic Activities—The following four sets of solutions were used in the evaluation procedures:

1. A 0.05 *M* phosphate buffer (pH 7.4);
2. A solution of 5 mg of a highly polymerized yeast RNA in 1 ml of the phosphate buffer;
3. A solution of 2.5 mg of bovine pancreatic ribonuclease[3] in 100 ml of distilled water;
4. Various molar concentrations (10^{-6} to 10^{-9}) of the steroidal derivatives in ethanol.

The media utilized were:

1. The medium containing the steroidal derivative and the enzyme was composed of a mixture of 0.4 ml of RNA solution, 0.4 ml of phosphate buffer, 0.1 ml of the steroidal solution, and 0.1 ml of ribonucleotase.
2. The blanks did not contain the enzyme but were composed of a mixture of 0.4 ml of RNA solution, 0.1 ml of the steroidal solution, and 0.5 ml of the buffer.
3. The control experiments were devoid of the steroidal components and contained a mixture of 0.1 ml of ribonucleotase, 0.4 ml of RNA, and 0.5 ml of the buffer solution.
4. The blank of the control contained only 0.4 ml of RNA completed to 1 ml volume by the buffer solution.

Table II—PMR Spectral Data of the Synthesized Steroidal Oxazoline Derivatives

Compound No.	Chemical Shift (δ ppm) in $CDCl_3$
III	0.92 (s, 3H, C_{18}—CH_3), 7.08 (s, 1H, C_4—H), 7.27 (s, 1H, C_1—H), 10.55 (broad and diffused singlet, disappearing on deuterization, 1H, N—H).
V	0.91 (s, 3H, C_{18}—CH_3), 2.71 (s, 3H, N—CH_3), 7.13 (s, 1H, C_4—H), 7.52 (s, 1H, C_1—H).

Chromatographic Assay of Neomycin B and C in Neomycin Sulfate Powders

W. DECOSTER, P. CLAES, and H. VANDERHAEGHE ˣ

Received July 31, 1981, from the *Rega and Pharmaceutical Institutes, University of Leuven, B-3000 Leuven, Belgium.* Accepted for publication November 24, 1981.

Abstract □ A chromatographic assay of neomycin sulfate powders on strongly alkaline ion-exchange resin (hydroxide form) is described. D-(+)-α,α-Trehalose was used as an internal standard. The amount of neomycin B and C in commercial samples was determined with the proposed method, and the results are compared with those obtained by microbiological assay. In addition, minor neomycin components were estimated by TLC and GLC methods.

Keyphrases □ Neomycin—ion-exclusion chromatographic assay of neomycin B and C in neomycin sulfate powders □ Chromatography, ion-exclusion—assay of neomycin B and C in neomycin sulfate powders □ Neomycin sulfate powders—ion-exclusion chromatographic assay of neomycin B and C

The microbiological assay of neomycin prescribed by most pharmacopoeias presents more difficulties than usually encountered with other antibiotics. It shows large interlaboratory variation (1) and may be suspected of a lack of accuracy inherent to the mixture assay where the components have markedly different activities. The influence of the composition on the microbiological assay (2) requires a preliminary quantitation of neomycin C as a fraction of neomycin B to ascertain a similar composition of the unknown and standard preparation. Therefore, alternative methods of assaying neomycin have been developed. A GLC method of totally silylated neomycin was reported previously (3). Poor resolution and critical experimental conditions (4) make this method difficult to perform. A high-pressure liquid chromatographic (HLPC) method of *N*-dinitrophenylated neomycins on normal phase was also reported (5).

The present report deals with a chromatographic assay on a strongly basic ion-exchange resin (hydroxide form) using water as the mobile phase and refractometric detection. It was developed from a medium-pressure chromatographic method used in this laboratory for the determination of relative amounts of neomycin B and C (6) and has the advantage of avoiding pre- and postcolumn derivatization. The use of an internal standard allowed the quantitation of absolute amounts of neomycin B and C. With the proposed method, commercial neomycin samples of different origin were assayed and the amount of several minor components were estimated.

EXPERIMENTAL

Apparatus—A stainless steel column[1] (1.0 cm × 30 cm) was provided with the necessary ferules, fittings, and metal low-dead volume tubing. The usual metal fritted disks were replaced by porous polyethylene disks[1]. The outlet was connected to a differential refractometer[2] (attenuator setting, 8×). The strip chart recorder[3] (10-mV range, chart speed, 10 mm/min) was replaced in some experiments by an electronic integrator[4]. The column was held at constant temperature by submersion in a bath of circulating water[5], which also served for thermostatization of the refractometer. The column inlet was provided with an injector[6]. The mobile phase, carbon dioxide-free distilled water, was delivered at a constant rate by a reciprocating piston pump[7]. A Bourdon-type pressure gauge, which also served as a pulse dampener, was placed between the pump and injector, and a stainless steel guard column (1.0 cm × 10 cm) was filled with the same resin as in the analytical column.

The procedure for conversion of the resins into the hydroxide form was discussed in detail in a previous report (6).

Peak areas were determined with a polar planimeter or with an electronic integrator.

Materials—Samples of neomycin sulfates were obtained from different firms. The European Pharmacopoeia CRS of neomycin sulfate was used as received, the USP reference standard (Issue E) was previously dried at 60° for 3 hr *in vacuo* as prescribed. Four resins[8–10] were used without further purification or sizing.

Mobile Phase—Freshly distilled water was used in all experiments. The flasks were closed with a rubber stopper holding a soda-lime trap.

Standard and Sample Solution—Pure neomycin B and C free bases were obtained by preparative chromatography on a carboxylic ion-exchange resin (7). They were converted into sulfates by adding 0.5 *N* sulfuric acid to yield a product containing 30.0% sulfate, expressed on a dry weight basis. The solution was freeze-dried and its sulfuric acid content and weight loss on drying were determined. From these values the free base content of the neomycin B and C sulfates was calculated.

The $[\alpha]_D$ of D-(+)-α,α-trehalose dihydrate[11] (+181°) was in close agreement with the value given by the manufacturer (+179.9°). Weight loss on drying was 9.73% (theoretical water content 9.67%). The internal standard stock solution was prepared by dissolving 4.00 g of trehalose in 50.0 ml of distilled water.

Neomycin sulfate (100 mg) was weighed accurately in a test tube, and 1.000 ml of internal standard stock solution was added with a micrometer syringe[12]. A calibration curve was obtained by chromatographing mixtures of pure neomycin B and C sulfate in 1 ml of internal standard stock solution. Then, 100 μl of all solutions was injected onto the column.

Weight Loss on Drying—Weight loss was determined after heating a 100-mg sample in a drying pistol[13] at 60° in a vacuum of 0.1 mm Hg for 3 hr over phosphorus pentoxide. The mean absolute standard deviation of the method was 0.13, calculated for five sets of four assays[14].

Sulfuric Acid Content—A previously reported titrimetric method (8) was modified slightly. A 100-mg sample of neomycin sulfate was applied to a 1 × 5 cm column of strongly acidic ion-exchange resin[15]. The column was washed with water and the eluate collected in a 50-ml volumetric flask. A 20-ml aliquot was diluted with 20 ml of methanol and buffered with 2 drops of 0.5 *M* magnesium acetate. After addition of 3 drops of 0.25% thorin[16] solution and 3 drops of 0.0125% aqueous methylene blue solution, the titration was carried out under vigorous stirring with 0.01 *M* barium chloride until the color changed from green to pink. The mean absolute standard deviation of the method was 0.15, calculated for five sets of four assays[14].

Thin-Layer Chromatography of Minor Components—Some eluate fractions from the resin column were evaporated to dryness and dissolved

[a] Hydroxide form resins in a 1 × 30-cm column at a flow rate of 270 ml/hr. [b] Bio-Rad AG I-X2 resin, minus 400 mesh. [c] Bio-Rad AG I-X4 resin, minus 400 mesh. [d] Durrum DA-X2, 1 × 10-cm column, flow rate 170 ml/hr. [e] Bio-Rex 9, 200–400 mesh.

in 0.5 ml of water. This solution (1, 2, 3, and 4 μl) was spotted on precoated silica gel plates[17], activated for 2 hr at 130°, and developed over 12 cm with a 15% (w/v) aqueous solution of potassium dihydrogen phosphate. It has been shown that these TLC plates[17] contain a polycarboxylic acid binder which is responsible for the separation of the aminoglycosides (9). After development, the dried plates were sprayed with a ninhydrin reagent (0.3 g in 100 ml of *n*-butanol containing 3% acetic acid) and heated for 5–7 min at 130°. Reference solutions of paromamine, mono-*N*-acetylneamine, mono-*N*-acetylneomycin B, and neamine contained 400 μg/ml. Comparison of the color intensities of the reference spots and the spots from the commercial samples allowed a semiquantitative determination of minor neomycin components.

GLC Determination of Acetyl Groups—In addition to the TLC method, the presence of acetylated products in commercial neomycin was also determined by a GLC method, preceded by acid hydrolysis and extraction of the liberated acetic acid with *tert*-butylmethyl ether. The stationary phase was 10% SP 1200[18] and 1% H_3PO_4 on 800/100 Chromosorb W AW (152.5 cm; o.d., 6 mm; i.d., 4 mm) at 95°. The flow rate of the carrier gas (nitrogen) was adjusted to 60 ml/min. The flame ion detector oven was set at 220°. Acid hydrolysis was performed on 100 mg of neomycin sulfate to which were added 0.4 ml of butyric acid internal standard solution (containing 1 mg/ml), 1 ml of concentrated sulfuric acid, and 0.8 ml of water. The test tube was sealed and heated at 100° for 4 hr in an oil bath. The reaction mixture was then extracted three times with 2.5 ml of *tert*-butyl methyl ether. The extracts were dried on anhydrous sodium sulfate, filtered, and reduced to ~0.5 ml with a stream of dry nitrogen; 5 μl of this concentrated extract then was injected on the column.

A calibration curve in the range of 50–500 μg/ml acetic acid was obtained by running known dilutions of acetic acid through the procedure described for the unknown samples. The peak height of acetic acid (retention time ~1 min) over the peak height of butyric acid (retention time ~2 min) was plotted against the amount of acetic acid present. The linear regression was $y = 0.471x - 0.008$ where the correlation coefficient is 0.9993.

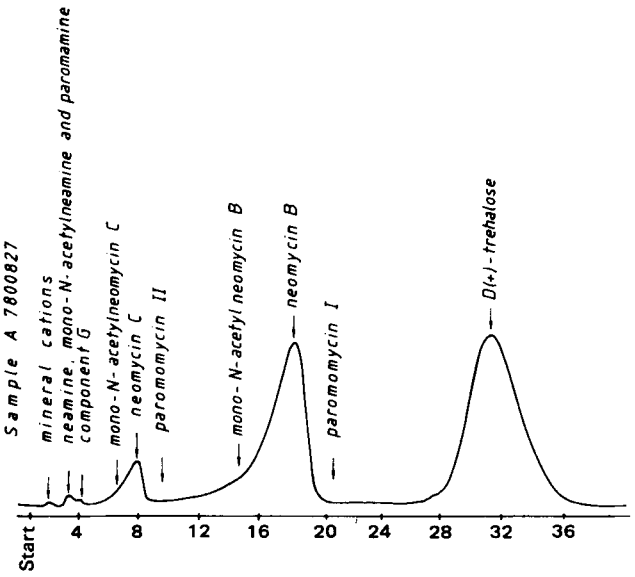

Figure 1—*Chromatogram of 10 mg of neomycin sulfate and 8 mg of internal standard, obtained on a 1 × 10 cm column of resin[21] connected to a 1 × 20 cm column of another resin[20]; flow rate, 270 ml/hr.*

RESULTS AND DISCUSSION

Internal Standard—When examining a chromatogram of neomycin on strongly alkaline resin in the hydroxide form (Fig. 1), an internal standard should elute after neomycin B. The only aminoglycoside that is commercially available and has a larger retention time than neomycin B is paromomycin I (10). This product cannot be used, as it may be present in some neomycin samples. Since refractometric detection does not necessitate a compound with amino groups, as would be the case with ninhydrin–colorimetric or fluorimetric detection, nonreducing oligosaccharides were examined. Reducing sugars cannot be used because they react with the strongly basic resin (11). The retention times of saccharose and raffinose were too long, but D-(+)-α,α-trehalose was suitable (Fig. 1).

Selection of the Resin—Three resins with benzyltrimethylammonium groups and one resin with methylpyridinium groups were examined (Table I). This last type of resin[8] gave good separations of neomycin B and C and the internal standard, trehalose. However, it was observed that the resin in the hydroxide form deteriorated rapidly. When the column was run for 1 week, injecting only two samples a day, the area of the neomycin B peak, relative to that of the trehalose peak, decreased regularly (Fig. 2). The resin degradation also could be seen from the drastically changing column parameters. The t_R of neomycin C, B, and the internal standard decreased after 1 week to retention times of 5.3, 10.2, and 15.2 min. The resolution between neomycin B and C changed from 2.5 to 1.7, and the resolution between neomycin B and the internal standard changed from 2.3 to 1.1. It is probable that the resin decomposes at the

site of the methylpyridinium groups yielding acidic functions. This would account for the regular decrease of the neomycin peaks.

One of the resins[19], which has a narrow particle size range (20 ± 5 μm for the resin in the chloride form) gave sharp peaks and a good separation of neomycin B and C. The separation of paromomycin I and the internal standard was not optimal (Table I). The main drawback was the low resistance to pressure of the resin in the hydroxide form. After 3 days at a pressure of 5 kg/cm², the resin bed was retracted to two-thirds of its original volume.

A second resin[20] gave good separation of neomycin B and C, but a poor resolution of paromomycin I and the internal standard, whereas for another resin[21] the opposite was true. With these resins a decrease with time of the neomycin peaks occurred also, although to a lesser extent than with a different resin[8] (Fig. 2). The pronounced change in column parameters was not observed.

Nonelution of a portion of the neomycin load is probably due to some carbon dioxide present in the water used as the mobile phase. Low concentrations could have an influence as large volumes of water are pumped through the columns during 1 week. When an aqueous solution of neomycin B base was saturated with carbon dioxide and applied to the column, no peak could be detected. When a freshly prepared column of resin[20] was loaded with 3 ml of carbon dioxide-saturated water or a 0.025% $NaHCO_3$ solution, the peak area of neomycin B relative to the peak area of trehalose decreased by 15 to 20%, although neomycin sulfate was applied. Formation of a carbonate link of the type $-\phi-CH_2-N^+(CH_3)_3$ CO_3^{-2} neomycin H^+ could explain the influence of carbon dioxide and carbonates on the elution of aminoglycosides. Similar problems have been encountered previously (12) when analyzing kanamycin free base on resin[22] in the hydroxide form. It was found that kanamycin base in aqueous solution converted partially into kanamycin carbonates by reaction with atmospheric carbon dioxide. The carbonates could only be eluted from the resin with water at pH 13 or 14 (12). The problem of carbonate accumulation on the analytical column was solved by connecting a guard column filled with one of the two resins[20,21] in the hydroxide form between the pump and the injector. This ensured a constant neomycin–internal standard ratio for at least 1 week (Fig. 2).

None of the two resins[20,21] gave an entirely satisfactory separation. Good separation of all components was obtained by replacing the 1 × 30 cm of resin[20] by a 1 × 10 cm column of resin[21] connected to a 1 × 20 cm column of resin[20] (Table I).

Calibration—Pure free bases of neomycin B and C were converted into their sulfates for reasons described. Since neomycin B and C had the same detector response in the experimental conditions (6), a mixture of known composition provided two points of the calibration curve per chromatogram. The peak area of the neomycin components over the internal standard peak area was plotted *versus* the calculated amount of free base present in the sample solution. In the 7–70 mg range of neomycin free base, the calibration curve was linear. The regression equation is $y = 0.0036 + 0.0130x$ and the correlation coefficient is 0.9995.

Interfering Compounds—Commercial neomycin contains mono-*N*-acetyl derivatives of the B and C compounds and of neamine (13) (the acetyl group is located at the amino function in the 3-position of the deoxystreptamine moiety) (14). Less active mono-*N*-acetylneomycins cause an overestimation of the B and C components, since they are eluted in the ascent of the main peaks (Fig. 1). Nevertheless, a TLC system allows the separation of neomycin B (or C) and mono-*N*-acetylneomycin B (or C) (Fig. 3). The eluate fractions corresponding to the first half of the neomycin B peak were collected and evaporated to dryness. The res-

idue was then dissolved in 0.50 ml of water, and 1, 2, 3, and 4 μl were spotted on the activated TLC plates, together with 1, 2, 3, and 4 μl of the mono-*N*-acetylneomycin B reference solution. After development and resolution with ninhydrin, a semiquantitative determination of the amount of mono-*N*-acetylneomycin B was made by estimating which spot of the unknown series corresponds best to a spot of the reference dilution. The amount of acetylated products can also be estimated by GLC assay of acetic acid liberated by acid hydrolysis. The correlation between TLC and GLC figures is good, as can be seen from Table II. Mono-*N*-acetylneomycin C, if present, would only represent a fraction of neomycin C, so it was not necessary to estimate such a small amount. If no mono-*N*-acetylneomycin B is available as the reference, it can be replaced by paromomycin, taking into account the sulfuric acid and moisture content of this commercial product. No detectable difference of the ninhydrin response between mono-*N*-acetylneomycin B or C and paromomycin I or II was found.

Although not interfering directly in the assay of the main products, other minor components were analyzed also by TLC. The eluate fractions containing neamine, paromamine, *N*-acetylneamine, and component G were also evaporated to dryness and dissolved in 0.50 ml of water. TLC and semiquantitative determination of these components were performed in a similar way as for mono-*N*-acetylneomycin B. Component G, an *O*-(diaminodideoxyhexosyl)-*myo*-inositol (7) was available, but it was not sufficiently pure to allow such an estimation. Its presence in neomycin samples will be indicated only qualitatively. As can be seen from Fig. 3, it cannot be distinguished whether mono-*N*-acetylamine or paromamine is present. However, from results obtained in the laboratory with ion-pair chromatography on a reversed-phase column[23] it can be seen that mono-*N*-acetylneamine is generally present in a larger quantity than paromamine.

Assuming an equal detector response of paromomycin I and neomycin B (or C) to the differential refractometer, the paromomycin I content of neomycin samples was calculated as for the main products.

Composition of Commercial Samples—A survey of the composition of recent neomycin sulfate samples of French (A–C), Norwegian (D, E), Japanese (F, G), and American (H, I) origin is given in Table II. The neomycin B free base content ranges from 52–59%. These values include mono-*N*-acetylneomycin B which is eventually present. The amount of neomycin C free base is between 4 and 9%. In addition to neomycin B and C, sulfuric acid content, weight loss on drying, and an estimation of the minor components are tabulated. Disregarding components that represent <0.5%, a summation of all other components closely approaches 100%.

Although an assay or estimation of neamine is prescribed by many pharmacopoeias, the present results prove this substance to be virtually absent from all samples analyzed. However, mono-*N*-acetylated neomycins and paromomycin I may be present in appreciable amounts. The nature of the minor neomycin components is typical for a particular manufacturer, possibly as a result of different fermentation and isolation processes.

Correlation Between Chromatographic and Microbiological Assay—To make a correlation of the amounts of neomycin B and C found for different samples with the results of the microbiological assay, it is necessary to know the relative response of neomycin C to neomycin B. However, this response depends on the microorganisms and media used in a diffusion or a turbidimetric assay. Relative responses of 30–40% have been obtained (15). Past experience indicates that the variation is even larger, and it has been assumed that the potency of neomycin C is half that of neomycin B (5). Using the amount of neomycin B and C in the European Standard (which is from the same batch as the International Standard) and its titer (775 IU/mg), it can be calculated that 1 μg of free base of the European (or International) Standard corresponds to:

$$\frac{775}{645.5 + \frac{62.5}{2}} = 1.145 \text{ potency units.}$$

Although potency units correspond to international units, an alternative symbol is preferred since international units are, strictly speaking, only valid for microbiological assays.

This conversion was applied to the different neomycin samples (Table III). If they contained paromomycin I, the amount of this component was added to the amount of neomycin B, because their antimicrobial activity is almost identical. It is interesting to note that the potency units of the First International Standard are nearly identical to the assigned IU value. For samples A–E, H and I, the correlation is also acceptable. The results of the microbiological assays of two samples (C and E) differ somewhat from one laboratory to another, even if they were obtained by analysts having much experience with this type of assay.

An attempt can be made to correlate the International Standard with the USP Reference Standard, although the potency in micrograms per milligram is defined in a different way and despite the fact that the latter preparation contains almost exclusively neomycin B. From the calculated 810 potency U/mg and the 767 μg/mg figures, it can be deduced that 1 μg/mg = 1.056 IU/mg

These calculations are not essential for the proposed chromatographic assay, which gives information concerning relative and absolute amounts of neomycin B and C and related compounds. Nevertheless, the calculations indicate that the proposed method could replace a microbiological assay.

The proposed method allows a chromatographic quantitation of neomycin B and C in neomycin sulfate powders without cumbersome sample derivatizations. The absolute standard deviation (mean value) is 0.67% for the determination of neomycin B and 0.33% for neomycin C. It can be performed with relatively simple apparatus which can be automated easily. Taking the precaution of not analyzing free bases, reliable values can be obtained.

[23] Method described in a private communication of Dr. A. Sezerat, Roussel-UCLAF Co., Romainville, France.

Potential Alkylating Agents Derived from Benzimidazole and Benzothiazole

A.-MOHSEN M. E. OMAR ˣ, N. S. HABIB, and OMAIMA M. ABOULWAFA

Received October 14, 1981, from the *Pharmaceutical Chemistry Department, Faculty of Pharmacy, University of Alexandria, Egypt.* Accepted for publication November 19, 1981.

Abstract □ Several benzimidazole and benzothiazole alkylating agents, bearing structural modification of certain drugs, were synthesized and evaluated for anticancer activity. Among the products, the dihydrochloride salt of 2-[*p*-[2-(bis(2-chloroethyl)amino)ethoxy]phenyl]benzimidazole (VI) exhibited a high antileukemic activity in P-388 lymphocytic leukemia.

Keyphrases □ Alkylating agents—derived from benzimidazole and benzothiazole, potential □ Benzimidazole—potential alkylating agents, benzothiazole □ Benzothiazole—potential alkylating agents, benzimidazole

The studies of benzimidazole alkylating agents reported the production of a variety of compounds (1–5) of which 4 - [2 - [5(6) - bis - (2-chloroethyl)amino]benzimidazolyl]-butyric acid[1] (6) and 2-[bis(2-chloroethyl)aminoethyl]-benzimidazole[2] (7, 8) are the most effective and clinically useful anticancer agents. In a previous investigation of the effect of structural modification on the anticancer activity of these compounds, several benzimidazole-2-thioethylsulfonic esters and nitrogen mustard derivatives were synthesized and evaluated for antileukemic properties (9). In continuation of these studies, this study describes the preparation of several new benzimidazole and benzothiazole alkylating agents (III, IV, VI, and X) and reports on the results of their evaluation against P-388 lymphocytic leukemia (Scheme I).

RESULTS AND DISCUSSION

Chemistry—*p*-(2-Hydroxyethoxy)benzaldehyde (I), prepared by etherification of *p*-hydroxybenzaldehyde with ethylene chlorohydrin (10) in the presence of sodium methoxide, was reacted with *o*-phenylenediamine and copper acetate, in accordance with the modified Weidenhagen reaction (11), to give 2-[*p*-(2-hydroxyethoxy)-phenyl]-benzimidazole hydrochloride (II). This was reacted with methanesulfonyl chloride or *p*-toluenesulfonyl chloride in pyridine to produce the corresponding sulfonic esters (III and IV). The *p*-toluenesulfonic ester (IV) was fused with excess diethanolamine and the produced 2-[*p*-[2-(bis-(2-hydroxyethyl)amino)ethoxy]phenyl]benzimidazole (V) converted into the dihydrochloride salt of the nitrogen mustard 2-[*p*-[2-(bis-(2-chloroethyl)amino)ethoxy]phenyl]benzimidazole (VI) by boiling with thionyl chloride in dioxane.

The reaction of *p*-(2-hydroxyethoxy)benzaldehyde (I) with o-aminothiophenol in pyridine gave 2-[*p*-(2-hydroxyethoxy)phenyl]benzothiazole (VII). This, on treatment with *p-toluenesulfonyl* chloride or methanesulfonyl chloride, yielded 2-[*p*-(2-chloroethoxy)phenyl]benzothiazole (VIII) rather than the corresponding sulfonic esters. Compound VIII was also obtained when the hydroxybenzothiazole derivative

Abstract □ Several benzimidazole and benzothiazole alkylating agents, bearing structural modification of certain drugs, were synthesized and evaluated for anticancer activity. Among the products, the dihydrochloride salt of 2-[*p*-[2-(bis(2-chloroethyl)amino)ethoxy]phenyl]benzimidazole (VI) exhibited a high antileukemic activity in P-388 lymphocytic leukemia.

Keyphrases □ Alkylating agents—derived from benzimidazole and benzothiazole, potential □ Benzimidazole—potential alkylating agents, benzothiazole □ Benzothiazole—potential alkylating agents, benzimidazole

The studies of benzimidazole alkylating agents reported the production of a variety of compounds (1–5) of which 4 - [2 - [5(6) - bis - (2-chloroethyl)amino]benzimidazolyl]-butyric acid[1] (6) and 2-[bis(2-chloroethyl)aminoethyl]-benzimidazole[2] (7, 8) are the most effective and clinically useful anticancer agents. In a previous investigation of the effect of structural modification on the anticancer activity of these compounds, several benzimidazole-2-thioethylsulfonic esters and nitrogen mustard derivatives were synthesized and evaluated for antileukemic properties (9). In continuation of these studies, this study describes the preparation of several new benzimidazole and benzothiazole alkylating agents (III, IV, VI, and X) and reports on the results of their evaluation against P-388 lymphocytic leukemia (Scheme I).

RESULTS AND DISCUSSION

Chemistry—*p*-(2-Hydroxyethoxy)benzaldehyde (I), prepared by etherification of *p*-hydroxybenzaldehyde with ethylene chlorohydrin (10) in the presence of sodium methoxide, was reacted with *o*-phenylenediamine and copper acetate, in accordance with the modified Weidenhagen reaction (11), to give 2-[*p*-(2-hydroxyethoxy)-phenyl]-benzimidazole hydrochloride (II). This was reacted with methanesulfonyl chloride or *p*-toluenesulfonyl chloride in pyridine to produce the corresponding sulfonic esters (III and IV). The *p*-toluenesulfonic ester (IV) was fused with excess diethanolamine and the produced 2-[*p*-[2-(bis-(2-hydroxyethyl)amino)ethoxy]phenyl]benzimidazole (V) converted into the dihydrochloride salt of the nitrogen mustard 2-[*p*-[2-(bis-(2-chloroethyl)amino)ethoxy]phenyl]benzimidazole (VI) by boiling with thionyl chloride in dioxane.

The reaction of *p*-(2-hydroxyethoxy)benzaldehyde (I) with o-aminothiophenol in pyridine gave 2-[*p*-(2-hydroxyethoxy)phenyl]benzothiazole (VII). This, on treatment with *p-toluenesulfonyl* chloride or methanesulfonyl chloride, yielded 2-[*p*-(2-chloroethoxy)phenyl]benzothiazole (VIII) rather than the corresponding sulfonic esters. Compound VIII was also obtained when the hydroxybenzothiazole derivative

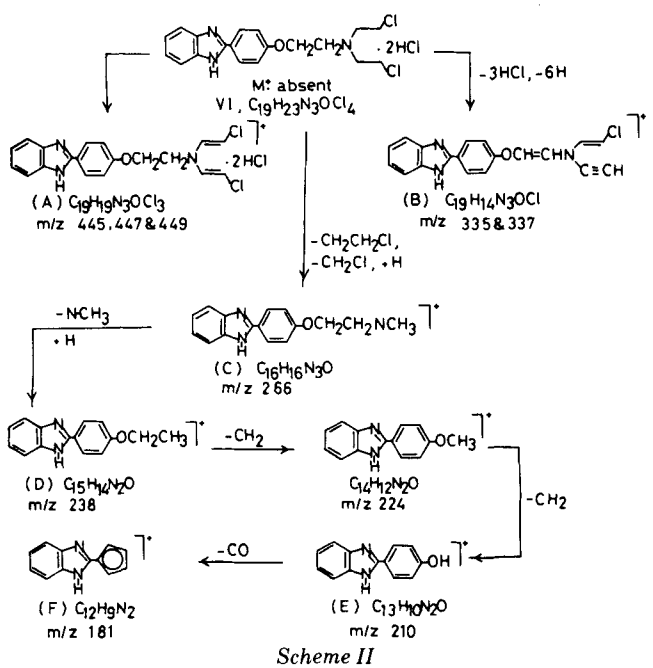
(VII) was treated with thionyl chloride in chloroform. It was then fused with diethanolamine to form the dihydroxyethylaminobenzothiazole derivative (IX) which on reaction with excess phosphorous oxychloride yielded the required nitrogen mustard, 2-[*p*-[2-(bis(2-chloroethyl)amino)ethoxy]phenyl]benzothiazole (X). The products were identified by microanalysis, IR and UV spectra and for representative examples by PMR and mass spectra.

The mass spectrum of the benzimidazole nitrogen mustard (VI) indicated the absence of the molecular ion peak at *m/z* 449. However, it showed that the molecule underwent a successive elimination of two pairs of hydrogens to give Ion A at *m/z* 445 and at 447 and 449 (for M+2 and M+4, respectively) (Scheme II). It also showed that Compound VI lost 3 moles of hydrogen chloride and six hydrogens to form Ion B at *m/z* 335 and 337 (for M+2). In an alternative fragmentation pathway, Compound VI eliminated a chloroethyl and a chloromethyl group and accepted a hydrogen to give Ion C at *m/z* 266. This, on further elimination of a methylamino moiety and acceptance of a hydrogen, gave Ion D at *m/z* 238. The successive removal of two methylene groups from Ion D led to formation of 2-(*p*-hydroxyphenyl)benzimidazole, Ion E, at *m/z* 210. The latter lost carbon monoxide to yield 2-cyclopentadienylbenzimidazole, Ion F, at *m/z* 181. The base peak was identified at *m/z* 28 corresponding to a carbon monoxide, an ethylene, or —N—CH_2 ion. The mass spectrum of benzothiazole nitrogen mustard (X) showed the molecular ion peak at *m/z* 394, and at 396 and 398 (for M+2 and M+4, respectively). The cleavage of a chlorine ion from Compound X gave the ion at *m/z* 359 and 361 which successively cleaved a methylene and a chloromethylamino fragment giving the ion at *m/z* 254. This in turn lost two successive methylene groups to form the 2-(*p*-hydroxyphenyl)benzothiazole ion at *m/z* 227, which on elimination of carbon monoxide gave the 2-cyclopentadienylbenzothiazole ion at *m/z* 198. The base peak, as shown in the data in the Experimental section, was shown at *m/z* 154, and at 156 and 158 (for M+2 and M+4, respectively) corresponding to the bis(2-chloroethyl)aminomethyl ion. The spectra of both Compounds VI and X have also shown the ions corresponding to the reported fragmentation of the heterocyclic rings (12–15).

Anticancer Screening—The products were evaluated against P-388 lymphocytic leukemia in mice (9). The activities were measured as the ratio of the mean survival time of the test animals to that of the control animals, expressed as a percentage (T/C %). The nitrogen mustard (VI) was the only product which exhibited T/C % values of 189, 144, and 132 when administered in doses of 12.5, 6.25, and 3.13 mg/kg of body weight, respectively.

As revealed from the reported studies of the benzimidazole nitrogen mustards, the majority of active products (1, 3, 4, 7) either retained the methylene group of 2-[bis(2-chloroethyl)aminoethyl]benzimidazole[2] or in only a few cases replaced it by phenyl or styryl moieties having the alkylating function directly attached to their benzene rings. In the present investigation, the high antileukemic activity of Product VI has demonstrated the efficacy of the *p*-ethoxyphenyl function as an additional carrier chain for alkylating groups. To confirm this finding, the compounds in preparation now for other structural activity relationship studies of alkylating agents have been designed to contain this chain.



Scheme II

EXPERIMENTAL[3]

2-[*p*-(2-Hydroxyethoxy)phenyl]benzimidazole Hydrochloride (II)—A solution of copper acetate monohydrate (6 g, 30 mmoles) in water (25 ml) was added to the solution of *o*-phenylenediamine (1.6 g, 14.8 mmoles) and *p*-(2-hydroxyethoxy)benzaldehyde (I) (2.42 g, 14.5 mmoles) in ethanol (10 ml) and the mixture, developing an immediate green precipitate, was heated under reflux for 30 min. The product was filtered, washed with water until the washing became colorless, and dissolved by heating under reflux in 2 *N* HCl solution (50 ml) for 2 hr. After cooling, the deposited shiny dark brown crystals were filtered and crystallized from ethanol (charcoal) giving the required product (II) as small needles melting at 272–274°. Yield: 3.2 g (76%). IR (mineral oil): 3460–3320 (OH), 1620 and 1610 (C=N), 1575 and 1500 (C=C, Ar), 1555 (δ NH), 1300 (δ OH), 1260 and 1045 cm^{-1} (—C—O—C—, asym and sym). UV λ_{max} (ethanol) (log ε): 255 (4.124), 312 (4.467), and at 325 nm (sh) (4.222).

Anal.—Calc. for $C_{15}H_{15}N_2O_2Cl$: N, 9.62; Cl, 12.2. Found: N, 10.00; Cl, 12.00.

2-[*p*-[2-(*p*-Toluenesulfonyloxy)ethoxy]phenyl]benzimidazole (IV)—*p*-Toluenesulfonyl chloride (5.5 g, 28.8 mmoles) was added to a cooled (ice-salt) solution of the benzimidazole derivative (II) (2.8 g, 9.6 mmoles) in dry pyridine (25 ml), and the mixture was stirred during cooling for 6 hr to form a white precipitate. Ice cold water (10 ml) was added dropwise and stirring was continued until the precipitate dissolved, and an orange solution was obtained. Further addition of water (100 ml) separated a solid which was filtered, washed with water, and crystallized from ethanol giving the sulfonic ester (III) melting at 155–157°. Yield: 2.87 g (74%). IR (mineral oil): 1605 (C=N), 1580, 1490 (C=C, Ar), 1560 (δ OH), 1340, 1170 (SO_2, asym and sym), 1250 and 1030 cm^{-1} (—C—O—C—).

Anal.—Calc. for $C_{22}H_{20}N_2O_4S$: C, 64.70; H, 4.94; N, 6.86. Found: C, 64.70; H, 5.20; N, 6.70.

Mass spectrum: *m/z* (relative abundance %) 408 (M^+) (1), 407 (6), 390 (2), 328 (5), 327 (6), 326 (29), 264 (2), 263 (7), 262 (35), 235 (5), 199 (14), 157 (6), 156 (11), 155 (100), 139 (10), 107 (11), 105 (11), 92 (12), 91 (96), 90 (5), 89 (6), 78 (13), 65 (17), 44 (9).

2-[*p*-[2-(Methanesulfonyloxy)ethoxy]phenyl]benzimidazole (III)—By reacting methanesulfonyl chloride (1.18 g, 10.3 mmoles) with the benzimidazole derivative (II) (1 g, 3.4 moles) in dry pyridine (15 ml), in the same manner as described for the synthesis of compound IV, the required methanesulfonic ester (III) was obtained as small white shiny crystals melting at 206–208° (ethanol). Yield: 750 mg (96%).

IR (mineral oil): 1610 (C=N), 1580, 1490 (C=C, Ar), 1540 (δ NH), 1330, 1100 (SO_2 asym and sym), 1260 and 1040 cm^{-1} (—C—O—C—). UV λ_{max} (ethanol) (log ε): 252 (4.182), 312 (4.507), and at 325 nm (sh) (4.262).

Anal.—Calc. for $C_{16}H_{16}N_2O_4S$: C, 57.83; H, 4.85; N, 8.43; S, 9.63. Found: C, 57.80; H, 4.80; N, 8.30; S, 9.70.

2-[*p*-[2-(Bis(2-hydroxyethyl)amino)ethoxy]phenyl]benzimidazole (V)—Excess diethanolamine (1 g, 9.5 mmoles) was added to the *p*-toluenesulfonic ester (IV) (1.7 g, 4.1 mmoles) and the mixture was heated at 120–130° (external temperature) for 1 hr. After cooling, the pale yellow solution was diluted with water (100 ml) to separate a white precipitate which was filtered and washed with water (4 × 50 ml) and crystallized from aqueous ethanol to yield the dihydroxy-ethylamino derivative (V) as white amorphous powder melting at 185–187°. Yield: 900 mg (90%). IR (mineral oil): 3375 (OH), 1605 (C=N), 1595, 1490 (C=C, Ar), 1540 (δ NH), 1240 and 1060 cm^{-1} (—C—O—C—).

Anal.—Calc. for $C_{19}H_{23}N_3O_3$: C, 66.84; H, 6.79; N, 12.31. Found: C, 67.00; H, 6.70; N, 12.30.

2-[*p*-[2-(Bis(2-chloroethyl)amino)ethoxy]phenyl]benzimidazole Dihydrochloride (VI)—Thionyl chloride (2 ml) was added dropwise to a hot and stirred solution of Compound V (650 mg, 2.6 mmoles) in dioxane (25 ml) to form a white precipitate. This soon dissolved as the reflux started, and fine white crystals began to form and increased in volume during reflux for 2 hr. Filtration followed by successive washing of the product with hot dioxane and dry acetone gave the

[3] All melting points are uncorrected. IR spectra were measured on a Beckman 4210 IR spectrophotometer. UV spectra were measured on a Beckman 24 spectrophotometer. PMR spectra were measured on a Varian A60, and mass spectra on an AEI-MS-50.

dihydrochloride salt of the nitrogen mustard VI, which softened with darkening at 245° and completely melted with decomposition at 283–285°. Yield: 920 mg (97%). IR (mineral oil): 3110 (NH), 1640, 1610 (C=N), 1590, 1510 (C=C, Ar), 1550 (δ NH), 1260 and 1065 cm^{-1} (—C—O—C—).

Anal.—Calc. for $C_{19}H_{23}N_3O\,Cl_4$: C, 50.50; H, 5.09; N, 9.31; Cl, 31.48. Found: C, 50.60; H, 4.70; N, 8.90; Cl, 31.50.

Mass spectrum: *m/z* (relative abundance) (M^+ absent) 449 (4), 447 (12), 445 (32), 379 (1), 378 (3), 337 (4), 335 (13), 266 (17), 238 (11), 237 (25), 236 (38), 235 (36), 224 (17), 223 (47), 211 (54), 210 (92), 209 (38), 181 (32), 180 (22), 129 (12), 127 (18), 121 (8), 120 (20), 119 (26), 112 (30), 107 (13), 105 (37), 100 (16), 99 (38), 97 (11), 93 (12), 91 (36), 84 (15), 78 (28), 77 (35), 72 (10), 70 (29), 65 (33), 64 (34), 63 (38), 58 (29), 57 (42), 56 (57), 55 (52), 52 (39), 44 (20), 42 (81), 38 (41), 28 (100).

2-[*p*-(2-Hydroxyethoxy)phenyl]benzothiazole (VII)—A solution of *o*-aminothiophenol (730 mg, 5.8 mmoles) in pyridine (5 ml) was added to the solution of *p*-(2-hydroxyethoxy)benzaldehyde (I) (970 mg, 5.8 mmoles) in pyridine (5 ml) and the mixture was heated on a water bath for 1 hr. After cooling, the product was poured onto water (100 ml), and the yellowish white emulsion so obtained was left overnight to deposit a whitish precipitate. This was filtered, washed with water (3 × 50 ml) and crystallized from ethanol (charcoal) to deposit the required product (VII) as small whitish shiny crystals melting at 157–159°. Yield: 1.28 g (81%). IR (mineral oil): 3200 (OH), 1595, 1570 (C=N mixed with C=C, Ar), 1305 (δ OH), 1245 and 1040 cm^{-1} (—C—O—C—). UV λ_{max} (ethanol) (log ε): 322 nm (4.447).

Anal.—Calc. for $C_{15}H_{13}NO_2S$: C, 66.41; H, 4.83; S, 11.78. Found: C, 65.90; H, 4.70; S, 11.40.

2-[*p*-(2-Chloroethoxy)phenyl]benzothiazole (VIII)—p-*Toluenesulfonyl Chloride or Methanesulfonyl Chloride*—The sulfonyl chloride derivative (11 mmoles) was added to a solution of Compound VII (1 g, 3.6 mmoles) in dry pyridine (25 ml), and the orange clear solution was stirred at ~60–70° (external temperature) for 1 hr. The final dark mixture was left for 3 days at room temperature and then diluted with ice cold water (100 ml). The separated buffer product was filtered, washed with water (3 × 100 ml) and crystallized from ethanol (charcoal) to give colorless shiny scales melting at 144–145°. This was found to be 2-[*p*-(2-chloroethoxy)phenyl]benzothiazole. Yield: 70–80%.

Phosphorous Oxychloride—Phosphorous oxychloride (10 ml) was added to the hydroxy derivative (VII) (2.15 g, 7.9 mmoles) and the mixture heated under reflux for 1 hr. The dark brown solution was evaporated *in vacuo*, to remove excess phosphorous oxychloride, and the residue was dissolved in hot ethanol, treated with sodium hydrogen carbonate (2 g), and left overnight. The alcoholic solution was filtered, concentrated, and cooled to give a white precipitate of the chloro derivative (VIII) which melted at 143–145° (ethanol). Yield: 1.8 g (73%). Product VIII obtained from all experiments did not show melting point depression and showed superimposability in IR and UV spectra. IR (mineral oil): 1600, 1575 (C=N and C=C, Ar), 1250 and 1040 cm^{-1} (—C—O—C— asym and sym). UV λ_{max} (ethanol) (log ε): 320 nm (4.551).

Anal.—Calc. for $C_{15}H_{12}NOSCl$: C, 62.10; H, 4.10; N, 4.80; S, 11.00. Found: C, 62.40; H, 4.50; N, 4.80; S, 11.10.

PMR: δ ($CDCl_3$) 3.83 (t, 2H, CH_2Cl, J = 7 Hz), 4.28 (t, 2H, CH_2O, J = 7 Hz), 6.90–8.19 (m, 8H, Ar—H) ppm.

Mass spectrum: *m/z* (relative abundance %) 291 (M^+) (47), (M+2 at 293), 292 (7), 290 (23), 289 (100), 228 (5), 227 (22), 226 (19), 199 (4), 198 (11), 197 (4), 154 (5), 108 (9), 69 (7), 63 (9).

2-[*p*-[2-(Bis(2-hydroxyethyl)amino)ethoxy]phenyl]benzothiazole (IX)—Excess diethanolamine (1 g, 9.5 mmoles) was added to the chloro derivative (VIII) (0.5 g, 1.17 mmoles), and the mixture was heated at 110–120° (external temperature) for 30 min. After cooling, chloroform (50 ml) was added and the mixture was shaken with water (2 × 100 ml). The aqueous layer was again extracted with chloroform (2 × 50 ml), and the combined chloroform extracts were washed with water (3 × 100 ml) until free from diethanolamine, dried (anhydrous Na_2SO_4), and evaporated. The produced viscous oil was dissolved in benzene, treated with light petroleum (bp 60–80°) until a permanent turbidity developed, scratched, and stored in a refrigerator. The deposited brown solid was crystallized from a benzene–light petroleum mixture to give the required product (IX), as a creamy amorphous powder melting at 77–79°. Yield: 420 mg (99.7%). IR (mineral oil): 3400–3220 (OH), 1600, 1575 (C=N and C=C, Ar), 1300 (δ OH), 1245 and 1085 cm^{-1} (—C—O—C—). UV λ_{max} (ethanol) (log ε): 322 nm (4.397).

Anal.—Calc. for $C_{19}H_{22}N_2O_3S$: C, 63.67; H, 6.19; N, 7.82. Found: C, 63.30; H, 6.20; N, 7.40.

2-[*p*-[2-(Bis(2-chloroethyl)amino)ethoxy]phenyl]benzothiazole (X)—Phosphorous oxychloride (5 ml) was slowly added to the dihydroxyethylamino derivative (IX) (580 mg, 1.62 mmoles) while being cooled in ice, and the mixture was allowed to warm slowly to room temperature and then heated under reflux for 1 hr. Excess phosphorous oxychloride was evaporated *in vacuo* and the black viscous residue decomposed by addition of crushed ice. Water (50 ml) and a few drops of 10% aqueous HCl solution were then added, and the mixture was heated, filtered while hot, cooled, and rendered alkaline with sodium bicarbonate. The crude buffer product so obtained exhibited two spots on TLC and could not be purified by repeated crystallization from ethanol. Therefore, it was purified on a column of silica gel[4] (10 g) using chloroform as the eluent. Evaporation of chloroform gave 200 mg (31%) of the nitrogen mustard X, which on crystallization from methanol separated as shiny white crystals melting with decomposition at 90–91°. IR (mineral oil): 1600, 1570 (C=N and C=C, Ar), 1245 and 1070 cm^{-1} (—C—O—C— asym and sym). UV λ_{max} (ethanol) (log ε): 321 nm (4.416).

Anal.—Calc. for $C_{19}H_{20}N_2OSCl_2$: C, 57.70; H, 5.06; N, 7.08; S, 8.10; Cl, 17.90. Found: C, 57.60; H, 5.30; N, 6.60; S, 8.50; Cl, 17.50.

PMR δ ($CDCl_3$): 2.85–3.25 [*m*, 6H, $N(CH_2)_3$], 3.55 (t, 4H, 2 × —CH_2Cl, J = 7 Hz), 4.15 (t, 2H, O—CH_2—, J = 7 Hz), 6.90–8.20 (m, 8H, Ar—H)ppm.

Mass spectrum: *m/z* (relative abundance %) 398 (5), 397 (6), 396 (31), 395 (11), 394 (39), 359 (2), 347 (3), 345 (11), 254 (3), 240 (2), 227 (5), 226 (5), 210 (12), 198 (5), 172 (8), 170 (8), 168 (11), 158 (14), 156 (80), 154 (100), 65 (5), 63 (14), 56 (12), 42 (10), 32 (8), 28 (30).

Complexation of Procainamide with Dextrose

V. DAS GUPTA

Received June 8, 1981, from the *University of Houston, College of Pharmacy, Department of Pharmaceutics, Houston, TX 77030.* Accepted for publication November 20, 1981.

Abstract □ The percent of procainamide complexed with dextrose was determined to be directly related to the concentration per mole fraction of dextrose in the solution. The complexation process was reversible and did not proceed at lower pH (~1.5). The rate of formation of complex was dependent on the initial pH value of the solution and the pH decreased as the concentration of the complex increased. The increase in the concentration of procainamide did not change the equilibrium concentration of the complex. The addition of sodium chloride or edetate disodium did not alter the rate of formation of the complex or its equilibrium concentration. The addition of hydrochloric acid prevented the formation of the complex and on adding hydrochloric acid after the formation of the complex, procainamide was completely freed.

Keyphrases □ Dextrose—complexation of procainamide □ Procainamide—complexation, with dextrose □ Complexation—procainamide with dextrose

Procainamide (I) is often mixed with 0.9% NaCl or 5% dextrose solution in water. The mixture is usually administered by continuous intravenous infusion for the treatment of certain cardiovascular diseases.

Procainamide is stable when mixed with sodium chloride solution (1) but in 5% dextrose solution, the stability is doubtful (1, 2). For example, one such solution lost ~12% of potency after 24 hr of storage (1). It has been predicted that procainamide may be forming a reversible association complex with dextrose (2). Procainamide is considered unusually stable towards hydrolysis in the pH range of 2–7 (3) even at higher temperatures.

The separation of procainamide from *p*-aminobenzoic acid (the major product of degradation) using high-pressure liquid chromatography (HPLC) has been reported (2). The other product of degradation, diethylethylenediamine, did not absorb light to record a peak in the chromatogram. An additional peak from the interaction of dextrose and I was observed in the chromatogram.

The purpose of this investigation was to study the complexation of procainamide with dextrose. The study was conducted using an HPLC method similar to that previously reported (2) in the literature.

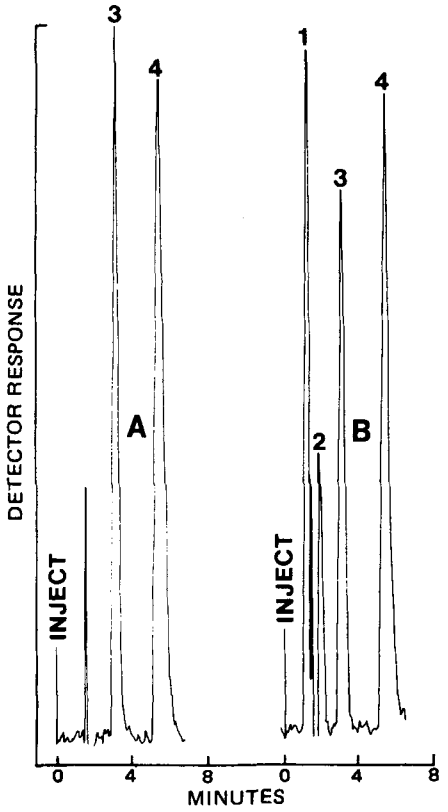

Figure 1—*Sample chromatograms: Peaks 1–4 are from* p-*aminobenzoic acid, complex of I with dextrose, free procainamide and methapyrilene (internal standard), respectively. Chromatogram A is from a standard solution and B from a 27-hr-old solution of procainamide (Solution 9 in Table I) to which 10.0 μg/ml of* p-*aminobenzoic acid was added before final dilution. For chromatographic conditions, see text.*

EXPERIMENTAL

Chemicals and Reagents—All chemicals and reagents were USP, NF, or American Chemical Society grade and were used as received. Procainamide hydrochloride[1] was used without further purification.

Apparatus—A high-pressure liquid chromatograph[2] equipped with a multiple wavelength detector[3], a recorder[4], and a digital integrator[5] was used.

Column—A semipolar column[6] (30 cm long × 4-mm i.d.) consisting of a monomolecular layer of cyanopropylsilane permanently bonded to silica gel was used.

Chromatographic Conditions—The mobile phase was 40% (v/v) acetonitrile in water containing 0.02 *M* ammonium acetate (pH ~7)[7], and

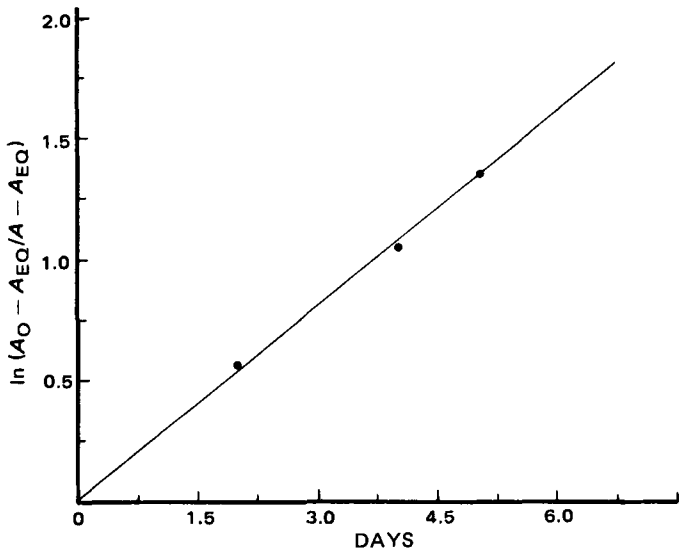

Figure 2—*A plot of complexation of dextrose with procainamide (Solution 6 in Table I) using the equation for a reversible reaction.*

[a] For composition of the solution, see Table I.

complex are reported in Table I. All were prepared using a simple solution method. The solutions were assayed (see procedure following) and transferred to amber-colored bottles[8] and stored at room temperature (24 ±1°). They were reassayed after appropriate intervals and pH values were also determined.

Preparation of Assay Solution—All the solutions were diluted with water to contain 15.0 μg/ml of I (based on the label claim) and 200.0 μg/ml of II (internal standard).

Assay Procedure—A 20.0-μl aliquot of the assay solution was injected into the chromatograph using the described conditions. For comparison, an identical volume of the standard solution was injected after the assay solution eluted.

Calculations—The results were calculated using:

$$\frac{Ph_a}{Ph_s} \times 100 = \text{Percent of the label claim}$$

Where Ph_a is the ratio of the peak heights of procainamide and methapyrilene of the assay solution and Ph_s that of the standard solution of an identical concentration.

[a] For composition of the solution, see Table I. [b] Accuracy ± 0.1.

Other Experiments—A 1.5-ml quantity of a 4-day-old solution in 3% dextrose (Solution 7 in Table I) was mixed with 2 ml of ~5 *N* HCl. The mixture was allowed to stand for ~20 min, then 4.0 ml of the stock solution of the internal standard was added, the mixture was brought to volume (100.0 ml) with water, and assayed.

In another experiment, 50.0 mg of *p*-aminobenzoic acid was dissolved in enough 5% aqueous solution of dextrose to make 50.0 ml. This solution was assayed after 0-, 2-, and 4-day intervals to determine if there was a reaction between dextrose and *p*-aminobenzoic acid. The assay was conducted using the HPLC method described previously since *p*-aminobenzoic acid separated (Peak 1 in Fig. 1) from I, II, and the complex between I and dextrose. Before injecting, the solution was diluted to a ratio of 1.0:100 with water. The concentration of *p*-aminobenzoic acid was determined by comparing the peak heights of the assay solution with a standard solution of an identical concentration (10.0 μg/ml).

RESULTS AND DISCUSSION

The results indicated that procainamide and dextrose formed a reversible complex (Fig. 2). This complexation could be completely prevented by adding 0.01 *N* HCl (Solution 15 in Table II). Furthermore, procainamide could be completely released from the complex by treating with hydrochloric acid (see Other Experiments). On treatment with ~5 *N* HCl, all of the procainamide was freed from the complex formed over a 4-day period in 3% aqueous solution of dextrose (Solution 7 in Table II). Preliminary investigations indicated that aged solutions of dextrose with procainamide did not interfere with the assay procedure for procainamide and its complex.

The rate of complex formation was dependent on the initial pH value of the solution. For example, in Solutions 22–25 that had higher initial pH values (Table III), the formation of complex was slower than in Solutions 5–8 (initial pH value 4.6). A direct comparison was possible between Solutions 9 and 22, since both contained 5% dextrose. In Solution 9, a commercial sterile solution was used (Table I) and in Solution 22, anhydrous dextrose was used. The sterile solution of dextrose had a lower pH (~4) *versus* a fresh solution made from the powder (pH ~6). The pH values after adding 0.1% of procainamide hydrochloride were 4.6 and 6 for Solutions 9 and 22, respectively. It is well-known (4) that solutions of dextrose become acidic on autoclaving.

A new set of solutions (16–20 in Table I) were prepared containing 0.05 *M* phosphate buffer. The rate of complexation in these solutions was slightly higher than those without buffer (Table II) which might be an experimental error. There is also a possibility of interaction of phosphates with dextrose (5), which is under investigation.

The pH values of the solutions on storage were decreasing (Table III), which is probably due to release of hydrogen ions upon the formation of complex. The concentration of the complex formed was directly related to the mole ratio of dextrose (Fig. 3) in the solution. However, at lower concentrations of dextrose (~2–4%), especially after 2 days of storage, dextrose concentrations were directly related (Fig. 4) to the concentrations of the complex.

Keeping the dextrose concentration constant and increasing the concentration of procainamide did not affect the rate of formation of complex or the equilibrium concentration (Solutions 9–11, Table II). Also, the increase in the ionic strength with sodium chloride did not alter the equilibrium or rate of formation of the complex (Solutions 7, 12–14, Table II). The addition of 0.05% edetate disodium did not affect the process of complexation (Solutions 9 and 21, Table II).

The process of complexation (a reversible reaction, Fig. 2) is slow and the time required for the equilibrium to establish is dependent on the initial pH of the solution (see above and data in Table II). The equilibrium concentration itself depended on the initial concentration of dextrose and pH of the solution.

For Solution 6, the K, k_f, and k_r values for the complexation (reversible process) were estimated to be 0.456, 0.0858, and 0.188 day^{-1}, respectively.

None of the solutions showed any peak in the chromatogram due to *p*-aminobenzoic acid even with a complex concentration of 50%. This compound could be easily separated from I, II, and the complex (Fig. 1). Moreover, in a separate experiment (see Other Experiments), it was determined that *p*-aminobenzoic acid did not form a complex with dextrose. Letting *p*-aminobenzoic acid stand in the presence of dextrose (≤4 days) did not change its concentration or peak(s) in the chromatogram.

Since all of procainamide could be released from the complex (see above) by treating with hydrochloric acid (see Other Experiments), the drug probably did not decompose. The complex itself may be as active as procainamide[9]. If so, there may be no stability problem on mixing I with dextrose. Since blood also contains dextrose, the implications of this process in biosystems requires further investigation.

The possibility of formation of 5-hydroxymethylfurfural rather than the complex is ruled out since it is a reversible reaction (Fig. 2), the hydrolysis of glucose to 5-hydroxymethylfurfural cannot be reversed (6), and the hydrolysis of glucose to 5-hydroxymethylfurfural usually occurs at higher temperatures (no heat was used in these studies).

Stability Assay of Allantoin in Lotions and Creams by High-Pressure Liquid Chromatography

Z. R. ZAIDI ˣ, F. J. SENA, and C. P. BASILIO

Received September 1, 1981, from the *R&D Laboratories, Block Drug Co. Inc., Jersey City, NJ 07302.* Accepted for publication November 23, 1981.

Abstract □ A high-pressure liquid chromatographic method for indicating stability is described for the rapid quantitative analysis of allantoin in lotions and creams. Allantoin was extracted from the preparations using distilled water containing 70% (v/v) methanol and separated from interferences by reversed-phase chromatography. The separation was carried out using an amino column (250 × 4.5-mm i.d.) and a mobile phase of distilled water containing 70% (v/v) acetonitrile. Quantitation was accomplished using a UV detector at 220 nm. The assay has a relative standard deviation of ~1.7% (n = 10) and the average recovery from laboratory prepared samples was 100%.

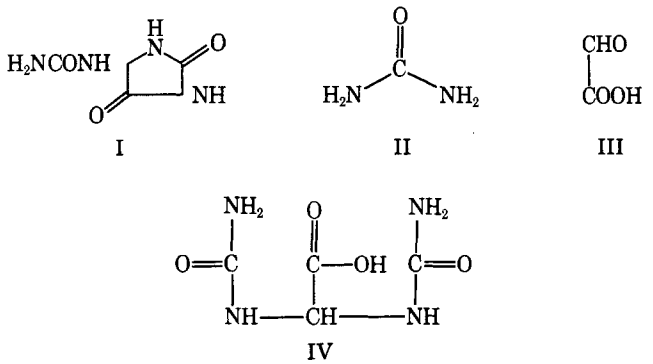
Keyphrases □ Allantoin—stability assay in lotions and creams by high-pressure liquid chromatography, degradation □ Stability—assay of allantoin in lotions and creams, high-pressure liquid chromatography, degradation □ Degradation—allantoin in lotions and creams, stability assay, high-pressure liquid chromatography

Allantoin and its derivatives have been used in various cosmetic preparations including skin creams, lotions, shampoos, lipsticks, and shaving preparations. A suitable analytical method is required for routine quality control as well as stability studies in the pharmaceutical/cosmetic industry. Allantoin (I) can be unstable in alkaline conditions and is known to hydrolyze to urea (II) and glyoxylic acid (III), perhaps *via* allantoic acid (IV):

Several methods (1–3) have been reported that are based on this hydrolysis route and subsequent colorimetric determination of III with phenylhydrazine. A fluorometric determination of sodium glyoxylate using phenylephrine hydrochloride described previously has been applied to the determination of allantoin in pharmaceutical preparations (4). However, for stability tracking, these procedures are deficient, because they measure urea or glyoxylic acid which are the products of normal allantoin degradation, rather than the residual intact allantoin.

Other techniques reported include titration (5, 6), classical chromatography (7), and a TLC separation with UV assay of allantoin at 220 nm (8, 9). In addition, a chromatographic procedure had been followed in these laboratories based on the separation of allantoin *via* TLC and determination by densitometry after chromophore formation.

All of these procedures are either time consuming or nonspecific. To overcome these problems, an assay procedure for allantoin in topical cream and lotion products by high-pressure reversed-phase liquid chromatography was investigated. The method described provides rapid, specific determination of intact allantoin with minimal sample preparation.



EXPERIMENTAL

Chemicals and Reagents—All reagents and chemicals were either HPLC or American Chemical Society grade and were used without further purification.

Apparatus—The liquid chromatograph[1] was fitted with a 50-μl septumless injector[2] and a variable wavelength UV detector[3] (set at 220 nm).

Average				100.0
RSD, %				1.20

Column—A 250 mm × 4.5-mm i.d. column containing 5 μm amino (NH_2) packing[4] was used.

Chromatographic Conditions—The chromatographic solvent was 70% (v/v) acetonitrile in distilled water. The solvent was vacuum filtered through a 0.50-μm (47 mm) filter[5] and vacuum degassed for 2 min with stirring before use. The temperature was ambient, the solvent flow rate was 2.5 ml/min, and the inlet pressure was ~2000 psi. Detector sensitivity was 0.04 aufs and the chart speed was 5.08 mm/min.

Standard Solutions—Standard solutions containing 30, 40, and 50 mg of allantoin/100 ml were prepared in distilled water containing 70% (v/v) methanol. Sonication was used to complete dissolution and the solutions were filtered using a 0.5-μm syringe filter[5] (25 mm) prior to injection.

Table II—Assay Results for Topical Cream Containing 2.0% Allantoin

Topical Cream	Allantoin, %	Percent of Label
1	2.03	101.5
2	1.95	97.5
3	1.98	99.0

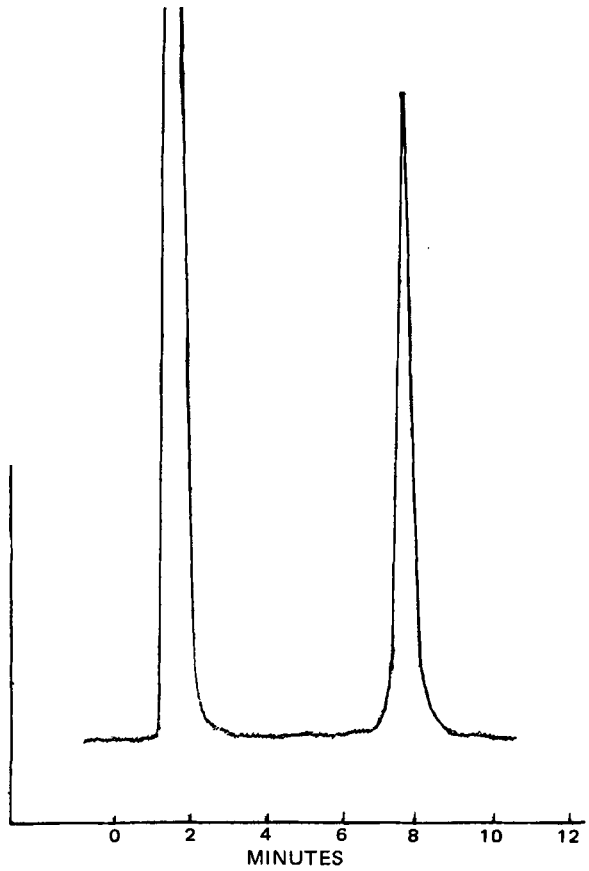

Figure 4—*HPLC of commercial lotion sample.*

transferred to a 100-ml volumetric flask, diluted to volume with methanol, mixed well, and filtered using a 0.5-μm syringe filter[5] (25 mm) prior to injection.

Spiked Samples—Accurately weighed quantities of allantoin were admixed with placebo portions of the topical creams and lotions. These samples were formulated to contain 1–2.5% (w/w) allantoin, and were assayed as described previously for commercial products.

Quantitation—Since peak heights of allantoin were directly proportional to concentration, all results were calculated by interpolation from a standard curve.

RESULTS AND DISCUSSION

Although satisfactory separations were achieved for samples of lotions and creams using distilled water containing 70% acetonitrile, for economic reasons, attempts were made to substitute methanol. However, no acceptable separations were obtained with various proportions of methanol water, therefore, acetonitrile was used for all further work.

The recovery data for allantoin from spiked samples of creams and lotions, presented in Table I, illustrate the validity of the method for these formulations. Average recoveries for cream and lotion were 100 and 99.7%, respectively. Linearity between peak height and concentration was excellent over the range of 0.3–0.5 mg of allantoin/ml with a correlation coefficient of 0.999. This method has been used routinely in a stability program and found to be accurate and precise with a *RSD* of 1.7% (n = 10). These data are summarized in Table II, and chromatograms obtained for allantoin standard and commercial cream sample are presented in Figs. 1 and 2, respectively. Since no sample clean up is required, assay time was ~15 min.

As noted earlier, allantoin is reported to degrade to urea and glyoxylic acid in alkaline conditions, perhaps through allantoic acid. To demonstrate the selectivity of the method for intact allantoin, standard and sample preparations containing allantoin were artificially degraded with alkali and analyzed according to the proposed conditions. No significant peaks were observed due to the degradation products at the retention time of allantoin peak, which was reduced in height.

To further demonstrate the stability-indicating nature of the method, several additional experiments were completed. Commercially available

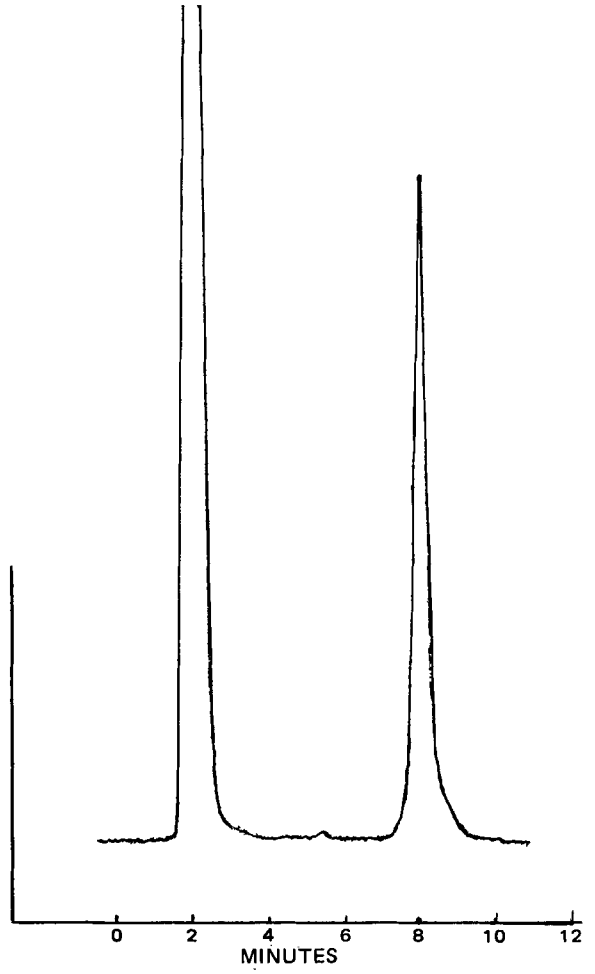

Figure 5—*HPLC of commercial lotion sample spiked with pure allantoic acid.*

urea and glyoxylic acid were chromatographed, and no peak was observed at the retention time of allantoin (Fig. 3). This was further confirmed by introducing 40–50 mg of these compounds to standard and sample preparations containing allantoin. In addition, commercially available allantoic acid was chromatographed as described (Fig. 3). It eluted at the same time as allantoin; however, when 0.4 mg/ml of allantoic acid (corresponding to 100% conversion from allantoin) was introduced to a standard allantoin solution (0.4 mg/ml) and chromatographed, an increase in allantoin peak height of <2% resulted.

A commercial lotion sample containing 40 mg of allantoin was analyzed in duplicate (Fig. 4). The samples were then spiked with 35–40 mg of allantoic acid and reanalyzed for allantoin (Fig. 5). Evaluation of these results indicated that within experimental error allantoic acid (if present) does not interfere in the analysis of allantoin.

It is concluded that the proposed method is selective for intact allantoin in the presence of probable degradation products.

Synthesis and Evaluation of Some Alkoxy-, Chloro-, and Acyloxy-Conjugated Styryl Ketones Against P-388 Lymphocytic Leukemia and an Examination of the Metabolism and Toxicological Effects of 1-(*m*-Ethoxymethyloxyphenyl)-1-nonen-3-one in Rats

J. R. DIMMOCK *x, D. L. KIRKPATRICK *, N. G. WEBB *, and B. M. CROSS ‡

Received August 24, 1981, from the **College of Pharmacy and* ‡*Department of Veterinary Pathology, Western College of Veterinary Medicine, University of Saskatchewan, Saskatoon, Saskatchewan, Canada S7N 0W0.* Accepted for publication December 15, 1981.

Abstract □ A number of analogs of a new antineoplastic agent, 1-(*m*-ethoxymethyloxyphenyl)-1-nonen-3-one (III*a*) were prepared and evaluated against murine P-388 lymphocytic leukemia. Metabolic studies of III*a* in rats showed that it was sequestered rapidly to the brain and hence probably to other adipose tissue, which may account for the absence of III*a* and metabolites in urine and feces. A detailed toxicological evaluation of III*a* in rats showed marked pathological changes principally in the liver and spleen as a result of erythrophagocytosis from bleeding into the abdomen.

Keyphrases □ Antineoplastics—alkoxy-, chloro-, and acyloxy-conjugated styryl ketones, synthesis and evaluation of activity □ Styryl ketones, conjugated—synthesis of alkoxy-, chloro-, and acyloxy-analogs, evaluation for antineoplastic activity □ 1-(*m*-Ethoxymethyloxyphenyl)-1-nonen-3-one—metabolic and toxicological studies

A number of Mannich bases (I) derived from conjugated styryl ketones synthesized in these laboratories displayed activity against P-388 lymphocytic leukemia, but murine toxicity was marked (1, 2). This observation was in contrast to the precursor α,β-unsaturated ketones (II) which, while not causing mortalities under the conditions of evaluation, were bereft of antineoplastic activity (1, 2). More recently, however, a number of conjugated styryl ketones, which were not Mannich bases, showed perceptible, beneficial responses in the P-388 lymphocytic leukemia screen. Thus, ethers III*a–c* increased the median survival time in mice by ~19% at the optimum dose levels, and assessment of III*a* against B-16 melanocarcinoma increased the lifespan by 30% with 1 mouse in 10 being cured (2). Furthermore, the unsubstituted and dichloro styryl ketones (IV*a–d*) also achieved increases in the lifespan of mice with P-388 lymphocytic leukemia of ~20% (3). With the exception of IV*b*, all of the compounds III and IV did not cause mortalities to mice during evaluation at the maximum doses administered (2, 3).

The purpose of the present investigation was twofold: First, molecular modification of the compounds in series III and IV to produce novel derivatives for evaluation in the P-388 screen was planned. Second, a study of the metabolism of III*a* was considered to be a viable undertaking, which may permit the identification of the breakdown products in the body followed by their antineoplastic evaluation and the subsequent design of new compounds on a rational basis.

RESULTS AND DISCUSSION

The synthetic program was directed toward the preparation of the ethers (V–VII), the ketones (VIII), the esters (IX), and finally some prodrugs of 4-phenyl-but-3-en-2-one, (X and XI). The reasons for proceeding in this direction were as follows. It has been claimed that the pH of a number of tumors is lower than normal tissue (4–6), and the average pH value for many tumors has been estimated to be ~6.5 (7). Therefore, it is conceivable that the levels of antineoplastic activity obtained with III*a*, namely, increases in mean survival times of 25 and 30% in mice bearing P-388 lymphocytic leukemia and B-16 melanocarcinoma, respectively (2), may be attributed to preferential hydrolysis to the corresponding phenol (II) (R_1 = 3-OH; R_2 = H) in the tumors. The inactivity of the precursor phenol (II) (R_1 = 3-OH; R_2 = H) may have been due to facile detoxification *via* the hydroxyl group prior to reaching the tumor. The synthesis of the corresponding *O*-benzyl ethers (V) was planned, since in simple nonbiological systems, many phenyl alkyl ethers regenerate the corresponding phenol under acidic conditions (8) but are stable under mildly alkaline conditions. In addition, alteration of the Hammett values of the nuclear substituents of the benzyl group in series V may permit variation in the rate of release of the precursor phenol (9) which may correlate with differences in antineoplastic activity. In the case of VI, the loss of the benzyl groups *in vivo* would permit the formation of an aromatic compound with vicinal hydroxy groups which may be con-

verted to an *ortho*-quinone. Since the two dimethoxy compounds (III*b* and *c*) were shown to possess some activity against P-388 lymphocytic leukemia, the question as to their mode of action was raised. *O*-Demethylation of phenols is a common metabolic pathway (10), and thus, the formation of the corresponding dihydroxy compounds could occur with subsequent oxidation to the corresponding *para*- and *ortho*-quinones (Scheme I), which may then interact with important cellular nucleophiles such as thiols (11, 12). Thus, the preparation of further nuclear methoxy styryl ketones (VII) was suggested, and in the absence of nuclear hydroxylation by metabolism, compounds VII*c*, *f*, *g*, and *i* are able to be converted *in vivo* into quinones, in contrast to VII*d*, *e*, and *h*.

In addition, while 1-phenyl-1-nonen-3-one (II, $R_1 = R_2 = H$) and the related dichloro derivative (II, $R_1 = 3\text{-}Cl$; $R_2 = 4\text{-}Cl$) are inactive against P-388 lymphocytic leukemia, branching of the alkyl chain α to the carbonyl group led to compounds IV*a* and *b* with perceptible beneficial responses in this screen (3). The increase in bioactivity could be due to a number of factors: Alignment at a receptor site with these branched-chain compounds may be favored, and also differences in the hydrophilic–lipophilic properties of IV*a* and *b* compared with the compounds containing the *n*-hexyl group are conceivable. Thus, increased branching of the alkyl chain in the case of three isomeric *n*-pentanols led to increased aqueous solubility (13), and a recent generalization that the biological activities of α,β-unsaturated carbonyl compounds depends largely on stereochemical considerations and modifications of the hydrophobic portion of the molecules (14) is of relevance. Furthermore, by altering the branching of the four-carbon alkyl group in compounds VIII*a–c* and *e–g*, the degree of enolization would be predicted to vary (15, 16), which in turn would affect the hydrophilic–lipophilic balance. In addition, since the bioactivities of α,β-unsaturated ketones are considered to be due to reaction in part with cellular nucleophiles (17, 18), chemical reaction would be expected to be reduced with increasing enolization. The cyclohexyl compounds (VIII*d* and *h*), like VIII*b* and *f*, have secondary carbon atoms adjacent to the carbonyl group, but differences in hydrophilic–lipophilic properties would be expected [*e.g.*, the aqueous solubilities of cyclohexanol and *s*-butanol at 20° are 3.6 and 12.5%, respectively (19)].

It has been shown recently that unsaturated alkyl ester groups, two carbon atoms distant from the carbonylene group, gave rise to compounds with antitumor properties, including activity against P-388 lymphocytic leukemia (20, 21), and hence, evaluation of the biological activity of series IX was deemed profitable.

Finally, the synthesis of prodrugs of 4-phenyl-but-3-en-2-one (IV*c*) was contemplated since the compound increased the median survival time in mice with P-388 lymphocytic leukemia by 26% (22). Since oximes may be prodrugs of ketones (23) and are known to be acid-labile (24), compound X may breakdown preferentially to IV*c* under the acidic conditions of certain neoplastic tissue. In addition, the dienol ether and related thio analog (XI*a* and *b*) would be expected to be stable under alkaline conditions but to be extremely sensitive to acid (25). The synthesis of these ethers (XI), if successful, could be applied to various Mannich bases (I) as well.

The second phase of the current investigation was to examine the metabolic route of III*a*. Primarily, this was to compare the antineoplastic activities of the metabolite(s) with the parent compound, and secondly, to observe the effect on anticancer properties of molecular modification of III*a* designed to retard metabolic processes.

The synthesis of compounds V–IX was achieved, and the effect on P-388 lymphocytic leukemia in mice for virtually all of the compounds is recorded in Table I. The *O*-benzyl ethers (V and VI), although not causing fatalities to mice under the test conditions, were inactive. An assessment of the stability of three of the ethers, (V*a*, *e*, and *f*) showed them to be stable in acetonitrile–phosphate buffer at physiological pH as well as at pH values of 6.9 and 6.4, which are likely to be found in various tumors. It is conceivable that a breakdown of the ethers V and VI to the corresponding phenols does not occur *in vivo*. None of the remaining ethers (VII) or ketones (VIII and IX) met the criterion for activity in the P-388 screen. Under the test conditions, no fatalities were noted at the maximum dose levels administered (200 mg/kg) for the compounds in Table I with the exception of VIII*g* and *h*. Oximation of the ketone IV*c* led to X which was nontoxic and inactive.

Attempts to synthesize the enol ether (XI*a*) were unsuccessful. Initially, a literature method used in the preparation of steroidal enol ethers (30) was employed but only unreacted ketone was isolated from the reaction mixture. When (*E*)-4-phenyl-3-buten-2-one and dimethoxypropane were heated in the presence of zinc chloride, two yellow oils, in ad-

dition to unreacted ketone, were obtained. Separation of the three components showed that the molecular ions of both yellow oils was 274, and both purified compounds reverted to an equilibrium mixture of these two compounds. Initially, it was considered that a Diels-Alder reaction between the desired product (XI*a*) and unreacted ketone (IV*c*) had occurred to give a cyclohexene derivative such as XII (or alternatively, where the aromatic rings are vicinal to each other), which subsequently lost a molecule of methanol to give cyclohexadienes, which may be represented by structures XIII*a* and *b* (Scheme II). Interconversion between XIII*a* and *b* is possible since similar molecular rearrangements in conjugated systems are known (31). However, an alternative explanation was considered in that under the reaction conditions which contain a Lewis acid, two molecules of protonated ketone could undergo an aldol condensation, which on dehydration would lead to the triolefine (XIV) also possessing a molecular weight of 274 (Scheme II). This compound could undergo (*E*)–(*Z*) isomerization at the double bonds in the molecule. Recourse to ^{13}C-NMR spectroscopy supported the structures of the yellow compounds as XIV, based on a comparison of the observed values of carbon absorptions with the calculated values of chemical shifts calculated from tables (32). The presence of XII was eliminated since no

absorbances at 30–40 ppm or 200–207 ppm were observed, indicating the absence of methylene and acetyl carbon atoms, respectively. No reaction was observed when II ($R_1 = R_2 = H$) was reacted with dimethoxypropane under the same experimental conditions in an attempt to produce XV*a*.

In an attempt to produce the thio ether (XV*b*) using a modification of the literature procedure (30), principally unreacted ketone (IV*c*) was found as well as two unidentified components. It has been observed that formation of thioenol ethers, in contrast to mercaptans, is enhanced by the carbon atom α to the carbonyl group being sterically hindered and having an electron-releasing group attached to it (33). These workers used thiophenol rather than ethanethiol, and hence, the reaction between VIII*b* and thiophenol was attempted. Examination of the product showed the presence of principally unreacted ketone (VIII*b*), the Michael adduct, 4-methyl-1-phenyl-1-phenylthiohexan-3-one (XVI*a*), and an unidentified product. To eliminate the formation of this Michael adduct, the dibromoketone (XVI*b*) was synthesized, but no reaction between this compound and thiophenol occurred under the experimental conditions employed.

Finally, a related enol ether (XV*d*) was synthesized essentially by literature procedures (34, 35) and shown to revert rapidly to 4-phenyl-3-buten-2-one (IV*c*). The marked instability of this compound precluded its assessment against P-388 lymphocytic leukemia. Hence, even if the desired compounds (XI) were prepared, it may be that they would be too unstable for pharmacological evaluation, even if the idea of XI reverting to 4-phenyl-3-buten-2-one is validated.

In an attempt to study the metabolism of III*a*, this compound was administered intraperitoneally into rats. No trace of III*a* nor metabolites was found in the urine and feces. Examination of rat plasma at different time intervals after intraperitoneal injection of III*a* did not reveal the presence of III*a* or metabolites, and it was considered that they may have been bound extensively to proteins [*e.g.*, an aromatic hydroxy compound used as a cholecystographic medium has been shown to be bound by covalent bonds to plasma protein albumin with a half-life of 2.5 years (36)]. However, analysis of plasma revealed the absence of xenobiotics. Since gross physiological effects were observed in the animals soon after intraperitoneal injection of III*a*, it was felt that this compound was being absorbed rapidly, so III*a* was administered by the intravenous route and blood obtained after short time intervals. Five minutes after injection of III*a*, the compound was detected, but after 10 min the concentration of this compound had been reduced 400 times compared to the quantity of III*a* measured at the end of 5 min. Since neither III*a* nor metabolites were found in the urine or feces, it was thought that rapid sequestration to adipose tissue in part could occur due to the lipophilicity of III*a*. Extraction of rat brain 15 min after intraperitoneal injection revealed the presence of ~5% of III*a*. This observation demonstrates that III*a* crosses the blood–brain barrier and is present in brain tissue not in the covalently bound state. This passage through the blood–brain barrier by III*a* may permit it to serve as a prototype of a series of compounds for evaluation against brain tumors. It is conceivable that this compound primarily is distributed to and retained by the fatty tissue of the rat.

After 6 weeks, some of the animals that had been dosed with III*a* died, and the remaining animals appeared sickly. The live animals were euthanized, and the gross pathological examination revealed peritonitis as well as enlarged livers and spleens. In addition, blood was found in various body cavities, and, although it did not clot on exposure to air, the prothrombin and partial thromboplastin times as well as platelet counts were normal. The capillaries in the reticular surface collagen surrounding livers and spleens seemed to be inadequately supported and may have permitted blood seepage into the organ capsules and abdomen. Changes in the mesenteric lymph nodes and the fact that no evident source of hemorrhage was found suggest that the bleeding into the abdomen noted in this group of treated rats occurred over several days. Histological examination revealed significant abnormalities in the liver and spleen. Figures 1 and 2 show the hepatic necrosis observed and the damage to the splenic capsules, respectively. In order to evaluate whether the pathological changes occurred soon after injection or gradually over a period of time, rats were injected with III*a* and euthanized at the end of 1, 2, 3, and 4 weeks. In general, the pathological changes noted were progressive. Finally, the dose of III*a* was reduced tenfold, and examination at the end of 4 weeks revealed cellular damage in the liver and spleen.

EXPERIMENTAL

Melting points and boiling points are uncorrected. Elemental analyses were undertaken locally[1], and the aluminum oxide[2] and silica gel[3] used in column chromatography were obtained commercially. TLC was carried out using aluminum oxide and silica gel with fluorescent indicator sheets[4],

while silica gel[5] (0.5-mm thick) on glass was used in preparative TLC. The plates were conditioned at 120° overnight and cooled prior to use. Unless otherwise stated, the boiling point of petroleum ether was 40–60°. Mass spectra[6-8] were run at 70 eV and the 60 MHz[9,10] and ^{13}C-NMR spectra[10] were determined using tetramethylsilane as the internal standard. GLC[11,12] analysis utilized a 122-cm × 3-mm column packed with phenylmethylsilicones on film calcined diatomite material of low density[13]. The injection port and detector temperatures were 250 and 300°, respectively, and the chromatograms were programmed from 150 to 250° at 4°/min. The physical data for Compounds V–IX are found in Table I.

1-(*m*-Benzyloxyphenyl)-1-nonen-3-ones (V*a–f*)—The compounds were prepared by alkylation of 1-(*m*-hydroxyphenyl)-1-nonen-3-one (2) with the appropriate benzyl chloride using a literature procedure (37) to give the crude product as a brown oil, purified as follows: The unsubstituted compound (V*a*) was chromatographed using a column of alumina and eluted with petroleum ether, followed by benzene and finally methanol. Recrystallization from petroleum ether afforded V*a* as a colorless powdery material. Compound V*b* was purified by trituration with cold petroleum ether to give colorless crystals which were recrystallized from petroleum ether. Compounds V*c* and *d* were purified by chromatography using alumina and a solvent system of chloroform–ethyl acetate–diethylamine (92:5:3). After the products were eluted, they were placed in a freezer (−5°) overnight and the solids obtained recrystallized from petroleum ether to give V*c* and *d* as a colorless powdery material. The nitro analog (V*e*) was purified by placing the crude oil in the freezer overnight and the crystals formed were recrystallized from anhydrous diethyl ether to give V*e* as a colorless product. The crude oil containing V*f* was placed in the freezer overnight and the crystals formed triturated with cold methanol. Recrystallization from methanol afforded V*f* as a colorless powdery material.

The stabilities of V*a*, *e*, and *f* in acetonitrile–phosphate buffers (1:1), which were prepared using the described methodology (38), were demonstrated as follows: The ketone (10^{-3} *M*) was dissolved in the buffer (250 ml) at pH values of 7.4, 6.9, and 6.4. The spectrum of the compound was obtained at dissolution ($t = 0$) and the solution retained at 37 ± 0.1° for 24 hr and monitored at regular time intervals. No change in the absorption at λ_{max} was noted.

1-(3,4-Dibenzyloxyphenyl)-1-nonen-3-one (VI)—A solution of 3,4-dibenzyloxybenzaldehyde (3.0 g, 0.010 mole), 2-octanone (1.4 g, 0.011 mole), piperidine (0.86 g, 0.01 mole), and glacial acetic acid (0.66 g, 0.011 mole) in benzene (50 ml) was heated under reflux for 36 hr. A Dean-Stark trap was attached to the reaction vessel. On cooling the solution was washed with water (3 × 20 ml) and the organic phase dried (anhydrous magnesium sulfate). After evaporation of benzene, the residue was cooled over ice to produce yellow crystals (2.6 g). Purification was accomplished by column chromatography using silica and benzene–acetone (4:1) to give VI as colorless needles (2.3 g). TLC using silica and developing with methylene chloride revealed one spot, $R_f = 0.80$. The mass spectrum of VI showed *m/z* 428 (M^+ 8%) and 91 (100%). NMR ($CDCl_3$): δ 7.30 (m, 13, aromatic H), 7.10 (d, 1, C_1H, J = 16 Hz), 6.55 (d, 1, C_2H, J = 16 Hz), 5.12 (s, 4, 2 × $CH_2C_6H_5$), 2.60 (t, 2, C_4H), and 1.40 [m, 11, $(CH_2)_4CH_3$]. Repeated elemental analyses invariably gave similar results to those quoted in Table I. Only unreacted aldehyde was isolated in an attempt to synthesize VI by the method employed for the preparation of V.

Methoxy-Substituted 1-Phenyl-1-nonen-3-ones (VII)—These ketones were prepared by a literature method (39). The yellow and colorless compounds obtained were recrystallized from methanol, except for VII*d* and *e*, which were recrystallized from petroleum ether.

Styryl Alkyl Ketones (VIII)—These compounds were prepared by the literature procedure (39). The crude products were recrystallized from petroleum ether to yield colorless crystals, except VIII*b*, which was distilled to give the desired compound as a pale yellow oil.

Esters of 1-(*o*-Hydroxyphenyl)-1-nonen-3-one (IX)—The esters (IX) were prepared from 1-(*o*-hydroxyphenyl)-1-nonen-3-one (40) and the appropriate acid chloride in the presence of triethylamine using a literature method (41), except that after the reactants were stirred at room temperature, diethyl ether was added to precipitate all of the triethylamine hydrochloride. Evaporation of the solvent produced yellow oils, which were passed through a column of alumina using methylene dichloride as the eluting solvent to give IX*a* and c as yellow oils, IX*b* as a pink oil, and IX*d* as a pale brown oil which solidified on standing. TLC using alumina and petroleum ether (bp 30–60°) as the eluting solvent showed only one spot.

(*E*)-4-Phenyl-3-buten-2-one oxime (X)—A mixture of (*E*)-4-phenyl-3-buten-2-one (5.0 g, 0.034 mole), hydroxylamine hydrochloride (1.2 g, 0.017 mole), sodium acetate (3.1 g, 0.038 mole), ethanol (25 ml), and water (25 ml) was heated under reflux for 5 hr. Water (200 ml) was added, and after cooling, the mixture was extracted with ether (3 × 50 ml) and the organic extracts washed with water, dried (anhydrous magnesium sulfate), and removal of the solvent afforded a yellow oil which solidified on standing. Recrystallization from petroleum ether (bp 40–60°) gave X as fawn crystals, mp 109° [lit. (42) mp 110°]; 52% yield.

Attempted Synthesis of (*E*)-3-Methoxy-1-phenyl-1,3-butadiene (XI*a*)—Conversion of (*E*)-4-phenyl-3-buten-2-one (IV*c*) into XI*a* was attempted initially using a literature procedure (30), but only unreacted ketone was isolated from the reaction mixture. The result was identical when the time of heating under reflux was extended from 3.5 to 24 hr. Employment of a published method (43) substituting dimethoxypropane for benzylmercaptan, gave a yellow-brown oil, which was shown by TLC using silica and a developing solvent of methylene chloride–benzene (4:1) to consist of unreacted ketone (IV*c*) $R_f = 0.44$ and two yellow components, $R_f = 0.52$ and 0.61. After replacement of the zinc chloride by stannic chloride, the reaction was monitored for 72 hr by TLC to observe the ratio of unreacted IV*c* to the two yellow compounds. After 3.5 hr, this ratio appeared to be constant. Attempts to separate the two yellow components by column chromatography using silica and a mixture of

methylene chloride and benzene (4:1) were unsuccessful. Preparative TLC using silica (0.5 mm) and a developing solvent of methylene chloride and benzene (4:1) gave two distinct yellow bands which were eluted with methylene dichloride and the solvent removed *in vacuo* at room temperatures. Evaporation of the solvent gave the two compounds and were subject to mass spectral and ^{13}C-NMR evaluations. After refrigeration with protection from light for 24 hr, both compounds had reverted to an identical mixture of two yellow derivatives. The molecular ions of both compounds were 274 (100%). The ^{13}C-NMR chemical shifts were determined in deuterochloroform and are consistent with structure XIV (assignment, calculated value): 136.61 (C-1 aromatic ring A, 137.3); 128.18 (C-2 aromatic ring A, 127.9); 130.09 (C-3 aromatic ring A, 130.5); 126.39 (C-4 aromatic ring A, 126.2); 129.47 (C-1, 129.8); 135.13 (C-2, 135.3); 151.63 (C-3, 153.9); 125.35 (C-4, 123.9); 190.17 (C-5, –); 142.03 (C-6, 144.5); 150.34 (C-7, 151.1); and 14.30 (C-8, –) ppm. A further attempt to produce XI*a* by a literature procedure (44) produced an orange-brown oil shown by TLC [silica and a developing solvent of methylene chloride and benzene (4:1) to consist of unreacted ketone, R_f = 0.44, and two yellow components, R_f = 0.52 and 0.61].

Attempted Syntheses of the Butadienes (XV*a–c*)—An attempted conversion of (*E*)-1-phenyl-1-nonen-3-one (39) into the corresponding butadiene (XV*a*) by the reported procedure (43) led to the isolation of unreacted ketone from the reaction mixture (TLC evidence using silica and methylene chloride as the developing solvent). In the attempted synthesis of XV*b* from (*E*)-4-phenyl-3-buten-2-one (IV*c*) and ethanethiol by the published procedure (43), only unreacted ketone was isolated from the reaction mixture as revealed by TLC (silica and methylene chloride). Modification of a literature procedure (30) in a further attempt to produce XV*b* was as follows: A mixture of IV*c* (5.72 g, 0.035 mole), ethanethiol (2.67 g, 0.043 mole), and *p*-toluenesulfonic acid (0.50 g, 0.003 mole) in benzene (100 ml) were heated under reflux for 24 hr. On cooling, the mixture was neutralized with sodium bicarbonate (1.5 g), added to ice water (200 ml), and stirred at room temperature for 0.5 hr. After extraction with benzene, the organic layer was washed with water, dried (anhydrous sodium sulfate), and removal of benzene afforded a brown oil (3.6 g). TLC on silica using methylene chloride as the developing solvent revealed the presence of unreacted ketone, R_f = 0.55, and two yellow components, R_f = 0.69 and 0.80.

The attempted synthesis of the thioether (XV*c*) from 4-methyl-1-phenyl-1-hexen-3-one, VIII*b*, and thiophenol using the published procedure (33) yielded a yellow oil. TLC of the product using silica and a developing solvent of cyclohexanone–benzene (94:6) revealed the presence of unreacted ketone, R_f = 0.60, and two other compounds, R_f = 0.72 and 0.83. Separation of the components by preparative TLC using silica and cyclohexanone–benzene (94:6) was achieved and the compound with an R_f value of 0.72 was identified as 4-methyl-1-phenyl-1-phenylthiohexan-3-one (XVI*a*) as a yellow oil, NMR ($CDCl_3$): δ 7.05 (m, 10, aromatic H); 4.75 (t, 1, C_1H, J = 7 Hz); 3.00 (d, 2, C_2H, J = 7 Hz); 2.3 (broad q, 1, C_4H, J = 7 Hz); 1.40 (m, 2, C_5H); and 0.80 (m, 6, C_4HCH_3, C_6H).

Anal.—Calc. for $C_{19}H_{22}OS$: C, 76.46; H, 7.43. Found: C, 76.41; H, 7.49.

The remaining compound, R_f = 0.83, was not identified. However, mass spectrometry revealed the molecular weight to be 280 and the NMR spectrum showed the presence of aromatic protons and various aliphatic hydrogen atoms.

In an attempt to prepare the dibromo analog of XV*c*, the required intermediate ketone, 1,2-dibromo-4-methyl-1-phenyl-3-hexanone (XVI*b*), was prepared by a literature method (45) to give the desired product as colorless needles (mp 97.5°, 64% yield).

Anal.—Calc. for $C_{13}H_{16}Br_2O$: C, 44.82; H, 4.60. Found: C, 44.79; H, 4.60.

Reaction of 1,2-dibromo-4-methyl-1-phenyl-3-hexanone with thiophenol by the literature method (33) was unsuccessful and only unreacted ketone was isolated from the reaction mixture, mp 96–97°.

3-Ethoxy-1-phenyl-1,3-butadiene (XV*d*)—*n*-Butyl lithium (0.14 g, 0.002 mole) in hexane (0.64 ml) was added dropwise to a vigorously stirred suspension of 2-ethoxypropenyl-triphenylphosphine iodide (34) (0.948 g, 0.002 mole) in anhydrous tetrahydrofuran (10 ml) under nitrogen which was cooled to −50°. After the addition was complete, the orange mixture was allowed to warm to −25° and stirring was continued for 2 hr. On cooling to −78°, benzaldehyde (0.212 g, 0.002 mole) was added and the mixture stirred at this temperature for 15 min, 0° for 2 hr, and overnight at room temperature. After heating the reaction mixture under reflux for 6 hr, it was diluted with water (40 ml) and extracted with hexane. The hexane extracts were combined, washed with water, and dried (anhydrous magnesium sulfate), and evaporation of the organic solvent afforded XV*d* as a brown oil (0.15 g). NMR ($CDCl_3$) spectrum was identical to the published data for the (*E*) and (*Z*) isomers of XV*d* (35, 46). On standing overnight at room temperature in a sealed dark container, IV*d* was shown by mass spectral, NMR, and TLC evidence to have been converted into (*E*)-4-phenyl-3-buten-2-one (IV*c*). Attempts at purification of the butadiene (XV*d*) by preparative TLC using silica and a hexane–ether mixture (60:40) caused a breakdown of XV*d* into IV*c*. Column chromatography on alumina and eluting with a hexane–ether mixture (60:40) did not permit purification of the components, and vacuum distillation caused the reaction product to decompose.

Screening of Compounds—The anticancer screening was carried out[14] using protocols described previously (47). The compounds were administered by the intraperitoneal route into either male or female CD_2F_1 mice and male $B_6D_2F_1$ mice. The compounds were administered for 9 consecutive days except in the case of V*b*, VI, IX*a–d*, and X, which were injected for 5 consecutive days. The compounds were administered as suspensions in saline with polysorbate 80[15] except for VIII*d*, *e*, *g*, and *h*, X, and XVI, which were injected in hydroxypropylcellulose and also Compounds IX*d* and V*b*, which were administered in saline with alcohol and in saline with polysorbate 80[15] plus alcohol, respectively.

Examination of the Effect of III*a* in Rats—Unless stated otherwise, III*a* was suspended in normal saline containing 3% polysorbate 80[15] and injected by the intraperitoneal route into male albino Wistar rats. Control animals were injected with normal saline containing 3% polysorbate 80[15].

Metabolism Studies—Dose of III*a* used in metabolism studies is as follows: It has been shown[16] that two doses of III*a* of 400 mg/kg given by the intraperitoneal route on Days 1 and 7 caused no mortalities in the $B_6D_2F_1$ strain of mice by Day 5, and initially it was decided to examine the effect of III*a* in rats at single dose levels of 400, 300, and 200 mg/kg over a 72-hr period. Injection of III*a* at the 400-mg/kg dose level into two rats caused an onset of action between 3 and 5 min. The animals remained inactive for 24 hr, laying on their sides. Only slight movement was initiated by physical stimuli and slight hemorrhaging was observed around the nose. During the first 24 hr, the urine output was 16% that of two control rats. After 48 hr the urine output was normal. Four rats dosed with 300 mg/kg of III*a* had a urine output similar to two control animals, although after 3–5 min, the animals appeared to be sedated. Slight hemorrhaging around the nose was noted after 24 hr, but after 48 hr the animals appeared normal. Two rats dosed with 200 mg/kg of III*a* displayed similar gross physiological effects as the animals dosed with 300 mg/kg of III*a*. Hence, a dose of 300 mg/kg was chosen for the metabolism studies.

Efficiency of Extraction of III*a* from Urine, Feces, Plasma, and Brain of Rats—The percent efficiency of extraction of III*a* from urine, feces, plasma, and brain of rats was determined by GLC by a modification of a literature procedure (48). Compound III*a* (0.04 mg) was added to control urine (2.00 ml), and after basification with aqueous sodium hydroxide solution (0.45 *N*) to pH 10.50, it was extracted with ether (2 × 5 ml). After evaporation of the organic solvent, the extract was dissolved in a solution (0.10 ml) of promazine hydrochloride in methanol (1.00 mg/ml). The peak height ratio of III*a*, promazine hydrochloride, recorded when 1 μl of this solution was injected onto a GLC column, was compared to the ratio obtained after injecting 1 μl of a solution containing 0.40 mg of III*a* and 1.00 mg of promazine hydrochloride/ml. It was observed that 98% of III*a* was recovered by this method.

Compound III*a* (8.00 mg) was added to 25 g of control feces and extracted by the literature method (48). The ether-soluble basic fraction was evaporated to dryness, dissolved in 100 μl of a solution containing II (R_1 = 3-OH; R_2 = H) in methanol (1.00 mg/ml), and the peak height ratio of III*a*, II (R_1 = 3-OH; R_2 = H), was compared with the peak height ratio of a 1-μl sample of a solution containing III*a* (8.00 mg) and II(R_1 = 3-OH; R_2 = H; 0.1 mg) in methanol/100 μl. The percentage of III*a* extracted by this method was 61%.

Compound III*a* (0.04 mg) was added to plasma (1 ml), basified with aqueous sodium hydroxide solution (0.45 *N*) to pH 11.5, and extracted with ether (2 × 5 ml). After the ether was evaporated, the extract was dissolved in 100 μl of a solution containing II (R_1 = 3-OH; R_2 = H) in methanol (1 mg/ml). The peak height ratios of III*a* with II (R_1 = 3-OH; R_2 = H) were compared with a 1-μl sample of a solution containing 0.04 mg of III*a* and 0.10 mg of II (R_1 = 3-OH; R_2 = H) in 100 μl of methanol. It was found that the efficiency of extraction of III*a* from plasma was 71%.

[14] Anticancer screening was carried out by the Drug Research and Development Division of the National Cancer Institute, Bethesda, Md.

[15] Tween-80, Atlas Chemical Laboratories.

[16] The National Cancer Institute, Bethesda, Md.

The brain of a rat was removed, homogenized[17], and after the addition of IIIa, the compound was extracted by the literature method (49), except that no basification was undertaken and the extraction solvent was ether, not 1-chlorobutane. Comparison of the peak heights of IIIa with II (R_1 = 3-OH; R_2 = H) by the method already described, indicated a percentage efficiency of extraction of IIIa of 75%.

Examination of Rat Urine and Feces for IIIa and Metabolites—Compound IIIa was injected into rats weighing between 200 and 300 g. Normally a trial consisted of 10 dosed rats and 5 control animals. The urine and feces were collected every 24 hr for 3 days and then at 1-week intervals for 4 subsequent weeks. If the samples were not utilized on the day of collection, they were frozen immediately at −5°. Both 24-hr test and control urine were extracted with ether and fractionated into the strongly acidic, weakly acidic, neutral, amphoteric, and basic components essentially by the literature procedure (48). The extracts were dissolved in methanol (100 μl) and a 1-μl sample injected onto a GLC column. No peaks were found in the extracts from the urine of animals dosed with IIIa, which also were not found in the extracts from the urine of the control animals. A similar observation was made after extracting the urine collected between 24 and 48 hr and also between 48 and 72 hr after injection of IIIa. Extraction of the 24-hr test and control feces (25 g) with ether was undertaken by the published procedure (48), the extracts were dissolved in methanol (100 μl), and a 1-μl sample injected onto a GLC column. The chromatograms generated did not reveal the presence of unchanged IIIa nor metabolites in the test feces. At this time, the toxicity of IIIa became apparent and the dose of IIIa was reduced tenfold. Samples of the 24, 48, and 72 hr and 1–4 week urine from six rats dosed with 30 mg/kg of IIIa and two control animals were extracted as described above, and no unchanged IIIa nor metabolites were found. Both test and control urine (2 ml) were adjusted to pH 5.2 with an acetate buffer and sulfatase[18] (20 μl containing β-glucuronidase) was added and the mixture was incubated at 37° overnight. Extraction and analysis by GLC indicated the absence of IIIa and related metabolites.

Examination of Rat Plasma after Intraperitoneal Injection of IIIa—Compound IIIa (30 mg/kg) was injected by the intraperitoneal route into rats weighing between 200 and 500 g. Rats were decapitated 15 min and 2, 24, and 48 hr after injection; the blood was collected and extracted by the following methods. First, test plasma (1.0 ml) was basified to pH 11.5 with aqueous sodium hydroxide solution (0.45 *N*), extracted with ether, and the organic extracts evaporated to dryness. The original plasma was then acidified with aqueous sulfuric acid (1 *N*) to pH 2.4, extracted with ether (2 × 5 ml), and the ether extracts evaporated to dryness (Method A). Second, plasma (1.0 ml) and 4 *N* aqueous HCl (1.0 ml) were incubated at 85° for 10 min. The plasma (pH 2.4) was extracted with ether (2 × 5 ml) and the ether removed *in vacuo*. The original plasma was then basified with aqueous sodium hydroxide solution (0.45 *N*) to pH 11.5, extracted with ether (2 × 5 ml), and the ether removed by evaporation. Third, plasma from dosed animals (1.0 ml) and 4 *N* aqueous HCl (1.0 ml) were incubated at room temperature for 24 hr. The plasma (pH 2.4) was extracted with ether (2 × 5 ml) and the ether evaporated. Basification of the original plasma to pH 11.5 was accomplished with aqueous sodium hydroxide solution (0.45 *N*), extracted with ether (2 × 5 ml), and the ethereal extract evaporated to dryness. Fourth, plasma (1.0 ml) was extracted by a literature procedure (36). In all cases control plasma was extracted by identical methods. Extracts from the plasma of dosed and control animals were dissolved in 100 μl of methanol and a 1-μl sample examined by GLC. Chromatograms of the dosed and control plasma extracts appeared identical.

Examination of Rat Plasma after Intravenous Injection of IIIa—Rats weighing between 200 and 250 g were injected into the femoral vein with IIIa (300 mg/kg). In the first experiment, blood was collected after 5 and 10 min, and in the second, blood was collected by cardiac puncture after 5 and 8 min. Plasma was separated and extracted by Method A. The extracts were dissolved in 100 μl of a solution of II (R_1 = 3-OH; R_2 = H) in methanol (1 mg/ml), and a 1-μl sample was analyzed by GLC. The quantity of IIIa in the plasma samples was determined by comparing the peak height ratio of IIIa to II (R_1 = 3-OH; R_2 = H) with a standard curve prepared from standard solutions of these two compounds. The results were determined by calibration and revealed that the concentrations of IIIa were 1.974 (2.132, 1.816), 0.602, and 0.005 mg/ml after 5, 8, and 10 min, respectively.

Examination of Rat Brain after Intraperitoneal Injection of IIIa—A dose of 300 mg/kg of IIIa was injected intraperitoneally into a rat weighing 340 g and the animal decapitated 15 min after injection. The brain was removed, homogenized[17], and the compound extracted by the literature procedure (49), except that basification prior to extraction was omitted, and the extraction solvent was ether, not 1-chlorobutane. The quantity of IIIa in the brain was measured using II (R_1 = 3-OH; R_2 = H) as the reference compound by the same procedure described earlier and found to represent 4.78% of the injected dose of the compound.

Pathological Study of IIIa—A dose of 300 mg/kg of IIIa was injected intraperitoneally into 10 male Wistar rats and two control animals were utilized. Deaths occurred in three animals after 40, 41, and 42 days, and at the end of 43 days the remaining seven animals were weak and bloated. There was paralysis in the hind legs and hemorrhaging from the nose. Necropsy was undertaken on these seven animals. Tissues were fixed in 10% buffered formaldehyde solution, sectioned at 5 μm, and stained with hematoxylin and eosin.

Blood samples were obtained by cardiac puncture prior to necropsy of the seven rats. Hemoperitoneum was noted in six of the seven rats. The markedly distended abdomens and scrotal sacs contained blood. Hemopericardium was noted in the seventh rat. The blood found in body cavities did not clot on exposure to air; however, the prothrombin times, partial thromboplastin times, and platelet counts of representative test animals were comparable to those of the controls. Two rats had a chronic diffuse peritonitis, whereas in the other five, the peritonitis was confined to the cranial abdomen where the diaphragm, liver, spleen, stomach, proximal duodenum, colon, and cranial poles of the kidneys adhered to one another by fibrous strands. Both the liver and spleen were enlarged in all of the rats examined. The stomach and intestines contained food and the other organs appeared normal.

The significant histological changes were found in the spleen, liver, and mesenteric lymph nodes. Chronic perihepatitis was characterized by a markedly thickened fibrous capsule. Loose granulation tissue attached to the peritoneal surface of the capsule contained capillaries, fibroblasts, and an infiltrate of polymorphonuclear leukocytes. Liver parenchymal changes were observed throughout all lobes and ranged from periportal vacuolation, basophilic cytoplasmic clumping, single hepatocyte necrosis, and occasional mitosis to multifocal centrilobular and midzonal coagulation necrosis. The periportal areas seemed to have been spared, although single necrotic cells were visible in these areas. Polymorphonuclear leukocytes were noted in the areas of necrosis.

Changes in the splenic capsule were similar to those in the liver capsule. The splenic red pulp was congested. Extramedullary hematopoiesis varied in degree among the rats from the occasional focus to more diffuse areas of hemopoietic activity.

Numerous erythrocytes were present in the medullary and subcapsular sinuses of the mesenteric lymph nodes. Siderocytes were numerous and erythrophagocytosis was evident.

To evaluate whether these pathological changes occurred soon after injection of the compound or gradually, four rats were injected intraperitoneally with IIIa at a dose of 300 mg/kg and euthanized for necropsy after 1, 2, 3, and 4 weeks. No gross abnormalities were noted in the rat 1 week postinjection. Mild hepatomegaly was noted 2 weeks postinjection. Perihepatitis, hepatomegaly, perisplenitis, and hemoperitoneum were noted 3 weeks postinjection, although the amount of blood in the abdominal cavity was very small. Perisplenitis, hepatomegaly, and congestion were noted 4 weeks postinjection. Liver parenchymal changes appeared to be progressive. Hydropic degeneration of periportal hepatocytes was mild 1 week postinjection but marked 2, 3, and 4 weeks postinjection. Over the 4 weeks, the vacuolation progressed towards the central veins. Mitotic figures were frequent in hepatocytes during the first 2 weeks postinjection but decreased during weeks 3 and 4. Many of the mitoses observed were abnormal and unlikely to produce viable cells. Single hepatocyte necrosis was noted after 1 week and progressed to focal tissue necrosis, principally in centrilobular areas, after 3 weeks. Clumps of leukocytes phagocytosing debris were noted in the areas of necrosis. Kupffer cell hyperplasia was evident in all livers examined. Capsular thickening was focal 1 week postinjection with lymphocytic infiltration. Three and 4 weeks postinjection the changes were diffuse. Dense fibrous tissue was present adjacent to the liver parenchyma. However, the surface collagen was very fine and contained many normal capillaries. Areas of old hemorrhage were present in the surface collagen, as was an infiltrate of lymphocytes, mast cells, plasma cells, and eosinophils. Subcapsular veins were ectatic and congested. Perisplenitis was noted 3 and 4 weeks postinjection. The capsule was thickened with fibrous tissue and infiltrated with lymphocytes. The amount of extramedullary hematopoiesis paralleled that of the controls.

Finally, IIIa was administered intraperitoneally to one rat at a reduced dose of 30 mg/kg, while a control animal was given polysorbate 80[15] (3%) in normal saline. The animals were examined at the end of a 4-week pe-

[17] Virtis homogenizer, model 45.

[18] Sigma Type H-2, Sigma Chemical Co., St. Louis, MO 63178.

riod. Perisplenitis was noted on gross examination of the test rat. Histological examination revealed focal thickenings of the splenic capsule with very fine reticulate connective tissue. Large capillaries were prominent in these areas and small hemorrhages were noted. Mast cells, some of which were degranulated, were numerous in the thickened capsule. Histologically the degree of liver change was mild with centrilobular degeneration characterized by basophilic clumping of cytoplasm, single cell necrosis with phagocytosis by invading leucocytes, and prominence of Kupffer cells.

ACKNOWLEDGMENTS

Financial support to D. L. Kirkpatrick came principally from an award of a University of Saskatchewan Graduate Scholarship and the John and Mary Spinks Graduate Scholarship and is recorded with gratitude.

The authors thank the Medical Research Council of Canada for an operating grant (MA 5538) to J. R. Dimmock.

The authors thank Dr. K. K. Midha and Mr. J. K. Cooper, College of Pharmacy, University of Saskatchewan, Saskatoon, for their advice and assistance during the course of this project; Mr. L. Hogge, Prairie Regional Laboratory, Saskatoon for generating most of the GC–MS data; Mrs. L. M. Smith, College of Pharmacy, University of Saskatchewan who synthesized compounds IX and X; and Mr. Ian Shirley, Western College of Veterinary Medicine, Saskatoon who prepared Figs. 1 and 2. The cooperation of the Drug Research and Development Division of the National Cancer Institute, Bethesda, Md. for evaluating the antineoplastic potential of many of the compounds described in this study is greatly appreciated.

Placental Transfer of Ranitidine During Steady-State Infusions of Maternal and Fetal Sheep

G. W. MIHALY *x, D. J. MORGAN ‡, A. W. MARSHALL *, R. A. SMALLWOOD *, S. COCKBAIN *, D. MacLELLAN §, and K. J. HARDY §

Received May 11, 1981, from the *Gastroenterology Unit, Department of Medicine; the §Department of Surgery, Austin Hospital, Heidelberg, Victoria 3084, Australia; and the ‡Victorian College of Pharmacy, 381 Royal Parade, Parkville, 3052 Victoria, Australia. Accepted for publication November 24, 1981.

Abstract □ The placental transfer of ranitidine was studied at pharmacokinetic steady state in anesthetized, full-term, pregnant sheep. Ranitidine was administered to the ewe in three preparations and to the fetus in three other sheep. In all experiments, dose size was based on the combined maternal–fetal weight. Steady-state plasma levels were reached within 4 hr by using an initial intravenous bolus dose followed by continuous infusion. Following maternal dosage, the mean maternal (jugular vein) steady-state concentration ($C_{M_{ss}}$) at 4 hr was 842 ± 66 ng/ml (*SEM*), the mean fetal (carotid artery) steady-state concentration ($C_{F_{ss}}$) was 26.5 ± 4.2 ng/ml, and the mean fetal umbilical venous steady-state concentration was 28.9 ± 3.5 ng/ml. Both the fetal and umbilical plasma concentrations were significantly less than the maternal plasma concentration ($p < 0.01$). With fetal dosage, mean $C_{M_{ss}}$ was 414 ± 42 ng/ml at 4 hr and was significantly less than the mean $C_{F_{ss}}$ value at the same time, which was 6890 ± 360 ng/ml ($p < 0.005$). Ranitidine was not bound extensively to plasma proteins in the ewe or the fetus (range 12–55% bound). The reversal of the $C_{M_{ss}}/C_{F_{ss}}$ gradient with the change from maternal to fetal administration and the low binding of the drug shows that the gradient following maternal dosage cannot be explained by ion-trapping or differential plasma protein binding. As active placental transport is considered unlikely, the low fetal plasma concentrations are probably due to the presence of significant fetal elimination of ranitidine. Furthermore, the substantial gradient between maternal and umbilical venous plasma concentrations suggests that placental elimination of ranitidine should also be considered.

Keyphrases □ Ranitidine—placental transfer during steady-state infusions of maternal and fetal sheep □ Placental transfer—ranitidine, during steady-state infusions, maternal and fetal sheep

The use of H_2-receptor antagonists in pregnancy is becoming widespread (1, 2), although little is known of their placental transfer. Cimetidine has been shown to cross the placenta (1) but ranitidine, a new H_2-receptor antagonist, has not been studied.

Since opportunities to make observations in pregnant women are necessarily limited, we have used a pregnant sheep model to study the placental transfer of ranitidine. A similar model has been used recently to examine the placental transfer of meperidine (3), indomethacin (4), and aspirin (5). In contrast to earlier work, the bidirectional transfer of drug has been studied in this report. Results establish that ranitidine does cross the placenta. They also indicate that the comparatively low drug concentrations found in the fetus after maternal dosage are probably accounted for by fetal and/or placental elimination.

EXPERIMENTAL

Methods—Experiments were carried out in pregnant Merino or Dorset-Horn sheep, 2–5-years old, during the last 2 weeks of gestation (term = 147 days). The animals were treated with fenbendazole[1] to clear intestinal parasites. Anesthesia was induced with sodium thiopental[2] (15 mg/kg iv) and maintained with a mixture of halothane and oxygen using intermittent positive pressure respiration. The partial pressure of oxygen was kept in excess of 100 mm of Hg, while the partial pressure of carbon dioxide was 25–35 mm of Hg. Surgery was performed with strict sterile techniques.

The uterus was incised and the fetus was delivered onto a small draped platform. The fetus was kept on the platform through the experiments and its rectal temperature was maintained at 38–39° with a heating pad. The fetus and umbilical cord were kept moist with saline packs.

The maternal jugular vein was cannulated with a dimethicone cannula (1.2-mm i.d.) to allow collection of maternal blood samples. The fetal carotid artery was cannulated with a dimethicone catheter (0.76-mm i.d.) to allow fetal blood sampling. In fetal dosage experiments, the internal jugular vein was cannulated with a dimethicone catheter (0.76-mm i.d.) for drug administration.

Liver function tests were carried out in both ewe and fetus before and after every experiment. No abnormalities were encountered. Fetal and maternal hematocrits changed by <3% over the course of the experiment.

Calculation of Bolus Dose and Infusion Rate—Steady-state plasma levels of ranitidine were achieved by the combination of an initial bolus dose together with a continuous intravenous infusion that was maintained throughout the experiment. The bolus dose for both maternal and fetal administration was calculated as follows (6):

$$\text{Bolus Dose} = C_{ss} \times V_\beta \times W$$

where C_{ss} (μg/liter) is the desired steady-state plasma concentration, V_β (liter/kg) is the total apparent volume of distribution, and W is the animal's weight (kg) (*i.e.*, the combined weight of sheep and fetus). Maternal and fetal infusion rates were calculated as follows (6):

$$\text{Infusion rate} = C_{ss} \times Q \times W$$

where Q (liter/hr) is the systemic plasma clearance of ranitidine. The desired steady-state concentrations in maternal plasma following maternal dosage was between 500 and 1000 ng/ml (500 ng/ml was used in the calculations). The values used for V_β (1.6 liter/kg) and Q (0.5 liter/hr/kg) were previously determined from a pilot pharmacokinetic study in a single nonpregnant sheep.

Since $t_{1/2\beta}$ for the adult sheep was ~2 hr, a constant infusion would not have achieved steady-state concentrations until 8–10 hr. Using this procedure, steady-state plasma concentrations were approached within 2 hr and were then maintained for the duration of the experiment.

Maternal Dosage Experiments—Ranitidine[3] was administered intravenously to three pregnant ewes *via* a foreleg vein. A predose blood sample was collected from the maternal jugular vein (8 ml) and from the fetal carotid artery (5 ml) and further samples were then collected from both the ewe and the fetus at 2, 4, 10, 15, 120, 180, 210, and 240 min postbolus dose. A sample was taken from the umbilical vein of each fetus at 240 min.

Fetal Dosage Experiments—Ranitidine was administered to three fetuses *via* the internal jugular vein. The same dosage regimen as used for maternal administration was applied, using the weight of the pregnant ewe for calculations. Blood samples were collected as described above from both the ewe and the fetus. Additional samples were collected at 240 min from umbilical artery and vein.

Protein Binding—Plasma protein binding of ranitidine in maternal and fetal plasma samples collected at 240 min was estimated by ultrafiltration (7).

Drug Analysis—Plasma concentrations of ranitidine were determined

by a high-performance liquid chromatographic (HPLC) method (8). This method was specific for ranitidine and had a sensitivity of 5 ng/ml of compound in plasma.

Statistical Analysis—Data are presented as mean ±*SEM*. Statistical comparisons were made using the Student's t test or linear regression analysis and statistical significance accepted when $p < 0.05$.

RESULTS

Maternal Dosage Experiments—The mean plasma ranitidine concentration *versus* time curves in both the ewe and the fetus, following maternal dosage, are shown in Fig. 1. The initial bolus dose produced an early peak in maternal plasma levels and steady state was achieved by 4 hr, since the slope of the linear regression line through the plasma concentration–time data from 2 to 4 hr was not significantly different from zero ($p > 0.05$). The mean steady-state concentration of ranitidine at 4 hr was 842 ± 66 ng/ml. Ranitidine was detected in fetal plasma within 10 min and fetal plasma concentrations also achieved steady state by 4 hr ($p > 0.05$). The mean fetal steady-state concentration of ranitidine at 4 hr was 26.5 ± 4.2 ng/ml and this value was significantly less than the maternal concentration at 4 hr (paired t test, $p < 0.01$). The mean umbilical venous concentration of ranitidine at 4 hr was 28.9 ± 3.5 ng/ml and was also significantly less than the corresponding maternal concentration (paired t test, $p < 0.01$) but did not appear to differ from the fetal concentration.

Fetal Dosage Experiments—The mean plasma ranitidine concentration *versus* time curves in both the ewe and the fetus, after fetal dosage, are shown in Fig. 2. Placental transfer was detected within 2 min, and a steady state was again reached in both the ewe and the fetus by 4 hr ($p > 0.05$). Fetal mean carotid arterial, umbilical arterial, and umbilical venous plasma concentrations of ranitidine at 4 hr were 6890 ± 360 ng/ml, 8010 ± 544 ng/ml, and 6990 ± 433 ng/ml, respectively. The mean maternal steady-state plasma concentration of ranitidine at 4 hr was 414 ± 42 ng/ml, which was significantly less than each of the above three mean fetal concentrations (paired t test, $p < 0.005$).

Plasma Protein Binding of Ranitidine—Plasma protein binding experiments are summarized in Table I. Approximately 30% of plasma was bound in both maternal and fetal plasma.

DISCUSSION

Studies of placental drug transfer and fetal pharmacokinetics cannot be readily undertaken in humans, in whom observations have been largely confined to the comparison of drug concentrations in maternal and umbilical vein plasma at birth. Such observations contribute little to the understanding of placental transfer, or of fetal drug distribution and elimination. The pregnant sheep preparation is not limited in this way, and the increased flexibility of experimental design allows much greater insight into the fetal handling of drugs.

The present study was carried out in anesthetized sheep. General anesthesia may cause hemodynamic changes (9), and this should be borne in mind when considering these results. However, all maternal and fetal sheep remained in excellent condition, and previous work suggests that anesthesia does not significantly alter propranolol disposition in this pregnant sheep preparation (10). Blood gases, pH, biochemical, and hematological profiles remained within normal physiological values (11) in mothers and fetuses in all experiments. The comparatively large doses of ranitidine administered to fetuses produced no detectable adverse effects, despite steady-state fetal plasma levels which were tenfold greater than the maternal levels obtained after maternal dosage. Fetal dosage was based on the combined maternal–fetal rather than fetal weight, because it was presumed that most of the drug would be eliminated by the mother, and a small fetal dose might have resulted in undetectable maternal plasma concentrations.

Following maternal dosage, steady-state levels of ranitidine in the ewe were 30 times that in the fetus. This cannot be explained by a delay in placental transfer, since a steady state existed. Furthermore, ranitidine was detected within 10 min in fetal plasma, suggesting that any hold up at the placenta is short lived.

It has been argued (12) that, after maternal dosage, the fetal–maternal steady-state concentration ratio should equal one, unless one of the following applies: (*a*) there is active transport of drug across the placenta, (*b*) there is differential binding of drug to fetal and maternal plasma proteins, (*c*) there is differential ionization of drug in maternal and fetal plasma due to differences in plasma pH, (*d*) the fetus eliminates the drug, or (*e*) the placenta eliminates the drug. The fact that fetal dosage reversed the placental gradient obtained after maternal dosage (Figs. 1 and 2)

Table I—Percentage of Total Plasma Ranitidine Bound to Proteins in Both Maternal and Fetal Plasma after Both Maternal and Fetal Administration

effectively rules out *a*, *b*, and *c* above. These three mechanisms would tend to maintain a gradient in the same direction, whatever the route of administration. Furthermore, the plasma protein binding data (Table I) shows that ranitidine is not extensively bound in maternal or fetal plasma. This also rules out any possibility that differential binding of drug in maternal and fetal plasma could be responsible for the placental gradient, because the unbound fraction of drug in fetal plasma would need to exceed that in maternal plasma 30-fold. It could be argued that since active transport is likely to be unidirectional (*e.g.*, fetus → mother) the higher fetal concentrations produced by drug administration to the fetus might saturate an active transport system and alter the maternal–fetal ratio. Such an active transport mechanism is unlikely (13), although there is insufficient data to allow us to rule it out completely.

The placental transfer of the other drugs has been studied in pregnant sheep. Following maternal administration, meperidine (3), indomethacin (4), and aspirin (5) were found to have lower fetal than maternal steady-state plasma concentrations of drug. Szeto *et al.* (3) used a pharmacokinetic model to propose that the difference in fetal and maternal steady-state meperidine concentrations was due partly to fetal drug elimination. This proposal was subsequently supported when it was demonstrated that renal excretion of meperidine does take place in the ovine fetus (14, 15).

Following maternal dosage, the fact that umbilical venous plasma concentrations of ranitidine were substantially less than maternal concentrations suggests that the gradient in concentration occurs across the placenta. Hence, the possibility of placental drug elimination in addition to fetal drug elimination should be considered. Several drug biotransformation processes have been identified in animal and human placentas (16), but the role of the placenta in xenobiotic metabolism still remains unclear (17). A previous study (13), in discussing the theoretical relationships between metabolism and fetal plasma levels of drugs, concluded that enzymes in the fetus would usually be more effective than those in the placenta in protecting the fetus against lipid-soluble drugs. Therefore, the relative importance of placental compared with fetal elimination of ranitidine requires further investigation. It may be that fetal exposure to ranitidine encountered during pregnancy is reduced by placental metabolism, at a time when the fetus' own capacity to eliminate this foreign substance is greatly limited.

Species Differences in the Urinary Excretion of the Novel Primary Amine Conjugate: Tocainide Carbamoyl *O*-β-D-Glucuronide

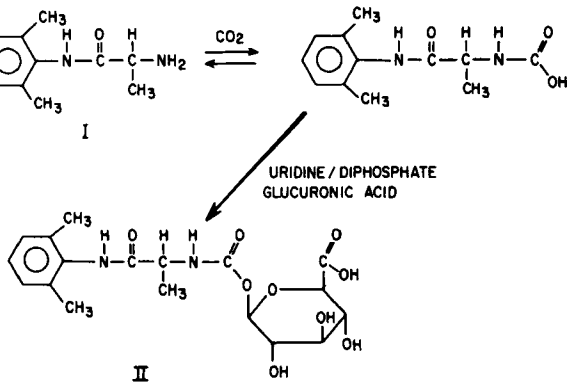
KEVIN J. GIPPLE, KIN TUNG CHAN, ALFRED T. ELVIN, DAVID LALKA, and JAMES E. AXELSON *x

Received July 21, 1981, from the *Department of Pharmaceutics, School of Pharmacy, State University of New York at Buffalo, Amherst, NY 14260*, and the **Faculty of Pharmaceutical Sciences, University of British Columbia, Vancouver V6T 1W5 BC Canada.* Accepted for publication November 19, 1981.

Abstract □ The metabolism of the antiarrhythmic drug tocainide (I) has been shown previously to occur *via* a novel pathway involving the addition of carbon dioxide to the primary amine nitrogen of I followed by conjugation with glucuronic acid. The product of this reaction, tocainide carbamoyl *O*-β-D-glucuronide (II), the principal metabolite of I in humans, has been found to cyclize under strongly basic conditions to form 3-(2,6-xylyl)-5-methylhydantoin (III). Thus, evidence for the existence of II can be obtained by two different procedures: conversion of II to III in the presence of strong base and by hydrolysis of II with β-glucuronidase. The principal purpose of the present investigation was to identify suitable species for studies of the mechanism involved in the formation of II, as well as to find an animal model suitable for toxicological evaluation of tocainide and structurally related compounds. Eight animal species were examined to identify those capable of metabolizing I into II. The fraction of an intraperitoneal dose excreted in urine as II was estimated by measurement of tocainide released by β-glucuronidase mediated hydrolysis of urine and by the quantitation of III formed after alkalinization of urine samples. Urinary recovery of unchanged drug ranged from 9.5% of the dose in the gerbil to 48.7% in the cat. The percent of the dose excreted in urine as acid hydrolyzable conjugates ranged from <1% in the gerbil to a mean of 13% in the rabbit. Guinea pigs, dogs, cats, rabbits, and pigtail monkeys excreted amounts of II ranging from 0.2 to 2.4% of the dose. Thus, none of the species appeared to be a suitable model for the study of the mechanism of formation of II because of the quantitative insignificance of this pathway.

Keyphrases □ Excretion—urinary, novel primary amine conjugate, tocainide carbamoyl *O*-β-D-glucuronide, species differences □ Tocainide carbamoyl *O*-β-D-glucuronide—species differences in urinary excretion, novel primary amine conjugate □ Metabolism—tocainide carbamoyl *O*-β-D-glucuronide, species differences in urinary excretion

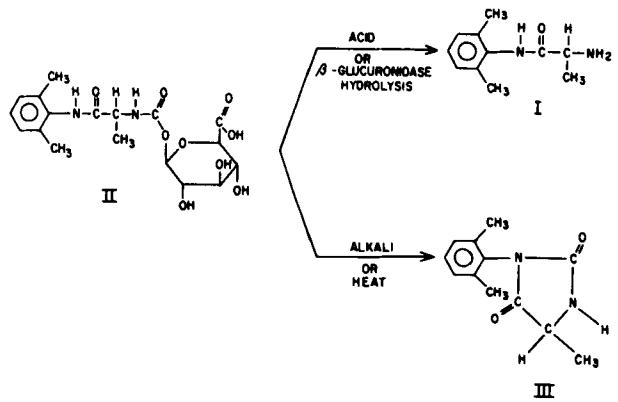
Tocainide (I) is an antiarrhythmic drug undergoing extensive clinical evaluation (1, 2). Substantial evidence suggests that the major pathway for the metabolism of I in humans is formation of a carbaminic acid from tocainide and carbon dioxide followed by conjugation with glucuronic acid (Scheme I). In normal healthy humans ~25–40% of a dose of I is excreted in urine as tocainide carbamoyl *O*-β-D-glucuronide (II) and another 25–40% is excreted as unchanged I (3). In the Wistar rat, urinary excretion of administered I was found to be dose-dependent with 15–50% of a dose excreted as I (4) and <10% as II (5, 6). Other mixed function oxidase products may account for the remainder of the dose in both species (5–7).



Scheme I

Formation of a carbaminic acid from an amine and carbon dioxide followed by conjugation with glucuronic acid is a metabolic pathway that has been reported only for tocainide (8). However, precedent exists for the formation of a glucuronide conjugate of a carbaminic acid in that formation of a carbamoyl glucuronide after administration of *p*-chlorophenyl cyanamide to rabbits has been reported (9). Furthermore, there is overwhelming evidence that covalent bonding of carbon dioxide to amine functions of hemoglobin (forming a carbaminic acid) is the principal mechanism of carbon dioxide transport in blood (10). Carbaminic acid formation followed by glucuronide conjugation may be an important metabolic pathway for primary amine drugs other than tocainide. However, substantial difficulties in isolation and detection may have prevented previous discovery of this pathway because acids of this type readily hydrolyze to parent drug and carbon dioxide (8). Compound II was discovered because the unique structural characteristics of I allowed facile cyclization of II to form 3-(2,6-xylyl)-5-methylhydantoin (III) under alkaline conditions (Scheme II). Since acid or β-glucuronidase mediated hydrolysis of II yields I (8), estimation of hydantoin (III) formed by alkalinization and the quantitation of free drug released by β-glucuronidase provide reliable independent methods to determine the concentration of this novel glucuronide in biological fluids[1].

Animal toxicological studies intended for extrapolation



Scheme II

[1] R. A. Ronfeld and coworkers have established that II is quantitatively converted to III; unpublished observation.

Figure 1—*Urinary recovery of unchanged tocainide (□), total acid hydrolyzable conjugates (▨) and tocainide carbamoyl O-β-D-glucuronide (■). The figure presented for tocainide carbamoyl O-β-D-glucuronide is the estimate of III formed from II.*

to humans must be conducted in species that have qualitative (and preferably quantitative) metabolic profiles similar to that observed in humans. Furthermore, the identification of interspecies differences in the capacity to carry out specific types of drug biotransformation (*i.e.*, acetylation, formation of ester glucuronides, *etc.*) has been of fundamental concern to pharmacologists for decades, since such information can sometimes explain interspecies differences in the toxicology and pharmacology of drugs (11, 12). Thus, after the discovery of the novel metabolic pathway which results in the conversion of tocainide to II, it was appropriate to determine which common laboratory animal species could also form this type of glucuronide. In all, eight animal species received intraperitoneal doses of I to determine if any of them could be used effectively to study this metabolic process.

EXPERIMENTAL

Chemicals—Tocainide (2-amino-2′,6′-propionoxylidide), glycine xylidide, bupivacaine (prepared as the hydrochloride salts), and 3-(2,6-xylyl)-5-methylhydantoin were provided by the same source[2]. Heptafluorobutyrylimidazole[3], mollusk β-glucuronidase[4] (lyophilized; 0.7% arylsulfatase), and saccharo-1,4-lactone[4] were obtained from commercial sources. All solvents were spectral or high-pressure liquid chromatographic (HPLC) grade.

Instrumentation—GLC was performed on dual column gas chromatographs[5] equipped with flame ionization detectors (FID). The GLC conditions were: glass columns, 1.8 m × 2-mm i.d. packed with 3% OV-17, 10% OV-17, or 3% OV-101 on 80–100 mesh chromosorb W-HP[6]. Helium, hydrogen, and air flow rates were 30, 30, and 300 ml/min, respectively. Injector and detector temperatures were 250°. Column temperatures for the various assays will be described.

Extraction and Preextraction Treatment of Urine Samples—The extraction procedures used to quantitate unchanged tocainide and tocainide released from conjugates in urine have been described previously. The following is a summary of the information provided by each procedure (8).

The quantitative estimation of I extracted from alkalinized urine allows the determination of the concentration of unchanged I. Acid hydrolysis followed by this standard extraction procedure yields the concentration of unchanged I plus acid labile conjugates.

Incubation with β-glucuronidase followed by the standard extraction procedure yields the sum of unchanged I, glucuronide conjugates, and other conjugates released by commercial mollusk β-glucuronidase preparations.

Incubation of urine samples with the mollusk β-glucuronidase preparation described above in the presence of saccharo-1,4-lactone (a selective β-glucuronidase inhibitor) followed by the standard extraction procedure yields an estimate of the sum of unchanged I plus conjugates of I other than glucuronides (presumably sulfates).

Quantitative Estimation of I in Urine—After the urine samples were extracted using the procedures described above, tocainide concentrations were determined using the GLC method described previously (8).

Quantitative Estimation of III in Urine—The following extraction procedures were used to quantitate tocainide carbamoyl *O*-β-D-glucuronide by measuring III formed by base catalyzed cyclization.

One milliliter of 1 *N* NaOH, 0.25 ml of urine, 0.25 ml of bupivacaine solution (10 μg/ml in deionized water, used as an internal standard), and 3.0 ml of methylene chloride were added to 15-ml centrifuge tubes. The tubes were shaken, centrifuged, and the aqueous layer removed and discarded. The organic phase was evaporated at 50°, reconstituted with 20 μl of methylene chloride, and 1–2 μl was injected into a gas chromatograph (3% OV-17) at a column temperature of 250°. When a peak with retention time and shape identical to III was found, the same samples were reassayed on a 3% OV-101 column (210°) to confirm the observations made in the standard assay. This procedure quantitated III formed *in vitro* from II plus any III which may have formed *in vivo*. A second extraction procedure quantitated III formed *in vivo*, *i.e.*, III that existed prior to alkalinization. This procedure was identical to the above method, except that 1.0 ml of 0.2 *M* acetate buffer (pH 5) was substituted for 1.0 ml of 1.0 *N* NaOH.

Additional Experimental Control Procedures—Predose urine samples were assayed before and after acid or enzymatic hydrolysis to ensure the absence of interfering compounds in urine.

Table I—Physical Characteristics of Animal Species Studied

No. of Animals Studied	Species	Strain	Sex	Weight Range, kg
3	Rat	Sprague-Dawley	male	0.350–0.360
3	Rat	Gunn	male	0.190–0.210
3	Rat	Wistar, inbred	male	0.190–0.210
4	Mouse	Brown Bal	female	0.022–0.032
3	Guinea Pig	Mixed breed	male	0.740–0.850
2	Gerbil	Mixed breed	male	0.034–0.041
4	Dog	Mixed breed	males	8.6–12.7
1	Cat	Siamese	male	
2		Mixed breed	1 female; 1 male	3.4–5.4
3	Rabbit	New Zealand White	male	3.6–3.8
1	Monkey	African Green	female	2.7
2	Monkey	Pigtail	female	5.0–8.6

[a] Expressed as percent of the dose excreted in urine; on a molar basis. Numbers in parentheses give the range of observed values. [b] Glucuronide conjugates were quantitated by measuring the difference between tocainide released by β-glucuronidase and β-glucuronidase plus saccharo-1,4-lactone. [c] Not detected. Based on the limited sensitivity of the GLC procedure utilized, the minimum percentage dose which could have been detected was between 1.0 and 1.5%. [d] Not detected. The minimum percentage of dose detectable was 0.02%. [e] The presence of III in urine of tocainide treated (intraperitoneally and orally in these species) Wistar-Vancouver rats has been noted (14, 15) using a highly sensitive qualitative electron-capture GC assay with confirmation by GLC–mass spectrometry. The quantitative study described here using GLC with FID failed to confirm the presence of III, due either to limitations in detection or because of differences in the animals studied. [f] Enzymatic hydrolysis was not performed because acid hydrolysis studies indicated that ≤1% of the dose was excreted as conjugated tocainide.

Three coded unknown urine samples, prepared to contain concentrations of tocainide from 0 to 135 μg/ml, were assayed every experimental day by an analyst blinded to the tocainide concentration. An error of ≥10% caused data to be rejected and mandated the reassay of all samples from that day. Since urine pH has previously been shown to influence the urinary excretion of tocainide in humans (13), the pH of all urine samples was measured.

A check for bacterial breakdown of II was performed by diluting urine known to contain approximately equal amounts of I and II (obtained from humans who had received tocainide) with blank animal urine in a 1:1 ratio. Both this sample and the undiluted sample were left at room temperature for 24 hr and were then assayed. If the 1:1 dilution contained <55% of the tocainide concentration seen in the undiluted sample, no significant bacterial breakdown of II to I was considered to have occurred. However, if >55% of the undiluted sample's concentration was in the 1:1 dilution, the extra tocainide was considered to have been liberated by the breakdown of II. In such cases the data obtained for the urinary recovery of II were considered to be an underestimate and were not to be used for further data analysis.

If acid hydrolysis failed to show significant generation (<10% increase in the concentration of I in the urine) of I from conjugates, urine was not subject to treatment with β-glucuronidase. However, these urines were assayed for the presence of III before and after treatment with NaOH to rule out the presence of II.

Animal Study Design—Animals were given an injection of 10 mg/kg ip of tocainide hydrochloride after fasting for 24 hr. Fasting was continued for at least 24 hr following injection. Water was allowed *ad libitum* throughout the experiment. Animals were housed in plexiglass or stainless steel metabolism cages. Predose urine specimens were obtained and urine was also collected until at least 24 hr following dosing. Urine specimens were frozen at −20° until assayed. The weight, sex, and strain of the animals used in these studies are detailed in Table I.

RESULTS

The principal observations made in the various species are summarized in Fig. 1 and Table II. The dogs, rabbits, guinea pigs, pigtail monkeys, and cats synthesized and excreted tocainide carbamoyl O-β-D-glucuronide (Table II). The amounts were small but were readily detectable as III formed upon alkalinization of the urine sample. No evidence was obtained to suggest the presence of II in the urine of mice, gerbils, the African green monkeys, or in any of the three strains of rats (*i.e.*, III was not observed upon alkalinization of the urine samples, and little or no I was released by β-glucuronidase mediated hydrolysis). All available evidence suggests that the III which was observed in the other species was formed from II; *i.e.*, no III was found in samples that had not been alkalinized.

The details of the urinary recovery studies are presented in Table II. The percent of the dose excreted as unchanged tocainide ranged from 9.5% in gerbils to 48.7% in cats. The percent of the dose recovered as II was ≤2.4% in all species studied (Table II). Total acid hydrolyzable conjugates accounted for ≤13% of the dose in all species. No evidence of bacterial breakdown of II to I by human or animal urine was observed. Furthermore, no trend in the urinary excretion of I or II was seen as a function of urine pH (data not presented).

DISCUSSION

A principal purpose of the present investigation was to identify a common laboratory animal that could biotransform tocainide into II. In an earlier investigation of tocainide metabolism (using GLC–mass spectrometry and electron capture GLC analysis), the presence of trace amounts of III in the urine of Wistar rats was reported prior to alkalinization (14, 15). Thus, it seemed reasonable to examine a number of rodents for their capacity to form II. However, the results from the present study suggested that among common rodents, only the guinea pig could form amounts of II measurable using FID detection methods. It was also observed that rabbits, cats, pigtail monkeys, and dogs excreted small amounts of II (~1% of the dose), but none approached the amount found in human urine (25–40% of dose). These results indicate that the enzyme(s) needed to produce II may be widespread in the animal kingdom, but the capacity to produce substantial amounts of II has only been documented in humans, following oral administration (3, 7, 8). Alternative explanations have not been ruled out. For example, the various animal species studied may have synthesized large amounts of II but eliminated it *via* an alternative pathway such as biliary excretion, or II may be formed by gut flora, and hence (in the absence of biliary excretion) could only be formed following oral administration. At present, no evidence exists suggesting the biliary excretion of II or metabolism of I to II by gut flora. Thus, it is reasonable to assume that none of the animals studied is an adequate model of humans. It is important to find a species that produces substantial amounts of II, both for toxicological studies and for investigations into the fundamental nature of this potentially widespread biochemical transformation. The toxicity, mechanism of formation, and factors that influence the rate of formation of II remain unknown. Such investigations will be greatly facilitated when an appropriate model (whole animal) study system has been identified.

From a toxicologic standpoint, the demonstrated lability of II, plus the large amount formed in humans raise questions as to whether II may play a role in the toxicity of tocainide. A recent publication noted that some patients exhibit allergic reactions (*i.e.*, rashes) when treated with tocainide (16). These reactions may be due to II. Though toxic glucuronide metabolites have only been recently recognized, two have been identified that irreversibly bind (covalently bond) to proteins (17) and nucleic acids (18). These reactive compounds share some structural analogy with tocainide carbamoyl O-β-D-glucuronide. However, it would be premature to attribute any of tocainide's toxicity to II or any of its other metabolites (5, 7).

Independent of the toxicological considerations, it is of fundamental interest to identify species producing carbamate glucuronides from amines, since such conjugates represent a category of drug metabolite which has been discovered only recently (8).

While precedents exist for enzymatic carbamylation of amine functional groups (10) and glucuronidation of carbamates (9), little is known of the mechanisms involved in the sequential carbamylation and glucuronidation of primary amine drugs. After an appropriate animal model has been identified, studies to ascertain these mechanisms will be possible. The elucidation of these mechanisms may substantially expand understanding of the glucuronidation process.

In Vitro Skin Evaporation and Penetration Characteristics of Mosquito Repellents

WILLIAM G. REIFENRATH ˣ and PETER B. ROBINSON

Received June 8, 1981, from the *Division of Cutaneous Hazards, Letterman Army Institute of Research, Presidio of San Francisco, CA 94129.* Accepted for publication November 24, 1981.

Abstract □ An *in vitro* apparatus was used to study mosquito repellent evaporation and penetration characteristics with skin. The mosquito repellents 2-ethyl-1,3-hexanediol, *N,N*-diethyl-*m*-toluamide, *N,N*-diethyl-*p*-toluamide, 1-(butylsulfonyl)hexahydro-1*H*-azepine, and *N,N'*-dicyclohexamethyleneurea were studied. *In vitro* repellent duration, calculated from repellent evaporation rates, was compared to *in vivo* duration at the same dose (0.3 mg/cm^2) to assess the validity of the model. *In vitro* durations for 2-ethyl-1,3-hexanediol, *N,N*-diethyl-*m*-toluamide, *N,N*-diethyl-*p*-toluamide, and *N,N'*-dicyclohexamethyleneurea correlated with *in vivo* durations ($r^2 = 0.94$), although *in vitro* duration was longer than *in vivo* duration. 1-(Butylsulfonyl)hexahydro-1*H*-azepine, which had the longest *in vivo* duration, had an *in vitro* duration that exceeded the test period (12 hr). The 0–12-hr *in vitro* percutaneous penetration correlated with corresponding data available from *in vivo* studies.

Keyphrases □ Mosquito repellents—*in vitro* skin evaporation, penetration □ Evaporation—*in vitro* skin penetration, mosquito repellents □ Penetration—*in vitro* skin evaporation, mosquito repellents

Evaporation of mosquito repellents from the skin surface and percutaneous penetration represent important modes of loss of mosquito repellents from the skin surface. Various estimates of the percutaneous penetration of mosquito repellents have been made (1–4). However, only one repellent (*N,N*-diethyl-*m*-toluamide) whose loss from the skin surface by evaporation and skin penetration has been quantified (5). The percentages of *in vitro* skin evaporation and percutaneous penetration of the following five mosquito repellents are reported in this paper: 2-ethyl-1,3-hexanediol (I), *N,N*-diethyl-*m*-toluamide (II), *N,N*-diethyl-*p*-toluamide (III), 1-(butylsulfonyl)hexahydro-1*H*-azepine (IV), and *N,N'*-dicyclohexamethyleneurea (IV). Two dose levels were used: a dose corresponding to a repellent's minimum effective dose against *Aedes aegypti* mosquitoes (6) and a dose of 0.3 mg/cm^2, which has been used to determine the effective duration of the repellents on the skin of humans (6).

The duration of steady-state evaporation rate of repellents from aluminum planchets has been compared with the duration of effectiveness of several mosquito repellents on the skin of humans (7). The findings suggest a possible relationship between evaporation rate from skin and repellent duration. In this report, this possible relationship was examined by computing the *in vitro* durations for each repellent from *in vitro* evaporation rates and comparing them to previously reported values for *in vivo* duration (6).

EXPERIMENTAL

Labeled Compounds—The following radiolabeled mosquito repellents were used: [1,3-^{14}C]2-ethyl-1,3-hexanediol(Ia)[1], specific activity, 6.06×10^4 dpm/μg; [carbonyl-^{14}C]*N,N*-diethyl-*m*-toluamide(IIIa) (8), specific activity, 1.15×10^4 dpm/μg; [carbonyl-^{14}C]*N,N*-diethyl-*m*-toluamide(IIa) (8), specific activity, 2.47×10^4 dpm/μg; 1-(butylsulfonyl)-[2,2'-^{14}C] hexahydro-1*H*-azepine(IVa), specific activity, 332 dpm/μg; and *N,N'*-[2,2'-^{14}C]dicyclohexamethyleneurea(Va), specific activity, 174 dpm/μg. For skin applications of I at the minimum effective dose and the 0.3 mg/cm^2 dose, cold I[3] was used to dilute the radiolabeled samples to give total radioactive doses of 0.02 and 0.14 μCi, respectively. For one replicate (skin No. A8478) of skin application of III at 0.3 mg/cm^2, cold III[4] was used to dilute the radiolabeled sample to give a final ra-

Labeled Compounds—The following radiolabeled mosquito repellents were used: [1,3-^{14}C]2-ethyl-1,3-hexanediol(Ia)[1], specific activity, 6.06×10^4 dpm/μg; [carbonyl-^{14}C]*N,N*-diethyl-*m*-toluamide(IIIa) (8), specific activity, 1.15×10^4 dpm/μg; [carbonyl-^{14}C]*N,N*-diethyl-*m*-toluamide(IIa) (8), specific activity, 2.47×10^4 dpm/μg; 1-(butylsulfonyl)-[2,2'-^{14}C] hexahydro-1*H*-azepine(IVa), specific activity, 332 dpm/μg; and *N,N'*-[2,2'-^{14}C]dicyclohexamethyleneurea(Va), specific activity, 174 dpm/μg. For skin applications of I at the minimum effective dose and the 0.3 mg/cm^2 dose, cold I[3] was used to dilute the radiolabeled samples to give total radioactive doses of 0.02 and 0.14 μCi, respectively. For one replicate (skin No. A8478) of skin application of III at 0.3 mg/cm^2, cold III[4] was used to dilute the radiolabeled sample to give a final ra-

dioactive dose of 0.03 μCi. All compounds were homogeneous as determined by TLC (silica gel[5] and chloroform).

Procedure—Whole skin (abdominal), obtained at autopsy, was stored at −65° in sealed plastic bags before use. Storage time did not exceed 3 months. Subcutaneous fat was removed from the thawed sample (~7 cm^2) before use.

The apparatus shown in Fig. 1[6] was used. A magnetic stirrer was placed in the lower chamber filled with Ringer's lactate solution[7], a skin sample was placed over the lower chamber visceral side down, a polytef o-ring which served as a seal between the lower and upper chamber was placed on top of the skin, and the evaporation manifold was clamped into place. Air bubbles underneath the skin were removed by tipping the assembly, allowing the skin to come in contact with the Ringer's lactate. After 20

min. the evaporation manifold was removed and the desired dose of labeled compound dissolved in ethanol (~10 μl) was applied to the skin area circumscribed by the o-ring (1.27 cm^2) by use of a syringe[8]. For controls, an equal volume was placed into counting vials. The evaporation manifold was then clamped to the lower chamber and the lower chamber was immersed in a water bath at 37°. One arm of the lower chamber was connected to a precision pump[9] which delivered 1.6 ml of Ringer's lactate/hr. The other arm of the lower chamber was connected to a short length of flexible tubing which led into a counting vial.

The vapor trap, a glass tube packed with 200 mg of absorbant[10] and plugged with cotton at its ends, was inserted into the threaded 14/20 standard taper adapter[11], and the assembly slipped into the ground-glass joint of the evaporation manifold so that the lower end of the vapor trap tube was 0.65 cm above the surface of the skin. The vapor trap was connected by flexible tubing to a bubbler trap which contained aqueous counting solution[12] and served as a safety trap. The bubbler trap was connected to a peristaltic pump[13], which pulled in air at 30 ml/min. The outlet from the peristaltic pump was connected to a flow gauge[14]. Air entering the evaporation manifold was entrained in the following manner: The four intake tubes of the evaporation manifold were connected by adapters to a common tube which was connected to a calcium sulfate drying tower. The inlet port of the drying tower was connected by tubing to an air flow gauge, whose reading corresponded to the other flow gauge reading if there were no leaks or plugged tubes in the system. Dry air at

[a] Radioactivity recovered from the vapor trap. [b] Total recovery includes small percentages of radioactivity recovered from the evaporation manifold. [c] Skin code not recorded. [d] Sample lost.

22° (ambient laboratory temperature) was thus drawn into the evaporation manifold, over the skin surface, and through the vapor trap, which absorbed any repellent evaporating from the skin surface. Air flowed above the skin and Ringer's lactate flowed below the skin for 1 hr after application of the minimum effective dose and for 12 hr after the 0.3 mg/cm² dose. During the 12-hr runs, the vapor trap and counting vial were changed at hourly intervals.

Radioactivity Measurements—After minimum effective dose applications, the Ringer's lactate in the lower chamber and the rinses of the lower chamber were combined with the Ringer's lactate in the counting vial used to collect lower chamber outflow. After the 0.3-mg/cm² dose, each of the 12 counting vials used to collect lower chamber outflow and the residual fluid in the lower chamber were counted separately[15]. The contents and counting solution rises of each vapor trap were placed in separate counting vials. The resultant disintegrations per minute were corrected for loss in counting efficiency introduced by the absorbant powder, determined by spiking vapor traps with a known amount of radiolabeled repellents. Efficiency varied from 89 to 92% of control for the five repellents. The stratum corneum surface of the skin sample was washed with aqueous counting solution and rinses were collected in a counting vial. The skin sample was then cut into pieces (each <250 mg in weight) and the separate pieces were oxidized[16]. The disintegration per minute was determined by the standard spike method. The evaporation manifold was rinsed with aqueous counting solution and the radioactivity recovered was added to the total percent recovery. The percentage of the applied radioactive dose, recovered from the polytef o-ring by counting solution rinse, was added to the percentage accounted for by the skin surface rinse.

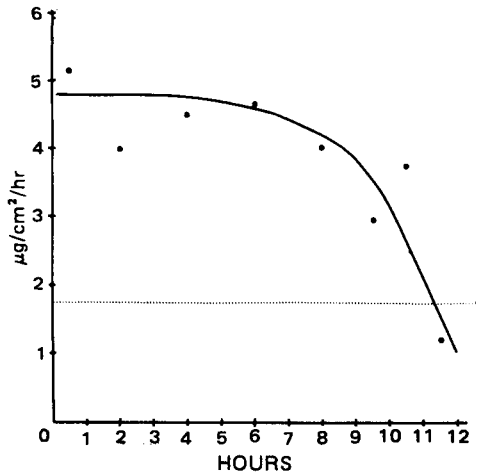

Figure 4—*Mean evaporation rate of III* versus *time at 0.3 mg/cm² (—); the minimum effective evaporation rate (·····).* In vitro *duration is 12 hr. Because of irregularly timed sample collection during the first 9 hr, hourly Sample 2 was combined with 3, 4 with 5, 6 with 7, and 8 with 9.*

RESULTS AND DISCUSSION

The mean evaporation rate *versus* time after the 0.3-mg/cm² dose for each repellent is plotted in Figs. 2–6 relative to the minimum effective evaporation rate of the repellent, the evaporation rate obtained from the

[a] Radioactivity recovered from the primary vapor trap. [b] Total recovery includes small percentage of radioactivity recovered from the evaporation manifold. [c] Skin code was not recorded.

minimum effective dose. (In Figs. 2–4, curves were fitted by eye. In Figs. 5 and 6, least-squares regression lines were drawn.)

The radioactivity recovered from each hour outflow from the lower chamber during the 0.3-mg/cm² dose–12-hr runs represents a time average of the amount of radioactivity in the lower chamber during a given hour. The amount of radioactivity recovered from the residual Ringer's lactate in the lower chamber at the end of the 12-hr runs was always higher than could be accounted for by the 12th-hr outflow. This was probably the result of adsorption of repellent to the glass walls of the lower chamber. Therefore, the amounts of radioactivity in each of the 12 counting vials from the lower chamber outflow, and residual radioactivity in the lower chamber were summed, expressed as the percent of applied dose, and termed as the percutaneous penetration (Table I).

The disposition of radioactivity, expressed as the percent of applied radioactive dose, following the minimum effective dose, is given in Table II, and following the 0.3-mg/cm² dose is given in Table I. The relative volatilities for the repellents are: V < IV < II < I[17]. The percent of radioactivity lost from the skin by evaporation was greater as volatility increased (Tables I and II). Except for I (the most volatile compound) in the 12-hr runs, the majority of the applied radioactive dose for each repellent was recovered from the skin surface and from the skin tissue.

In vitro duration for each repellent at the 0.3-mg/cm² dose was computed by determining the time it took for the evaporation rate from the 0.3-mg/cm² dose to reach the evaporation rate arising from the minimum effective dose or minimum effective evaporation rate for that repellent. The *in vitro* duration so obtained was plotted against the duration on humans (6) of each repellent at 0.3 mg/cm² (Fig. 7). Although *in vitro* duration was always longer than *in vivo* duration, a good correlation existed between them ($r^2 = 0.94$).

The minimum effective evaporation rate for each repellent represents the minimum amount of repellent vapor necessary to repel *A. aegypti* mosquitoes under given test conditions and, therefore, is a measure of the intrinsic repellency or potency of a compound. Minimum effective evaporation rate is calculated by dividing the amount (micrograms) of repellent evaporating from the skin surface by the skin surface area (1.27 cm²) and by the time (1 hr). The minimum effective evaporation rates (μg/cm²/hr ± *SD*) for the repellents studied are as follows: IV, 0.20 ± 0.09; V, 1.1 ± 0.1; II 1.2 ± 0.3; III, 1.8 ± 0.8; I, 7.5 ± 1.7. Compound IV is the most potent repellent, V, II, and III are equipotent, and I is the least potent repellent among the five. Repellent minimum effective evaporation rate will not necessarily be the same for different types of mosquitoes and would be expected to increase when test conditions are more severe (*e.g.*, increased avidity of mosquitoes). For V, the least volatile repellent, the evaporation rate following the 0.3-mg/cm² dose (Fig. 6) is essentially

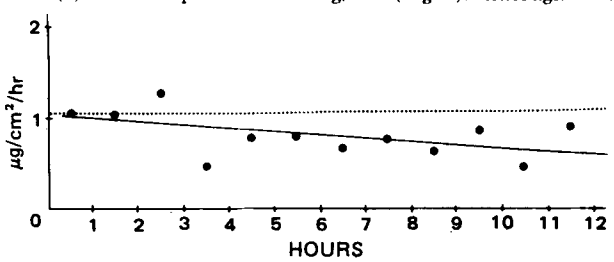

Figure 6—*Mean evaporation rate of V* versus *time at 0.3 mg/cm² (—); the minimum effective evaporation rate (·····).* In vitro *duration is 1 hr.*

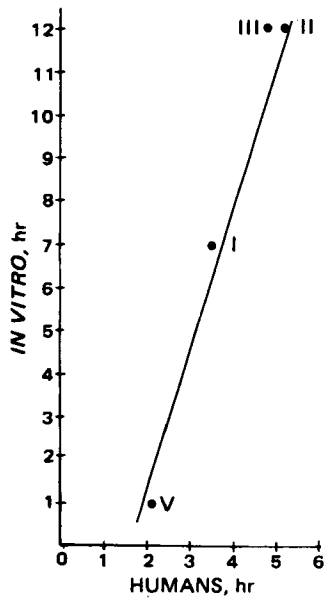

Figure 7—*Calculated* in vitro *duration* versus in vivo *duration of protection of five repellents at a dose of 0.3 mg/cm² against* A. aegypti *mosquitos.*

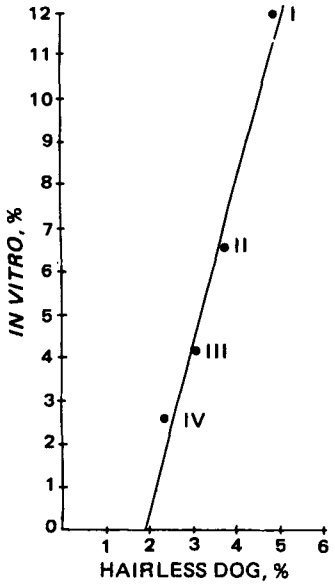

Figure 8—*Mean 12-hr percutaneous penetration (percent of applied radioactive dose)* in vitro versus *hairless dog.*

a horizontal line near its minimum effective evaporation rate. In this instance, the repellent failed almost immediately when challenged with mosquitoes (6). However, if the minimum effective evaporation rate were lower, the repellent could last a long time. The low volatility of V probably accounts for its sporadic performance[18].

In Fig. 8, 12-hr *in vitro* percutaneous penetration at the 0.3-mg/cm^2 dose is compared to 12-hr percutaneous penetration in the hairless dog at the same dose (2, 9) for four of the repellents studied (data for *in vivo–in vitro* comparison of IV were not available). Although *in vitro* percutaneous penetration was always greater than *in vivo* penetration, a good correlation exists between them ($r^2 = 0.96$).

The disposition of radioactivity 1 hr after topical application of radiolabeled II at its minimum effective dose (0.025 mg/cm^2) has been previously reported (5), both *in vitro* and *in vivo*. For the *in vitro* studies, 9.7 ± 5.9% of the applied radioactive dose evaporated, 19.7 ± 3.1% remained on the skin surface, and 50.8 ± 15.0% remained in the skin. For the *in vivo* studies, 9.6 ± 3.6% of the applied radioactive dose evaporated and 27.1 ± 11.6% remained on the skin surface. In this study, a lower percentage (4.3 ± 1.2%) of the radioactive dose of II evaporated 1 hr after *in vitro* application at the minimum effective dose. This difference may result from a closer proximity of the vapor entraining tube to the skin surface (1.5 mm *versus* 6.5 mm) in the previous report (5). A larger portion (52.8 ± 11.4%) of the applied radioactive dose was recovered from the skin surface and a correspondingly smaller portion (29.6 ± 12.9%) of the applied radioactive dose was recovered by skin oxidation, compared to the percentages cited in the previous study (5). This difference may result from the thoroughness of the skin surface rinse procedure, as the sum of the percentages of applied radioactive dose recovered by skin rinse and skin oxidation in the two studies are similar in magnitude.

The *in vitro* apparatus described here can be a useful tool for the screening of mosquito repellent formulations that incorporate a repellent whose evaporation and penetration characteristics and minimum effective evaporation rate are known. Formulations can be selected that reduce excessive evaporation, maintain evaporation rates above the minimum effective evaporation rate for longer periods of time, and reduce percutaneous penetration as compared with the unformulated repellent.

High-Performance Liquid Chromatographic Analysis of Digitoxin Formulations

BELACHEW DESTA and K. M. McERLANE ˣ

Received June 25, 1981, from the *Faculty of Pharmaceutical Sciences, University of British Columbia, Vancouver, B.C. V6T 1W5, Canada.* Accepted for publication November 27, 1981.

Abstract □ A rapid, selective, and simple high-performance liquid chromatographic assay for digitoxin formulations is described. The method utilizes a conventional octadecyl-bonded phase column with detection at 220 nm. The isocratic solvent system resolves digitoxin from its potential degradation products and provides an accurate assay for tablet and injectable formulations with a relative standard deviation of 1.4 and 3.3%, respectively. The method is sufficiently sensitive to monitor content uniformity of tablets and the minimum quantifiable amount of digitoxin was determined to be 20 ng. The total chromatograph time was ~15 min.

Keyphrases □ Digitoxin—high-performance liquid chromatographic analysis of formulations, content uniformity □ Formulations—digitoxin, high-performance liquid chromatographic analysis, content uniformity □ High-performance liquid chromatography—content uniformity, analysis of digitoxin formulations

Digitoxin is a cardiac glycoside obtained from the leaves of *Digitalis purpurea* and is used in the treatment of congestive heart failure. Due to its long biological half-life the unit dose is generally low (0.1 mg). Assurance of potency and content uniformity of tablets is, therefore, a necessity for proper dosage. The determination of such a potent drug in the dosage form requires a method that is accurate, selective, and sensitive.

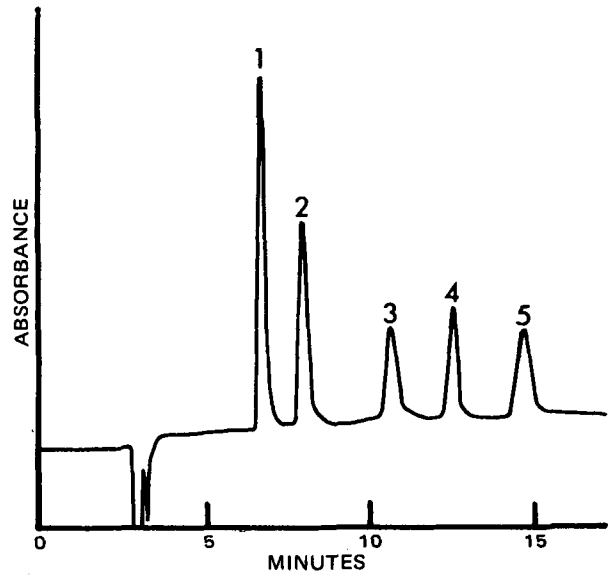

Figure 1—*Isocratic HPLC separation of digitoxin and its potential degradation products. Sequence of elution: digitoxigenin (1), digitoxigenin monodigitoxoside (2), digitoxigenin bisdigitoxoside (3), 17α-methyltestosterone (4), and digitoxin (5). Mobile phase: water–methanol–isopropanol–methylene chloride (45:38:11:6); flow rate: 1.1 ml/min.*

Quantitative colorimetric methods (1–8) lack selectivity, since the chromogenic agent reacts with either the lactone ring or the digitoxose sugar residue of the digitoxin molecule and would not determine the quantity of intact drug in the presence of any degradation products. In addition, these techniques are relatively insensitive. Fluorometric procedures (9–13) are based on the dehydration of the aglycone moiety, and although sensitive, are largely nonspecific. TLC techniques (14–17) although selective, are semiquantitative at best. A GC assay method (18) provided a highly sensitive method utilizing a heptafluorobutyrate derivative with electron-capture detection. However, the procedure requires conversion of the drug and potential impurities to the digitoxigenin portion of the glycoside and thus is nonselective. High-performance liquid chromatographic (HPLC) techniques have been reported (19–23) for the resolution of digitoxin and its potential metabolites, degradation products, and impurities; however, quantitative procedures for digitoxin in its dosage forms have not been reported.

This paper describes an HPLC method that is fast, selective, and sufficiently sensitive to allow accurate quantitation of digitoxin in single-tablet assays.

EXPERIMENTAL

Materials and Methods—A high-performance liquid chromatograph[1] equipped with dual pumps[2], a microprocessor system controller[3], a dynamically stirred mixing chamber[4], and a 20-μl loop injector[5] were used throughout. A variable wavelength detector[6] was operated at 220 nm. Data acquisition was accomplished with an electronic printer/plotter integrator[7]. The HPLC column[8] had a dimension of 4.6 mm × 250-mm i.d. and was packed with octadecyl (C-18) 5-μm bonded phase.

Table I—Recovery Data for the HPLC Analysis of Digitoxin Tablets[a]

Number	Theoretical Digitoxin Concentration, mg	Amount Added, mg	Recovery, %
1	1.0	0.5	98.6
2	1.0	0.5	102.6
3	1.0	0.5	95.8
4	1.0	0.5	101.9
Mean			99.7
RSD (%)[b]			3.1

[a] 0.1-mg tablet. [b] Relative standard deviation.

Water, methanol, isopropanol, and methylene chloride were of HPLC grade[9]. Digitoxin[10], digitoxigenin[10], digitoxigenin monodigitoxoside[10], digitoxigenin bisdigitoxoside[10], and 17α-methyltestosterone[11] were used without further purification.

The mobile phase used for the isocratic assay consisted of water–methanol–isopropanol–methylene chloride (45:38:11:6); flow rate was 1.1 ml/min and the UV detector was set at 220 nm.

An internal standard solution of 17α-methyltestosterone was prepared by dissolving 100 mg in 100 ml of methanol.

A standard solution of digitoxin was prepared by dissolving 10 mg in 60 ml of boiling methanol in a 100-ml volumetric flask. After cooling the resulting solution to room temperature, the flask was brought to volume with methanol and thoroughly mixed.

Calibration Curve—Aliquots of 1, 2, 5, 10, 20, and 30 ml of the digitoxin reference standard solution were added into 100-ml volumetric flasks along with 1 ml of internal standard solution. The solutions were diluted with methanol to produce a volume of 35 ml in each case. The resulting solutions were then brought to volume with water and thoroughly mixed. Three 20-μl aliquots of each of the calibration standards were used to determine the response ratio and linearity.

Tablet Formulation Assay—Forty tablets (0.1 mg/tablet) were weighed and triturated to a fine powder. An accurately weighed aliquot equivalent to ~1 mg of digitoxin was transferred to a 100-ml volumetric flask. Distilled water (10 ml) was added and the flask was swirled for 2–3 min, followed by the addition of 34 ml of methanol. The flask was shaken for 15 min, and the resulting suspension was filtered through filter paper[12] and the residue was washed with three, 5-ml portions of distilled water. The filtrate and washings were collected in a 100-ml volumetric flask containing 1 ml of the internal standard solution. The flask was brought to volume with water and a 20-μl aliquot was injected into the liquid chromatograph.

A single tablet assay was performed by placing one tablet in a 50-ml

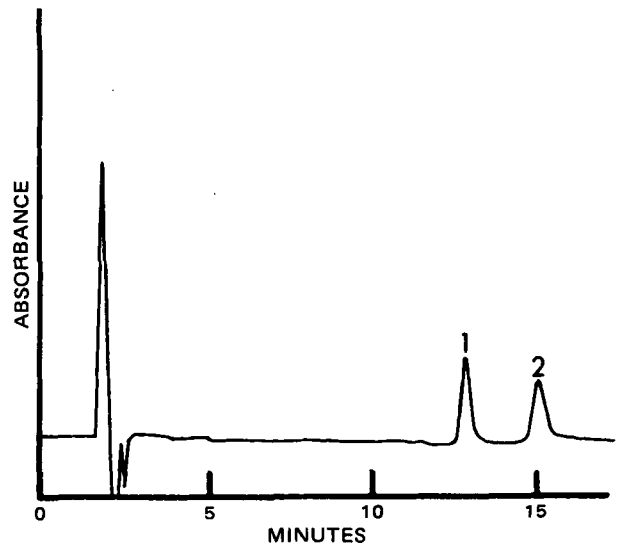

Figure 2—*High-performance liquid chromatogram of a digitoxin tablet formulation. Sequence of elution: 17α-methyltestosterone (1), digitoxin (2). Refer to Fig. 1 for HPLC conditions.*

8	—	107.0	—
9	—	98.2	—
10	—	103.8	—
Mean	97.2	98.8	96.9
RSD (%)[c]	1.4	4.8	3.3

[a] 0.1-mg tablet. [b] 0.2 mg/ml. [c] Relative standard deviation.

volumetric flask and following the same procedure as for the tablet formulation assay.

Injectable Formulation Assay—Exactly 1 ml of digitoxin injection was quantitatively transferred to a 10-ml volumetric flask. A 0.1-ml aliquot of the internal standard solution along with 3.3 ml of methanol were added, and the flask was brought to volume with water.

To determine assay precision, 70 tablets were weighed and triturated to a fine powder. Six aliquots equivalent to ~1 mg of digitoxin were individually treated as described under tablet formulation assay. Three 20-μl injections were made from each of the six aliquots.

Recovery of Digitoxin from Tablets—Eighty tablets (0.1 mg/tablet) were weighed and ground to a fine powder. Three aliquots were treated and assayed in the same manner as for the tablet formulation to determine a mean assay value. Four aliquots of the ground digitoxin tablets, equivalent to an assay value of 1 mg, were prepared, and an accurately weighed quantity of digitoxin reference standard[9] equivalent to 0.5 mg was added to each sample. The samples were further treated as described under tablet assay. Three injections were made for each sample.

RESULTS AND DISCUSSION

A representative chromatogram for a standard mixture of digitoxin, its mono- and bisdigitoxosides, digitoxigenin, and the internal standard, 17α-methyltestosterone, is given in Fig. 1. From the chromatogram it can be determined that the potential impurities or degradation products are well resolved and are separated from the peak due to digitoxin. The overall chromatographic time of 15 min provides efficient assay capabilities.

The chromatogram obtained for a tablet composite assay is given in Fig. 2. The chromatogram is essentially devoid of any interfering peaks due to other glycosides or tablet excipients. As a further check, common tablet excipients such as lactose, starch, methylcellulose, and stearate lubricants were subjected to the extraction and assay procedures and were found not to interfere with the peaks due to the digitalis glycosides or the internal standard.

The composite sample used for the recovery study was initially assayed in triplicate and a mean value of 99.8% was obtained. The recovery of digitoxin from tablet formulations was thus determined by adding an amount equivalent to 50% of the tablet potency adjusted for the 99.8% potency observed. The data given in Table I indicate that the mean recovery was 99.7% of the expected total potency of the theoretical composite potency plus the amount of digitoxin added. The precision of the assay was determined by independent analysis of six tablet aliquots of a 0.1-mg tablet formulation and was found to yield a mean assay value of 97.2% with a 1.4% *RSD* (Table II).

USP assay (8) for digitoxin tablets is a relatively time-consuming procedure requiring column chromatographic isolation of the digitalis glycoside followed by a chromogenic reaction and colorimetric measurement. As such, the method requires several hours of analytical time. The HPLC method described in this paper, however, requires <1 hr to complete each assay determination. The USP limits for digitoxin tablets specify a content of 90–110% of label claim. From the data for a composite tablet assay given in Table II, the formulation examined falls within the pharmacopeial requirements. Because of the need to ensure content uniformity of digitoxin tablets, the USP specifies a sensitive but lengthy fluorometric procedure. The HPLC method described herein is sufficiently sensitive to determine content uniformity of 0.1-mg tablets. The resulting data obtained from a random sample of 10 tablets is given in Table II. The general pharmacopeial requirements for tablets specify that each dosage unit must contain 85–115% of the labeled potency. The data given in Table II indicate that the tablets examined have a mean potency of 98.8% with a 4.8% *RSD*. The range of 92.8 to 107.0% observed falls within the required limits.

Table III—Results of the Analysis of Digitoxin Tablets Using the USP XX Method[a]

Number	Label Claim, %
1	103.1
2	101.1
3	97.4
Mean	100.5
RSD (%)[b]	2.9

[a] 0.1-mg tablet. [b] Relative standard deviation.

As a final comparison with the USP assay for tablet potency, three aliquots of the 0.1-mg tablet composite used to determine the potencies given in Table II were assayed according to the pharmacopeial method. The results given in Table III for this analysis indicate that the formulation had a mean potency of 100.5% with a 2.9% *RSD*. It can be seen that the assay results obtained with the HPLC method compare favorably with those obtained with the USP method.

The HPLC analysis of a digitoxin injectable formulation is given in Table II. The assay mean (96.9%) indicates that the formulation is within the limits (90–110%) specified in the USP (8). The HPLC analytical procedure requires that the formulation only be diluted, whereas the USP method requires a prior column chromatographic procedure followed by timed chromogenic reaction and serial spectrophotometric readings. A significant time advantage is obtained with the HPLC procedure described.

The HPLC assay method described herein for tablet and injectable formulations is simple, rapid, and precise, and provides a sufficiently sensitive method for the determination of individual tablet content. The potency determinations compare favorably with those obtained with the USP assay method.

Chromatographic Study of Interactions Between Polyvinylpyrrolidone and Drugs

D. HORN ˣ and W. DITTER

Received July 21, 1981, from the *Hauptlaboratorium der BASF Aktiengesellschaft, D-6700 Ludwigshafen/Rhein, West Germany.* Accepted for publication November 27, 1981.

Abstract □ A chromatographic technique for the study of possible interactions of drugs with soluble or insoluble polymer additives is proposed. Crospovidone was used as a stationary phase. The method allowed the rapid determination of interaction constants in the range of $>1\ M^{-1}$ as relevant for applications in practice. The interaction of 39 drugs and model compounds of diverse chemical structure with povidone and crospovidone was studied. The results closely agreed with data obtained from conventional equilibrium dialysis and sorption studies. The complexation reaction was found to be dominated by hydrogen binding. A close correspondence between the strength of interaction and the nature, number, and position of hydrogen-donating functional groups in the active ingredient was observed. The binding tendency was enhanced when the functional groups were connected with aromatic residues. The carboxyl group was more effective than the hydroxide or amino groups. The binding can be quantified by the binding constants, K_p and K_s, respectively, describing the interaction with polyvinylpyrrolidone *via* independent binding sites. At pH 1, with the exception of tannic acid, all investigated drugs exhibited K_p and/or K_s values well below an upper limit of $10\ M^{-1}$. Hence, with additive–drug ratios commonly used in pharmaceutical preparations, the bound amount of drug after oral administration can hardly exceed 3%. In view of this already low degree of potential binding and considering its reversible character and its decreasing tendency with increasing pH during GI passage, the presence of polyvinylpyrrolidone in pharmaceutical preparations is not expected to interfere with GI drug absorption.

Keyphrases □ Polyvinylpyrrolidone—chromatographic study of interactions with drugs, soluble and insoluble polymer additives □ Chromatography—study of interactions with polyvinylpyrrolidone and drugs, soluble and insoluble polymer additives □ Polymers—soluble and insoluble additives, chromatographic study of interactions between polyvinylpyrrolidone and drugs

N-Vinylpyrrolidone can be polymerized to yield povidone (I), a polymer readily soluble in water and numerous other solvents, producing solutions with remarkably low viscosities (1). It can also be transformed into an insoluble polymer, crospovidone (II), by proliferous polymerization (2, 3). In pharmaceutical technology, both forms of the polymer are used mainly in the production of tablets. The pronounced disintegrating effect of II is based on an exceptionally high swelling pressure in aqueous systems (4–6).

Additives used in formulations of drugs are expected to be nontoxic and therapeutically inactive. In both respects polyvinylpyrrolidone meets these requirements. The degree to which the additive might form complexes with the active component is another consideration; a low tendency for complex formation is preferred, unless a sustained-release effect is of interest.

BACKGROUND

Because of the dipolar character of I and II, specific interactions with certain drugs are possible and have been observed in several cases. A recent review covers the published data concerning the interaction properties of various macromolecular additives (7). Data characterizing the interaction properties of I have been reported in numerous studies (8–23).

Much more limited are relevant data concerning the interaction tendency of Compound II. The binding of phenolic substances and its relevance for their removal from beer has been studied (24–26). Similarly, II has been used to remove phenols from plant tissues in the process of isolating active enzymes from plants (27). Furthermore, tannic acid and related compounds are known to be bound strongly by II (3). Other compounds such as acetaminophen, benzocaine, metamizole, and salicylamide exhibited no stronger interaction with II than with corn starch, carboxymethyl starch, and microcrystalline cellulose (28). First results of a systematic study of the interaction properties of II with various pharmaceuticals have been reported (29).

The objectives of the present study are: to develop new experimental techniques that simplify the performance of binding studies, to study the binding of selected model compounds to improve the basic understanding of the mode of interaction with I and II, and to present the binding data obtained from various drugs of diverse chemical structure in a way ready to be applied to systems of practical interest. The application of a novel chromatographic technique is emphasized.

EXPERIMENTAL

Materials—The following were obtained from commercial sources: acetaminophen[1], aspirin[2], aniline[3], benzocaine[4], benzoic acid[2], benzyl alcohol[5], caffeine[2], chloramphenicol[6], 1,2-dicarboxybenzene[2], 1,3-dicarboxybenzene[3], 1,4-dicarboxybenzene[3], 1,2-dihydroxybenzene[2], resorcinol[2], 1,4-dihydroxybenzene[5], 2,4-dihydroxybenzoic acid[1], 3,4-dihydroxybenzoic acid[7], 3,5-dihydroxybenzoic acid[5], 2,4-dimethylphenol[1], salicylic acid[2], 3-hydroxybenzoic acid[1], 4-hydroxybenzoic acid[1], methotrimeprazine[5], methyldopa[6], methylparaben[8], 2-methylphenol[1], papaverine hydrochloride[2], phenol[2], promethazine hydrochloride[5], riboflavin[2], salicylamide[2], sorbic acid[9], sulfamethazine[10], sulfamoxole[11], sulfathiazole[12], tetracaine hydrochloride[13] gallic acid[2], trimethoprim[11], 2,4,6-trimethylphenol[7], and tannic acid[2]. All materials were of the highest available grade and were used without further purification.

Povidone[14] was used as received (weight average of molecular weight $\overline{M}_w = 49{,}000$; number average of molecular weight $\overline{M}_n = 10{,}000$).

The sorption studies were performed applying crospovidone[15], characterized by a specific surface area[16] of $S_{N_2} = 6.0\ m^2/g$ and a density of $1.2\ g/cm^3$. A coarse fraction of II was used for the stationary phase in the chromatographic column.

Chromatography—In preparing the chromatographic column (length, 10 cm; diameter, 0.25 cm) an aqueous slurry of a coarse fraction of II, as specified above, was poured into the column and allowed to pack by gravity flow. The column was coupled with a UV-visible spectrophotometer[17] equipped with a 1-cm micro flow-through cell. The column was charged with 10-μl samples of the drug solution. For the easily soluble substances, 1000 mg was dissolved in 1000 ml of 0.1 *N* HCl. Where the solubility was insufficient, saturated solutions at 25° were used. In general, 0.1 *N* HCl, plain or loaded with 10–30 g/liter of I, was used for elution[18] with a rate of 7.5 ml/hr at ambient temperature (25 ± 1°).

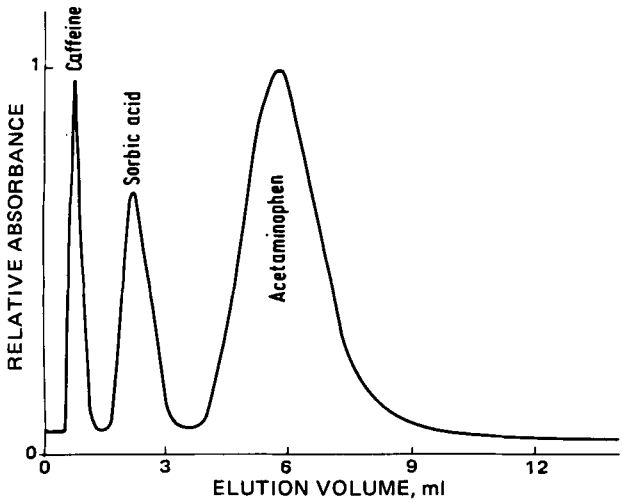

Figure 1—*Chromatographic fractionation of drugs using II as stationary phase and 0.1* N *HCl as eluent. The degree of interaction with II is indicated by specific retention volumes.*

Sorption Studies—For easily soluble substances, aqueous solutions containing 250 mg/liter of the active ingredient were prepared. The solution pH was adjusted in the range of 1.0–12.0 by adding the required amounts of hydrochloric acid or sodium hydroxide. For less soluble substances, saturated solutions were used as received at 25°.

The sorption experiments were performed in 250-ml flasks at 25 ± 0.5°. Compound II was added in amounts of 20–1000 mg/200 ml of solution. The suspension was maintained under steady vibration stirring for 10 min then centrifuged[19]. The amount of unbound drug was determined spectrophotometrically[20] in the supernate.

For the binding studies with Compound I, the sorption experiments were performed after I was added as a cosolute in amounts of 2–6 g/200 ml of solution.

Equilibrium Dialysis—Equilibrium dialysis[21] was carried out at controlled temperature (25 ± 0.5°) using cellulosehydrate membranes[22] with a molecular weight cutoff of 5000 daltons. The effective surface area was 11.3 cm^2 in each cell, separating two compartments of 2 ml of volume. Equilibration was attained under steady rotation after 2 hr. The distribution of the active ingredient was determined spectrophotometrically[21]. With the exception of tannic acid, with all drugs and model substances, no detrimental interaction with the membrane was observed.

THEORETICAL

Evaluation of Data—There have been only a few attempts to apply various modes of gel permeation chromatography for investigating the complex formation between macromolecules and drugs (7). Molecular sieves as a stationary phase are only useful in exceptional cases where the dissociation rate is small compared to the rate of elution (30–33). Certain precautions have to be taken in order to obtain significant experimental results (34–36).

In contrast, the chromatographic technique proposed in the present study requires a rapid adjustment of the equilibrium of complex formation. One component of the complex formation of interest, compound II, is used as a stationary phase. In a few cases a similar polymer has been used before to separate phenolic acids (37) and purine and pyrimidine bases (38, 39) by liquid chromatography.

As was shown in a previous study, interactions of drugs with II are volume-controlled, and any possible influence of the extent of the specific surface area of II is negligible (29). Hence, the active ingredient will be distributed between the insoluble polymer phase and the liquid phase according to the Nernst distribution law:

$$k = \frac{[A]_s}{[A]} \qquad \text{(Eq. 1)}$$

where $[A]_s$ and $[A]$ denote the drug concentrations in the insoluble polymer and the liquid compartment, respectively.

[19] Omnifuge, Heraeus, Hanau, West Germany.

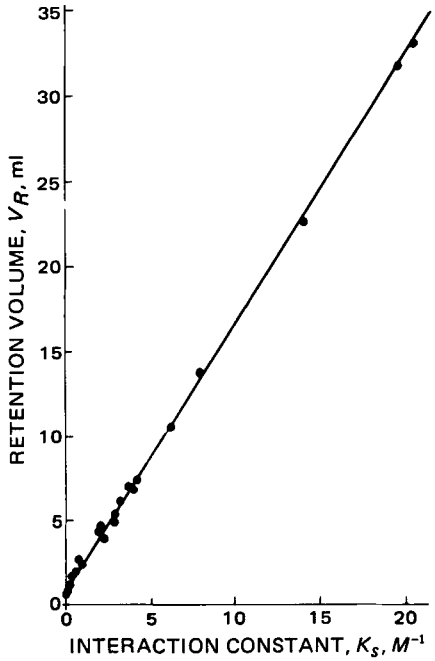

Figure 2—*Calibration of the chromatographic column. The retention volume,* V_R, *depends linearly on the interaction constant,* K_s, *as predicted by Eq. 11.* K_s *was determined by sorption experiments.*

Only part of $[A]_s$ is bound to active sites of the polymer (29). To first approximation, $[A]_s$ of Eq. 1 can be separated according to:

$$[A]_s = [A] + [FA]_s \qquad \text{(Eq. 2)}$$

where $[FA]_s$ denotes the portion of $[A]_s$ bound to active binding sites, while the concentration of the remaining fraction of $[A]_s$ that is unspecifically bound by the polymer compartment is assumed to be equilibrated to $[A]$ of the surrounding liquid phase (29).

With the liquid compartment containing, besides the active ingredient, A, an additional polymer cosolute, *e.g.*, Compound I, a similar relation holds true for $[A]_L$, the concentration of the drug in the liquid compartment:

$$[A]_L = [A] + [FA]_p \qquad \text{(Eq. 3)}$$

where $[FA]_p$ denotes the portion of $[A]_L$ bound in a drug–polymer complex.

For a system containing I and II simultaneously besides the active ingredient, A, the Nernst distribution law becomes:

$$k^* = \frac{[A] + [FA]_s}{[A] + [FA]_p} \qquad \text{(Eq. 4)}$$

Now, the equilibrium law of complex formation in the liquid phase and of the interaction in the insoluble polymer compartment becomes:

$$K_p = \frac{[FA]_p}{[A]([F_0]_p - [FA]_p)} \qquad \text{(Eq. 5)}$$

and:

$$K_s = \frac{[FA]_s}{[A]([F_0]_s - [FA]_s)} \qquad \text{(Eq. 6)}$$

respectively, where $[F]$, the concentration of free binding sites, is already replaced by the relation $[F] = [F_0] - [FA]$ in which $[F_0]$ represents the total concentration of available binding sites in the respective compartment of the system.

In distribution chromatography, the retention volume, V_R, is given by (40):

$$V_R = n(V'_L + kV'_s) \qquad \text{(Eq. 7)}$$

where n is the number of theoretical plates and V'_L and V'_s denote the volumes per theoretical plate of the mobile and the stationary phases, respectively. After introducing the phase ratio $\varphi = V_s/V_L$, and considering that for the chromatographic column: $V_s = nV'_s$ and $V_L = nV'_L$, Eq. 7 becomes:

$$V_R = V_L(1 + k\varphi) \qquad \text{(Eq. 8)}$$

Table I—Binding Data of the Interaction of Drugs with II in 0.1 *N* HCl at 25°

Compound	Interaction Constant, K_s, M^{-1} Sorption Method	Chromatographic Method
Acetaminophen	2.0	2.4
Aspirin	1.5	2.1
Benzocaine	~0	~0
Caffeine	~0	~0
Chloramphenicol	~0	~0
Methotrimeprazine	0.7	1.2
Methyldopa	0.2	~0
Methylparaben	4.2	4.2
Papaverine hydrochloride	0.1	0.2
Promethazine hydrochloride	0.4	0.6
Riboflavin	~0	~0
Salicylamide	3.7	4.0
Sorbic acid	0.5	0.7
Sulfamethazine	~0	~0
Sulfamoxole	~0	~0
Sulfathiazole	1.0	1.0
Tetracaine hydrochloride	~0	~0
Trimethoprim	~0	~0

where V_L and φ are constants for a given column. Hence, V_R is expected to be proportional to k.

As was shown earlier (29, 41), considering the mass balance of the drug:

$$[A_0]V_L = [A]V_L + [A]V_s + [FA]_sV_s \qquad \text{(Eq. 9)}$$

where $[A_0]$ represents the weighing-in concentration of the active ingredient, Eq. 6 can be combined with Eq. 1 to give:

$$k = 1 + \frac{[F_0]_sK_s}{1 + [A]K_s} \qquad \text{(Eq. 10)}$$

With the formal assumption that each monomeric subunit of the polymer may serve as a binding site, $[F_0]_s$ becomes ~9 M.

In most cases of interaction investigated in the present study, the approximation, $K_s[A] \ll 1$, holds true, since $K_s < 10$ and $[A] \approx 10^{-3}$ M. M.

Hence, substituting Eq. 10 into Eq. 8 gives:

$$K_s = \frac{1}{9}\left[\frac{V_R}{V_s} - \left(\frac{V_L}{V_s} + 1\right)\right] \qquad \text{(Eq. 11)}$$

Therefore, the retention volume, V_R, is linearly correlated with the interaction constant K_s.

Similarly, K_p can be determined by adding a definite amount of the soluble polymer (I) to the mobile phase. Considering Eqs. 4 and 8, the retention volume is altered to:

$$V_R^* = V_L(1 + k^*\varphi) \qquad \text{(Eq. 12)}$$

Dividing Eq. 12 by Eq. 8 yields for the ratio of the Nernst coefficients:

$$\frac{k^*}{k} = \frac{V_R^* - V_L}{V_R - V_L} \qquad \text{(Eq. 13)}$$

This ratio can be expressed in terms of the constant of complex formation in the liquid compartment, K_p, by combining Eqs. 1, 4, and 5:

$$\frac{k^*}{k} = \left(1 + \frac{K_p[F_0]_p}{1 + K_p[A]}\right)^{-1} \qquad \text{(Eq. 14)}$$

Again, the approximation $K_p[A] \ll 1$ is in general valid, and substituting Eq. 14 in Eq. 13 leads to:

$$K_p = \frac{(V_R - V_R^*)}{(V_R - V_L)}\frac{1}{[F_0]_p} \qquad \text{(Eq. 15)}$$

Therefore, K_p is readily determined by adding a certain amount of I, $[F_0]_p$, to the mobile phase and measuring the change of the retention volume, $V_R - V_R^*$, of the active ingredient.

In order to prove the validity of the chromatographic results, K_s and K_p were also determined by sorption studies, as reported previously (29). The variable K_s is readily evaluated from k (Eq. 1) according to the rearranged Eq. 10:

$$K_s = \frac{k - 1}{[F_0]_s - [A](k - 1)} \qquad \text{(Eq. 16)}$$

Table II—Binding Data of the Interaction of Model Compounds with II in 0.1 *N* HCl at 25°

Compound	Interaction Constant, K_s, M^{-1} Sorption Method	Chromatographic Method
Aniline	1.0	0
Benzyl alcohol	1.3	0.3
Phenol	1.9	2.3
2-Methylphenol	2.9	2.9
2,4-Dimethylphenol	2.3	2.0
2,4,6-Trimethylphenol	3.2	3.4
1,2-Dihydroxybenzene	3.9	3.9
Resorcinol	13.1	14.0
1,4-Dihydroxybenzene	8.0	8.3
1,2,3-Trihydroxybenzene	10.0	6.3
Benzoic acid	2.9	2.6
1,2-Dicarboxybenzene	5.0	4.7
1,3-Dicarboxybenzene	20.5	[a]
1,4-Dicarboxybenzene	50.0	[a]
Salicylic Acid	6.2	6.2
3-Hydroxybenzoic acid	20.8	20.5
4-Hydroxybenzoic acid	19.8	19.6
2,4-Dihydroxybenzoic acid	71.9	[a]
3,4-Dihydroxybenzoic acid	93.2	[a]
3,5-Dihydroxybenzoic acid	125.6	[a]
Gallic Acid	>1000	[a]

[a] Not measured: retention volume too large.

Then, after adding a definite amount of the soluble polymer, $[F_0]_p$, to the system, k^* is measured according to Eq. 4. For systems where $K_p[A] \ll 1$ is valid, the rearranged Eq. 14 gives:

$$K_p = \frac{k - k^*}{k^*[F_0]_p} \qquad \text{(Eq. 17)}$$

Equilibrium dialysis was used as a supplementary technique to perform binding studies of some systems.

In this case the evaluation of data is based on Eq. 5:

$$K_p = \frac{k^{**} - 1}{[F_0]_p - (k^{**} - 1)[A]} \qquad \text{(Eq. 18)}$$

where the experimentally accessible coefficient k^{**} is introduced describing the distribution of the drug between the polymer-free and polymer-containing dialysis compartments, according to:

$$k^{**} = \frac{[A] + [FA]_p}{[A]} \qquad \text{(Eq. 19)}$$

For the strongly interacting tannic acid, the approximation, $K_s[A] \ll 1$, is invalid, and the Nernst coefficient, k, becomes strongly dependent upon $[A]$. The experimental results of the interaction with II can be described with a model where two classes of independent binding sites are assumed to be operative. Each class is characterized by a specific interaction constant, $K_{s,1}$ and $K_{s,2}$, respectively. With reference to Eq. 10, the interaction can be described by:

$$k_{1,2} = 1 + \frac{K_{s,1}[F_0]_1}{1 + K_{s,1}[A]} + \frac{K_{s,2}[F_0]_2}{1 + K_{s,2}[A]} \qquad \text{(Eq. 20)}$$

where $[F_0]_1$ and $[F_0]_2$ refer to the concentration of available binding sites of Class 1 and Class 2.

There exists a simple relationship between K_p, as defined by Eq. 5, and the binding constant, K, defined by the basic theory of ligand–polymer interaction as advanced by Klotz *et al.* (42) and by Scatchard (43). The interaction with independent binding sites is described by:

$$r = \frac{nK[A]}{1 + K[A]} \qquad \text{(Eq. 21)}$$

where r is the number of moles of ligand bound per monomer unit of the polymer, $r = [FA]/[F_0]_p$, n represents the total number of sites available, and K is the binding constant. Introducing Eq. 5 into Eq. 21 and considering $[FA] \ll [F_0]_p$ gives:

$$K_p \approx \frac{nK}{1 + K[A]} \qquad \text{(Eq. 22)}$$

and for $K[A] \ll 1$:

$$K_p \approx nK \qquad \text{(Eq. 23)}$$

The product, nK, is equal to the first binding constant, k_1, which is a measure for the strength of the binding. Values of $nK = k_1$ are commonly

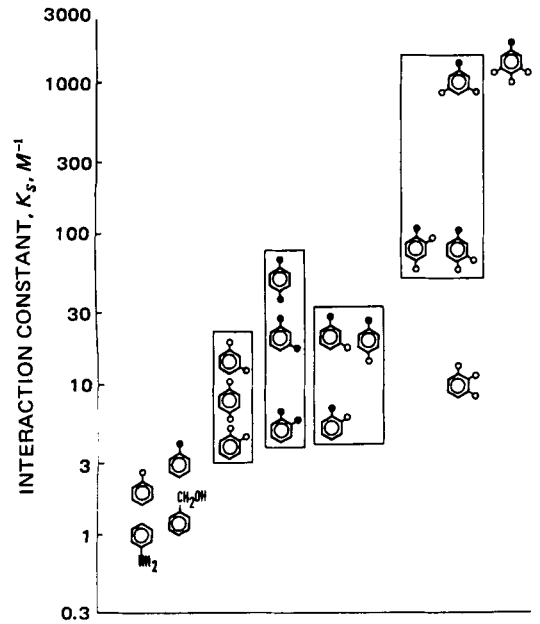

Figure 3—*Interaction constant, K_s, of various aromatic model compounds characterizing the influence of the nature, number, and position of hydrogen donating functional groups on the interaction with II. Key: (○) hydroxide group; (●) carboxyl group.*

deduced from the slopes of linear binding plots according to Klotz *et al.* (42) or Scatchard (43). Values of n, however, can be determined only with much uncertainty (44). Their physical relevance is doubtful.

RESULTS AND DISCUSSION

Figure 1 shows a typical chromatogram of a sample solution composed of three drugs. Each component is characterized by a specific retention volume indicating the degree of interaction with II. The theoretically proposed linear correlation between the interaction constant, K_s, and the retention volume, V_r, (Eq. 11) is experimentally corroborated in Fig. 2 where for a series of drugs and drug models the retention volume, V_R, is plotted against the interaction constant, K_s, as obtained from sorption studies. The linear correlation between the results of the sorption experiments and the chromatographic studies clearly indicates a reversible interaction of the active ingredients with II. Apparently, the adjustment of equilibrium takes place rapidly enough so that the provisions for true partition chromatography are satisfied. Hence, by the data of Fig. 2, a chromatographic technique is established that offers new and convenient means for the investigation of interactions between drugs and crospovidone. As was shown before, the method is readily extended to binding studies with soluble polymer additives by adding the respective polymer to the mobile phase.

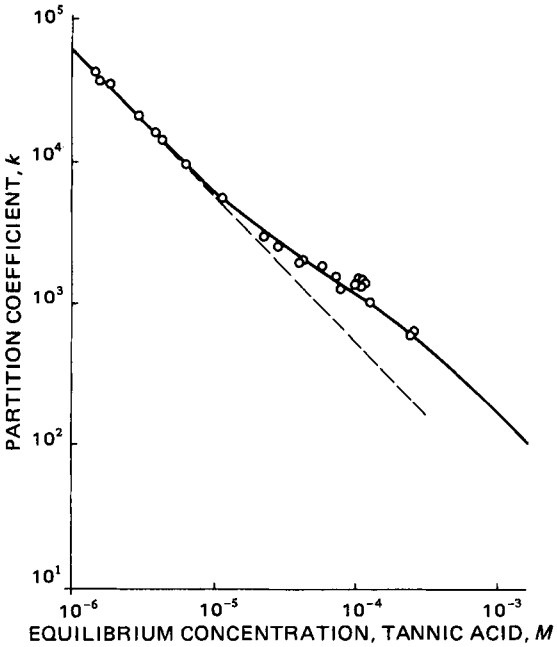

Figure 4—*Dependence of the Nernst coefficient, k, on the equilibrium concentration of tannic acid interacting with II in 0.1 N HCl suspensions. The curve was calculated according to Eq. 20 using $[F_0]_1 = 0.12$ M; $K_{s,1} = 10^4$ M^{-1}; $[F_0]_2 = 0.06$ M; $K_{s,2} = 10^7$ M^{-1}.*

Table III—Binding Data of the Interaction Model Compounds and Drugs with I in 0.1 *N* HCl at 25°

Compound	Binding Constant, K_p, M^{-1} Sorption Method	Chromatography Method	Dialysis Method
Acetaminophen	<1	<1	1.5
Aspirin	<1	<1	0.7
Benzoic acid	<1	<1	0.9
Chloramphenicol	[a]	[a]	0.4
1,2-Dihydroxybenzene	<1	<1	0.8

Sulfamoxole	[a]	[a]	0.3
Trimethoprim	[a]	[a]	0.2

[a] Not measurable: K_s too small.

The chromatographically determined K_s-values of various drugs are listed in Table I. As expected from Fig. 2, they are found in close agreement with the corresponding values obtained from sorption experiments. All drugs are characterized by K_s-values <5 M^{-1}. The K_s-values of the model compounds are listed in Table II. They range from 1 M^{-1} to ~1000 M^{-1}.

The data of Tables I and II agree with findings of an earlier study (29) where the tendency for the complex formation with II was found closely correlated with the ability of the drugs to act as hydrogen donators. Accordingly, none of the compounds of Table I characterized by K_s-values <0.1 M^{-1} carries hydroxide or carboxyl groups bound to aromatic residues. The ability of aromatic amines to act as hydrogen donators is known to be small, and compounds of Table I belonging to this class exhibit K_s-values <1 M^{-1}. Besides hydrogen binding, mechanisms of hydrophobic interaction can be operative, as found with several phenothiazine derivatives, in close agreement with observations of Voigt *et al.* (18). However, interactions with I or II based on this hydrophobic mechanism are found to be moderate.

The significance of hydrogen binding for the occurrence of strong interactions with I or II can best be shown by the data obtained with the model compounds, as listed in Table II. In Fig. 3, the correspondence between the strength of interaction and the number and position of hydrogen-donating functional groups is documented. Aromatic carboxylic acids form stronger complexes than phenols. The complexation tendency increases with the number of hydrogen-donating functional groups. In all bifunctional compounds, the weakest complexes are formed by the *ortho* isomers. Steric effects are apparently responsible for the fact that with biphenols, the *meta* isomer, and with the corresponding carboxylic acids, the *para* isomer exhibit the strongest interaction tendency.

For trifunctional compounds the importance of the *meta* position of the active ligands is again emphasized: the K_s-value of 3,5-dihydroxybenzoic acid is by an order of magnitude larger than that of the corresponding 2,4- and 3,4-isomers, where in both cases an unfavorable *ortho* substitution reduces the interaction tendency. The accumulation of *ortho* substituents in 1,2,3-trihydroxybenzene causes a further reduction of K_s by an order of magnitude.

As reported earlier (29), tannic acid forms exceptionally strong complexes with II; the same is true for the interaction with I. An explanation for this exceptional interaction tendency immediately follows from its multifunctional chemical structure based on gallic acid and digallic acid. According to Fig. 3, gallic acid already exhibits a K_s-value of ~1000 M^{-1}. The accumulation of residues of this nature within the tannic acid mol-

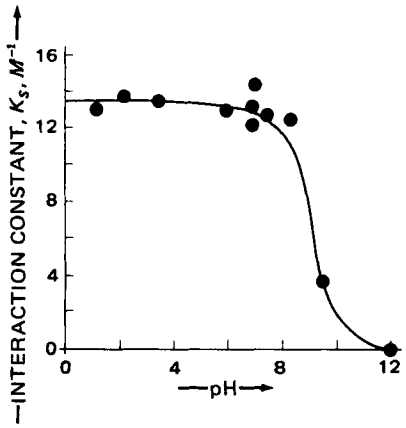

Figure 5—*Influence of pH on the interaction of resorcinol with II.*

ecule leads to a further increase of K_s. The approximation, $K_s\,[A] \ll 1$, is no longer valid and k becomes dependent on A.

Figure 4 shows the results of interaction studies with II extending beyond the concentration range of earlier investigations (29). The dependence of the partition coefficient, k, upon $[A]$ is satisfactorily described by model calculations based on Eq. 20, assuming two classes of binding sites, F_1 and F_2, on part of the polymer. The corresponding interaction constants, $K_{s,1}$ and $K_{s,2}$, are determined to be of the order of 10^4 and 10^7 M^{-1}, respectively. Hence, tannic acid exceeds other model compounds and drugs in its interaction tendency toward II by several orders of magnitude. Similar results were obtained for the interaction with I but are not shown here in detail. The concentration of available binding sites, $[F_o]_1$ and $[F_0]_2$, is determined to be 0.12 and 0.06 M, respectively. These figures are well below the theoretical limit of 9 M for polyvinylpyrrolidone, underlining the fact that one interacting molecule of tannic acid, owing to its extended molecular structure, covers many vinylpyrrolidone units in the polymer.

The results of the binding studies with I are listed in Table III. The chromatographically determined values of K_p satisfactorily agree with those data obtained by standard equilibrium dialysis. (In the present study all values of K_s or K_p are defined by relating to the molecular weight of a monomer segment of the polymer. This is preferable to using often ill-defined molecular weight data of the polymer.)

The application of the chromatographic technique for determining K_p requires a minimum interaction between the investigated active ingredient and II used as a stationary phase. In general, the interaction tendencies of drugs with both I and II are closely corresponding (29). Therefore, the chromatographic technique can best be applied in cases where moderate to strong interaction is occurring. In studies of weak interaction, equilibrium dialysis yields more reliable data.

All interaction data presented so far relate to pH conditions of gastric fluids. They define upper limits for the interaction constants for all systems where hydrogen binding dominates the complexation reaction. With increasing pH, the degree of dissociation of the hydrogen donating functional groups rises, and, correspondingly, the interaction tendency is expected to decrease. For example, Fig. 5 depicts the pH dependence of K_s as observed with resorcinol. Other examples of a similar pH dependence were recently reported (45). Even in cases of very strong interaction, as observed with several model compounds, the interaction constants start to drop at pH values >4. With tannic acid, a decrease of the K_s values was observed, starting from $\gg$10,000 M^{-1} at pH 1 and ending at ~50 M^{-1} at pH 12. These observations further support the notion of hydrogen-binding being the dominating mechanism in moderate to strong interactions with I or II, even in cases of high molecular weight compounds like tannic acid. In hydrophobically interacting systems, a significant influence of pH on the strength of interaction was observed only with some phenothiazines (18). The reason for the decrease with increasing pH is not fully understood.

The significance of the reported data for practical applications becomes apparent in calculations of the bound amount of an active ingredient in a pharmaceutical formulation or after administering the drug. Knowing the respective values of K_s or K_p, the assessment can be based on Eqs. 5 or 6, since reversibility of the interaction has been proved with a representative selection of systems by desorption studies (29). The feasibility of the chromatographic technique requiring a reversible interaction of the involved components further supports this notion.

In Fig. 6 the bound fraction of the active ingredient is plotted as a function of the interaction constant, K_s, for various concentrations of the polymer additive, II. The graph is applicable for weighing-in concentrations of the active ingredient between 1×10^{-4} and 2×10^{-3} M, covering the concentration range usually encountered in practice. If the oral administration of two tablets containing 10% by weight of the additive II is considered as an example of practical relevance, then the additive concentration in the gastric fluid can hardly exceed a value of 0.5 g/liter. In Fig. 6 the relevant area is marked by shading. Considering the fact that—with the exception of tannic acid and related compounds—K_s of active ingredients is limited to values <10 M^{-1}, the bound amount can not excel the 3% limit. Differences in the salt concentration, not accounted for in this estimate, cannot affect this figure to a significant degree. As was pointed out before, in respect to a possible dependence upon pH, this figure constitutes an upper limit.

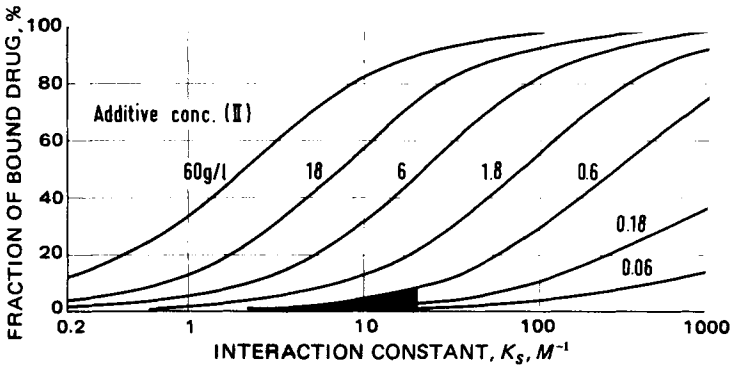

Figure 6—*Fraction of drug bound to II as a function of the interaction constant, K_s, for various concentrations of II. The graph is valid for concentrations of the active ingredient $[A_0]$, between 1×10^{-4} and 2×10^{-3} M, covering the range of practical interest. The significance of the shaded area is explained in the text.*

Another way of interpreting the data is offered in Fig. 7, where the bound fraction of the drug is plotted as a function of the additive I concentration for various values of K_p. Considering the data of Table III, it immediately follows that for all practical purposes the fraction of the drug bound by the additive after oral administration is estimated in the range of a few percent.

Graphs as shown in Figs. 6 and 7 offer the opportunity to transfer binding data that are sometimes, for experimental reasons, obtained at excessively high levels of additive concentration into a concentration range of more practical relevance. In studies of the interaction properties of I, polymer concentrations as high as 50 g/liter were frequently used (7, 10, 46, 47). From Fig. 7 it can be deduced that at this level of additive concentration, the bound fraction of compounds with even moderate binding tendency, as corresponding to $K_p \sim 1$ M^{-1}, amounts to ~30%. This is illustrated by a recent investigation of the inhibitory effect polyvinylpyrrolidone may exhibit on the absorption of acetaminophen (47). The binding constant, K, was determined (42) at pH 6.4 as 23 M^{-1} with $1/n = 18.5$. Considering Eq. 23, it follows that $k_1 = 1.24$ M^{-1}, which

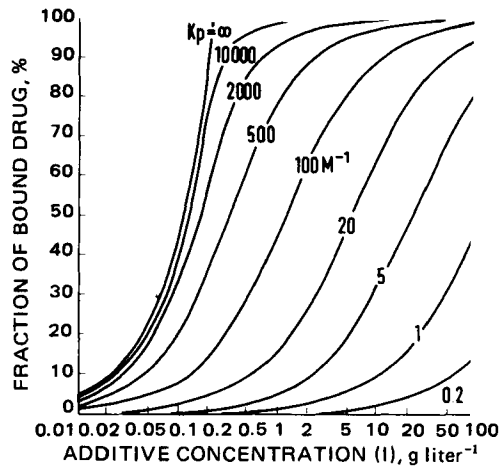

Figure 7—*Fraction of drug bound to I as a function of the additive concentration (I), for various values of the binding constant, K_p. The graph is valid for concentrations of the active ingredient, $[A_0]$, between 1×10^{-4} and 2×10^{-3} M.*

is in close agreement with $K_p = 1.5\ M^{-1}$ of the present study. By inspection of Fig. 7, a bound fraction of ~35% is estimated at an additive concentration of 50 g/liter as was applied in the respective study.

At an additive concentration of 0.5 g/liter, however, considered as typical for the oral administration of drugs, the bound fraction of the drug falls to a level close to zero, as shown in Fig. 7.

For tannic acid and related compounds in the acidic pH range, even at a polymer concentration as low as 0.5 g/liter, the bound fraction is >95%, a fact that is advantageously used in practice (24–26).

CONCLUSIONS

The chromatographic method proposed in the present study represents an easy to use experimental technique for a rapid assessment of interaction properties of drugs in systems containing soluble or insoluble polymer additives. The determination of interaction constants in the range of $>1\ M^{-1}$ is reduced to the readily performed determination of retention volumes. As was shown in detail, only interactions with K_s and/or K_p values above this limit are of practical interest. With the exception of tannic acid and related compounds, all drugs investigated in the present study exhibited K_p- or K_s-values well below an upper limit of $10\ M^{-1}$, indicating that with commonly used additive concentrations of I or II, the bound fraction of the drug after oral administration can hardly exceed a limit of the order of 3%. Considering further the fact that binding is reversible, and in view of the observed pH dependence of binding strength, the presence of these additives is not expected to interfere with the GI absorption of the pharmaceutical.

However, as can be seen from Fig. 7, at additive concentrations of 10–50 g/liter, often used in standard binding studies, the fraction of bound active ingredient can readily amount to 30%, even in cases of moderate binding. Additive concentrations of this order of magnitude are never applied in practice. The graphs of Figs. 6 and 7 may, therefore, assist in using the large body of available binding data for a sensible assessment of the degree of binding in systems of practical relevance.

Isocratic High-Performance Liquid Chromatographic Method for the Determination of Tricyclic Antidepressants and Metabolites in Plasma

S. M. JOHNSON, C. CHAN, S. CHENG, J. L. SHIMEK, G. NYGARD, and S. K. WAHBA KHALIL ˣ

Received August 21, 1981, from the *Pharmacokinetic Drug Analysis Laboratory, College of Pharmacy, North Dakota State University and Veterans Administration Medical Center, Fargo, ND 58102.* Accepted for publication December 10, 1981.

Abstract □ An isocratic high-performance liquid chromatographic method for the determination of six tricyclic antidepressants and their major metabolites is presented. Hexane containing 0.5% diethylamine was used as an extraction solvent to minimize adsorption onto glass. A reversed-phase cyanopropylsilane column was used with a mobile phase consisting of 70% acetonitrile and 30% 0.03 *M* acetate buffer, pH 7.0. Good identification and quantitation were obtained by the use of both UV detection at 245 nm and spectrofluorometric detection with an excitation wavelength of 276 nm and an emission filter with a 370-nm cutoff. A minimum detectable limit of <5 ng/ml of plasma is possible with this system. The reproducibility and precision of the method are shown from the analysis of samples containing 20–400 ng/ml in plasma.

Keyphrases □ Antidepressants—tricyclic, isocratic high-performance liquid chromatographic method for the determination of metabolites in plasma □ Metabolites—isocratic high-performance liquid chromatographic method for the determination of tricyclic antidepressants in plasma □ High-performance liquid chromatography—isocratic determination of tricyclic antidepressants and metabolites in plasma

Tricyclic antidepressants have been used extensively in the treatment of psychiatric patients suffering from depression. The relationship between the plasma concentration of these drugs and their clinical effect on depressive symptoms is controversial (1), but monitoring therapeutic levels is important, since the side effects of these drugs are quite common and mainly dose related (2). The major metabolic pathways are demethylation and hydroxylation (3).

In a recent two-part review article (4, 5), both the methodology and the pharmacokinetics of tricyclics were reviewed. The methodology review lists several methods for the determination of tricyclics and their metabolites. Many of the methods, including UV spectrometry (6, 7), fluorimetry (8), and TLC (9), are nonspecific, since the compounds are difficult to separate and the major metabolites have spectral characteristics similar to the parent drugs. Radioimmunoassay has been used, although many antisera show substantial cross reactivity (10).

GLC methods require either derivatization of the compounds or a selective detector (11–14). Quantitation of tricyclic antidepressants and their metabolites have also been performed by high-performance liquid chromatography (HPLC) (15–19), but most of the reported methods did not include the hydroxy metabolites which have been shown to be pharmacologically active (20). Most methods also involve an elaborate multistep extraction procedure.

The present report describes the separation and determination of the most commonly prescribed tricyclic antidepressants. The method involves one extraction step followed by HPLC using a reversed-phase cyanopropylsilane column and dual UV and fluorescence detection. The method is applicable to the direct determination of plasma levels in the presence of one or more of several drugs which might be prescribed concurrently. The applicability of the method has been demonstrated by the analysis of plasma from patients receiving tricyclic antidepressants. The determination of amitriptyline includes the simultaneous analysis of its most important metabolites in plasma.

EXPERIMENTAL

Instrumentation—A high-performance liquid chromatograph[1] was equipped with a fluorometric detector[2] and a cyanopropylsilane[3] column (250 mm long, 4.6-mm i.d.). The degassed mobile phase was pumped through the column at 3.0 ml/min (20–22 mPa). The column compart-

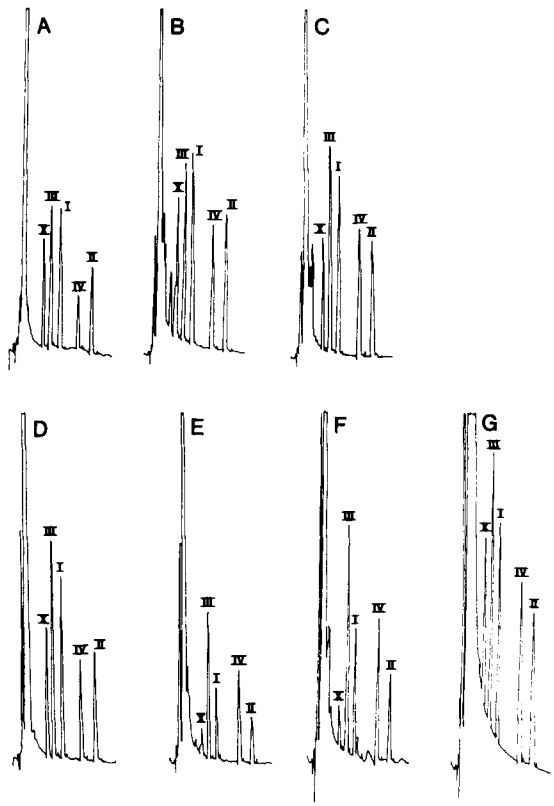

Figure 1—*Chromatograms of the extracts of 1.0 ml of plasma containing 200 ng/ml each of I, II, III, and IV. The extracts were reconstituted with 100 μl of methanol, injection volume 30 μl, absorbance at 245 nm. ment was maintained at 45°. The UV was monitored at 245 nm and the fluorometer was set at an excitation wavelength of 276 nm. An emission cutoff filter (type 370 nm) was used.

Chemicals and Reagents—Sodium acetate, sodium phosphate, acetic acid, phosphoric acid, diethylamine, sodium hydroxide, isoamyl alcohol, and isobutyl alcohol were reagent grade. HPLC grade methanol, acetonitrile, hexane, heptane, ethyl acetate, and methylene chloride were used. Amitriptyline hydrochloride (I)[4], nortriptyline hydrochloride (II)[5], 10-hydroxyamitriptyline (III)[4], 10-hydroxynortriptyline hydrogen maleate (IV)[4], imipramine hydrochloride (V)[6], desipramine hydrochloride (VI)[7], doxepin hydrochloride (VII)[8], demethyldoxepin hydrochloride (VIII)[8], protriptyline hydrochloride (IX)[4], and trimipramine hydrochloride (X)[9] were obtained commercially.

Mobile Phase—Sodium acetate solution (0.03 *M*) was prepared in deionized distilled water, and the pH was adjusted to 7 by the gradual addition of acetic acid. The mobile phase consisted of 70% acetonitrile and 30% buffer.

Solution Preparation—*Drug Stock Solutions*—Separate solutions of each drug and metabolite were made containing 5 mg of free base/10 ml of methanol.

Working Drug Solutions—Dilutions to working concentrations (5 ng/μl) were made with methanol for drug–metabolite groups (I–IV; V–VI; VII–VIII) or for a single drug (IX).

Extraction Solution—The internal standard stock solution (X) was diluted with hexane containing 0.5% diethylamine to a concentration of 20 ng/ml.

Sample Preparation—An aliquot (4–80 μl) of the drug working solution containing 20–400 ng, 0.5 ml of 0.1 *M* NaOH, and 10 ml of extraction solution were added to 1.0 ml of heparinized plasma in a 15-ml screwcapped centrifuge tube. The tubes were vortexed for 10 sec and centrifuged for 5 min at 900×*g*. A 9-ml volume of the organic phase was transferred to special concentration tubes[10] and evaporated to dryness at 30° under a gentle stream of nitrogen.

HPLC Separation and Quantitation—The residue was dissolved in 100 μl of methanol and transferred to a polypropylene micro-vial[11] before injection of 30 μl into the HPLC. A standard curve was constructed utilizing a minimum of four replicate plasma extractions simulating concentrations of drugs and metabolites from 20 to 400 ng/ml. The chromatograms were recorded at a chart speed of 5 mm/min. The peak heights were measured, and the ratios (drug/internal standard and metabolite/internal standard) were calculated and plotted *versus* concentration expressed as nanograms per milliliter of plasma.

Interferences—Possible interferences from normal plasma constituents, as well as other drugs and metabolites, were studied.

Factors Affecting Extraction Efficiency—The amounts of drugs and their metabolites extracted at pH 12 were studied using hexane, methylene chloride, ethyl acetate, hexane containing 0.5% diethylamine, hexane containing 2% isoamyl alcohol, methylene chloride containing 0.5% diethylamine, and heptane containing 4% isobutyl alcohol. Extractions were carried out at three different pH values (7.4, 9.5, and 12) with the following solvents: hexane, hexane containing 0.5% diethylamine, and methylene chloride.

Adsorption onto Glass—The effect of several agents on the adsorption of tricyclics and their metabolites onto glass during extraction and evaporation was studied. Diethylamine, isoamyl alcohol, isobutyl alcohol, and silanization of glass were tried.

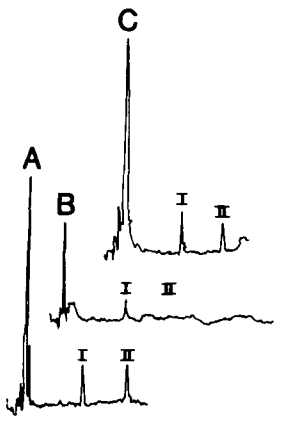

Figure 2—*Chromatograms showing the effect of solvents on adsorption of I and II onto glass. Injection volume 20 μl of 0.2 ng/μl, absorbance at 245 nm. Key: (A) methanol; (B) hexane; (c) hexane plus 0.5% diethylamine.*

Mesoridazine	8.75	+	+

[a] Absorbance at 245 nm. [b] Fluorescence at 276/370 nm. [c] SF is the solvent front.

Patient Samples—Heparinized plasma samples from patients receiving oral tricyclic antidepressant therapy were extracted in duplicate using the same procedure. The amounts of drug and metabolites in patient samples were calculated by comparison with a standard curve prepared daily.

RESULTS AND DISCUSSION

The choice of extraction conditions is based on a compromise between extraction yield and selectivity of extraction. Extraction with hexane afforded a cleaner extract than several other solvents (Fig. 1). The addition of 0.5% diethylamine to the hexane minimized the adsorption of the tricyclics onto the glass surface (Fig. 2). This observation confirms that reported previously (21). Evaporation under nitrogen at 30° minimized volatilization of drugs and metabolites and yet is sufficient for ready evaporation of diethylamine and hexane. In addition, the use of an organic phase–aqueous phase ratio in extraction of 10:1.5 made it possible to have a high yield in one extraction step. A slightly higher yield was obtained at pH 12 than pH 7.4 or 9.5. Reconstitution in methanol was chosen over the mobile phase because glass adsorption from acetonitrile considerably reduced the peak heights and prevented accurate quantitation. The effect was the greatest for the metabolites.

The use of a cyanopropylsilane column in a reversed-phase mode with a mobile phase of 70% acetonitrile and 30% acetate buffer (0.03 *M*, pH 7) produced good separation of several tricyclics (Fig. 3) and between each drug and its respective major metabolites. The separation of I–IV depends on the pH and molarity of the buffer as well as the percent acetonitrile in the mobile phase. This is illustrated by the change of *K* values (Fig. 4). The pH, molarity, and percent acetonitrile of the mobile phase may be varied slightly to obtain separation on cyanopropylsilane columns of different manufacturers or on a column after a period of use. The use of fluorescence detection is not necessary for the analysis, since all of the drugs and metabolites absorb at 245 nm and only V, VI, and IX fluoresce. Dual detection using both absorbance and fluorescence is helpful, however, to afford exact identification and good quantitation. The drugs may be monitored at 254 nm with only a slight loss of sensitivity. Monitoring at 288 nm or by fluorescence will enhance the sensitivity for IX. Trimipramine was chosen as the internal standard because it has almost equal absorbance and fluorescence under the experimental conditions and is well separated from all the drugs and metabolites.

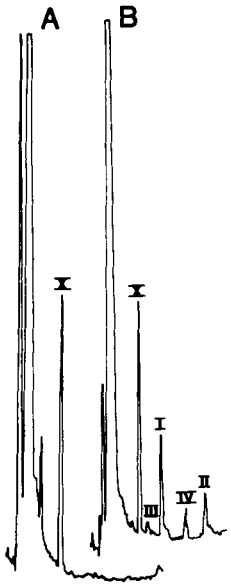

Figure 5—*Typical chromatograms of extracts of 1 ml of plasma, injection volume 30 μl, absorbance at 245 nm. Key: (A) drug free; (B) patient receiving I orally. Concentrations of compounds expressed as ng/ml of plasma are I = 87, II = 50, III = 7, and IV = 38.*

The ratios of the peak heights of the drugs and metabolites to the peak height of the internal standard were calculated. Statistical analysis of the data (Table I) by linear regression indicated linearity and reproducibility in the 20–400-ng/ml range of plasma. This range includes the therapeutic range of the drugs. Absolute recovery of the drugs and metabolites ranged from 55 to 80% of the theoretical amounts. This low recovery may be responsible for the variation in the amount found at low concentrations (Table I). The minimum detectable limit for the compounds is <5 ng/ml of plasma.

No interference from normal plasma constituents was observed (Fig. 5A). Also, several drugs which might be prescribed simultaneously with tricyclics were chromatographed. The retention times are listed in Table II.

The method has been applied to many patient samples and is being used routinely in the laboratory for monitoring therapeutic levels (Fig. 5B). Major advantages of the method are its simplicity, rapidity, and high sensitivity. All of the drugs and metabolites, including the 10-hydroxy metabolites of amitriptyline and nortriptyline, are determined using a single procedure. Adsorbance of the drugs onto glass has been minimized.

Chelation of Mercury by Polymercaptal Microspheres: New Potential Antidote for Mercury Poisoning

S. MARGEL ˣ **and J. HIRSH**

Received February 18, 1981, from the *Department of Plastics Research, The Weizmann Institute of Science, Rehovot, Israel.* Accepted for publication November 17, 1981.

Abstract □ Newly synthesized polymercaptal microspheres of 0.8 ± 0.02 μm were shown to have a specific and fast intake of mercury compounds over a whole range of pH while maintaining low toxicity. The microspheres bind easily with mercury compounds which are already bound to the biological mercury binders, albumin or cysteine. Mercury was recovered completely from the microspheres by using a solution of thiourea in hydrochloric acid. Due to their high surface area, low toxicity, and strong affinity toward mercury compounds, the microspheres have a potential use as a new oral drug for treatment in cases of mercury poisoning.

Keyphrases □ Microspheres—chelation of mercury, polymercaptal, new potential antidote for mercury poisoning □ Mercury—chelation by polymercaptal microspheres, new potential antidote for poisoning □ Chelation—mercury, polymercaptal microspheres, new potential antidote for mercury poisoning

Mercury compounds, both organic and inorganic, constitute an environmental and agricultural hazard (1, 2). Severe poisoning is known to cause brain damage, fetal disabilities, and death (2, 3). The therapy for mercury poisoning includes intravenous administration of the chelating drugs dimercaprol and/or penicillamine (4).

Chelation of Mercury by Polymercaptal Microspheres: New Potential Antidote for Mercury Poisoning

S. MARGEL ˣ **and J. HIRSH**

Received February 18, 1981, from the *Department of Plastics Research, The Weizmann Institute of Science, Rehovot, Israel.* Accepted for publication November 17, 1981.

Abstract □ Newly synthesized polymercaptal microspheres of 0.8 ± 0.02 μm were shown to have a specific and fast intake of mercury compounds over a whole range of pH while maintaining low toxicity. The microspheres bind easily with mercury compounds which are already bound to the biological mercury binders, albumin or cysteine. Mercury was recovered completely from the microspheres by using a solution of thiourea in hydrochloric acid. Due to their high surface area, low toxicity, and strong affinity toward mercury compounds, the microspheres have a potential use as a new oral drug for treatment in cases of mercury poisoning.

Keyphrases □ Microspheres—chelation of mercury, polymercaptal, new potential antidote for mercury poisoning □ Mercury—chelation by polymercaptal microspheres, new potential antidote for poisoning □ Chelation—mercury, polymercaptal microspheres, new potential antidote for mercury poisoning

Mercury compounds, both organic and inorganic, constitute an environmental and agricultural hazard (1, 2). Severe poisoning is known to cause brain damage, fetal disabilities, and death (2, 3). The therapy for mercury poisoning includes intravenous administration of the chelating drugs dimercaprol and/or penicillamine (4).

0022-3549/82/0900-1030$01.00/0

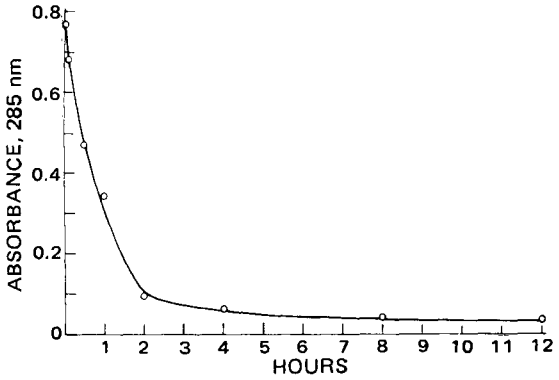

Figure 1—*Change of the absorbance at 285 nm during the reaction between glutaraldehyde and pentaerythritol tetrathioglycolate. The reaction was carried out by stirring 4.5 mmoles of glutaraldehyde with 4.5 mmole of pentaerythritol tetrathioglycolate in 30 ml of H_2O at pH 4.0, at room temperature.*

Recently, new types of water soluble drugs, 2,3-dimercapto-succinic acid (5) and dithiocarbamate compounds (6) were synthesized and suggested as intravenously administered antidotes for mercury poisoning. Another approach which has been tried successfully in cases of mercury poisoning, in particular methyl mercury, is based on the oral administration of insoluble polythiol resins which bind mercury compounds and thereby increase their fecal excretion (7–9).

In the present study the use of insoluble chelating microspheres specific for mercury compounds as a potential oral antidote for mercury poisoning is suggested. For this purpose polymercaptal microspheres of 0.8 ± 0.02 μm were synthesized. The large surface area of these microspheres, as well as their low toxicity and strong affinity toward mercury compounds renders them as good candidates to be used in cases of mercury poisoning.

EXPERIMENTAL

Reagents—All reagents were of analytical grade and used as received. A phosphate-buffered solution was prepared by adding sodium hydrogen phosphate solution (0.1 *M*) to an aqueous solution of sodium dihydrogen phosphate (0.1 *M*) until a pH of 7.2 was reached. The solution was then diluted 10 times with distilled water. Phosphate-buffered saline solution was prepared by adding sodium chloride to the phosphate-buffered solution to obtain a final concentration of 0.15 *M*. The following reagents gave a very small mercury blank value and could be used without further purification: sulfuric acid, hydrochloric acid, stannous chloride, hydroxylamine hydrochloride, potassium permanganate, and deionized water. The stock solution of mercuric chloride and of methyl mercury chloride was prepared in 10% HCl. Standards were prepared from the stock solution by diluting with 10% HCl. Glassware was soaked in concentrated nitric acid for several hours before use.

Mercury Analysis—Mercury was determined by cold vapor atomic absorption with a cold vapor analyser kit[1] (10). The limit of detection for this procedure is 0.15 ng in 1.0 ml of solution.

Binding of Mercury Compounds to Albumin—A phosphate-buffered saline solution containing 4.0% normal human albumin was shaken for 2 hr with methyl mercury chloride or with mercuric chloride (20 ppm Hg). The binding with mercuric chloride was determined by placing the solution into ultrafiltration membranes[2] and centrifuging it for 5 min at 1000 rpm. The binding with methyl mercury chloride was determined by ultrafiltration of the solution through a dialyzing membrane with a permeability corresponding to a molecular weight of 10,000. In both cases mercury was not detected in the ultrafiltrate, indicating that the mercury compounds were completely bound to albumin.

Chelating Microspheres—An aqueous solution containing 0.2% (v/v) polyoxyethylene sorbitan monolaurate[3] as surfactant and 5% (v/v) pentaerythritol tetrathioglycolate was vigorously stirred for several hours until a stable aqueous emulsion of pentaerythritol tetrathioglycolate was produced. Thereafter, 5.5 ml of 25% glutaraldehyde was added to the emulsion solution which was then shaken for 12 hr. The reaction product was composed of a solid sticky compound that resulted from the agglutination of chelating microspheres and 60% disperse solid chelating microspheres. The microspheres were separated by decantation from the sticky part and cleaned from impurities either by dialysis or by slow spinning. The appearance and size of the microspheres was determined by scanning electron and light microscopy.

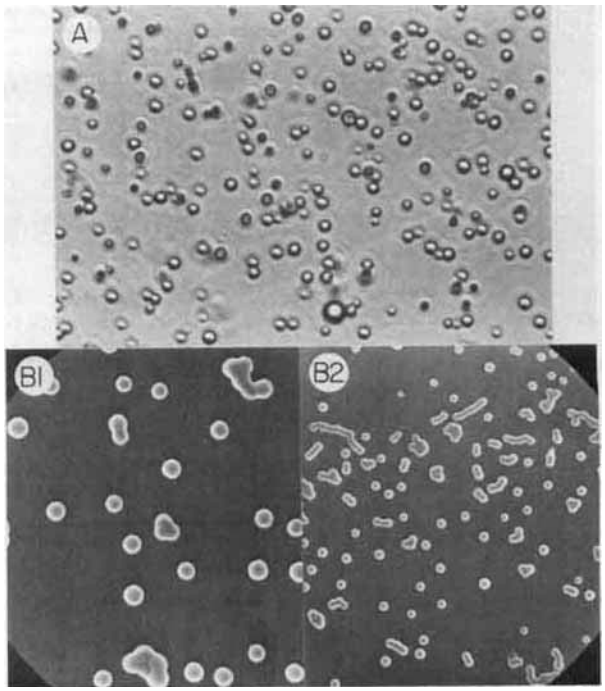

Figure 2—*(A) Light microscopy photomicrograph of chelating microspheres (×3000). (B) Scanning electron microscopic photomicrographs of chelating microspheres (1, 3100×; 2, 6300×).*

Toxicity—The acute median lethal dose (LD_{50} orally) to 40 mice[4] of the chelating microspheres was found to be 1.0 g/kg of body weight.

Intake of Mercury Compounds by Chelating Microspheres—The chelating microspheres were added to a stirred phosphate-buffered saline solution containing mercury compounds. Samples to be tested for mercury concentration were spun at 10,000 rpm for 10 min, thereby separating the solution from the precipitating microspheres. Control experiments were carried out in the same way but without chelating microspheres. (Spinning of the control samples did not show any precipitation of mercury compounds.)

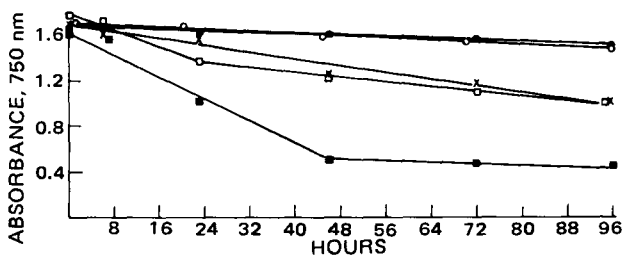

Figure 3—*Aggregation properties of the chelating microspheres. The absorbances at 750 nm were obtained by diluting 0.05 ml of the chelating microsphere suspension (containing 20 mg/ml) with 2.5 ml of H_2O. Key: (○) microspheres in H_2O; (×) microspheres in phosphate-buffered solution; (□) microspheres in phosphate-buffered saline solution; (■) microspheres in aqueous solution at pH 1.1; and (●) microspheres in phosphate-buffered saline solution under shaking.*

Table I—Yield of Chelating Microspheres as a Function of pH [a]

pH [b]	Yield, %
7.0	70
4.0	60
2.0	6
0.5	1

[a] Glutaraldehyde (25%, 5.5 ml) was added to a shaken aqueous suspension (100 ml) of pentaerythritol tetrathioglycolate (5 ml), at various pHs. [b] pH 7.0 was obtained by adding sodium hydroxide to the aqueous suspension; pH 2.0 and pH 0.5 were obtained by adding hydrochloric acid to the aqueous suspension.

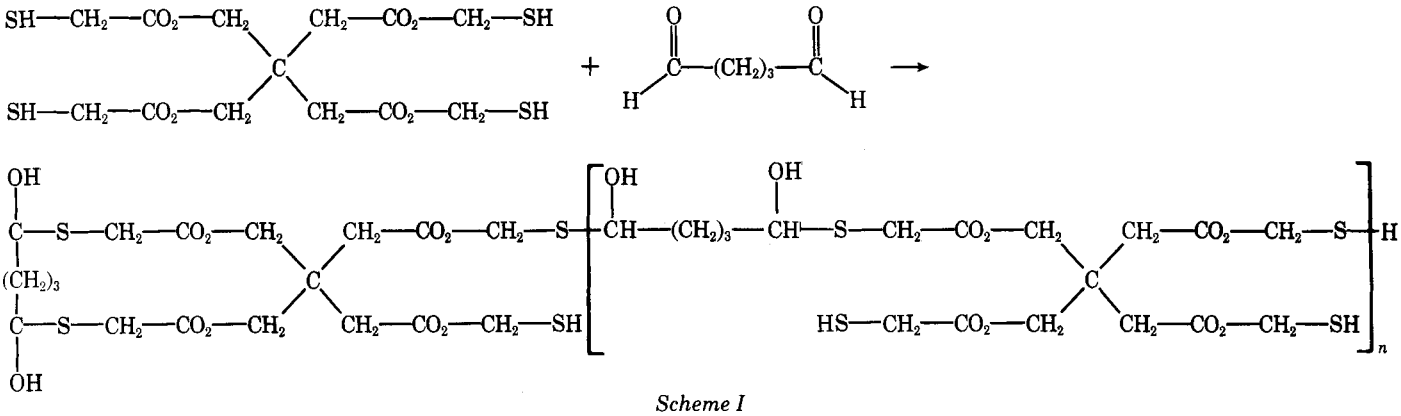
Recovery of Mercury Compounds from Chelating Microspheres—Fast and quantitative recovery of mercury compounds bound to microspheres was carried out by adding thiourea and hydrochloric acid to a stirred solution up to a final concentration of 1.0% CH_4N_2S and 0.5% HCl. In <10 min 100% of the mercuric chloride or of the methyl mercury chloride were recovered from the microspheres.

Photomicrographs—A photomicrograph of the microspheres was prepared by using a photographic flash light attached to a light microscope, thereby obtaining a focused picture of most of the moving microspheres.

A sample for scanning electron microscopy was prepared by drying a drop of a diluted solution of the microspheres on a cover slide which was then coated with gold.

RESULTS

The chelating microspheres were prepared by carrying out the reaction of glutaraldehyde and pentaerythritol tetrathioglycolate in the presence of the mentioned surfactant. The assumed reaction is shown in Scheme I:



Scheme I

The rate of the reaction was measured by following the disappearance of the absorbance at 285 nm, related to the aldehyde groups of glutaraldehyde (Fig. 1). The surfactant stabilized micelles of pentaerythritol tetrathioglycolate which were interacted with glutaraldehyde to form the insoluble microspheres (Fig. 2).

The chelating microspheres were found to be monodispersed with a diameter of 0.8 ± 0.02 μm. They were spherical with a calculated surface area with an average microsphere size of 8.04×10^{-8} cm^2. The yield of the microspheres is dependent on the pH of the reaction. At a lower pH the microspheres tend to agglutinate more and therefore their yield is lower (Table I). The stability of the chelating microsphere suspension was checked by following the change in the turbidity of the suspension (Fig. 3). Aggregation of microspheres was indicated by the decrease in the turbidity. The chelating microsphere suspension is stable in water and there was no indication of aggregation even after a year. The microspheres tend to sink slowly to the bottom of the container and can be resuspended by shaking them again. The tendency of the microspheres to aggregate at acidic pH or at a high salt concentration was prevented by continuous shaking. Supporting evidence for the stability results was obtained by looking at the monodispersity of the microspheres under a light microscope (Fig. 2A). In water, the monodispersed microspheres moved in a Brownian motion, and there was no indication of agglutinated microspheres even after a year. Under strong acidic conditions (pH 1.0) large aggregates slowly formed. Attempts were made to obtain a scanning electron microscopic photomicrograph of the microspheres (Fig. 2B-1 and B-2). However, some small aggregates of microspheres were obtained

Table II—Intake of Mercury Compounds by Chelating Microspheres in Presence of Alkali and Alkaline Earth Metallic Compounds [a]

[Hg], ppm	Metallic Compounds, *M*	Microspheres, mg	Hg Intake, %	Ca, Na, and Mg Intake, %
20 (Mercuric Chloride)	0.001 $CaCl_2$	15	100	0
20 (Mercuric Chloride)	0.15 NaCl	15	100	0
1 (Mercuric Chloride)	0.1 NaCl + $CaCl_2$ + $MgCl_2$	10	~95	0
20 (Methyl Mercury Chloride)	0.15 NaCl	15	100	0
1 (Methyl Mercury Chloride)	0.1 NaCl + $CaCl_2$ + $MgCl_2$	10	~95	0

[a] The mercury compounds were stirred with chelating microspheres for 15 min in 20 ml of aqueous solution.

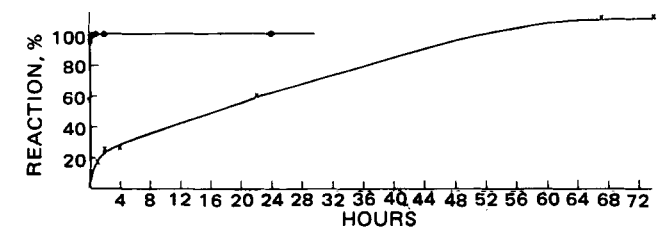


Figure 4—*Comparison of the rate of intake of mercuric chloride by chelating microspheres and agglutinated chelating microspheres. The reaction was carried out by stirring 10^{-4} M mercuric chloride (20 ppm Hg) and 20 mg of the chelating polymer in 50 ml of phosphate-buffered saline solution. Key: (●) chelating microspheres; (X) agglutinated chelating microspheres.*

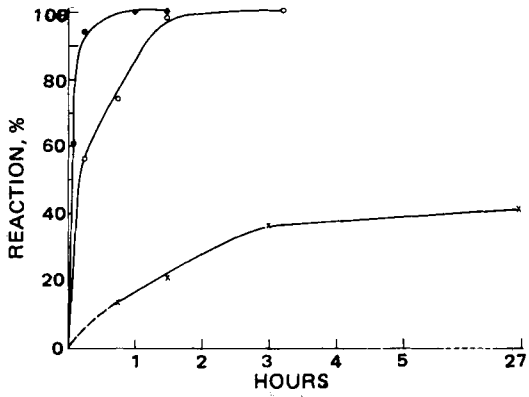

Figure 5—*Rate of intake of mercuric chloride by chelating microspheres. The reaction was carried out by stirring 10^{-4} M mercuric chloride in 80 ml of phosphate-buffered saline solution in presence of: (X) 3.5-mg microspheres; (○) 20-mg microspheres; (●) 60-mg microspheres.*

Table III—Percent Reaction of Mercuric Chloride with Chelating Microspheres at Various pH [a]

Time, min	pH [b]			
	2.0	4.0	7.1	8.5
10	98	98	97	98
120	100	100	100	97
240	100	100	100	95

[a] Mercuric chloride (10^{-4} *M*) was stirred with chelating microspheres (25 mg) in 50 ml of aqueous solution. [b] pH 2.0 and pH 4.0 were obtained by adding hydrochloric acid to 0.1 *M* sodium hydrogen phosphate aqueous solution. pH 8.5 was received by adding sodium hydroxide to 0.1 *M* H_2NaO_4P aqueous solution.

due to the drying of the sample. A photograph of higher concentration of microspheres could not be obtained since large aggregates of the microspheres were formed and single microspheres could not be found.

The chelating microspheres had a high surface area, and therefore, their rate of mercury intake was much higher than that of the same chelating compound in bulk (Fig. 4). Organic and inorganic mercury compounds are taken in by the microspheres very rapidly (Figs. 5 and 6), but do not interact with alkaline or alkaline earth metallic compounds (Table II). They bind the mercury compounds over a broad range of pH (Table III) and compete and bind mercury compounds which are already bound to albumin or to cysteine (Tables IV and V). Comparison with commercial resins reported to have a high affinity for mercury, *e.g.*, styrene–divinylbenzene derivatized either with iminodiacetates[5] or with Srafion NMRR[6] (11) showed that the iminodiacetate derivative did not bind methyl mercury chloride, although it bound quantitatively Hg^{2+}, while the Srafion NMRR bound mercury compounds under physiological conditions much slower than the chelating microspheres (Fig. 7). A quantitative elution of the bound mercury is obtained by adding thiourea and hydrochloric acid to the suspended microspheres.

DISCUSSION

The structure of the chelating compound produced by the reaction of the aldehyde groups of glutaraldehyde and the thiol groups of pentaerythritol tetrathioglycolate seems to be complicated, and does not agree with the ideal structure of a polymer as suggested previously (12). The mercury compounds are probably bound to the chelating compound through its free thiol groups, and the S—C(OH) groups (hemi thio acetal). The structure of the chelating compound and of its binding to mercury compounds is currently being investigated. The chelating microspheres bind the mercury compound very strongly and reverse the binding from the biological receptors to the microspheres:

$$\text{Metallic compounds (R—M)} \xrightarrow{\text{Biological receptor}} \text{R—M} \cdots \text{Biological receptor} \xrightarrow{\text{Microspheres}} \text{R—M} \cdots \text{Microspheres} + \text{Biological receptors}$$

Scheme II

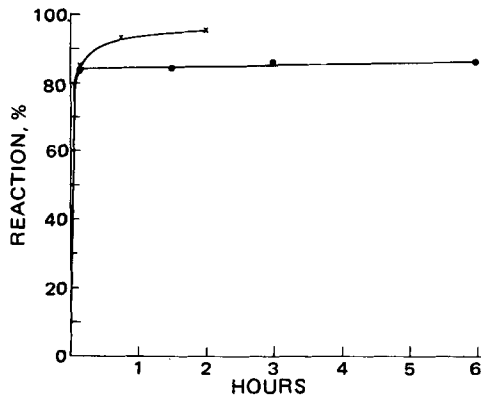

Figure 6—*Rate of intake of methyl mercury chloride by chelating microspheres. The reaction was carried out by stirring 10^{-4} M methyl mercury chloride in 80 ml of phosphate-buffered saline solution in the presence of: (●) 4.6-mg microspheres; (X) 60-mg microspheres.*

Table IV—Rate of Intake of Mercury Compounds from Albumin [a]

Mercury Compound	Time, min	Reaction, %
Mercuric chloride	10	81
Mercuric chloride	60	81
Mercuric chloride	120	83
Mercuric chloride	1320	88
Methyl mercury chloride	10	78
Methyl mercury chloride	120	68
Methyl mercury chloride	1320	72

[a] Mercury compounds (5 ppm Hg) were stirred for 2 hr with 60 ml of 4% human albumin in phosphate-buffered saline solution, and then chelating microspheres were added (48 mg in the reaction with mercuric chloride and 60 mg in the reaction with methyl mercury chloride). In control experiments the loss of mercury compounds was negligible (<3%).

Many of the heavy metallic compounds are excreted by the liver *via* the bileduct and intestinal tract, but a great part of the metallic compound (~90% of methyl mercury chloride) is reabsorbed by the intestine. Therefore, it seems feasible that a nonabsorptive binding material, administered orally might bind the metallic compound secreted *via* the bile, prevent reabsorption of the metal, and greatly increase its fecal excretion. Several investigators (7–9) showed that oral administration of indigestible and nonabsorbable resin that binds methyl mercury enhances the fecal excretion of methyl mercury from animals. It was also observed (7) that nonabsorbable polythiol resin given orally can substantially reduce the level of methyl mercury in the blood, brain, kidney, and liver. In an epidemic of methyl mercury poisoning in Iraq (13) a group of scientists reported that oral administration of the same polythiol resin to humans significantly decreased their whole body levels of mercury. In most cases (diffusion control) the rate of mercury intake is directly proportional to the surface area of the mercury binder resin. For a resin with a spherical shape, the rate is directly proportional to the ratio $1/r$:

$$v \alpha n \pi r^2 = \frac{3V}{4\pi r^3} \pi r^2 = 0.75\, V \frac{1}{r} = k \frac{1}{r} \qquad \text{(Eq. 1)}$$

where v is the rate of mercury intake, V is the spherical volume, and n is the number of spheres having a radius r.

For example, spheres with a radius of 1 μm will intake mercury 100 times faster than those with a radius of 100 μm. The dramatic effect of the high surface area of the chelating microspheres (radius of 0.4 μm as compared with hundreds of micrometers of the polythiol resin) are clearly shown in Fig. 4. In 30 min 100% of mercuric chloride was taken in by the microspheres while during the same period of time the agglutinated microspheres bound only 5% of the mercuric chloride.

In conclusion, polymeric microspheres were shown to have a potential use for various applications such as cell labeling and cell separation (14, 15), drug delivery (16), and diagnostic purposes (17). A new application for microspheres is suggested. Chelating microspheres may be very useful

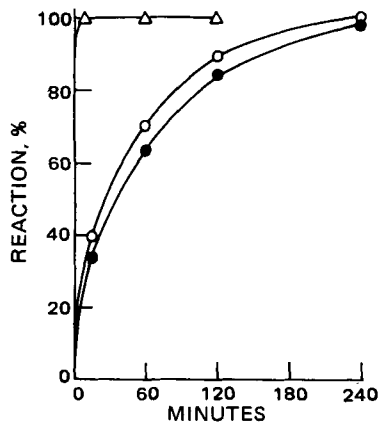

Figure 7—*Rate of intake of mercuric chloride and methyl mercury chloride by the Srafion NMRR–styrene divinylbenzene copolymer resin and the chelating microspheres. The reaction was carried out by stirring 50 ml of phosphate-buffered saline solution containing 10^{-4} M mercuric chloride or methyl mercury chloride with 100 mg of the chelating polymers. Key: (●) Srafion NMRR–styrene divinylbenzene copolymer resin with mercuric chloride; (○) Srafion NMRR–styrene divinylbenzene copolymer resin with methyl mercury chloride; (△) chelating microspheres with either mercuric chloride or methyl mercury chloride.*

Table V—Rate of Intake of Mercury Compounds from Cysteine [a]

Mercury Compounds	Time, min	Reaction, %
Mercuric chloride	10	95
Mercuric chloride	60	97
Mercuric chloride	240	99
Mercuric chloride	1320	100
Methyl mercury chloride	10	91
Methyl mercury chloride	60	91
Methyl mercury chloride	240	91

[a] Mercury compounds (20 ppm Hg) were stirred for 2 hr with 20 ml of 10^{-2} *M* cysteine in phosphate-buffered saline solution. Chelating microspheres were then added (20 mg in the reaction with methyl mercury chloride and 50 mg in the reaction with mercuric chloride). In control experiments the loss of mercury compounds was negligible.

as an oral antidote for treatment in cases of heavy metal poisoning, due to their high surface area. As a model, the potential of polymercaptal microspheres for mercury poisoning was demonstrated *in vitro* and future experiments will have to be carried out *in vivo* as well. Moreover, the affinity of chelating microspheres toward other heavy metallic compounds such as arsenic, cadmium, lead, and copper, *etc.*, will be investigated to evaluate their potential use for treatment of poisoning with these heavy metals.

Relative Bioavailability of Commercially Available Ibuprofen Oral Dosage Forms in Humans

W. R. GILLESPIE, A. R. DiSANTO, R. E. MONOVICH, and K. S. ALBERT ˣ

Received August 20, 1981, from the *Clinical Biopharmaceutics Research Unit, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication December 1, 1981.

Abstract □ Two human bioavailability studies were conducted to assess the *in vivo* performances of recently marketed 200-, 300-, and 400-mg ibuprofen capsules relative to the innovator's 300- and 400-mg tablets when administered as single oral 300- or 400-mg doses. An ibuprofen oral solution was also administered in each trial. Within each study, the products were equivalent to each other and to the oral solution with respect to the extent of ibuprofen absorption. Absorption rates, however, differed markedly among the products studied. Ibuprofen was more slowly absorbed from the 300- and 400-mg capsules than from the respective strength tablets. The 200-mg capsule exhibited an absorption rate comparable to the 400-mg tablet but more rapid than the 400-mg capsule. It was concluded that two of the duplicator's 200-mg capsules were bioequivalent to one of the innovator's 400-mg tablet. The duplicator's 300- and 400-mg capsules were bioinequivalent to the innovator's 300- and 400-mg tablets, respectively, due to their slower rates of absorption.

Keyphrases □ Bioavailability—commercially available ibuprofen oral dosage forms in humans □ Ibuprofen—bioavailability of commercially available oral dosage forms in humans □ Dosage forms, oral—bioavailability of commercially available ibuprofen in humans

Ibuprofen is a propionic acid derivative with anti-inflammatory, analgesic, and antipyretic activities and is widely utilized in the treatment of osteoarthritis, rheumatoid arthritis, and mild to moderate pain (1, 2). Recently, it has become a multiple-source drug product in Canada; thus, the question arises whether the new products are equivalent relative to the quality and performance of the innovator's products. Of particular importance is their *in vivo* performance in terms of the extent and rate of ibuprofen GI absorption from the solid oral dosage forms.

A previous study demonstrated the bioequivalence of a pilot plant lot of the 300-mg capsule product to the innovator's 300-mg tablet (3). The present studies were conducted to assess the bioavailability of full-scale production lots of the recently introduced 200-, 300-, and 400-mg capsules relative to the innovator's 300- and 400-mg tablets.

EXPERIMENTAL

Products Studied—Two comparative bioavailability studies were conducted to evaluate the five commercially available ibuprofen products (A, B, C, D, and E) listed in Table I.

An aqueous solution of sodium ibuprofen (F, Table I) was utilized as a reference standard to which the other formulations could be compared. With the exception of the solution, the products were obtained from usual commercial sources without any attempt to procure or select specific lots.

The ibuprofen dosage forms were administered as single, oral 300-mg doses in Study I and as single, oral 400-mg doses in Study II.

Table I—Description of Ibuprofen Dosage Forms Tested

Formulation Type	Lot Number	Formulation Code
Capsule, 300 mg[a]	8E08N	A
Tablet, 300 mg[b]	E284	B
Capsule, 400 mg[a]	9D079	C
Capsule, 200 mg[a]	8E07N	D
Tablet, 400 mg[b]	E426	E
Solution, 20 mg/ml[c]	18,025-6	F

[a] Amersol capsules; manufactured and marketed by Frank W. Horner Ltd., Montreal, Quebec, Canada. [b] Motrin tablets; manufactured and marketed by The Upjohn Co. of Canada, Don Mills, Ontario, Canada. [c] Manufactured by The Upjohn Co., Kalamazoo, Mich.

Human Subjects—Eighteen normal volunteers between the ages of 18 and 35 years and 20 normal volunteers between the ages of 20 and 33 years were selected to participate in Study I and Study II, respectively. They were accepted into the studies following informed consent, a physical examination, and blood and urine analyses.

Study Design—In Study I, Formulations A, B, and F were administered according to a 3 × 3 Latin-square crossover design with six replications. In Study II, Formulations C, D, E, and F were administered according to a 4 × 4 Latin-square crossover design with five replications (Table II). The ibuprofen doses were separated by 4 days. Each dose was administered with 180 ml of water following an overnight fast. The fasting period continued for 2 hr following the dose. No food or beverage other than water was permitted during the fasting period.

Blood (7 ml) was collected from a forearm vein by individual venipunctures just prior to dosing and at 0.17 (10 min), 0.33 (20 min), 0.5, 1, 1.5, 2, 3, 4, 6, 8, 10, and 12 hr following drug administration. Serum was harvested from the blood samples ~40 min after collection, immediately frozen, and kept in a frozen state until assayed.

The serum specimens were quantitatively analyzed for unchanged ibuprofen utilizing GLC with flame ionization detection as described previously (4).

THEORETICAL

Symbols—The following symbols were used in the calculations and are defined as follows:

- AUC_t = area under the serum ibuprofen concentration–time curve from time zero through time t
- AUC_∞ = area under the serum ibuprofen concentration–time curve from time zero through infinite time
- $AUMC_t$ = area under the (first) moment curve from time zero through time t
- $AUMC_\infty$ = area under the (first) moment curve from time zero through infinite time
- C_t = ibuprofen serum concentration at time t (measured)
- $\hat{C}_t$ = ibuprofen serum concentration at time t (calculated)
- C_{max} = peak ibuprofen serum concentration
- CFA_{rel} = cumulative fraction absorbed relative to the oral solution
- MDT = mean *in vivo* dissolution time
- MRT = mean residence time
- t = elapsed time after ibuprofen administration
- T = time at which the last measurable ibuprofen serum concentration (≥1.0 μg/ml) was observed
- t_{max} = time at which C_{max} occurred
- λ_z = apparent ibuprofen elimination rate constant

Model Independent Parameters—AUC_t and $AUMC_t$ were calculated by trapezoidal rule. Extrapolations through infinite time utilized:

$$AUC_\infty = AUC_T + \frac{\hat{C}_T}{\lambda_z} \quad \text{(Eq. 1)}$$

$$AUMC_\infty = AUMC_T + \left[T + \frac{1}{\lambda_z}\right]\frac{\hat{C}_T}{\lambda_z} \quad \text{(Eq. 2)}$$

The apparent elimination rate constant (λ_z) was estimated by fitting the ibuprofen serum concentrations following administration of the oral solution (Formulation F) to a biexponential equation using nonlinear least-squares regression (NONLIN) (5). Estimates of $\hat{C}_T$ following administration of Formulation F were calculated from the same biexponential equation. Estimates of $\hat{C}_T$ following administration of the solid dosage forms were calculated from the equation of the line resulting from linear least-squares regression of $\ln C_t$ *versus* t using those data points in the terminal log-linear region. Attempts to estimate λ_z from the slope of that line resulted in significantly smaller values for Capsules A and C (Table III), suggesting prolonged GI absorption of ibuprofen. The elimination rate constant estimated from the oral solution data was considered a more reliable description of the elimination rate and was utilized in all subsequent calculations. This decision required the assumptions that λ_z remained constant for each volunteer throughout the study and that absorption was essentially complete by 12 hr following drug administration.

Table II—Latin-Square Crossover Designs for Ibuprofen Bioavailability Studies

Study I (Dose = 300 mg)

Group	Subjects	Formulation Phase I	Phase II	Phase III
1	5, 7, 8, 10, 13, 16	A	B	F

[a] Level of significance for test of equal treatment means. [b] The means for formulations connected by overhead bars were not significantly different ($p > 0.05$).

MRT for an oral solution (Eq. 4) has been termed the mean *in vivo* dissolution time (MDT) by Riegelman and Collier (7):

$$MDT = MRT_{solid} - MRT_{solution} \quad \text{(Eq. 4)}$$

Theoretically, MDT is an estimate of the mean time which a drug molecule remains as a solid in the GI tract. In reality, MDT is probably not an absolute estimator of dissolution rate due to the differing influences of stomach emptying rate on solid and solution dosage forms. It is, nonetheless, an excellent tool for comparing absorption rates among treatments administered to the same subjects in a bioavailability trial.

Model Dependent Parameters—The serum ibuprofen concentrations following the administration of the oral solution to each subject were well described by a biexponential equation. This indicated that the pharmacokinetics of ibuprofen could be explained in terms of a one-compartment open model. As a result, cumulative absorption profiles could be constructed according to the method of Wagner and Nelson (8). *Modification* of that method resulted in Eq. 5, which was utilized to estimate the cumulative amount of ibuprofen absorbed from the solid dosage form divided by the total amount absorbed from the oral solution, *e.g.*, cumulative fraction absorbed relative to the oral solution (CFA_{rel}):

$$CFA_{rel} = \frac{C_t + \lambda_z [AUC_t]}{\lambda_z [AUC_{\infty}^{solution}]} \quad \text{(Eq. 5)}$$

Estimates of cumulative fraction absorbed relative to the oral solution (CFA_{rel}) provided both visual and statistical comparisons of absorption rate and extent among the treatments.

Statistical Comparisons—Within each study, statistical comparisons of C_t, C_{max}, t_{max}, and AUC_∞ data were performed utilizing ANOVA with group, subject within group, phase, and treatment as factors. In cases where treatment effects were significant ($p < 0.05$), pairwise comparisons were evaluated with Tukey's multiple range test. A two-tailed paired t test was applied to MDT and CFA_{rel} data from Study I. The described ANOVA model was utilized to evaluate MDT and CFA_{rel} data from Study II except that the pairwise comparisons were performed using linear contrasts of the regression coefficients resulting from the ANOVA (9).

RESULTS

All 18 subjects enrolled in Study I successfully completed the three treatment phases. Of the 20 subjects enrolled in Study II, one (Subject 17) discontinued participation following Phase I for reasons unrelated to the study. Another (Subject 18) exhibited such unusual ibuprofen concentration–time courses that the person was considered unrepresentative of a normal subject population. Neither of these subjects' results were utilized in any subsequent data analyses.

Concentration at Each Sampling Time (C_t)—Table III and Fig. 1 present the mean serum ibuprofen concentrations at each sampling time which resulted from the administration of Formulations A, B, and F as single, oral 300-mg doses in Study I and formulations C, D, E, and F as single, oral 400-mg doses in Study II.

In Study I, statistically significant ($p < 0.05$) differences were observed among the treatments at all but two sampling times. The pairwise comparisons indicated that those differences were predominantly the result of a concentration–time profile for the oral solution which differed markedly from those for the two solid dosage forms. Tablet B, however, did exhibit significantly lower concentrations than Capsule A at 2, 4, 6, and 8 hr following drug administration.

In Study II, statistically significant differences among the formulations were observed at each sampling time. Most of those differences were attributable to solid dosage form *versus* solution comparisons. Concentrations following Capsule C administration did differ significantly from those following Capsule D administration at 1, 6, and 12 hr, and from those following Tablet E administration at 1.5, 2, and 6 hr postdose. No significant differences were observed for Formulations D *versus* E comparisons at any sampling time.

Area Under the Concentration–Time Curve (AUC_∞)—The average areas under the serum ibuprofen concentration–time curves (AUC_∞) resulting from administration of each formulation are also shown in Table III. Within each study, no statistically significant differences were observed among the formulations. The following ratios of mean AUC_∞ for the solid dosage forms to the mean AUC_∞ for the oral solution were observed:

A/F	B/F	C/F	D/F	E/F
1.03	1.02	1.05	1.08	1.01

Those results indicated that the tablet and capsule products were equivalent to each other and to the oral solution with respect to the extent of ibuprofen absorption.

Peak Concentration (C_{max}) and Peak Time (t_{max})—Statistical analyses of the C_{max} and t_{max} values observed following the administration of the various ibuprofen formulations (Table III) yielded significant differences among the treatment means in both studies. The oral solution exhibited the most rapid rate of absorption with an average t_{max} in both studies of ~0.5 hr and average C_{max} estimates of 31.9 and 45.5 μg/ml in Studies I and II, respectively.

In Study I, the 300-mg capsule (A) resulted in an average C_{max} which was 35% less and a t_{max} which was 64% greater than those achieved by the 300-mg tablet (B). Those differences were statistically significant and indicated that ibuprofen was more rapidly absorbed from the tablet than from the capsule.

In Study II, the results of pairwise comparisons between the 400-mg tablet (E) and capsule (C) were similar to those seen in Study I for the 300-mg formulations. Capsule C produced an average C_{max} which was 17% less and a t_{max} which was 44% greater than those resulting from Tablet E. Only the t_{max} difference was statistically significant. The mean C_{max} and t_{max} results for the 200-mg capsule (D) were similar to those for the 400-mg tablet (E) and significantly different from those for the 400-mg capsule (C). These results indicated that Formulations D and E were absorbed at similar rates and that both were absorbed more rapidly than Formulation C.

Mean *In Vivo* Dissolution Time (*MDT*)—The average *MDT* estimates shown in Table IV distinguish the solid dosage forms on the basis of absorption rate. The 300-mg capsule (A) exhibited an average *MDT* nearly twice that for the 300-mg tablet (B) (1.44 *versus* 0.73 hr). In Study

II, the 200-mg capsule (D) and the 400-mg tablet (E) resulted in approximately equal *MDT* estimates (0.80 *versus* 0.79 hr). The 400-mg capsule (C), however, was more slowly absorbed with an average *MDT* of 1.27 hr. The differences for the pairwise comparisons of A *versus* B, C *versus* D, and C *versus* E were statistically significant.

Cumulative Fraction Absorbed Relative to the Oral Solution (CFA_{rel})—Modified Wagner-Nelson plots of mean CFA_{rel} *versus* time for the ibuprofen products are presented as Fig. 2. Inspection of the plots suggests that, on the average, Formulations A and C required 4–6 hr to achieve an extent of absorption within 95% of the oral solution. Formulations B, D, and E, however, reached the same endpoint by the 2-hr sampling time.

Statistical comparisons of the CFA_{rel} estimates at each sampling time up to 6 hr are shown in Table IV. The 300-mg tablet (B) resulted in significantly greater mean CFA_{rel} values at 1, 1.5, and 2 hr than the 300-mg capsule (A). The 400-mg tablet (E) and the 200-mg capsule (D) exhibited similar mean CFA_{rel} estimates with a significant difference occurring only at the 20-min sampling time. The 400-mg capsule (C) results were significantly less than those for Formulation D at 1, 1.5, 2, and 3 hr and those for Formulation E at 1.5, 2, and 3 hr. Since no differences were observed in the extent of absorption among the products studied, the relatively low estimates of CFA_{rel} resulting from Formulations A and C were indicative of their slower rates of absorption.

DISCUSSION

Though all of the commercially available ibuprofen products studied were equivalent with respect to the amount of drug absorbed from the dosage forms, they differed markedly in terms of absorption rate. Specifically, the 300-mg tablet (B) was more rapidly absorbed than the 300-mg capsule (A), and the 400-mg tablet (E) and the 200-mg capsule (D) were more rapidly absorbed than the 400-mg capsule (C).

The results of a previously reported study indicated that a pilot plant lot of the 300-mg capsule was bioequivalent to the innovator's 300-mg tablet (3). The present study suggested that some change associated with scale-up to commercial production resulted in a less rapidly absorbed dosage form.

Since bioequivalence has been defined as equivalence in both extent and rate of drug absorption (10), it has been concluded that Formulations A and C were bioinequivalent to the innovator's products (B and E) due to their slower absorption rates. Whether this conclusion could be translated to indicate clinical inequivalence could not be determined from these studies. It would be hypothesized, however, that differences in clinical efficacy might be observed when ibuprofen is administered as single doses for the relief of mild to moderate pain.

A more general conclusion resulting from these studies was that the potential exists for bioavailability problems among ibuprofen solid oral dosage forms.

The Role of Surfactants in the Release of Very Slightly Soluble Drugs from Tablets

HANS SCHOTT ˣ, LILIAN CHONG KWAN *, and STUART FELDMAN ‡

Received August 4, 1981, from the *School of Pharmacy, Temple University, Philadelphia, PA 19140.* Accepted for publication November 24, 1981.

*Present address: William H. Rorer, Inc., Fort Washington, PA 19034. ‡Present address: College of Pharmacy, University of Houston, Houston, TX 77030.

Abstract □ The ability of surfactants to accelerate the *in vitro* dissolution of very slightly soluble drugs has been ascribed to wetting and/or micellar solubilization. Deflocculation as a mechanism to accelerate dissolution has not been investigated. In the present study, the effect of a surfactant on the dissolution kinetics of prednisolone from tablets and the mode of action of the surfactant were investigated. The dissolution of prednisolone at 37° in 0.1 *N* HCl containing different concentrations of the nonionic surfactant, octoxynol 9, followed zero-order kinetics. The rate constant was increased by 15, 150, and 950% when octoxynol was added to the dissolution medium at 0.0039 and 0.032% (~0.5 and 4.0 times the critical micelle concentration) and incorporated into the tablets (for a final concentration of 0.0039%), respectively. The surface tensions of the dissolution media were 71, 35, and 31 dyne/cm for 0, 0.0039, and 0.032% octoxynol, respectively. The largest decrease in surface tension corresponded to the smallest increase in dissolution rate, indicating that wetting was unimportant. The micellar solubilization capacity of octoxynol was much too small to account for the increases in dissolution rate. Microscopic particle size measurements and sedimentation volume determinations showed the pronounced deflocculation of prednisolone by the surfactant. The observed increases in specific surface area at the two octoxynol concentrations were in good quantitative agreement with the increases in dissolution rate according to the Noyes–Whitney equation.

Keyphrases □ Deflocculation—surfactants, release of very slightly soluble drugs, tablets, dissolution kinetics □ Surfactants—release of very slightly soluble drugs, tablets, dissolution kinetics □ Kinetics—dissolution, surfactants, release of very slightly soluble drugs, tablets, deflocculation

The most likely mechanisms by which surfactants could speed up the release of very slightly soluble drugs from tablets are wetting, micellar solubilization, and deflocculation (1). The purpose of the present study was to assess their relative importance in accelerating the dissolution of prednisolone by octoxynol.

0022-3549/82/0900-1038$01.00/0

II, the 200-mg capsule (D) and the 400-mg tablet (E) resulted in approximately equal *MDT* estimates (0.80 *versus* 0.79 hr). The 400-mg capsule (C), however, was more slowly absorbed with an average *MDT* of 1.27 hr. The differences for the pairwise comparisons of A *versus* B, C *versus* D, and C *versus* E were statistically significant.

Cumulative Fraction Absorbed Relative to the Oral Solution (CFA_{rel})—Modified Wagner-Nelson plots of mean CFA_{rel} *versus* time for the ibuprofen products are presented as Fig. 2. Inspection of the plots suggests that, on the average, Formulations A and C required 4–6 hr to achieve an extent of absorption within 95% of the oral solution. Formulations B, D, and E, however, reached the same endpoint by the 2-hr sampling time.

Statistical comparisons of the CFA_{rel} estimates at each sampling time up to 6 hr are shown in Table IV. The 300-mg tablet (B) resulted in significantly greater mean CFA_{rel} values at 1, 1.5, and 2 hr than the 300-mg capsule (A). The 400-mg tablet (E) and the 200-mg capsule (D) exhibited similar mean CFA_{rel} estimates with a significant difference occurring only at the 20-min sampling time. The 400-mg capsule (C) results were significantly less than those for Formulation D at 1, 1.5, 2, and 3 hr and those for Formulation E at 1.5, 2, and 3 hr. Since no differences were observed in the extent of absorption among the products studied, the relatively low estimates of CFA_{rel} resulting from Formulations A and C were indicative of their slower rates of absorption.

DISCUSSION

Though all of the commercially available ibuprofen products studied were equivalent with respect to the amount of drug absorbed from the dosage forms, they differed markedly in terms of absorption rate. Specifically, the 300-mg tablet (B) was more rapidly absorbed than the 300-mg capsule (A), and the 400-mg tablet (E) and the 200-mg capsule (D) were more rapidly absorbed than the 400-mg capsule (C).

The results of a previously reported study indicated that a pilot plant lot of the 300-mg capsule was bioequivalent to the innovator's 300-mg tablet (3). The present study suggested that some change associated with scale-up to commercial production resulted in a less rapidly absorbed dosage form.

Since bioequivalence has been defined as equivalence in both extent and rate of drug absorption (10), it has been concluded that Formulations A and C were bioinequivalent to the innovator's products (B and E) due to their slower absorption rates. Whether this conclusion could be translated to indicate clinical inequivalence could not be determined from these studies. It would be hypothesized, however, that differences in clinical efficacy might be observed when ibuprofen is administered as single doses for the relief of mild to moderate pain.

A more general conclusion resulting from these studies was that the potential exists for bioavailability problems among ibuprofen solid oral dosage forms.

BACKGROUND

Wetting—The wetting process consists in replacing a solid–air interface with a solid–liquid interface. Wetting agents speed up the penetration of gastric fluid into the tablets and, hence, tablet disintegration. This effect, which is due to the lowering of contact angles and of surface and interfacial tensions of the aqueous medium by the surfactants, has been well documented (2–22).

The improper use of surfactants could conceivably retard the dissolution of solid drugs by dewetting. When hydrophilic solid surfaces of relatively high charge density come into contact with aqueous solutions of ionic surfactants of the opposite charge, the surface-active ions are chemisorbed by an ion-exchange mechanism with their hydrocarbon chains oriented toward the aqueous phase. This process reduces the *zeta* potential of the solid surface to very low values or even zero (23). It also covers that surface with hydrocarbon chains, rendering it more hydrophobic and poorly wetted. The contact angles of water on such hydrophilic surfaces as barium sulfate (24) and glass (25) were thus increased from 0 to 60° or more.

The following observation also illustrates this point. The addition of the anionic surfactant, dioctyl sodium sulfosuccinate, to water increased the rate of penetration into a powder bed of negatively charged aspirin particles but lowered the rate of penetration into a bed of positively charged magnesium oxide particles (8).

Solubilization—Micellar solubilization occurs only when the dissolved surfactant is present at concentrations exceeding its critical micelle concentration. In most instances, the amount of surfactant that can be conveniently incorporated into a tablet supplies less than that needed to exceed the critical micelle concentration once the surfactant is dissolved and uniformly distributed throughout the gastric fluid. Owing to their size, shape, and chemical nature, most drug molecules capable of being solubilized by micelles cause little or no reduction in the critical micelle concentration.

Immediately after ingestion, aqueous fluid penetrates into tablets and begins to dissolve the surfactant contained therein. This process could temporarily produce, inside the tablets, a surfactant solution of concentration well in excess of the critical micelle concentration. This transitory micellar solution may temporarily dissolve a very slightly water-soluble drug by micellar solubilization. After the tablets disintegrate and/or the surfactant is leached out, the surfactant solution inside the tablets is diluted by the entire volume of gastric fluid and its concentration drops below the critical micelle concentration. As the micelles dissociate, the solubilized drug precipitates. However, this precipitation produces a colloidal dispersion of the drug characterized by a large specific surface area, and, therefore, by a high subsequent dissolution rate. The fine particle size of the drug during precipitation is maintained by the low drug solubility and a small concentration. This combination results in a low degree of supersaturation and provides little precipitating solid drug for growth of the nuclei. Adsorption of the surfactant and of pepsin and mucin dissolved in the gastric fluid onto the nuclei further limits their growth.

Numerous publications deal with the effect of micellar solubilization on the dissolution rate of very slightly soluble drugs from tablets (26–38).

Miscellaneous—A few investigators found that surfactants incorporated into tablets or dissolution media had no effect on the disintegration and/or dissolution times (39, 40). Others observed reduced dissolution times in the presence of surfactants but did not identify the mode of action of the surfactants (41). Still other investigators rejected surface tension lowering and micellar solubilization as causes for the observed increase in dissolution rate, because these factors were not large enough to account for the magnitude of that increase, but offered no alternative explanation (42).

In the case of relatively hydrophilic tablets, surfactants reduced the disintegration times by weakening adhesion, as shown by reduced tablet hardness, rather than by enhancing the penetration of the dissolution medium (43–45). Nonionic surfactants increased the rate of dissolution according to their hydrophile–lipophile balance. Increases in the rate of disintegration depended on the chemical category of the nonionic surfactant (46).

Deflocculation—Deflocculation, deaggregation, or peptization is the breaking up or dispersing of aggregates or secondary particles into smaller aggregates or primary particles. This process increases the specific surface area of the solid drug particles and, thereby, their rate of dissolution. It enhances the bioavailability of very slightly soluble and practically insoluble drugs, whose absorption is limited by their dissolution rate.

The role of surfactants in deflocculating or deaggregating the solid phase in lyophobic aqueous and nonaqueous dispersions and suspensions is well recognized (47). However, the possibility that surfactants employed as tablet excipients increase the dissolution rate of very slightly soluble drugs by peptization or deflocculation has, to the best of our knowledge, neither been explicitly recognized nor documented (48).

However, it was postulated that the presence of sodium lauryl sulfate dissolved in the granulating liquid greatly increased the rate of dissolution by preventing the formation of agglomerates of hydrophobic drug particles in the tablet (49). The increase in the dissolution rate of aspirin from tablets in the presence of surfactants (17) was ascribed to "a wetting and/or deaggregation effect" (21).

The present data on the release of prednisolone from tablets in the presence of a nonionic surfactant show that the major mechanism through which the surfactant increased the dissolution rate of this very slightly soluble drug was a deflocculating or peptizing action.

EXPERIMENTAL

Materials—Prednisolone was anhydrous, USP grade, and micronized[1]. Octoxynol 9, an anhydrous, viscous liquid[2], and microcrystalline cellulose[3] were NF grade. Magnesium stearate[4], supplied as an impalpable powder, and spray-dried lactose[5] were USP grade. All other chemicals were American Chemical Society reagent grade. Water was twice distilled.

Tablet Preparation—Three formulations of 500-mg tablets were prepared by triturating 5.000 g of the ingredients, enough to make 10 tablets, in a mortar and pestle in the order of addition listed in Table I. Microcrystalline cellulose was included to absorb the liquid octoxynol and prevent it from rendering the tablet excessively soft. The 75-mg portion of microcrystalline cellulose was the minimum amount required to absorb 35 mg of octoxynol and maintain their mixture as a nonsoggy, free-flowing powder. The lactose was incorporated in two portions. The

first was added between the surfactant and the prednisolone to minimize direct contact between the latter two ingredients.

A cylindrical stainless steel die with a diameter of 1.27 cm (0.5 in) and a flat-faced punch were used on a hydraulic press[6] equipped with a pressure gauge. The 500-mg aliquots were compressed for 30 sec with a weight of 4536 kg (10,000 lbs), which corresponds to a pressure of 50,900 psi. This weight produced tablets of more uniform disintegration times than did 2268 kg (5000 lbs).

Tablet hardness was measured with a manual, spring-operated tester[7].

Liquid Media—The three media used for disintegration and dissolution studies consisted of 900 ml of 0.1 *N* HCl maintained at 37.0 ± 0.2°. Medium A contained no other additives. Its surface tension was 71.1 dyne/cm. Medium B contained 0.0039% (w/v) octoxynol, *i.e.*, 35 mg in 900 ml, and had a surface tension of 35.4 dyne/cm. Medium C contained 0.032% (w/v) octoxynol and had a surface tension of 30.9 dyne/cm. Since the critical micelle concentration of octoxynol in 0.1 *N* HCl at 37° is 0.0083%, the surfactant concentrations in Media B and C correspond approximately to 0.5 and 4.0 times the critical micelle concentration, respectively.

Tablet Disintegration—Disintegration times were measured with the USP apparatus[8]. The plastic disks (50) were omitted. The 1-liter beaker was jacketed, and water from a constant-temperature bath at 37° was circulated through the jacket. Individual disintegration times, measured for each tablet, were the times required for all fragments to fall through the 10-mesh bottom screen.

Prednisolone Dissolution—A USP single-position dissolution apparatus (50) was used with the basket rotating at 100 ±5 rpm[8]. Aliquots were withdrawn at predetermined intervals and filtered before analyzing for dissolved prednisolone to remove suspended, insoluble tablet ingredients as well as any colloidally dispersed prednisolone that may have been present. Pressure filtration through membrane filters[9] with a pore size of 0.22 μm was employed. The stainless steel barrel of the pressure filter holder was thermostated at 37°.

Prednisolone assay by direct UV absorption spectroscopy was not sensitive enough. Therefore, a colorimetric assay based on the Porter and Silber method (51) was developed. It will be described in a separate publication. Its accuracy and reproducibility in the presence of the tableting ingredients were evaluated as follows: A tablet containing 25.0 mg of prednisolone was triturated with 10 ml of methanol to dissolve the prednisolone and the entire mass was diluted to 1.000 liter with 0.1 *N* HCl. Prednisolone assays were performed in duplicate on filtered aliquots. This procedure was repeated with two additional tablets, for a total of six determinations.

Four to six dissolution experiments were conducted at each of the four experimental conditions. Octoxynol interacted with the acid phenylhydrazine solution to produce a faint yellow tint. To compensate for this effect, comparable concentrations of octoxynol were incorporated into the blank solutions.

Octoxynol Dissolution—The release rate of octoxynol from tablets made according to Formulation III was determined by measuring the

surface tension of the dissolution medium as a function of time. A calibration plot of surface tension *versus* octoxynol concentration was prepared at 37° in 0.1 *N* HCl. When the octoxynol concentration in the dissolution medium exceeded the critical micelle concentration, octoxynol determinations were made by surface tension measurements at 37° on aliquots after appropriate dilution with 0.1 *N* HCl to concentrations below the critical micelle concentration.

Surface tensions were measured with a Wilhelmy balance[10] equipped with a sand-blasted platinum blade on 40-ml portions of octoxynol solutions or aliquots of the dissolution medium. These solutions were equilibrated at 37.0 ± 0.1° for 1 hr or 24 hr prior to the measurements.

Micellar Solubilization of Prednisolone—The solubility of prednisolone in 0.1 *N* HCl solutions containing octoxynol at concentrations ranging from 0 to 0.128% was determined by colorimetric and gravimetric assays. In both methods, 50-mg portions of prednisolone triturated to a fine powder were mixed with 50-ml portions of the dissolving media in amber glass bottles. The bottles were flushed with nitrogen, stoppered, and shaken on an oscillating water bath[11] at 37°.

For the colorimetric assay, 5-ml aliquots were withdrawn after 2, 6, and 16 days of shaking, filtered through 0.1-μm membrane filters, and assayed according to the modified Porter and Silber method (51). The blank solutions contained octoxynol at the same concentrations as the test solutions.

In the gravimetric method, the suspensions were shaken at 37° for 3, 6, or 22 days. The entire 50-ml suspension volumes containing 50 mg of prednisolone were then filtered through tared fritted glass filtering crucibles. The filters, containing the undissolved prednisolone, were washed and dried to constant weight at 100°.

Sedimentation Volumes of Prednisolone Suspensions—Suspensions containing 50 mg of prednisolone in 50 ml of 0.1 *N* HCl with different octoxynol concentrations were prepared as described under Micellar Solubilization. Each suspension was vigorously shaken on the shaker bath for 3 days at 140 oscillations/min and poured immediately into a glass funnel with a top diameter of 12 cm connected to a 12-ml graduated glass centrifuge tube with a conical bottom. The volume of the bottom milliliter could be read with an accuracy of ±0.01 ml.

Particle Size Distribution of Prednisolone Suspensions—The number and sizes of the coarse particles contained in 0.1 ml of suspensions prepared as in the preceding section were determined by withdrawing a 0.1-ml aliquot immediately after vigorous shaking, using a graduated pipet with a tip of 2-mm i.d. The size of every coarse particle in that volume was measured with a magnifying glass and a ruler. Since the coarse particles were irregular, their equivalent spherical diameters were recorded.

The number and sizes of the fine particles were measured with a hemacytometer. A drop of a suspension was put into the counting chamber. When the cover glass was placed over it, the liquid layer was reduced to a thickness of 0.1 mm. The dimensions of every particle in four adjacent

0.2-mm squares, corresponding to a volume of $4 \times (0.2\text{ mm})^2 \times 0.1\text{ mm} = 0.016\text{ mm}^3$, was measured by means of a microscope equipped with an eyepiece micrometer. Since the fine particles were rod-shaped, their lengths and diameters were recorded.

RESULTS

The tablet characteristics are listed in Table II. The small standard errors of the averages indicate that the properties were reproducible.

Tablet Disintegration—Disintegration times are listed in Table III. All tablets, regardless of the presence or absence of octoxynol, retained their integrity during most of the duration of the disintegration test. Only toward the end did they break up into separate fragments.

In liquid Medium A (0.1 *N* HCl), the tablets disintegrated into coarse grains which settled quickly. When octoxynol was added to the disintegrating liquid (Media B and C) or incorporated into the tablets, they disintegrated into fine granules that remained suspended in the liquid, turning it turbid.

Comparing the mean disintegration time of 107.0 min in the absence of octoxynol with the mean value of 104.3 min in the presence of 0.0039% octoxynol by means of the *t* test shows that their 2.5% difference is not statistically significant even at the 20% probability level.

Increasing the octoxynol content of the liquid medium to 0.032% reduced the disintegration time by 37% compared to no octoxynol and by 35% compared to 0.0039% octoxynol. These differences are statistically significant because the two calculated *t* values are larger than the 0.1% critical value for *t*. Incorporation of octoxynol into the tablets reduced the disintegration time by 82%.

The observation that the shortest disintegration times were obtained when octoxynol was incorporated into the tablets may in part be due to their reduced hardness (Table II). However, the major cause is probably the temporary high concentration of dissolved octoxynol inside the tablets as the disintegration liquid penetrates them and leaches the surfactant out of the microcrystalline cellulose granules.

The spread of the individual disintegration times about their mean, as represented by the standard deviation and range, was largest when the medium contained 0.0039% octoxynol and smallest when the octoxynol was incorporated into the tablet, paralleling the rank order of the disintegration times themselves. The rank order of the breadth of the statistical dispersion of the individual values about their means remained the same regardless of whether the standard deviation and range were expressed as percent of the means or as absolute values.

Octoxynol Dissolution Rate—Micelles of nonionic surfactants are slow to dissociate and the nonassociated surfactant molecules are slow to reach equilibrium adsorption at the air–water interface. While most measurements to establish the concentration–surface tension relationship were made after equilibrating the octoxynol solutions at 37° for 1 hr, some surface tensions were measured after 24 hr of equilibration. As is seen in Fig. 1, longer equilibration times did not result in noticeably lower surface tensions.

The calibration plot of surface tension *versus* the log of concentration is linear between the critical micelle concentration of 0.0083% (w/v) (surface tension = 30.9 dyne/cm) and 0.0008% (surface tension = 44.7 dyne/cm). This concentration range corresponds to the region of saturation adsorption of the surfactant at the air–water interface. The least-squares correlation between surface tension, γ, in dyne/cm and octoxynol concentration, C %, (w/v), valid for this concentration range, is:

$$\gamma = 2.59 - 13.62 \log C \qquad \text{(Eq. 1)}$$

with a correlation coefficient of 0.993 ($N = 8$).

When determining the dissolution rate of octoxynol from tablets, 40-ml aliquots were withdrawn from the 900-ml medium for surface tension measurements. These withdrawals represented substantial reductions in the volume of the medium and in the amount of dissolved surfactant. Correction was made by the following equation, derived for that purpose:

$$C_{i,\text{corr}} = \left[\frac{900 - (i-1)40}{900}\right] C_{i,\text{obs}} + \frac{40}{900} \sum_{i-1=1}^{i-1} C_{i-1,\text{obs}} \qquad \text{(Eq. 2)}$$

where $C_{i,\text{corr}}$ is the surfactant concentration in the dissolution medium at the time when the ith aliquot was withdrawn, corrected for the withdrawal of all previous aliquots, *i.e.*, $C_{i,\text{corr}}$ is the concentration that would have been measured if no aliquots had been withdrawn previously. The surfactant concentration in the ith 40-ml aliquot is $C_{i,\text{obs}}$. Both $C_{i,\text{corr}}$ and $C_{i,\text{obs}}$ are expressed as percent (w/v). The summation term starts with the second aliquot, *i.e.*, with $i - 1 = 1$ or $i = 2$; in this term, $i \neq 1$. The summation term is always one aliquot behind the other two terms of Eq. 2.

The values for $C_{i,\text{obs}}$ were obtained from the surface tensions either by means of the calibration plot of Fig. 1 or at octoxynol concentrations between 0.008% and the critical micelle concentration, by Eq. 1.

The presence of debris of insoluble tablet ingredients suspended in the dissolution medium did not affect the surface tension measurements, nor was there substantial adsorption of octoxynol by the debris. The surface tensions of the following media were identical within the precision of the measurements, namely, ±0.1 dyne/cm, at comparable nominal octoxynol concentrations: (*a*) octoxynol solutions in 0.1 *N* HCl, before and after filtration through membrane filters with pore sizes of 0.22 and 0.1 μm; (*b*) octoxynol solutions in dissolution media containing disintegrated tablets, before and after filtration through 0.22- and 0.1-μm filters.

Tablets made from Formulation III and a dissolution medium of 0.1 *N* HCl were used to study the rate of release of octoxynol. A plot of the octoxynol concentration in the dissolution medium *versus* time, obtained with two tablets, was linear and went through the origin (Fig. 2). A plot of the logarithm of the concentration of dissolved octoxynol *versus* time

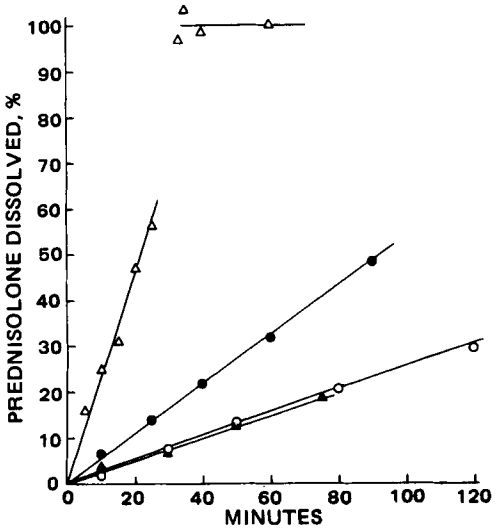

Figure 3—*Effect of octoxynol on the dissolution rate of prednisolone in 0.1 N HCl at 37°. Key: (▲) no octoxynol; (○) 0.0039%, (●) 0.032%; and (△) 0.0039% equivalent octoxynol in tablet but none added to medium.*

was concave toward the time axis. After a dissolution period of 35 min, at which time all of the octoxynol had been dissolved, the tablets disintegrated completely and all fragments fell through the screen of the dissolution basket.

The dissolution of octoxynol from tablets follows zero-order kinetics. The slope of Fig. 2, calculated by the method of least squares, is 0.000112% (w/v)/min, the correlation coefficient is 0.990. The total amount of octoxynol present in the tablet, 35 mg, dissolved in the 900-ml volume of dissolution liquid, would have produced a concentration of 0.00389% (w/v). Therefore, the dissolution rate constant of octoxynol is:

$$k = \frac{dC}{dt} = \left(\frac{0.000112\%\ (w/v)}{\text{min}}\right)\left(\frac{100\%}{0.00389\%\ (w/v)}\right) = 2.88\%/\text{min} \qquad \text{(Eq. 3)}$$

where percent refers to the amount of octoxynol released, expressed as percent of the total amount present or C_∞.

Prednisolone Dissolution Rate—Octoxynol is an effective deflocculating agent and may have dispersed some of the solid prednisolone into colloidal particles. If these particles passed the 0.22-μm membrane filter, they would be assayed together with the dissolved prednisolone, resulting in an excessively high dissolution rate.

When three 5-ml portions of a dissolution medium were filtered in succession through a membrane filter with a pore size of 0.22 μm and an additional three 5-ml portions of the same medium were filtered in succession through a membrane filter with a pore size of 0.1 μm, all six filtrates had identical prednisolone contents. Moreover, the filtrates were clear and did not exhibit Tyndall beams. These facts indicate that only molecularly dissolved prednisolone, and possibly prednisolone solubilized in micelles, were present in the filtrates, and that the membrane filters did not absorb measurable quantities of the steroid. No colloidally dispersed and undissolved prednisolone was present in the filtrates.

The accuracy and reproducibility of the prednisolone assay in the presence of the tableting ingredients was evaluated by assaying three tablets containing 25.0 mg each of prednisolone as described above. After trituration with methanol to dissolve the steroid, the entire mass was diluted to 1.000 liter with 0.1 *N* HCl. Duplicate assays on filtered aliquots for each tablet gave the following results: The mean of six values of prednisolone concentration was 25.05 mg/liter, the standard error 0.07 mg/liter, and the range 0.4 mg/liter. The standard error represents only 0.3% of the mean.

Table V—Sedimentation Volumes of Prednisolone Suspensions at Different Octoxynol Concentrations

Octoxynol Concentration, % (w/v)	Sedimentation Volume, ml		
	Coarse Particles	Fine Particles	Total
0	0.20	0.65	0.85
0.0039	0.19	0.23	0.42
0.012	0.16	0.39	0.55
0.016	0.14	1.02	1.16
0.032	0.13	1.32	1.45
0.128	0.05	2.00	2.05

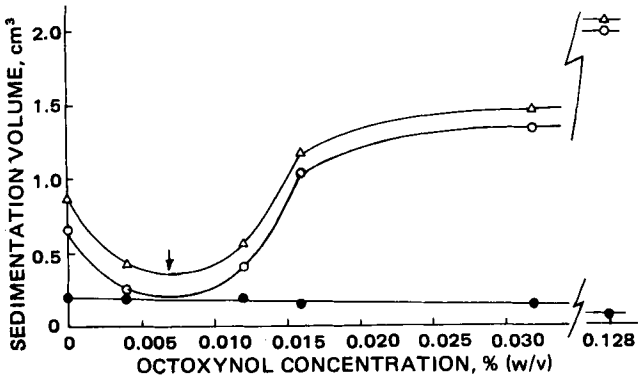

Figure 4—*Sedimentation volume of prednisolone suspensions in 0.1 N HCl at 25° as a function of octoxynol concentration. Key: (●) coarse aggregates; (○) fine; and (△) total volume. Arrow indicates critical micelle concentration.*

The dissolution data are summarized in Table IV. Plots of the logarithms of percent prednisolone dissolved *versus* dissolution time were concave toward the time axis. Plots of percent prednisolone dissolved *versus* dissolution time were straight lines going through the origin, indicating that the dissolution was zero order (Fig. 3).

Dissolution studies were conducted for up to 2 hr. In that period, tablets of Formulation I (no surfactant) in Media A and B released 25–30% of the prednisolone. Under these conditions, tablet disintegration times were somewhat under 2 hr. Nearly half of the prednisolone was dissolved within 1.5 hr in Medium C, where the disintegration time was somewhat >1 hr. When octoxynol was incorporated into the tablet, complete dissolution of the prednisolone occurred in ~30 min, compared with disintegration times of <20 min. Thus, tablet disintegration always preceded complete prednisolone dissolution.

The zero-order rate constants for the dissolution of prednisolone were calculated by (52):

$$k = \frac{\sum tp}{\sum t^2} \qquad \text{(Eq. 4)}$$

where p represents the percent prednisolone dissolved, based on the total amount of prednisolone present in the tablets, namely, 25 mg, and t represents dissolution time.

The standard deviation of k, S_k, was calculated by (52):

$$S_k = \sqrt{\frac{S^2_{t,p}}{\sum t^2}} \qquad \text{(Eq. 5)}$$

The variance of regression is:

$$S^2_{t,p} = \frac{1}{N-1}\left[\sum p^2 - \frac{(\sum tp)^2}{\sum t^2}\right] \qquad \text{(Eq. 6)}$$

where N is the number of measurements and $N-1$ the number of degrees of freedom.

Zero-order dissolution rate constants for the four systems and their standard deviations are listed in Table IV. The mean rate constant in Medium B, containing octoxynol at a concentration of 0.0039% (w/v) or 47% of the critical micelle concentration, is somewhat larger than the one in Medium A without octoxynol. However, the difference between the two values is not statistically significant because the observed t value of 1.816 is smaller than the critical t value at the 5% level for $N_1 + N_2 - 2 = 50$, namely, 2.008 (52).

A higher level of octoxynol in the dissolution medium, 3.9 times the critical micelle concentration, doubled the rate of dissolution. However, the rate of dissolution was increased tenfold when the surfactant was incorporated into the tablet rather than dissolved in the dissolution medium.

Micellar Solubilization of Prednisolone—To ascertain whether micellar solubilization of prednisolone by octoxynol could play a role in speeding up its dissolution from tablets, the solubility of prednisolone in 0.1 *N* HCl solutions containing different concentrations of octoxynol up to 0.128% (w/v) was measured at 37°.

To ensure that equilibration was attained, prednisolone suspensions in 0.1 *N* HCl containing different octoxynol concentrations were shaken at 37° for 2, 6, and 16 days prior to the colorimetric assay, and for 3, 6, and

Table VI—Particle Size Distribution of Prednisolone Suspensions at Different Octoxynol Concentrations

[a] Defined by Eq. 8. [b] Number of particles per milliliter.

22 days prior to analysis by the gravimetric method. In both methods, the longer shaking times did not significantly increase the amount of prednisolone solubilized, indicating that equilibrium had been reached within the shortest shaking times.

The linear relation between the solubility of prednisolone in 0.1 *N* HCl containing octoxynol at concentrations above the critical micelle concentration and the concentration of octoxynol was calculated by the least-squares method. If the solubility limit of prednisolone was expressed in milligrams per liter and the octoxynol concentration in percent (w/v), the colorimetric method yielded an intercept of 309 and a slope of 453. The gravimetric method yielded an intercept of 367 and a slope of 510. According to the *t* test (52), the difference between the two intercepts is not statistically significant at the 5% probability level. Moreover, the intercepts do not differ significantly from the solubility of prednisolone in 0.1 *N* HCl solutions with octoxynol levels between zero and the critical micelle concentration.

Because the difference between the slopes of the two regression lines was not statistically significant either, the two sets of data were pooled. The critical micelle concentration of 0.0083% was subtracted from the total octoxynol concentration C to give the concentration of octoxynol associated into micelles, expressed as percent (w/v). With the solubility of prednisolone S in milligrams per liter as the dependent variable, the equation of the regression line (N = 17) was:

$$S = 342 + 326\,(C - 0.0083) \qquad \text{(Eq. 7)}$$

with a correlation coefficient of 0.804.

The intercept, 342 mg/liter, represents the solubility of prednisolone in the aqueous environment. It is identical with the mean solubility value of prednisolone in 0.1 *N* HCl containing between 0 and 0.008% octoxynol, 343 ± 42 (N = 14).

The slope, 326 mg/liter of prednisolone/% (w/v) micellar octoxynol, represents the solubilizing capacity of octoxynol micelles for prednisolone. For Medium C, containing 0.0320 − 0.0083 = 0.0237% micellar octoxynol, the total solubility of prednisolone S is 350 mg/liter according to Eq. 7. Of this amount, only 8 mg/liter (350 − 342 = 0.0237 × 326 = 8) is solubilized in micelles.

Sedimentation Volumes of Prednisolone Suspensions—The sedimentation volumes of 50-ml suspensions containing 50 mg of prednisolone in 0.1 *N* HCl and different octoxynol concentrations are listed in Table V. Constant sedimentation volumes were reached within 24–48 hr. In the absence or at low concentrations of octoxynol, the suspensions consisted mostly of coarse particles, which were granular aggregates. At intermediate concentrations, in the vicinity of the critical micelle concentration, octoxynol broke these up progressively into fine particles which were rod-shaped. The latter tended to agglomerate into loose flocs at high octoxynol concentrations.

The sediments were stratified into two distinct layers consisting of the coarse and fine particles, respectively, separated by a sharp boundary. The sedimentation volumes of both types of particles were recorded separately and added together in Table V. Octoxynol decreased the sedimentation volumes of the coarse particles in two ways. With increasing concentration, the surfactant peptized progressive amounts of the coarse particles into fine, rod-shaped particles. It also caused the remaining coarse particles to pack more tightly into sediments that were more compact and, hence, occupied progressively smaller volumes.

The sedimentation volume of the fine, rod-shaped particles was not a monotonic function of the octoxynol concentration but went through a minimum in the vicinity of the critical micelle concentration (Fig. 4). The initial decrease was caused by deflocculation of the fine particles into primary rods. Flocs were rarely seen under the microscope below the critical micelle concentration.

As the surfactant concentration increased above the critical micelle concentration, the sedimentation volume of the fine particles increased in two ways. Their number increased because of the progressive breaking up of coarse particles. Moreover, the rod-shaped particles became more extensively aggregated into loose flocs of progressively larger size. Many flocs containing 40–60 rod-shaped particles were observed in 0.128% octoxynol.

Flocculation of the rod-shaped primary particles may be due to bridging by octoxynol micelles. As the surfactant concentration increased, the number and size of the micelles increased, thereby increasing their ability to bridge and bind together rod-shaped prednisolone particles. At concentrations exceeding the critical micelle concentration tenfold or more, cylindrical micelles probably begin to form which, at still higher

concentrations, produce the middle phase (53). Increasing micellar asymmetry increases the number of prednisolone particles on which a single micelle may be adsorbed, cementing them together into flocs.

Particle Size Distribution of Prednisolone Suspensions—Microscopic measurements were conducted on three suspensions in 0.1 *N* HCl containing 0, 0.0039, and 0.032% octoxynol, corresponding to dissolution Media A, B, and C, respectively. The fine particles were rods of length L and width or diameter W. To obtain a particle size distribution which included the fine rod-shaped particles and the coarse irregular particles, a single dimension was needed for the former. The dimension chosen was the surface diameter D (54, 55), *i.e.*, the diameter of a sphere having the same surface area as the rod, because the dissolution rate of very slightly soluble drugs depends largely on their surface area:

$$D = \sqrt{W(L + W/2)} \qquad \text{(Eq. 8)}$$

The particle size distribution data for the three media are listed in Table VI. Number- and weight-distribution frequencies were calculated by standard procedures (54–56). Cumulative plots yielding median diameters were not made because the size distributions are bimodal. However, mean volume–surface diameters D_{vs} (54–56) were calculated:

$$D_{vs} = \sum N_i D_i^3 / \sum N_i D_i^2 \qquad \text{(Eq. 9)}$$

where D_i is the diameter of the midpoint of the ith size range. For the rod-shaped particles, the D values were calculated by Eq. 8.

The D_{vs} values at different octoxynol concentrations and the corresponding specific surface areas, estimated as $6/D_{vs}$, are listed in Table VII. The surfactant increased the specific surface area A of the suspended prednisolone particles by only 10% below the critical micelle concentration but more than doubled it above that concentration.

Within the range of data of Table VII, there is a linear relation between the specific surface area A in cm^2/cm^3 and the octoxynol concentration C in % (w/v):

$$A = 347 + 12{,}900\,C \qquad \text{(Eq. 10)}$$

with a correlation coefficient of 0.99956. This proportionality cannot extend to higher octoxynol concentrations at which the coarse particles are completely broken down because, at these concentrations, the surfactant flocculates the primary, rod-shaped particles extensively.

DISCUSSION

The experimental data afford an assessment of the relative contributions of wetting, micellar solubilization, and deflocculation towards the enhancement of the dissolution rate of prednisolone by octoxynol.

Wetting—The first step in the disintegration of tablets and dissolution of the active ingredient is the displacement of air from the internal surface of the tablet by the dissolution medium, replacing the solid–air with a solid–liquid interface. This wetting process is expedited if the dissolution medium makes a small or zero contact angle on the solid surface. Small contact angles are generally produced by liquids of low surface tension.

The following facts demonstrate that wetting affected neither the disintegration time of the tablets nor the dissolution rate of the active ingredient. Medium A, consisting of 0.1 *N* HCl with a surface tension of 71.1 dyne/cm at 37°, produced only marginally greater disintegration times than Medium B, which consisted of 0.100 *N* HCl + 0.0039% octoxynol with only half the surface tension. Medium C, consisting of 0.1 *N* HCl + 0.032% octoxynol with a surface tension of 30.9 dyne/cm, which is only 4.5 dyne/cm below that of Medium B, reduced the disintegration time by one-third (Table III).

No additional air bubbles were released from the disintegrating tablets after the initial immersion time of 1 min. Therefore, wetting, *i.e.*, the penetration of the dissolution medium into the pores of the tablets and the displacement of the air therein, was completed within that period.

The dissolution rate of prednisolone in Medium B was only marginally higher than that in Medium A, despite the fact that the latter had twice the surface tension of the former. The dissolution rate in Medium C was twice that in Medium B (Table IV), despite the small difference in their surface tensions.

Since wetting depends markedly on surface tension, while the disintegration times and dissolution rates were not correlated with surface tension, wetting was not a rate-determining step for these processes.

Micellar Solubilization of Prednisolone—According to Eq. 7, 326 mg/liter prednisolone is solubilized by 1% (w/v) or 10,000 mg/liter micellar octoxynol at saturation. The solubilizing capacity of octoxynol is thus 0.0326 g of prednisolone/g of micellar octoxynol; *i.e.*, 0.057 mole of prednisolone/mole of micellar octoxynol, or 18 moles of micellar octoxynol/mole of solubilized prednisolone. This value is typical for micellar solubilization of steroids by nonionic surfactants (57, 58).

The following two facts demonstrate that micellar solubilization cannot play a significant role in the enhancement of the dissolution rate of prednisolone by octoxynol. Medium C, with 0.0320 − 0.0083 = 0.0237% micellar octoxynol, dissolves 350 mg/liter prednisolone at saturation, or a maximum of 315 mg for the actual 900-ml volume of the dissolution medium. Of the latter amount, only 7 mg is solubilized in micelles, while most of the prednisolone is dissolved in the aqueous environment.

Of the 25 mg of prednisolone contained in a tablet, only a small fraction will be solubilized by micelles, <3% if the partition coefficient of prednisolone dissolved in the aqueous phase and in the micelles of a 0.032% octoxynol solution equals the ratio of its solubility limits, namely, (350 − 8)/8 or 43:1.

The greatest enhancement of the dissolution rate of prednisolone was observed with Formulation III (Tables I and IV), where octoxynol was incorporated into the tablets. This 35 mg of octoxynol, if it existed entirely in the micellar form, could solubilize a maximum of 1.1 mg of prednisolone according to Eq. 7, *i.e.*, no more than 5% of the prednisolone present in the tablets. Thus, micellar solubilization cannot play a major role in speeding up the dissolution of prednisolone even in the hypothetical situation where the dissolution medium flowing into a tablet dissolves all of the octoxynol contained therein, and where the micellar solution thus produced becomes saturated with prednisolone inside the tablet before octoxynol begins to diffuse out.

Deflocculation—The tablet disintegration experiments provided a visual demonstration of deflocculation. Even at octoxynol concentrations below the critical micelle concentration, the tablets broke up into fine granules that remained in suspension, compared with coarse, quickly sedimenting grains in the absence of surfactant.

The data of Table VII and Eq. 10 indicate that octoxynol deflocculated the suspended prednisolone and that the extent of deflocculation was proportional to the surfactant concentration. It is interesting to compare quantitatively the increase in dissolution rate with the increase in specific surface area measured at comparable octoxynol concentrations to ascertain whether the deflocculation was extensive enough to produce the observed increases in dissolution rate.

The Noyes–Whitney (59) and Nernst–Brunner (60) equation relates the rate of change of drug concentration C in the dissolution medium with time t to the specific surface area A of the drug particles, the thickness h of the stagnant saturated solvent layer surrounding the drug particle, the solubility limit of the drug, C_s, which is its concentration in the stagnant layer, and the drug concentration C_t in the bulk solvent at time t:

$$\frac{dC}{dt} = \frac{DA}{h}(C_s - C_t) \qquad \text{(Eq. 11)}$$

where D represents the diffusion coefficient of the drug molecules in solution.

The maximum values of C_t in the present experiments, attained when the 25 mg of prednisolone present in the tablets is completely dissolved in the 0.9-liter volume of dissolution medium, is 25 mg/0.9 liter or 28 mg/liter. This value is <10% of the lower prednisolone solubility limit of 342 mg/liter obtained in the absence of octoxynol. Therefore, $C_s \gg C_t$ and $C_s - C_t \cong C_s$. The left term in Eq. 11 represents the zero-order dissolution rate constant k obtained from Fig. 3 and listed in Table IV. Thus, Eq. 11 simplifies to:

$$k = DAC_s/h \qquad \text{(Eq. 12)}$$

indicating that k should be directly proportional to A if h is independent of A.

The last column of Table VII lists the ratios k/A. They increased by a mere 16% while A and k more than doubled. The slight increase in the k/A ratio with increasing k and A values may not be statistically significant despite the consistent trend. If the increase is significant, it can be ascribed to a slight decrease in h caused by an increase in A. A slight decrease in the thickness of the stagnant layer caused by a large reduction in particle size is to be expected.

Of the three possible mechanisms by which octoxynol could have increased the rate of dissolution of prednisolone, only deflocculation was extensive enough to account for the magnitude of the observed rate enhancement. Neither wetting nor micellar solubilization made significant contributions to the observed effect.

Higher octoxynol concentrations, *e.g.*, 16 times its critical micelle concentration, produced extensive flocculation of the primary rod-shaped particles. However, these surfactant concentrations were much larger than those attainable in a practical situation.

Table VII—Mean Volume–Surface Diameters and Specific Surface Areas of Prednisolone Suspensions and Their Relation with Dissolution Rate Constants

Octoxynol Concentration, % (w/v)	D_{vs}, μm	A, cm^2/cm^3	k[a], %/min	k/A, 10^4(%/min)/(cm^2/cm^3)
0	170	353	0.218	6.2
0.0039	154	390	0.251	6.4
0.032	79	760	0.547	7.2

[a] Values of zero-order dissolution rate constant from Table IV.

The highest dissolution rates were obtained when the octoxynol was incorporated into the tablets. The transient, relatively concentrated octoxynol solutions produced inside tablets when the octoxynol was extracted from the microcrystalline cellulose by the inflowing dissolution medium produced the most extensive deflocculation of prednisolone. Even these solutions, however, broke up the coarse particles without flocculating the resulting rod-shaped particles. Moreover, flocs of the rod-shaped particles dispersed readily when the suspending medium of concentrated octoxynol was diluted with water or 0.1 *N* HCl.

Relation between Tablet Disintegration Time and Prednisolone Dissolution Rate—Octoxynol reduced the tablet disintegration time and increased the prednisolone dissolution rate considerably. Therefore, the mean tablet disintegration times t in minutes (Table III) and the zero-order rate constants for the dissolution of prednisolone k, in percent per minute (Table IV), were compared for tablets of Composition I in Media A, B, and C and for tablets of Composition II in Medium A.

The relation between log k and t was linear:

$$\log k = 0.546 - 0.0113\,t \qquad \text{(Eq. 13)}$$

with a correlation coefficient of 0.997. While it is to be expected that a given factor, such as the presence of a surfactant, which reduces disintegration times also increases dissolution rates (61, 62), no physical meaning is ascribed to the fact that the two parameters were related by a linear relationship on a semilogarithmic scale.

Abstract □ Condensation of 5-formyl-6-methoxy-2,3-diphenylbenzofuran (I) and 6-formyl-5-methoxy-2,3-diphenylbenzofuran (II) with aliphatic or aromatic primary amines led to the formation of the corresponding anils (III*a–k* and IV*a–c*). The anils (III*a,f,k* or IV*a–c*) reacted with ethyl cyanoacetate, ethyl acetoacetate, or diethyl malonate to form the respective esters (V*a–c* or VI*a–c*). When V*a–c* or VI*a–c* were treated with pyridine hydrochloride, demethylation occurred followed by cyclization to form the corresponding furocoumarins (VII*a–c* or VIII*a–c*). Reduction of the anils using sodium borohydride furnished the corresponding Mannich bases (X*a–d* and XI). The antimicrobial activity of compounds III*i*, IV*c*, V*a*, VI*a*, and VIII*a* was investigated.

Keyphrases □ Benzofuran—derivatives, synthesis for possible biological activity □ Furocoumarin—derivatives, synthesis for possible biological activity □ Antimicrobial activity—synthesis of some benzofuran and furocoumarin derivatives for possible biological activity

Furocoumarins (1–3) are used as photosensitizing agents, and some of their derivatives possess tuberculostatic (4) as well as molluskicidal (5) activity. Following up a previous investigation (6), synthesis of some new furocoumarins (VII and VIII) derived from 5-formyl-6-methoxy-2,3-diphenylbenzofuran (I) (7) and 6-formyl-5-methoxy-2,3-diphenylbenzofuran (II) (6, 7) was undertaken to investigate these compounds.

DISCUSSION

Condensation of I or II with equimolar quantities of the appropriate amines gave the corresponding anils (III or IV), respectively. The amines employed were propyl-, isopropyl-, hexyl-, cyclohexyl-, benzylamine; aniline; *m*-toluidine; *p*-toluidine; *p*-anisidine; and *m*-chloro- and *p*-chloroaniline.

The structure assigned to these anils was supported by IR spectra,

c, R=$C_6H_4OCH_3$ (*para*)

which showed absorption at 1625–1635 cm^{-1} assignable to —CH=N (8). The PMR spectrum of III*e* showed singlets at δ 3.92 (OCH_3, 3H), 4.84 (CH_2—, 2H), 7.08 (C-4, 1H), and 8.18 (C-7, 1H). The aromatic protons appeared as multiplets at 7.40–7.66 (15H). The mass spectra of III*e* and *k* showed intense molecular ions (M^+) at *m/z* (relative intensity) 417 and 437/439, respectively. In both spectra the imino moieties were eliminated yielding a base peak at *m/z* 311.

Compounds III*e*, *f*, or *k* and IV*a–c* reacted with ethyl cyanoacetate in dry benzene to give the respective esters, V*a* and VI*a*. Compounds V*a* and VI*a* were also obtained by the reaction of I and II with ethyl cyanoacetate in the presence of piperidine. The IR spectrum of V*a* revealed a band at 2220 cm^{-1} characteristic for C≡N group and a band at 1705

cm^{-1}, indicating an ester carbonyl ($—COOC_2H_5$). The mass spectrum of Va showed an M^+ at m/z (relative intensity) 423.

When Va or VIa were treated with pyridine hydrochloride, the furocoumarins VIIa or VIIIa were formed, respectively. The reaction involved demethylation followed by cyclization to form the intermediate derivative IX, which underwent hydrolysis followed by decarboxylation.

The IR spectrum of VIIa showed a band at 1725 cm^{-1} characteristic for the >C=O vibration of coumarins (9). Moreover, absorption bands, corresponding to C≡N and ester >C=O, were not present as in the parent ester Va. The mass spectrum of VIIa showed an M^+ at m/z (relative intensity) 338.

In a similar manner, reaction of IIIf or IVa with ethyl acetoacetate and diethyl malonate yielded Vb and c or VIb and c, respectively.

The mass spectrum of Vb and c showed an M^+ at m/z 440 and 470, respectively.

Treatment of Vb and c and VIb and c with pyridine hydrochloride yielded the corresponding acetyl and carboethoxyfurocoumarin derivatives, VIIb and c and VIIIb and c, respectively.

The structures of VIIb and c and VIIIb and c were confirmed by their melting points and mixed melting points with authentic samples prepared by the reaction of I and II with ethyl acetoacetate and diethyl malonate in the presence of piperidine (7).

Sodium borohydride reduction of the benzofuran anils, IIIa, f, i, and k and IVa, were carried out in ethanol and gave the corresponding Mannich bases Xa–d and XI.

The IR spectrum of Xb showed absorption at 3380 cm^{-1} due to NH

Table III—Physical Data of Mannich Bases X*a–d* and XI

Compound	mp	Yield, %	Formula	Analysis Calc.	Found
X*a*	184–186	69	$C_{25}H_{25}NO_2$	C 80.86 H 6.74 N 3.77	C 81.23 H 7.01 N 3.98
X*b*	154–156	80	$C_{28}H_{23}NO_2$	C 82.96 H 5.68 N 3.46	C 83.17 H 5.82 N 3.58
X*c*	148–150	66	$C_{29}H_{25}NO_3$	C 80.00 H 5.75 N 3.22	C 79.69 H 5.60 N 2.97
X*d*	103–105	53	$C_{28}H_{22}ClNO_2$	C 76.45 H 5.01 Cl 8.08 N 3.19	C 76.71 H 5.35 Cl 8.24 N 3.22
X*I*	124–126	47	$C_{28}H_{23}NO_2$	C 82.96 H 5.68 N 3.45	C 82.76 H 5.80 N 3.07

and no absorption characteristic for C=N appeared. The PMR spectrum of X*b* revealed singlets at δ 3.85 (OCH_3, 3H), 4.40 (CH_2, 2H), 6.75 (C-4, 1H), and 7.72 (C-7, 1H). The NH proton appeared as a broad band at δ 4.00 which disappeared after adding deuterium oxide. Finally, the multiplets at δ 7.17–7.46 corresponded to 15 aromatic protons. The mass spectrum of X*b* showd an M^+ at *m/z* (relative intensity) 405 as a base peak.

EXPERIMENTAL[1]

Studies for Antimicrobial Activity—The activity of some compounds were tested on *Bacillus subtilis*, NRRL 543; *Escherichia coli*, NRRL 210; *Klebsiella pneumoniae*, NRRL 117; *Proteus mirabilis; Sarcina lutea; Salmonella typhosea*, NRRL 537 (bacteria); *Candida lypolitica; Candida pellicula; Sacharomyces cerviceae*, NRRL Y567 (yeasts); *Aspergillus nigar*, NRRL 599; *Fusarium moniliforme*, and *Penicillium funiculosum* (fungi[2]).

Preparation of Benzofuran Anils (III*a–k* and IV*a–c*)—The appropriate amine (0.03 mole) and piperidine (0.5 ml) were added to a solution of I or II (0.03 mole) in benzene or ethanol (50 ml). The reaction mixture was refluxed for 3 hr, then concentrated to ~10 ml and left to cool. The solid was filtered and crystallized from ethanol to give III*a–k* and IV*a–c* as white-yellow crystals (Table I).

Preparation of the Esters (V*a–c* and VI*a–c*)—*Method A*—A mixture of III or IV (1 g) in dry benzene (20 ml) and either ethyl cyanoacetate, ethyl acetoacetate, or diethyl malonate (1.5 ml) was stirred for 0.5 hr and left overnight. The solvent was evaporated under reduced pressure and 5 ml of water was added. The solution was heated and then left to cool. The solid that separated was filtered and crystallized from ethanol to give V*a–c* or VI*a–c* as yellow crystals.

Method B—A mixture of I or II (1 g), 1.5 ml of ethyl cyanoacetate, ethyl acetoacetate, and diethyl malonate esters and piperidine (0.5 ml) in ethanol (50 ml) was refluxed for 1 hr and left to cool. The solid that formed was crystallized from ethanol as yellow crystals.

Methods A and B gave the same products (melting point and mixed melting point gave no depression) (Table II).

Action of Pyridine Hydrochloride on V*a–c* and VI*a–c*—A mixture of V*a–c* or VI*a–c* (1 g) and freshly prepared pyridine hydrochloride (3 g) was kept at 200° for 20 min, left to cool, then acidified with dilute hydrochloric acid. The solid was filtered and crystallized from an appropriate solvent.

Compound VII*a* was obtained at a 56% yield as pale brownish crystals from ethanol, mp 223–225°.

Anal.—Calc. for $C_{23}H_{14}O_3$: C, 81.66; H, 4.14. Found: C, 81.93; H, 3.99.

Compound VII*b* was crystallized from ethanol as pale brownish crystals, mp 256–258°; yield 55% (melting point and mixed melting point with an authentic sample (7) gave no depression).

Compound VII*c* was obtained as pale brownish crystals from ethanol, mp 196–198°; yield 34% (melting point and mixed melting point with an authentic sample (7) gave no depression).

Compound VIII*a* gave a 53% yield as pale brownish crystals from methanol, mp 220–222°.

Anal.—Calc. for $C_{23}H_{14}O_3$: C, 81.66; H, 4.14. Found: C, 81.41; H, 4.36.

Compound VIII*b* produced a 49% yield as pale brownish crystals from ethanol, mp 256° (melting point and mixed melting point with an authentic sample (7) gave no depression).

Compound VIII*c* gave a 52% yield as pale brownish crystals from acetone, mp 195° (melting point and mixed melting point with an authentic sample (7) gave no depression).

Preparation of the Mannich Bases (X*a–d* and XI)—A mixture of III*c, f, i, k*, or IV*a* (1 g) and sodium borohydride (2 g) in ethanol (50 ml) was heated at 50° for 5 min to start the reaction. The reaction mixture was stirred for 2 hr, and 20 ml water was added and left overnight. The solution was filtered, and the solid washed with water and crystallized from ethanol to give the Mannich bases X*a–d* and XI as colorless needles (Table III).

Antimicrobial Activity—A freshly prepared suspension of the test organisms was used to inoculate three plates, each with nutrient agar (bacterial strain), media containing glucose (10 g), yeast extract (3 g), peptone (5 g), and agar (20 g). All ingredients were dissolved in 1 liter of distilled water and adjusted at pH 6.0. The fungi were cultivated on Dox's agar plates. Fungal inoculum was prepared from 14-day old cultures. The paper disk method was used to test III*i*, IV*c*, V*a*, VI*a*, and VII*a*; one representing each series selected at random to screen their antimicrobial activity. A filter paper disk (5-mm diameter) containing 100 μg from each compound was soaked, dried, and firmly applied to the surface of the inoculated agar plates and then the plates with the bacterial strain were incubated at 37° for 48 hr, while those containing yeast and fungi were

Table IV—Antimicrobial Activity of Compounds III*i*, IV*c*, V*a*, VI*a*, and VII*a* Against Bacteria, Yeasts, and Fungi

[a] Diameters of inhibition zone in millimeters.

[1] All melting points are not corrected. The IR spectra were recorded on Carl-Zeiss Spectrophotometer model UR 10. The PMR spectra were run in $CDCl_3$ at 60 MHz, with tetramethylsilane as internal standard on a Varian instrument. Mass spectra were carried out at 70 eV on a Varian Mat 112 Spectrometer.

[2] The organisms with no identification numbers were isolated locally and were isolated by M. M. Fahim, Y. A. Abduo, and M. M. Atalla, Third Egypt. Phytopathol. Congress, Cairo, pp 734–744 (1979).

incubated at 30° for 48–72 hr. The inhibition zone was measured around each disk (Table IV).

CONCLUSIONS

The present results indicate that the microorganisms tested were sensitive to the action of the anils (IIIi and IVc) and the esters (Va and VIa) except for *A. nigar* and *F. moniliforme*. The results also illustrated that the anils potentiate the activity more than the esters. However, it was observed that the presence of the methoxy group in the *para* position to the benzofuran oxygen (IVc and VIa) increased the activity. The cyclization of Va blocked the activity against most of the microorganisms tested. Such preliminary results would encourage further studies to elucidate the relationship between structure and activity.

Aspirin—A National Survey V: Determination of Aspirin and Impurities in Enteric Coated Tablets and Suppository Formulations and *In Vitro* Dissolution of Enteric Coated Tablets

ROSS D. KIRCHHOEFER ˣ, EVERETT JEFFERSON, and PAUL E. FLINN

Received September 18, 1981, from the *National Center for Drug Analysis, Food and Drug Administration, St. Louis MO 63101.* Accepted for publication December 9, 1981.

Abstract □ The results of a national survey on the quality of enteric coated aspirin tablets and aspirin suppositories are presented. The tablets were analyzed for strength, salicylic acid content, *in vitro* dissolution rate, and related aspirin impurities. The suppositories were analyzed for strength and salicylic acid content. The methods of analysis and validation of data are also presented.

Keyphrases □ Aspirin—semiautomated procedure for enteric coated tablets □ Dissolution—automated *in vitro* profiles of enteric coated aspirin tablets □ Analgesics—determination of aspirin and impurities in enteric coated tablets

A national survey of aspirin tablet products was conducted at the National Center for Drug Analysis in 1978 and 1979 to ascertain the quality of these products.

Parts I–III (1–3) of this series deal with the analysis of aspirin, salicylic acid, and aspirin related impurities in plain and buffered tablets. Part IV (4) compares *in vitro* dissolution results for these dosage forms using both the USP XX paddle and basket procedures (5). The present report describes the quality of enteric coated tablets with respect to content uniformity, dissolution characteristics, and impurities. Suppository formulations were also checked for content uniformity and impurities.

The official compendia do not provide a method or criterion for the *in vitro* dissolution of enteric coated tablets. Embil and Torosian (6) described the dissolution behavior of two brands of enteric coated tablets using a basket procedure. Over 60% of the aspirin content in the two brands dissolved within 3 hr, but there were significant differences in the release rates. Johansen (7) investigated the correlation between dissolution and absorption rates for plain and enteric coated aspirin tablets. The dissolution rate determinations were made with both a Sartorius apparatus and a USP XIX basket apparatus. Johansen found that the USP XIX basket apparatus, when applied to enteric coated tablets, gave a poor *in vitro/in vivo* correlation. He attributed this to the fact that the USP apparatus dissolved aspirin rather quickly after changing from simulated gastric fluid to intestinal fluid. To obtain a better correlation he recommended decreasing the rotational speed of the basket.

The purpose of this study was to investigate a semiau-

[a] (A) Eli Lilly & Co., Indianapolis, Ind.; (B) Smith Kline Corp., Philadelphia, Pa.; (C) Vale Chemical Co., Allentown, Pa.; (D) Standard Pharmacal Co., Chicago, Ill. [b] Each value represents 60 determinations unless otherwise noted. Number in parentheses is standard deviation. [c] Met compendial requirements. [d] Represents 30 determinations.

tomated UV (1) method for the determination of aspirin in enteric coated tablets, an automated method for the determination of the *in vitro* dissolution rate of aspirin from enteric coated tablets, and a manual UV method for the determination of aspirin in suppositories. In addition, five batches of enteric coated tablets were tested for aspirin-related impurities by the procedures described previously (3).

EXPERIMENTAL

Content Uniformity of Enteric Coated Tablets—*Apparatus, Reagents, and Determination*—These have been described previously (1).

Standard Preparation—About 325 mg of USP reference standard aspirin was accurately weighed and dissolved in 50.0 ml of buffer–ethanol solution (1:1). The standard solution was prepared fresh daily.

Sample Preparation—Each 325-mg enteric coated tablet was cracked and partially crushed in a piece of weighing paper[1] with a hammer and then transferred to separate 50-ml volumetric flasks. Alcoholic pH 2.2 buffer solution was added, and the flasks were placed in an ultrasonic bath[2] for ~1.5 hr with frequent shaking. The flasks were kept cool with circulating tap water. The flasks then were removed and the contents diluted to volume with alcoholic pH 2.2 buffer solution. After settling for 30 min, the solution in the flasks was analyzed as described previously (1).

Dissolution—*Apparatus*—A dissolution apparatus[3], equipped with a paddle [apparatus 2, (5)], and an automated sampler described previously (8) were used. The USP paddle method was used because it has been preferred historically in the laboratory.

For the determinative step, an automatic analyzer with a pump[4], manifold, spectrophotometer[5], flowcell[6], and recorder[7] was connected to the automatic sampler (8).

Reagents—American Chemical Society (ACS) grade chloroform was washed with water and filtered through paper on the day of use. The 0.4 *N* HCl was prepared by diluting 34.0 ml of concentrated hydrochloric acid to 1.0 liter with water. The simulated gastric fluid and simulated intestinal fluid was prepared according to the procedure in the USP XX (5) but without enzyme.

Standard Preparation—About 324 mg of USP reference standard aspirin was accurately weighed and dissolved in 500.0 ml of simulated intestinal fluid. The standard was prepared fresh daily and used without delay. Similar standards were prepared for the 486- and 648-mg tablets.

Sample Preparation—One tablet was placed in each dissolution vessel, which contained 500 ml of simulated gastric fluid. The paddles were rotated at 50 rpm for 1 hr, then the fluid was replaced with 500 ml of simulated intestinal fluid.

Automated Sampling—The aliquots were removed automatically every 15 min. The six dissolution sample probes were first placed into the standard solution, and the standard was sampled through the first cycle. The probes were then removed from the standard solution and placed in the dissolution medium. The aliquots were diluted with simulated intestinal fluid and stored in the holding–mixing coil. As the aliquots were pumped sequentially out of the holding–mixing coil, the stream was acidified with 0.4 *N* HCl and mixed.

Automated Determination—The automated system was assembled as shown in Fig. 1. Air was first removed from the acidified stream, which was drawn continuously into the manifold. The acidified stream was extracted with chloroform and resampled. The absorbance of the chloroform solution was monitored at 280 nm. The standard reading obtained through each probe was used to calculate the result from the sample reading obtained through that probe.

Suppositories—A recording spectrophotometer[8] and ACS reagent grade chloroform and glacial acetic acid were used.

Standard Preparation—About 100 mg of USP reference standard aspirin was accurately weighed and dissolved in 100.0 ml of chloroform. A 5.0-ml aliquot was diluted to 100.0 ml with a 1% acetic acid in chloroform solution.

Sample Preparation—Each suppository was dissolved in chloroform and diluted to volume with chloroform in an appropriate volumetric flask. An aliquot was taken and diluted with 1% acetic acid in chloroform to give a concentration similar to the standard.

Quantitation—The absorbance of both the standard and sample was measured from 350 to 220 nm in a 1-cm cell with 1% acetic acid in chloroform as the reference solution. The corrected net absorbance at 280 nm was used for the calculation of aspirin in each suppository.

Aspirin Identification and Salicylic Acid Limit Test—An ascending chromatography tank[9] (use unlined), silica gel plates[10], and a fluorescence detector[11] were used. Petroleum ether (bp range 30–60°), ethyl acetate, chloroform, glacial acetic acid, methanol, and ferric chloride hexahydrate were ACS reagent grade and/or suitable for chromatography. The mobile phase consisted of petroleum ether–ethyl acetate–glacial acetic acid (85:18:3).

Standard Aspirin Preparation—A concentration of 20.0 mg/ml of aspirin in chloroform was prepared and used as quickly as possible.

Standard Salicylic Acid Preparation—Solutions containing 0.02, 0.05, 0.10, 0.20, 0.40, and 0.80 mg/ml of salicylic acid in chloroform were prepared by quantitative dilution of a stock solution.

Sample Preparation—For the tablets a portion of a powdered composite was mixed with a 1.5% acetic acid in methanol solution to give an aspirin concentration of 20 mg/ml. The solution was centrifuged to obtain a clear supernate.

The suppositories were dissolved in chloroform to give a concentration of 20 mg/ml, except the 60-mg dose, which was diluted to a final concentration of 10 mg/ml.

Determination—About 100 ml of mobile phase was poured into the developing tank. The TLC plate was prewashed. The plate was removed and protected from evaporation by covering with two clear glass plates. The protective glass plates were separated to expose the origin or spotting line. One-microliter aliquots of each sample and standard were spotted 2 cm apart on the origin line. The mobile phase used for prewash was replaced with fresh mobile phase. The plate was developed until the solvent front had migrated at least 10 cm from the origin line. The plate was removed and dried on a hot plate until only a faint odor of acetic acid remained.

[a] Average of six tablets; number in parenthesis is standard deviation. [b] See Table I, footnote *a*.

Salicylic acid was determined by scanning the plate with the densitometer. The spot intensities of the standard and sample were compared. An amount of salicylic acid in the spotted sample corresponding to the 0.20-mg/ml standard would be equivalent to the 1% limit. After the limit test, the remaining spots were visualized by spraying with ferric chloride TS (5) and heating at 110° for 10 min. Aspirin was identified by comparison of the R_f of the sample and standard spots.

Table IV—Comparison of Salicylic Acid (Percent of Aspirin) Data from the TLC and USP XX Procedures

Material	TLC	USP
648-mg Enteric coated tablet composite	1.3	1.3
Aspirin powder	0.1	0.1
324-mg Enteric coated tablet composite	0.6	0.5
648-mg Suppository composite	0.7	0.6
120-mg Suppository composite	0.2	0.3

RESULTS AND DISCUSSION

Tablet Content Uniformity Validation Test—The original validation for the content uniformity determination was described previously (1). Portions of a ground tablet composite equivalent to single tablets were analyzed by the proposed method and the USP XX (5). The ground tablet composite was prepared from a commercial 648-mg enteric coated tablet. The average of 22 results was 102.0% with a coefficient of variation of 1.91%. The USP XX result was 103.2%. The results obtained for the content uniformity determination of aspirin and the salicylic acid concentrations in enteric coated tablets are given in Table I. No batches were found outside USP XX specifications for strength or salicylic acid.

Dissolution Validation Tests—A series of validation tests were performed on the automated dissolution system. A linear response was obtained when four solutions of standard containing from 0.324 to 1.296 mg of aspirin/ml (corresponding to 50–200% of a 324-mg label declaration) were tested. Carry-over for 100–200–100–50% series of aspirin solutions was also determined with satisfactory results. A portion of the ground composite equivalent to one tablet was accurately weighed and subjected to the dissolution test for 5 hr. The analysis obtained for aspirin was 101.3% of that declared. The hydrolysis rate of aspirin determined on this sample over 5 hr was calculated to be 2.1%/hr.

Table V—Impurities [a] as Percent of Label Declaration of Aspirin Found in Enteric Coated Aspirin Tablets

Manufacturer [b] Batch	Tablet Dosage, mg	I,%	II,%	III,%
A_1	324	— [c]	0.243	— [d]
A_2	648	— [c]	0.224	— [d]
B_1	324	— [c]	0.094	Trace [e]
C_1	324	— [c]	0.050	— [d]
D_2	486	0.006	0.087	— [d]

[a] Impurities: I, acetylsalicylic anhydride; II, acetylsalicylsalicylic acid; III, *O*-salicylsalicylic acid. [b] See Table I, footnote *a*. [c] Assay could not be performed on this formulation. Colloidal suspension in benzene layer. [d] Not detected. [e] Trace = 0.01%.

Table II shows the dissolution rates for the batches representing various manufacturers. The batch results are not corrected for aspirin hydrolysis. Only three of the seven batches showed significant amounts of dissolution in the 3–4 hr period. A physical inspection of the residues from batches C_1, D_1, D_2, and D_3 revealed that the tablets were still firm and 90% intact. Batch D_3, which gave one of the lowest percentage rates, was analyzed again at a paddle speed of 100 rpm. There was no increase in dissolution. The percentages were almost identical to the results obtained at 50 rpm. No sample showed signs of dissolution in the 1-hr pretreatment with gastric fluid.

Both batch A_1 and D_1 gave similar salicylate blood level concentrations[12]. Therefore, this dissolution test, in its present form, is not satisfactory for predicting bioavailability.

Suppository Validation Test—Portions of a composite prepared from a commercial 324-mg suppository were analyzed by the USP XX and the dilute-and-read procedures. The result for the USP procedure was 102.5% of declared and 104.9% for the proposed procedure. The UV curves obtained from the standard and sample solutions were nearly identical and showed very little background interference from the suppository excipients. The results obtained for the content uniformity determination of aspirin and the salicylic acid concentrations in suppositories are given in Table III. Three batches from Manufacturer E exceeded the USP XX limit for salicylic acid.

Salicylic Acid Limit Test Validation by TLC—A linear calibration curve was obtained for salicylic acid when concentrations from 0 to 800 ng/μl were spotted. The fluorescent readings were made by scanning the chromatogram with the spectrodensitometer in the reflectance mode at a fluorescence excitation wavelength of 310 nm and an emission wavelength of 410 nm. Table IV shows the data obtained by the TLC and USP XX (5) procedures on commercial samples. Salicylic acid has a relative R_f value of 1.7 compared to aspirin. In addition, five batches of enteric coated tablets (A_1, A_2, B_1, C_1, and D_2) were analyzed for aspirin-related impurities by the HPLC method described previously (3). Table V shows the amounts of impurities found in these batches. Suppository samples were not tested for impurities.

NOTES

Potential Anticonvulsants IV: Condensation of Isatin with Benzoylacetone and Isopropyl Methyl Ketone

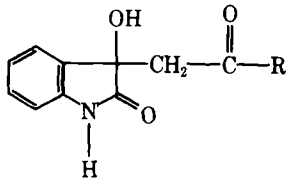
FRANK D. POPP ˣ and HOSSEIN PAJOUHESH

Received June 8, 1981, from the *Department of Chemistry, University of Missouri-Kansas City, Kansas City, MO 64110.* Accepted for publication November 16, 1981.

Abstract □ A series of new 3-hydroxy-3-substituted oxindoles were prepared and screened for anticonvulsant activity. A number of these 3-hydroxyoxindoles had activity in the maximal electroshock seizure test.

Keyphrases □ Anticonvulsants—condensation of isatin, benzoylacetone, isopropyl methyl ketone □ Isatin—anticonvulsants, condensation, benzoylacetone, isopropyl methyl ketone □ Benzoylacetone—anticonvulsants, condensation of isatin, isopropyl methyl ketone □ Isopropyl methyl ketone—anticonvulsants, condensation of isatin, benzoylacetone

The anticonvulsant activity[1] of 3-hydroxy-3-phenacyloxindole (I) (1) and 3-hydroxy-3-acetonyloxindole (II) has been reported previously. In a study of analogs of I and II (2) it was found in initial screening that III, derived from isatin and benzoylacetone and having features of both I and II, was inactive at 600 mg/kg in the maximal electroshock seizure test (MES)[1] but was active at 100 mg/kg in the pentylenetetrazol seizure threshold test (Met)[1]. Compound IV related to II and derived from isatin and isopropyl methyl ketone, was active at 100 mg/kg in the MES test and inactive in the Met test. This report de-



I R = C_6H_5
II R = CH_3
IV R = $CH(CH_3)_2$

FRANK D. POPP ˣ and HOSSEIN PAJOUHESH

Received June 8, 1981, from the *Department of Chemistry, University of Missouri-Kansas City, Kansas City, MO 64110.* Accepted for publication November 16, 1981.

Abstract □ A series of new 3-hydroxy-3-substituted oxindoles were prepared and screened for anticonvulsant activity. A number of these 3-hydroxyoxindoles had activity in the maximal electroshock seizure test.

Keyphrases □ Anticonvulsants—condensation of isatin, benzoylacetone, isopropyl methyl ketone □ Isatin—anticonvulsants, condensation, benzoylacetone, isopropyl methyl ketone □ Benzoylacetone—anticonvulsants, condensation of isatin, isopropyl methyl ketone □ Isopropyl methyl ketone—anticonvulsants, condensation of isatin, benzoylacetone

The anticonvulsant activity[1] of 3-hydroxy-3-phenacyloxindole (I) (1) and 3-hydroxy-3-acetonyloxindole (II) has been reported previously. In a study of analogs of I and II (2) it was found in initial screening that III, derived from isatin and benzoylacetone and having features of both I and II, was inactive at 600 mg/kg in the maximal electroshock seizure test (MES)[1] but was active at 100 mg/kg in the pentylenetetrazol seizure threshold test (Met)[1]. Compound IV related to II and derived from isatin and isopropyl methyl ketone, was active at 100 mg/kg in the MES test and inactive in the Met test. This report de-

scribes the synthesis and anticonvulsant activity of analogs of III and IV and related compounds.

RESULTS AND DISCUSSION

A number of substituted isatins were condensed with isopropyl methyl ketone to give the analogs of IV shown in Table I. None of these compounds were as active as II. Benzoylacetone was also condensed with a number of substituted isatins to give the analogs of III shown in Table II. None of these compounds were active in the MES test and only the 5-bromo analog of III was as active as III in the Met test. Subsequent screening of IV has shown an ED_{50} of 151.8 in the MES test, 242.9 in the Met test, and 211.8 in the subcutaneous picrotoxin test with a TD_{50} of 843.6. This compound gave a maximum protection of 62.5% at 200 mg/kg in the subcutaneous bicuculline test.

Dehydration of analogs of III derived from 5-bromoisatin and from 4-chloro-7-methoxyisatin gave compounds (V) inactive at 600 mg/kg in both the MES and Met screens.

Anticonvulsant screening results of a number of related compounds are included in Table III and further screening results on analogs of II (2) are included in Table IV.

In the 3-hydroxyoxindoles studied to date, II has the best activity and protective index in the MES test. None of the compounds in this report

have outstanding activity in the Met test. The effect of structure to activity in the 3-hydroxyoxindoles is still not clear, although it appears that substituents on the oxindole portion of the molecule do not enhance and generally decrease the activity. The study of the effect of substituents in the 3-position is being continued.

EXPERIMENTAL[2]

Condensation of Isatins with Ketones—The compounds in Tables I, II, and III were prepared, as previously described (1–3), by heating a solution of isatin and the appropriate ketone in absolute ethanol containing a few drops of diethylamine on a steam bath.

Dehydration of 3-Hydroxyoxindoles.—Following the procedure of Braude and Lindwall (4) the product from 5-bromoisatin and benzoylacetone was heated on a steam bath in acetic acid containing a small amount of hydrochloric acid to give V (R = 5-Br), mp 232–234° (ethanol).

Anal.—Calc. for $C_{18}H_{12}BrNO_3$: C, 58.40; H, 3.27; N, 3.78. Found: C, 58.22; H, 3.55; N, 3.64.

In a similar manner V (R = 4-Cl-7-OCH_3), mp 225–226° (ethanol), was obtained.

Anal.—Calc. for $C_{19}H_{14}ClNO_4$: C, 64.14; H, 3.97; N, 3.94. Found: C, 64.18; H, 4.03; N, 3.86.

[2] All compounds exhibited IR spectra consistent with the structures shown and with those previously reported (1–3). Melting points are uncorrected, and analyses were carried out by the Spang Microanalytical Laboratory.

GC Analysis of Imidazopyrazole in Plasma Using Nitrogen-Specific Detection

GARRY W. BOSWELL * **and JORDAN L. COHEN** ˣ

Received September 18, 1981, from the *School of Pharmacy, University of Southern California, Los Angeles, CA 90033.* Accepted for publication December 15, 1981. *Present address: Letterman Army Institute of Research, San Francisco, CA 94129.

Abstract □ A sensitive, specific GC assay for imidazopyrazole in plasma was developed using nitrogen-specific detection. The samples are extracted with methylene chloride containing 7-bromo-imidazopyrazole as the internal standard and the extract derivatized with pentaflourobenzoyl chloride prior to isothermal chromatography on an OV-17 column. Peak-height ratio measurements produced linear standard curves over the concentration range of 0.045–40 μg/ml. The practical limit of sensitivity was 50 ng/ml and typical between-run variability for replicate analysis of a control specimen produced a coefficient of variation of 5.1%. This method is applicable to the study of the pharmacokinetics of imidazopyrazole following therapeutic doses and was used to support such studies in parallel with Phase I clinical studies in children.

Keyphrases □ Imidazopyrazole—GC analysis, plasma, nitrogen-specific detection □ Plasma—GC analysis of imidazopyrazole, nitrogen-specific detection □ Nitrogen-specific detection—GC analysis of imidazopyrazole, plasma □ GC analysis—imidazopyrazole in plasma

Imidazopyrazole[1] (2,3-dihydro-1-H-imidazo[1,2,-6]-pyrazole[2], I) is an investigational antineoplastic agent which selectively inhibits DNA synthesis (1). Preclinical studies have shown I to have significant antitumor activity especially against L-1210 leukemia cells, including those variants resistant to similar chemotherapeutic agents (2). The suggested mechanism of action is inhibition of ribonucleotide reductase, and in mice the drug showed the capacity to synchronize tumor, bone marrow, and duodenal crypt cells in the S-phase of the cell cycle (3). Phase I clinical trials of this novel agent have been initiated in children and adults with initial doses of 150 mg/m^3 body surface area (4), and an obvious need to collect early pharmacologic disposition data exists.

A limited number of methods for determining I in biological media have been preliminarily reported including liquid scintillation of radiolabeled drug (5), radioimmunoassay (6), and electron-capture GC (7). The former two methods require reagents not readily available and lack evidence of specificity, while the latter suffers from the lack of ruggedness generally associated with electron-capture detection when applied to analysis of biological specimens. The present method was developed to allow nitrogen-specific detection and still maintain adequate sensitivity to support Phase I clinical and pharmacokinetic studies in children being treated for cancer.

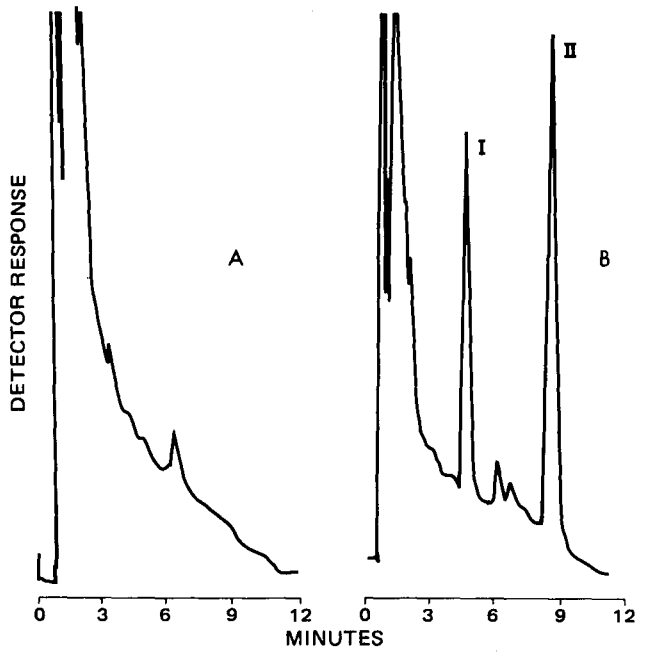

Figure 1—*Gas-liquid chromatographic tracing of (A) a blank serum sample and (B) a serum sample to which was added 2.37 μg/ml of I and internal standard at an attenuation of 16 × 10^{-11}.*

EXPERIMENTAL

Chemicals and Reagents—Compound I and 7-bromoimidazopyrazole[3] (7-bromo,2,3-dihydro-1-H-imidazo[1,2-6]pyrazole, II) were used directly. Pentafluorobenzoyl chloride[4] was used as received and stored under dry nitrogen at −20° in 1-ml ampules to protect from moisture. A 1.0 *M*, pH 10.5 carbonate buffer was prepared using reagent grade sodium carbonate[5] and sodium bicarbonate[5]. Methanol and methylene chloride were both HPLC grade[6]; all other chemicals and solvents were reagent grade. All glassware was acid washed then treated with 5% dichloromethylsilane in toluene[5] and rinsed successively with toluene and

39.40	4	40.37 ± 0.92

methanol and then oven dried. Deionized water was prepared using a filter reverse osmosis system[7].

Instrumentation—A gas chromatograph[8] equipped with a nitrogen phosphorous thermionic detector and 1-mV recorder was used. Chromatography was performed on a U-shaped glass column (1.8 m × 2 mm i.d.) packed with 3% OV-17 on 100/120 mesh[9], which was conditioned overnight at 250° and pretreated with several injections (10–25 μl)[10]. Nitrogen at a flow rate of 30 ml/min was used as the carrier gas, and air and hydrogen flows were optimized for maximum detector response. Operating temperatures were: oven, 195°; injector, 235°; and detector, 250°. Mass spectral data were obtained using a GC–MS–computer system[11]. Chromatography was performed using a coiled glass column (1.2 m × 2-mm i.d.) packed with 3% OV-101 on 100/120 mesh[9] operated isothermally at 170° with an injector temperature of 250°. The instrument was equipped with a jet separator and used 70 V as the ionization energy.

Standard Curves—Stock standards were prepared by dissolving 1 mg of I in 10 ml of water and 1 mg of II in 10 ml of methylene chloride. These were diluted to produce working standards of 10 μg/ml and stored at 4° where they were stable for at least 2 weeks. Appropriate aliquots were added to human serum[12] to produce either a low-concentration series of 0.05, 0.1, 0.5, 1.0, and 2.0 μg/ml of I (1 μg of II), or a high-concentration series of 1, 5, 10, 20, 30, and 40 μg/ml of I (28 μg of II). Calibration curves were constructed from peak-height ratio measurement of I/II.

Analytical Procedure—Seven milliliters of methylene chloride, 50 μl (5 μg) of internal standard (II) solution, 2 g of sodium chloride, and 1 ml of carbonate buffer (1.0 *M*, pH 10.5) were added to 1.0 ml of a patient

[a] Solutions originally spiked with 1.0 μg/ml of I and stored under refrigeration.

plasma or spiked serum sample in a 15-ml centrifuge tube. The tube was then mechanically shaken for 30 min, centrifuged at 2000 rpm for 10 min, and the lower (organic) layer filtered into a clean tube containing 1 g of sodium sulfate. This was vortexed for 1 min and allowed to stand for 10 min. The organic phase was transferred to a clean tube to which was added 5 μl of pentafluorobenzoyl chloride. This was incubated for 30 min in a 50° water bath, and 0.5 ml of methanol was added. The tube was reincubated for 15 min and then evaporated to dryness under a stream of dry air at room temperature. The residue was redissolved in 2 ml of methylene chloride, shaken with 5 ml of carbonate buffer for 20 min, centrifuged for 10 min, and the lower (organic) layer transferred to a 5 ml conical centrifuge tube. This was evaporated to dryness under air and redissolved in 50 μl of methanol prior to injection of 1–2 μl into the gas chromatograph.

Clinical Study—Human plasma samples were obtained from pediatric oncology patients receiving I under an approved Phase I study protocol of the Childrens Cancer Study Group. Doses were administered by rapid intravenous infusion over 30–60 min, and blood samples of 1–3 ml were collected prior to dosing and at 0.25, 0.5, 1.0, 2.0, 6.0, 12.0, and 24.0 hr postdose. Blood samples were immediately centrifuged and the plasma separated and stored at −80° until analyzed.

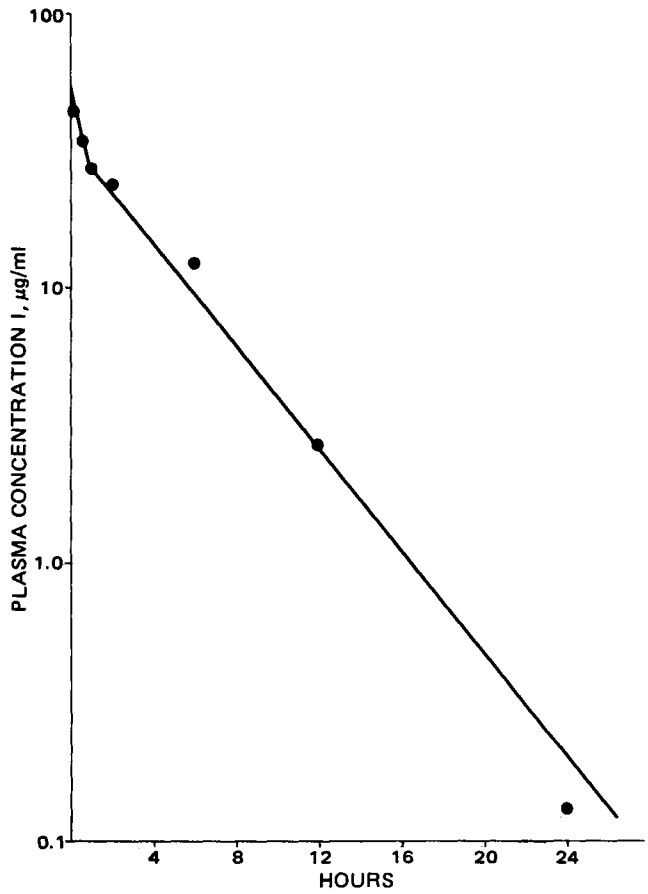

Figure 3—*Patient plasma–time profile of I following an intravenous bolus infusion of 450 mg.*

RESULTS AND DISCUSSION

Typical chromatograms from the analysis of a human serum blank and a spiked serum standard are shown in Fig. 1. Under the analytical conditions described, the retention times of derivatized I and II were 4.0 and 8.7 min, respectively. Standard curves prepared from a series of duplicate serum standards were linear over two concentration ranges typically encountered in pharmacokinetic monitoring. Linear regression for a series of low concentration standard (0.05–2.0 μg/ml) curves produced a slope of 1.642 ± 0.068, an intercept of −0.043 ± 0.063 with a mean correlation coefficient of 0.992. Corresponding results for the high-concentration range (1–40 μg/ml) produced a slope of 0.106 ± 0.002, an intercept of −0.0119 ± 0.031, and a mean (r) of 0.998. This reflects excellent between-run reproducibility, which is further supported by the recovery data over a wide concentration range shown in Table I. Replicate analysis of two spiked serum control specimens resulted in between-run coefficients of variation of 6.3% ($\bar{x}$ = 0.107 μg/ml) and 3.8% ($\bar{x}$ = 4.54 μg/ml). The practical lower limit of sensitivity for this procedure, for which a signal–baseline noise ratio of 3:1 can be seen, was 50 ng/ml. This is the same as that reported using a GC–electron-capture detection procedure (7). The entire procedure requires ~4 hr and allows analysis of ~20 specimens/analyst/working day.

The identity of the derivatized I GC peak was confirmed by comparing its mass spectrum to that of authentic, synthesized pentafluorobenzoyl imidazopyrazole (III). These were identical and demonstrated a parent peak at m/z 303 and a base peak at m/z 195, which corresponded to the pentafluorobenzoyl fragment. Other characteristic peaks occurred at m/z 167, 108, and 81 as seen in the proposed fragmentation pattern in Fig. 2.

The pharmacokinetic behavior of I was followed in four pediatric patients receiving intravenous bolus doses in a Phase I clinical trial. The plasma time course for one patient who received 450 mg is shown in Fig. 3. The mean terminal phase half-life and volume of distribution for all patients was 4.4 hr and 1.5 liters/kg, respectively. These values were in reasonable agreement with those reported for adult patients (6) ($t_{1/2}$ = 3–10 hr, Vd = 5–15 liters), although other widely divergent values using less specific radioactivity detection methods have also been reported (8). No other data in pediatric patients have been reported to date.

In the course of studying the reproducibility of the assay, it was observed that significant decreases in measured concentrations of I occurred if the spiked serum sample was allowed to sit unfrozen over a few hours. This had not been reported in the previous literature and appears to have serious implications for I measurements in biological media. A limited stability study was performed of I in pH 7.4 buffer, human serum, and 5% purified serum albumin. The results are summarized in Table II and indicate a relatively rapid decline in I in the presence of protein, which appears to stabilize at a level of 65–70% of the initial level over time.

A preliminary experiment examining the possibility of rapid irreversible protein binding suggested that this did not explain the relatively rapid decline observed. Although this problem can be circumvented by either immediate analysis of samples or quick freezing in methanol–dry ice, the mechanism of this apparent instability merits further study. Lack of recognition of this problem could lead to altered serum concentrations and errors in pharmacokinetic analysis *in vivo*.

The method reported appears sufficiently sensitive, reproducible, and rapid to support extended pharmacokinetic studies of I in humans or animals provided caution is used in rapidly handling samples to avoid an apparent instability in biological specimens.

Stability of Concentrated Aqueous Solutions of Pralidoxime Chloride

ROBERT I. ELLIN

Received August 18, 1981, from the *U.S. Army Medical Research Institute of Chemical Defense, Aberdeen Proving Ground, MD 21010.* Accepted for publication November 20, 1981.

Abstract □ Concentrated aqueous solutions of pralidoxime chloride degrade more rapidly than dilute solutions. The rate and degree of degradation is dependent on the initial and final pH as well as the container in which the solution is stored. The effects of glass, metal, plastic, and rubber stoppers on the stability of concentrated and dilute solutions are discussed. The stability and shelf lives of 50% aqueous concentrates at different temperatures were determined.

Keyphrases □ Pralidoxime chloride—stability of concentrated aqueous solutions, kinetics □ Stability—concentrated aqueous solutions of pralidoxime chloride, kinetics □ Kinetics—comparison of stability in concentrated aqueous solutions of pralidoxime chloride

Pyridinium oximes in combination with atropine provide effective therapy in poisoning by many organophosphorus cholinesterase inhibitors (1). More clinical data are available for pralidoxime salts than other pyridinium oximes, as this oxime is in wider use. Pralidoxime also reportedly produces few undesirable side effects (2, 3). It is generally accepted that, for therapeutic efficacy, pralidoxime plasma concentrations should be at least 4 μg/ml (4). A 600-mg im dose is required to produce this level. A dilute solution would require an injection of an impractical volume. Since pralidoxime chloride is very water soluble, 30–50% concentrates can be used to provide a 4-μg/ml plasma level (5, 6). The purpose of this study was to determine stabilities and the effect of containers on the shelf life of aqueous concentrates of pralidoxime chloride[1].

RESULTS AND DISCUSSION

Typical chromatograms from the analysis of a human serum blank and a spiked serum standard are shown in Fig. 1. Under the analytical conditions described, the retention times of derivatized I and II were 4.0 and 8.7 min, respectively. Standard curves prepared from a series of duplicate serum standards were linear over two concentration ranges typically encountered in pharmacokinetic monitoring. Linear regression for a series of low concentration standard (0.05–2.0 μg/ml) curves produced a slope of 1.642 ± 0.068, an intercept of −0.043 ± 0.063 with a mean correlation coefficient of 0.992. Corresponding results for the high-concentration range (1–40 μg/ml) produced a slope of 0.106 ± 0.002, an intercept of −0.0119 ± 0.031, and a mean (r) of 0.998. This reflects excellent between-run reproducibility, which is further supported by the recovery data over a wide concentration range shown in Table I. Replicate analysis of two spiked serum control specimens resulted in between-run coefficients of variation of 6.3% ($\bar{x}$ = 0.107 μg/ml) and 3.8% ($\bar{x}$ = 4.54 μg/ml). The practical lower limit of sensitivity for this procedure, for which a signal–baseline noise ratio of 3:1 can be seen, was 50 ng/ml. This is the same as that reported using a GC–electron-capture detection procedure (7). The entire procedure requires ~4 hr and allows analysis of ~20 specimens/analyst/working day.

The identity of the derivatized I GC peak was confirmed by comparing its mass spectrum to that of authentic, synthesized pentafluorobenzoyl imidazopyrazole (III). These were identical and demonstrated a parent peak at m/z 303 and a base peak at m/z 195, which corresponded to the pentafluorobenzoyl fragment. Other characteristic peaks occurred at m/z 167, 108, and 81 as seen in the proposed fragmentation pattern in Fig. 2.

The pharmacokinetic behavior of I was followed in four pediatric patients receiving intravenous bolus doses in a Phase I clinical trial. The plasma time course for one patient who received 450 mg is shown in Fig. 3. The mean terminal phase half-life and volume of distribution for all patients was 4.4 hr and 1.5 liters/kg, respectively. These values were in reasonable agreement with those reported for adult patients (6) ($t_{1/2}$ = 3–10 hr, Vd = 5–15 liters), although other widely divergent values using less specific radioactivity detection methods have also been reported (8). No other data in pediatric patients have been reported to date.

In the course of studying the reproducibility of the assay, it was observed that significant decreases in measured concentrations of I occurred if the spiked serum sample was allowed to sit unfrozen over a few hours. This had not been reported in the previous literature and appears to have serious implications for I measurements in biological media. A limited stability study was performed of I in pH 7.4 buffer, human serum, and 5% purified serum albumin. The results are summarized in Table II and indicate a relatively rapid decline in I in the presence of protein, which appears to stabilize at a level of 65–70% of the initial level over time.

A preliminary experiment examining the possibility of rapid irreversible protein binding suggested that this did not explain the relatively rapid decline observed. Although this problem can be circumvented by either immediate analysis of samples or quick freezing in methanol–dry ice, the mechanism of this apparent instability merits further study. Lack of recognition of this problem could lead to altered serum concentrations and errors in pharmacokinetic analysis *in vivo*.

The method reported appears sufficiently sensitive, reproducible, and rapid to support extended pharmacokinetic studies of I in humans or animals provided caution is used in rapidly handling samples to avoid an apparent instability in biological specimens.

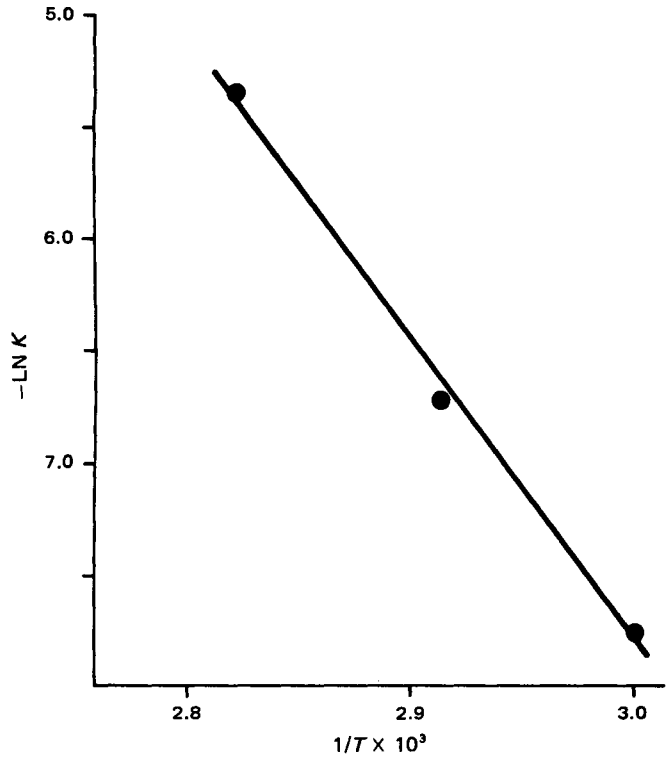

Figure 1—*Temperature Dependency of the Degradation of 50% Aqueous Solution of Pralidoxime in Glass Ampuls.*

EXPERIMENTAL

Twenty-five grams of pralidoxime chloride were transferred into a 50-ml volumetric flask and brought to volume with triple distilled water. Approximately 1.0-ml volumes were added to 2-ml glass ampuls which had been acid washed (0.01 *N* HCl), water-rinsed, and dried in an oven at 110°. The ampuls were sealed with an oxygen torch, then placed in hot air ovens at 60, 70, and 81°. Ampuls were removed at selected time periods. An aliquot was diluted with distilled water (0.2–500), then rediluted with 0.05 *N* NaOH (3.0–100) to obtain a final concentration of ~6 μg/ml. Samples were assayed by UV analysis at 336 nm (7).

Approximately 1.0-ml volumes were also added to glass, metal, stainless steel, and plastic (polypropylene) cylinders which were sealed at one end with a neoprene rubber stopper. After filling, the cylinder was closed with another neoprene rubber stopper, then weighed on a balance. Cylinders were placed in a holding device which consisted of a plastic base, 1.91-cm thick, containing holes slightly wider than the diameter of the glass cylinders. A plastic cap was placed over the top of each filled cylinder and a metal plate placed over the filled cylinders. The cylinders were secured by two screws. The holder containing the cylinders was placed in the oven, and the cylinders were removed as needed. Prior to analysis, cylinders were reweighed to determine possible losses due to evaporation or leakage. Pralidoxime chloride concentrations were determined as described above.

RESULTS

Stability of 50% Aqueous Solutions of Pralidoxime in Glass Ampuls—The rate of degradation of concentrates of pralidoxime at 60, 70, and 81° conforms to a first-order equation. As a 50% solution of pralidoxime at initial pH 3.65 is hypertonic, buffer was not added to maintain a constant pH. The rate constants at 60, 70, and 81° were 4.27×10^{-4}, 1.22×10^{-3}, and 4.68×10^{-3} hr^{-1}, respectively. The logarithm of velocity constants was plotted against the reciprocal of the absolute temperatures (Fig. 1). A linear relationship indicated the mechanism responsible for oxime decay is not altered by changes in temperature. The relationship is shown by the Arrhenius equation:

$$k = Ae^{-Ea/RT} \qquad \text{(Eq. 1)}$$

where Ea, the energy of activation, was 26,755 cal/mole; A was 4.08×10^{10} min^{-1}; R was the molar gas constant; and T the absolute temperature.

[2] Unpublished data.

Table I—Calculated Shelf Lives for 50% Aqueous Solutions of Pralidoxime Chloride in Glass Ampuls

Temperature°	Shelf Life[a] 10%	25%
10	37.0 *y*	101.0 *y*
15	16.0 *y*	44.0 *y*
20	7.3 *y*	20.0 *y*
25	3.4 *y*	9.3 *y*
30	1.6 *y*	4.4 *y*
35	286.0 *d*	2.1 *y*
40	142.0 *d*	1.1 *y*
45	72.0 *d*	198.0 *d*
50	38.0 *d*	103.0 *d*

[a] *y* = years; *d* = days.

Degradation of Concentrated Aqueous Solution of Pralidoxime—Glass ampuls and glass, metal, and plastic cylinders sealed with neoprene and butyl rubber stoppers were used. The degradation rates of 50% aqueous solutions of pralidoxime chloride were similar in plastic and glass cylinders sealed with neoprene stoppers and more rapid in metal cylinders when determined at 40°. The pH dropped with time, 3.6–3.2 after 40 days in glass and plastic, but increased in metal 3.6–4.2. When performed at 45 and 60° in glass with 30% solutions of pralidoxime chloride in cylinders stoppered with either neoprene or butyl rubber, the pH fell more rapidly in the butyl rubber than in the neoprene-stoppered containers[2].

DISCUSSION

The stability of 50% concentrates of pralidoxime chloride in unbuffered aqueous solutions in glass ampuls was studied under accelerated temperatures. Calculated 10 and 25% shelf lives are shown in Table I. At 25°, 10 and 25% shelf lives were found to be 3.4 and 9.3 years, respectively. The report also indicates the importance of considering the effects of material(s) in the container in which a formulation is packaged.

When results of the report are compared with the results of related investigations (5, 8), discrepancies in reported stabilities of pralidoxime might be assumed by the reader. However, on examination of data, one finds this is not so. Stability studies on 16% (w/v) solutions of pralidoxime methanesulfonate in sealed glass ampuls buffered at pH values 2.0–3.5 have been reported (5). Stability efforts on unbuffered solutions of 10–33% (w/v) pralidoxime chloride in glass ampuls and also glass vials sealed with butyl rubber stoppers have also been performed (8). Acid was added to obtain initial pH values of 1.3–2.0. In this study the stabilities of unbuffered, pH-unadjusted 50% solutions of pralidoxime chloride (w/v) in glass ampuls were investigated. In preliminary studies[3] with concentrates of pralidoxime chloride in cylinders made of glass, plastic, and metal sealed with rubber enclosures, significant variations in stability were found. Consequently, when comparing stability data, the reader must take into consideration different oxime salts, oxime concentrations, initial pH values, formulations, and storage containers. Fortunately, there are data where direct comparisons can be made. Stabilities for pralidoxime concentrates in sealed glass ampuls at 25 and 45° have been reported (5, 8).

Previous studies (9) on solutions (0.1%) of pralidoxime chloride showed that pralidoxime solutions possess maximum stability at pH 4.3 with a shelf life to 10 years at 25°. Here equilibria at pH 1–3 were noted but not considered in the shelf life estimations. If equilibria data had been included, the predicted shelf lives at these pHs would have been significantly greater. In later efforts 30% concentrated solutions were found to be less stable than 0.1% solutions, in that concentrated solutions of pralidoxime chloride degraded 2.5 times more rapidly than the dilute solution[2].

On examination of all data, one finds that: (*a*) oxime loss in a 50% solution of pralidoxime chloride and a 16% buffered solution of pralidoxime methanesulfonate, both stored in glass ampuls at 45°, are similar (a 16% solution of pralidoxime methanesulfonate is equivalent in oxime content to a 12% solution of pralidoxime chloride), (*b*) lowering of the initial pH in unbuffered concentrates results in greater stability (8), (*c*) use of buffer at pH 2.5 in 16% solutions of pralidoxime methanesulfonate decreased stability drastically when compared with 30% unbuffered solutions, (*d*) rubber closures affect the pH and stability of pralidoxime chloride concentrates stored in glass, plastic, and metal cylinders[2,3]. The drop in pH

[3] J. R. May, U.S. Chemical Research and Development Laboratories, Aberdeen Proving Ground, MD 21010, 1965.

was greater in the glass and plastic containers than in metal. When butyl rubber was used, a lower pH resulted than when neoprene rubber was tested. A lower pH is desirable because of the unique occurrence of equilibria.

The reason(s) that high concentrations of pralidoxime chloride degrade more rapidly than dilute concentrations is not known. To resolve this problem, studies should be carried out to determine and quantitate degradation products and their rate of formation. By establishing the proper mechanism(s) one should be able to design stable formulations of concentrated solutions of drugs.

Growth and Characterization of Calcium Oxalate Dihydrate Crystals (Weddellite)

L. LEPAGE and R. TAWASHI[x]

Received July 14, 1980, from the *Faculté de Pharmacie, Université de Montréal, Montreal, Quebec, Canada.* Accepted for publication November 25, 1981.

Abstract □ Conditions are given for the growth of calcium oxalate dihydrate crystals (weddellite) in aqueous solution. The crystals obtained were characterized by scanning electron microscopic, spectroscopic, and thermal methods. The dissolution kinetics and electrophoretic mobility were determined; the thermodynamically unstable calcium oxalate dihydrate had a higher dissolution rate and a lower zeta potential than the monohydrate and underwent a phase transformation into the more stable calcium oxalate monohydrate. The results obtained on the chemical stability and the surface charge of calcium oxalate dihydrate offered additional information for assessing the current theories on the formation of calcium oxalate renal stones.

Keyphrases □ Crystals—calcium oxalate dihydrate, growth and characterization □ Dissolution, kinetics—determination, calcium oxalate dihydrate crystals, growth and characterization □ Electrophoretic mobility—determination, calcium oxalate dihydrate crystals, growth and characterization

In recent years there has been much discussion on the role of different hydrated calcium oxalate crystals in the formation of calcium oxalate stones (1–4). Chemically, two varieties of calcium oxalate crystals occur in renal calculi: calcium oxalate monohydrate (whewellite) and calcium oxalate dihydrate (weddellite). The variable amount of water of crystallization is a direct consequence of the urine composition. The formation of these phases and the possible transformation between them is important from the urinary calcification standpoint.

The growth of calcium oxalate dihydrate in natural urine, synthetic urine, and in a mixture of both has been a subject of a number of investigations (5–7). In a recent study from this laboratory, it has been noticed that the calcium oxalate dihydrate was formed in the rat kidney after the injection of 4-hydroxy-L-proline. These crystals transformed gradually into the more stable calcium oxalate monohydrate (8). Previously it was reported that it is possible to grow calcium oxalate dihydrate crystals from a medium consisting of natural and synthetic urine (9). The chemical reaction between the sodium oxalate (0.005 *M*) and calcium chloride (1 *M*) at 37° in the previously described medium produced the octahedral dipyramidal calcium oxalate dihydrate. The crystals obtained were mixed with ~5% monohydrate. This work is intended to describe an improved technique for the growth of calcium oxalate dihydrate in aqueous solution and to study the dissolution kinetics and electrophoretic mobility of this form. Some aspects of the structure-dependent properties of both whewellite and weddellite crystals will be discussed.

EXPERIMENTAL

Materials—The following materials were used: synthetic urine [an aqueous medium containing various electrolytes present in normal urine which has been described previously (5, 9)], calcium chloride dihydrate[1], sodium oxalate[1], and calcium oxalate monohydrate[1] (high purity reagent grade), and freshly bidistilled water.

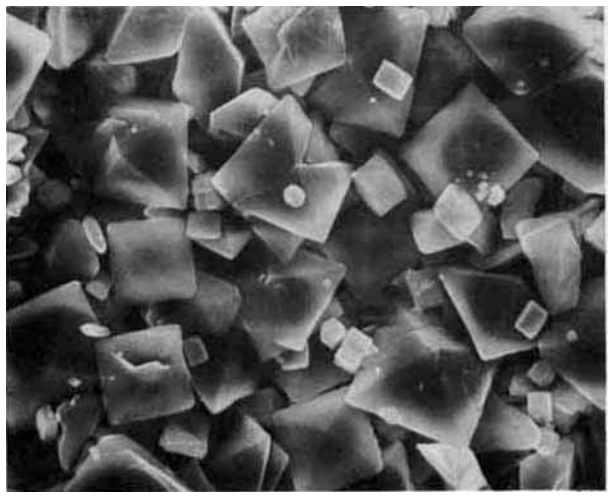

Figure 1—*Scanning electron micrograph of calcium oxalate dihydrate (2000×).*

[a] Diffraction patterns compared with those of the mineral whewellite (calcium oxalate monohydrate) and weddellite (calcium oxalate dihydrate) from powder diffraction File 20-231 and File 17-540, Joint Committee Powder Diffraction Standards.

Table II—Summary of the Structure-Dependent Properties of Calcium Oxalate Monohydrate and Calcium Oxalate Dihydrate

	Crystal Morphology	Density (12), g/cm³	Solubility at 37° in Normal Saline, mg of $Ca_2C_2O_4$/liter	Dissolution rate Constant, $g^{1/3}$/sec	Zeta Potential, ± SE, mV	Stability at 37° in Normal Saline
Calcium Oxalate Monohydrate	Prisms Tabular	2.23	24.37	5.67×10^{-5}	−32.67 ± 0.49	Stable
Calcium Oxalate Dihydrate	Bipyramidal Octahedral	1.99	38.74	11.3×10^{-5}	−29.46 ± 0.13	Transformed to Monohydrate after 24 hr

Crystal Growth—The precise conditions necessary for the growth of uncontaminated calcium oxalate dihydrate are as follows: 24 ml of sodium oxalate in bidistilled water (0.005 *M*) at room temperature was added to 40 ml of calcium chloride solution in bidistilled water (1 *M*) at 4° in glass tubes (2-cm diameter, 20-cm height). The sodium oxalate solution was added to the center of the air–liquid interface of the calcium chloride solution using a pipet. The mixture was left without agitation for 24 hr at 4°. The calcium oxalate dihydrate crystals deposited were separated by filtration[2]. The crystals obtained were characterized by scanning electron microscopy[3], IR spectra[4], X-ray powder diffraction[5], and differential thermal analysis[6]. The results of the diffractometer scan, the d-spacing, and the intensities matched those listed for the mineral weddellite in powder diffraction file[7]. Those of the standard calcium oxalate monohydrate used in this study matched the data for the mineral whewellite[8] (Table I). The differential thermal analysis and the IR spectra of calcium oxalate dihydrate grown in this study and calcium oxalate monohydrate used as the standard agree with previously reported data (9, 10).

Dissolution Rates Studies—The dissolution rate of calcium oxalate dihydrate was determined in normal saline at 37° (under sink conditions). Calcium oxalate dihydrate (5 mg) was added to 500 ml of normal saline and agitated by a mechanical stirrer at 150 rpm. Samples were taken from the dissolution media at different time periods, filtered[9], and analyzed for calcium by a complexometric method using a calcium autoanalyzer[10] (11). The solubility of both calcium oxalate dihydrate and monohydrate were also determined in normal saline at 37° (Table II).

Electrophoretic Mobility Studies—The electrophoretic mobility of calcium oxalate dihydrate was measured by a zeta-meter[11] in a synthetic urine at pH 7.5. The zeta potential was determined by tracking 150 particles of the calcium oxalate crystals. The technique of measuring the zeta potential is described elsewhere (13, 14).

Phase Transformation—The conversion of calcium oxalate dihydrate to calcium oxalate monohydrate was studied at 37° in normal saline. Calcium oxalate dihydrate (50 mg) was suspended in 100 ml of normal saline and the concentration of calcium was determined as a function of time using a calcium autoanalyzer. A drop in the concentration of calcium oxalate from 38.43 mg/liter (solubility of calcium oxalate dihydrate) to

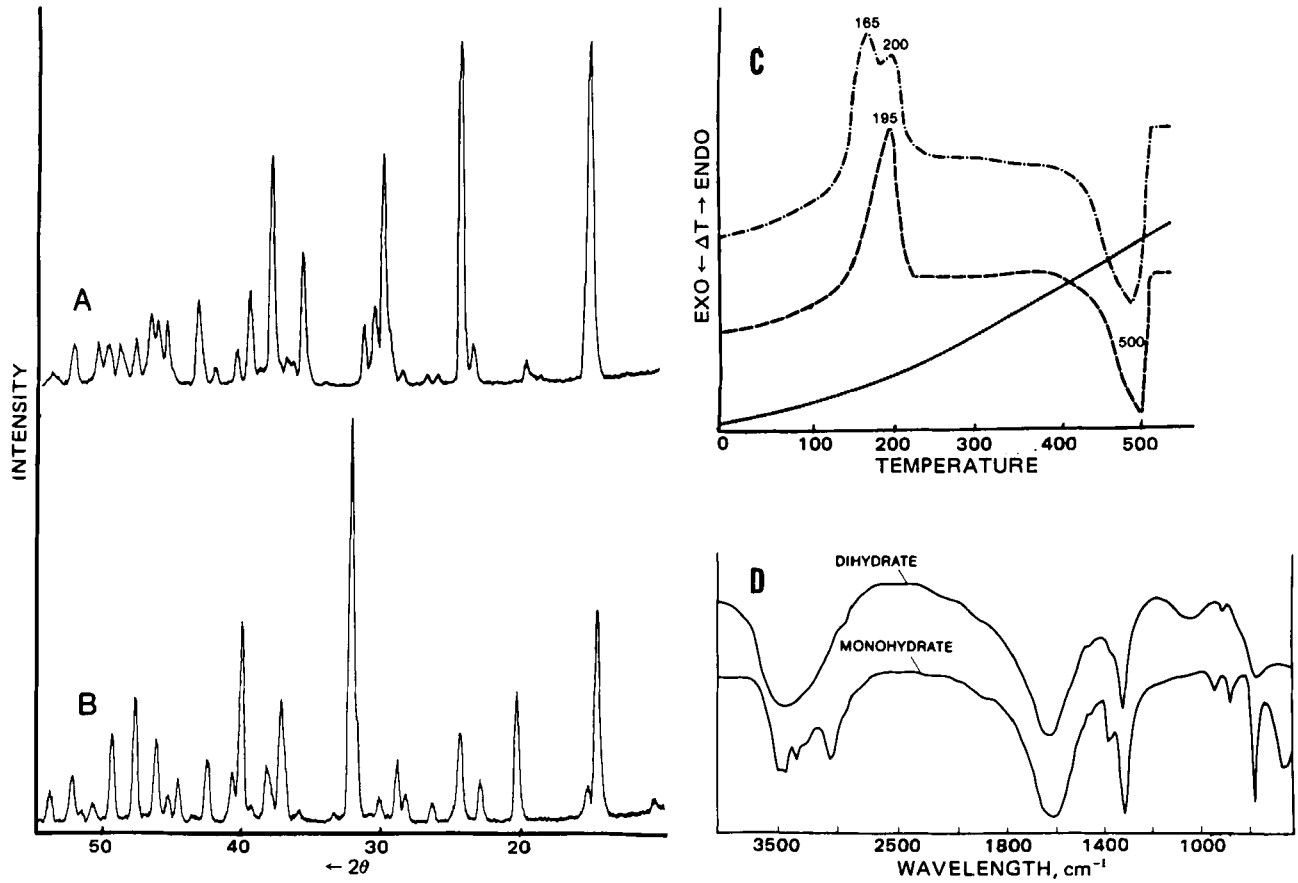

Figure 2—*X-Ray diffraction spectra of calcium oxalate monohydrate (A) and dihydrate (B); differential thermal analysis of calcium oxalate monohydrate (- - -) and calcium oxalate dihydrate (----); temperature: 10°/min (C); and IR spectra (D) of calcium oxalate monohydrate and dihydrate crystals, which were grown by the method described in the text. Calcium oxalate monohydrate crystals are the standard crystals described in the text.*

24.37 mg/liter (solubility of calcium oxalate monohydrate) was observed after 24 hr suggesting phase transformation. This transformation was confirmed by optical and spectroscopic examination of the oxalate crystals.

RESULTS AND DISCUSSION

Figure 1 shows the characteristic octahedral bipyramidal calcium oxalate dihydrate crystals grown by the described method. These crystals have different IR and X-ray powder diffraction spectra and differential thermal analysis from the standard calcium oxalate monohydrate crystals (Fig. 2). Table I shows powder diffraction patterns of the two calcium oxalate crystals compared with the phase of the minerals whewellite and weddellite.

The dissolution data of calcium oxalate dihydrate is given in Fig. 3. The results were presented according to the cube root law (15): $Kt = W_0^{1/3} - W^{1/3}$, where W_0 is the weight of crystals at the start or when time $t = 0$, W is the weight of the crystals at time t, and K is the dissolution rate constant (Fig. 4). Figure 4 shows that the calcium oxalate dihydrate dissolves faster than the calcium oxalate monohydrate. The higher dissolution rate of the dihydrate cannot be attributed to surface area effect, because the size distribution analysis indicated that calcium oxalate monohydrate crystals are smaller in size than calcium oxalate dihydrate

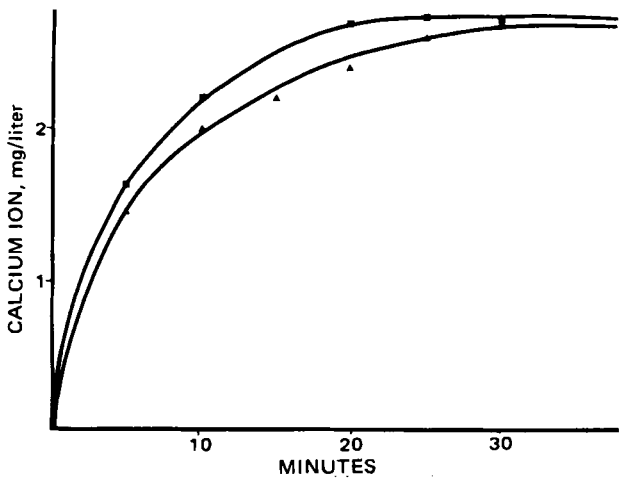

Figure 3—*Dissolution curves of calcium oxalate dihydrate prepared by the method described in the text (■) and calcium oxalate monohydrate standard (▲) under sink conditions at 37°.*

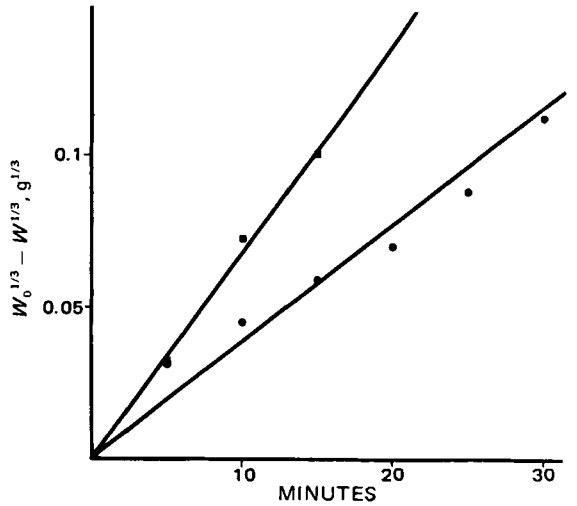

Figure 4—*Cube root plot of the dissolution data of calcium oxalate monohydrate (●) and calcium oxalate dihydrate (■).*

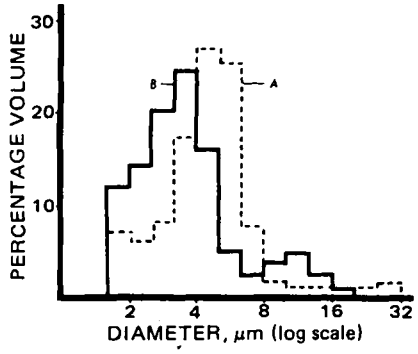

Figure 5—*Crystal size distribution of calcium oxalate dihydrate (A) and calcium oxalate monohydrate (B) used for the dissolution rate studies.*

[determined by automated particle counter[12] (Fig. 5)]. Table II summarizes the structure-dependent properties of calcium oxalate monohydrate and dihydrate. The dihydrate has a higher solubility and dissolution rate and a lower zeta potential than the monohydrate. The dihydrate crystals are stable in air at 4° for 2 weeks; however, when these crystals are kept in normal saline at 37°, they are stable for only 24 hr. After 24 hr, gradual conversion to monohydrate occurs.

The observation that calcium oxalate dihydrate has a higher solubility, higher dissolution rate, and undergoes gradual dissolution–recrystallization to calcium oxalate monohydrate is consistent with recent results reported on the crystallization of calcium oxalate in the rat kidney (8). It offers the most probable explanation for the gradual transformation of calcium oxalate dihydrate to calcium oxalate monohydrate in rat kidney following the administration of 4-hydroxy-L-proline. Detailed study of the difference in the zeta potential between the monohydrate and the dihydrate could lead to a better understanding of the role of crystal aggregation in stone formation.

Potential Thyroliberin Affinity Labels II: Chloroacetyl Substituted Phenylalanyl Prolineamides

RICHARD J. GOEBEL *, BRUCE L. CURRIE *x, and CYRIL Y. BOWERS ‡

Received August 3, 1981, from the **Department of Medicinal Chemistry, College of Pharmacy, University of Illinois at the Medical Center, Chicago, IL 60680*, and the ‡*Department of Medicine, School of Medicine, Tulane University, New Orleans, LA 70112.* Accepted for publication December 9, 1981.

Abstract □ Three analogs of thyroliberin (I) were prepared. These compounds, *N-m*-chloroacetylbenzoyl-phenylalanyl-prolineamide (VI*a*), *N-p*-chloroacetylbenzoyl-phenylalanyl-prolineamide (VI*b*) and *N*-chloroacetyl-alanyl-phenylalanyl-prolineamide (IX), were designed as potential I antagonist affinity labels. However, no significant antagonist activity was observed. Compounds VI*a* and IX were found to have weak agonist activity. Cyclo (Phe-Pro) an analog of the I metabolite, cyclo (His-Pro), was found, however, to have significant I antagonist activity, but no agonist activity.

Keyphrases □ Thyroliberin—potential affinity labels, chloroacetyl substituted phenylalanyl prolineamides □ Hormones—peptide, thyroliberin affinity labels, chloroacetyl substituted phenylalanyl prolineamides □ Receptor-hormone interactions—affinity label analogs, characterization, thyroliberin

Thyroliberin (I) is a peptide hormone from the hypothalamus that can release thyrotropin (1) and prolactin (2) from the anterior pituitary both *in vivo* and *in vitro*. Affinity label analogs of I that irreversibly bind to the I receptor could aid in the characterization of the I receptor and the study of receptor–hormone interactions. The use of a naltrexamine affinity label to isolate a complex with an opiate receptor, which was recently reported (3) while these studies were in progress, is a similar approach.

Potential Thyroliberin Affinity Labels II: Chloroacetyl Substituted Phenylalanyl Prolineamides

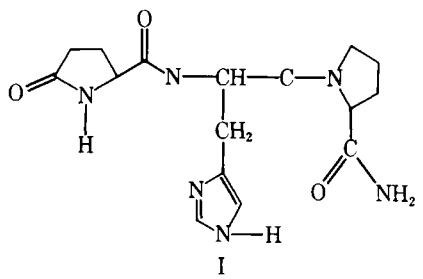
RICHARD J. GOEBEL *, BRUCE L. CURRIE *x, and CYRIL Y. BOWERS ‡

Received August 3, 1981, from the **Department of Medicinal Chemistry, College of Pharmacy, University of Illinois at the Medical Center, Chicago, IL 60680*, and the ‡*Department of Medicine, School of Medicine, Tulane University, New Orleans, LA 70112.* Accepted for publication December 9, 1981.

Abstract □ Three analogs of thyroliberin (I) were prepared. These compounds, *N-m*-chloroacetylbenzoyl-phenylalanyl-prolineamide (VI*a*), *N-p*-chloroacetylbenzoyl-phenylalanyl-prolineamide (VI*b*) and *N*-chloroacetyl-alanyl-phenylalanyl-prolineamide (IX), were designed as potential I antagonist affinity labels. However, no significant antagonist activity was observed. Compounds VI*a* and IX were found to have weak agonist activity. Cyclo (Phe-Pro) an analog of the I metabolite, cyclo (His-Pro), was found, however, to have significant I antagonist activity, but no agonist activity.

Keyphrases □ Thyroliberin—potential affinity labels, chloroacetyl substituted phenylalanyl prolineamides □ Hormones—peptide, thyroliberin affinity labels, chloroacetyl substituted phenylalanyl prolineamides □ Receptor-hormone interactions—affinity label analogs, characterization, thyroliberin

Thyroliberin (I) is a peptide hormone from the hypothalamus that can release thyrotropin (1) and prolactin (2) from the anterior pituitary both *in vivo* and *in vitro*. Affinity label analogs of I that irreversibly bind to the I receptor could aid in the characterization of the I receptor and the study of receptor–hormone interactions. The use of a naltrexamine affinity label to isolate a complex with an opiate receptor, which was recently reported (3) while these studies were in progress, is a similar approach.



I

Initial attempts to develop analogs of I as potential af-

0022-3549/82/0900-1062$01.00/0

finity labels were based on previously reported structure–activity relationships and were expected to result in compounds that were antagonists of I. These compounds, with general structure *N*-chloroacetyl [ ]Phe-Pyrr, were found, however, to be only weak agonists (4).

In an effort to improve receptor binding affinity, the prolineamide moiety was included in the present compounds. The resulting analogs were expected to have improved agonist potency based on previously reported structure–activity relationships (5). Therefore, compounds of general structure, *N*-chloroacetyl[ ]Phe-Pro-NH_2, were synthesized. Cyclo (Phe-Pro) was also synthesized as an analog of cyclo (His-Pro), a metabolite of I (6, 7).

EXPERIMENTAL

Melting points[1] reported are uncorrected. All amino acid derivatives used were of the L configuration. Thin-layer chromatography was performed on 250 μm silica gel G plates with fluorescent indicator[2]. The following solvent systems were used: (A) chloroform–methanol (39:1); (B) chloroform–methanol (19:1); (C) chloroform–methanol–concentrated ammonium hydroxide (18:1:1), lower phase; (D) chloroform–methanol–concentrated ammonium hydroxide (17:2:1), lower phase. Methods of detection are indicated with the data. Proton magnetic resonance[3] spectra were recorded at 60 MHz in the solvent indicated for each compound and the data are reported in parts per million (δ) downfield from internal tetramethylsilane. Optical rotations were determined with a digital readout polarimeter[4], and the solvent used is indicated with the data. Elemental analyses are reported for new compounds[5].

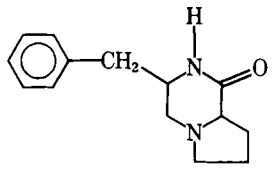
L-Phe-L-Pro-NH_2 Hydrochloride (III)—*N*-Carbobenzoxy-L-Phe (1.5 g, 5.02 mmoles) was dissolved in dry ethyl acetate (60 ml) with stirring and cooled to −40°. *N*-methylmorpholine (0.61 ml, 5.55 mmoles) was added followed immediately with isobutyl chloroformate (8) (0.62 ml, 4.78 mmoles). After 8 min, L-Pro-NH_2 hydrochloride (0.72 g, 4.78 mmoles) was added followed by additional *N*-methylmorpholine (0.53 ml). The reaction mixture was allowed to warm to room temperature and stirred overnight. The mixture was washed with 5% $NaHCO_3$ (2 × 25 ml), 1 *N* HCl (2 × 25 ml), water (2 × 25 ml), dried over anhydrous magnesium sulfate, and evaporated to dryness (3.95 g).

Chromatographic purification on a silica gel column (90 g, 2.5 × 51.5 cm) and elution with chloroform (450 ml) and 5% methanol in chloroform (600 ml) yielded 3.05 g of *N*-carbobenzoxy-L-Phe-L-Pro-NH_2 (II) as a sticky foam from fractions (4 ml) 205 through 230; one spot on TLC, Solvent B, UV and chlorine–tolidine positive, ninhydrin negative; with a confirming PMR spectrum.

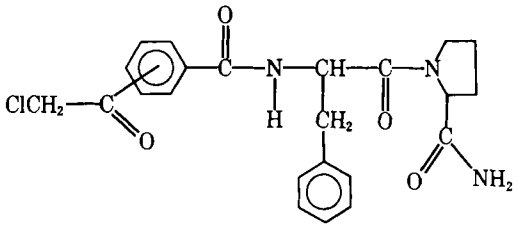
A solution of II (3.05 g) in methanol (55 ml) containing gaseous hydrogen chloride (0.16 g) was hydrogenolyzed for 1 hr at 10 psi and room temperature over 5% palladium on charcoal. Removal of the catalyst and concentration *in vacuo* provided III as a hygroscopic solid which could be used directly in subsequent reactions. Further purification was not possible due to conversion into cyclo (L-Phe-L-Pro) (IV) during crystallization attempts. The PMR spectrum confirmed the assigned structure; one spot on TLC, Solvent D, UV, ninhydrin and chlorine–tolidine positive.

Cyclo (L-Phe-L-Pro) (IV)—Hydrogenolysis of II (2.75 g) in methanol (20 ml) and glacial acetic acid (0.5 ml) at 10 psi over 5% palladium on charcoal for 2 hr, removal of the catalyst, and evaporation to dryness gave a residue. This residue was refluxed for 1 hr in benzene (20 ml), filtered hot, and crystals of IV obtained upon addition of petroleum ether, 0.28 g, mp 126–128° [lit. (9) mp 125–127°], one spot on TLC, Solvent A, UV and iodine positive, ninhydrin negative.

3-Chloroacetylbenzoyl-L-Phe-L-Pro-NH_2 (VI*a*)—To a solution of III (0.40 g, 1.34 mmoles), in dry dimethylformamide (4 ml), methylene chloride (6 ml), and *N*-methylmorpholine (0.14 ml), was added 0.21 g of 3-chloroacetylbenzoyl chloride (V*a*) (4) in methylene chloride (4 ml) followed by additional *N*-methylmorpholine (0.11 ml). The reaction mixture was stirred for 3 hr at room temperature.



IV



VI*a*: = *m*-$ClCH_2CO$—
VI*b*: = *p*-$ClCH_2CO$—

Methylene chloride (25 ml) was added, and the mixture was washed with 5% $NaHCO_3$ (35 ml), 1 *N* HCl (25 ml), and water (25 ml). The organic layer was dried over magnesium sulfate, evaporated to dryness, and crystalline VI*a* obtained from ethyl acetate–petroleum ether; yield 0.11 g (25%); mp 152–154°; one spot on TLC, Solvent B, UV and chlorine–tolidine positive, ninhydrin negative; $[\alpha]_D^{28} = -52.4°$ (*C* = 0.867, chloroform). The NMR spectrum supported the assigned structure.

Anal.—Calc. for $C_{23}H_{24}ClN_3O_4$: C, 62.51; H, 5.47; Cl, 8.02; N, 9.51. Found: C, 62.49; H, 5.54; Cl, 8.22; N, 9.44.

4-Chloroacetylbenzoyl-L-Phe-L-Pro-NH_2 (VI*b*)—A solution of III (0.40 g, 1.34 mmoles), in dimethylformamide (4 ml), methylene chloride (6 ml), and *N*-methylmorpholine (0.14 ml), was treated with 0.25 g of 4-chloroacetylbenzoyl chloride (V*b*) (4) in methylene chloride (4 ml) followed by additional *N*-methylmorpholine (0.11 ml). The reaction was stirred for 3 hr at room temperature. Workup was similar to that for VI*a*.

Crude VI*b* (0.44 g) required column purification on a chloroform packed silica gel column (35 g, 2.5 × 28 cm) eluted with chloroform (200 ml), 30% ethyl acetate in chloroform (200 ml), 60% ethyl acetate in chloroform (200 ml), and ethyl acetate (600 ml). Fractions (4 ml) 235 through 285 contained VI*b* which was crystallized from ethyl acetate–petroleum ether. Purified VI*b* crystallized with 0.5 mole of ethyl acetate, which was confirmed in the PMR spectrum; yield 0.17 g (35%); mp 103–107°; one spot on TLC, Solvent B, UV and chlorine–tolidine positive, ninhydrin negative; $[\alpha]_D^{28} = -32.4°$ (*C* = 1.125, chloroform).

Anal.—Calc. for $C_{23}H_{24}ClN_3O_4 \cdot 0.5\ C_4H_8O_2$: C, 61.79; H, 5.81; Cl, 7.29; N, 8.65. Found: C, 61.77; H, 5.72; Cl, 7.11; N, 8.74.

***N*-Chloroacetyl-L-Ala-L-Phe-L-Pro-NH_2 (IX)**—A solution of *N*-carbobenzoxy-L-Ala (0.95 g, 4.26 mmoles) in dry tetrahydrofuran (80 ml) was cooled to −40°, *N*-methylmorpholine (0.52 ml, 4.73 mmoles) was added, followed by isobutyl chloroformate (0.53 ml, 4.09 mmoles). After 15 sec, III (1.25 g, 4.20 mmoles) was added followed by additional *N*-methylmorpholine (0.46 ml, 4.18 mmoles). The reaction was warmed to room temperature, stirred overnight, and then evaporated to dryness.

The residue was dissolved in methylene chloride (100 ml) and washed with bicarbonate, acid, and water similar to the procedure used for II. The organic layer was dried over magnesium sulfate and taken to dryness. The residue was applied to a chloroform packed silica gel column (35 g, 28 × 2.5 cm) which was eluted with chloroform (250 ml), 1% methanol in chloroform (300 ml), and 1.5% methanol in chloroform (400 ml). The desired product was collected in fractions (4 ml) 167 to 202 that were concentrated to a residue (0.80 g), one spot on TLC, Solvent B, UV and

chlorine–tolidine positive, ninhydrin negative. The PMR spectrum indicated the expected product, *N*-carbobenzoxy-Ala-Phe-Pro-NH_2 (VII) which could be used directly in the next step.

A solution of VII (1.04 g) in methanol (40 ml) containing gaseous hydrogen chloride (0.10 g) and 5% palladium on charcoal (0.35 g) was hydrogenolyzed for 1 hr at 10 psi and room temperature. Removal of the catalyst by filtration, concentration *in vacuo*, and coevaporation with benzene gave Ala-Phe-Pro-NH_2 hydrochloride (VIII) (0.82 g) as a glass which gave the appropriate PMR spectrum, and was one spot on TLC, Solvent C, UV, chlorine–tolidine, and ninhydrin positive.

Chloroacetic anhydride (0.20 g, 1.17 nmoles) was added to a solution of VIII (0.47 g, 1.27 mmoles) in dimethylformamide (3 ml) and methylene chloride (7 ml) followed by *N*-methylmorpholine (0.14 ml, 1.27 mmoles). The reaction was stirred for 6 hr, methylene chloride (10 ml) was added, and the mixture was washed with 5% $NaHCO_3$ (2 × 10 ml), 1 *N* HCl (2 × 10 ml), and water (2 × 10 ml). The organic layer was dried over magnesium sulfate and concentrated to dryness to yield 0.27 g of IX.

The crude product was applied to a silica gel column (35 g, 28 × 2.5 cm) packed in chloroform and eluted with chloroform (200 ml), 10% acetone in chloroform (200 ml), 20% acetone in chloroform (200 ml), and acetone (200 ml). The desired product was collected in fractions (4 ml) 265 to 280. Pure IX was obtained by crystallization from ethyl acetate–petroleum ether; yield 0.02 g (4%); one spot on TLC, Solvent B, UV and chlorine–tolidine positive, ninhydrin negative; mp 198–202°; $[\alpha]_D^{28} = -68.0°$ (C = 0.883, chloroform); PMR spectrum in deuterochloroform: δ 1.31 [d, $J \simeq$ 7 Hz, 3H(β—CH_3 of Ala)], 1.75 [m, 2H(δ—CH_2 of Pro—NH_2)], 2.06 [m, 4H(β and γ—CH_2 of Pro—NH_2)], 3.00 [m, 2H(β—CH_2 of Phe)], 4.01 [s, 2H (—$COCH_2Cl$)], 4.53–5.25 [m, 3H(overlapping α—CH)], 7.23 [s, 5H (aromatic H of Phe)].

Anal.—Calc. for $C_{19}H_{25}ClN_4O_4$: C, 55.81; H, 6.16; Cl, 8.67; N, 13.71. Found: C, 55.52; H, 6.17; Cl, 8.62; N, 13.43.

Biological Assay—The initial evaluation of the thyroliberin agonist and antagonist activity of these compounds was by the *in vitro* method of Bowers *et al.* (10). Freshly excised whole pituitaries from 20-day-old female rats were incubated in Krebs–Ringer bicarbonate for six 1-hr periods. The incubation medium was replaced after each hour. Test samples were added during the third through the sixth hours (I_3–I_6), and the resultant thyrotropin concentration in the incubation media was measured by radioimmunoassay and compared with the second hour (P_2). Agonist activity was measured by the effects of the analogs alone on the pituitaries. Antagonist activity was measured by the net effect of the analog in combination with synthetic thyroliberin. The bioassay results are summarized in Table I.

RESULTS AND DISCUSSION

As shown in Table I, the agonist potency is weak and is on the same order as that reported previously (4) for the pyrrolidine analogs. The incorporation of prolineamide into thyroliberin analogs has usually resulted in a significant increase in the agonist potency of the resulting peptides relative to the corresponding pyrrolidine derivatives. However, this was not the case for the reported analogs.

The case of IX is striking. Chloroacetylalanyl can be considered to be an open ring analog of pyroglutamyl. Thus, there is only a minor change in structure from the relatively potent analog, *p*-Glu-Phe-Pro-NH_2 (11). Compound IX, however, had only 0.0002% of the agonist potency of thyroliberin. No significant antagonist activity was found for VI*a*, VI*b*, or IX.

The synthesis of IV has been previously reported (9) in conjunction with some spectroscopic studies. The evaluation of the endocrine activity of IV was of interest because of the importance of cyclo (His-Pro) as a metabolite (6, 7) of thyroliberin and the observation that cyclo (His-Pro) could inhibit the thyroliberin-stimulated release of prolactin both *in vitro* (12, 13) and *in vivo* (12). An uncharacterized pineal substance that can inhibit thyroliberin-stimulated thyrotropin release has also been recently reported (14).

Cyclo (Phe-Pro) had no significant agonist activity up to a 30-μg dose; however, antagonist activity was apparent. Thyroliberin (0.6 ng) alone caused the release of 17.3 μg of thyrotropin. In the presence of IV (3 μg and 30 μg), the thyrotropin release was 11.0 μg ($p < 0.01$) and 13.1 μg ($p < 0.05$), respectively. This is of interest because cyclo (His-Pro) has not been reported to have thyroliberin antagonist activity.

Fast Atom Bombardment Mass Spectra of Azthreonam and Its Salts

Keyphrases □ Fast atom bombardment—mass spectra of azthreonam and its salts □ Azthreonam—biologically active azetidinesulfonic acids, monobactams, fast atom bombardment mass spectra □ Mass spectrometry—fast atom bombardment of azthreonam and its salts □ Monobactams—biologically active azetidinesulfonic acids, azthreonam, fast atom bombardment mass spectra

To the Editor:

Recently, Cimarusti *et al.* (1) reported the synthesis of a new class of biologically active azetidinesulfonic acids, termed monobactams. One of these monobactams, azthreonam[1], is highly selective against aerobic Gram-negative bacteria (2), including *Pseudomonas aeruginosa* (3).

This communication reports the results of the mass spectra of the named compound and its monosodium and dipotassium salts by the fast atom bombardment technique pioneered by Barber *et al.* (4) and applied by various investigators in the analysis of vexatious polar compounds (5–12).

Mass spectra were obtained on a double-focusing magnetic sector instrument[2] equipped with a fast atom bombardment source using 4–8 kV xenon neutral atoms. Azthreonam (I) gave a very prominent $[M—H]^-$ ion (base peak) in the negative-ion detection mode[3] (Table I) and a significant MH^+ ion in the positive-ion detection mode (Table II). Weak, but perceptible, dimeric ions were also observed. Based upon the expected losses, the fragmentation patterns in each ion detection mode yielded diagnostic information.

	R′	R″	MW	MH^+	$[M·H]^-$
I Azthreonam	H	H	435	436	434
II	Na	H	457	458	456
III	K	K	511	512	510

In the negative ion spectrum, the ions resulting from the direct N—O bond cleavage yields the $[m/z\ 332]^-$ ion and its $[m/z\ 103]^-$ ion complement (Table I). The principal high mass fragment ion in the positive-ion mass spectrum results from the loss of sulfur trioxide from the MH^+ ion (Table II). Cleavage of the monobactam ring of I gives rise to the $[m/z\ 313]^+$ ion in the positive-ion detection mode and its $[m/z\ 122]^-$ complement in the negative-ion detection mode.

Because polar acids are often isolated as alkali salts, the fast atom bombardment spectra of the monosodium (II) and dipotassium (III) salts (13) were compared to the spectra of azthreonam (I). The negative-ion spectra produced readily assignable $[M—H]^-$ and $[M—R']^-$ ions (Table I). The positive-ion spectra yielded complimentary information, although ions generated from mono- and dicationization were more intense than the MH^+ ions. Consequently, care should be taken to introduce as minimum extraneous inorganic salts, or, if unavoidable, only a single species of cation. Fast atom bombardment mass spectrometry has been used in the characterization of related naturally occurring monobactams, synthetic intermediates for azthreonam, and impurities.

Effect of Initial Conditions and Drug–Protein Binding on the Time to Equilibrium in Dialysis Systems

Keyphrases □ Drug–protein binding—effect of initial conditions on the time to equilibrium in dialysis systems □ Equilibrium dialysis—effect of initial conditions and drug–protein binding

To The Editor:

A major disadvantage of using equilibrium dialysis methods for determining *in vitro* plasma protein binding of drugs is the time needed to reach equilibrium. Recently, Øie and Guentert (1) mathematically showed that equilibration is more rapid when the drug is initially added to the plasma side as opposed to the buffer side. The approach to equilibrium was described by integrated equations for the concentration of drug on the buffer side as a function of time. The relative time to equilibrium for the two initial configurations was found to be:

$$R = \frac{t_B}{t_P} = \frac{\ln \delta + \ln \alpha}{\ln \delta} = 1 + \frac{\ln \alpha}{\ln \delta} \qquad \text{(Eq. 1)}$$

where t_B and t_P are the times to reach some fraction (δ) from the equilibrium concentration when the drug is initially added to the buffer or plasma side, respectively, and α is the unbound fraction in plasma which is assumed to be constant during the dialysis. For example, a δ value of 0.05 indicates a deviation of 5% from the true equilibrium value.

The authors indicated that the closer to the true equilibrium value one wants to be, the closer the ratio is to unity. Furthermore, a smaller α (stronger binding) or a larger δ increases the advantage of spiking the plasma side. While we are in complete agreement with these conclusions, some interesting and practical information may be lost if the examination of this system is limited only to the ratio of the times to equilibrium. In this communication the concept of approach to equilibrium in dialysis systems will be further developed and factors affecting comparative equilibration times will be discussed.

When drug is initially added to the plasma side, the concentration on the buffer side (C_B) at any time (t) is:

$$C_B = \frac{C_0\alpha}{1+\alpha}(1 - e^{-K_T(1+\alpha)t}) \qquad \text{(Eq. 2)}$$

where C_0 is the initial concentration, and K_T is the rate constant governing the transfer of drug across the membrane (1).

When drug is initially placed in the buffer side, a similar equation is obtained:

$$C_B = \frac{C_0}{1+\alpha}(\alpha + e^{-K_T(1+\alpha)t}) \qquad \text{(Eq. 3)}$$

Although the actual concentration on the buffer side is the variable of interest, a more useful relationship for examining the influence of α on equilibrium times would be an expression of C_B in relative terms. A fraction away from the equilibrium concentration in the buffer side (δ) is defined as:

$$\delta = \frac{\text{Absolute Value } (C_B^\infty - C_B)}{C_B^\infty} \qquad \text{(Eq. 4)}$$

where C_B^∞ is the concentration of C_B as $t \to \infty$ and $C_B^\infty = C_0\alpha/(1+\alpha)$ for both cases (buffer or plasma spiked).

In a form analogous to Eq. 2, the time course of this fraction when drug is initially on the plasma side is then described by:

$$\delta_P = e^{-K_T(1+\alpha)t} \qquad \text{(Eq. 5)}$$

When drug is initially placed on the buffer side, the time course of δ is described by:

$$\delta_B = \frac{e^{-K_T(1+\alpha)t}}{\alpha} \qquad \text{(Eq. 6)}$$

A hypothetical semilog plot for the time course of these fractions from equilibrium concentration is shown in Fig. 1. As dictated by Eqs. 5 and 6, the δ values decline exponentially with time. For a given value of α, $\ln \delta_P$ and $\ln \delta_B$ decrease at the same rate with slope $= -K_T(1+\alpha)$. As $\alpha \to 0$, the slopes become $-K_T$ and as $\alpha \to 1$, the slopes become $-2K_T$. At $t = 0$, $\delta_P = 1$, whereas the $\delta_B = 1/\alpha$. Thus, δ_P values are always ≤ 1 whereas δ_B has no limit. Although the actual rate constants for approach to equilibrium are the same for both buffer and plasma spiked systems, the buffer spiked system requires more time to reach comparable δ values, because a greater amount of drug must be

Effect of Initial Conditions and Drug–Protein Binding on the Time to Equilibrium in Dialysis Systems

Keyphrases □ Drug–protein binding—effect of initial conditions on the time to equilibrium in dialysis systems □ Equilibrium dialysis—effect of initial conditions and drug–protein binding

To The Editor:

A major disadvantage of using equilibrium dialysis methods for determining *in vitro* plasma protein binding of drugs is the time needed to reach equilibrium. Recently, Øie and Guentert (1) mathematically showed that equilibration is more rapid when the drug is initially added to the plasma side as opposed to the buffer side. The approach to equilibrium was described by integrated equations for the concentration of drug on the buffer side as a function of time. The relative time to equilibrium for the two initial configurations was found to be:

$$R = \frac{t_B}{t_P} = \frac{\ln \delta + \ln \alpha}{\ln \delta} = 1 + \frac{\ln \alpha}{\ln \delta} \qquad \text{(Eq. 1)}$$

where t_B and t_P are the times to reach some fraction (δ) from the equilibrium concentration when the drug is initially added to the buffer or plasma side, respectively, and α is the unbound fraction in plasma which is assumed to be constant during the dialysis. For example, a δ value of 0.05 indicates a deviation of 5% from the true equilibrium value.

The authors indicated that the closer to the true equilibrium value one wants to be, the closer the ratio is to unity. Furthermore, a smaller α (stronger binding) or a larger δ increases the advantage of spiking the plasma side. While we are in complete agreement with these conclusions, some interesting and practical information may be lost if the examination of this system is limited only to the ratio of the times to equilibrium. In this communication the concept of approach to equilibrium in dialysis systems will be further developed and factors affecting comparative equilibration times will be discussed.

When drug is initially added to the plasma side, the concentration on the buffer side (C_B) at any time (t) is:

$$C_B = \frac{C_0\alpha}{1+\alpha}(1 - e^{-K_T(1+\alpha)t}) \qquad \text{(Eq. 2)}$$

where C_0 is the initial concentration, and K_T is the rate constant governing the transfer of drug across the membrane (1).

When drug is initially placed in the buffer side, a similar equation is obtained:

$$C_B = \frac{C_0}{1+\alpha}(\alpha + e^{-K_T(1+\alpha)t}) \qquad \text{(Eq. 3)}$$

Although the actual concentration on the buffer side is the variable of interest, a more useful relationship for examining the influence of α on equilibrium times would be an expression of C_B in relative terms. A fraction away from the equilibrium concentration in the buffer side (δ) is defined as:

$$\delta = \frac{\text{Absolute Value } (C_B^\infty - C_B)}{C_B^\infty} \qquad \text{(Eq. 4)}$$

where C_B^∞ is the concentration of C_B as $t \to \infty$ and $C_B^\infty = C_0\alpha/(1+\alpha)$ for both cases (buffer or plasma spiked).

In a form analogous to Eq. 2, the time course of this fraction when drug is initially on the plasma side is then described by:

$$\delta_P = e^{-K_T(1+\alpha)t} \qquad \text{(Eq. 5)}$$

When drug is initially placed on the buffer side, the time course of δ is described by:

$$\delta_B = \frac{e^{-K_T(1+\alpha)t}}{\alpha} \qquad \text{(Eq. 6)}$$

A hypothetical semilog plot for the time course of these fractions from equilibrium concentration is shown in Fig. 1. As dictated by Eqs. 5 and 6, the δ values decline exponentially with time. For a given value of α, $\ln \delta_P$ and $\ln \delta_B$ decrease at the same rate with slope $= -K_T(1+\alpha)$. As $\alpha \to 0$, the slopes become $-K_T$ and as $\alpha \to 1$, the slopes become $-2K_T$. At $t = 0$, $\delta_P = 1$, whereas the $\delta_B = 1/\alpha$. Thus, δ_P values are always ≤ 1 whereas δ_B has no limit. Although the actual rate constants for approach to equilibrium are the same for both buffer and plasma spiked systems, the buffer spiked system requires more time to reach comparable δ values, because a greater amount of drug must be

0022-3549/82/0900-1066$01.00/0

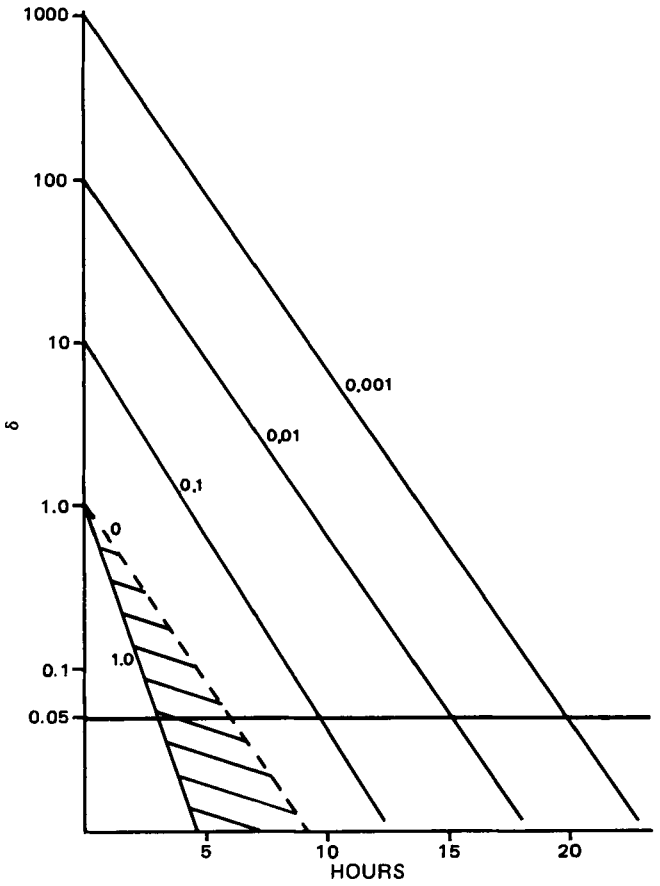

Figure 1—*The time course of the fraction away from equilibrium buffer concentration (δ) when* $K_T = 0.5\ hr^{-1}$. *The α values are given on the continuous lines representing* δ_B. *The dashed line is* δ_P *as* $\alpha \to 0$. *All plasma spiked systems fall within the shaded area bounded by the α = 1.0 (*$\delta_B = \delta_P$*) and dashed lines. The horizontal line at δ = 0.05 indicates a 5% deviation from the true equilibrium value for all conditions.*

transported across the membrane. For example, 99% of the initial mass present in a buffer spiked system ($\alpha = 0.01$) must cross the membrane to reach equilibrium. In a comparable plasma spiked system, only 1% of the initial mass must diffuse to the buffer side at equilibrium.

These comparisons can be shown more clearly by considering the times required to reach a given δ level. Rearrangement of Eq. 5 for the plasma spiked system gives:

$$t_p = \frac{-\ln \delta_P}{K_T(1 + \alpha)} \qquad \text{(Eq. 7)}$$

Thus, as α becomes smaller, t_p reaches a limiting value [$\lim_{\alpha \to 0} t_P = -(\ln \delta_P / K_T)$].

Conversely, when the buffer is spiked, the value of t_B is written as:

$$t_B = \frac{-(\ln \delta + \ln \alpha)}{K_T(1 + \alpha)} \qquad \text{(Eq. 8)}$$

Instead of reaching a limiting value as α decreases, t_B continues to increase in proportion to the negative logarithm of α ($\lim_{\alpha \to 0} t_B = \infty$).

Table I compares the time to reach concentrations 5 and 1% from the true equilibrium concentration. These levels were chosen since they are similar to differences which would be experimentally acceptable. The practical advantage of initially placing drug in the plasma side is obvious throughout the range of α, but becomes most striking below $\alpha \simeq 0.05$. Although t_P becomes essentially constant, t_B continues to increase with decreasing α. If only the ratio of t_B/t_P were used, the important observation of an essentially constant equilibration time (t_P) below $\alpha \simeq 0.05$ would be overlooked. Table I also illustrates a second point brought out by Øie and Guentert (1): the closer to the true equilibrium value one wishes to be, the closer the ratio is to unity. Thus, at $\delta = 0.05$ spiking of plasma would be 78% faster, whereas at $\delta = 0.01$, the advantage is 51%, assuming a constant α value of 0.1.

Table 1—Influence of Initial Conditions and Fraction Unbound in Plasma (α) on the Time to Reach a Fraction (δ) away from Equilibrium Concentration [a]

	α	t_B	t_P	t_B/t_P

[a] $K_T = 0.5\ hr^{-1}$.

Most clinically important drug–protein interactions occur with compounds having unbound fractions (α) of ≤0.2. Experimentally, the time to equilibrium is usually established (and fixed) in preliminary studies using plasma obtained from healthy subjects, and it is rarely re-examined, even if the extent of binding varies in subsequent samples. To avoid potentially serious errors in binding data, the following points should be considered when conducting equilibrium dialysis experiments:

1. Preliminary studies should include establishment of the equilibration time in a buffer *versus* buffer system. If the logarithm of δ is plotted *versus* time (Eq. 5 or 6 with $\alpha = 1$), the slope = $2K_T$. Changes in the membrane, drug, cell volume, or agitation method may require that K_T be redetermined. With a value for K_T and an estimate for α in plasma for a particular drug, the time to equilibrium and time difference between plasma- and buffer-spiked configurations can be estimated.

2. The time to equilibrium when spiking buffer increases with decreasing α values, whereas when spiking plasma it is essentially independent of α. The maximum equilibration time in a plasma spiked system should not be more than twice that of a buffer *versus* buffer system. No such maximum exists when drug is initially added to the buffer side (Table I).

3. Unbound (buffer) drug concentrations or fraction unbound should be used to monitor the approach to equilibrium, since total (plasma) concentrations and the fraction bound are relatively insensitive parameters at low α values.

4. If there are no significant advantages in sample preparation, the drug should be added on the plasma side. This minimizes equilibration time and reduces potential

problems such as drug degradation, microbiological growth (2), protein dilution (3), and lipolysis (4).

5. When spiking the buffer side is desirable, establish the time to equilibrium for the system with the smallest expected α value. The smallest α values do not always occur with healthy adult plasma. For example, the interaction of cationic drugs with α_1-acid glycoprotein increased in certain disease states and under various stress conditions (5, 6). When spiking plasma under these conditions, the apparent α value would be smaller than the true equilibrium value, whereas the opposite would occur when spiking the buffer side.

BOOKS

REVIEWS

The Peptides. Analysis, Synthesis, Biology. Vol. 4. Edited by ERHARD GROSS and JOHANNES MEIENHOFFER. Academic, 111 Fifth Ave., New York, NY 10017. 1981. 309 pp. 15 × 23 cm.

The first three volumes of *The Peptides* were devoted to the methodology concerning the synthesis of peptides. The fourth volume is the first of several volumes planned, according to the editors, dealing with the analytical aspects of peptides. The fourth volume eminently succeeds in reaching the high standards set for it by its predecessors.

The six chapters are divided evenly among the physical and chemical methods for peptide–protein-structure determination. Of those concerned with the physical methods, the first two focus on the crystal structure analysis by X-ray studies. In the first chapter, I. L. Karle discusses the crystal structures of linear and cyclic peptides containing 2 to 15 peptide units. Several useful generalizations are mentioned; for example, "4 → 1 H-bonds begin to appear in cyclic hexapeptides" and "the possibility for several different conformations assumed by the same compound arises starting with the cyclic heptapeptides." The author has made liberal use of tables and figures, which also list pertinent references.

J. Gunning and T. Blundell present in Chapter 2 a crystal structure analysis of the larger peptide hormones. The crystal structures of insulin (A-chain, 21 residues; B-chain, 30 residues), glucagon (29 residues), and the pancreatic polypeptide (36 residues) have been determined. On the basis of the known homology with the amino acid sequence of insulin, the structures of proinsulin and relaxin have been proposed and are discussed.

The chiroptical method for the determination of the absolute configuration of α-amino acids and small peptides is the topic of Chapter 3 by V. Toome and M. Weigle. The chiroptical properties of both the free α-amino acids and of the free oligopeptides, as well as of their metal complexes and chromophoric derivatives, are discussed.

In the fourth chapter, S. Stein describes the technique of peptide and protein-analysis at the picomole level employing HPLC and fluorescence spectrophotometry. The combination of HPLC and fluorescence detection raises the possibility of determination of peptides and proteins in tissues and organs of individual animals. This combination of techniques has also been employed for the determination of the amino acid sequence.

Chapter 5, by J. R. Benson, P. C. Louie, and R. A. Bradshaw, deals with the single-column amino acid analysis of peptides. For the purpose of discussion, the authors have divided the amino acids into four categories according to whether they are (*a*) normally found in proteins, (*b*) formed *in vivo* from the first group by post- or cotranslation, (*c*) formed by chemical modification from Group 1, or (*d*) nonprotein amino acids. Several protocols are given for the separation of these amino acids.

R. A. Laursen in Chapter 6 probes in exquisite detail the solid-phase sequencing technique, which would help overcome problems (such as overlap, increased-background, amino-terminal blocking) experienced with the Edman method.

Both the editors and the authors are to be congratulated for the excellence of this volume, which is a must for those concerned with any and all aspects of proteins and peptides, and for those contemplating a start in this area of research.

Medicinal Chemistry VI (Proceedings of the 6th International Symposium on Medicinal Chemistry). Edited by M. A. SIMKINS. Wiley, 605 Third Ave., New York, NY 10016. 1979. 477 pp. 16 × 24 cm. Price $94.00.

Medicinal Chemistry VI is a collection of papers presented at the 6th Internation Symposium on Medicinal Chemistry held in Brighton, England in 1978. They were chosen for this volume by the members of the Society for Drug Research and cover a wide range of interests, many being a blend of chemistry, biology, biochemistry, and medicine. The majority of the papers are based on disease states while others discuss theoretical concepts relating to substrate–receptor interactions or predicting activity of molecules based solely on structure.

This volume is divided into plenary lectures and symposium papers. The plenary lectures are given by Dr. Linus Pauling, who speaks of "orthomolecular medicine," a new concept in treating diseases, which he defines as the achievement and preservation of the best of health and the prevention and treatment of disease by using substances (right molecules in the right amounts) that are normally present in the body; professor Sir John Cornforth provides the reader with a greater awareness of

problems such as drug degradation, microbiological growth (2), protein dilution (3), and lipolysis (4).

5. When spiking the buffer side is desirable, establish the time to equilibrium for the system with the smallest expected α value. The smallest α values do not always occur with healthy adult plasma. For example, the interaction of cationic drugs with α_1-acid glycoprotein increased in certain disease states and under various stress conditions (5, 6). When spiking plasma under these conditions, the apparent α value would be smaller than the true equilibrium value, whereas the opposite would occur when spiking the buffer side.

Medicinal Chemistry VI (Proceedings of the 6th International Symposium on Medicinal Chemistry). Edited by M. A. SIMKINS. Wiley, 605 Third Ave., New York, NY 10016. 1979. 477 pp. 16 × 24 cm. Price $94.00.

Medicinal Chemistry VI is a collection of papers presented at the 6th Internation Symposium on Medicinal Chemistry held in Brighton, England in 1978. They were chosen for this volume by the members of the Society for Drug Research and cover a wide range of interests, many being a blend of chemistry, biology, biochemistry, and medicine. The majority of the papers are based on disease states while others discuss theoretical concepts relating to substrate–receptor interactions or predicting activity of molecules based solely on structure.

This volume is divided into plenary lectures and symposium papers. The plenary lectures are given by Dr. Linus Pauling, who speaks of "orthomolecular medicine," a new concept in treating diseases, which he defines as the achievement and preservation of the best of health and the prevention and treatment of disease by using substances (right molecules in the right amounts) that are normally present in the body; professor Sir John Cornforth provides the reader with a greater awareness of

structural characteristics of enzymes; and Sir Arnold Burgen along with N. J. M. Birdsall and E. C. Hume introduce the reader to modern techniques which provide a better understanding of receptors.

In the foreword J. F. Cavalla and M. A. Simkin offer an interesting proposal about what it takes for a medicinal chemist to become successful. They propose that the medicinal chemist must associate himself/herself with a biologist, and for further success, must acquire a working knowledge of basic pharmacology in the area in which he/she is working, coupled with a detailed awareness of structure–activity relationships; then, they say, the medicinal chemist should succeed in discovering new and better medicines. This reviewer finds himself in agreement with their offer, except that I would propose the use of the adjective "molecular" before biologist (and pharmacologist) to describe the needs of medicinal chemists today. Much more knowledge at the molecular level is needed, and it is a pleasure to find the theoretical papers of this volume fulfilling this need.

Overall, the volume is quite good and makes a worthwhile contribution to medicinal chemistry and allied fields. The authors are experts in their field and their papers are well-written, containing sufficient references. The organization of this book is not unlike most proceedings of meetings and symposia in which there is the absence of major sections and chapter numbers.

The greatest use of this volume will be by graduate students and researchers in the areas for which this volume was intended: medicinal chemistry, pharmacology (pharmacokinetics), and medicine. It also can be recommended as an important source for new ideas and for use in many graduate courses.

Textbook of Adverse Drug Reactions. 2nd ed. Edited by D. M. DAVIES. Oxford University Press. 200 Madison Ave., New York, NY 10016. 1981. 693 pp. 18 × 25 cm. Price $67.50.

This second edition is an expansion of the first that originally filled the void that had existed for an authoritative reference source for all major and minor adverse drug reactions. It is the work of 36 contributors authoring 30 chapters and 4 appendixes. The newest chapter discusses disorders of temperature regulation brought upon by disease, hypersensitivity, and drugs. The remaining chapters have been slightly rewritten with the addition of material and updated references.

This reference text makes it clear that perhaps 10% of patients suffer from physicians' efforts to treat them and that iatrogenic diseases and side-effects are certain consequences to drug therapy. Therefore, the public should be made aware that risk in any treatment is always there, and particularly so when new drugs and regimens come along that have not been used extensively in large numbers of patients. In addition, the problem of risk *versus* benefit is compounded when there is excessive or even irresponsible prescribing.

Most chapters use a classification of adverse drug reactions that divides them into two types. The first, Type A, are augmented effects but predictable on their known pharmacologic action and affect many people but cause few deaths. The second, Type B, are bizarre effects, not predictable from their known pharmacologic action when administered in regular doses to patients with average metabolic processes. These types of adverse drug reactions have a low incidence but, when they occur, often are lethal. It is also pointed out that some adverse drug reactions must be tolerated, because for a drug to work, it always shows toxicity at some dosage level. So, some reactions to medications are a necessary cross to bear in order to remedy the myriad of maladies that affect mankind.

This edition maintains the clarity of the earlier edition. Its first appendix lists the drugs alphabetically with the most outstanding possible untoward effects and includes the pages on which they are discussed. This makes it a quick reference source without having to resort to the index, which often leads to delay.

This book is recommended for individuals requiring the most up-to-date information on adverse drug reactions. Specifically, hospital pharmacists; clinical pharmacologists; internists; medical clinics; and all pharmacy, medical, and dental libraries.

Tableting Specifications Manual. American Pharmaceutical Association, Washington, DC 20037. 1981. 39 pp. 20 × 28 cm (three-holed punch, loose-leaf format). Price $42.00 ($28.00 for APhA members).

This extensively updated and revised version of the original (1971) book, *IPT Standard Specifications for Tableting Tools*, contains the latest information available on tablet tooling and available equipment. *The Tableting Specifications Manual* is a new book prepared by the Industrial Pharmaceutical Technology Section of the American Pharmaceutical Association's Academy of Pharmaceutical Sciences with the cooperation of tableting tool suppliers.

The manual supplies the standards needed by both drug manufacturers and tool suppliers: Drug manufacturers will find the publication useful in preventing premature tool wear and costly work stoppages, while improving tablet quality and production rate. Pharmaceutical tool suppliers will benefit from the reduced lead times and manufacturing costs possible and the smaller inventory that standardization allows.

The manual also includes: a set of dimensional specifications and tolerances for rotary tableting machines in both graphic and tabular forms; a tool interchangeability chart with the five most commonly used tablet machines in the United States; a list of tool manufacturers and suppliers; and additional information on the bisection bar.

With numerous tables and IPT drawings and a loose-leaf, shrink-wrapped format for greater convenience and ease of updating, this manual will be a useful resource for those needing the most up-to-date information on tableting.

Tableting Specifications Manual. American Pharmaceutical Association, Washington, DC 20037. 1981. 39 pp. 20 × 28 cm (three-holed punch, loose-leaf format). Price $42.00 ($28.00 for APhA members).

This extensively updated and revised version of the original (1971) book, *IPT Standard Specifications for Tableting Tools*, contains the latest information available on tablet tooling and available equipment. *The Tableting Specifications Manual* is a new book prepared by the Industrial Pharmaceutical Technology Section of the American Pharmaceutical Association's Academy of Pharmaceutical Sciences with the cooperation of tableting tool suppliers.

The manual supplies the standards needed by both drug manufacturers and tool suppliers: Drug manufacturers will find the publication useful in preventing premature tool wear and costly work stoppages, while improving tablet quality and production rate. Pharmaceutical tool suppliers will benefit from the reduced lead times and manufacturing costs possible and the smaller inventory that standardization allows.

The manual also includes: a set of dimensional specifications and tolerances for rotary tableting machines in both graphic and tabular forms; a tool interchangeability chart with the five most commonly used tablet machines in the United States; a list of tool manufacturers and suppliers; and additional information on the bisection bar.

With numerous tables and IPT drawings and a loose-leaf, shrink-wrapped format for greater convenience and ease of updating, this manual will be a useful resource for those needing the most up-to-date information on tableting.

Adolescent Marijuana Abusers and Their Families. (NIDA Research 40—9/81). By HERBERT HENDIN, ANN POLLINGER, RICHARD ULMAN, and ARTHUR C. CARR. National Institute on Drug Abuse, Division of Research, 5600 Fishers Lane, Rockville, MD 20857.

Amino Acids, Peptides and Proteins. Vol. 12. Senior Reporter, R. C. SHEPPARD. Royal Society of Chemistry, Burlington House, London, WIV OBN, England. 1982. 634 pp. 13 × 22 cm. Price $153.00.

The Aminoglycosides: Microbiology, Clinical Use and Toxicology. (Kindley Disease Series, Vol. 2). Edited by ANDREW WHELTON and HAROLD C. NEU. Dekker, 270 Madison Ave., New York, NY 10016. 1982. 640 pp. 17 × 26 cm. Price $75.00.

Assessment of Public Health and Social Problems Associated with the Use of Psychotropic Drugs. (Report of the WHO Expert Committee on Implementation of the Convention on Psychotropic Substances 1971). World Health Organization, 1211 Geneva 27, Switzerland. 1981. 54 pp. 14 × 20 cm. Price Sw. fr. 4.

Bailey's Industrial Oil and Fat Products. Vol. 2. 4th Ed. Edited by DANIEL SWERN. By ROBERT R. ALLEN, MARVIN W. FORMO, R. G. KRISHNAMURTHY, G. N. McDERMOTT, FRANK A. NORRIS, and NORMAL O. V. SONNTAG. Wiley, 605 Third Ave., New York, NY 10016. 1982. 603 pp. 15 × 23 cm.

Behavioral Pharmacology of Human Drug Dependence. (NIDA Research Monograph 37, 7/81). Edited by TRAVIS THOMPSON and

structural characteristics of enzymes; and Sir Arnold Burgen along with N. J. M. Birdsall and E. C. Hume introduce the reader to modern techniques which provide a better understanding of receptors.

In the foreword J. F. Cavalla and M. A. Simkin offer an interesting proposal about what it takes for a medicinal chemist to become successful. They propose that the medicinal chemist must associate himself/herself with a biologist, and for further success, must acquire a working knowledge of basic pharmacology in the area in which he/she is working, coupled with a detailed awareness of structure–activity relationships; then, they say, the medicinal chemist should succeed in discovering new and better medicines. This reviewer finds himself in agreement with their offer, except that I would propose the use of the adjective "molecular" before biologist (and pharmacologist) to describe the needs of medicinal chemists today. Much more knowledge at the molecular level is needed, and it is a pleasure to find the theoretical papers of this volume fulfilling this need.

Overall, the volume is quite good and makes a worthwhile contribution to medicinal chemistry and allied fields. The authors are experts in their field and their papers are well-written, containing sufficient references. The organization of this book is not unlike most proceedings of meetings and symposia in which there is the absence of major sections and chapter numbers.

The greatest use of this volume will be by graduate students and researchers in the areas for which this volume was intended: medicinal chemistry, pharmacology (pharmacokinetics), and medicine. It also can be recommended as an important source for new ideas and for use in many graduate courses.

Textbook of Adverse Drug Reactions. 2nd ed. Edited by D. M. DAVIES. Oxford University Press. 200 Madison Ave., New York, NY 10016. 1981. 693 pp. 18 × 25 cm. Price $67.50.

This second edition is an expansion of the first that originally filled the void that had existed for an authoritative reference source for all major and minor adverse drug reactions. It is the work of 36 contributors authoring 30 chapters and 4 appendixes. The newest chapter discusses disorders of temperature regulation brought upon by disease, hypersensitivity, and drugs. The remaining chapters have been slightly rewritten with the addition of material and updated references.

This reference text makes it clear that perhaps 10% of patients suffer from physicians' efforts to treat them and that iatrogenic diseases and side-effects are certain consequences to drug therapy. Therefore, the public should be made aware that risk in any treatment is always there, and particularly so when new drugs and regimens come along that have not been used extensively in large numbers of patients. In addition, the problem of risk *versus* benefit is compounded when there is excessive or even irresponsible prescribing.

Most chapters use a classification of adverse drug reactions that divides them into two types. The first, Type A, are augmented effects but predictable on their known pharmacologic action and affect many people but cause few deaths. The second, Type B, are bizarre effects, not predictable from their known pharmacologic action when administered in regular doses to patients with average metabolic processes. These types of adverse drug reactions have a low incidence but, when they occur, often are lethal. It is also pointed out that some adverse drug reactions must be tolerated, because for a drug to work, it always shows toxicity at some dosage level. So, some reactions to medications are a necessary cross to bear in order to remedy the myriad of maladies that affect mankind.

This edition maintains the clarity of the earlier edition. Its first appendix lists the drugs alphabetically with the most outstanding possible untoward effects and includes the pages on which they are discussed. This makes it a quick reference source without having to resort to the index, which often leads to delay.

This book is recommended for individuals requiring the most up-to-date information on adverse drug reactions. Specifically, hospital pharmacists; clinical pharmacologists; internists; medical clinics; and all pharmacy, medical, and dental libraries.

On "Being There"—Professionally

On about half the Sunday afternoons each autumn, a sell-out crowd of approximately 55,000 Washington, DC, area residents will pack RFK Stadium to watch the Washington Redskins professional football team do battle with one or another of its league rivals. This phenomenon occurs despite the fact that (a) each of those games can be watched on television for free from the comfort of one's home, (b) both the admission tickets and various incidental costs—such as parking and refreshments—are all very expensive, and (c) the stadium, its seats, and often the weather conditions leave much to be desired in the way of creature comforts. In fact, thousands of other people clamor for the opportunity to buy Redskins tickets even at prices above their already costly face value.

Similar fan enthusiasm is apparent in many other cities and with regard to various other sports both professional and amateur.

If one were to ask those sports fans why it is worth the expense, inconvenience, and discomfort to see the game in person when they can see it more clearly on color television, with professional audio commentary, and with the added dimension of instant replays, they will offer a variety of explanations. However, no matter how the replies are stated, virtually all of the explanations boil down to: "There is no adequate substitute for personally being there—namely, where the real action is!"

The same can be said with respect to professional and scientific meetings or conferences.

Reading newsletter summaries of the highlights of a conference, or reviewing journal articles covering research presented at a technical session, amounts to a very inadequate substitute for first-hand attendance at the meeting itself.

Moreover, in contrast to the sporting event, personal attendance at a meeting or symposium gives one many additional advantages and benefits. For example, one can personally meet and talk to the researcher, and ask questions and obtain clarifications and insights. There is also the opportunity to meet other experts or notables in the field; the opportunity to share experiences through informal conversation; and the opportunity to exchange other important career-related information such as job openings, employment benefits, and comparative remuneration. Finally, there is the built-in vehicle to become more active professionally and organization-wise through opening the door to voluntary participation, committee appointments, and elective office.

Many meetings or conferences can provide such opportunities. But for American pharmaceutical scientists, there are really two meetings that annually offer the greatest means of satisfying such needs and expectations. These are the combined APhA–APS Annual Meeting in the spring of each year, and the APS mid-year meeting in the fall.

The special benefit to be derived from these meetings is that the pharmaceutical scientist has the ready opportunity to broaden horizons via direct contact, dialog, and interchange with colleagues in other scientific fields as well as in other environments of practice. Hence, pharmaceutical scientists who are primarily chemists mingle and exchange views with others who are primarily pharmacologists, or biologists, or analysts, or whatever. And the person employed in industry not only associates with other industry colleagues but also others in academia, government, and elsewhere.

Furthermore, at the combined APhA–APS meetings, the scientist rubs elbows with and can have dialog with people not in science or research but who share a common interest and concern regarding pharmaceuticals and pharmaceutical products; namely, community and hospital practitioners, pharmacy officials, and students.

All of this cannot help but have some effect and beneficial influence on the person so exposed.

In an effort to maximize the opportunity for professional growth and to make the experience of attending an APhA Annual Meeting even more valuable, the programming for the 1983 Annual Meeting in New Orleans is being organized into a series of four "tracks." One or more of these "tracks" will be of major interest and value to each registrant.

In the past, many registrants might have overlooked a session that would have been of interest simply because the session was sponsored by a group in another discipline. For example, the FDA pharmaceutical analyst might have ignored sessions dealing with institutional pharmacy on the assumption that he or she had no interest in "hospital pharmacy." As a result, that person completely overlooked the session on "Complying with FDA's Good Manufacturing Practice (GMP) Regulations in the Hospital Pharmacy Manufacturing Laboratory."

Hopefully, the "track" system will eliminate future such oversights. Program content of special interest to practitioners, to scientists, and to students will be grouped in separate lists for ready and convenient reference by these respective people. So, too, will be grouped the broader, more general program content involving Association policy and general information. As a result, the "scientist track" will list not only APS sessions but also SAPhA programs on increasing graduate student enrollment, APP programs on comparative bioavailability of competing drug products, and APhA General Session speakers such as the Director of the National Institutes of Health or the Commissioner of the Food and Drug Administration.

Consequently, we urge our readers to make plans now to attend the up-coming APS National Meeting, November 14–18, 1982, in San Diego, California, and APhA–APS Annual Meeting, April 9–14, 1983, in New Orleans, Louisiana. "Being there" will be more important and rewarding than ever before.

LITERATURE SURVEY

Vitamins in Pharmaceutical Formulations

ELMER DeRITTER

Received from the *Product Development and Application, Roche Chemical Division, Hoffmann-LaRoche, Nutley, NJ 07110.*

Keyphrases □ Vitamins—pharmaceutical formulations, literature survey □ Pharmaceutical formulations—vitamins, literature survey

CONTENTS

The formulation of pharmaceutical vitamin products having adequate physical and chemical stability as well as suitable taste, odor, color, and freedom from bacterial contamination can entail numerous problems arising from the differing physical form, stability, and solubility characteristics of the individual vitamins. For liquid products, choice of the optimal pH is a crucial factor. Interactions between some of the vitamins and between vitamins and other product constituents must also be considered. Successful development of vitamin products requires knowledge of the fundamental aspects of the physical and chemical properties of the various forms of the vitamins available, the use of adequate techniques of manufacture, and the addition of suitable manufacturing overages based on critical stability studies.

SOLUBILITY OF THE VITAMINS

Vitamins are categorized into two general groups: fat-soluble and water-soluble. The fat-soluble vitamins include vitamins A, E, and K and cholecalciferol (vitamin D). Vitamin A is available as the free alcohol, retinol, and its acetate, palmitate, and propionate esters. Vitamin E is listed by USP as both *d*- and *dl*-forms of tocopherol and its acetate and acid succinate esters. Cholecalciferol is normally utilized in pharmaceuticals as ergocalciferol (vitamin D_2) or cholecalciferol (vitamin D_3), both of which are equally active in humans. Oil-soluble forms of vitamin K include phytonadione (vitamin K_1), menadione, menadiol diacetate, and menadiol dibutyrate. Incorporation of fat-soluble vitamins into an aqueous preparation requires the use of an efficient emulsifying agent (*e.g.*, polysorbate 80) to produce homogeneous and physically stable formulations. In the case of vitamin K, there are a number of water-soluble forms such as menadiol sodium diphosphate, the dipotassium salt of menadiol disulfate, and menadione sodium bisulfite.

Solubilities of the water-soluble vitamins at 25° in water are listed in Table I. For several of the relatively insoluble vitamins such as riboflavin and biotin, the solubility is dependent on the nature of the crystal structure. For acids such as biotin and folic acid, addition of alkali significantly increases solubility. In the case of biotin it is possible to prepare a 20% aqueous solution of the sodium salt by this method. Figure 1 illustrates the increasing solubility of

0022-3549/82/01000-1073$01.00/0

Table I—Solubility of Vitamins in Water at 25°

	mg/ml
Panthenol	Freely soluble
Thiamine hydrochloride	1000
Thiamine mononitrate	27
Niacinamide	1000
Sodium ascorbate	620
Ascorbic acid	333
Calcium pantothenate	356
Pyridoxine hydrochloride	220
Riboflavin-5′-phosphate sodium	43–112
Riboflavin	0.066–0.33
Cyanocobalamin	12.5
Biotin	0.3–0.4
Folic acid	0.0016

folic acid with increasing pH and shows the solubilizing effect on folic acid of gentisic acid ethanolamide as related to pH (1). An amorphous form of *d*-calcium pantothenate was reported (2) to dissolve ~10% faster than the crystalline form in aqueous media (pH 7.0 buffer).

STABILITY CHARACTERISTICS OF THE VITAMINS

Factors influencing the stability of the individual vitamins and their relative effects on different forms of a particular vitamin are listed in Table II. Although temperature is not mentioned in the tabulation, it is normal that an increase in temperature will accelerate any of the decomposition reactions. Macek (5) has reviewed the stability problems encountered with some vitamins.

A number of the vitamins may be classified as stable since they usually present no major problems regarding stability in pharmaceutical dosage forms. These include cholecalciferol, vitamin E acetate or acid succinate, biotin, niacin or niacinamide, pyridoxine, and riboflavin. The labile vitamins which are likely to present problems of instability in dosage forms are vitamin A (retinol and retinyl esters), vitamin K, ascorbic acid, cyanocobalamin, folic acid, pantothenic acid, panthenol, and thiamine.

The presence of one or more double bonds in the structures of vitamin A, cholecalciferol, and phytonadione makes them subject to isomerization under conditions frequently encountered in pharmaceutical products. For example, vitamin A undergoes isomerization in aqueous preparations at an acid pH. Vitamin A added to such products as essentially the all-*trans* form will isomerize on storage to an equilibrium mixture of approximately two-thirds all-*trans* and one-third *cis* isomers, the predominant *cis* isomer being 2-*cis* or neovitamin A, which has biological activity of 75% of that of the all-*trans* isomer. Lesser amounts of the 6-*cis* and 2,6-di-*cis* isomers may also form. The latter have only ~23% of the biological potency of all-*trans* vitamin A. Lehman *et al.* (6) have reported on the extent of isomerization that occurs in stored multivitamin drops. Equations have been proposed (7, 8) for calculating the biological potency of the isomerized vitamin A from the maleic values determined by Carr-Price colorimetry before and after reaction of vitamin A with maleic anhydride, in which isomers having a *cis* configuration at the terminal double bond (the 2-position) do not react to form an adduct.

Vitamin A suppliers have made available mixtures of vitamin A palmitate isomers at the equilibrium ratio of

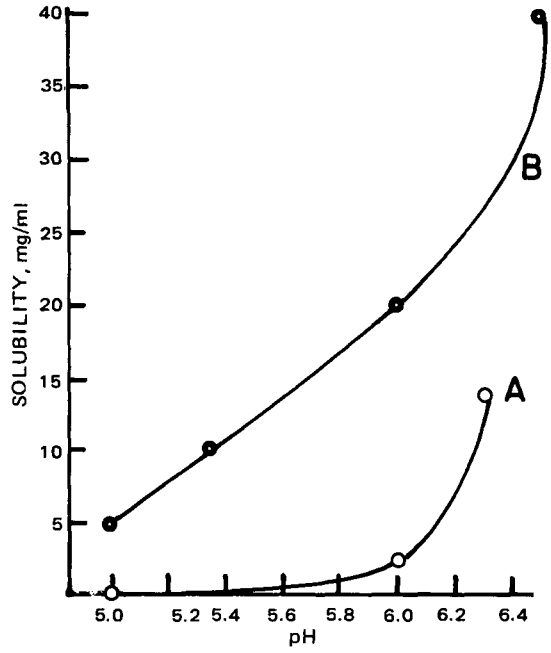

Figure 1—*Solubility of folic acid* versus *pH. Key: (A) with no solubilizer, (B) with 3% gentisic acid ethanolamide.*

Table II—Stability Characteristics of Vitamins

Vitamin A	sensitive to atmospheric oxygen (retinol less stable than its esters); trace metals catalyze decomposition; inactivated by UV light; isomerizes at acid pH; stable in alkali; in aqueous dispersions palmitate ester more stable to heat than retinol <pH 5.5; palmitate most stable ester under moisture stress; stabilized by antioxidants and protective coatings.
Cholecalciferol (vitamin D)	sensitive to atmospheric oxygen; trace metals and carriers with acid surface activity catalyze isomerization or decomposition; generally more stable than vitamin A; stabilized by antioxidants and protective coatings.
Vitamin E	tocopherol sensitive to atmospheric oxygen, especially in alkali and sensitive to UV light; esters very stable.
Vitamin K	fairly stable to heat; decomposed by sunlight and alkali.
Ascorbic acid (vitamin C)	stable when dry; readily oxidized in solution; decomposition catalyzed by metal ions (copper and iron); greatest instability at ~pH 4.
Biotin	stable to air and acid and at neutral pH; slightly unstable in alkali.
Cyanocobalamin (vitamin B_{12})	decomposed by oxidizing and reducing agents; slightly unstable in acid or alkaline solution; ascorbic acid and thiamine–niacinamide accelerate the decomposition; sensitive to light in very dilute solutions for assay.
Folic acid	unstable <pH 5; decomposed by sunlight and riboflavin; decomposed by reducing agents.
Niacin and niacinamide	normally very stable.
Calcium pantothenate	unstable in acid (< pH 5) and alkali; maximum stability at pH 6–7.
Panthenol	more stable than calcium pantothenate at ≤pH 5.
Pyridoxine (vitamin B_6)	normally very stable; metal ions can catalyze decomposition; dilute solutions for assay are sensitive to light.
Riboflavin (vitamin B_2)	stable in acid solution; unstable in alkaline solution; sensitive to light, especially in alkaline solution or in very dilute acid solutions for assay; decomposed by reducing agents.
Thiamine (vitamin B_1)	increasingly unstable in solution as pH rises; decomposed by oxidizing or reducing agents; cleaved by sulfite very rapidly at high pH (Ref. 3); hydrochloride more hygroscopic than mononitrate (Ref. 4).

two-thirds all-*trans* and one-third *cis* for use in aqueous products where isomerization is known to occur (9). With such use, the drop in potency by USP assay due to isomerization does not occur in the multivitamin product and, consequently, the stability of vitamin A in the product is somewhat better with the preisomerized mixtures than with all-*trans* vitamin A. Figure 2 illustrates this advantage of the preisomerized equilibrium mixture over all-*trans* vitamin A palmitate in a number of multivitamin drop preparations at pH 5.0 stored at room temperature for 12 months. On the average, after 6–12 months, vitamin A retention is 7% greater with the preisomerized vitamin A. A similar difference was found in storage tests at 45°.

The reversible isomerization reaction in solutions of cholecalciferol has been discussed by Keverling Buisman *et al.* (10). In this reaction an equilibrium is formed over time between ergocalciferol and precalciferol, the equilibrium ratio of the isomers being dependent on temperature. The isomerization rates of ergocalciferol and cholecalciferol are virtually equal (11) and are not influenced by the solvent, acidity, UV light, catalysts, and free-radical reaction inhibitors (12, 13).

Inactive byproducts that may be present from the irradiation process used for manufacture of cholecalciferol, such as tachysterol, isotachysterol, and *trans*-cholecalciferol, give the same pink color with Nield's reagent used for assay of ergocalciferol plus precalciferol. The interference by tachysterol and *trans*-cholecalciferol can be eliminated by forming an adduct of those compounds with maleic anhydride, which can be done in 30 min at 20°. Isotachysterol can be estimated after formation of adducts of ergocalciferol and precalciferol with maleic anhydride by heating for 3 hr at 100°. Isotachysterol does not react significantly with maleic anhydride (14) under these conditions.

In a series of papers, Takahashi and Yamamoto (15) studied the isomerization of ergocalciferol that occurs in powders prepared with various excipients such as $CaSO_4$, $CaHPO_4$, talc, aluminum silicate, and magnesium trisilicate. This isomerization is catalyzed by the surface acid of the excipients. Compounds such as monoethanolamine and polyoxyethylene glycol 4000, which are able to reduce the surface acidity of the excipients, act as stabilizers of ergocalciferol. Storage of ergocalciferol powders at high humidity increases their stability because the surface acidity is reduced through absorption of moisture. However, coating agents such as shellac, ethylcellulose, or cellulose acetate phthalate were unable to prevent the isomerization of the vitamin. The isomers identified were 5,6-*trans*-ergocalciferol, precalciferol, isocalciferol, a *cis* isomer of isocalciferol, isotachysterol, and tachysterol.

Phytonadione, having a double bond in the side chain, exists in the form of both *trans* and *cis* isomers. The *trans* isomer is the naturally occurring form, which is biologically active. The *cis* form has no significant biological activity.

DEGRADATION STUDIES

Vitamin A—The degradation of retinol in solution in an oil with polysorbate 80 was shown by Carstensen (16) to be a pseudo first-order reaction. Carstensen (16) and Tardif (17) reported first-order decomposition of vitamin A in tablets with adherence to an Arrhenius equation, and Shah *et al.* (18) found that vitamin A in two multivitamin preparations decomposed in accordance with a first-order reaction.

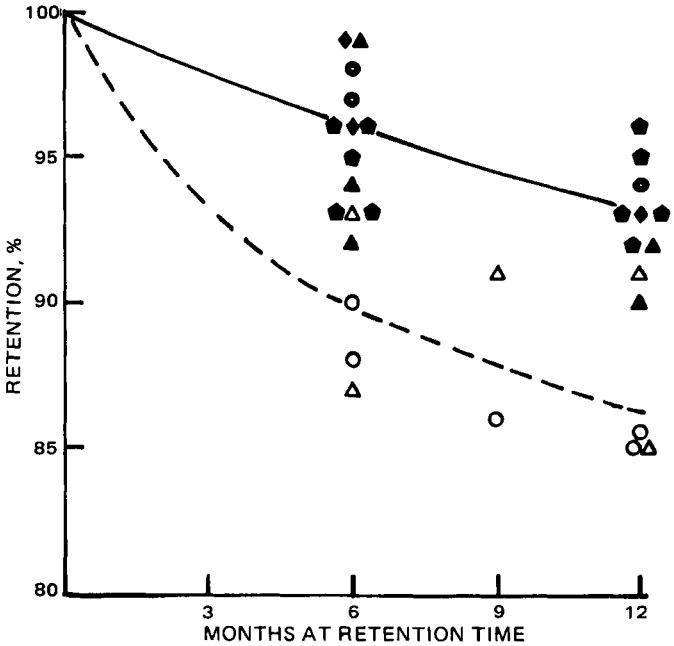

Figure 2—*Stability of vitamin A palmitate in aqueous multivitamin drops at pH 5; symbols represent different formulations with all-*trans *(●, △) or preisomerized (○, ▲, ■, ◆) vitamin A.*

Cholecalciferol (Vitamin D)—The decomposition of ergocalciferol and cholecalciferol at 25 and 40° under dry, humid conditions was studied by Grady and Thakker (19). Ergocalciferol decomposed rapidly at both temperatures in dry air, leading to formation of products of higher polarity. It was more stable at higher humidity than in dry air. Cholecalciferol was not as labile in dry air but decomposed rapidly at 40° and high humidity levels.

Vitamin E (α-Tocopheryl Acetate)—Vitamin E is relatively stable, but the unesterified α-tocopherol is less stable due to the free phenolic hydroxy group. Oxidation of α-tocopherol with agents such as nitric acid, ferric chloride, or ceric sulfate leads successively to the formation of α-tocopherolquinone, α-tocored, the *para*-quinone, and α-tocopurple (20, 21). In the absence of air, α-tocopherol is stable to heat but will be degraded if exposed to air. Thus, during saponification for analysis, protection by an antioxidant such as ascorbic acid or pyrogallol is practiced. Exposure to light will cause gradual darkening.

Vitamin K—Vire *et al.* (22) studied the degradation of menadione and menadione bisulfite in neutral and alkaline solution using polarographic methods. In alkaline solution the predominant degradation of the bisulfite addition product is to menadione, but in neutral solution isomerization to a naphthoquinone sulfinate becomes significant. In the absence of oxygen, menadione is degraded primarily *via* rearrangement to epoxynaphthohydroquinone.

Thiamine (Vitamin B_1)—The chemistry of the degradation of thiamine under the influence of heat and pH has been reported by Dwivedi *et al.* (23–25). The kinetics of the degradation of thiamine have been studied by various workers (17, 18, 25–29) who have reported first-order reactions with a rate increasing with increasing pH. Mulley *et al.* (28) also studied the degradation of cocarboxylase,

which was less stable than thiamine hydrochloride between pH 4.5 and 6.5 in phosphate buffer. Kobayashi (30) found that decomposition of thiamine in the neutral range is accelerated by the presence of Cu^{+2} at high temperature. The decomposition was affected by initial concentrations of thiamine and Cu^{+2}, time and temperature of heating, pH, and kind of buffer. In the presence of sodium nitrite, Kaya (31) found that heating of thiamine solutions for 60 min at 75° caused formation of elemental sulfur and thiochrome as well as 4-methyl-5-(β-hydroxyethyl)thiazole. The cleavage of thiamine by sulfite or bisulfite as noted in Table II is very rapid at high pH. Almost complete destruction of thiamine within 24 hr has been observed when thiamine was added to parenteral infusion fluids containing bisulfite as a preservative and having a pH ≥6.

Stepuro and Ostrovskii (32) studied the effect of pH on the photochemical reaction rate of thiamine, thiamine derivatives, and decomposition products using UV irradiation at 253.7 nm. The reactions take place at pH 3.0–9.0 with a rapid speeding up at pH 4–5 for thiamines. At pH < 3, the photolyzed thiazoles produce thiamide precipitates. Moorthy *et al.* (33) reported the reversible 1-electron redox potential of thiamine to be ~−0.5 V.

Riboflavin—Irradiation of riboflavin in neutral or acid solution yields lumichrome and in alkaline solution lumiflavine (34). The rate of decomposition is dependent on temperature, pH, and light intensity and wavelength. The decay of riboflavin-5′-phosphate exposed to light is dependent on the same factors (35).

Pantothenic Acid—Degradation has been shown to be a first-order reaction in solution at pH 3.8 by Frost and McIntire (36), in tablets by Campbell *et al.* (37–39), and in multivitamin liquids by Shah *et al.* (18).

Cyanocobalamin (Vitamin B_{12})—The decomposition of cyanocobalamin in tablets follows a first-order reaction (37–39). Marcus and Stanley (40) stored solutions of hydroxocobalamin in either acetate or citrate–phosphate buffer at 70, 80, and 90° and found the vitamin to degrade by a first-order reaction. Macek and Feller (41) show the decomposition of cyanocobalamin at higher temperatures to be catalyzed by thiamine decomposition and, hence, to be complicated. Shah *et al.* (18) found that cyanocobalamin in two multivitamin liquids stored at higher temperatures did not decompose in accordance with first-order kinetics. The oxidation–reduction thermodynamics of cyanocobalamin, cobalamins, and cobinamides have been reported by Ely (42).

The rates of destruction of cyanocobalamin in neutral aqueous solutions when exposed to various light sources have been reported by DeMerre and Wilson (43). Below 300 foot candles no destruction is noticeable. Sunlight at a brightness of 8000 foot candles caused 10% loss for each 30 min of exposure.

Losses of cyanocobalamin in solutions sterilized by gamma irradiation were lower at −78 and −196° than at −22 or −50° and were greatest at 0 and 18° (44).

Folic Acid—Dick *et al.* (45) studied the thermal stability of folic acid in buffered solutions at 100 and 120 ± 1°. Considerable destruction was found <pH 4, but >pH 5 there was no destruction in 1 hr at 100° or 15 min at 121°. Stokstad *et al.* (46) found rapid destruction of folic acid when a solution was exposed to direct sunlight. Degradation was most rapid at pH 7.0 and most slow in alkaline solution. Exposure to fluorescent light for 6 hr produced only slight inactivation. By extrapolation of results obtained at 55, 70, and 85° and 30, 50, and 70% relative humidity, Tripet and Kesselring (47) calculated 1%/year decomposition rate for folic acid either in solid form or in solutions with 5, 10, and 50% avicel. In two multivitamin liquids at higher temperatures, Shah *et al.* (18) found that folic acid did not follow first-order kinetics.

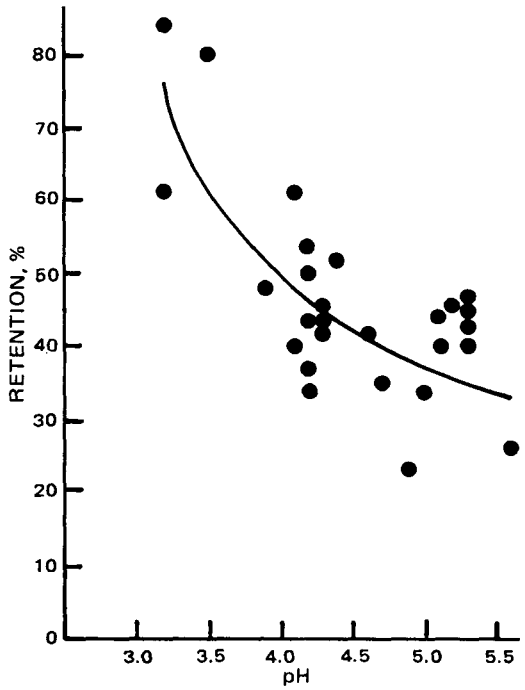

Figure 3—*Stability of thiamine* versus *pH in multivitamin drops; 6 weeks/45°.*

Ascorbic Acid (Vitamin C)—Reversible oxidation of ascorbic acid yields dehydroascorbic acid which has full ascorbic acid activity. Levandoski *et al.* (48) demonstrated that this reaction proceeds through an intermediate compound, identified as monodehydroascorbic acid, which may be complexed with ascorbic acid. Ascorbic acid stability in certain aqueous and fruit juice vehicles was reported by Uprety *et al.* (49). Ogata *et al.* (50) studied the kinetics of cupric salt-catalyzed autoxidation of ascorbic acid in aqueous solutions. Kassem *et al.* (51) reported that metal-catalyzed degradation of ascorbic acid in 10% injectable solutions took place by first-order kinetics. The order of effectiveness of metal ions as catalysts was $Cu^{+2} > Fe^{+2} > Zn^{+2}$; Fe^{+3}, Mn^{+2}, and Mg^{+2} had negligible effect. Dissolved oxygen had a deleterious effect increasing with concentration. Hayakawa and Hayashi (52) identified a Cu^{+2}–ascorbate complex as intermediate in the oxidation of ascorbic acid in the presence of Cu^{+2} ions.

The rate of anaerobic degradation of ascorbic acid in aqueous solution and the corresponding rate of formation of carbon dioxide as a breakdown product were reported by Finholt *et al.* (53, 54). Rogers and Yacomeni (55) and Blaug and Hajratwala (56) studied the effect of pH on the aerobic degradation of ascorbic acid in aqueous solution, which proceeded by a first-order reaction. Maximum rate of degradation occurred at pH 4 near the pK_{a_1} of ascorbic acid, and the minimum rate was at pH 5.6. Tingstad *et al.* (57) reported first-order degradation of ascorbic acid in a

multivitamin emulsion containing sodium fluoride stored at 70° and pH 3.15, 3.40, and 3.80.

Sattar *et al.* (58) found fluorescent light to have practically no effect on the destruction of ascorbic acid in pure solution, but the addition of riboflavin accelerated the decomposition. Losses of ascorbic acid were markedly increased by Cu^{+2} and Fe^{+3} under light exposed and unexposed conditions. The pro-oxidant effect of Cu^{+2} increased with increasing temperature and was relatively low under limited oxygen supply as compared to that in air, whereas oxygen supply had no influence on the effect of Fe^{+3}. Addition of Zn^{+2}, Ni^{+2}, and Mn^{+2} exhibited almost no effect under limited or excess oxygen availability. Uno *et al.* (59) and Switek and Modrzejewski (60) described the decomposition of ascorbic acid due to high frequency or gamma radiation used to sterilize aqueous solutions.

Vitamins, General—Huettenrauch (61) recommended the following as useful experimental parameters for kinetic studies of interactions and degradation of water-soluble vitamin preparations: temperature, pressure, solvent, degree of ionization, pH, concentration, and catalytic activity.

MUTUAL INTERACTIONS OF THE VITAMINS

Thiamine–Riboflavin—An incompatibility in aqueous vitamin B complex solutions has been described by Gambier and Rahn (62). The oxidative action of riboflavin on thiamine leads to the formation and precipitation of thiochrome. Subsequently, chloroflavin, the reduction product of riboflavin, may also precipitate. In vitamin B complex solutions containing ascorbic acid, thiochrome formation is not observed.

Thiamine–Folic Acid—Biamonte and Schneller (63) found thiamine to cause considerable decomposition of folic acid at pH 5.9 and 6.9 in aqueous, buffered solutions. Darnule and Colah (64) found the breakdown of folic acid to be accelerated by the presence of decomposition products of thiamine. The key element was the hydrogen sulfide produced during the breakdown of thiamine.

Thiamine–Cyanocobalamin—Blitz *et al.* (65) reported that the combination of thiamine and niacinamide in a vitamin B complex solution caused considerable decomposition of cyanocobalamin. It was shown by Macek and Feller (41, 66) that the breakdown of cyanocobalamin could be attributed largely to the 4-methyl-5-(β-hydroxyethyl)thiazole formed by cleavage of thiamine. At low levels of thiamine (1–10 mg/ml) losses of cyanocobalamin after a year at room temperature were small, but the losses were much higher at higher levels of thiamine or at elevated temperatures.

Riboflavin–Niacinamide—The presence of niacinamide in aqueous solution increases the solubility of riboflavin, due apparently to a complex formation between the two vitamins. This effect of niacinamide was useful in the preparation of vitamin solutions before the more soluble riboflavin-5′-phosphate became available. El-Khawas and El-Gindy (67) studied this interaction and reported that below 1% niacinamide, the effect on the solubility of riboflavin is small, but as the concentration of niacinamide is increased above 1%, the solubilizing effect on riboflavin becomes more pronounced and greater than that of urea.

Riboflavin–Folic Acid—Biamonte and Schneller (63) reported the deleterious effect of riboflavin on folic acid in aqueous, buffered solutions, particularly at pH ≥ 5.0. The combined action of light and riboflavin causes rapid oxidative cleavage of folic acid. Scheindlin *et al.* (68) studied this reaction and found it to occur more rapidly at pH 6.5 than at pH 4.0. The reaction is retarded, but not halted, by the exclusion of air and will proceed even when the solution is kept in amber glass.

Riboflavin–Ascorbic Acid—Hand *et al.* (69) and Sattar *et al.* (58) have reported that riboflavin catalyzes the photochemical decomposition of ascorbic acid during exposure of solutions to light and air.

Niacinamide–Ascorbic Acid—Wenner (70) described the preparation of a niacinamide–ascorbic acid complex in solid form. This yellow compound (71), containing one molecule each of niacinamide and ascorbic acid, forms readily in solution by what appears to be a charge–transfer reaction. It has been claimed (72) that preforming of this complex prevents difficulties with thickening and hardening of the mixtures employed in soft gelatin capsules. Guttman and Brooke (73) studied the formation of this yellow complex in the acid pH range at room temperature by measuring the absorbance at 365 nm. Maximum color was formed at pH 3.8 under the conditions employed. Osberger (74) described the commercial preparation of this complex and its applications in direct-compression tablets.

Niacinamide–Folic Acid—Taub and Lieberman (75) found that niacinamide acts as a solubilizer of folic acid. A 10% solution of niacinamide maintained a concentration of 5 mg/ml of folic acid at pH as low as 5.6, whereas the normal solubility of folic acid at pH 6.0 is 2 mg/ml.

Ascorbic Acid–Folic Acid—The cleavage of folic acid due to the reducing action of ascorbic acid was studied by Scheindlin and Griffith (76). In an acid medium the reaction products are *p*-aminobenzoylglutamic acid and 2-amino-4-hydroxy-6-methylpteridine. The free amino group of *p*-aminobenzoylglutamic acid is then destroyed by ascorbic acid or its oxidation products. The decomposition of folic acid was rapid at pH 3.0–3.3 and slow at pH 6.5–6.7.

Ascorbic Acid–Cyanocobalamin—Gakenheimer and Feller (77) observed an incompatibility between ascorbic acid and cyanocobalamin with losses of cyanocobalamin being least at pH 0–1 and increasing to a maximum at pH 7. Trenner *et al.* (78) found that hydroxycobalamin was much less stable in the presence of ascorbic acid then cyanocobalamin. Studies by Frost *et al.* (79) indicated that cyanocobalamin analogs in which the cobalt atom is strongly coordinated are the most stable toward ascorbate. Bartilucci and Foss (80) reported that decomposition products of ascorbic acid may play an important role in the effect on cyanocobalamin stability. Since copper ions catalyze the decomposition of ascorbic acid, it is not surprising that Stapert *et al.* (81) found that copper ions greatly enhance the destructive action of ascorbic acid on cyanocobalamin. Studies by Rosenberg (82) showed that Cu^{+2} itself has no effect on cyanocobalamin, and that ascorbic acid in the complete absence of Cu^{+2} causes relatively little decomposition of cyanocobalamin, but the combinations of ascorbic acid–Cu^{+2} or dehydroascorbic acid–Cu^{+2} were destructive of cyanocobalamin.

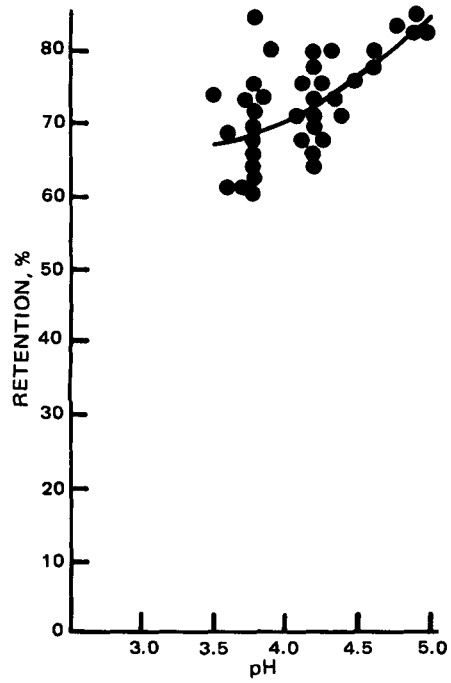

Figure 4—*Stability of ascorbic acid* versus *pH in vitamin B complex–ascorbic acid injectables; 6 weeks/45°.*

Utsumi *et al.* (83) studied the effect of various cobalamin analogs in catalyzing the oxidation of ascorbic acid in solution in acetate buffer at pH 5. The catalytic activity decreased in the order of hydroxycobalamin > hydroxocobinamide > cyanocobalamin coenzyme > cyanocobalamin > cyanocobinamide.

Other Interactions—Papp *et al.* (84) reported that several binary mixtures of thiamine, riboflavin, pyridoxine, niacin, and ascorbic acid showed nonlinear interferometric and conductometric curves, suggesting interactions. Hsu (85) found that niacinamide added to a solution of riboflavin-5′-phosphate sodium and ascorbic acid significantly increased the loss of riboflavin-5′-phosphate during photolysis, whereas added tryptophan stabilized both vitamins. Valls *et al.* (86) determined the stability of pyridoxal-5-phosphate and found it to be poor at pH 6 in aqueous solution. Increase in the degradation rate was caused by either thiamine, thiamine diphosphate, riboflavin-5′-phosphate, cobamamide, pyridoxal, or pyridoxine but not by riboflavin or cyanocobalamin. Takahashi and Yamamoto (87) found that ergocalciferol in powder preparations was readily isomerized by ascorbic acid, folic acid, thiamine hydrochloride, or pyridoxine hydrochloride but not by niacinamide or calcium pantothenate.

pH-STABILITY RELATIONSHIPS

In Aqueous Model Systems—*Thiamine versus Pantothenic Acid*—As noted in Table II, the stability of thiamine is best at low pH and decreases rapidly as the pH increases toward neutrality. In contrast, the stability of calcium pantothenate is optimal at pH 6.5–7 and decreases as the pH decreases. Frost and McIntire (36) studied the retention of thiamine hydrochloride and calcium pantothenate in 0.1% solutions at various pH levels after autoclaving for 15 min at 6.81 kg. Equal retentions of thiamine and calcium pantothenate were found at ~pH 4.5, the point at which the two curves of stability *versus* pH

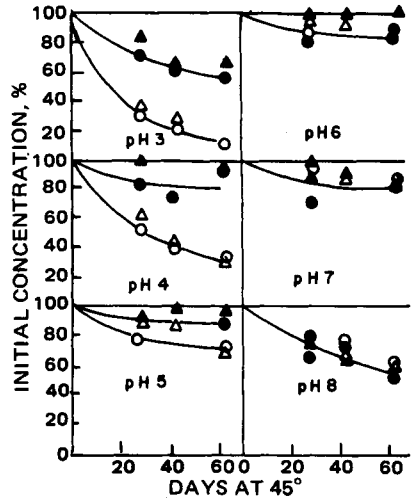

Figure 5—*Comparative stability of pantothenic acid (○, △) and panthenol (●, ▲) at pH 3–8.*

intersected. It may be noted that Figs. 3 and 4, which show 6 week/45° stability curves for thiamine and calcium pantothenate, respectively, in multivitamin drops, indicate 40% retention of both vitamins at pH 4.7.

Panthenol versus Calcium Pantothenate—Rubin (88) studied the comparative stability of these two forms of the vitamin in pure solutions with added buffers and a preservative. Both microbiological and rat bioassays were employed to assess stability. Figure 5 shows the comparative stability data obtained in tests at 45° for as much as 63 days. In the pH range of 3–5, commonly encountered in multivitamin liquids, panthenol shows markedly better stability than pantothenic acid.

Ascorbic Acid—The degradation of ascorbic acid in

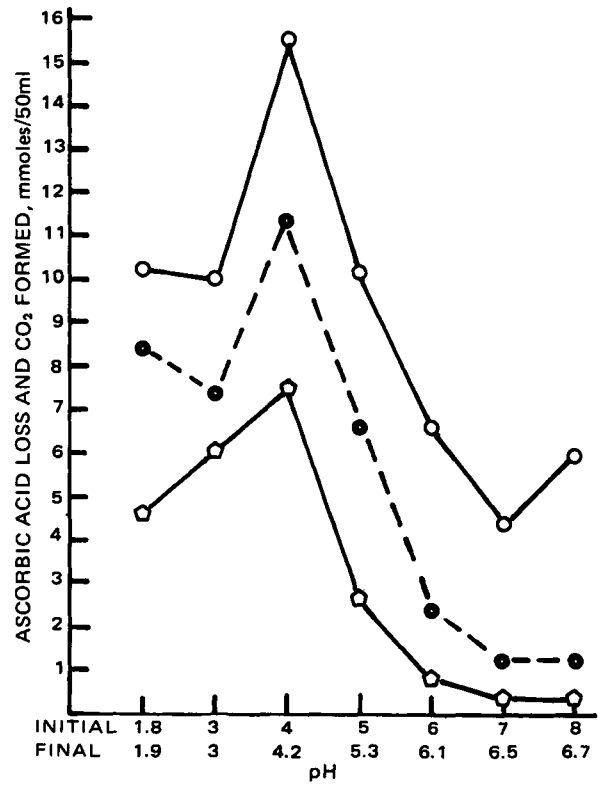

Figure 6—*Effect of pH on decomposition of ascorbic acid in 25% aqueous solution sealed in ampuls and stored 93 hr at 55°. Key: (○) ascorbic acid; (●) total ascorbic acid; (□) carbon dioxide formed.*

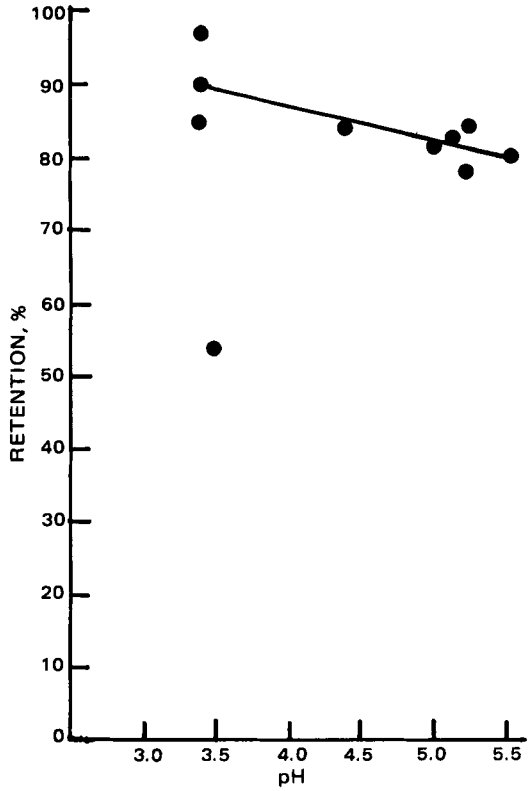

Figure 7—*Stability of thiamine* versus *pH in multivitamin products for teaspoon dosage; 6 weeks/45°.*

solution is pH-dependent. Finholt *et al.* (53) studied the pH–rate profile of the anaerobic degradation of ascorbic acid in solution at 96°. A maximum rate was observed at pH 4.1 which corresponds to the pK_1 of ascorbic acid. A study conducted in the author's laboratory also showed maximum degradation at ~pH 4.1 in solutions of 25% ascorbic acid in 50-ml sealed ampuls stored for 93 hr at 55°. Assays were made for ascorbic acid and dehydroascorbic acid contents and carbon dioxide formed. The results are shown in Fig. 6. The three graphs showing losses of ascorbic acid and total ascorbic acid (reduced and dehydro) and carbon dioxide formed all show a peak at ~pH 4.1. Pressure build-up in containers of products containing ascorbic acid can be especially troublesome at that pH as compared to either lower or higher pH.

In Aqueous Multivitamin Products—The influence of pH on the stability of some of the labile vitamins has been studied in a number of commercial as well as experimental multivitamin formulations. The pH–stability relationships are illustrated in Figs. 3, 4, 7–12 which show the results of storage for 6 weeks at 45°.

Thiamine—Figures 3, 7, and 8 show the retention of thiamine over the usual pH range for multivitamin drops, teaspoon dosage forms, and vitamin B complex and ascorbic acid injectables, respectively. All three types of products show progressively decreasing stability with increasing pH. Thiamine stability is particularly poor in the drop preparations, intermediate in the injectables, and best in the syrups and elixirs for teaspoon dosage. In the latter case, the better stability may be due to the influence of a high sugar content.

Ascorbic Acid—Figures 4, 9, and 10 show the pH–stability relations for ascorbic acid in multivitamin drops, teaspoon dosage forms, and vitamin B complex–ascorbic

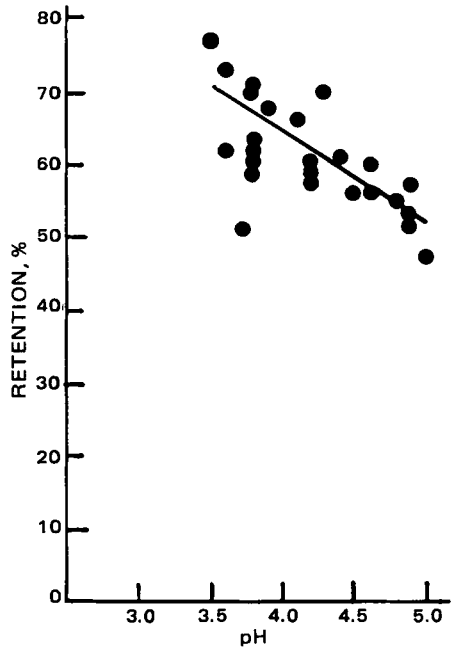

Figure 8—*Stability of thiamine* versus *pH in vitamin B complex–ascorbic acid injectables; 6 weeks/45°.*

acid injectables, respectively. In the drop preparations (Fig. 9), the curve shows maximum loss to occur at ~pH 4.2, which is similar to the pattern found in model systems (Fig. 6). In the other two types of preparation (Figs. 4 and 10), the losses at a given pH are similar and both show progressively decreasing loss as the pH increases from 3.5 to 5 or 5.5.

Panthenol and Calcium Pantothenate—The relative stability of panthenol and calcium pantothenate *versus* pH is shown in Fig. 11 for multivitamin drops and teaspoon dosage forms, which show similar stability patterns for panthenol. Figure 12 gives a similar comparison for vitamin B complex–ascorbic acid injectables. Panthenol shows the expected trend toward increasing losses with decreasing pH similar to the losses observed in the model systems shown in Fig. 5. Below pH 5 the losses of calcium pantothenate are much higher than those of panthenol.

Vitamin A—The relation of vitamin A palmitate stability to pH in multivitamin preparations for teaspoon dosage is shown in Fig. 13. Increasing the pH improves vitamin A stability. In the case of multivitamin drops, no clear-cut pattern of pH stability could be established due to wide variations found at any given pH level due to non-pH-related factors in the formulations tested.

FACTORS THAT ENHANCE VITAMIN STABILITY

Reduction of Water Content—Anmo *et al.* (89) determined the stability of retinol in 60–100% aqueous ethanol and found increasing losses as the water content increased. In a study of an oral liquid vitamin preparation made with various proportions of water, glycerin, and/or propylene glycol, Delgado *et al.* (90) reached the general conclusion that formulations containing lesser amounts of water possessed relatively higher stability values than those containing larger amounts of water. Parikh and Lofgren (91) demonstrated increased stability of ascorbic acid and thiamine when glycerin or propylene glycol was substituted for part of the water in an oral multivitamin

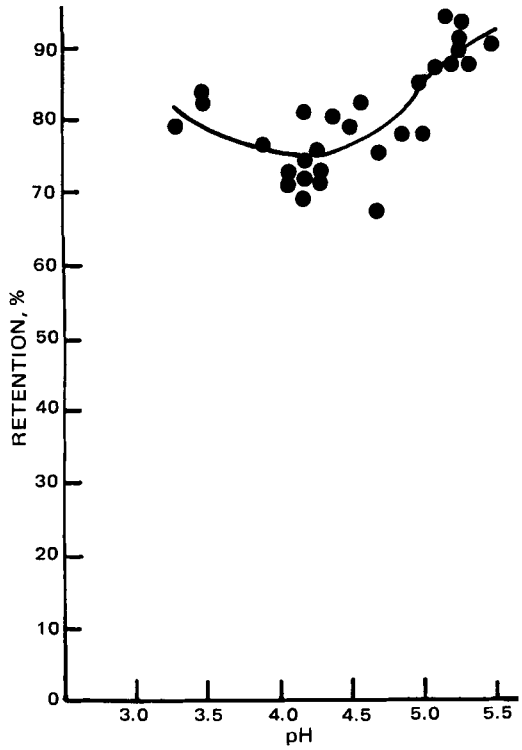

Figure 9—*Stability of ascorbic acid* versus *pH in multivitamin drops; 6 weeks/45°.*

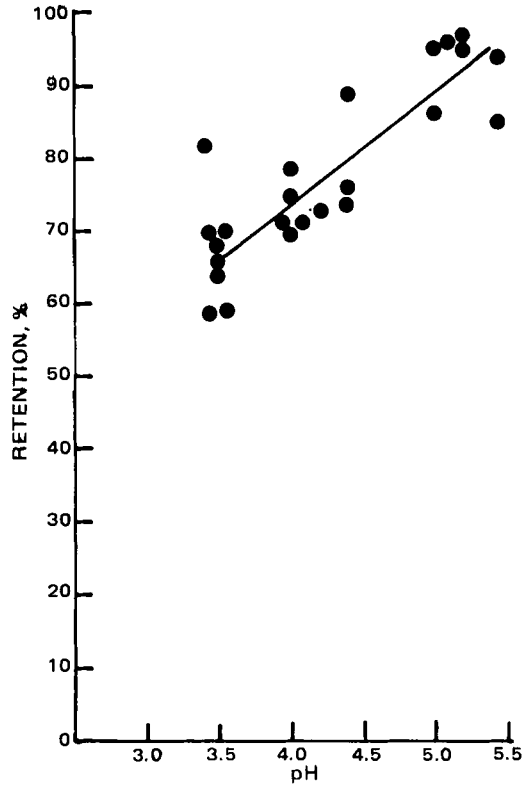

Figure 10—*Stability of ascorbic acid* versus *pH in multivitamin products for teaspoon dosage; 6 weeks/45°.*

liquid. Bandelin and Tuschhoff (92) reported similar findings on ascorbic acid and, in addition, found that ethanol or sugars such as sucrose, corn syrup, and dextrose also provide a stabilizing effect on ascorbic acid. Poust and Colaizzi (93) found that the first-order rate constants for oxidative decomposition of ascorbic acid at 30° decrease as a function of polysorbate 80 concentration up to 30%. In a study of the stability of ascorbic acid *per se* for 3 weeks at 45°, DeRitter *et al.* (94) found increasing stability as the moisture content decreased. Gerber *et al.* (95) reported increased stability of cyanocobalamin with high levels of sorbitol or sorbitol and glycerin. These authors found reasonable stability of both cyanocobalamin and ascorbic acid in a mixture with ferrous gluconate in 70% sorbitol. Gulesich (96) described an aqueous preparation containing ascorbic acid and iron, preferably ferrous sulfate, with 60–75% sorbitol.

Antioxidants—The stability of vitamins sensitive to oxidative decomposition can be increased in many cases by addition of antioxidants. Vitamin A and cholecalciferol are decomposed by exposure to air and are generally stabilized, in concentrates as well as pharmaceutical products, by addition of small amounts of antioxidants such as tocopherol, butylated hydroxyanisole, butylated hydroxytoluene, propyl gallate, ascorbyl palmitate, or a combination of several antioxidants (97–100). Koslov *et al.* (101) described model systems for studying the effectiveness of antioxidants in stabilizing vitamin A acetate and palmitate in thin films. At 10–40° butylated hydroxytoluene was superior to butylated hydroxyanisole, but ≥50° both were equally effective.

Ascorbic acid may also be more stable in the presence of antioxidants. Gladkikh (102) has reviewed methods for increasing the stability of ascorbic acid in medicinal forms. According to Tansey and Schneller (103), phenolic antioxidants such as butylated hydroxyanisole, nordihydroguaiaretic acid, and ethyl hydrocaffeate at levels of 0.02–0.05% retard the decomposition of folic acid by light in the presence of riboflavin and also protect folic acid somewhat in the dark.

Chelating Agents—The presence of trace metal ions, especially Cu^{+2} and to a lesser extent Fe^{+2}, accelerate the breakdown of ascorbic acid. The addition of a chelating agent such as edetic acid and its salts has been shown to enhance the stability of ascorbic acid *via* formation of metal chelates (90, 104). Kirkova *et al.* (105) tested nine stabilizers for ascorbic acid solutions and found a mixture of 0.1% disodium edetic acid and 0.25% $Na_2S_2O_4$ most effective. Reyes (106) found chelates of ascorbic acid with stearates of magnesium, calcium, or aluminum to provide improved stability of ascorbic acid in aqueous solutions.

Pyridoxine in solution is also sensitive to trace metal ions (107). Huang (108) found that Fe^{+2} in multivitamin products led to low recoveries of pyridoxine in microbiological assays. Recoveries of pyridoxine were 75 or 77% for 20:1 or 12:1 ratios of Fe^{+2}–pyridoxine, respectively. Addition of edetic acid before acid hydrolysis of such samples brought recovery of pyridoxine to 100%.

Cort *et al.* (109) found that the degradation of *dl*-α-tocopherol and *dl*-γ-tocopherol by Cu^{+2} could be completely inhibited by the combination of ascorbic acid and edetic acid, whereas ascorbic acid alone could prevent the oxidation of tocopherol in the presence of Fe^{+3}. Pure tocopherols when undiluted were stable to air and light over a period of years.

Other Compounds—Knobloch *et al.* (110) reported that the decomposition of vitamin A and cholecalciferol catalyzed by fine grain silicic acid can be inhibited by trolamine. An adduct of cholecalciferol with cholesterol

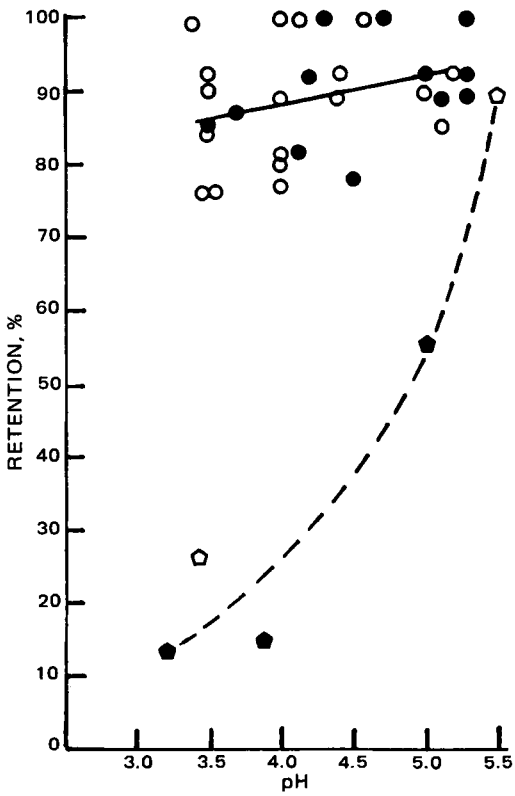

Figure 11—*Stability of panthenol (—●, ○) and pantothenate (- - -■, □) versus pH in multivitamin solutions-drops (●, ■) and teaspoon dosage forms (○, □); 6 weeks/45°.*

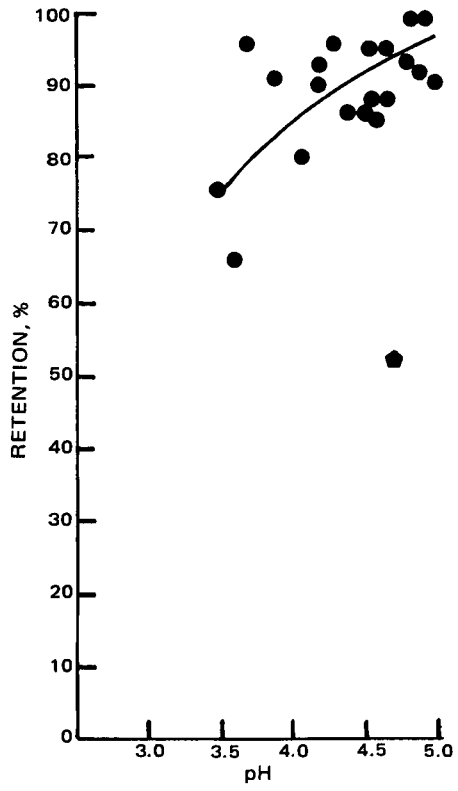

Figure 12—*Stability of panthenol (●) and pantothenate (■) versus pH in vitamin B complex injectables; 6 weeks/45°.*

was also found to be more stable than ergocalciferol or cholecalciferol.

Stabilization of riboflavin was achieved by Nobukuni *et al.* (111) by the addition of 1–20 moles of 2′-, 3′- and/or 5′-guanylic acid/mole of riboflavin. Protection of riboflavin, flavin mononucleotide, and flavin-adenine dinucleotide from photodecomposition was studied by Hata *et al.* (112–114). *para*-Substituted phenol derivatives, salicylic acid, tryptophan, and caffeine increased the stability of flavin mononucleotide through interactions in aqueous solution. Antipyrine and sulpyrine added to solutions of the flavins caused changes in their absorption spectra in the visible region suggesting interactions.

O'Broin *et al.* (115) compared the stability of folic acid to that of 5-formyl-, 10-formyl-, 5-methyl-, and unsubstituted tetrahydropteroylglutamate. Ascorbate was a superior stabilizing agent to 2-mercaptoethanol at comparable concentrations.

The effect of various compounds as stabilizers of B complex vitamins during gamma irradiation for the purpose of sterilizing aqueous solutions has been determined by Kishore *et al.* (116, 117). The combinations of nitrous oxide and glucose or oxygen and glucose as well as thiourea, tryptophan, and tyrosine provided good protection to thiamine, riboflavin, pyridoxine, niacinamide, and folic acid. Irradiation of aqueous solutions of these vitamins in the frozen state and with addition of glucose reduces radiolytic degradation. Irradiation in the dry, solid state causes no detectable damage, indicating that the best method for radiation sterilization of vitamin preparations may be to irradiate the components in the dry, solid state and then compound them together.

Rosenblum and Woodbury (118) reported the stabilizing effect of ferrous and ferric ions on cyanocobalamin in a multiple vitamin capsule. Newmark (119) described the effective stabilization of cyanocobalamin in solution in the presence of thiamine, niacinamide, and ascorbic acid by addition of various iron compounds and salts, including iron peptonate, ferric ammonium citrate, ferric chloride, ferrous gluconate, ferric glycerophosphate, ferric or ferrous sulfate, ferric or ferrous oxide, and ferric or ferrous complexes with such substances as edetic acid and its salts. Zuck and Conine (120) compared the relative effectiveness of complex cyanides and iron salts and found the cyanides to provide more effective stabilization of cyanocobalamin under conditions designed to exclude air as well as in partially filled containers having a large volume of air over the product. The complex cyanides were also effective in reducing the destruction of cyanocobalamin induced by UV irradiation.

Stabilization of thiamine solutions by addition of 0.05–5% monothioglycerol, thiosorbitol, or thioglucose has been the subject of a patent by Bray (121). Sodium formaldehyde sulfoxylate is used also for stabilizing injectable solutions of thiamine.

A considerable number of compounds have been reported to be stabilizers of ascorbic acid in solutions. In extracting solutions used in analyses of ascorbic acid, the stabilizers that have been used include metaphosphoric acid (122), oxalic acid (123), acetic acid (124, 125), and trichloroacetic acid. A combination of metaphosphoric acid and edetic acid has been recommended for use in the presence of Cu^{+2} and Fe^{+2} (104). Flavonoids inhibit the Cu^{+2} catalyzed oxidation of ascorbic acid (126). The order of activity reported by Takamura and Ito (127) is 3-hydroxyflavone < rutin < quercetin, and no inhibition was observed for flavone. Other compounds reported to have

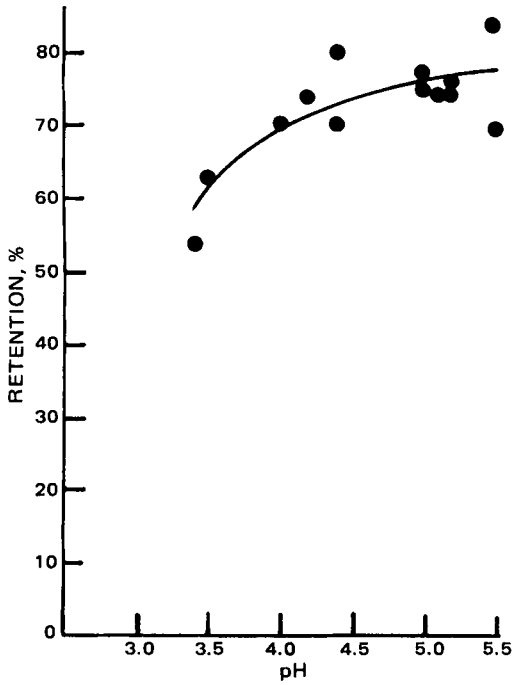

Figure 13—*Stability of vitamin A palmitate* versus *pH in multivitamin products for teaspoon dosage; 6 weeks/45°.*

similar activity are *O*-diphenols (128), aryl thioureas (129), rubeanic acid (130), acidic polysaccharides (131), sodium alginate (132), high concentrations of sucrose, glucose, or fructose (133), lysine and glutamic acid (117), a combination of *dl*-*N*-acetylhomocystine-thiolactone and sodium sulfite (134), gelatin (135), urocanic acid and/or its alkyl esters (136), and RNA, DNA, or salts (137). A review on the stabilization of ascorbic acid in liquid and solid preparations has been published by Gladkikh (102).

Coating and Encapsulation—A list of the various coating materials and processes used on single vitamins or combinations of several vitamins is given in Table III. Improving stability of labile vitamins under stress conditions is an important function of coating agents, but they are also useful for converting liquid vitamins into free-flowing, dry powders, masking taste in chewable tablets, improving handling and tableting characteristics, or stabilizing the color of ascorbic acid tablets, which otherwise may develop a tan color on aging.

Preparation of Adsorbates—Adsorption of fat-soluble vitamins on suitable adsorbents has been utilized as a means of conversion of the vitamins to dry, free-flowing powders as well as to enhance their stability. Espoy (182) described the preparation of an adsorbate of vitamin A on calcium silicate[1]. Neutral or weakly alkaline carriers such as magnesium oxide tend to stabilize vitamin A and cholecalciferol, whereas carriers with acid surface activity catalyze their decomposition (110, 183). This acid catalysis on fine grain silicic acid[2] can be inhibited by trolamine. Takahashi and Yamamoto (15) reported that ethanolamines and polyoxyethylene compounds were effective in preventing the isomerization of ergocalciferol caused by surface acidity of excipients.

Cannalonga and Czarecki (184) described a process for preparing agglomerated, free-flowing powders containing

Table III—Coating or Encapsulation Processes for Vitamins

Vitamin	Stabilization Process	Reference
	Fat-Soluble Vitamins[a]	
A	Emulsify oil solution in gelatin, agar, or pectin or combinations thereof, plus sugar solution, cast into sheets, dry, freeze, and grind.	138, 139
A	Emulsify in gelatin–sugar solution and spray into starch ester containing hydrophobic groups[b].	140
A	Emulsify solution in hot well oil in wax and spray chill.	141
A	Granulate with partially hydrolyzed casein–formaldehyde and dry.	142
A	Emulsify in water-soluble gelable colloid, freeze, grind, and dry.	143
A	Emulsify in alkaline gelatin solution–pectin and water-soluble calcium salt and spray dry.	144
A	Emulsify in solution of low molecular weight amylose–glucose, dry on glass plate, and powder.	145
A	Emulsify vitamin A palmitate in hydrolyzed gelatin solution, spray dry, and agglomerate.	146
A and/or cholecalciferol	Emulsify in solution of gelatin–dextrin and maltose and spray dry.	147
A and/or cholecalciferol	Prepare clathrate in desoxycholic acid and subdivide.	148
A and/or cholecalciferol	Emulsify in wax or hydrogenated oil–vegetable flour and lecithin or polyoxyethylene sorbitan monopalmitate and spray.	149
A and/or cholecalciferol	Emulsify in film former (selected from dextrin, gelatin, casein or sodium carboxymethyl cellulose, maltose, sucrose, gum arabic)–emulsifier and spray into a current of atomized dehydrating agent (ethylene glycol, propylene glycol, glycerin, sorbitol, benzyl alcohol, ethanol, propanol, or butanol).	150
E	Emulsify in gum acacia–sugar solution and drum dry.	151
E	Emulsify in gum acacia solution–surface-active agent and convert into dry product.	152
E (acetate)	Emulsify in hydrolyzed gelatin solution with preservatives and spray dry.	153, 154
E (acetate)	Emulsify in hydrolyzed gelatin solution with preservatives and spray dry with agglomeration.	155
A, E, K, and/or cholecalciferol	Emulsify in solution of gum acacia or polyoxyethylene derivative of a partial ester of sorbitol and a fatty acid–glucose, sucrose, or corn syrup, cool and drop from a candy drop machine.	156
A, E, K, and/or cholecalciferol	Emulsify in gelatin and/or gum–a sugar alcohol–emulsifier such as lecithin and spray dry.	98
A, E, K, and/or cholecalciferol	Emulsify in solution of gum arabic or gum ghatti–lactose and spray dry; add 2% calcium silicate[c] as flour agent.	157
A, E, K, and/or cholecalciferol	Emulsify in wax, lecithin–synthetic polysaccharide[d], spray, and dust with one part soya flour to two parts of vitamin beadlets.	158
A, E, K, and/or cholecalciferol	Emulsify in solvent solution of a prolamine[e]–polymerized corn syrup and spray onto warm surface to remove solvent.	159
A, E, K, and/or cholecalciferol	Mix with gum acacia solution and dry gum acacia to form a plastic dough, dry, and comminute.	160
A, E, K, and/or cholecalciferol	Emulsify into gelatin solution previously heated with ascorbic acid–citric acid–plasticizer and spray into alcohol.	161

vitamin A palmitate, *dl*-α-tocopheryl acetate, riboflavin, or perfumes which could be easily tableted. The adsorbents used included SiO_2, kaolin, $CaHPO_4$, and $MgCO_3$.

Protection from Light—Vitamins such as riboflavin and phytonadione, which are sensitive to light, particularly in solution, should be protected from light by suitable packaging of the vitamin solution. Surowiecki and Krowcznyski (185) reported that decay of riboflavin-5′-phosphate depended on temperature and intensity and wavelength of light. To prevent such decomposition, storage in amber glass capable of absorbing light up to a wavelength of 650 nm was recommended.

Lyophilization—For single or multivitamin solutions where instability of one or more vitamins in the formulation is a serious problem, lyophilization is an effective means of achieving improved vitamin stability. The lyophilization process has been applied in the preparation of multidose vials of vitamin B complex vitamins for parenteral use.

FORMULATION OF VITAMIN PRODUCTS

Aqueous Emulsions of Fat-Soluble Vitamins—Various surface-active agents (Table IV) have been used in the preparation of aqueous dispersions of fat-soluble vitamins. Optically clear dispersions can be made with efficient surfactants. Dispersions of single vitamins and multivitamin products containing vitamins A and E and cholecalciferol are prepared in aqueous media for both oral and intramuscular uses. A water-dispersible vitamin E compound was prepared by Cawley and Stern (193), namely, the polyethylene glycol ester of α-tocopheryl acid succinate.

Injectables—*Vitamins A and E and Cholecalciferol (vitamin D)*—Sobel (194) prepared veterinary injectables containing 0.0001–0.1% of vitamin A ester plus 0.005–0.06 g/ml of sorethytan monooleate in an aqueous, isotonic vehicle. Robeson (195) described a clear parenteral preparation in which vitamin A and cholecalciferol plus α-tocopherol or α-tocopheryl acetate were dispersed in an aqueous solution of α-tocopheryl polyoxyethylene glycol 1000 succinate. Aiello and Bauernfeind (196) prepared veterinary injectables of vitamins A, A–cholecalciferol, and A–E–cholecalciferol using a glyceryl triester of low molecular weight fatty acids (6–12 carbons and not more than 10% C-14 or greater) plus a polyoxyethylene-sorbitan ester of palmitic, stearic, oleic, or ricinoleic acid. A semisolid preparation for intramuscular injection of vitamins A and E and cholecalciferol was described by Feigh (197) as a substantially water-free mixture of the vitamins with polyethylene glycol 4000 and 200 plus antioxidant and preservative. Gherghinof *et al.* (198) prepared an aqueous injectable solution containing 22,000 IU/ml of vitamin A palmitate with 10 parts of polysorbate 80[3] to 1.1 parts of vitamin A. Butylated hydroxytoluene was added as antioxidant, the pH adjusted to 3–4 with ascorbic acid, and the solution sealed in vials under nitrogen and sterilized three times at 80° for 60 min with intervals of 24 hr. A solution was described which contained 300,000 IU of cholecalciferol/ml made with 15% (w/v) polysorbate 80[3] and 2.25% (w/v) isoamyl alcohol with ascorbic acid added to bring pH to 3–4. The vials were sealed under nitrogen without heat sterilization.

Vitamin K—Water-soluble derivatives of menadione such as menadiol tetrasodium diphosphate salt are used in injectable formulations. The fat-soluble phytonadione has been prepared in colloidal emulsion form with an efficient surfactant such as polyoxyethylene vegetable oil[4]. Fujita *et al.* (199, 200) prepared an injectable in which vitamin K was dissolved in a mixture of a hardened castor oil polyoxyethylene derivative and propylene glycol, after which sorbitol, trolamine, and water were added prior to sealing in ampuls and autoclaving for 30 min at 4.54 kg. Koshiro *et al.* (201) studied the compatibility of three

[3] Tween 80.
[4] Emulphor-620.

Table IV—Surfactants Used in Preparation of Aqueous Dispersions of Fat-Soluble Vitamins

Surfactants or Dispersing Agents	Reference
Polyalkalene oxide derivatives of partially esterified polyhydric alcohols or their anhydrides.	186
Bone gelatin from the lime process, ascorbyl palmitate, and a monoester of glycerin or of propylene glycol.	187
Polyoxyethylene glycol monoricinoleate containing 30–50 oxyethylene units.	188
Monoester (laurate, oleate, *etc.*) of polyethylene glycol 400 and a predominantly nonionic surfactant.	189
Polyoxyethylene vegetable oil[a] or other emulsifier[b].	190
Polysorbate[c] 40, 60, or 80–polyethylene glycol 200–600.	191
Polysorbate[d] 20 and algin[e].	192

parenteral solutions of vitamin K with 98 commercial injectables.

Thiamine—For a single vitamin injectable with thiamine, the hydrochloride salt is generally preferred, but purity of the vitamin is an important factor. A special ampul grade of thiamine hydrochloride has been made for this purpose. Monciu and Boteanu (202) prepared 2.5 and 5% solutions of thiamine hydrochloride and found retention of at least 90% of initial concentration in the 2.5% solution after 4 years at room temperature and in the 5% solution after 5 years at room temperature. Various additives have been tested for their effect on the stability of thiamine hydrochloride solutions for injection. Ammar (203) compared the effects of edetic acid, *N*-hydroxyethyledetic acid, and pentetic acid and found the latter two to be superior to edetic acid in stabilizing thiamine. The optimum concentration of edetic acid was 3 mmoles/liter and 0.5 mmole/liter of *N*-hydroxyethyledetic acid. Ammar (204) also studied the effect of DL-α-lipoic acid, which at low concentrations (0.5–1.0 mmole/liter) increased the stability of solutions of thiamine hydrochloride for injection, but at higher concentrations (3–10 mmoles/liter) decreased the stability of thiamine hydrochloride. In the presence of 20 ppm of copper, the concentration of lipoic acid for maximum stability of thiamine was shifted from 0.5–1.0 mmole/liter, indicating that the concentration of additive for maximum stability of thiamine is dependent on the level of trace metals in the solution. Kirkova and Nedelova (205) studied the effect of different buffers, propyl gallate, benzyl alcohol, sodium edetate, sorbitol, glucose, and heat sterilization on the stability of thiamine solutions for injection. The most important factor was found to be the quality of the thiamine hydrochloride.

Taub *et al.* (206) reported that thiamine in parenteral solutions in admixture with riboflavin and niacinamide exhibited maximum stability with respect to potency and clarity of solution at pH 4 under a nitrogen atmosphere. In admixture with iron compounds, thiamine was more stable in the presence of ferrous gluconate than of iron peptonate or ferric ammonium citrate, and again, the optimum pH was 4. In these studies it was found that thiamine mononitrate is somewhat more stable than the hydrochloride.

Ascorbic Acid—Stable, buffered solutions containing 50–200 mg of ascorbic acid/ml were prepared by Cimenera and Wilcox (207) by buffering to pH 6.0–6.5 with trisodium phosphate, adding 0.5% phenol, heating 2-ml sealed ampuls at 100° for 10 min and cooling rapidly. Stability was achieved by adhering to rigid anaerobic conditions by the use of nitrogen throughout manufacture and avoiding contact with metals. Popovic *et al.* (208) obtained best stability in a parenteral solution containing 10 g of ascorbic acid, 4.75 g of $NaHCO_3$, 1 g of $Na_2S_2O_5$ and 0.1 g of edetic acid/liter and through which carbon dioxide was passed. Kassem *et al.* (209) studied the stabilizing effect of various metal complexing agents on ascorbic acid solutions. *N*-Hydroxyethylethylenediaminetriacetic acid was most effective, but the optimum concentration depended on the amount of heavy metal ions in the solution and had to be determined experimentally for each formulation.

Pyridoxine (Vitamin B_6)—Stabilized 2.5 and 5.0% solutions of pyridoxine were prepared by Nikolov and Nedelova (210) at pH 2.8–3.0 with 0.1% Na_2SO_3 added. The filling was done under a stream of nitrogen and aseptic conditions were used. Inoue *et al.* (211) determined the stability of an injectable solution of pyridoxamine phosphate in the presence of 70 other injectables.

Multivitamins—Ban (212) reviewed the preparation, storage, and usage of injectable solutions of the water-soluble vitamins. Boyazhieva *et al.* (213) described a veterinary preparation for intramuscular use containing ferro-dextran, gamma globulin, trace elements, and vitamins, which was claimed to be stable for 1 year. Blitz *et al.* (214) studied the stability of cyanocobalamin in vitamin B complex injectables and found cyanocobalamin to be unstable in the presence of thiamine and niacinamide at concentrations from 25–100 mg/cm^3 of each at pH 4.25 but relatively stable at lower concentrations of each component. Rigoli (215) reported good stability of cyanocobalamin and ascorbic acid after lyophilization of a solution containing both vitamins. Haeger and Nash (216) described a two-compartment syringe for injectable water-soluble vitamins with sodium ascorbate, folic acid, and niacinamide in the upper compartment and thiamine hydrochloride, riboflavin-5′-phosphate sodium, niacinamide, panthenol, pyridoxine, cyanocobalamin, and ferrous citrate in the lower compartment. A complete multivitamin injectable preparation was also described (217) which is similar to that described previously but with vitamin A palmitate, *d*-α-tocopheryl acetate, and ergocalciferol emulsified in the solution in the upper compartment by means of polysorbate 80 and propylene glycol.

The stability of vitamins after addition of injectable preparations to intravenous fluids is also a matter of concern. Although storage of such mixtures is normally for short periods, losses of labile vitamins such as vitamin A, thiamine, cyanocobalamin, and ascorbic acid can be significant and are higher during light exposure than in the dark. In addition, sorption of vitamins on the surface of plastic infusion fluid bags can contribute to unavailability of a portion of the vitamin content to the patient. Moorhatch and Chiou (218) studied the sorption of 10 vitamins on such bags. Howard *et al.* (219) studied the effect on vitamin A activity of storage of a parenteral nutrient solution in polyvinyl bags in the dark at 4°. After 8 and 72 hr and 2 weeks, the vitamin A content was 86, 73, and 23% of the initial concentration. Approximately 30% of the vitamin A losses were due to sorption on the plastic bags. The

use of bisulfite as a preservative in parenteral infusion fluids can cause high losses of added thiamine, particularly at ≥pH 5.5. In the laboratory only 3–8% retention of thiamine was found after 24 hr at room temperature in an amino acid infusion fluid at pH 6.5 and containing, according to label, 1 mg of sodium bisulfite/ml. Kobayashi and King (220) reported that the addition of vitamins to a protein hydrolysate–dextrose parenteral solution caused no physical incompatibilities.

Tablets—The fat-soluble vitamins A and E and cholecalciferol are normally incorporated into tablets in the form of dry, stabilized coated products or adsorbates as described above. The B complex vitamins, thiamine, riboflavin, niacinamide, and pyridoxine, which can contribute off-flavor to chewable tablets, are available in coated forms, usually containing 25–33% of the vitamin. Fatty acids or mono- and diglycerides of fatty acids are utilized as coating agents for effective masking of taste and also contribute to the stability of thiamine. Ascorbic acid is stabilized with a small percentage of ethylcellulose and is also available as granulations containing 90–95% ascorbic acid, which are particularly suited for preparation of high-potency ascorbic acid tablets by direct compression. Biotin and cyanocobalamin are used in tablets in the form of triturates, adsorbates, or spray-dried powders containing 0.1–1.0% of the vitamin to facilitate the distribution of the microgram quantities normally used. Nessel *et al.* (221) have studied the uniformity of distribution of cyanocobalamin in tablet formulations using 0.1 and 1% gelatin products and a 1% resinate in both wet-granulated and dry-blended formulations.

Single or multiple vitamin tablets have been made by both wet and dry granulation processes and by direct compression and either left uncoated or coated by compression, film, or sugar-coating processes. A number of reports dealing with vitamin tablet technology are listed in Table V. Seugling (239) has reviewed the use of various tableting aids in the development of pharmaceutical products, including conventional and chewable vitamin tablets. Lieberman and Lachman (240) have presented a comprehensive review of tablet technology which also deals with vitamin products. Wai *et al.* (241) studied stability of vitamin A, thiamine, and ascorbic acid compressed in eight commonly used solid vehicle matrixes. Mannitol and lactose were found to yield superior stability. All three vitamins were quite stable when the moisture content of the tablets was ≤1%. In multivitamin chewable tablets, these authors found that the use of coated ascorbic acid, thiamine, riboflavin, and niacinamide enhanced vitamin stability. The best stability results were obtained when vitamin A, ergocalciferol, and thiamine were granulated with one-fourth of the mannitol-magnesium stearate, ascorbic acid with one-half of the matrix, and the remaining B vitamins with one-fourth of the matrix. The use of water or dilute alcohol for granulation caused more rapid discoloration on storage than did alcohol granulation or dry slugging procedures.

Campbell and McLeod (39) studied the stability of vitamins in several commercial tablet formulations and found a rather wide range of stability for some of the labile vitamins. Maekawa *et al.* (242) studied the stability of vitamins in sugar-coated decavitamin tablets and the mutual interactions of the various vitamins. The best stability was obtained when vitamin A, ergocalciferol, calcium pantothenate, cyanocobalamin, and folic acid were in the coatings and the other vitamins in the tablet core. Bojarski *et al.* (243) compared vitamin stability in decavitamin tablets and dragees and found better stability in the tablets. Only thiamine and calcium pantothenate were unstable, and water had a major influence, especially on the stability of thiamine. Thiamine nitrate was more stable in these tests than thiamine hydrochloride. Ragazzi and Veronese (244) reported much better stability of vitamin A, ergocalciferol, and cyanocobalamin when these vitamins were protected by gelatin-sugar coating prior to incorporation into multivitamin tablets. Coated ascorbic acid, however, was not different from uncoated. Maekawa *et al.* (245) found much better stability of ascorbic acid in sugar-coated tablets than in uncoated tablets upon storage for 3 weeks at 37° and 74% relative humidity. Bolatre *et al.* (246) determined that ascorbic acid in tablets can discolor badly without much change in ascorbic acid content. Carstensen *et al.* (247) studied the degradation of thiamine tableted with magnesium stearate and microcrystalline cellulose. As the moisture level was increased to 5.5%, thiamine loss increased, but at higher moisture levels stability was enhanced with increased moisture content. The model proposed to explain this phenomenon was that thiamine dissolved in the water present adsorbs on the microcrystalline cellulose, and the thiamine present in the monolayer degrades totally, whereas the thiamine in layers beyond the monolayer does not degrade.

The preparation of sustained-release vitamin tablets has been a matter of interest, particularly in the case of high-potency ascorbic acid, but very little has been published on the technology of formulation of such tablets. Nuernberg *et al.* (248) described the preparation and *in vitro* release testing of 250-mg ascorbic acid tablets in which the release of the vitamin was sustained by the addition of more than 20% galactomannans. Cazals (249) prepared tablets of cyanocobalamin containing a mixture of mannitol and aminoacetic acid, which were claimed to yield prolonged and enhanced effectiveness. Kassem *et al.* (250) described a tablet of riboflavin-5′-phosphate with a maintenance dose in the core and an initial dose in the coating. The vitamin was embedded in a matrix of tragacanth, acacia, ethylcellulose, and stearic acid and granulated through a sieve to an optimal size of 1.6 μm. Subsequent coating with a thin layer of ethylcellulose suppressed the initial release. Hardening the granules at 30° for 2 hr improved the release. Lubrication with magnesium stearate and talc was recommended.

The major problem in formulating a sustained-release multivitamin product is to achieve full bioavailability of the vitamins in addition to sustained-release for a significant number of hours. Riboflavin is particularly troublesome in this regard due to its very low solubility in water. Morrison *et al.* (251) studied *in vitro* release rates and the corresponding physiological availability of riboflavin in sustained-release vitamin preparations and pointed out the frequent association of incomplete bioavailability with prolonged *in vitro* release. Other work by this group (252–255) pointed out similar difficulties with availability of riboflavin in normal, enteric coated, and chewable vitamin tablets. It was concluded that *in vitro* disintegration times longer than 1 hr or coating processes

Table V—Vitamin Tablet Technology

Vitamins	Formulation Technology	Reference
A, E, and cholecalciferol	Absorbed from oil solution on magnesium oxide with ascorbic acid and *dl*-α-tocopherol added; granulate with calcium pantothenate, starch, and calcium stearate before tableting.	184
Thiamine	Granulation with 1.5% ethylcellulose or 15% polyethylene glycol in alcohol plus dry binder.	222
Ascorbic acid	Addition of ~1% of sorbose, lactose, or a mixture of the two in the granulation tends to stabilize tablet color.	223
Ascorbic acid	Granulate 50–80 parts of ascorbic acid with 5–16 parts starch and 2.5–5 parts hydroxypropyl methylcellulose (viscosity 20–4000); add 0.25–0.35 liter of alcohol/kg and 5.5–16 parts starch; dry and pass through 10–16 mesh screen. Add lubricants (0.25–2 parts colloidal silicon, 0.5–2 parts hydrogenated vegetable oil, 0.1–0.5 parts zinc stearate, and 2.8–8 parts starch) and compress.	224
Ascorbic acid	Add physically modified starch, magnesium silicate as hardener, and hydrogenated vegetable oil as lubricant and compress directly.	225
Ascorbic acid	Vinyl acetate–crotonic acid copolymer yields harder and less friable tablets by direct compression than polyethylene glycol 6000.	226
Ascorbic acid	Microcrystalline cellulose is superior to microfine cellulose (less compression required and less capping).	227
Thiamine, ascorbic acid, or folic acid	Tablets formulated[a] and subjected to accelerated aging; ascorbic acid was unstable but thiamine and folic acid were stable.	228
Thiamine and ascorbic acid	Tablets coated with 2% aqueous solution of hydroxypropyl cellulose (viscosity 6.1 cps at 20°) were more stable than tablets coated with a sugar solution.	229
Thiamine and ascorbic acid	Tablets coated with syrup containing sugar, gelatin, and gum arabic over a subcoating of carboxymethyl–starch–talc disintegrated in 14 min while controls without the carboxymethyl–starch in subcoating took 42 min.	230
Thiamine and ascorbic acid	pH of tablets also containing aspirin adjusted to 2.5–4 with tartaric acid; tablets coated with 10% povidone and 4% shellac.	231
Cyanocobalamin and ascorbic acid	Granulating cyanocobalamin and ascorbic acid with trace element caseinates improved vitamin stability; without ascorbic acid caseinates did not improve cyanocobalamin stability.	232
Cyanocobalamin, thiamine, and pyridoxine	Best stability of cyanocobalamin achieved with cyanocobalamin in a separate layer in a sugar-coated tablet.	233
Multivitamin	Granulation with alcohol and addition of 5% povidone.	234
Multivitamin	Vitamin E adsorbed on silica gel and 0.5–5% finely divided silica gel added to smoothing syrup.	235
Multivitamin	Granulation of vitamin E and ascorbic acid.	236
Multivitamin	Effervescent tablets stabilized with 0.1 g of cyclamic acid and 0.2 g of α-aminoacetic acid/tablet.	237
Multivitamin	Lyophilization of vitamin substance in a solvent containing a binder, granulating and compressing; binders used were gum arabic, alginates, pectins, dextrins, glucose, povidone, polyvinyl alcohol, carboxymethyl cellulose, polyethylene glycol, *etc.*	238

[a] Formulated with Encompress Std.

can reduce the bioavailability of vitamins to humans and that any product with such characteristics should be tested in humans to determine that the vitamins are available.

Oral Single Vitamin Liquids—Vitamin A, in the form of an aqueous dispersion with an effective surface-active agent, yields much more rapid absorption *in vivo* than oil solutions. Adamski and Sawick (256) found the stability of vitamin A palmitate in aqueous dispersions to depend on the concentration of the vitamin A, the nature of the surfactant, and the buffer applied. A derivative of castor oil and ethylene oxide[5] yielded the best stability.

Stabilized aqueous solutions of thiamine were prepared by Bray (121) using thioglycerol, thiosorbitol, and thioglucose as stabilizing agents. Italfarmaco S.p.A. (257) described a 1% solution of thiamine hydrochloride with 5% povidone, 0.05% propyl gallate, and 0.005% sodium edetic acid, which was chemically and organoleptically stable for more than 2 years. Riboflavin and pyridoxine were also incorporated into similar compositions. Genova and Papazova (258) found cyanocobalamin stable for 5 months at 40° in a solution containing 100 μg/ml of cyanocobalamin in 1% solutions of orotic acid and monoethanolamine. Exposure to UV light caused destruction of cyanocobalamin, which was more rapid at pH 4.9–5.2 than at pH 3.9–4.2. Bajeva and Jonega (259) studied the stability of ascorbic acid–citrate formulations and found maximum stability with addition of 30% (v/v) propylene glycol and 0.1% cysteine hydrochloride.

Oral Multivitamin Liquids—General directions for preparation of stabilized multivitamin liquids have been given by Djourno and Thoumyre (260) and Belova and Litvinenko (261). Delgado *et al.* (90) prepared 10 different multivitamin drop formulations with various combinations of water, glycerin, and/or propylene glycol as vehicle. The most stable preparation contained 80% propylene glycol + 20% water with ethyl hydrocaffeate and Na_2Ca edetic acid. Parikh and Lofgren (91) studied the stability of seven different oral multivitamin drop preparations with sorbitol alone or in combinations with propylene glycel and glycerin in the aqueous vehicle. The studies showed: (*a*) butylated hydroxyanisole retards oxidative decomposition of vitamin A; (*b*) glycerin is a better substitute for a portion of the water than propylene glycol as far as stability of thiamine is concerned; (*c*) reducing the percentage of water by substituting propylene glycol or glycerin yields better stability of ascorbic acid; (*d*) stability of cyanocobalamin increased as pH was increased from 3.5 to 4.5; (*e*) folic acid, when in solution in preparations containing propylene glycol, was very unstable at pH 3.4. Biamonte and Schneller (63) also found folic acid in solution very un-

[5] Cremophor EL.

stable at acid pH, but when in suspension at low pH due to insolubility, folic acid is quite stable.

Stone (262) determined the stability of drop formulations containing thiamine, riboflavin, and niacinamide with and without ascorbic acid, using propylene glycol as a vehicle either alone or with 25 and 50% glycerin, simple syrup, or water. Greater retention of thiamine was found in solutions containing the greater percentage of water, whereas higher stability values were obtained for ascorbic acid in formulations containing lesser amounts of water. Similar relationships are seen in Figs. 3, 7, 9, and 10 where drop preparations show higher losses of thiamine than the more dilute elixirs or syrups, whereas ascorbic acid is more stable at pH 4 in the drop formulations than in the teaspoon dosage forms. Discoloration by yellowing and darkening was found by Stone (262) to be proportional to the percentage of water present.

Zoni and Lazzeretti (263) obtained satisfactory stability in a drop preparation containing B vitamins and L-lysine by adding povidone to the aqueous base. Synergistic enhancement of the stabilizing effect of povidone was found with the addition of polymerized povidone[6], 0.05% propyl gallate, and 0.005% (w/v) edetate disodium at pH 4. Maekawa and Egawa (264) achieved stability of an aqueous multivitamin preparation by the use of a partitioned container with vitamin A palmitate, niacinamide, and ascorbic acid in one chamber and thiamine in the other. The liquids contained stabilizing and flavoring agents and were admixed just prior to use. Youssef *et al.* (265) reported that the decomposition of vitamins and sodium metabisulfite is accelerated by storage of aqueous solutions in polyethylene containers.

Ointments, Creams, and Lotions—The utility of topically applied vitamins has been discussed by Siemers and Sleezer (266), DeRitter *et al.* (267), and Clement and Jones (268). Rubin (269) reviewed the percutaneous absorption of vitamins. Formulations of topical preparations containing panthenol were described by Rubin *et al.* (270), and the incorporation of various topically active vitamins into application forms was reviewed by DeRitter *et al.* (267). Anmo and Fueller (271) described a stable vitamin A ointment, and Haronikova and Mandak (272) found that the stability of vitamin A and cholecalciferol in an ointment was increased by adding a mixture of two antioxidants, nordihydroguaiaretic acid, butylated hydroxyanisole, and/or quercitin, or one antioxidant plus edetic acid or potassium pectinate. The composition of the ointment base influences the stability of vitamin A in the ointment (273, 274); the presence of polyethylene glycol and sodium lauryl sulfate in the base enhances the degradation of vitamin A. The decomposition of vitamin A palmitate in emulsion ointments is accelerated by lime water and lavindin (275), and the stability of vitamin A in cosmetic creams has been reported to be highly variable (276).

Syrups—Yashiki *et al.* (277) described a stable vitamin A palmitate syrup that prevented the sorption of vitamin A to plastic containers on storage. Bandelin and Tuschhoff (278) studied the stability of ascorbic acid in syrups at pH 3.0 and at concentrations of 25 and 100 mg/teaspoonful with two sucrose and one glycerin–sorbitol bases. Smaller losses of ascorbic acid were found with the glycerin–sorbitol combination, and the losses were relatively less at the higher concentration of ascorbic acid. The rate of loss of ascorbic acid in solution was determined (92) with ethanol, glycerin, propylene glycol, sorbitol, sucrose, corn sugar, or dextrose added and all yielded a stabilizing effect on ascorbic acid. Sucrose, sorbitol, glycerin, and propylene glycol were superior to the others in this respect. Vegetable gums added to such solutions to increase viscosity accelerated destruction of the vitamin. Vitamin B complex factors added to ascorbic acid syrups in USP syrup and in sorbitol appeared to increase the stability of ascorbic acid. The stability of ascorbic acid in glycerin and sorbitol bases containing salts and stabilizers was investigated by Agarwal and Agarwal (279). In solutions at pH 4 stored for 90 days at 47°, glycerin afforded better protection to ascorbic acid than sorbitol; the effect of stabilizers was less pronounced in the case of the glycerin base. Yao and Hsu (280) prepared multivitamin solutions in syrup, glucose, sorbitol, or sucrose solutions at pH 3.2, 4.5, and 7.0. In stability tests at 41.5 and 60° thiamine was more stable at pH 3.2 and ascorbic acid at pH 7.0. The use of antioxidants, including ascorbyl palmitate and butylated hydroxyanisole, and lecithin and an oxidized starch derivative, W14/S, was found by Fabrizzi *et al.* (281) to stabilize vitamin A, thiamine, and ascorbic acid in a syrup having low vitamin content. Ismaiel and Ismaiel (282) reported that thiamine, riboflavin, and ascorbic acid in syrups could be stabilized by replacing sucrose, vanillin, and various aldehyde-rich essential oils with sorbitol, sodium saccharin, sodium edetate, and essence of banana or apple.

Bartilucci *et al.* (283) studied the stability of cyanocobalamin in aqueous solutions of sorbitol, glycerin, dextrose, and sucrose stored at 25 and 45° for up to 140 days. Cyanocobalamin was compatible with sorbitol and glycerin, but dextrose and sucrose caused losses of cyanocobalamin with dextrose being worse. Gerber *et al.* (284) found that the instability of cyanocobalamin and ascorbic acid in solution with ferrous sulfate could be largely overcome by using 70% sorbitol as the vehicle.

Capsules—Campbell and McLeod (39) determined the vitamin contents of three multivitamin capsule products purchased on the retail market in Canada. Pantothenic acid appeared to be markedly affected by shelf life and storage conditions. In a shelf storage test of one product, pantothenic acid showed high losses and vitamin A, thiamine, and ascorbic acid small losses, while riboflavin, pyridoxine, and niacinamide were stable.

Stability tests of soft gelatin capsules in the laboratory revealed riboflavin, pyridoxine, vitamin E, ascorbic acid, biotin, and niacinamide to have excellent stability. Vitamin A and cholecalciferol showed reasonably good stability, while cyanocobalamin and folic acid tended to vary from product to product. Calcium pantothenate generally had poor stability at pH levels < 3.5, and panthenol was more stable than calcium pantothenate at < pH 4.5; > pH 4 both forms have good stability. Thiamine hydrochloride suffered high losses at pH > 4, whereas thiamine mononitrate showed fair to good stability up to pH 6.4. Macek *et al.* (4) also found thiamine mononitrate to be more stable than the hydrochloride salt in soft gelatin capsules as well as in multivitamin and vitamin B complex, dry-filled capsules. Acidification of the contents of the vitamin B complex capsules was necessary to stabilize the hydrochloride, but

[6] 15% Kollidon 17.

the mononitrate was stable without acidification, which was very destructive of calcium pantothenate. With thiamine mononitrate and a higher pH, it was possible to achieve good stability of both thiamine and calcium pantothenate.

PREDICTION OF VITAMIN STABILITY FROM ACCELERATED AGING TESTS

Garrett and Carper (285) proposed a procedure for predicting degradation of vitamins in liquid multivitamin preparations at normal shelf-life temperatures by measurement of degradation at several elevated temperatures and application of the Arrhenius equation. Garrett (286–288) applied this method in studies of complex multivitamin liquids and demonstrated the validity of the stability predictions for vitamin A, thiamine, ascorbic acid, dexpanthenol, folic acid, and cyanocobalamin. Since a slight change in vehicle composition does not significantly change the heat of activation or the rate of change of degradation with temperature, it was suggested by Garrett (287) that it may be practical in such cases to predict stability on the basis of one elevated temperature once the behavior of the system has been established at several elevated temperatures. The Arrhenius approach to stability prediction is limited according to Garrett (287) to degradation mechanisms that have heats of activation of sufficiently high magnitude (*i.e.*, in excess of 10 kcal/mole), but too high a heat of activation of components (sugars, *etc.*) that trigger a degradation of other components may give unreliable estimates of stability.

McLeod *et al.* (289) confirmed the validity of Garrett's method of predicting degradation rates of liquid multivitamin preparations at room temperature and described a simple graphical method of extrapolation to avoid the time-consuming mathematical calculations. Tardif (17) verified the applicability of the graphical method to the prediction of stability of a multivitamin tablet. Pelletier (290) found that storage tests at 50, 60, and 70° were suitable to predict the stability of thiamine and ascorbic acid in several multivitamin tablets and capsules and verified the predictions by analysis of samples stored at room temperature for 3 years. A short preliminary test at 70° was suggested for guidance in the selection of the most appropriate elevated temperatures, the equations used for the calculations were summarized, and a computer program for handling the calculations listed.

BIOAVAILABILITY TESTING OF VITAMIN PRODUCTS

Bioavailability of a vitamin may be defined as the relative amount of that vitamin contained in a dosage form, which enters the systemic circulation in an active form after administration as compared to the amount after administration of a comparable standard dose of the vitamin in fully available form such as a solution.

Various biochemical laboratory techniques have been employed in assessing bioavailability (291). The majority of these techniques fall into the following categories: (*a*) measurement of the nutrient level in the blood; (*b*) measurement of the urinary excretion rate of the nutrient; (*c*) measurement of urinary metabolites of the nutrient; (*d*) measurement of changes in blood components or enzyme activities that can be related to intakes of the nutrient; and (*e*) load, saturation, and isotopic tests. In the human population one is limited to urine and blood samples. Generally, one is restricted to measuring the concentration of a particular nutrient which is either excreted in the urine or circulating in the vascular system. Blood samples do permit the investigator a slightly greater latitude than urine, since the former can be partitioned into whole blood, serum, plasma, and/or red blood cells if a refinement of technique is justified. It is important that appropriate guidelines are available for the interpretation of the meaning of these measurements. A serum vitamin A level or a urinary value for riboflavin has little meaning until it can be compared with standard levels which have been measured experimentally under comparable conditions.

Measurement of absorption of vitamins *in vivo* requires specific and sensitive methods for determining the concentration of the vitamins or their metabolic products in human body fluids. For the fat-soluble vitamins A and E and cholecalciferol, measurement of blood levels provides a means of assessing absorption directly. For the water-soluble vitamins, except cyanocobalamin, urinary excretion of the vitamins or vitamin metabolites (indirect measurements) are most commonly used. Since normal human subjects consuming average diets without additional supplementation with vitamin products vary widely in the degree of saturation of their tissues with vitamins, relatively uniform excretion patterns can only be achieved by saturating the subjects with the vitamin under test before administering the test doses of the vitamin and measuring urinary excretions. For example, little or no urinary excretion of ascorbic acid is frequently observed following a 500-mg dose of ascorbic acid to subjects not previously saturated, whereas ~50% of such a dose is excreted in the urine of subjects after a state of saturation is reached.

Absorption and Excretion Patterns of the Vitamins—The patterns of absorption, metabolism, and excretion of the individual vitamins that serve as a basis for the test procedures are as follows:

Vitamin A—For evaluation studies in humans, blood level measurements are the only practical means of assessing the absorption of this nutrient. There are, however, many factors that influence the absorption of vitamin A, including type and amount of fat in the diet; interfering substances in diet such as nitrites, ethanol, absorbants, and drugs; size of dose; emulsion (rapid absorption) *versus* oil solution (slower absorption); vitamin E adequacy of subject; zinc adequacy of subject; state of protein nutrition of subject; respiratory, intestinal, renal, or parasitic disease in subject.

By the use of normal subjects in a cross-over design, control of diet, size of dose and the vitamin E level accompanying the dose, and measurement at specific time intervals after dosing to establish a tolerance curve, it is possible to utilize blood levels in humans for assessment of bioavailability of vitamin A products. Although adequate analytical methods are available for measuring blood levels of vitamin A, the difficulties in withdrawing repeated samples of blood under proper supervision make this type of testing unattractive, even when the facilities for conducting such tests are available. In addition, large numbers of subjects are needed if results within a small error range are desired.

Cholecalciferol—The metabolism of cholecalciferol in humans involves conversion to hydroxylated derivatives. Measurement of cholecalciferol or its metabolites in the blood is possible but has not been applied for bioavailability testing. Since cholecalciferol is normally present in a multivitamin product in the same physical form as vitamin A (*i.e.*, as an oil solution, an emulsion, or a dry stabilized beadlet or powder), evidence for bioavailability of vitamin A is likely to be valid for cholecalciferol as well in the majority of products.

Vitamin E—Bioavailability of vitamin E can also be evaluated by determining blood level curves after loading doses. Methodology for determining blood levels of tocopherol has been reviewed by Bunnell (292). The factors listed earlier which influence the absorption of vitamin A may also affect absorption of vitamin E. In addition, the differing biopotencies of the *d*- and *dl*-forms of tocopherol, the differences in absorption between tocopherol, tocopheryl acetate, tocopheryl succinate, and tocopheryl polyethylene glycol 1000 succinate (293) and the possible need to measure specific tocopherols in blood are factors which must be considered in interpreting blood level data. The practical difficulties in conducting blood level studies, as noted under *Vitamin A*, apply also to such tests of vitamin E in blood.

Vitamin K—Increases in blood levels of vitamin K after loading doses have not been used as a measure of bioavailability of dosage forms since most supplemental vitamin K is given parenterally. Oral doses in the form of an oil solution or emulsion would not be expected to present significant problems with bioavailability. Water-dispersible beadlets containing phytonadione have been demonstrated to be biologically available *via* animal tests and are used as a reference standard for animal bioassays (294). Hence, if these are used in solid dosage forms, a rapid *in vitro* disintegration would be indicative of adequate bioavailability.

Thiamine—Of the various biochemical procedures which have been developed for assessing thiamine absorption, the most common one is the measurement of urinary levels. At levels in the range of the daily requirement, thiamine is absorbed fairly well. Thomson (295) reported that 54% of the 1-mg dose of ^{35}S-labeled thiamine hydrochloride given orally after an overnight fast was found in the urine within 24 hr by radioactivity measurements. Continuing the urine collection in one subject for 9 days gave only an additional 7.5% of the dose in the standard test. It appears that the absorption of thiamine in humans is mainly in the upper small intestine. Melnick *et al.* (296) and Jowett (297) also concluded that the absorption of thiamine seems to be confined largely to the upper intestinal tract.

As the oral dose of thiamine is increased (298, 299), the percentage absorption decreases progressively although the total amount absorbed increases. With a single oral dose of 5 mg given on successive days, Schultz *et al.* (300) reported recoveries in urine of 24–42% of the dose and levels of thiamine in the stools were increased. On giving 10-mg doses, only 19–21% was recovered in the urine. The percentage of a thiamine test dose excreted is increased slightly when the dose is given with food (298).

Riboflavin—Riboflavin is absorbed efficiently by humans in any practical dosage range. Friedemann *et al.* (298) state that at least several hundred milligrams of riboflavin is absorbed readily. Human urinary excretion studies by Morrison and Campbell (299) showed that the total extra excretion of riboflavin averaged close to 60% of the oral dose over the dosage range of 1–20 mg. The studies have shown also that 50% or more of an oral dose of riboflavin up to 30 mg is excreted in the urine within 24 hr when the dose was given after breakfast. Levy and Hewitt (301) obtained only 19.3% excretion of a dose of 41 mg of riboflavin phosphate given on an empty stomach as compared to 52.6% when the same dose was given after breakfast.

Niacin or Niacinamide—Hundreds of milligrams of niacin or niacinamide are absorbed readily after oral dosage. Approximately three-fourths of such large doses can be accounted for in the urine of human subjects within 72 hr as a combination of niacin, niacinamide, trigonelline, N^1-methylnicotinamide, and N^1-methyl-2-pyridone-5-carboxamide. The latter is the main metabolite appearing in the urine. If the rate of release of niacin is retarded, the metabolism proceeds to a somewhat greater extent to the end product, the pyridone.

Pyridoxine—Pyridoxine is absorbed readily from the intestinal tract by human subjects. Efficient absorption of several hundred milligrams is normal. Only a small fraction of ingested pyridoxine is excreted unchanged in the urine (only 4–8% of doses in the range of 8–100 mg). In humans, 4-pyridoxic acid accounts for 70–90% of the urinary excretion products of pyridoxine (302).

Calcium Pantothenate or Panthenol—Both pantothenic acid (or its calcium salt) and panthenol are absorbed readily from the intestinal tract. At RDA dose levels, only a small percentage of the dose is excreted in the urine as pantothenic acid but the excretion of the vitamin *per se* increases to ~16% after a 100-mg oral dose and to 36% of a 250-mg dose (303).

Biotin—One milligram of biotin was administered orally to a human male subject on each of two successive days. Urinary excretion of biotin, measured microbiologically with *Lactobacillus arabinosus* as the test organism, amounted to 20 and 48% of the dose in the 24-hr periods after the two doses (304). Although bioavailability of biotin in vitamin products has not been reported, urinary excretion measurements of biotin after oral dosage to saturated subjects may represent a possible approach to this problem.

Folic Acid—By saturating human subjects with high doses of folic acid (10 mg on the first day, 5 mg on the second day, 2 mg on the third and fourth days, and every second day thereafter while excretion tests are in progress), it is possible to obtain urinary excretion of a reasonable percentage of a normal test dose (305). In the author's trials, this technique yielded 5–13% excretion of an oral dose of 0.65 mg of folic acid in a group of five subjects.

Cyanocobalamin—Cyanocobalamin is absorbed maximally in the middle segment of the small intestine and is poorly absorbed in the distal segments (306–308). The size of the dose significantly influences the percent absorption (309). Conley *et al.* (310) reported that oral doses up to 10 mg of cyanocobalamin resulted in no detectable increase of the vitamin in urine within 48 hr. Normal subjects and patients with pernicious anemia behaved similarly. Thus, no bioavailability test for cyanocobalamin can be based on

urinary excretion measurements. Adams *et al.* (311) state that cyanocobalamin absorption can only be studied by using radioactive cyanocobalamin. These authors used a whole-body counting technique in their absorption studies on human subjects. Such techniques are beyond the capability of many laboratories. It is evident that there is no simple method of assessing the bioavailability of cyanocobalamin in pharmaceutical products which would permit testing of bioavailability.

Ascorbic Acid—Ascorbic acid is absorbed efficiently from the upper part of the small intestine. Nicholson and Chornock (312), using an intubation technique, found that 50% of an oral dose of 600 mg of ascorbic acid given in 600 ml of water or saline was absorbed in 1 hr. Saturation of the subjects by giving 500 mg of ascorbic acid daily in addition to the regular diet had no significant effect on their absorption of ascorbic acid. The authors state that the upper part of the small intestine has a capacity for absorption of ascorbic acid far in excess of the optimal daily requirement. Kübler and Gehler (313) studied blood serum levels and rates of urinary excretion of ascorbic acid in previously saturated subjects and concluded that the rate of absorption in the distal part of the absorbing intestine was about half the rate in the proximal portion. These authors found that with increasing doses of ascorbic acid the percent absorption decreases. They reported 71.5% absorption of a dose of 180 mg, 49.5% for 1.5 g, and 16.1% for 12 g. In the dose range of 1.5–12 g, the mean urinary excretion was 62 ± 3.7% of the absorbed ascorbic acid. Proportionality between ingestion and intestinal absorption was claimed up to a single dose of ~180 mg.

Stewart and Booth (314) gave one subject single doses of ascorbic acid at 4-day intervals of 0.2, 0.4, 0.5, 0.7, 1.0, 1.5, 2, and 3 g. Total urinary excretion in up to 30 hr rose steeply up to the 0.5-g dose where ~50% was excreted, and then much less steeply with increasing doses, with an excretion of ~16.7% of the 3-g dose. At the lowest dosage in the range (200 mg) there is practically no excretion of the ascorbic acid dose in the feces. Chieffi and Kirk (315) reported fecal excretion averaging 1.2 mg of ascorbic acid daily by 13 elderly men on an ordinary diet. With a 200-mg supplement of ascorbic acid in the form of a tablet, the fecal excretion averaged 1.5 mg/day, indicating no significant excretion of the supplement in the feces.

Absorption Tests—*Fat-Soluble Vitamins (Blood Level Tolerance Test): Vitamin A*—The application of the blood level tolerance test to determination of the biological availability of vitamin A in three different multivitamin capsules was reported by Sobel and Rosenberg (316). Either 1000 or 2000 IU of vitamin/kg of body weight was administered to eight normal adults in the postabsorptive state. Blood specimens were taken prior to the test and 3, 6, 9, and 24 hr posttreatment. The capsules were swallowed without chewing. As a reference of absorption, oleovitamins A and D was used. Intervals betweeen doses were 2–7 days. If the response as serum vitamin A for the oil dose is taken as 100%, the three capsules showed comparative responses of 198, 185, and 70% based on the mean maximal rise and ~150, 170, and 50% based on the area within the tolerance curves for the 24-hr period.

The authors mention three factors that influence the physiological availability of fat-soluble vitamins: (*a*) the site at which the capsule releases its contents, (*b*) the stability of vitamin A in the GI contents, (*c*) the state of dispersion of the vitamin A released to the GI content (finely dispersed particles are absorbed more readily). The study of Sobel and Rosenberg illustrates some of the difficulties in assessing bioavailability in humans by measuring blood levels of a fat-soluble vitamin such as vitamin A. Such tests have not been utilized to any great extent for determining bioavailability of pharmaceutical products.

Vitamin E—Increases in blood plasma levels of tocopherol in response to oral doses have been reported. For example, Filer *et al.* (317) gave premature and full-term infants oral doses of α-tocopherol and α-tocopheryl esters of 20 mg/kg of body weight and measured blood level increases after 3, 6, 9, 12, and 24 hr. No significant differences in plasma tolerance curves were found between tocopherol and its esters in healthy infants. In disease states diagnosed as fibrocystic disease of the pancreas, diarrhea, and cirrhosis, low vitamin E tolerance curves were observed. Metabolic disorders associated with hypercholesterolemia gave abnormally high values for the areas under the tolerance curve.

Week *et al.* (318) gave oral doses of 1000 mg of *dl*-α-tocopherol or an equivalent amount of *dl*-α-tocopheryl acetate in corn oil in capsules to 10 male and 10 female adult subjects. Blood levels of tocopherol were measured at 0, 2, 4, 5, 6, 8, 12, and 24 hr. The average area under the tolerance curve was 35% higher for free tocopherol than for the acetate ester.

Overman *et al.* (319) found higher blood levels after oral doses of *dl*-α-tocopheryl acetate to humans in the form of aqueous emulsion than after a capsule dosage. They concluded that the amount of vitamin E given and the vehicle are important in determining the effectiveness of vitamin E preparations in increasing the plasma levels of free tocopherol.

Water-Soluble Vitamins (Urinary Excretion Tests)—The human bioassay technique for determining bioavailability of water-soluble vitamins was introduced by Melnick *et al.* in 1945 (320, 321). The principle of this method was summarized as follows: "In normal human subjects the urinary excretion of the water-soluble vitamins, as such or as their derivatives, is directly proportionial to the quantity consumed, provided that at the time of the tests the subjects are subsisting on an adequate diet. The linear dose–response relationship established by feeding the vitamins in pure solution, *i.e.*, in their most completely available form, constitutes the basis of the bioassay."

Outline of the Testing Program—A group of at least five nutritionally normal subjects is chosen. If possible, the subjects should keep their diet the same on two consecutive urine collection days and avoid vitamin supplements and foods unusually high in vitamins such as liver. Urine is collected over a 24-hr period for each of these 2 days. Tuesday and Wednesday are the days of choice for conducting the experiment. Thus, urine collections are made from Tuesday morning after the first voiding and continued until after the first voiding the following morning and repeated the second day similarly. The two 24-hr samples are collected in amber bottles containing a total of 20 ml of 3.5 *N* H_2SO_4 or 2 g of thymol and kept in the refrigerator whenever feasible. On the first day the subjects ingest nothing but their usual diet; the urinary

excretion for this period represents the basal urinary excretion. At the beginning of the second day the subjects take either a standard control dose or a test dose which is reversed to each subject the following week. The control dose contains known amounts of the pure vitamins on test in aqueous solution or suspension. By subtracting the basal excretion from the excretion after the control or test dose, the extra urinary excretion due to dose is determined. The results for each subject are expressed in terms of percent of dose. These tests can be run weekly. The control dose and the test dose should contain similar concentrations of the vitamins.

Saturation Dosage—To ensure maximum and uniform urinary excretion of the extra vitamins fed, it is necessary to saturate the subjects with the vitamins under test. Since the excretion of an individual vitamin is relatively independent of the other vitamins, a high potency multiple vitamin preparation can be used, provided it contains at least the following quantities of the vitamins under test: thiamine (5 mg); riboflavin (5 mg); ascorbic acid (500 mg); calcium pantothenate (50 mg); niacinamide (50 mg); pyridoxine (5 mg). The saturating dose is taken for 4 days and 1 day without this dosage is allowed before the day on which the basal urine is collected. (The saturating dosage schedule for folic acid was mentioned previously.)

Control and Test Doses—The standard control dose of pure vitamins is given in water. The amount of the control dose of each vitamin should be as nearly equal as possible to the amount of each vitamin in the pharmaceutical product to be tested. Following are suggested dosing ranges of the vitamins for use in bioavailability tests:

Thiamine	5–15 mg
Riboflavin	5–30 mg
Niacinamide	50–100 mg
Ascorbic acid	500–1000 mg
Calcium pantothenate or panthenol	25–100 mg
Pyridoxine	5–15 mg
Folic acid	0.5–1 mg

Urine Assay Methods—The following methods may be used for measuring excretions of the vitamins or metabolites:

Thiamine	—fluorometric assay by the thiochrome method of Mawson and Thompson (322)
Riboflavin	—direct dilution with pH 6 acetate buffer in final solution for fluorometric measurement
Niacinamide	—assay of the metabolite, N^1-methylnicotinamide, by the method of Pelletier and Campbell (323)
Calcium pantothenate	—microbiologically with *L. plantarum* as test organism and the medium of Skeggs and Wright (324)
Pyridoxine	—assay of the metabolite, 4-pyridoxic acid, by the method of Pearson (325)
Folic acid	—microbiologically with *Streptococcus faecalis* as test organism and the medium of Rabinowitz and Snell (326) modified by the omission of folic acid and the addition of 2 μg of pyridoxamine/tube
Ascorbic acid	—colorimetrically, using the dichlorophenolindophenol–xylene technique of Rubin *et al.* (327)

Basal and Extra Excretions—In Table VI the average basal excretions and average extra urinary excretions for saturated subjects receiving the above doses are presented.

Availability of a Test Dose—The physiological availability of a test preparation is ascertained by the following calculation:

$$\frac{\text{Percent recovery of test dose}}{\text{Percent recovery of control dose}} \times 100 = \text{Percent availability}$$

Due to the variability of physiological responses in different subjects and in the same subject from time to time, the analytical errors, and the fact that availability is measured as the ratio of two recoveries, which in themselves are the difference between two excretion values, an error of ±20% is not thought excessive. Therefore, a value ≥80% is considered indicative of satisfactory availability. Oser *et al.* (321) present data obtained by this technique on various multivitamin tablets and discuss some factors that might lead to low availabilities.

Rate of Excretion of Dose—According to Johnson *et al.* (328) urinary excretion of oral vitamin doses dissolved in water is practically complete in 8–10 hr. Results obtained in the author's laboratory using the sodium salt of riboflavin phosphate as the test material indicate that this is essentially correct. In these studies a dose of the phosphate, equivalent to 30 mg of riboflavin, was dissolved in water and taken by the test subjects. The hourly excretion (as percent of dose) is summarized below.

Hours after Dose	Average Excretion of Dose, %
0–1	6.5
1–2	12.9
2–3	9.4
3–4	6.0
4–5	3.8
5–6	2.8
6–7	2.2
7–8	1.3
Total percentage of dose excreted in 8 hr	44.9

From the data, one would not expect much excretion beyond a 10-hr collection period. Excretion data after oral dosage of thiamine, ascorbic acid, and niacinamide show that the bulk of the urinary output occurs in the first 12 hr postdose.

However, when the dose is taken in capsule or tablet form, significant excretion may occur in the 12–24-hr period postdose. Therefore, as a standard procedure, it is advisable to run both test and control collections for 24 hr.

Correlation of Excretion Tests with In Vitro *Disintegration and Dissolution Tests*—There is considerable evidence that the pharmaceutical form has a marked influence on the availability of vitamins to the body. Chap-

Table VI—Average Basal Urinary Excretions and Average Extra Excretions of Vitamins or Metabolites After Control Doses

Vitamin	Vitamin or Metabolite Measured	Basal Excretion (on normal diets), mg	Approximate Extra Excretion Due to Control Dose[a]
			Percent of dose
Riboflavin	Riboflavin	0.5–2.5	45–70
Thiamine	Thiamine	0.3–0.5	5–20[b]
Ascorbic acid	Ascorbic acid	30–60	40–60
Calcium pantothenate	Pantothenic acid	4–9[c]	10–20
Panthenol	Pantothenic acid	4–9[c]	10–20
Niacinamide	N^1-Methylnicotinamide[d]	6–12	10–20
Pyridoxine	4-Pyridoxic acid[e]	0.6–1.2	10–15
Folic acid	Folic acid	0.003–0.006	10–15

[a] If the test product is completely available, the percent excretion of the test dose will be equivalent within experimental limits to the percent excretion of the control dose given in aqueous solution. [b] In the case of thiamine, the percent of dose excreted diminishes markedly as the dose is increased; in the case of a 30-mg dose, the excretion may be only ~2–5% of the dose. [c] Expressed in terms of pantothenic acid. [d] When N^1-methylnicotinamide hydrochloride is used as the standard, multiplication of the urinary results by 0.707 converts them to the equivalent niacinamide levels. [e] To convert milligrams of 4-pyridoxic acid to pyridoxine hydrochloride, multiply by 1.123. At higher doses the percent of dose excreted as 4-pyridoxic acid will be higher.

man *et al.* (252) found by a specified *in vitro* test that vitamin tablets that did not disintegrate in 1 hr were not fully available to the body, as judged by the amount of riboflavin excreted in the urine. This was confirmed by Morrison *et al.* (253) and has been the basis for a regulation promulgated under the Canadian Food and Drugs Act setting a 1-hr time limit for the disintegration of ordinary tablets. Middleton *et al.* (329) examined the relationships between *in vitro* dissolution rate, disintegration time, and physiological availability of riboflavin in sugar-coated tablets. They found a close relationship between disintegration time and dissolution rate, and both *in vitro* procedures correlated reasonably well with physiological availablity as measured by urinary excretion of riboflavin. It was concluded that either of these two *in vitro* procedures can provide a useful estimate of the availability to the body of riboflavin in sugar-coated tablets.

Libby *et al.* (330) studied riboflavin excretion by human subjects ingesting sustained-release capsules or tablets which did not pass the official USP disintegration test. Urinary recoveries of riboflavin from these preparations were extremely low in comparison to those obtained with an equal dose of riboflavin standard. These authors also showed reduced urinary excretion of riboflavin when six tablets containing calcium, ascorbic acid and cholecalciferol were fed together with fully available riboflavin tablets. Ida *et al.* (331) reported a lower rate of excretion in the first 6 hr after dose of compressed film-coated tablets, even though these disintegrated in 4 min in water and in 5–10 min in simulated gastric juice by the USP XVI method. These workers, however, did not measure excretions in later hours, which may have indicated complete absorption of the riboflavin over a longer period.

Evaluation of the absorption of most of the vitamins in a multivitamin preparation is a very time-consuming and expensive operation, involving skilled staff and analytical methodology for vitamin metabolites which is not normally used in vitamin assay laboratories. Emphasis in various studies of vitamin absorption has been placed on the excretion of riboflavin, primarily because of its relative insolubility compared with most other water-soluble vitamins. With the exception of biotin, the solubility of which is close to that of riboflavin in water, and folic acid, the solubility of which is strongly dependent on pH, all other vitamins are many times more soluble than riboflavin. Thus, if a tablet granulation is made with a uniform mixture of the water-soluble vitamins and water-dispersible beadlets or powders containing the fat-soluble vitamins (a usual procedure), the finding in a urinary excretion test that the riboflavin from the finished tablet is fully available to the body makes it evident that the tablet has disintegrated suitably. Since the riboflavin has then obviously dissolved in order to have been absorbed in the upper part of the intestinal tract, it is most likely that the more soluble vitamins and the readily dispersible powders have also been readily available for absorption. If, on the other hand, any of the other individual vitamins are coated or added to the tablet mix in a different manner for a special solid dosage form than the riboflavin component, then it becomes desirable to establish the correlation of disintegration and/or dissolution tests with an *in vivo* absorption test for such vitamins. Once a relationship of *in vivo* tests to *in vitro* tests has been established, the *in vitro* tests should be an adequate means of control for ensuring suitable absorption characteristics of solid pharmaceutical dosage forms in routine pharmaceutical manufacturing operations.

(127) K. Takamura and M. Ito, *Chem. Pharm. Bull.*, **25,** 3218 (1977).
(128) E. Géro, *Compt. Rend.*, **240,** 1818 (1955).
(129) C. Inagaki, H. Fukuba, M. Mukai, and S. Toyosato, *Nippon Nogei Kagaku Kaishi*, **29,** 416 (1955).
(130) A. Smoczkiewiczowa and J. Grochmalicka, *Nature (London)*, **192,** 161 (1961).
(131) J. Herrmann and H. G. Grossman, *Pharm. Zentralhalle*, **101,** 743 (1962).
(132) T. Fukuda, K. Miyakawa, and K. Ro, *Shokuhin Eiseigaku Zasshi*, **7,** 508 (1966).
(133) S. Baczyk, A. Lempka, and K. Baranowska, *Pr. Zakresu Towarozn Chem., Wyzza Szk. Ekon. u Poznaniu Zesg. Nauk., Ser. I*, **26,** 39 (1966).
(134) T. Katari, J. Sato, T. Iida, and S. Makino, Japan. Kokai, 74 92,219, Sept. 3, 1974.
(135) R. D. Davis, Japan. Kokai, 77 66,672, June 2, 1977.
(136) K. Hasunuma, Japan. Kokai 74 86,524, Aug. 19, 1974.
(137) K. Hasunuma, Japan. Kokai 74 32,935, Sept. 4, 1974.
(138) A. Bavley, C. J. Knuth, W. A. Laxler, and A. E. Timreck, U.S. Patent 2,689,202, Sept. 14, 1954.
(139) A. Bavley and A. E. Timreck, U.S. Patent 2,702,262, Feb. 15, 1955.
(140) J. C. Bauernfeind and L. Magid, U.S. Patent 2,708,628, May 17, 1955.
(141) A. Rosenberg, U.S. Patent 2,855,306, Oct. 7, 1958.
(142) J. E. Allegretti, U.S. Patent 2,897,118, July 28, 1959.
(143) H. W. Flandreau, Jr., U.S. Patent 3,529,065, Sept. 15, 1970.
(144) W. Cort and H. L. Newmark, U.S. Patent 3,749,799, July 31, 1973.
(145) T. Furuhashi and T. Hayashibara, Japan. Kokai 75 13,521, Feb. 13, 1975.
(146) M. A. Cannalonga and L. V. Czarecki, U.S. Patent 3,947,596, Mar. 30, 1976.
(147) J. C. Wallenmeyer, F. G. McDonald, and R. L. Henry, U.S. Patent 2,650,895, Sept. 1, 1953.
(148) R. D. Wakely, U.S. Patents 2,758,923 and 2,758,924, Aug. 14, 1956.
(149) M. Hochberg, U.S. Patents 2,777,797 and 2,777,798, Jan. 15, 1957.
(150) S. Ohtaki, U.S. Patent 3,050,728, Oct. 2, 1962.
(151) C. H. Benton, Jr. and L. A. Anderson, U.S. Patent 2,940,900, Jan. 14, 1960.
(152) G. Brooks, U.S. Patent 3,173,838, Mar. 16, 1965.
(153) R. H. Bunnell and M. A. Cannalonga, U.S. Patent 3,608,083, Sept. 21, 1971.
(154) R. H. Bunnell and M. A. Cannalonga, Ger. Offen. 2,135,247, Jan. 25, 1973.
(155) M. A. Cannalonga and L. V. Czarecki, U.S. Patent 3,914,430, Oct. 21, 1975.
(156) J. Myhre, U.S. Patent, 2,676,136, Apr. 20, 1954.
(157) H. J. Dunn, U.S. Patent 2,897,119, July 28, 1959.
(158) M. Hochberg and C. Ely, U.S. Patent 3,067,104, Dec. 4, 1962.
(159) H. D. Ratish and M. Hochberg, U.S. Patent, 3,067,105, Dec. 4, 1962.
(160) L. A. Anderson, U.S. Patent 3,099,602, July 30, 1963.
(161) R. E. Aiello and P. P. Eisenstein, U.S. Patent 3,138,532, June 23, 1964.
(162) A. Rosenberg, U.S. Patent 3,124,510, Mar. 10, 1964.
(163) L. A. Anderson, U.S. Patent 3,184,385, May 18, 1965.
(164) A. Berseneva, *Khim.-Farm. Zh.*, **11,** 131 (1977).
(165) J. Spaleny, J. Kucharsky, J. Lomjansky, and P. Tomlein, Czech. Patent 172,543, May 15, 1978.
(166) I. V. Kozlova, G. I. Dontsova, V. A. Chenov, V. Y. Lebedenko, and G. P. Gryadunova, *Farmatsiya (Moscow)*, **26,** 37, (1977).
(167) M. A. Cannalonga and J. E. Raymond, Ger. Offen. 2,402,413, July 25, 1974.
(168) E. Nuernberg, German Patent 1,290,611, Mar. 13, 1969.
(169) L. E. Stoyle, Jr., U.S. Patent 3,293,132, Dec. 20, 1966.
(170) W. Haas and H. G. Zeller, S. Afr. Patent 68 03,687, Jan. 15, 1969.
(171) W. Haas and H. G. Zeller, U.S. Patent 3,873,713, Mar. 25, 1975.
(172) A. Kassem, S. Said, and S. El-Bassouni, *Manuf. Chem. Aerosol News*, **46,** 53 (1975).
(173) I. Chaudry, J. A. Concha, and N. F. deCastro, *Asian J. Pharm.*, **3,** 10 (1977).
(174) S. Kondo and H. Nakano, Ger. Offen. 2,706,705, Feb. 23, 1978.
(175) H. Tamura, M. Kawasaki, and T. Yamaguchi, Japan. Kokai Tokyo Koho 78 127,819, Nov. 8, 1978.
(176) A. Koff, U.S. Patent 3,080,292, Mar. 5, 1963.
(177) A. Koff, U.S. Patent, 3,080,293, Mar. 5, 1963.
(178) E. DeRitter and J. E. Raymond, U.S. Patent 3,676,556, July 11, 1972.
(179) L. E. Stoyle, Jr., P. A. Owellette, and E. J. Hanus, U.S. Patent 3,037,911, June 5, 1962.
(180) L. D. Morse and P. A. Hammes, Ger. Offen. 2,255,236, May 16, 1974 and Brit. Patent 1,371,840, Oct. 30, 1974.
(181) C. N. Andersen, U.S. Patent 2,410,417, Nov. 5, 1946.
(182) H. M. Espoy, U.S. Patent 2,858,215, Oct. 28, 1958.
(183) E. Knobloch, V. Janata, and E. Likarova, Czech. Patent 159,454, Aug. 15, 1975.
(184) M. Cannalonga and L. V. Czarecki, Fr. Demande 2,179,899, Dec. 28, 1973.
(185) J. Surowiecki and L. Krowcznyski, *Acta Pol. Pharm.*, **29,** 399 (1972).
(186) L. Freedman and E. Green, U.S. Patent 2,417,299, Mar. 11, 1947.
(187) M. R. Zentner, U.S. Patent 2,628,930, Feb. 17, 1953.
(188) A. Wander, Brit. Patent 710,817, June 16, 1954.
(189) R. A. Lehman, U.S. Patent 3,036,957, May 29, 1962.
(190) J. D. Mullins and T. J. Macek, U.S. Patent 3,070,499, Dec. 25, 1962.
(191) A. E. Timreck, U.S. Patent 3,359,167, Dec. 19, 1967.
(192) L. Tomasini, E. Trandafilova, V. Boyanova, and P. Grigorov, *Farmatsiya (Sofia)*, **25,** 33 (1975).
(193) J. D. Cawley and M. H. Stern, U.S. Patent 2,680,749, June 8, 1954.
(194) A. E. Sobel, U.S. Patent 2,816,855, Dec. 17, 1957.
(195) C. D. Robeson, U.S. Patent 3,102,078, Aug. 27, 1963.
(196) R. E. Aiello and J. C. Bauernfeind, U.S. Patent 3,149,037, Sept. 15, 1964.
(197) W. H. Feigh, U.S. Patent 3,244,595, Apr. 5, 1966.
(198) R. Gherghinof, V. Pilea, M. Ionescu, and R. Paiusan, *Farmacia (Bucharest)*, **14,** 681 (1966).
(199) M. Fujita, T. Shimamoto, and J. Takahashi, Japan. Kokai 74 42,818, Apr. 22, 1974.
(200) M. Fujita, T. Shimamoto, J. Takahashi, and K. Ishizuka, Japan. Kokai 78 07,489, Mar. 18, 1978.
(201) A. Koshiro, K. Fujimoto, K. Ishimoto, K. Matsuoka, E. Uchida, K. Fujimura, S. Harada, K. Takahama, and T. Ogata, *Kyushu Yakugakkai Kaiho*, **32,** 31 (1978).
(202) D. Monciu and M. Boteanu, *Farmacia (Bucharest)*, **25,** 159 (1977).

RESEARCH ARTICLES

Solid-State Stability of Aspirin in the Presence of Excipients: Kinetic Interpretation, Modeling, and Prediction

P. V. MROSO, A. LI WAN PO ˣ, and W. J. IRWIN

Received August 7, 1981, from the *Department of Pharmacy, University of Aston, Gosta Green, Birmingham B4 7ET England.* Accepted for publication December 14, 1981.

Abstract □ Salicylsalicylic acid and acetylsalicylsalicylic acid were identified as decomposition products of aspirin when mixtures of the drug, with magnesium stearate, were stored in the solid state at 60° and 75% relative humidity. The effect of increasing the concentration of magnesium stearate and the addition of other alkali stearates on the rate of decomposition of aspirin were studied. The validity of the theory that pH changes induced by the alkali stearates account for the catalytic effect of the lubricants on the decomposition was tested. The changes observed were modeled and the mechanism involved elucidated. The potential use of the melting points of aspirin mixtures in predicting the stability of the drug in such drug–excipient mixtures is demonstrated.

Keyphrases □ Aspirin—solid-state stability in presence of excipients, kinetic interpretation, modeling and prediction, decomposition □ Decomposition—solid-state stability, aspirin, excipients, kinetic interpretation, modeling and prediction □ Stability—solid state, aspirin, in presence of excipients, kinetic interpretation, modeling and prediction

The mechanisms of decomposition of drugs in the solid state are complex and difficult to unravel (1–3). The problems are compounded by the fact that most drugs are formulated with excipients, and decomposition in such systems is even more complicated. This, together with the usually slow rates of decomposition in the solid state relative to solutions, may explain the comparatively small number of reports on the quantitation of decomposition of drugs in formulated solid-dosage forms. Many of the reports that have appeared have tended to be semiquantitative, although a few detailed studies have been reported (4–9). To overcome the time constraints, some workers have resorted to the prediction of the solid-state stability of hydrolabile drugs by studying their decomposition in suspension systems. Kornblum and Zoglio (10) for example attempted to predict the stability of aspirin in the presence of tablet lubricants in the solid state by this approach. Although the method described is attractive, the mechanisms of decomposition in solid dosage systems may be different from those observed in systems containing a higher proportion of water.

More recent studies have shown that in addition to

salicylic acid (II), salicylsalicylic acid (III) and acetylsalicylsalicylic acid (IV) could be detected in aspirin tablets (11–13). Since these compounds (III and IV) have been shown (14, 15) to be potentially immunogenic, limiting their presence in formulated products is important. It has been previously reported that although III was detected in aspirin tablets, it was not detected in various aspirin samples, thus suggesting that its formation could be excipient-induced (12).

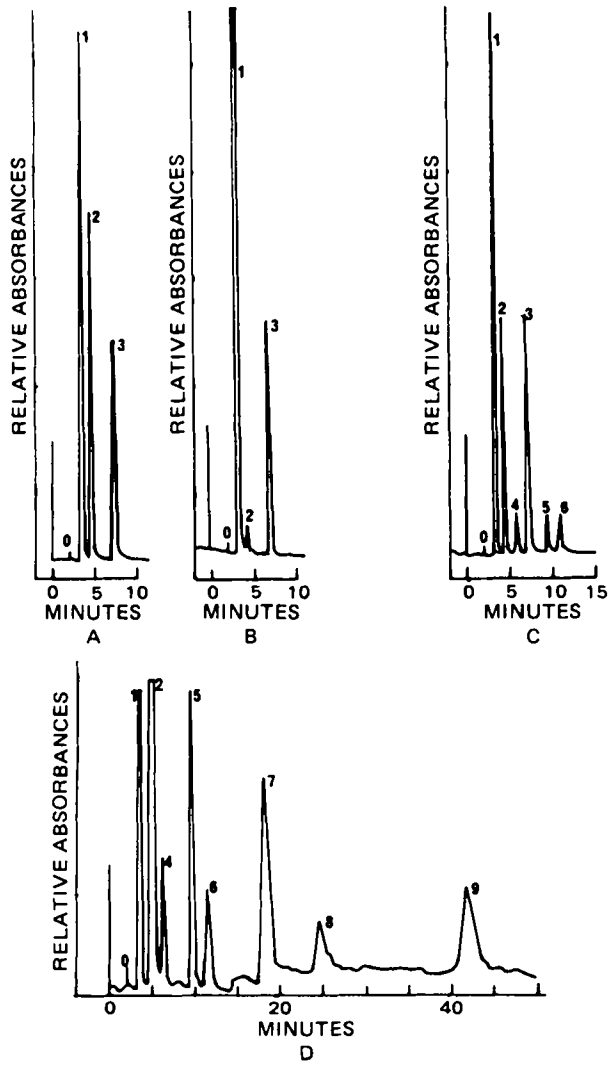

Figure 1—*High-performance liquid chromatograms of aspirin and its decomposition products: (A) aspirin in the presence of salicylic acid and propyl paraben (n-propyl-p-hydroxybenzoate); (B) aspirin–1% magnesium stearate mixture at time 0; (C) mixture after storage for 18 days at 60° and 75% humidity; (D) mixture after 21 days without internal standard. Key: (0) solvent front; (1) aspirin; (2) salicylic acid; (3) internal standard; (4) acetylsalicylsalicylic acid; (5) salicylsalicylic acid; (6–9) unidentified products.*

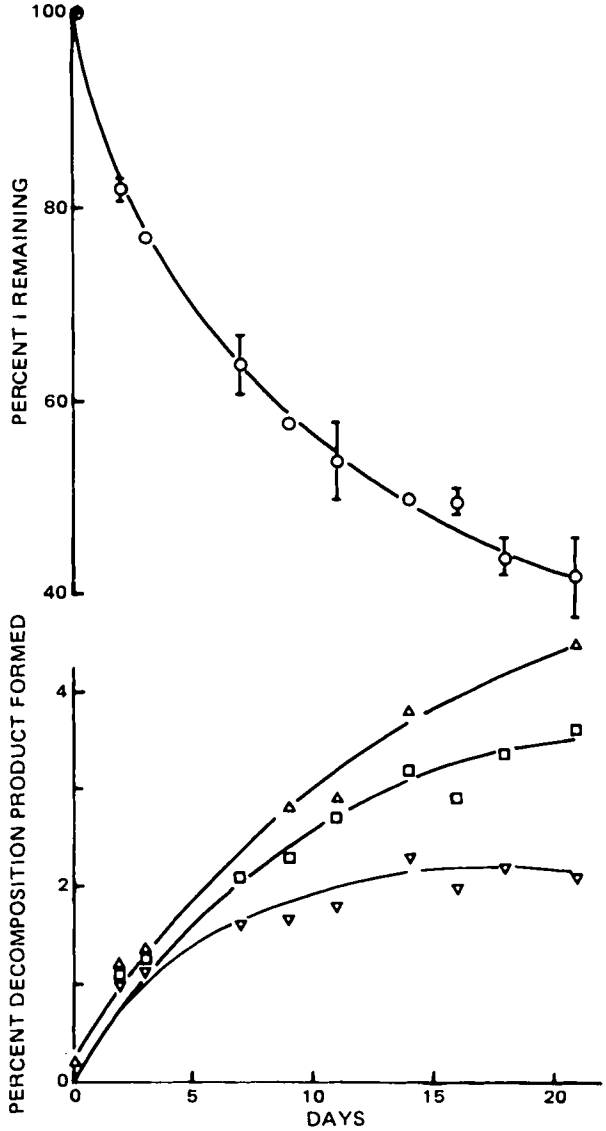

Figure 2—*Kinetics of decomposition of aspirin (I) in the presence of 1% magnesium stearate (60° and 75% relative humidity) and amounts of II, III, and IV. Key: (○) aspirin remaining; (△) II detected, (□) III; (▽) IV.*

The present study was initiated to determine whether III and IV were formed during the decomposition of aspirin in the presence of excipients in the solid state, to quantify the kinetics of decomposition of aspirin in the presence of excipients, and to elucidate the mechanisms of interaction of aspirin with tablet lubricants and in particular with magnesium stearate.

EXPERIMENTAL

Materials—Salicylic acid[1], phosphoric acid[1], *n*-propyl-*p*-hydroxy benzoate[2], and calcium, aluminum, sodium, and zinc stearates[3] were obtained from a single manufacturer[4]. Magnesium stearate samples were

[1] Analar grade.

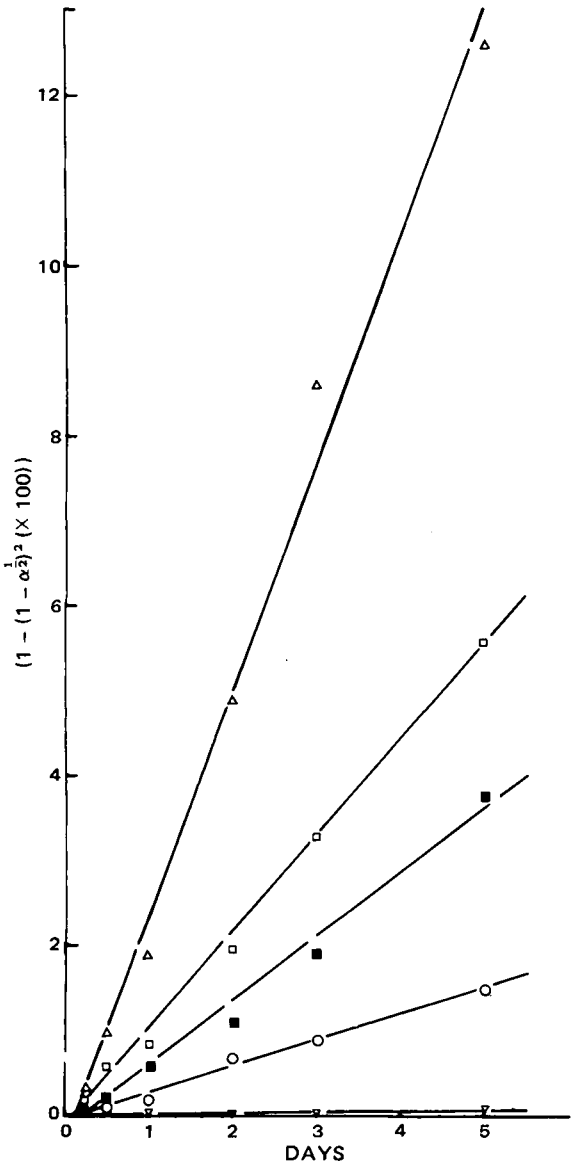

Figure 3—*Effect of magnesium stearate concentration on the rate of decomposition of aspirin plot according to Eq. 6. Key: (▽) aspirin without additive; (○) 1%; (■) 2%; (□) 3%; (△) 5% magnesium stearate.*

obtained from two different sources[4,5]. Sodium chloride (BP)[6], methanol[7], and salicylsalicylic acid[8] were used as obtained. Acetylsalicylsalicylic acid was synthesized as described (16) and tested for chromatographic purity by high-performance liquid chromatography (HPLC).

Methods—*Analysis of the Metal Stearates*—For the assay of free fatty acid 100 mg of each metal stearate was weighed out and extracted with 5 ml of chloroform. The chloroformic extract was filtered through a glass fiber filter paper and 1 ml of the filtrate was analyzed by GLC. For the assay of total fatty acid 60 mg of each stearate was weighed into a separating funnel and 30 ml of concentrated hydrochloric acid was added. The free acids liberated were extracted with 50 ml of chloroform and 1 ml of the extract assayed by GLC. Preliminary studies showed that concentrated acid was necessary to obtain clear chloroformic extracts.

GLC Analysis for Stearic, Palmitic and Myristic Acids—The GC system used for assaying the free and the total fatty acids in the alkali stearates consisted of a gas chromatograph[9] fitted with a silicone[10] coated open tubular glass capillary column (10 m × 0.8-mm o.d.) and an all-glass solids injector. Temperature settings were at 200° for the column and 250° for the detector and injector. Nitrogen, hydrogen, and air pressures were 0.9, 1.0, and 0.75 kg/cm^2, respectively. The nitrogen flow rate was 1 ml/min. Peak areas were obtained by integration.

One milliliter of extract was mixed with 0.8 ml of a chloroformic linoleic acid (1 mg/ml) solution and evaporated to dryness at 60° under nitrogen. The residues were methylated using a boron trifluoride–methanol mixture[11] maintained at 60° for 15 min. The product was extracted with 1 ml of *n*-hexane and 1 μl was injected into the chromatograph. Standard solutions prepared from the pure free acids[12] were derivatized and assayed simultaneously.

Analysis of the Salicylates—Analyses were performed using an HPLC constructed from a constant-flow solvent-metering pump[13], a valve[14] fitted with a 20-μl loop, and a variable wavelength monitor[15] equipped with an 8-μl flow cell and operated at 285 nm with a sensitivity of 0.32 aufs. Reversed-phase chromatography was performed using a 5-μm ODS (25-cm × 4.6-mm i.d.) column[16] and a mobile phase consisting of 0.02% phosphoric acid in 60% methanol in water and delivered at 1.4 ml/min.

Sample Preparation and Storage—Aspirin crystals were mixed with fixed proportions of magnesium, zinc, aluminum, sodium, or calcium stearate, and 100-mg quantities of each of the mixtures or of pure aspirin were weighed into individual glass vials[17] and loosely covered with cotton wool to prevent entry of condensed water droplets. The samples were then stored in a humidity cabinet[18] maintained at 60°. A 75% relative humidity environment was maintained at this temperature using a saturated sodium chloride solution. Samples were taken at predetermined intervals and assayed for aspirin and its decomposition products by the HPLC method.

Sample Preparation for HPLC—The contents of the vial sampled were dissolved in methanol, quantitatively transferred to a 25-ml volumetric flask, and brought up to volume with methanol. The resultant solution was analyzed by HPLC.

Particle-Size Analysis—The aspirin crystals were sized by sieve analysis (17) and a geometric mean of 280 ± 1.85 μm was obtained.

Washed Magnesium Stearate—Samples of magnesium stearate were washed by adding 5 g to 200 ml of 0.1 *M* HCl to remove any alkaline impurities and filtering the residues through a No. 3 sintered glass filter. The stearate was then washed by shaking with 50 ml of alcohol to remove stearic acid precipitated out during the acid wash. The powder was rinsed with several changes of double-distilled water until the resultant pH was in the 6.9–7.0 range. After a second filtration, the residues were dried overnight on filter paper at room temperature and finally at 50° for one-half hour before storage in tightly closed glass containers.

Melting-Point Determinations—The melting points of aspirin and its mixtures were determined by the standard capillary-tube method using an electrothermal melting point apparatus[19]. A second set of melting points were also obtained using a differential scanning calorimeter[20] operated at a heating rate of 8°/min and a nitrogen atmosphere of 2 bar. Samples (20–30 mg) were used with aluminum as the reference material.

Mathematical Model—The model used for explaining the results obtained in this study is based on liquid reaction-product layer formation during the decomposition of the aspirin. Jander (18) first showed that if one considers the formation of a liquid reaction-product layer, during the decomposition of spherical particles and if the reaction is diffusion limited, then it is possible to derive an expression relating the fraction decomposed with time. Such a model has been used previously (19).

Microscopic examination of the particles shows that the shape of the aspirin crystals used in this study were better approximated by cylinders than by spheres. Using Jander's assumptions of a diffusion-limited reaction and of a rate of thickening of the liquid layer dy/dt being inversely proportional to its thickness, y, Eq. 1 is obtained:

$$dy/dt = k/y \qquad \text{(Eq. 1)}$$

On integration:

$$y^2 = 2kt \qquad \text{(Eq. 2)}$$

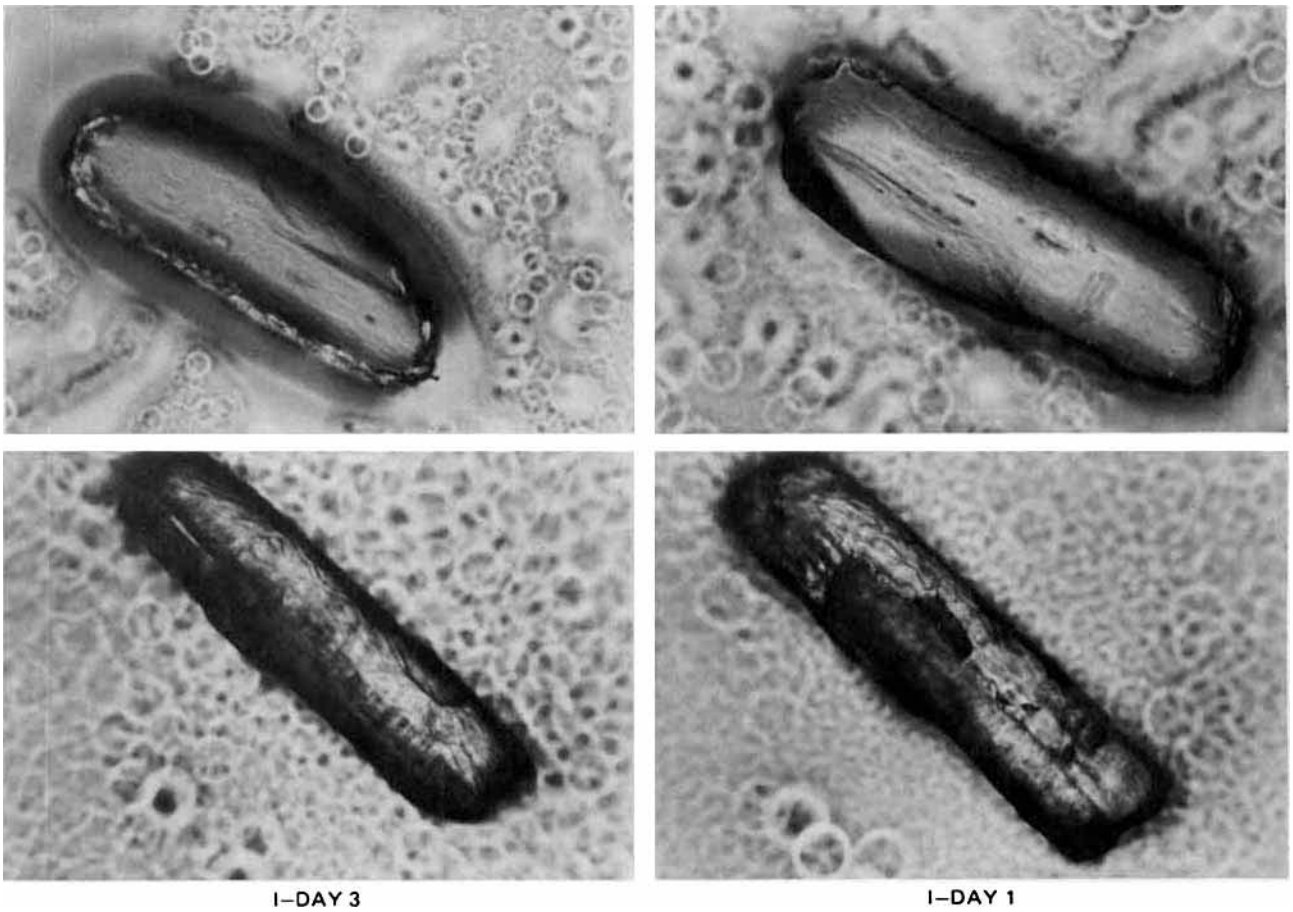

Figure 4—*Photomicrographs of decomposing aspirin (I) crystals with and without magnesium stearate at 50° and 75% relative humidity.*

The fraction decomposed (x) after time (t) can be expressed in terms of the total weight of the cylindrical particles studied:

$$\frac{\eta\rho\pi r_0^2 h - \eta\rho\pi(r_0 - y)^2}{\eta\rho\pi r_0^2 h} h = x \qquad \text{(Eq. 3)}$$

where r_0 = initial radius, h = height of cylinder, η = number of cylinders, ρ = density.

$$r_0^2 - (r_0 - y)^2 = x r_0^2 \qquad \text{(Eq. 4)}$$

Rearranging Eq. 4:

$$r_0[1 - (1 - x)^{1/2}] = y \qquad \text{(Eq. 5)}$$

Substituting for y in Eq. 5 from Eq. 2 and squaring:

$$[1 - (1 - x)^{1/2}]^2 = \frac{2k}{r_0^2} t \qquad \text{(Eq. 6)}$$

A plot of $[(1 - (1 - x)^{1/2}]^2$ against t should therefore give a straight line with zero intercept if the liquid-layer diffusion-controlled model describes the system studied. The model assumes that the length–diameter ratio of the aspirin crystals is such that end effects are negligible.

RESULTS AND DISCUSSION

Analysis of the stored samples by HPLC showed that II, III, and IV (Fig. 1) were formed during storage of aspirin at 60° and 75% relative humidity in the presence of magnesium stearate. Samples of aspirin on its own stored under identical conditions did not lead to the formation of III and IV when followed over the same time period. Figure 1 shows chromatograms of nonstored (Fig. 1B) as well as of stored samples (Fig. 1C) of aspirin.

Peak identification was achieved by comparison of retention times with authentic specimens as well as the ratio of the wavelength (20). HPLC of samples stored for longer periods of time showed that the decomposition is even more complex and several products which have not yet been identified were observed (Fig. 1D). These results are in agreement with those reported by Taguchi *et al.* (21) who showed that storage of aspirin tablets at 50° led to the formation of II, III, and IV, and that when further stressed at 95°, additional components could be detected in significant amounts. HPLC analysis of an aspirin sample stored for 4 weeks at 60° and 75% relative humidity showed traces of all the decomposition products detected in the presence of magnesium stearate. This shows that the stearates accelerate rather than induce their formation.

The decomposition of aspirin in the presence of 1% magnesium stearate is shown in Fig. 2 together with the amounts of II, III, and IV detected in the samples. It is important to note that these amounts of decomposition products can only be used as guide values since an open system was used. This particularly applies to salicylic acid which has been shown to sublime readily (22). Studies in which aspirin decomposition has been followed in the solid state, by following the kinetics of formation of salicylic acid, will therefore lead to erroneous results unless closed systems are used. In the present study an open system that allowed exposure of the samples to a constant relative humidity was preferred. Aspirin was assayed in addition to salicylic acid.

To investigate whether the concentration of lubricant present affected the rate of decomposition of aspirin, the degradation was followed in the presence of a series of concentrations of magnesium stearate. The results of these studies are shown in Fig. 3. An increase in magnesium stearate concentration quite clearly accelerated the decomposition of aspirin.

Various authors have reported on the catalytic effect of excipients on aspirin decomposition (23–25). The explanation put forward for explaining the effect of magnesium stearate has generally been based on hydrolysis taking place in an adsorbed moisture layer and on an alteration in the pH of this layer by the added excipient (26). It is known that the magnesium stearate used for tablet lubrication contains a significant amount of magnesium oxide. The USP and the BP specifications for magnesium stearate allow for up to 8.5% of magnesium oxide (27, 28). The 1980 BP however now defines the pH range of a 5% suspension and states that it should be between 6.2 and 7.4 (29).

A relationship between the observed zero rate constant of salicylic acid formation and the pH of the suspension after addition of the lubricants has been shown previously (10) in aspirin–tablet lubricant suspension

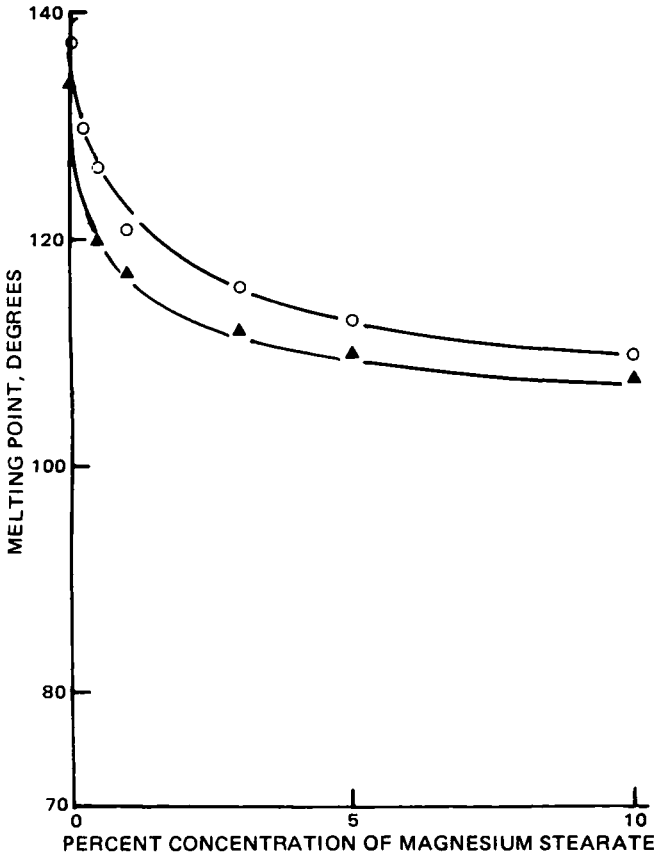

Figure 5—*Effect of addition of different concentrations of magnesium stearate on the melting point of aspirin; (○) using traditional melting point apparatus and (▲) using differential scanning calorimetry.*

systems. Magnesium stearate produced the largest pH shift and the highest rate constant. It has not been conclusively shown, however, that the pH change plays a significant part in the decomposition of aspirin in the solid state. To test this, the rate of decomposition of aspirin was measured in the presence of washed and unwashed magnesium stearate. The washed sample gave a suspension (1%) with a pH near neutrality (6.9), whereas an unwashed sample prepared similarly gave a pH of 9.9. The observed rate constants as mirrored by the slope of Eq. 6 were almost identical; the slopes were 0.0033 and 0.0030/day, respectively. Clearly the results do not exclude pH-induced changes in the rates of decomposition. The results indicate that any such change was too small to be detected during the study and was swamped by other effects when the stability of pure aspirin is compared with aspirin in the presence of magnesium stearate. GLC analysis of the magnesium stearate used both before and after washing showed that the total acids recovered (89.5 and 88.3%) were not significantly different. The amount of free acid recovered increased from 0.6 to 5.8% upon washing. It has been suggested (30) that because sublimation of II is observed on the surface of aspirin under stress conditions (22), factors other than those involved in solutions must be operable. However, sublimation out of a solution is also conceivable. Once the moisture microfilm is saturated with II, additional formation will lead to precipitation, decomposition onto adjacent surfaces, and eventually sublimation.

Microscopic (Fig. 4) and visual examination of the stored samples showed the presence of liquid films around the decomposing particles. Any theory put forward for explaining the observed increase in decomposition of aspirin in the presence of magnesium stearate must therefore take this into account.

A linear relationship between the logarithm of the observed rate constant of decomposition, and the reciprocal of the melting temperature (°K), has been found in a previous study on the solid-state stability of Vitamin A compounds (5). This was derived from the relationship between the fraction of material in the liquid state (x_1) and the melting point of the pure crystalline solid (T_m):

$$\ln x_1 = \frac{-L_f}{R}\left(\frac{1}{T} - \frac{1}{T_m}\right) \qquad \text{(Eq. 7)}$$

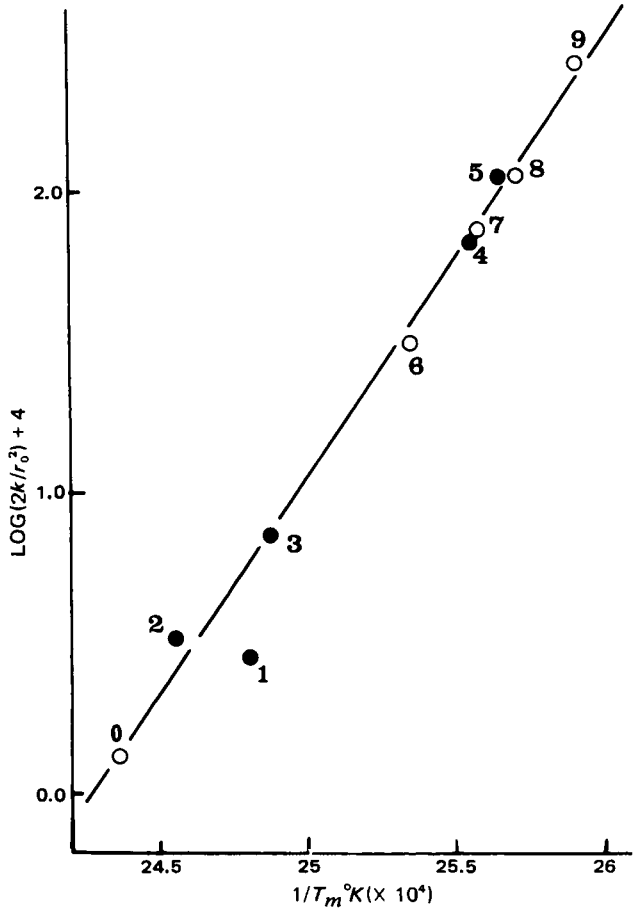

Figure 6—*Relationship between the rate constant of decomposition of aspirin in the presence of alkali stearates as mirrored by the slopes of Eq. 6 and the reciprocal of the melting points of the mixtures. Key: (0) aspirin on its own; (●) with 3% Zn (1), Al (2), Na (3), Ca (4), and Mg (5) stearates; (○) aspirin with 1% (6), 2% (7), 3% (8) and, 5% (9) magnesium stearates.*

where L_f is the molar heat of fusion and represents the difference in internal energy between the two states, the liquid being much more reactive than the solid; T is the temperature of storage; and R is the gas constant.

To test whether this relationship might explain the effect of magnesium stearate on the decomposition of aspirin the melting points of the mixtures were determined. Figure 5 shows the relationship between the melting point observed and the magnesium stearate content. The same trend was observed using both the traditional capillary tube melting point determinations and differential scanning calorimetry although differences in the absolute values were observed.

The slopes of Eq. 6 for the reactions shown in Fig. 4 were then plotted against the reciprocal of the corresponding melting points. Figure 6 shows that this relationship holds for the systems studied. One would also expect that other stearates would also alter the decomposition rates of aspirin, the magnitude of the change being determined by the size of the depression in melting point. Experiments were carried out to test this and the results are superimposed on the magnesium stearate results (Fig. 6). It is evident that the general relation holds here too.

Analysis of the stearates used in this study showed that the acid composition of the samples was significantly different (Table I). In addition to the samples used in the stability studies, other batches of magnesium and sodium stearates were also assayed for the three acids. As can be seen, interbatch and intermanufacturer variability in relative compositions were obvious. These can, in turn, be expected to produce different effects on aspirin decomposition and should be screened for during formulation studies.

CONCLUSIONS

The present study shows that III and IV are decomposition products of aspirin when the latter is stored in the solid state in the presence of alkaline lubricants such as magnesium stearate. Compounds III and IV

Table I—GLC Analysis of Alkali Stearates Used in the Stability Study

Metal Stearate	Relative Composition, % Myristate	Palmitate	Stearate	Recovery, %[a]	Free Acid, %[a]
Zinc stearate	1.9	39.2	58.9	90.5	0.3
Calcium stearate	3.7	33.4	62.9	97.1	2.8
Aluminum stearate	2.8	33.9	63.3	85.7	3.5
Sodium stearate (Manufacturer A, Batch 1)	2.4	53.0	44.6	89.1	2.8
Sodium stearate[b] (Manufacturer A, Batch 2)	4.0	40.6	55.4	95.5	1.8
Magnesium stearate (Manufacturer A, Batch 1)	5.7	37.2	57.1	87.1	0.6
Magnesium stearate (Manufacturer A, Batch 2)[b]	5.2	38.5	56.3	83.7	0.6
Magnesium stearate (Manufacturer B, Batch 1)[b]	3.2	54.0	42.8	76.7	1.2

[a] Refers to percent of initial weight accounted for by the three stearates. [b] These batches were not used in the stability studies.

were not detected in samples of aspirin stored under identical conditions for the same length of time. More prolonged storage, however, led to the formation of traces of the products. These data would suggest that the stearates accelerate the formation of these products and provide an explanation for the earlier report showing that III was detected in most of the commercial aspirin tablets analyzed but not in bulk aspirin samples. A direct relationship was shown between the rate constant of decomposition, as expressed by the slopes of plots of Eq. 6, and the concentration of magnesium stearate present. It has further been demonstrated that there was a linear relationship between the logarithm of slopes of Eq. 6 and the reciprocal of the melting points of the aspirin–stearate mixtures. Using a series of stearates it was shown that the relationship is of wide applicability. Changes in melting point rather than shifts in pH of the moisture microfilms surrounding the particles would appear to be the more plausible explanation for the observed effects of magnesium and other alkali stearates on aspirin stability. Melting point determinations would appear to provide a rapid method for predicting the stability of aspirin in aspirin–lubricant mixtures. The inverse relationship between aspirin decomposition in aspirin–lubricant mixtures and the reciprocal of the melting point (31) is quantitatively confirmed. Alkali stearates show batch-to-batch and intermanufacturer variability in acid composition and should be screened for during formulation studies.

In Vivo Pharmacokinetics of Triazinate in L-1210 and W-256 Cells

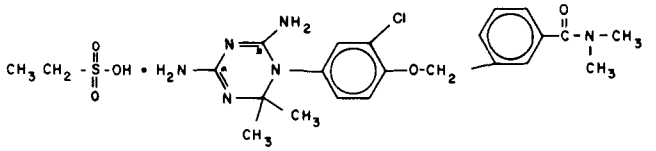
J. GREGORY TOWNSEND *§, **RAKESH K. JAIN** *x, and **ARLENE R. CASHMORE** ‡

Received April 6, 1981, from the *Department of Chemical Engineering, Carnegie-Mellon University, Pittsburgh, PA 15213 and the ‡Department of Pharmacology, Yale University, New Haven, CT 06510. Accepted for publication November 20, 1981. §Present Address: Sun Tech Inc., Process Development, Marcus Hook, PA 19061.

Abstract □ A pharmacokinetic model for triazinate uptake in L-1210 cells in mice and W-256 cells in rats was developed to describe the observed concentration profiles with time in these cells following a 36 mg/m^2 ip injection. The L-1210 cell permeability to triazinate was found to be ~15 times smaller compared with W-256 cells. Similarly, the partition coefficient for L-1210 cells was calculated to be ~175 times smaller than for W-256 cells. Cell membrane permeability appears to be the key parameter determining drug transport at a short time after injection.

Keyphrases □ Pharmacokinetics—of triazinate *in vivo* in L-1210 and W-256 cells □ Binding—*in vivo* pharmacokinetics of triazinate in L-1210 and W-256 cells □ Permeability, cell membrane—*in vivo* pharmacokinetics of triazinate in L-1210 and W-256 cells

Triazinate[1] (I) (NSC-139105) is a triazine folate antagonist which inhibits the enzyme dihydrofolate reductase in nucleic acid synthesis. Triazinate penetrates cells passively (1) unlike another prominent dihydrofolate reductase inhibitor, methotrexate, which enters cells by active transport. Although effective in the cure of Walker 256 ascites tumors, triazinate is not active against the L-1210 leukemia (2). This contrast in antineoplastic activity appears related to the significant accumulation of triazinate in the W-256 cells compared with the L-1210 cells (3). Since differences in drug transport probably account for the marked differences in triazinate activity observed in these cell lines (3), a quantitative analysis of triazinate transport and uptake through a mathematical model may be useful in understanding this behavior.



I

A preliminary pharmacokinetic model for triazinate transport in L-1210 leukemia and W-256 ascites cells is reported based on the uptake data in tumor-bearing mice and rats of Cashmore *et al.* (2). The model parameters include: cell permeabilities, drug–dihydrofolate reductase binding constants, and drug partition coefficients.

EXPERIMENTAL

Details of the experimental procedures are given elsewhere (2). Normal male rats weighing 55 to 60 g were given intraperitoneal inoculations of 5 × 10^6 W-256 ascites cells; normal male mice weighing 25 to 30 g were given intraperitoneal inoculations of 5 × 10^6 L-1210 ascites cells. Four days later, the animals were given intraperitoneal injections of 0.2 μCi[^{14}C]triazinate (0.3 μCi/μmole); this corresponded to dosage levels of 36 mg/m^2 (12 mg/kg in mice and 6 mg/kg in rats).

At intervals from 15 min to 6 hr, three animals of each species were sacrificed. Twelve milliliters of Eagle's minimal essential medium were then injected into the peritoneal cavity, and the ascites cells and fluid were removed. After separation by centrifugation, the cells and supernatant fluids were stored frozen.

The ascites cells were lysed by freeze-thawing twice in four volumes of 0.9% NaCl solution. After centrifugation, 0.5 ml of each supernatant was added to 10.0 ml of scintillation fluid[2] and counted. The counting efficiency, as determined by external standardization and standard curves for the carbon 14 radioactivity in the scintillation fluid, was 80–85%.

Thin-layer chromatography was used to determine whether triazinate was metabolized when administered *in vivo*. Silica gel glass plates[3], 5 × 20 cm, with 0.25-mm coating, were prewashed with ethyl acetate. The solvent system of either 2-methoxyethanol–ethanesulfonic acid (1000:3) or 2-methoxyethanol–glacial acetic acid (1000:3) was used. One milliliter

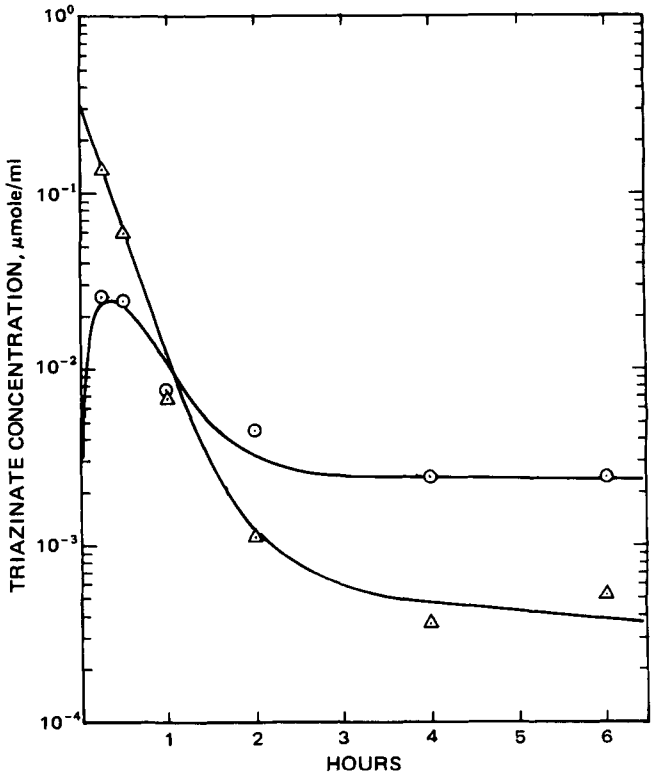


Figure 1—*Concentrations of triazinate in the peritoneal fluid and L-1210 cells as a function of time following injections of 12 mg/kg ip (36 mg/m^2) in mice. Points represent experimental determinations (2). The solid lines represent the peritoneal fluid-forcing function (C_{pe}) and the model predictions of L-1210 cell triazinate concentrations (C_c). The peritoneal fluid triazinate concentration was fitted by the expression:*

$$C_{pe} = 0.286\, e^{-0.0691t} + 0.0741\, e^{-0.0414t} + 0.000707\, e^{-0.00165t}$$

Table I—Model Parameters for L-1210 Ascites Cells in Male Mice and W-256 Ascites Cells in Male Rats

Parameter	Mice (L-1210 cells)	Rats (W-256 cells)
V_c, cell volume, ml	0.21[a]	
V_{pe}, peritoneal cavity volume, ml	1.5[b]	3.1[b]
a, dihydrofolate reductase binding constant, μmole/ml	2.3×10^{-3} [c]	2.2×10^{-4} [d]
ϵ, dissociation constant, μmole/ml	2.2×10^{-8} [e]	
Average protein content[f]		
Cells, mg	69	140
Peritoneal fluid, mg	32.4	56.1
Estimated physicochemical parameters		
PA/V_c, cell permeability or passive transfer coefficient, min^{-1}	0.01	0.15
R, fluid–cell partition coefficient, dimensionless	0.2	35

[a] Calculated from average of experimental measurements of L-1210 cell numbers with time (2) and properties of tumor cells given by Sirotnak and Donsbach(4). [b] Estimated from values of Weissbrod *et al.* (5). [c] Adapted from Goldman *et al.* (6). [d] From Werkheiser (7). [e] Methotrexate dissociation constant from Bischoff *et al.* (8). [f] Experimentally measured.

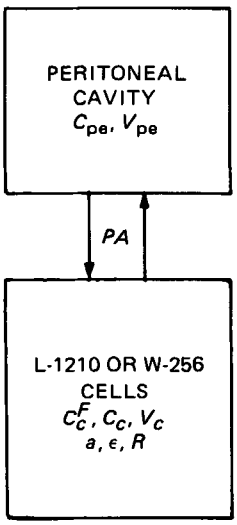
of methanol was added to 0.5 ml of crude cell extract, mixed, and centrifuged, and the resulting solution was evaporated to 0.2 ml. Five microliters of this solution was applied onto the silica gel plates. Reference and control samples consisting of [^{14}C]triazinate, unlabeled triazinate, and control tissue extracts plus [^{14}C]triazinate were run with each set. The plates were run for 3 hr at room temperature and then air dried. Examination under UV light revealed a fluorescent green background with dark quenching spots. The spots were scraped and placed in a counting vial containing the scintillation fluid, and the radioactivity was determined.

No evidence for drug metabolism was obtained using the methanol extracts of tumor cells, as well as liver, kidney, and spleen cells, obtained up to 8 hr after drug administration. Analysis of methanol extracts of urine and feces also indicated no evidence for metabolism of ^{14}C-labeled triazinate in mice or rats.

The values of drug concentrations (in micromoles per milligram of protein) reported previously (2) were converted into micromoles per gram of cells or micromoles per milliliter of ascites fluid in this study using the values given in Table I.

MODEL DEVELOPMENT

A schematic of the model for triazinate pharmacokinetics in tumor cells is shown in Scheme I. The drug is injected into the peritoneal cavity, from which it enters the tumor cells and other body tissues and blood. Previous investigators of methotrexate transport *in vivo* simulated plasma or peritoneal fluid drug concentrations with multiple exponential expressions, which then served as inputs to the tumor model simulations (5, 9, 10). This approach focuses on drug kinetics in the tumor cells and obviates the need to consider details of triazinate distribution in the rest of the body.



Scheme I—*The pharmacokinetic model for triazinate in L-1210 and W-256 cells. Symbols are defined in the text.*

In this study, instantaneous mixing of drug in the peritoneal cavity following intraperitoneal injection is assumed. A three-term exponential decay function of the form:

$$C_{pe} = a_1 e^{-b_1 t} + a_2 e^{-b_2 t} + a_3 e^{-b_3 t} \quad \text{(Eq. 1)}$$

is fit to the available peritoneal fluid concentration (C_{pe}) data as a function of time (t). (Here, $a_1 - a_3$ and $b_1 - b_3$ are empirical constants.) This expression serves as a forcing function in the mass balance for drug accumulation in the tumor cells:

$$\frac{dC_c}{dt} = \left(\frac{PA}{V_c}\right)\left(C_{pe} - \frac{C_c^F}{R}\right) \quad \text{(Eq. 2)}$$

where V_c is the volume of the tumor cells in milliliters; C_c is the total concentration of free and bound triazinate in the cells in micromoles per milliliter; PA is the cell permeability to drug in milliliters per minute; C_{pe} is the triazinate concentration in the peritoneal fluid in micromoles per milliliter; C_c^F is the concentration of free triazinate in the cells in micromoles per milliliter; and R is the partition coefficient relating peritoneal fluid concentration to free tumor cell concentration of triazinate at equilibrium (dimensionless). Drug transport in the model is considered to occur by passive diffusion, with drug binding to dihydrofolate reductase occurring in the cells.

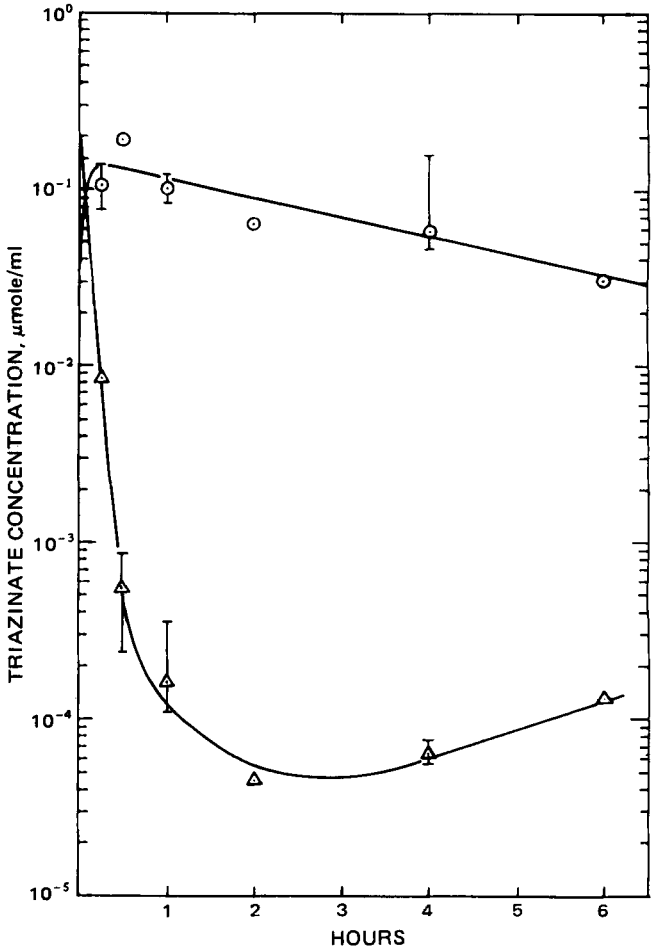


Figure 2—*Concentrations of triazinate in the peritoneal fluid and W-256 cells as a function of time following injections of 6 mg/kg ip (36 mg/m^2) in rats. Points represent experimental determinations (2). The solid lines represent the peritoneal fluid-forcing function (C_{pe}) and the model predictions of W-256 cell triazinate concentration (C_c). The peritoneal fluid triazinate concentration was fitted by the expression:*

$$C_{pe} = 0.203\, e^{-0.213t} + 4.31 \times 10^{-4}\, e^{-0.0224t} + 1.33 \times 10^{-5}\, e^{+0.00639t}$$

Other parameters are given in Table I. The bars represent ranges of the determinations. Key: (⊙) W-256 cells; (△) peritoneal fluid.

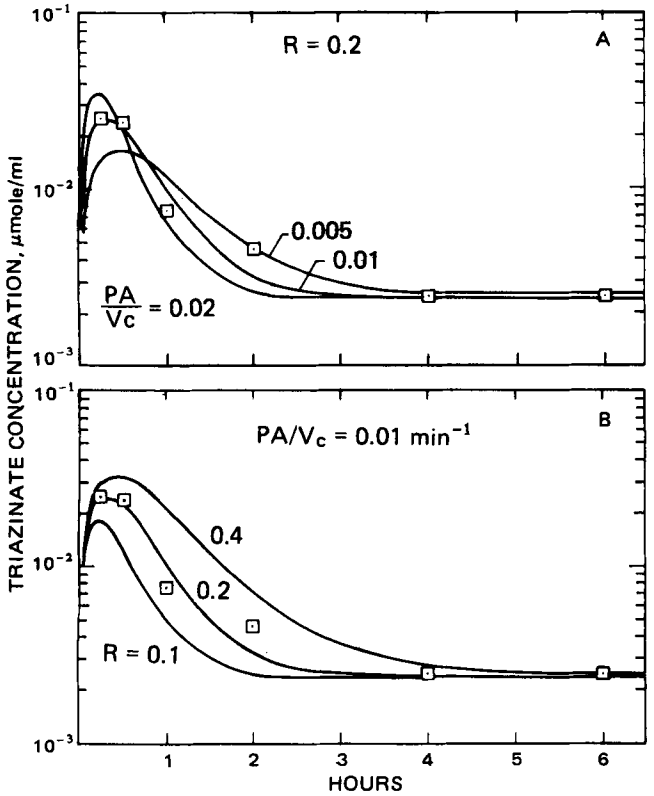

Figure 3—*Sensitivity of the model to changes in the parameters of (A) cell permeability (PA/V$_c$); and (B) partition coefficient (R) for the L-1210 cells in mice following injections of 12 mg/kg ip (36 mg/m^2). The points represent experimental determinations (2). The solid lines represent the model predictions of triazinate concentration in the L-1210 cells as a function of time.*

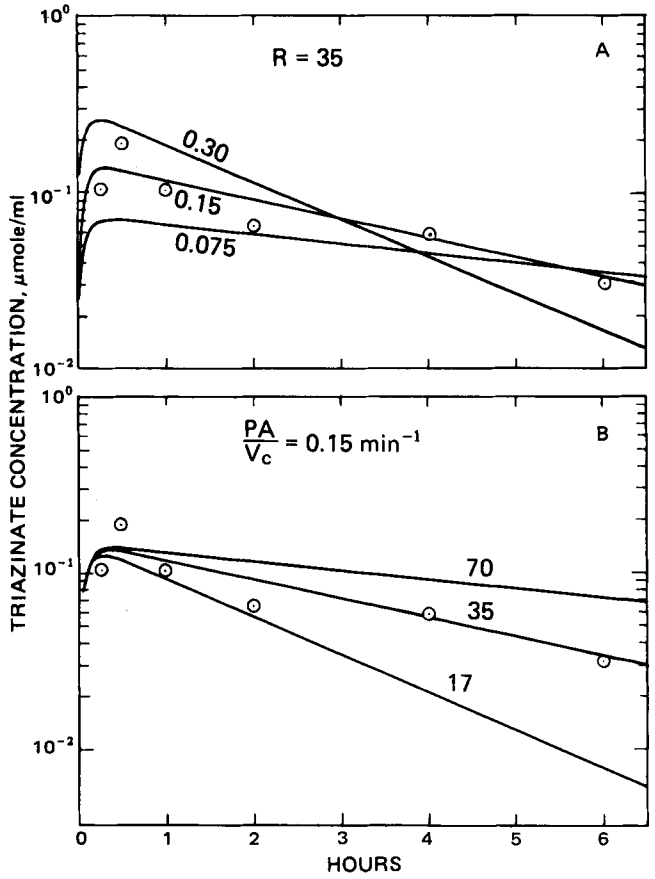

Figure 4—*Sensitivity of the model to changes in the parameters of (A) cell permeability (PA/V$_c$); and (B) partition coefficient (R) for the W-256 cells in rats following injections of 6 mg/kg ip (36 mg/m^2). The points represent experimental determinations (2). The solid lines represent the model predictions of triazinate concentration in the W-256 cells as a function of time.*

The total intracellular triazinate concentration in the tumor cells is the sum of free drug and drug bound to dihydrofolate reductase. The total tumor concentration in the model is related to the free drug concentration by the following relationship used previously for methotrexate (8):

$$C_c = C_c^F + \frac{aC_c^F}{\epsilon + C_c^F} \qquad \text{(Eq. 3)}$$

where a is the drug binding capacity of dihydrofolate reductase and ϵ is the dissociation constant of the drug–enzyme complex, both in micromoles per milliliter.

Values of the tumor cell permeabilities to triazinate, expressed as the quantity PA/V_c (min^{-1}), and the fluid–cell partition coefficients (R) are estimated by fitting Eq. 2 to the available data. These physicochemical parameters are summarized in Table I with the other model parameters. The system equations are solved by a Runge-Kutta routine (11) by computer to yield predictions of tumor cell triazinate concentration as a function of time.

RESULTS

Figures 1 and 2 show the peritoneal fluid and tumor cell concentrations of triazinate after injections of 36 mg/m^2 ip in mice and rats (12 and 6 mg/kg, respectively). The points represent the average of three individual determinations. The solid lines indicate the multiple exponential fits to the peritoneal fluid data and the model predictions of drug uptake by the L-1210 cells in mice (Fig. 1) and the W-256 cells in rats (Fig. 2). The average errors between model predictions and data are 16% for the L-1210 cells and 20% for the W-256 cells.

DISCUSSION

A pharmacokinetic model for triazinate uptake by L-1210 and W-256 ascites cells *in vivo* following a 36 mg/m^2 ip injection adequately simulates the observed concentration–time behavior in these cells. The model includes passive drug transport into the cells and binding of triazinate to intracellular dihydrofolate reductase. Values of binding constants and peritoneal fluid volumes are estimated from the literature (Table I), while the tumor cell volumes and other transport parameters (PA/V_c, R) are determined from the data (2).

A precise value for the dissociation constant (ϵ) for the triazinate–dihydrofolate reductase complex is not available. The value used here is that for methotrexate (8). Because triazinate is more tightly bound to dihydrofolate reductase than methotrexate, the ϵ for triazinate–dihydrofolate reductase should be smaller than ϵ for methotrexate–dihydrofolate reductase. However, since concentrations of free drug in the cells considered here are much greater than the magnitude of ϵ (of order 10^{-8} μmole/ml or less for triazinate), the expression for the amount of intracellular bound drug reduces to:

$$\frac{aC_c^F}{\epsilon + C_c^F} \rightarrow a \text{ (for } C_c^F \gg \epsilon) \qquad \text{(Eq. 4)}$$

Thus, a precise value of ϵ is not required.

The dramatic differences in triazinate uptake by the L-1210 and W-256 ascites cells are reflected in the model parameters determined from this study. The L-1210 cell permeability to drug (0.01 min^{-1}) is significantly smaller than that of the W-256 cells (0.15 min^{-1}), consistent with the observed difficulty of triazinate penetration in the leukemic cells compared with the W-256 cells (2, 3). While a partition coefficient of less than unity was determined for L-1210 cells, the W-256 partition coefficient is 35. These values also reflect the marked differences in drug accumulation in the two cell lines.

To assess the relative importance of permeability and partitioning in drug uptake and retention, a series of computer simulations was carried out. The effects of changing the transport parameters (PA/V_c) and distribution coefficients (R) are shown in Figs. 3 and 4 for the L-1210 cells and the W-256 cells, respectively. Each parameter is increased or decreased twofold while holding the remaining parameter constant. These simulations suggest that the cell permeability (PA/V_c) is the primary determinant of early accumulation of drug in tumor cells.

The preliminary model for triazinate pharmacokinetics presented here provides a logical basis for further investigation of the mechanism of triazinate transport and activity in different tumor lines.

Disposition and Absolute Bioavailability of Furosemide in Healthy Males

ELAINE S. WALLER *[x], STEPHEN F. HAMILTON *, JOSEPH W. MASSARELLA *, MOTRIA A. SHARANEVYCH [‡], ROBERT V. SMITH *, GERALD J. YAKATAN [§], and JAMES T. DOLUISIO *

Received October 23, 1981, from the **Drug Dynamics Institute, College of Pharmacy, The University of Texas at Austin, Austin, TX 78712*, the [‡]*Hoechst-Roussel Pharmaceuticals Inc., Somerville, NJ 08876*, and the [§]*Warner-Lambert Company, Ann Arbor, MI 48105.* Accepted for publication December 10, 1981.

Abstract □ Furosemide (40 mg) was administered to 18 healthy adult males as an intravenous dose, an oral solution, and in tablet form. The pharmacokinetics of intravenous furosemide were studied, determining a total body clearance rate of 117.6 ± 41.3 ml/min and a harmonic mean half-life of 78 min. The mean absolute bioavailability determined by ratio of areas under the plasma–time curves was 64 and 71% for the solution and tablet, respectively. The mean absolute bioavailability determined by the ratio of urinary cumulative excretion data was 61 and 66% for the solution and tablet, respectively. The absolute bioavailabilities of furosemide determined with plasma and urine data were not significantly different. Thus, urine data alone may be used to establish bioavailability of furosemide. Inspection of plasma–time curves revealed secondary maxima in several subjects, suggesting enterohepatic cycling.

Keyphrases □ Furosemide—disposition and absolute bioavailability in healthy males □ Pharmacokinetics—disposition and absolute bioavailability of furosemide in healthy males □ Bioavailability—disposition, furosemide in healthy males

Furosemide is one of a series of anthranilic acid derivatives which is commonly used as a potent diuretic. Depending on the severity of clinical indication for its use, it is usually administered either orally or intravenously. Therefore, it is of interest to determine the bioavailability of oral preparations with respect to intravenous dosing.

Absolute bioavailability of furosemide has been studied previously by several investigators. Intravenous and oral doses of furosemide were administered previously to four subjects and the absolute bioavailability of tablets was determined to be 65%; the oral aqueous solution was 69% bioavailable (1). [^{35}S]Furosemide was administered orally as an aqueous solution to seven volunteers and intravenously to two different volunteers in another study (2). Comparison of the areas under the plasma curves across subjects determined the solution was 67% bioavailable. In a study with six volunteers (3), absolute bioavailability of oral furosemide (dosage form not identified) was found to be 49%. Eleven normal volunteers were studied (4); tablet and solution preparations were determined to be 69% bioavailable.

The present study was conducted to determine the absolute bioavailability of furosemide (40 mg) given in tablet form and as an oral solution to a large population of healthy males. In addition, the feasibility of using urinary excretion data alone to establish bioavailability was investigated. This would allow future bioavailability studies to be conducted without exposing subjects to numerous blood collections.

Absolute bioavailability of furosemide tablets and solution was established by both ratio of the areas under the plasma–time curves and ratio of cumulative excretion data. The disposition of furosemide given intravenously was also determined. Analysis of the resulting data strongly suggests enterohepatic cycling of furosemide.

EXPERIMENTAL

Subject Selection—Twenty-one healthy males, 20–31 years of age (mean 24) weighing between 61 and 83 kg (mean 71), who were in good physical condition as determined by physical examination, volunteered to participate in the study. Informed consent was obtained from each subject[1].

Study Design—An open Latin-square design was used to study 21 subjects divided into three groups of seven. Subjects were randomly as-

The preliminary model for triazinate pharmacokinetics presented here provides a logical basis for further investigation of the mechanism of triazinate transport and activity in different tumor lines.

Disposition and Absolute Bioavailability of Furosemide in Healthy Males

ELAINE S. WALLER *[x], STEPHEN F. HAMILTON *, JOSEPH W. MASSARELLA *, MOTRIA A. SHARANEVYCH [‡], ROBERT V. SMITH *, GERALD J. YAKATAN [§], and JAMES T. DOLUISIO *

Received October 23, 1981, from the **Drug Dynamics Institute, College of Pharmacy, The University of Texas at Austin, Austin, TX 78712*, the [‡]*Hoechst-Roussel Pharmaceuticals Inc., Somerville, NJ 08876*, and the [§]*Warner-Lambert Company, Ann Arbor, MI 48105.* Accepted for publication December 10, 1981.

Abstract □ Furosemide (40 mg) was administered to 18 healthy adult males as an intravenous dose, an oral solution, and in tablet form. The pharmacokinetics of intravenous furosemide were studied, determining a total body clearance rate of 117.6 ± 41.3 ml/min and a harmonic mean half-life of 78 min. The mean absolute bioavailability determined by ratio of areas under the plasma–time curves was 64 and 71% for the solution and tablet, respectively. The mean absolute bioavailability determined by the ratio of urinary cumulative excretion data was 61 and 66% for the solution and tablet, respectively. The absolute bioavailabilities of furosemide determined with plasma and urine data were not significantly different. Thus, urine data alone may be used to establish bioavailability of furosemide. Inspection of plasma–time curves revealed secondary maxima in several subjects, suggesting enterohepatic cycling.

Keyphrases □ Furosemide—disposition and absolute bioavailability in healthy males □ Pharmacokinetics—disposition and absolute bioavailability of furosemide in healthy males □ Bioavailability—disposition, furosemide in healthy males

Furosemide is one of a series of anthranilic acid derivatives which is commonly used as a potent diuretic. Depending on the severity of clinical indication for its use, it is usually administered either orally or intravenously. Therefore, it is of interest to determine the bioavailability of oral preparations with respect to intravenous dosing.

Absolute bioavailability of furosemide has been studied previously by several investigators. Intravenous and oral doses of furosemide were administered previously to four subjects and the absolute bioavailability of tablets was determined to be 65%; the oral aqueous solution was 69% bioavailable (1). [^{35}S]Furosemide was administered orally as an aqueous solution to seven volunteers and intravenously to two different volunteers in another study (2). Comparison of the areas under the plasma curves across subjects determined the solution was 67% bioavailable. In a study with six volunteers (3), absolute bioavailability of oral furosemide (dosage form not identified) was found to be 49%. Eleven normal volunteers were studied (4); tablet and solution preparations were determined to be 69% bioavailable.

The present study was conducted to determine the absolute bioavailability of furosemide (40 mg) given in tablet form and as an oral solution to a large population of healthy males. In addition, the feasibility of using urinary excretion data alone to establish bioavailability was investigated. This would allow future bioavailability studies to be conducted without exposing subjects to numerous blood collections.

Absolute bioavailability of furosemide tablets and solution was established by both ratio of the areas under the plasma–time curves and ratio of cumulative excretion data. The disposition of furosemide given intravenously was also determined. Analysis of the resulting data strongly suggests enterohepatic cycling of furosemide.

EXPERIMENTAL

Subject Selection—Twenty-one healthy males, 20–31 years of age (mean 24) weighing between 61 and 83 kg (mean 71), who were in good physical condition as determined by physical examination, volunteered to participate in the study. Informed consent was obtained from each subject[1].

Study Design—An open Latin-square design was used to study 21 subjects divided into three groups of seven. Subjects were randomly as-

[1] The protocol has approval of the University of Texas at Austin Human Investigation Review Committee.

0022-3549/82/01000-1105$01.00/0

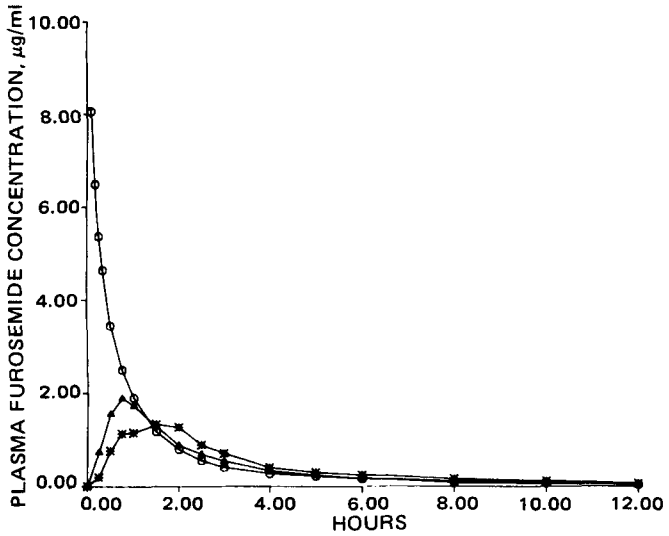

Figure 1—*Mean furosemide plasma concentrations following 40 mg administered as an intravenous solution (○), oral solution (△), and tablet (*) to 18 healthy adult males.*

signed to each group. A single dose of furosemide[2] (40 mg) was administered on 3 different days as an intravenous injection, oral aqueous solution, and tablet. Seven-day washout periods separated the study days.

All subjects abstained from medications, smoking, and alcohol for 1 week prior to and throughout the study. Subjects fasted for 12 hr before each drug administration and 3 hr thereafter. Furosemide tablets were taken with 200 ml of water. Four milliliters of furosemide oral solution was administered with 200 ml of water. The intravenous furosemide dose was injected over a 2-min period.

Following drug administration, blood samples (10 ml) were collected from a forearm vein using a plastic syringe with immediate transfer to heparinized tubes. Blood was collected immediately before and at 0.25, 0.5, 0.75, 1, 1.5, 2, 2.5, 3, 4, 5, 6, 8, 10, and 12 hr after oral drug administration. Blood was collected immediately before and at 5, 10, 15, 20, 30, and 45 min and 1, 1.5, 2, 2.5, 3, 4, 5, 6, 8, 10, and 12 hr after the intravenous injection was completed. Plasma was separated and frozen at −20° until assayed. During each study day, urine was collected immediately before drug administration and for the following periods: 0–1, 1–2, 2–3, 3–4, 4–5, 5–6, 6–8, 8–12, and 12–24 hr. Urine volumes were recorded and an aliquot was frozen at −20° until assayed.

Assay—The plasma and urine specimens were assayed by reversed-phase high-performance liquid chromatography (HPLC) using a method described previously (5). The only substantive change in procedure was the use of hydroflumethiazide as internal standard instead of furosemide methyl ester. The methods described in the literature and used in the author's laboratories are specific for the intact furosemide and showed no interference from its hydrolysis product, 4-chloro-5-sulfamoyl anthranilic acid. Furthermore, no interference was observed at the retention time for the internal standard, hydroflumethiazide.

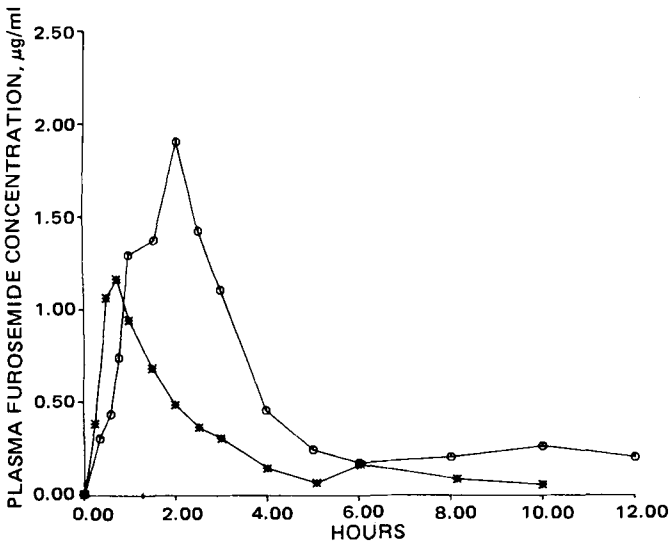

Figure 2—*Furosemide plasma concentrations following 40 mg administered as an intravenous solution to two healthy adult males (Subjects 2 and 13).*

Table I—Pharmacokinetic Parameters (Mean ± *SD*) in 16 Normal Males Following Intravenous Administration of Furosemide (40 mg)

Parameter	Value
A, μg/ml	8.7 ± 2.7
B, μg/ml	2.1 ± 1.3
α, min^{-1}	0.063 ± 0.051
β, min^{-1}	0.0089 ± 0.0052
Ke, min^{-1}	0.028 ± 0.014
K_{21}, min^{-1}	0.021 ± 0.017
K_{12}, min^{-1}	0.024 ± 0.027
$AUC_{0\to\infty}$ μg $min\ ml^{-1}$	374.28 ± 110.49
Vc, liter/kg	0.056 ± 0.017
Vd_{ss}, liter/kg	0.13 ± 0.06
Cl_T, ml/min	117.6 ± 41.3
Cl_R, ml/min	88.9 ± 44.8 (n = 13)
Cl_{NR}, ml/min	32.4 ± 11.9 (n = 13)

The analytical method employed involved extraction of acidified urine or plasma (spiked with internal standard) with a fivefold excess of diethyl ether. In the case of plasma, the ether was reduced to dryness under a stream of nitrogen, the residue reconstituted in glycine buffer (pH 11.0), and subjected to chromatographic development. Urine ether extracts were back-extracted with glycine buffer (pH 11.0) and the latter alkaline extracts subjected to HPLC. Peak areas (furosemide and internal standard) were determined with a computing integrator dedicated to the HPLC apparatus used in the determinations. Peak area ratios from samples were compared with similar data developed from eight standard samples for plasma determinations (in the range of 0.05–20.05 μg/ml) and five standard samples for urine determinations (in the range of 0.1–50.0 μg/ml), which were used in preparing standard curves ($r \geq 0.999$). The average relative standard deviation of the standard samples for plasma determinations was 7.3%; 2.6% was found for urine determinations. All samples were protected from light prior to analysis.

Data Analysis—Area under the plasma concentration–time curve (AUC) was calculated for 0–12 hr using the trapezoidal rule. The $AUC_{0\to\infty}$ for intravenously administered furosemide included a terminal slope correction factor, Cp^n/β, where Cp^n is the last measured concentration–time point, and β is the slope of the terminal log-linear phase of the semilog plot of concentration *versus* time. The maximum plasma concentration achieved (Cp_{max}) and time to maximum plasma concentration (t_{max}) were observed from the measured plasma concentrations following oral drug administration.

Plasma concentration data following termination of the rapid intravenous infusion were fitted to the biexponential equation:

$$Cp = Ae^{-\alpha t} + Be^{-\beta t} \qquad \text{(Eq. 1)}$$

where Cp is the plasma concentration in micrograms per milliliter at time t, A and B are pre-exponential terms in units of concentration, and α and β are hybrid first-order rate constants with units of reciprocal time. The data were fitted using nonlinear least-squares regression analysis with the program NONLIN (6) (weight = $1/Cp$). Microconstants were calculated for each individual subject using:

$$K_{21} = \frac{A\beta + B\alpha}{A + B} \qquad Ke = \frac{\alpha\beta}{K_{21}} \qquad K_{12} = \alpha + \beta - K_{21} - Ke$$

(Eq. 2)

The volume of distribution of the central compartment (Vc) was calculated from:

$$Vc = \frac{\text{Dose}}{A + B} \qquad \text{(Eq. 3)}$$

The steady-state volume of distribution (Vd_{ss}) was calculated from the definition:

$$Vd_{ss} = \left(1 + \frac{K_{12}}{K_{21}}\right) Vc \qquad \text{(Eq. 4)}$$

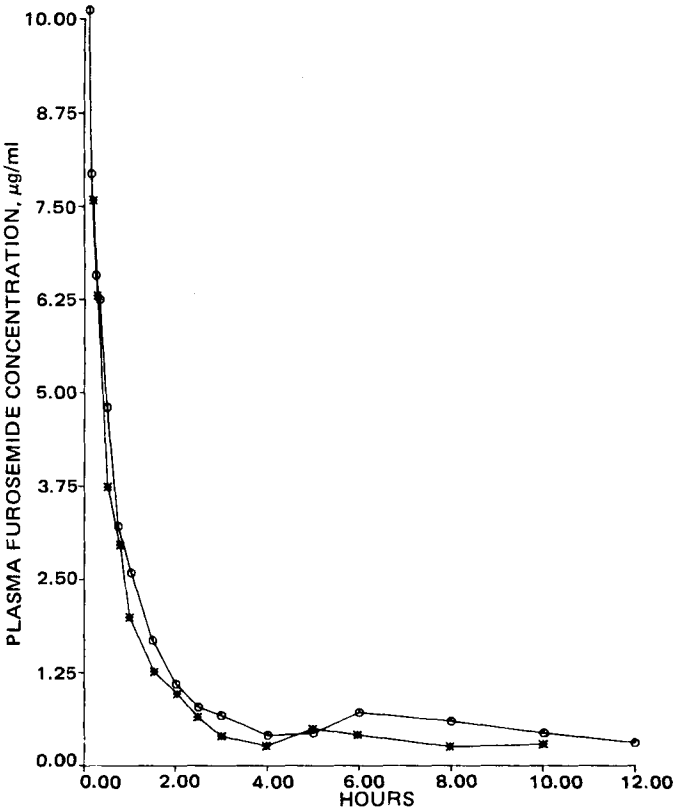

Figure 3—*Furosemide plasma concentrations following 40 mg administered as tablet (*) and oral solution (O) to two healthy adult males (Subjects 8 and 16).*

Total body clearance (Cl_T) was determined from:

$$Cl_T = \frac{\text{Dose}}{AUC_{0\to\infty}} \qquad \text{(Eq. 5)}$$

Renal clearance (Cl_R) was calculated from the relation:

$$Cl_R = \frac{X_{u0\text{-}24}}{AUC_{0\to\infty}} \qquad \text{(Eq. 6)}$$

where $X_{u0\text{-}24}$ is the total amount of unchanged drug eliminated in the urine in 24 hr. The difference between total body clearance and renal clearance was labeled the nonrenal clearance (Cl_{NR}).

The absolute bioavailability (F) was determined from plasma and urine data from:

$$F_{\text{plasma}} = \frac{AUC_{0\text{-}12}^{\text{oral}}}{AUC_{0\text{-}12}^{\text{iv}}} \qquad \text{(Eq. 7)}$$

$$F_{\text{urine}} = \frac{X_{u0\text{-}24}^{\text{oral}}}{X_{u0\text{-}24}^{\text{iv}}} \qquad \text{(Eq. 8)}$$

Analysis of variance with the least significant difference test utilized for *a posteriori* comparison and Student's t test for paired data were used to make statistical evaluations of the data. An α-level of <0.05 was accepted as evidence of statistical significance.

RESULTS AND DISCUSSION

Eighteen subjects completed the study. Three subjects dropped from the study for reasons unrelated to the administered drug. Data collected from these three subjects were not included in the data analysis.

Mean plasma furosemide concentrations given intravenously and orally are depicted in Fig. 1. Two subjects administered the intravenous dose had a second peak in their plasma furosemide concentrations at 5–6 hr. The data from these two subjects were not included in the determination of the disposition of intravenous furosemide. The pharmacokinetic parameters for the remaining 16 subjects are given in Table I. The mean terminal log-linear phase disposition rate constant corresponds to a half-life of 78 min. This is reasonably consistent with other half-life values of 26–72 min following intravenous furosemide dosing (7). Other pharmacokinetic parameters are in agreement with those previously reported in the literature, though the total body clearance of 118 ml/min is among the lower clearance values reported (112–268 ml/min) (7).

Table II—Bioavailability Parameters (Mean ± *SD*) in 18 Normal Males Following Administration of Furosemide (40 mg) [a]

Parameter	Value
$AUC_{0\text{-}12}$ iv, μg min ml^{-1}	383.9 ± 121.9
$AUC_{0\text{-}12}$ solution (μg min ml^{-1})	240.9 ± 98.8
$AUC_{0\text{-}12}$ tablet (μg min ml^{-1})	250.0 ± 116.2
$X_u^{0\text{-}24}$/dose iv	0.71 ± 0.10 (n = 14)
$X_u^{0\text{-}24}$/dose solution	0.41 ± 0.02 (n = 16)
$X_u^{0\text{-}24}$/dose tablet	0.44 ± 0.15
$AUC^{\text{solution}}/AUC^{\text{iv}}$	0.64 ± 0.22
$AUC^{\text{tablet}}/AUC^{\text{iv}}$	0.71 ± 0.35
$X_u^{\text{solution}}/X_u^{\text{iv}}$	0.61 ± 0.17 (n = 12)
$X_u^{\text{tablet}}/X_u^{\text{iv}}$	0.66 ± 0.23 (n = 14)
$Cp_{\max}$ solution, μg/ml	1.8 ± 0.6
$Cp_{\max}$ tablet, μg/ml	1.7 ± 0.9
$t_{\max}$ solution, min	50.1 ± 23.8
$t_{\max}$ tablet, min	86.2 ± 50.3

[a] Given as tablet, oral solution, and intravenous solution.

Individual plasma concentrations in the two subjects with a second peak in plasma furosemide concentrations are displayed in Fig. 2. The appearance of this second peak suggests the possibility of biliary secretion of furosemide and/or metabolite(s) with subsequent reabsorption of the parent drug. An attempt to study biliary secretion of furosemide in humans was made previously (2). This group found increased radioactivity counts in duodenal aspirates of two subjects given intravenous [^{35}S]furosemide with cholecystokinin stimulation. It was not determined if the increased counts represented intact furosemide or metabolites. [^{35}S]-Furosemide was administered intravenously to two dogs, and an average of 51.4% was found in the feces (8). It was deduced that biliary secretion may play a major role in the elimination of furosemide and/or metabolites. In additional work, cannulation of the bile duct with complete bile collection in one dog given intravenous furosemide showed furosemide to be present in the bile[3]. Secondary maxima have been reported in normal subjects given oral furosemide, and biliary recycling was suggested as an explanation (9).

While no conclusive studies have been conducted in humans to determine if furosemide undergoes enterohepatic cycling, the presence of intact furosemide in the bile of one animal species and the observed secondary maxima in the plasma concentration–time curves in two subjects in the present study suggest enterohepatic cycling may occur. This hypothesis is further supported by plasma concentration–time curves obtained from data following oral doses of furosemide. Secondary maxima were seen in several subjects receiving the drug orally; representative curves are shown in Fig. 3.

Mean bioavailability parameters are displayed in Table II. The AUC was truncated at 12 hr because secondary maxima in plasma concentrations obscured the terminal log-linear phase in many subjects, making corrections to $AUC_{0\to\infty}$ unreliable. Because most subjects had plasma concentrations below assay sensitivity or near the sensitivity limit at the time of the last blood sample, a significant portion of the AUC was not lost by not calculating the AUC to infinity. The $AUC_{0\text{-}12}$ for the intravenous dose was significantly greater than the $AUC_{0\text{-}12}$ for either the oral solution or tablet. The mean absolute bioavailability determined from the plasma data was 64 and 71% for the solution and tablet, respectively. The bioavailabilities for the solution and tablet preparations were not statistically significantly different for either the plasma or urine determinations.

The absolute bioavailabilities of furosemide determined with plasma and urine data were not significantly different ($p > 0.05$); however, there was a trend toward a greater bioavailability ratio determined from plasma data, compared with the ratio determined from the urine data. This is similar to previously reported data (2), in which 67% bioavailability of furosemide solution determined from plasma data and 65% bioavailability determined from urinary data was reported. In contrast, 49% bioavailability determined from plasma data was reported and 52% bioavailability determined from urinary data (3). The slightly greater bioavailability determined with plasma data in the present study may possibly be explained by biliary recycling of furosemide. The observed secondary maxima increased the AUC. There was also considerable intrasubject variability in the appearance of these peaks. The bioavailability determined by AUC may be inflated from secondary plasma peaks while the

[3] G. Yakatan and J. Johnston, unpublished data.

bioavailability determined from urine data may give a more accurate reflection of the true bioavailability. Thus, the feasibility of using urinary excretion data alone to determine bioavailability of furosemide is good, given the statistical agreement of absolute bioavailability determined by plasma and urine data. Also, the possibility of overestimation of bioavailability by plasma data because of enterohepatic recycling makes bioavailability determined from urine data appear more reliable.

The t_{max} and Cp_{max} determinations were not statistically significantly different for the tablet and solution. There was a trend toward later peak plasma concentrations following tablet administration, probably due to time required for tablet disintegration and dissolution. The seeming disagreement of Cp_{max} determinations presented in Table II and Fig. 1 is a function of mean data being graphically presented, while the means of individual subjects are presented in the table.

The bioavailabilities of the tablet and solution are essentially the same, though <70% of the dose was absorbed. This suggests the absorption may not be solely dependent on solubility, but may also be limited by absorption occurring only from a specific site in the GI tract. Site-limited absorption may explain intrasubject variability in absolute bioavailability.

In summary, the disposition of intravenous furosemide as determined by this study is in agreement with previous reports. The mean absolute bioavailability determined from cumulative urinary excretion data was 61 and 66% for the solution and tablet, respectively. The bioavailability determined with urine data may be more reliable than bioavailability determined with plasma data because of a possible enterohepatic recycling process. Site-limited absorption of furosemide is suggested.

Determination of Amine Ingredients in Cough–Cold Liquids by Reversed-Phase Ion-Pair High-Performance Liquid Chromatography

G. W. HALSTEAD

Received October 9, 1981, from *Control Analytical Research and Development, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication December 14, 1981.

Abstract □ The chromatographic behavior of phenylephrine, codeine, pseudoephedrine, phenylpropanolamine, methoxyphenamine, pheniramine, pyrilamine, dextromethorphan, and chlorpheniramine was examined by reversed-phase, ion-pair high-performance liquid chromatography. An isocratic chromatographic system was devised for the analysis of cough–cold liquids containing these amine drugs by optimization of the mobile phase ionic strength, buffer pH, pairing ion concentration, and secondary ion concentration. Quantitative recovery and excellent precision were demonstrated for the simultaneous determination of phenylpropanolamine, dextromethorphan, and chlorpheniramine in a typical formulation. The method was successfully applied to various commercial cough–cold liquids for the analysis of a wide range of amine drugs.

Keyphrases □ Cough–cold liquids—determination of amine ingredients by reversed-phase, ion-pair high-performance liquid chromatography □ High-performance liquid chromatography—determination of amine ingredients in cough–cold liquids □ Amine drugs—determination in cough–cold liquids by reversed-phase ion-pair high-performance liquid chromatography

Cough–cold liquids are usually complex formulations containing several active ingredients and a broad spectrum of excipients such as dyes, flavors, sweeteners, and preservatives. Many of these products are designed to be multisymptom preparations typically containing a variety of basic amino compounds acting as antihistamines, decongestants, or cough suppressants. Some of the common amino agents utilized include phenylephrine, phenylpropanolamine, pseudoephedrine, pyrilamine, pheniramine, chlorpheniramine, codeine, and dextromethorphan. The analgesics, phenacetin and acetaminophen, are also commonly found in cough–cold liquids adding further complexity to the list of possible ingredients. Preservatives such as methyl- and propylparaben or sodium benzoate are normally present in a formulation. It was the purpose of this study to develop a simple high-performance liquid

chromatographic (HPLC) procedure capable of determining the full range of amines commonly found in cough–cold liquids. Efforts were concentrated on the simultaneous determination of the antihistamine, chlorpheniramine (I); the decongestant, phenylpropanolamine (II); and the cough suppressant, dextromethorphan (III) in a typical cough–cold liquid. Applicability of the chromatographic separation to these and other amine drugs in a variety of different formulations was demonstrated by the analysis of cough–cold liquids from a variety of different sources.

BACKGROUND

Chromatographic determination of cough–cold amines has previously been performed using GLC (1–3) and ion-pair, reversed-phase HPLC (4–10). The GLC methods are generally less efficient due to the necessity of derivatization of some or all of the amines, and because the sample preparation usually involves an extraction step or evaporation of the sample and redissolution in a suitable solvent. Several of the available HPLC procedures were designed for the determination of one component and are not able to handle all of the amine ingredients found in combination products (4–6, 8). Another chromatographic system for the determination of pseudoephedrine, brompheniramine, and dextromethorphan elutes pseudoephedrine near the solvent front before major excipient peaks (7). This situation is undesirable, since excipient interferences are likely to arise when different formulations from a variety of sources are analyzed. The determination of codeine, phenylpropanolamine, pheniramine, and pyrilamine has also been described (10). This procedure fails to separate the two antihistamines, pheniramine and pyrilamine, and they must be quantitated separately by a spectrophotometric method.

Reversed-phase, ion-paired HPLC was chosen as the most suitable chromatographic system due to the desire for a sample preparation that would require only dilution of the cough–cold liquid prior to injection onto the column. The ideal chromatographic system would use a pairing ion that would not cause precipitation in the samples and yet provide enough retention to resolve the drugs of interest from the formulation excipients. All of the drugs would be adequately resolved and the analysis time should be sufficiently short (*i.e.*, ≤20 min). These goals were accomplished by the manipulation of the mobile phase ionic strength, mobile phase solvent strength, buffer pH, pairing ion concentration, and secondary ion concentration. The results of these studies and an HPLC method for a variety of cough–cold amines that requires a minimum of sample treatment are presented.

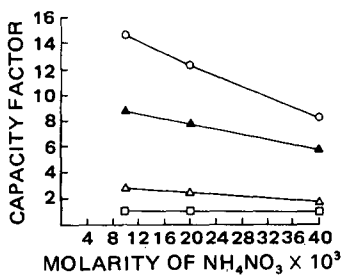

Figure 2—*Relationship between the capacity factor and the concentration of the secondary ion, ammonium nitrate. Key: (△) phenylpropanolamine; (▲) dextromethorphan; (○) chlorpheniramine; (□) propylparaben. Mobile phase: 70% methanol, 0.013* M *sodium dioctylsulfosuccinate, 1.5% glacial acetic acid.*

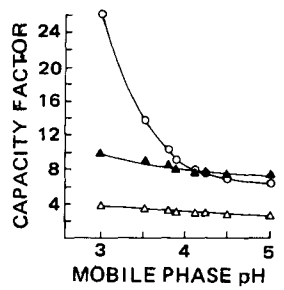

Figure 3—*Relationship between retention and pH of the mobile phase. Key: (△) phenylpropanolamine; (▲) dextromethorphan; (○) chlorpheniramine. Mobile phase: methanol–water–tetrahydrofuran–85% phosphoric acid (68:29:4:1); the sodium dioctyl sulfosuccinate concentration was 0.013* M. *Ammonium hydroxide was used for pH adjustment.*

EXPERIMENTAL

Materials—The various cough–cold ingredients, acetaminophen, guaifenesin, phenacetin, phenylephrine hydrochloride, codeine sulfate, ephedrine sulfate, phenylpropanolamine hydrochloride, methoxyphenamine hydrochloride, pheniramine maleate, benzphetamine hydrochloride, pyrilamine maleate, dextromethorphan hydrobromide, chlorpheniramine maleate, and α-aminopropiophenone were USP-NF quality. Sodium dioctyl sulfosuccinate[1], 3-hydroxy-*N*-methylmorphinan[2], *N*,*N*-dimethylaniline[1], acetophenone[1], methylparaben[2], and propylparaben[2] were used as received. Methanol and tetrahydrofuran were distilled in glass[3], and distilled water was used in all mobile phases. All other chemicals were reagent grade. The cough–cold liquids from various manufacturers were nonprescription products purchased at local drugstores.

Apparatus—A modular high-performance liquid chromatograph, consisting of a reciprocating piston pump equipped with a pulse dampener[4], an automated autosampler[5], a UV detector[6] (254 nm), and a recorder[7], was used for all measurements. For quantitative measurements, data were collected and processed by a digital computer[8].

[a] Internal standard method.

Mobile Phase—The mobile phase was prepared as follows. Methanol (680 ml) was added to 5.8 g of sodium dioctyl sulfosuccinate. Stirring was continued and 290 ml of distilled water, 40 ml of tetrahydrofuran, and 1 ml of 85% phosphoric acid were added. The pH was adjusted to 3.80 ± 0.05 with concentrated ammonium hydroxide solution. The solution was filtered through a 5-μm filter before use.

Separation between dextromethorphan and chlorpheniramine could be increased without affecting the other components by decreasing the pH of the mobile phase. If greater separation was necessary between phenylpropanolamine and the excipients, the methanol content of the mobile phase was decreased.

Columns—A microparticulate octadecylsilane column[9] (10-μm particles, 30 cm × 4 mm) was used throughout this study. The column was washed with a mobile phase consisting of methanol–water–tetrahydrofuran (68:29:4) when not in use to ensure long column life. The column temperature was ambient, column pressure ~2000 psi, injection volume ~50 μl, and the flow rate was 1.3 ml/min. These conditions gave satisfactory chromatography.

Internal Standard Solution—A solution with a concentration of ~7.0 mg/ml of benzphetamine hydrochloride was prepared.

Standard Preparation—About 8.3 mg of phenylpropanolamine hydrochloride, 6.7 mg of dextromethorphan hydrobromide, and 1.3 mg of chlorpheniramine maleate were accurately weighed, and 1.0 ml of the internal standard solution and ~35 ml of the mobile phase were added.

Sample Preparation—An appropriate amount of sample (accurately measured) was diluted with 1.0 ml of internal standard solution and ~30 ml of mobile phase. The resulting solution was mixed for 5 min. The amounts of commercial cough–cold liquid and mobile phase used were varied depending on the drug concentrations in the various products.

Procedure—The sample or standard (50 μl) was chromatographed using the conditions described. The detector setting was ~0.03 aufs. Concentrations were determined by comparison of peak height ratios from sample preparations to those from the standard preparation (USP reference standards were used).

RESULTS AND DISCUSSION

The primary requirements of the chromatographic system would be its ability to separate the amine drugs from the latest eluting excipient peak and yet maintain a chromatographic run time of <20 min. If adequate separation could be obtained, then sample preparation for the cough–cold liquids would merely require dilution of the sample with the mobile phase. Preliminary experiments indicated that the preservative, propylparaben, was the latest eluting excipient in the formulation chosen for initial development. Its retention behavior was compared with those of phenylpropanolamine, dextromethorphan, and chlorpheniramine in later studies to optimize the mobile phase.

The effects of the carbon chain length of the pairing ion on the capacity factors of phenylpropanolamine, dextromethorphan, and chlorpheniramine were initially investigated. The capacity factor of propylparaben was observed to remain nearly constant as the pairing ion was varied due to its presence in the unionized state at the pH of the initial mobile phase (pH 3.3). The chain length of alkylsulfonate or alkylsulfate pairing ions was varied from 6 to 20. It was observed that a pairing ion with a chain length of >12 carbons would be necessary to ensure adequate resolution of phenylpropanolamine from propylparaben. An upper limit on the size of the pairing ion was established by the fact that the C_{20} (eicosyl) pairing ion caused precipitates to form in the diluted syrup samples. Sodium dioctyl sulfosuccinate was ultimately chosen as the pairing ion based on its ability to produce adequate retention of phenylpropanolamine, dextromethorphan, and chlorpheniramine and its solubility, availability, and low cost.

By lowering the methanol content of the mobile phase, the resolution between propylparaben and phenylpropanolamine can be increased to obtain the desired degree of separation but only at the expense of extremely long retention times for chlorpheniramine. At this point it was clear that what was needed was greater selectivity between the amine drugs and propylparaben. Increasing the size of the pairing ion would increase the resolution between phenylpropanolamine and propylparaben, but this approach was unsuccessful due to the formation of precipitates when the samples were diluted with the mobile phase containing these larger pairing ions. Examination of a possible mechanism for retention in ion-paired, reversed-phase chromatography (Eqs. 1 and 2) suggested that a smaller, more soluble pairing ion could be used by increasing its concentration in the mobile phase to increase the k' of the amines while leaving the k' of propylparaben unaffected:

$$k' = \frac{V_s}{V_m}\frac{[R^+ I^-]_{org}}{[R^+]_{aq}} \quad \text{(Eq. 1)}$$

$$k' = \frac{V_s}{V_m} E\,[I^-]_{aq} \quad \text{(Eq. 2)}$$

where

$$E = \frac{[R^+ I^-]_{org}}{[R^+]_{aq}[I^-]_{aq}}$$

k' is the capacity factor, V_s is the volume of the stationary phase, V_m is

See Table III for mobile phase composition.*

the volume of the mobile phase, $[I^-]$ is the concentration of the pairing ion, $[R^+]$ is the concentration of the protonated amine, $[R^+ I^-]$ is the concentration of the ion pair, and E is the extraction constant (11).

The relationship between the capacity factors (k') and the pairing ion concentration for phenylpropanolamine, dextromethorphan, chlorpheniramine, and propylparaben is shown in Fig. 1. Equation 2 predicts k' to be proportional to the pairing ion concentration, and this type of behavior is observed in the early portions of the curves. The optimum pairing ion concentration was chosen as 0.013 M. As expected, the protonated form of propylparaben exhibited no change in capacity factor with increasing pairing ion concentration in the acetate buffer.

In the past, ammonium nitrate had been used in the mobile phase as a secondary ion to improve peak shape and reduce tailing (4, 5). It was initially included here based mainly on past history. Secondary ions compete with the pairing ion to form ion pairs and would be expected to decrease the retention of the amines by effectively decreasing the concentration of dioctyl sulfosuccinate ion pairs in the stationary phase. The effect of the nitrate ion concentration on the retention of phenylpropanolamine, dextromethorphan, chlorpheniramine, and propylparaben is shown in Fig. 2. The retention of the amines is observed to decrease with increasing nitrate ion concentration. As expected, the retention of propylparaben is unaffected by the concentration of the secondary ion. When ammonium nitrate was completely removed from the mobile phase, retention increased while tailing was changed very little. Tetrahydrofuran was added to the mobile phase and was found to be more effective in reducing tailing than nitrate ion.

Adequate resolution between propylparaben and phenylpropanolamine was obtained by increasing the retention with increased pairing ion concentration and removal of the secondary ion from the mobile phase, but the retention time of chlorpheniramine became excessive. The retention of chlorpheniramine was reduced relative to dextromethorphan, phenylpropanolamine, and propylparaben by changing from an acetate buffer to a carefully controlled phosphate buffer system of lower ionic strength. Figure 3 demonstrates the relationship between retention of the amines and mobile phase pH. In the pH region of 3–5, the capacity factors of phenylpropanolamine and dextromethorphan remain relatively constant, while chlorpheniramine's retention changes dramatically. The amine groups of phenylpropanolamine and dextromethorphan (pKa ~10) are fully protonated in this pH range and are behaving as monocations with respect to the ion-pairing system. Chlorpheniramine is capable of being protonated twice with reported pKa values of 4.0 (pyridinium group) and 9.2 (tertiary amine group) (12). In the pH 5.0 region, chlorpheniramine is exhibiting retention behavior more compatible with that of a monocation, while at pH 3.0 the increased retention is due to large concentrations of the dication form. For bivalent sample ions, the capacity factor is predicted to be proportional to the square of the pairing ion concentration (11), and the rapid increase in retention of chlorpheniramine at lower pH is consistent with this proposition. A mobile phase pH of 3.8 was chosen to shorten the chromatographic run time and still retain

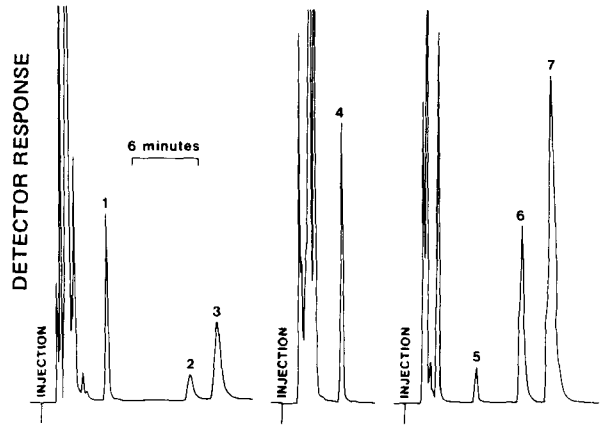

Figure 6—*Chromatograms of three different commercial cough–cold syrups demonstrating the separation of pseudoephedrine (1), dextromethorphan (2), chlorpheniramine (3), codeine (4), phenylpropanolamine (5), pheniramine (6), and pyrilamine (7) from the excipients found in these syrups.*

baseline separation of chlorpheniramine and dextromethorphan. Selectivity between dextromethorphan and chlorpheniramine is affected to such a great extent that the order of elution can be reversed by adjusting the pH of the mobile phase (Fig. 3).

Figure 4 shows a typical chromatogram of a 5.0-ml syrup sample (8.3 mg of phenylpropanolamine hydrochloride, 6.7 mg of dextromethorphan hydrobromide, and 1.3 mg of chlorpheniramine maleate/5 ml) spiked with 1.0 ml of internal standard solution and diluted to ~35 ml with mobile phase. Excellent separation of the three drugs and the internal standard were obtained with all syrup excipients eluting in the early portions of the chromatogram. The percent recovery of phenylpropanolamine, dextromethorphan, and chlorpheniramine from spiked syrup placebo averaged 100.0 ± 0.7 (n = 9), 99.9 ± 1.4 (n = 8), and 99.9 ± 1.1 (n = 8), respectively, over the ranges of 4.1–12.5, 3.2–9.9, and 0.8–1.9 mg/5 ml. Replicate analyses of one lot of cough–cold syrup gave average values of 24.9 ± 0.2 (phenylpropanolamine, theoretical: 25 mg/15 ml), 19.8 ± 0.2 (dextromethorphan, theoretical: 20 mg/15 ml), and 3.97 ± 0.05 (chlorpheniramine, theoretical: 4 mg/15 ml). Data for the first and second day analyses of this lot are given in Table I.

Eight samples of commercial cough–cold liquids containing phenylpropanolamine, dextromethorphan, or chloropheniramine, alone or in combination, were analyzed with no changes in the mobile phase or chromatographic parameters. Good agreement with the labeled content for phenylpropanolamine, dextromethorphan, and chlorpheniramine was obtained (Table II). In each case simple dilution of the sample with mobile phase was used, and no excipient inteference problems were noted with the exception of Sample C where an unknown excipient peak obscured phenylpropanolamine. However, dextromethorphan and chlorpheniramine were successfully quantitated in Sample C. In Sample A dextromethorphan was not adequately resolved from pyrilamine (also present in Sample A) to allow quantitation. Adjustment of the mobile phase pH would undoubtedly increase the separation of dextromethorphan and pyrilamine, since analogous behavior to that observed for chlorpheniramine and dextromethorphan in Fig. 3 would be expected in this case.

The retention behavior of other cough–cold ingredients was also investigated using this assay methodology to test the applicability of the chromatographic system to a wider range of product formulations. Table III lists the capacity factors (k') found for some common cough–cold drugs. Figure 5 contains a chromatogram of the separation of a synthetic mixture of many of these compounds. Commercial cough–cold liquids containing amine drugs other than or in addition to phenylpropanolamine, dextromethorphan, and chlorpheniramine were also investigated (Fig. 6). No excipient interferences were noted in commercial samples containing codeine, pseudoephedrine, methoxyphenamine, pheniramine, and pyrilamine. Analgesics such as acetaminophen eluted near the solvent front and were easily separated from the amine drugs of interest. While quantitation of these amine drugs was not attempted, the applicability of the present methodology to a wide range of amine drugs was confirmed.

The reversed-phase, ion-pairing HPLC procedure described is shown to be precise and accurate for the simultaneous determination of phenylpropanolamine, dextromethorphan, and chlorpheniramine in

cough–cold liquids. In addition, the results indicate that the methodology is applicable to a wide range of amine drugs commonly found in cough–cold liquids. The chromatographic system is capable of separating the amines of interest from the dyes, preservatives, and flavorings normally associated with a liquid cough–cold formulation. In all cases the sample preparation consisted of dissolution of the sample in the mobile phase and the total chromatographic run time was <20 min.

Precise High-Performance Liquid Chromatographic Procedure for the Determination of Cefsulodin, a New Antipseudomonal Cephalosporin Antibiotic, in Plasma

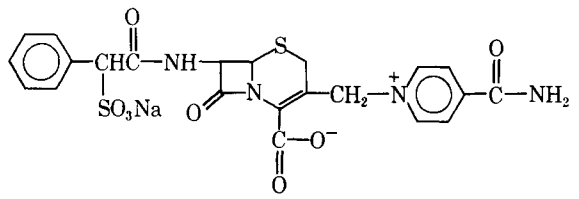
G. RICHARD GRANNEMAN and LAWRENCE T. SENNELLO ˣ

Received August 25, 1981, from the *Drug Metabolism Department, Division of Drug Safety Evaluation, Abbott Laboratories, North Chicago, IL 60064.* Accepted for publication December 9, 1981.

Abstract □ A simple and precise high-performance liquid chromatographic (HPLC) procedure was developed for the determination of cefsulodin, a new antipseudomonal cephalosporin antibiotic, in plasma. The analytical procedure involved ultrafiltration of samples that were buffered to prevent cefsulodin degradation, followed by injection into an HPLC system, utilizing a C_{18} reversed-phase analytical column, a mobile phase of acetonitrile–modified aqueous acetate buffer, and a UV spectrophotometric detector. Because of the simplicity of the procedure, the intraassay (~2%) and interassay (~3–4%) coefficients of variation were extremely low. Recoveries of drug were essentially quantitative in freshly buffered specimens and in those stored buffered and frozen for nearly 3 months. Calibration curves were rectilinear from the limit of quantification (~0.2 μg/ml) to 200 μg/ml, as demonstrated by regression correlation coefficients averaging >0.999 during routine analyses.

Keyphrases □ High-performance liquid chromatography—procedure for the determination of cefsulodin in plasma, new antipseudomonal cephalosporin antibiotic □ Cefsulodin—new cephalosporin antibiotic, high-performance liquid chromatographic determination □ Ultrafiltration—high-performance liquid chromatographic determination of cefsulodin in plasma, new antipseudomonal cephalosporin antibiotic

Cefsulodin sodium [3-(4-carbamoyl-1-pyridiniomethyl) - 7β - (D - α -sulfophenylacetamido) - ceph - 3 - em-4-carboxylate monosodium salt] (I), a semisynthetic cephalosporin antibiotic (Fig. 1)[1], has been shown to have excellent antipseudomonal activity (1, 2).



I

Microbiological assays have traditionally been used for analysis of biological specimens containing antibiotics; however, such procedures are occasionally disadvantageous due to long analysis times, nonlinear calibration curves, inadequate specificity, and relatively poor precision. In addition, preliminary experiments suggested that problems might arise during microbiological assays for cefsulodin due to drug hydrolysis during incubation of inoculated analysis plates.

With these factors in mind, work was started to develop an alternate procedure which had adequate sensitivity, high precision, short analysis time, and which did not allow hydrolysis of the cefsulodin. High-performance liquid chromatography (HPLC) is ideally suited for the analysis of the relatively polar, nonvolatile cephalosporins. Since the therapeutic concentrations of these compounds are usually in the microgram per milliliter range, concentrating techniques are usually not required. However, the majority of the high molecular weight proteins and fibrin must be removed from plasma samples to prevent column filter and bed damage. Several HPLC procedures for cephalosporins, employing classical deproteination reagents such as tri-

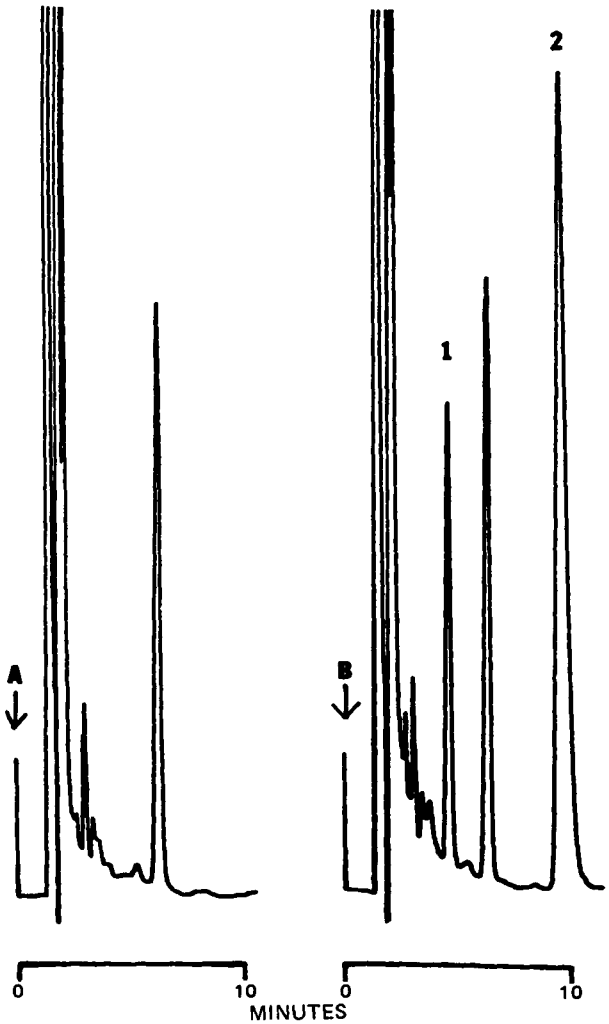

Figure 1—*Typical HPLC traces for ultrafiltrates of (A) predose and (B) postdose plasma from a subject who received a 500-mg dose of cefsulodin. The calculated concentration of cefsulodin was 4.3 μg/ml. Compound II was added to a final concentration in plasma of 400 μg/ml. Key: (1) cefsulodin; (2) II.*

chloroacetic acid (3, 4) or organic solvents (5–8) have been reported recently. The described HPLC procedure, involving removal of plasma proteins by ultrafiltration, offers the advantages of simplicity and high reproducibility, obviating the problems associated with the precipitation procedures, such as sample dilution, incomplete protein precipitation, drug coprecipitation, and acid catalyzed degradation of labile drugs. Furthermore, the ultrafiltration procedure would allow the determination of the free and total drug concentrations in plasma, if desired.

EXPERIMENTAL

Chromatography—HPLC analyses were conducted using a reciprocating pump[2] in conjunction with a UV detector[3] operated at an analytical wavelength of 254 nm. The mobile phase, consisting of 4.5% acetonitrile[4] in 0.02 *M* ammonium acetate, which was adjusted to pH 4.2 with glacial acetic acid, was maintained at a flow rate of 2.0 ml/min through a C_{18}[5] analytical column.

Ultrafiltration Apparatus—Ultrafiltrates of plasma samples were obtained using conical centrifuge tubes[6], conical supports[7], and membrane cones[8], with respective molecular weight cutoff values of 25,000 and 50,000. Use of the former cone model was slightly favored due to its higher apparent flux and protein retentivity. For reasons to be discussed, the two types of cones should not be mixed within an analytical run.

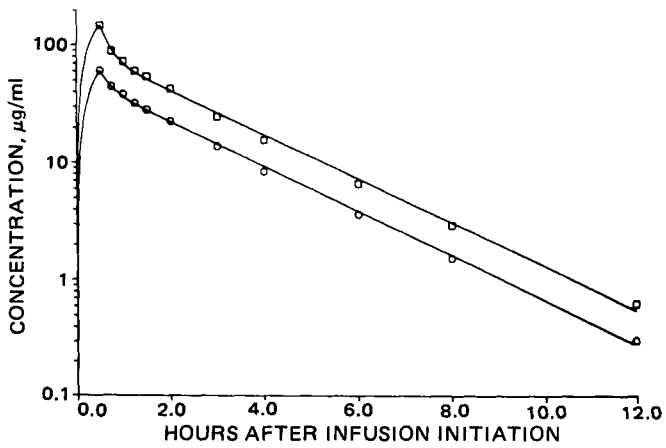

Figure 2—*Plasma cefsulodin levels determined for two subjects receiving 1000-mg (○) and 2000-mg (□), 30-min intravenous infusions of cefsulodin. Plotted curves represent nonlinear best-fit regressions.*

Sample Preparation—The stability of cefsulodin in plasma was demonstrated to be greatly improved by addition of phosphate buffer to bring the final pH to 6.5 or less. Thus, plasma samples should be mixed with an equal volume of 1.0 *M* phosphate buffer (pH 6) prior to freezing.

The 1.0 *M* phosphate buffer (pH 6) was prepared by addition of three parts (by weight) of 1.0 *M* $NaH_2PO_4 \cdot H_2O$ to one part 1.0 *M* $Na_2HPO_4 \cdot 7H_2O$, which was equivalent to 103.5 g of $NaH_2PO_4 \cdot H_2O$ and 67.05 g of $Na_2HPO_4 \cdot 7H_2O$/liter of solution. Mixture of this solution with an equal volume of plasma resulted in a solution with pH 6.1–6.3.

Standard Preparation—Since the plasma samples were diluted by the 1:1 mixture with phosphate buffer, standards had to be diluted similarly. Typically, a 200 μg/ml solution of the reference material, freshly prepared in 1.0 *M* phosphate buffer (pH 6) was mixed with an equal volume of fresh plasma. This standard thereafter was serially diluted with an equivolume mixture of phosphate buffer and plasma to provide the remaining standards.

Sample Workup—Sample processing involved ultrafiltration of a mixture of accurately pipeted aliquants of the sample and internal standard. The use of *p*-fluoro-α-methylbenzylamine hydrochloride (II) as an internal standard was found to be satisfactory. Typically, 0.05 ml of an 8.0 mg/ml solution of II hydrochloride was thoroughly mixed with 2.0 ml of the standards and unknowns. Control blanks and predose samples were processed without internal standard. After transfer to a clean filtration apparatus, the samples were centrifuged at the same relative centrifugal force for the same length of time. Centrifugation at 450×*g* for ~20 min produced ~1.0 ml of ultrafiltrate. Whenever possible, samples in the various stages of workup were refrigerated until all samples were processed. Thereafter, the ultrafiltrates could be stored frozen for several days prior to analysis.

Injection of 70 μl of these ultrafiltrates into the described HPLC system resulted in a nearly full-scale recorder reading for the internal standard (retention volume ~22 ml) at a detector attenuation of 0.02 aufs. Under the same conditions, the response for a sample containing 0.2 g of cefsulodin/ml would be two to three times greater than instrumental noise. To minimize the degradation of cefsulodin in the ultrafiltrates, they should not be allowed to stand at room temperature for more than 2 hr prior to analysis. Typical chromatograms are shown in Fig. 1.

RESULTS AND DISCUSSION

Method Development—*Cleanup Procedures*—Several of the classical procedures for the removal of protein from samples were investigated. Procedures involving deproteination with organic solvents, such as methanol, acetonitrile, and acetone, were all unsatisfactory due to coprecipitation of cefsulodin, chromatographic aberrations due to the

high organic content of directly injected supernates, and degradation of cefsulodin during the evaporation of the supernates. Similarly, other deproteination reagents such as concentrated salt solutions (*e.g.*, sodium sulfate) and acids (*e.g.*, trichloroacetic, sulfosalicylic) were unacceptable due to coprecipitation of cefsulodin, incomplete protein precipitation, cefsulodin degradation, and chromatographic difficulties. Isolation of cefsulodin by column chromatographic techniques, such as anion and cation exchange, silica absorption, alumina absorption, and gel exclusion, was also not feasible due to inadequate protein removal, sample dilution, and the limited number of samples that could be analyzed per day.

Ultrafiltration proved to be ideally suited for the removal of protein from cefsulodin-containing plasma samples. Due to the low apparent protein binding of cefsulodin in the buffered plasma samples, recoveries were nearly quantitative. However, pressurized ultrafiltration techniques using cells or membrane tubing were slow, cumbersome, and involved variable sample dilution due to the necessity of prewetting the membrane. Alternatively, ultrafiltration by centrifugation with the apparatus described was found to be simple, fast, and highly reproducible.

Recovery—The recoveries of cefsulodin and II in the first 50–100 μl of ultrafiltrate were slightly lower than in subsequent fractions. Additionally, in some experiments, the peak height ratio from the initial ultrafiltrate was higher than the true ratio. Lower recoveries for the initial ultrafiltrate may be attributed to one or more of the following phenomena: (*a*) leaching of glycerin or other liquid materials from the membrane; (*b*) low-level binding to the membrane; and/or (*c*) molecular sieving. Regardless, when ultrafiltrate volumes approaching or exceeding 0.50 ml were collected, recoveries were nearly quantitative for both cefsulodin (>95%) and II (>93%), and their peak height ratio became constant.

Intersubject variability in ultrafiltration recovery was assessed by supplementing plasma samples from six subjects with cefsulodin and II. The intersubject coefficient of variation for cefsulodin recovery was 1.3% without II and 1.2% with II as the internal standard. Recovery also did not appear to be dependent on the concentration of cefsulodin in the sample. Mean recoveries for quadruplicate standards ranging from 0.8 to 100 μg/ml averaged 99.1%.

The 25,000 and 50,000 molecular weight cutoff membranes were compared for samples spiked with 2, 20, and 200 μg of cefsulodin/ml. Although the recoveries of cefsulodin were essentially the same for both types of membranes, recoveries of II were slightly lower for the lower cutoff cones. Thus, it is recommended that the two types of filters not be mixed within the same assay run.

Precision and Linearity—The precision and linearity of the procedure was assessed by quadruplicate analyses of buffered plasma samples supplemented with cefsulodin in the concentration range of 0.78–100 μg/ml. The results are summarized in Table I. With no correction made for the internal standard response, the mean assay coefficient of variation (*CV*) was 1.2 ± 1.1%. Correction of the data with the internal standard responses resulted in a mean *CV* of 2.0 ± 1.2%. The errors involved with either approach are uncharacteristically low for the analysis of drugs in biological matrixes. This is due to the simplicity of the workup procedure and the high recoveries.

Linear regression analyses were performed with the mean data from the above experiment, using reciprocal analytical variances as the weights (9). The same data were then refitted using 1, 1/concentration (1/*C*), and 1/concentration-squared ($1/C^2$) as the weighting schemes.

The high correlation coefficients from the regressions (~0.9999) demonstrate that the responses are rectilinearly related to the concentration of cefsulodin in the samples. The near-zero intercepts demonstrate that the blank plasma had negligible interferences for cefsulodin, and that recovery of drug in the ultrafiltrates was not concentration dependent. From careful consideration of the dispersion of the residual errors, the $1/C^2$ weighting scheme was found to best represent the reciprocal analytical variances when the internal standard was not used; hence, weighting by reciprocal squared concentrations should be used in regression analyses of peak height ratio data obtained during sample analyses. Alternatively, if an internal standard is not used, the best choice of the weighting scheme is $1/C$.

The interassay precision of the procedure was assessed from quality control data obtained during routine analyses. For the first application of the procedure to a clinical study, plasma was supplemented on-site at concentrations of 4 and 20 μg/ml of cefsulodin/ml. For the first group of subjects, the quality control standards averaged 3.9 ± 0.2 (n = 9) and 20.0 ± 0.7 (n = 9) μg/ml, respectively. In a second series of analyses, the references averaged 4.0 ± 0.2 (n = 5) and 19.9 ± 0.6 (n = 8) μg/ml. In the most recent use of the procedure, the mean value for a 10.0 μg/ml quality control pool, determined in 20 analytical runs performed over a 1-month period by two technicians, was 10.2 ± 0.3 μg/ml. The mean regression correlation coefficient for the 6–8 point calibration curves was 0.9996. Thus, under routine conditions, the interassay coefficient of variation is ~3–4%, and accuracy errors are negligible.

Stability—Preliminary experiments in this laboratory suggested that 15–40% of the cefsulodin activity in plasma or serum could be lost after storage at ~−17° for 7 weeks, and that the rate of degradation was dependent on the freshness of the plasma. The stability of the compound in buffer was considerably greater, especially in the pH range of 3–7. Degradation of cefsulodin in aqueous media is most pronounced under alkaline conditions, which facilitate isomerization, hydrolysis, and nucleophilic displacement at the various functional centers of the compound. As a result, acidification with phosphate buffer was evaluated as a means of enhancing the stability of cefsulodin in plasma. After incubation at 8° for 3 days, or 24° for 1 day, essentially quantitative recoveries of drug were realized from plasmas which were acidified within the pH range of 3–6.5 with 1.0 *M* phosphate buffer. In contrast, cefsulodin was ~50 and 80% inactivated when stored in unbuffered plasma under the same conditions.

Since sensitivity reduction of the microbiological assay, and protein denaturation were encountered in plasma samples buffered in the pH range of 3–5.5, a final pH of ~6 was found to be the most desirable. An equivolume mixture of plasma and buffer was deemed the most convenient and accurate acidification procedure for diverse clinical settings. Since the implementation of this stabilization procedure, degradation of cefsulodin during frozen storage or workup has not been encountered based on quality control data. In another experiment, the recovery of cefsulodin in frozen plasma was 101.4 ± 1.7% after 36 days and 98.5 ± 1.7% after 81 days; thus, prolonged frozen storage of cefsulodin-containing samples appears to present no significant problems.

Since the half-life of cefsulodin in unbuffered plasma at room temperature is roughly 8 hr, care must be taken to prevent appreciable degradation. Whole blood samples should be cooled prior to the harvest of serum or plasma and the subsequent acidification. After the specimens have been buffered, drug degradation is no longer a serious problem.

Sample Analysis—There are indications that cefsulodin may degrade in the ultrafiltrates at a slightly greater rate than in buffered plasma. Hourly analyses of an ultrafiltrate of a buffered plasma sample containing cefsulodin and internal standard showed that after 15 hr, ~11.7% of the cefsulodin had been lost, and that the concentration was declining at ~0.8%/hr.

Accordingly, on the day of analysis, ultrafiltrates are refrigerated before and after manual injection into the HPLC system, and are usually left at room temperature for <2–3 hr. For automated analyses of large numbers of samples, the ultrafiltrates can be loaded into the sampler in batches of 10–20. Alternatively, for long unattended analyses, standards allowing for compensation for degradation may be interspersed among the samples.

After analysis of over 2000 plasma samples with this procedure, the necessity of altering the described chromatographic conditions has been rare; however, column efficiency loss or chromatographic interference from atypical plasma samples, such as those from patients with severe renal impairment, has occasionally required alternate mobile phases. Generally, small changes in the pH of the eluent greatly affects the relative retention volume of cefsulodin and plasma components, providing flexibility for difficult separations. For extremely difficult separations, the use of an ion-pair reversed-phase system, employing tetrabutylam-

monium (III) as the counter ion, has been used successfully. To compensate for addition of 0.005 *M* III to the regular mobile phase, the acetonitrile content must be increased to ~12%. Since cefsulodin, by virtue of its sulfonic acid moiety, is more acidic than most compounds encountered in plasma, the III-containing mobile phases provide additional versatility. Although II cannot be used as the internal standard in such a system, analytical precision is not compromised, due to the extreme simplicity and quantitative recoveries of the ultrafiltration procedure.

Figure 2 shows the results of the analysis of plasma samples from two subjects who received single 1000- and 2000-mg, 30-min intravenous infusions of cefsulodin. The solid lines represent the nonlinear best-fit regressions calculated for these data.

Comparison to Microbiological Assay Procedures—In the first application of this HPLC procedure to a clinical study, 270 plasma samples were assayed both microbiologically, using *Pseudomonas aeruginosa* (NCTC 10490) as the test organism, and with HPLC as described. Figure 3 shows that results from the two procedures were highly correlated. Linear regression of the data yielded a correlation coefficient of 0.993.

The centrifugal ultrafiltration technique is a good alternative to classical deproteinization procedures because it is rapid and simple and requires no sample adulteration. For more highly protein-bound compounds, the ultrafiltration procedure allows direct quantification of unbound drug levels.

Simultaneous Assay of Hydrocodone Bitartrate and Acetaminophen in a Tablet Formulation

WARREN E. WALLO ˣ and ANTHONY D'ADAMO

Received September 1, 1981, from the *Analytical Research Department, Knoll Pharmaceutical Co., Whippany, NJ 07981.* Accepted for publication December 11, 1981.

Abstract □ A reversed-phase pressurized liquid chromatographic procedure is presented for the simultaneous quantitation of hydrocodone bitartrate and acetaminophen in a tablet formulation. The separation method was based on an octadecylsilane column with a buffered (pH 4.5) methanol–water mobile phase. Measurement was with a UV spectrophotometer set at 283 nm, compared to external standards. Assays for the active ingredients in tablet samples averaged 99.7% of the label claim for hydrocodone bitartrate and 100.3% for acetaminophen. The respective relative standard deviations of the retention time and precision were 2.2 and 1.75% for hydrocodone and 3.3 and 0.95% for acetaminophen. The range of interest studied was 0.035 to 0.065 mg/ml for hydrocodone bitartrate and 3.50 to 6.50 mg/ml for acetaminophen. The assay method was also compared to colorimetric and USP procedures for the active ingredients. The method was suitable for control, content uniformity, and stability-indicating use.

Keyphrases □ Hydrocodone bitartrate—simultaneous assay in a tablet formulation, acetaminophen □ Acetaminophen—simultaneous assay in a tablet formulation, hydrocodone bitartrate □ Tablet formulation—simultaneous assay of hydrocodone bitartrate and acetaminophen

The determinations of acetaminophen (I), hydrocodone (II), and related compounds have been reported by gas (1–3) and high-pressure liquid chromatographic (HPLC) methods (4–14). However, none of the methods has been applied to the simultaneous determination of these compounds.

Due to interferences, the pharmacopeial procedures for the individual drugs are also unsuitable for simultaneous analysis (15, 16). In addition, the authors are not aware of any published stability-indicating method for hydrocodone.

The present report presents an HPLC method for the quantitative analysis of both substances in a two-component tablet formulation. The content uniformity test of the minor component (II) in the tablet formulation is also feasible by this method. An analysis can be conducted in <13 min and separates possible impurities and degradation products.

EXPERIMENTAL

Reagents and Materials—Water and methanol were HPLC grade solvents. Hydrocodone bitartrate, acetaminophen, codeine phosphate, and hydromorphone hydrochloride were USP reference standards. Other materials were ACS grade or the highest quality commercial grade available.

The high-pressure liquid chromatograph[1] was connected to an automatic sampler[2], a variable wavelength UV detector[3], and an integrator/recorder[4]. A bonded reversed-phase C_{18} column[5] was used.

Chromatographic Conditions—The mobile phase consisted of 25% methanol and 75% of an aqueous solution containing 0.01 *N* monobasic potassium phosphate and 0.05 *N* potassium nitrate, adjusted to a pH of ~4.5 by dropwise addition of 3 *N* phosphoric acid solution. The mobile phase was degassed prior to use by vacuum. A flow rate of ~1.1 ml/min was established. The detector sensitivity was 2.0 aufs for acetaminophen and 0.010 aufs for hydrocodone, both measured at 283 nm. The chart speed was 0.7 cm/min.

External Standard Solutions—A two-component standard solution containing 5 mg/ml of I and 0.05 mg/ml of II bitartrate was prepared in water.

0022-3549/82/01000-1115$01.00/0

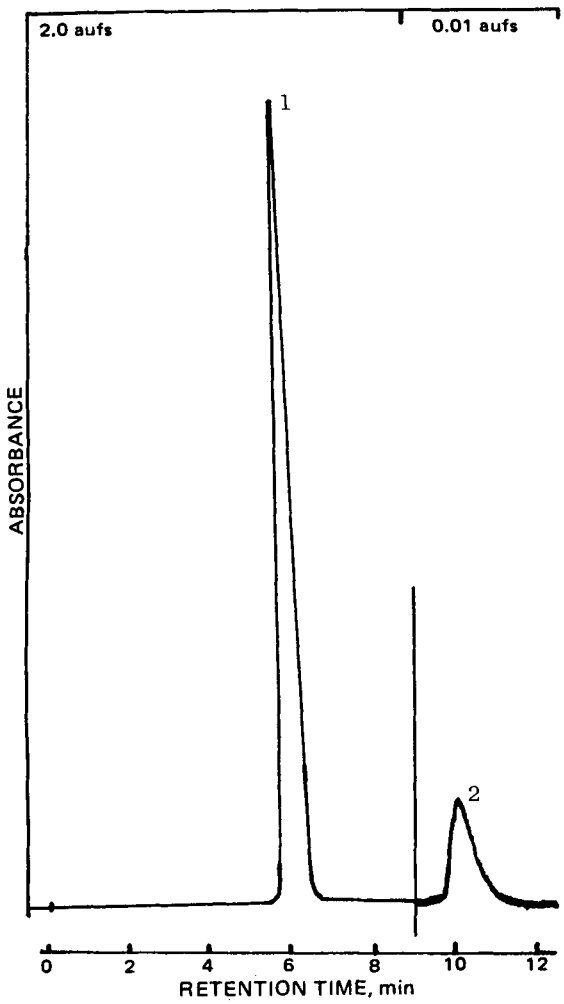

Figure 1—*HPLC chromatogram for standard preparation of (1) acetaminophen and (2) hydrocodone.*

Sample Preparation—For the content uniformity test and tablet composite assay, a tablet[6] or an amount equivalent to 1 average tablet was transferred to a 100-ml volumetric flask. About 95 ml of water was added and the flask was placed on a steam bath. After 15 min, the flask was removed, mixed for 15 min, sonicated, and allowed to stand. A portion of this solution was filtered[7] and placed in a sealed vial[8].

Assay Method—Equal volumes (~13 μl) of standard preparations and assay preparations were introduced into the HPLC operated at room temperature by means of the automatic injector.

Calculation—Quantitation was done by measuring peak heights electronically compared to external standards. To determine the number of milligrams per tablet of acetaminophen, the following equation was used:

$$\frac{Pha}{Phs} \times \frac{Ws}{5} \times \frac{ATW}{Wa} \qquad \text{(Eq. 1)}$$

Similarly, for the mg/tablet hydrocodone bitartrate:

$$\frac{Pha}{Phs} \times Ws \times 4 \times \frac{ATW}{Wa} \qquad \text{(Eq. 2)}$$

where *Pha* is the average peak height of the assay preparation; *Phs* is the average peak height of the standard preparation; *Ws* is the weight of the standard in milligrams; *Wa* is the weight of the assay sample in milligrams; and *ATW* is the average tablet weight in milligrams.

Accelerated Decomposition Studies—Accelerated, extreme degradation of hydrocodone bitartrate was accomplished by several methods and its peak height was measured by data module integration:

(a) Hydrocodone bitartrate powder was heated at 105° for 1-week.
(b) Hydrocodone bitartrate (1 mg/ml) was refluxed in 0.1 *N* NaOH for 24 hr.
(c) Hydrocodone bitartrate (1 mg/ml) was refluxed in 1.0 *N* HCl for 48 hr.
(d) Hydrocodone bitartrate (1 mg/ml) was dissolved in water, placed in a quartz cell, and irradiated with a 275-watt sunlamp for 2 hr.
(e) Hydrocodone bitartrate (1 mg/ml) was dissolved in 3% H_2O_2 and allowed to stand for 1 month.

These decomposition studies were compared with the following control samples:
(a) Hydrocodone bitartrate dissolved in water (1 mg/ml).
(b) Hydrocodone bitartrate refluxed in aqueous solution (1 mg/ml) for 24 hr.

Precision Analysis—Ten tablets were weighed then powdered by mortar and pestle. An amount of powder equivalent to about one average tablet was accurately weighed and transferred to each of eight separate 100-ml volumetric flasks. These samples were treated as described in *Sample Preparation*. Duplicate injections of each sample solution were made.

Accuracy Analysis—Known amounts at the 100% of tablet claim of hydrocodone bitartrate and acetaminophen were added to a placebo powder mixture dissolved in water. This sample was treated as described and six replicate injections were made into the high-pressure liquid chromatograph.

RESULTS

In a typical standard run, good separation of I and II can be seen (Fig. 1). The following related compounds were shown to be separable by this

[a] Vicodin tablets. [b] Based on method by Das Gupta (Ref. 17).

method: *p*-aminophenol, *p*-chloroacetanilide, codeine, and hydromorphone. The two compounds, *p*-aminophenol and *p*-chloroacetanilide, are possible hydrolysis and precursor compounds, respectively, of acetaminophen (17). Codeine and hydromorphone are narcotic drugs chemically related to hydrocodone. This separation demonstrates the specificity of the assay. The respective retention times of the related compounds are listed in Table I.

Linearity—Calibration standard solutions were prepared at 10% intervals between 70 and 130% levels in the expected range of analysis. A plot of peak heights *versus* the amount of the two components injected was linear as evidenced by a correlation coefficient of 0.998 for I between 3.5 and 6.5 mg/ml and 0.996 for II between 0.035 and 0.065 mg/ml.

Accuracy—In a study of a spiked placebo, results showed a mean accuracy of 100.3% for I and 99.7% for II. No interference due to the placebo ingredients could be detected in the chromatograms produced. Reproducibility of retention time was sufficiently precise to ensure separation and identity of I and II (Table II).

Precision—The relative standard deviations for eight samples of a commercial tablet were 0.95% for I and 1.75% for II (Table III). Comparison of this HPLC method and the bromothymol blue complex method for II and the USP method for I are shown in Table IV. HPLC assay results on these commercial tablet samples varied on an average of 2.3% from those of the USP assay for I and 1.45% from those of the dye complex assay for II.

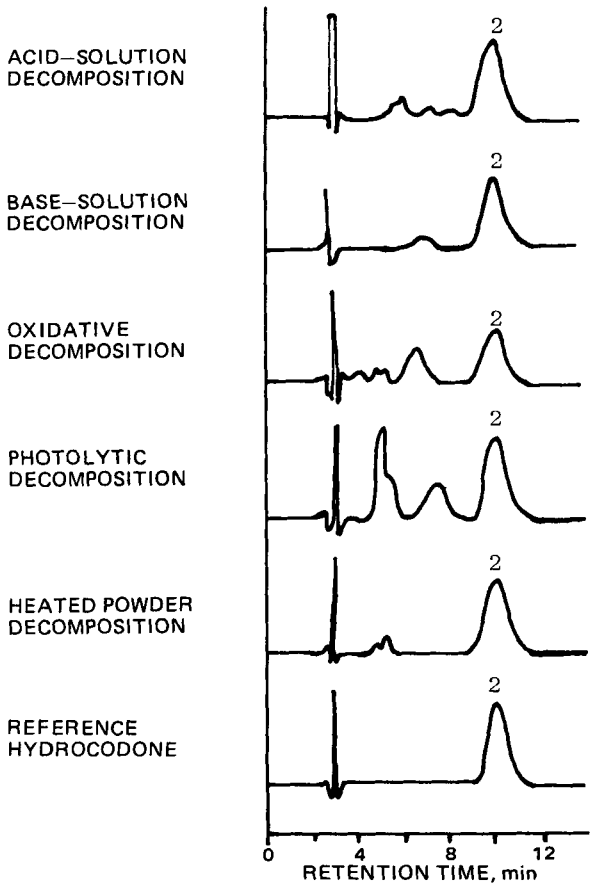

Figure 2—*Retention times of decomposition products resulting from extreme, accelerated decomposition studies of (Ref. 2) hydrocodone.*

Decomposition—No extraneous peak was detected in the analysis of the sample hydrocodone refluxed in water for 24 hr. Comparison of the chromatogram with USP reference standard hydrocodone bitartrate control solution showed a 100% quantitative recovery. Similar measurements of the main chromatographic peak from the decomposed solutions showed various amounts of residual drug depending on its treatment (Fig. 2).

The quantities remaining were found to be 81% after thermal, 79% after base hydrolysis, 87% after acid hydrolysis, 94% after UV photolysis, and 62% after oxidative treatment.

DISCUSSION

The proposed method requires less time than the USP method for acetaminophen tablets (15) which requires column preparation, elution, and absorbance measurements. A titration of an extract is reported for hydrocodone bitartrate tablets (16). For control assay purposes, a colorimetric ion-pairing assay has been adapted in this laboratory for determining II as described for codeine (17).

The chromatographic difficulty associated with the simultaneous quantitation of acetaminophen and codeine has been reported (12). The problem is even more severe in this dosage form. The quantitation of the 100:1 ratio of I to II is made possible by the electronic data module and optimum wavelength absorbance for II. For the tablet product, extracting the dosage form with water completely dissolved both components. Attention to detail in the chromatographic process was necessary so that the peak height of acetaminophen would be as large as possible without overloading the detector, thereby allowing the hydrocodone peak to be more easily and reproducibly quantitated. The elution times are also important, since band broadening increases with increasing elution time and subsequently decreases the peak height. In an additional analysis using the above method, a 10:1 weight ratio of acetaminophen to codeine was assayed simultaneously by measurements at the maximum wavelength of codeine.

The HPLC separation of degradation impurities that result when II is subjected to accelerated extreme decomposition is demonstrated in Fig. 2. The quantitative and qualitative content of unchanged II is easily determined, showing the stability-indicating nature of the analysis. To eliminate the possibility of an interference, no internal standard is employed. In this two-component solid dosage with many possible impurities and degradation products, this approach appears preferable.

It may be possible for a stress-produced degradation product of II to be within the peak for I. However, the response for I (>100:1) is so large

Table V—Comparison of Content Uniformity Assay for Hydrocodone Bitartrate by HPLC and by Ion-Pairing Method

Sample	Hydrocodone Bitartrate, %		
	HPLC	Ion-Pairing	Deviation
1	94.5	90.5	−4.0
2	95.9	96.1	+0.2
3	102.3	98.2	−4.1
4	95.4	91.8	−3.6
5	101.0	100.5	−0.5
6	96.1	94.3	−1.8
7	103.7	100.0	−3.7
8	98.4	98.6	+0.2
9	102.5	100.9	−1.6
10	103.4	102.3	−1.1
Average	99.3	97.3	−2.0

compared with II that the effect on I would be insignificant. In addition, the analysis for intact II is sufficiently specific and quantitative for stability purposes. The known degradation product, *p*-aminophenol, and the impurity of I have different retention times compared with II (Table I). Good assay data have been obtained for several 5-year-old tablet samples. Since there was only an interest in the strength of the hydrocodone, no attempt was made to identify the decomposition products formed under stress.

For the content uniformity run, aliquots of the same 10 tablet samples were assayed by the HPLC and ion-pairing methods for II as paired comparison. Assay data for the ion-pairing analysis are generally lower compared with HPLC (Table V).

Through the utilization of the selected wavelength of maximum absorbance for II, this procedure is being routinely used as an automated simultaneous determination. The HPLC method reported in this study allows for rapid, specific, stability-indicating, and simultaneous quantitation of both substances in a two-component tablet formulation.

High-Pressure Liquid Chromatographic Assays for Ticarcillin in Serum and Urine

R. H. KWAN, S. M. MacLEOD, M. SPINO, and F. W. TEARE *x

Received April 6, 1981, from the **Faculty of Pharmacy, University of Toronto, Toronto, Ontario M5S 1A1, Canada*, and the *Department of Clinical Pharmacology, The Hospital for Sick Children, Toronto, Ontario M5S 1A1, Canada.* Accepted for publication December 9, 1981.

Abstract □ Rapid and sensitive high-pressure liquid chromatographic (HPLC) assays for ticarcillin in serum and urine have been developed. Sample pretreatment and optimized chromatographic conditions are presented for a C-18-bonded reversed-phase column used in an internal standard assay method. Ticarcillin has a retention time of ~5.3 min at a flow rate of 1.5 ml/min for a mobile phase of acetonitrile–aqueous 0.06 *M* sodium biphosphate, pH 2.05, (50.5:100). In a two-step extraction procedure, the ticarcillin extraction efficiencies from serum and urine were 76.1 ± 4.7 and 80.9 ± 3.2%, respectively. The assay sensitivity limit for ticarcillin in these fluids is ~1.0 μg/ml. A comparison is made of the HPLC and microbiological assay results for ticarcillin in 20 different but equally divided serum samples obtained from two volunteers.

Keyphrases □ Ticarcillin—high-pressure liquid chromatographic assays, serum and urine □ Urine—ticarcillin, high-pressure liquid chromatographic assays, serum □ Serum—ticarcillin, high-pressure liquid chromatographic assays, urine □ High-pressure liquid chromatography—ticarcillin in serum and urine

During the past decade, measurements of ticarcillin concentrations in clinical studies have been performed mainly by microbiological assays (1–9). A microtitration method (10, 11) has been applied to broth. Although numerous chemical and physical assay methods have been reported for the detection and assay of penicillins, they suffer from a variety of disadvantages. For instance, iodometric titration (12–15) cannot be applied to penicillins having unsaturated side chains. Spectrophotometric methods (16–18) are not very sensitive and a colorimetric assay (19–21) involving the reaction of hydroxylamine with penicillins in the presence of ferric ions to form a colored salt lacks both specificity and sensitivity, having a limit of ~20 μg/ml. A spectrofluorometric assay (22) has application only for fluorophoric penicillins. More recently, precise, convenient, and specific HPLC assays for various penicillins have been reported (23–29).

At the time the present study commenced there was, to the best of our knowledge, no HPLC assay reported for ticarcillin in biological fluids. This report presents a rapid, specific, and accurate HPLC assay for ticarcillin in human serum and urine.

EXPERIMENTAL

Materials—Powdered ticarcillin[1] (disodium salt) and carbenicillin[2], the internal standard, were used as received without further purification as standards. All solvents and reagents were analytical reagent grade, except for acetonitrile[3] which was HPLC grade, 190 nm cutoff.

Apparatus—The HPLC pump[4] was fitted with an injector[5] and variable wavelength detector[6] set at 210 nm and attenuated at 0.04 aufs. The signal was recorded either on a 10-mV recorder[7] at a speed of 0.5 cm/min or an integrator-plotter[8].

Columns—A prepacked 10- × 0.8-cm i.d. cartridge[9] containing a reversed-phase, C-18, chemically bonded to 10 μm of silica, and contained in a radial compression device[10] was employed at ambient temperature. A guard column[11] was placed between the injector and the column. Ti-
