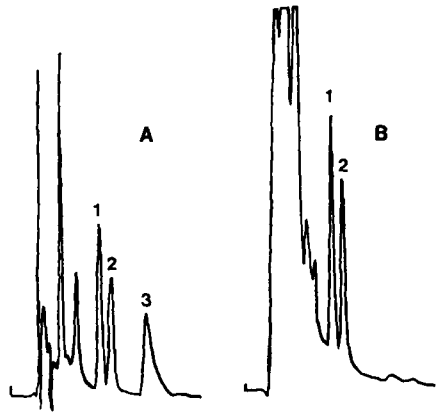

Figure 1—*Typical chromatograms of ticarcillin and carbenicillin (internal standard) in(A) serum and (B) urine sample. Peaks: (1) ticarcillin, (2) carbenicillin, and (3) endogenous material.*

carcillin sample and standard solutions containing the internal standard were injected in 10-, 25-, and 50-μl volumes with microliter syringes[12] into the injector valve.

Mobile Phase—A solution was prepared consisting of acetonitrile–aqueous 0.06 *M* sodium biphosphate (50.5:100), and the pH was adjusted to 2.05 with ~35 ml of 85% phosphoric acid. This solution was filtered and degassed by passage through a membrane filter[13] under reduced pressure. The mobile phase was pumped isocratically through the column at ambient temperature with a flow rate of 1.5 ml/min under a back pressure of ~350 psi/g.

Internal Standard—Aqueous carbenicillin sodium stock solution containing 59 mg/liter was prepared fresh weekly and stored at 4°. Accurate volume aliquots equivalent to 2.95 μg/50 μl of serum and 14.75 μg/250 μl of urine were used as internal standards in the assay for ticarcillin.

Standard Solutions—An aqueous stock solution of ticarcillin disodium (0.5113 g/100 ml) was prepared weekly and stored at 4°. Serial dilutions were performed daily to prepare six working standards in the range of 0–1400 μg/ml. Serum standards contained 200 μl of human control serum, 10 μl of a working ticarcillin standard solution, and 50 μl of the internal standard solution. Urine standards contained 500 μl of control human urine, 50 μl of a ticarcillin working standard, and 250 μl of the internal standard solution. In each instance calibration curves were initially constructed by plotting the integrated peak area ratios of the standard ticarcillin to internal standard against the corresponding ticarcillin standard concentration. Sample serums and urines were similarly prepared and the measured peak area ratios referred to the calibration curve to read the concentration of ticarcillin present.

Assay Method for Serum—A serum sample (200 μl) was transferred to a 12- × 75-mm polypropylene test tube, followed in succession by 50 μl of internal standard, and 50 μl of 1 *M* sulfuric acid. The tube contents were vigorously agitated with a mechanical mixer[14] for 5 sec, then 1.0 ml of ethyl acetate was added and the tube capped and shaken for 2 min prior to centrifugation[15] for another 2 min. The supernate was transferred to another similar tube and evaporated to dryness under reduced pressure at 35°. To this extract residue was added 200 μl each of methylene chloride and aqueous 0.04 *M* sodium biphosphate, pH 6.8. The tube contents were gently agitated for 1 min then centrifuged for 2 min. The top aqueous layer (~75%) was accurately transferred to another similar test tube and briefly shaken mechanically in a water bath at 35° to remove traces of methylene chloride. An accurate aliquot of 10–50 μl of this final sample solution was injected onto the RP-18 column.

Method for Urine—A 500-μl urine sample was treated in a manner similar to that described for serum, except for the volumes of solvents employed. A 250-μl volume of the internal standard solution was added to the 500-μl urine sample (or known dilution if required) and the mixture extracted once with 2 ml of ethyl acetate. The extract was evaporated to dryness as described for serum and the residue reconstituted in a mixture of 1.0 ml of methylene chloride and 1.0 ml of aqueous 0.04 *M* sodium biphosphate, pH 6.80. Beyond this point the sample was handled in the same manner as that for the serum.

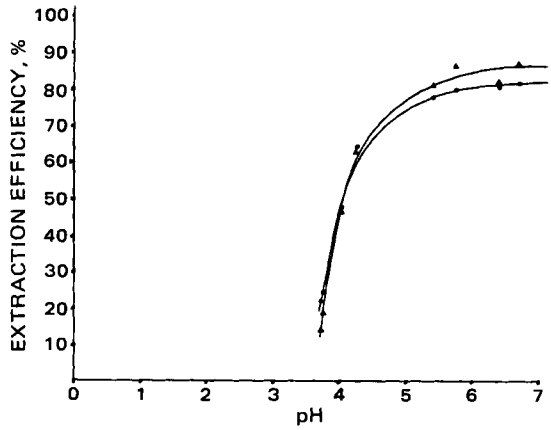

Figure 2—*Extraction efficiency of ticarcillin (●) and carbenicillin (▲) from urine as a function of the pH of the back-extraction phosphate buffer.*

Serum and Urine Collection and Assay—In an HPLC assay *versus* microbiological assay, nine 5-ml blood samples were obtained at specified intervals from each of two healthy volunteers following a 10-min intravenous infusion of a solution containing 2.0 g of ticarcillin disodium. Sera were separated by centrifugation and each was divided into two identical portions. One portion was subjected to a microbiological assay procedure analogous to that of Bannatyne and Cheung (30) and the other to the HPLC assay described. Triplicate determinations were made on each serum sample with both methods.

Concomitantly, urine samples were obtained from one of the volunteers receiving the 2.0-g dose of ticarcillin. Both time and urine volumes were recorded at each collection. Triplicate determinations were performed by the HPLC method only on each urine sample.

RESULTS AND DISCUSSION

The goals were to select a suitable reversed-phase column and mobile phase to separate the two penicillins, then develop a rapid and sensitive HPLC assay for ticarcillin in both serum and urine. The choices of columns and mobile phases studied were made on the basis of good peak symmetry, resolution, and short retention times suitable for measuring many biological samples in a relatively short period with good accuracy.

When the RP-8[16] column was used with several mobile phases, the ticarcillin was either poorly retained or eluted as asymmetric or fused peaks. Whether this result is due to varying degrees of ionization of the two carboxylic acid groups present, to the presence of sterisomeric structures, or to some other cause remains to be shown.

When these same solvent systems were used to elute ticarcillin from

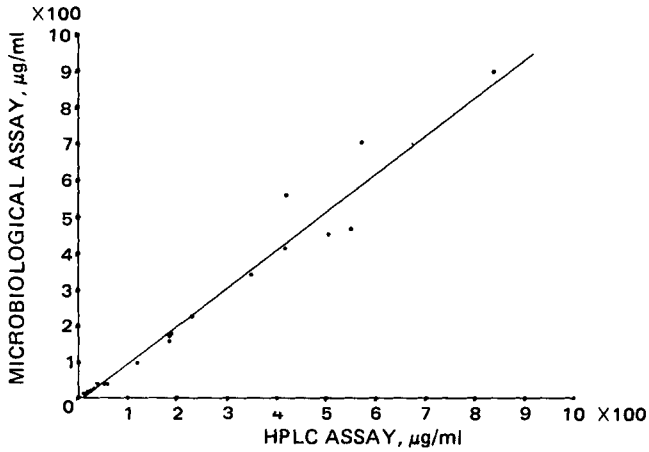

Figure 3—*Comparison of assays for ticarcillin in human urine. Identical samples were assayed by HPLC and microbiological methods. Linear regression analysis of this data yields the equation* $y = 1.0716x - 13.2182$, $r = 0.9809$.

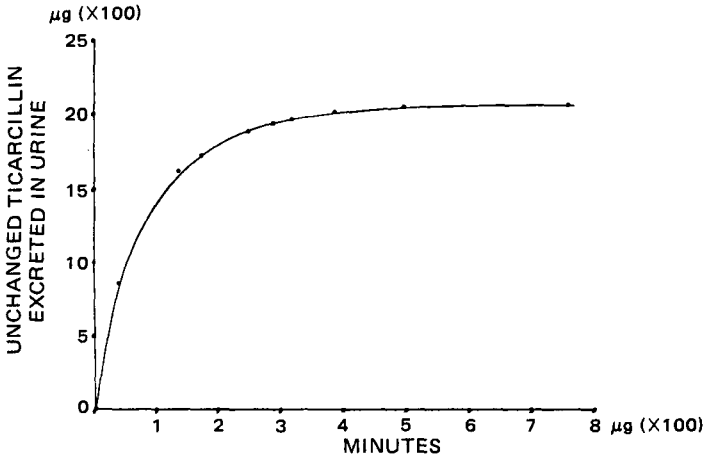

Figure 4—*Cumulative ticarcillin excreted in urine following slow intravenous infusion of a 2-g dose to a 70-kg normal male.*

a RP-2[16] column, retention times were improved, but the problem of fused or asymmetric peaks remains. Among the solvent systems tried was one comprised of 1 liter of aqueous 0.06 *M* sodium biphosphate and 125 ml of acetonitrile plus ~5 ml of 95% phosphoric acid to give a final pH value of 2.75. This mobile phase gave rise to a symmetrical peak for ticarcillin with a reasonable retention time of 5.50 min at a flow rate of 2.0 ml/min. Using the same conditions, except for the adjustment of pH values ranging from 5.0 to 2.0, the retention time was observed to increase from 1.5 to 11.0 min as the acidity increased. At pH values between 2.8 and 3.3, the ticarcillin peak was sharp but too close to the solvent peak resulting from each injection. At a pH of 2.75, both ticarcillin and carbenicillin gave symmetrical and well-resolved peaks having favorable retention times of 5.30 and 6.80 min, respectively.

Another reversed-phase column, RP-18[9], was found to work very well. Since ticarcillin is potentially a relatively polar compound having two carboxylic acid groups, its retention on the nonpolar RP-18 column could be increased through either ion-suppression or the ion-pairing techniques. The former was attempted due to its simplicity. Ticarcillin has a reported pKa value of between 2.70 and 2.73 (31); therefore, a new mobile phase consisting of 505 ml of acetonitrile and 1 liter of 0.06 *M* sodium biphosphate monobasic was adjusted by means of 85% phosphoric acid to a pH of 2.05. Use of this solvent system produced well-resolved, sharp symmetrical peaks at ~5.30 min and 6.00 min for ticarcillin and carbenicillin, respectively, at a flow rate of 1.50 ml/min (Fig. 1). If the pH was 2.20, ticarcillin eluted as two fused peaks at 4.42 and 4.85 min. These observations underscore the necessity of having the mobile phase accurately buffered to a pH of 2.05.

Serum and Urine Assays—Assays were developed using simulated samples. Penicillins lack a strong chromophoric group in their structure. The wavelength of maximum absorption for ticarcillin occurs slightly below 200 nm, and this region would give the highest sensitivity for measurement. However, several endogenous substances in these biological fluids also give rise to absorption leading to interference in this region. Therefore, in order to obtain specificity and maximum sensitivity for ticarcillin, these interferences had to be eliminated. Several approaches (32) were taken to solve this problem. First, several deproteinizing agents such as acetonitrile, cold methanol, and 5% trichloroacetic acid in methanol were investigated. Second, drug extractions using various organic solvents alone were attempted. Finally, organic solvent extraction followed with back-extraction into aqueous buffers was attempted. The protein precipitation method met with little success. The one-step organic solvent extraction of ticarcillin and carbenicillin from serum and urine at pH 2.0 using four volumes of ethyl acetate showed some promise but also extracted interfering endogenous materials. These were slow to elute from the column, interfered with the separation of subsequent sample, and necessitated frequent column cleaning.

A back-extraction of the ethyl acetate extract with 0.04 *M* sodium biphosphate, pH 6.8, to separate the ticarcillin and the internal standard from these biological interferences proved very successful. However, when the UV detector was set at 210 nm, an intense peak appeared (t_r = 5.52 min) which severely interfered with the quantitation of the ticarcillin peak. It was subsequently identified as a peak due to ethyl acetate in the aqueous buffer extract. This problem was circumvented by evaporating the ethyl acetate extract to dryness under reduced pressure at 35°, then adding to the residue equal 0.2-ml volumes of methylene chloride and aqueous 0.04 *M* sodium biphosphate (pH 6.8), and vigorously agitating for 1 min prior to centrifugation for 2 min to separate the immiscible phases. The interfering ethyl acetate remained in the methylene chloride phase, while the two penicillins passed into the aqueous buffer layer. A small trace of interference by methylene chloride was readily removed from the aqueous layer by a brief vigorous agitation at 35° prior to the injection of an aliquot of this phase.

Extraction Efficiency—This was expressed as a percent recovery, defined here as the quotient of the peak height of a ticarcillin standard extracted from the biological fluid divided by the peak height of the corresponding amount of drug prepared as a standard solution in the mobile phase and injected directly, all multiplied by 100. The pH value of the aqueous 0.04 *M* sodium biphosphate used in the back-extraction step had a very important effect on the extraction efficiency of both ticarcillin and carbenicillin as shown in Fig. 2. The recovery of both drugs was optimized at >pH 6.0, and the ratio of the ticarcillin peak height divided by that for carbenicillin became constant. A pH >7 was avoided due to possible base-catalyzed degradation of these penicillins. The mean recovery of six replicate serum standards of ticarcillin and carbenicillin was 76.1 ± 4.7% (*CV* = 6.2%) and 76.3 ± 4.5% (*CV* = 5.8%), respectively. The mean recovery of nine urine standards was 80.9 ± 3.2% (*CV* = 4.0%) and 84.5 ± 5.3% (*CV* = 6.3%), for ticarcillin and carbenicillin, respectively.

Accuracy of the HPLC Assays—The quantitation was based on the internal standard method, *i.e.*, the linearity of the plot of the peak area ratios of ticarcillin standards divided by carbenicillin, *versus* the known concentrations of ticarcillin used in the preparation of the standards in mixed human control serum and urine. The linearity of this plot was determined by linear regression analysis using six serum and six urine ticarcillin standards with each standard concentration measured in duplicate. The results were found to be: $y = 0.0061 + 0.0371x$ ($r = 0.9998$), and $y = 0.0150 + 0.343x$ ($r = 0.9995$), for serum and urine standard curves, respectively. The concentration of ticarcillin in the biological sample was obtained by calculating the peak area ratio, substituting the value for y in the appropriate equation, and solving for x.

HPLC and Microbiological Assay Comparison—In the comparison of the HPLC and microbiological assays for ticarcillin in identical *in vivo* serum samples, it is evident from Fig. 3 that these methods are in good agreement having an excellent correlation coefficient ($r = 0.9809$). The overall mean of the percent difference between the microbiological and HPLC values was 13.1%, when all serum samples were considered. One reason for this seemingly large difference is due to the fact that a broad range of ticarcillin concentrations (0–1000 μg/ml) in serum was compared. It must be remembered that the microbiological assay was less accurate at the lower end of the concentration range, *i.e.*, at <50 μg/ml, while the HPLC method was more accurate at <200 μg/ml.

Precision—One simulated ticarcillin serum sample and one urine sample were treated and extracted in the manner outlined earlier. Six replicate injections of each sample were made onto the RP-18 column, and the integrated peak area ratios were calculated. The mean peak area ratios of ticarcillin–carbenicillin were 0.711 ± 0.010 (*CV* = 1.3%) and 1.148 ± 0.013 (*CV* = 1.2%) for serum and urine samples, respectively.

The minimum quantitation limit was ~1 μg/ml for ticarcillin in these biological fluids based on a signal to noise level ratio of three.

Ticarcillin urine levels from one human volunteer were measured with the HPLC assay described. The cumulative amount of unchanged ticarcillin excreted is shown in Fig. 4. Over a period of 12 hr, 103.5% of the administered intravenous dose was measured in the urine. This value agrees well with the 6-hr urine excretion of 99% of a dose administered intramuscularly (33). No degradation product of ticarcillin was detected in any urine sample assayed.

Preliminary pharmacokinetic results (32) obtained using the developed HPLC assay are in very good agreement with those reported in the literature using other assays (34, 35). Further pharmacokinetic studies employing this assay are in progress.

The results indicate that a rapid, convenient, sensitive, specific, and accurate HPLC assay for ticarcillin in serum and urine has been developed and shown to have potential application for pharmacokinetic and clinical studies with this penicillin.

Concomitant Adsorption and Stability of Some Anthracycline Antibiotics

E. TOMLINSON *x and L. MALSPEIS

Received October 20, 1981, from the *Division of Pharmaceutics and Pharmaceutical Chemistry, College of Pharmacy, Ohio State University, Columbus, OH 43210.* Accepted for publication December 14, 1981. *Present address: Department of Pharmacy, University of Amsterdam, Plantage Muidergracht 24, 1018 TV Amsterdam, The Netherlands.

Abstract □ Using liquid scintillation counting and liquid chromatographic techniques, it has been demonstrated that the anthracycline antibiotics, doxorubicin hydrochloride, *N*-trifluoroacetyladriamycin-14-valerate, and *N*-trifluoroacetyladriamycin-14-octanoate, can be strongly adsorbed to the walls of containers, depending on the nature of both the container material and the solute. It also has been shown that the esters are unstable in the chemical growth media commonly used in cell culture studies. Both the adsorption and stability effects are suggested as being factors which should be carefully considered in interpretation of the *in vitro* and perhaps *in vivo* activities of the anthracycline esters.

Keyphrases □ Anthracyclines—concomitant adsorption and stability, esters, cell culture studies □ Antibiotics—anthracyclines, concomitant adsorption and stability, cell culture studies □ Adsorption—concomitant adsorption and stability of some anthracyclines, cell culture studies

The anthracycline antibiotic, doxorubicin hydrochloride (I), has a wide range of antitumor activity (1). Although I given singly or in combination is now used extensively in the treatment of a variety of tumors (2, 3), its clinical value is limited due to its acute myelotoxicity and to the frequent development of irreversible cardiomyopathy [normally observed when the accumulated dose is >550 mg m^{-2} (4)]. The use of structural analogs of I has been proposed (5, 6) as a means of obviating these two effects; in this respect particular interest has been given to the proposed use of the esters of I and its *O*- and *N*-acetylated derivatives (7–14).

During a study examining the uptake of I and its analogs into tumor cells *in vitro* using both cell monolayers and suspensions, effects were observed on the mass balances of some radiolabeled anthracyclines which could only be reconciled in terms of solute adsorption to container walls. Accordingly, the role of adsorption and stability on the solution properties of I and two of its *N*-trifluoroacetyl esters (*i.e.*, the 14-valerate and the 14-octanoate) have been investigated more completely. The present report presents the results found in this investigation.

EXPERIMENTAL

Chemicals—Anthracycline antibiotics were obtained commercially[1]. ^{14}C-Labeled antibiotics were synthesized as described previously (15). Samples of solid I, *N*-trifluoroacetyladriamycin-14-valerate (II), and *N*-trifluoroacetyladriamycin-14-octanoate (III) had specific activities of 17.1, 22.5, and 28.3 μCi $\mu mole^{-1}$, respectively.

Concomitant Adsorption and Stability of Some Anthracycline Antibiotics

E. TOMLINSON *x and L. MALSPEIS

Received October 20, 1981, from the *Division of Pharmaceutics and Pharmaceutical Chemistry, College of Pharmacy, Ohio State University, Columbus, OH 43210.* Accepted for publication December 14, 1981. *Present address: Department of Pharmacy, University of Amsterdam, Plantage Muidergracht 24, 1018 TV Amsterdam, The Netherlands.

Abstract □ Using liquid scintillation counting and liquid chromatographic techniques, it has been demonstrated that the anthracycline antibiotics, doxorubicin hydrochloride, *N*-trifluoroacetyladriamycin-14-valerate, and *N*-trifluoroacetyladriamycin-14-octanoate, can be strongly adsorbed to the walls of containers, depending on the nature of both the container material and the solute. It also has been shown that the esters are unstable in the chemical growth media commonly used in cell culture studies. Both the adsorption and stability effects are suggested as being factors which should be carefully considered in interpretation of the *in vitro* and perhaps *in vivo* activities of the anthracycline esters.

Keyphrases □ Anthracyclines—concomitant adsorption and stability, esters, cell culture studies □ Antibiotics—anthracyclines, concomitant adsorption and stability, cell culture studies □ Adsorption—concomitant adsorption and stability of some anthracyclines, cell culture studies

The anthracycline antibiotic, doxorubicin hydrochloride (I), has a wide range of antitumor activity (1). Although I given singly or in combination is now used extensively in the treatment of a variety of tumors (2, 3), its clinical value is limited due to its acute myelotoxicity and to the frequent development of irreversible cardiomyopathy [normally observed when the accumulated dose is >550 mg m^{-2} (4)]. The use of structural analogs of I has been proposed (5, 6) as a means of obviating these two effects; in this respect particular interest has been given to the proposed use of the esters of I and its *O*- and *N*-acetylated derivatives (7–14).

During a study examining the uptake of I and its analogs into tumor cells *in vitro* using both cell monolayers and suspensions, effects were observed on the mass balances of some radiolabeled anthracyclines which could only be reconciled in terms of solute adsorption to container walls. Accordingly, the role of adsorption and stability on the solution properties of I and two of its *N*-trifluoroacetyl esters (*i.e.*, the 14-valerate and the 14-octanoate) have been investigated more completely. The present report presents the results found in this investigation.

EXPERIMENTAL

Chemicals—Anthracycline antibiotics were obtained commercially[1]. ^{14}C-Labeled antibiotics were synthesized as described previously (15). Samples of solid I, *N*-trifluoroacetyladriamycin-14-valerate (II), and *N*-trifluoroacetyladriamycin-14-octanoate (III) had specific activities of 17.1, 22.5, and 28.3 μCi $\mu mole^{-1}$, respectively.

II	$CO(CH_2)_3.CH_3$	$COCF_3$	1.6
III	$CO(CH_2)_6.CH_3$	$COCF_3$	3.1
IV	H	$COCF_3$	0.6

The Hanks culture media used was an isotonic buffered (pH 7.2–7.6) solution[2] containing essential salts and glucose, together with 10% fetal calf serum, streptomycin, penicillin, gentamicin, and glutamine. For studies examining only adsorption effects, the Hanks solution contained only the essential salts and glucose.

Analysis—^{14}C-labeled anthracycline was assayed using a liquid scintillation counter[3]. Unlabeled anthracycline was assayed by high-performance liquid chromatography (HPLC) using a stationary phase packing of RP-18[4]: mobile phase, methanol–water (9:1); fluorescence detection[5] with 239 nm excitation and a 550 nm cutoff filter; potassium dichromate as nonretained compound; and quantitation using total integrated peak areas[6]. During assay care was taken to ensure that inner-filter effects (16) were avoided by measuring only in the linear portion region of the anthracycline concentration *versus* peak area relationship. The good reproducibility of the method (coefficient of variation <1.0%) permitted the use of an internal standard to be avoided. The chromatographic capacity ratios measured using this system were 1.6, 3.1, and 0.6 for II, III, and IV, respectively.

Adsorption-Stability Studies—*With Tumor Cells*—Hamster benzpyrene-induced adenocarcinoma cells were prepared as monolayers by seeding 10^5 cells into either 35-mm diameter sterile polyethylene petri dishes[7], or glass (silica) monolayer growth tubes (area of growth was ~2 cm^2) followed by incubation at 37° for 24 hr. The incubation media was removed by suction, and 1 ml of Hanks media was added to wash the cells. This solution was then removed and 1 ml of radiolabeled anthracycline was added (2 μM in Hanks media). Tubes or dishes were then placed in an incubator at 37°. After appropriate incubation times, the drug solution was removed from the culture vessels by suction, and these vessels were washed three times with 1 ml of Hanks solution; 1 ml of 0.5% sodium

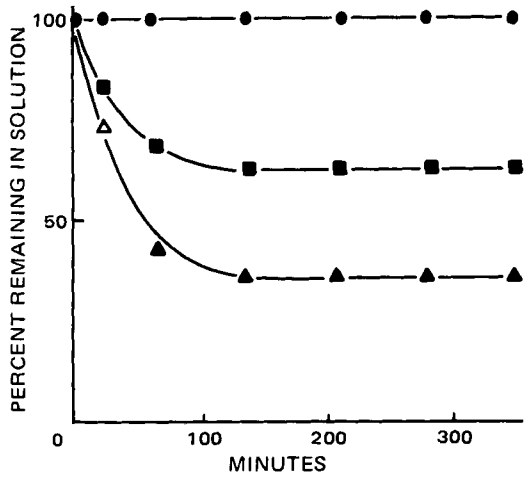

Figure 4—*Percent total radioactivity in Hanks solution with time (pH 7.4, 37°) using a polypropylene container and 1 and 2 μM initial concentrations of antibiotic. Key: (●) I; (■) II; (▲) III, and as Fig. 2.*

lauryl sulfate (as cell digestion agent) was added. After an additional 10 min, 0.5 ml of this digestion fluid was transferred to 19.5 ml of scintillation cocktail and the radioactivity measured. All data given are the mean of three separate determinations carried out in duplicate. For the blank experiments, the described procedure was followed; however, no cells were present in the culture vessels.

Absence of Tumor Cells—Solutions (1 or 2 μM) of the anthracyclines were prepared in Hanks media by dilution of a 100- or 200-μM stock methanolic solution of compound, which was stored in the dark at 0° for not longer than 7 days. (Storage of the stock solution for this length of time was shown by HPLC analysis to be possible without any significant deterioration in the solution.) The dilution was performed by adding 0.1–0.4 ml of stock solution to 19.6–19.9 ml of Hanks media at 37°. The solutions were stirred at 100 rpm using an overhead stirrer and a stirring paddle constructed of the same material as the container. Containers examined were 150-ml silica glass beakers siliconized by immersion in 5% silicone solution with oven drying, 100-ml polytetrafluoroethylene beakers, 50-ml polypropylene conical tapered tubes, and 100-ml stainless steel beakers. All containers were new when used and were discarded after use. For assay using HPLC, 5-, 10-, or 20-μl samples were taken using an HPLC syringe[8] aged using a 2-μM solution of antibiotic. For assay by scintillation counting, 0.1-ml samples were taken using an automatic syringe having polypropylene tips, transferring in the minimum amount of time to 19.9 ml of scintillation cocktail fluid. Anthracycline solutions were kept in the dark whenever possible. All data given are the means of three separate determinations.

RESULTS AND DISCUSSION

Adsorption effects by large hydrophobic drugs have been reported (17–23) with respect to their apparent loss from solution onto and into the walls of their containers. The adsorption of I onto container walls, although a recognized phenomenon, has been noted only briefly in the literature as the probable cause of the observed nonideal behavior of I in its analysis (24) and during its sampling from solution (25). In addition, the use of various cosolvent extraction schemes have been proposed (24, 26, 27) to overcome these effects. Although it has been shown that I undergoes self-association in water (28), others have suggested (29) that no evidence for air–water interfacial adsorption of I can be found.

Although the *in vivo* metabolism of I and its esters have been reported (11), little attention has been given to their solution stability. Kaniewska (30) showed that the aqueous stability of I over a temperature range of 50–60° and a pH range of 2.6–5.5 is greater at lower temperatures and the higher pHs, with a half-life of 136 hr in water at 25° and pH 5.5 (0.2% phosphate buffer) being suggested by extrapolation. Other workers have studied recently the photostability of doxorubicin (31) and the stability of some anthracyclines in infusion fluids (32).

Using the described procedures, Fig. 1 shows the amount of radioactive anthracycline antibiotic determined in the cell digestion fluid after various contact times. Similar cell uptake kinetics are reported often in the literature for these molecules and show that the more hydrophobic the molecule, the greater its rate and extent of uptake by cells (7, 8, 14, 33, 34). However, using the same digestion technique, but in the absence of cells, it can be demonstrated (Figs. 2 and 3) that for I, II, and III, more or less anthracycline antibiotic can be extracted from the system, de-

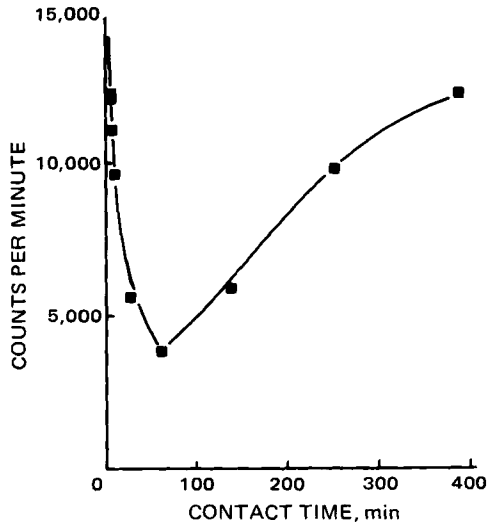

Figure 7—*Percent total radioactivity in Hanks solution (pH 7.4, 37°), for II (2 μM) using a stainless steel container.*

Table I—Percent Maximum Loss of Anthracycline from Solution to Container Wall

Material	Percent Maximum Loss[a] Compound I	II	III	IV[b]

k_{13}	1.150	1.150
k_{34}	0.012	0.012
k_{43}	0.001	0.001
k_{35}	0.085	0.085

pending on the analog and the type of container material used. This suggests an adsorption of anthracycline onto the container walls.

Loss of Radioactive Label from Solution—Figures 4–7 show how the loss of anthracycline is affected by the type of container material in use. Although polypropylene has no adsorbent properties, glass, polyethylene, polytetrafluoroethylene, and stainless steel do have adsorbent properties for I. Both esters are taken up well by all the materials studied, with the more hydrophobic molecule being taken up at a faster rate and to a greater extent. Table I is a summary of these effects. The unusual phenomenon found with stainless steel will be discussed.

All three anthracycline antibiotics studied can be lost from aqueous solution solely by adsorption or sorption. The extent of this adsorption depends on the nature of the container material used. Similar effects have been observed (19) for hydrophobic amines on wall adsorption material dependency. The present results indicate strongly that it is necessary to take care in practice to avoid these effects by: (*a*) reducing the number of wall surface contacts made; (*b*) choosing a container material with care;

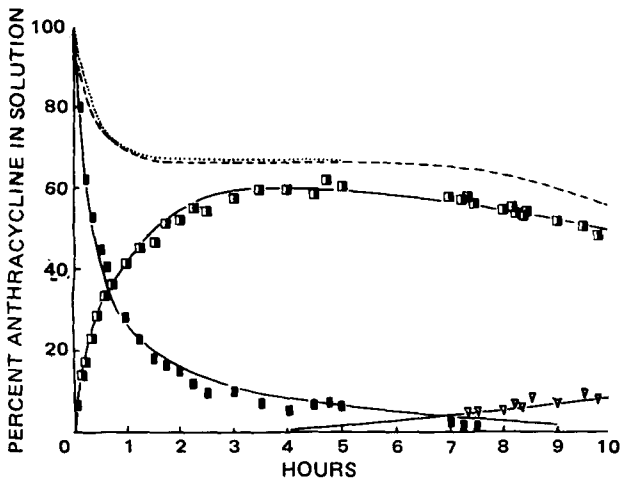

Figure 8—*Concomitant adsorption and stability of II at pH 7.4 and 37° using polypropylene containers. Solid lines are generated using the model given by Scheme I and the rate constants of Table II. Figure 9—*Concomitant adsorption and stability of III at pH 7.4 and 37° using polypropylene containers. Solid lines are generated as for Fig. 8. Key: (▲) III; (◨) IV; (▽) breakdown product of IV; (·····) total radioactivity found in solution; (- - -) the total normalized HPLC peak area.*

(*c*) making use of possible preaging of containers with compound before use; and (*d*) using cosolvents (19, 24, 26, 27).

Concomitant Stability and Adsorption of II and III—Israel *et al.* (11, 12) demonstrated that *in vivo* II is not metabolized extensively to I, but that *N*-trifluoroacetyladriamycin (IV) and *N*-trifluoroacetyladriamycinol are important metabolites of this drug. In addition, the lack of DNA binding of II suggests that its *in vivo* antitumor activity is due to either its conversion to a DNA-binding metabolite or to a mechanism of action different from that accepted (10) for I. Thus, since II and other esters of I are proposed as antitumor agents with a high therapeutic index, and with the knowledge that both the esters examined in this study are adsorbed onto container walls, it was appropriate to examine ester stability in conjunction with these adsorption effects. Figures 8 and 9 give the combined HPLC and radioactivity information for II and III. The initial breakdown product of both II and III is considered to be IV, since the chromatographic capacity ratio of this product corresponded exactly to the value for authentic samples of IV. The second breakdown product had a chromatographic capacity factor which indicated that it was more hydrophobic than the parent molecule.

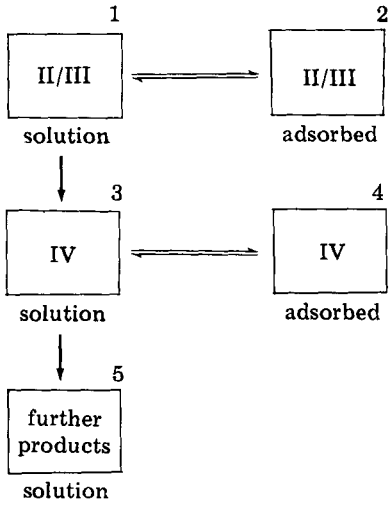
Although the initial HPLC data up to 4 hr indicate that the total anthracycline mass detected is equal to that found using radioactivity measurements, the subsequent falls in the total fluorescent peak values (Figs. 8 and 9) suggest that the first breakdown product is itself weakly adsorbed onto the polypropylene container wall. These data suggest that the solution equilibria for II and III in aqueous solution at pH 7.4 can be described by Scheme I when adsorption effects are in evidence. These schemes have been modeled using an analog computer[9], and the lines drawn in Figs. 8 and 9 are computer generated using the rate constants determined (Table II).

Good agreement is obtained between the experimental results and the theoretical results using Scheme I as a model of the equilibria occurring in these systems. Thus, the rapid loss of either ester from solution can be attributed to both adsorption and chemical transformation to IV.

Notable features of the rate constants are that the desorption steps are small, and, although for III adsorption is faster, for neither ester can hydrolysis or adsorption be described as the rate-determining step in the loss process. Combination of the peak areas for either ester and IV (normalized for differences in extinction) gives mass balances equivalent to those found using radioactivity measurements. Compound IV is unstable to a small extent and also adsorbs, which is confirmed by inspection of Fig. 10 where the results of an HPLC examination of the behavior of this compound in Hanks media are given.

If it is assumed that the ester is stable in the adsorbed state, then the container acts as a reservoir. For the polypropylene material, since the degradation products of the esters are less adsorbed due to their lower hydrophobicity, it follows that the relationship between total anthracycline concentration in solution and time should exhibit a minimum. Due to the slow rates of desorption (Table II), these minima are not seen

[9] Type RA 742, Telefunken.



Scheme I

within the experimental time, although there is some indication of this effect in the case of II and siliconized glass (Fig. 5). A similar phenomenon would be observed if the ester were unstable at the container surface resulting in the production of a species with a high desorption rate. This effect is observed for II adsorbed at the stainless steel surface (Fig. 7). If this were the case, the altered stability of II at the stainless steel surface could be indicative of metal ion catalysis, which is possible since the structures of these anthracycline antibiotics suggest that they can act as chelating agents.

The results indicate that anthracycline antibiotics can adsorb strongly onto the walls of containers, and that the rate and extent of adsorption depends on both the nature of the anthracycline and the wall material

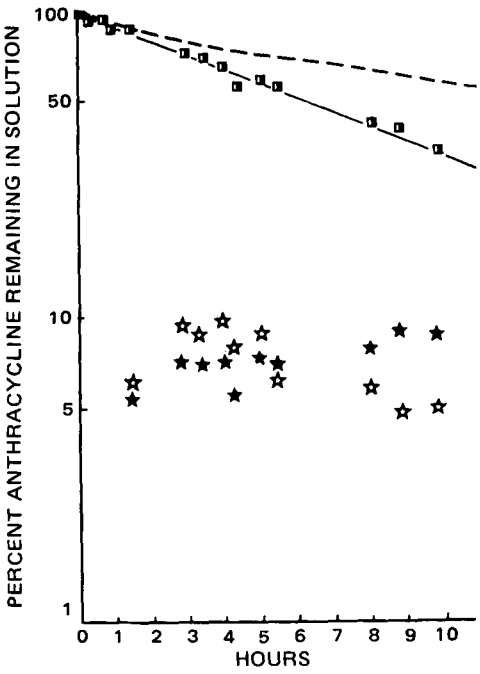


Figure 10—*Stability of IV in Hanks media (pH 7.4, 37°) using polypropylene containers. Key: (- - -) total peak area obtained by summation of the IV HPLC peak area (■) and the peak areas of its two fluorescent breakdown products (☆ ★).*

used. It is believed that these effects have an importance in the analysis of these compounds, as well as in those studies attempting to measure the effect of these antibiotics in living cell cultures. Finally, it can be argued that the combined effects of adsorption and ester instability have implications for the bioavailability and delivery of these drugs.

Synthesis and Biological Evaluation of *gem*-Dichlorocyclopropyl and Cyclopropyl Analogs of Stilbene Congeners as Potential Antiestrogens

JOHN F. STOBAUGH *, ROBERT A. MAGARIAN ‡x, and J. THOMAS PENTO §

Received October 6, 1981, from the ‡*Department of Medicinal Chemistry and the* §*Department of Pharmacodynamics and Toxicology, College of Pharmacy, University of Oklahoma Health Sciences Center, Oklahoma City, OK 73190.* Accepted for publication December 15, 1981. * Present address: Department of Pharmaceutical Chemistry, College of Pharmacy, University of Kansas, Lawrence, KS 66045.

Abstract □ A series of *gem*-dichlorocyclopropyl and cyclopropyl analogs of stilbene congeners was synthesized and examined for estrogenic and antiestrogenic activity using the uterotropic assay in the immature mouse. The relative receptor affinity *in vitro* was determined by measuring [^{3}H]estradiol displacement from the rat uterine cytosol receptor. The 11 test compounds synthesized in this study did not produce estrogenic or antiestrogenic activity at the dosage levels used (1–25 μg), but did produce a significant displacement of [^{3}H]estradiol in the rat uterine receptor binding assay with analog XVIII possessing the greatest binding affinity and compound XI the lowest affinity. Structure–affinity relationships of this series were established from the receptor binding assay and comparisons between these analogs and a previously reported series are summarized.

Keyphrases □ *gem*-Dichlorocyclopropyl analogs—synthesis, biological evaluation, cyclopropyl analogs, stilbene congeners, potential antiestrogens □ Stilbene—congeners, potential antiestrogens, synthesis, biological evaluation of *gem*-dichlorocyclopropyl and cyclopropyl analogs □ Antiestrogens—synthesis, biological evaluation of *gem*-dichlorocyclopropyl and cyclopropyl analogs of stilbene congeners □ Biological evaluation—synthesis, *gem*-dichlorocyclopropyl and cyclopropyl analogs of stilbene congeners, potential antiestrogens □ Cyclopropyl analogs—synthesis and biological evaluation, stilbene congeners, potential antiestrogens

In a previous paper (1)[1], a series of cyclopropyl analogs (I–X) of stilbene and stilbenediol was reported as a novel class of nonsteroidal estrogens and antiestrogens. The interesting pharmacological properties of these analogs prompted the investigation of a new series of related compounds. The preparation of some related cyclopropyl analogs (XI–XXI), their estrogenic, antiestrogenic, and receptor binding activities are reported here. The receptor binding effects of this new series were compared to the first series (1) to examine more fully the total structure–affinity relationships with the hope of providing additional insight into the steric requirements of the ligand that binds to the estrogenic receptor. This relationship between the ligand–receptor binding and biological response is of great interest, because elucidation of this relationship would help to clarify the mechanism of action of both estrogenic and antiestrogenic compounds at the cellular level.

EXPERIMENTAL[2]

Preparation of Starting Olefins—These compounds were not available and were prepared by previously reported procedures (2–12).

General Method for the Preparation of *gem*-Dichlorocyclopropyl Analogs XI–XVI (Table I) (13–15)—A molar ratio (1:10) of triethylbenzylammonium chloride to the starting olefin was dissolved in excess chloroform (10 times the molar concentration of olefin) contained in a three-neck flask fitted with an air condenser and dropping funnel. The

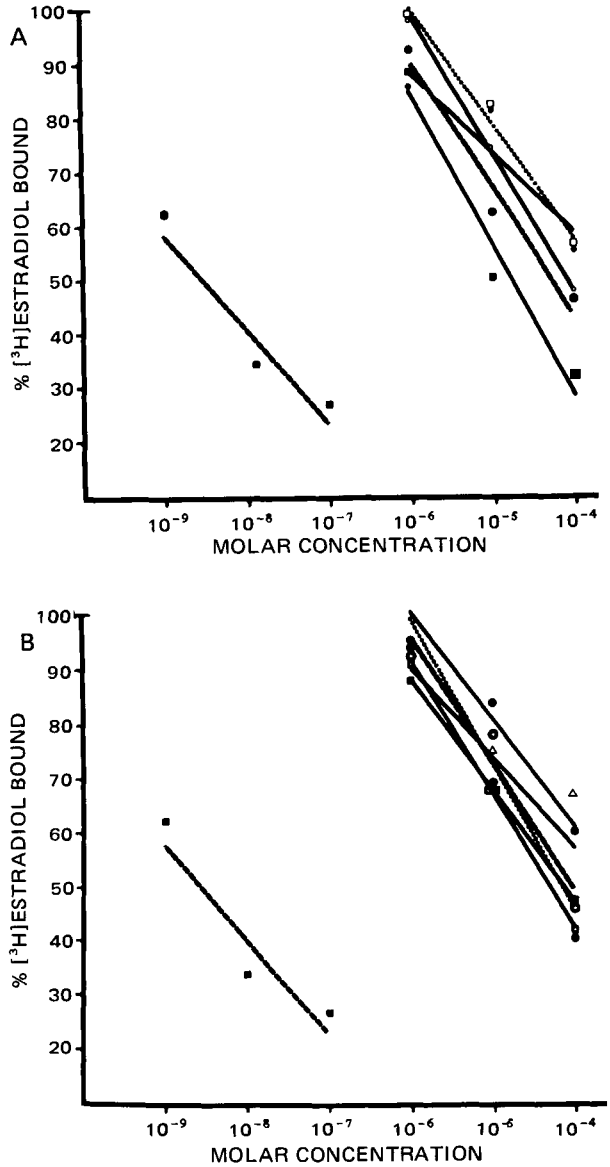

Figure 1—*Uterine receptor binding activity of the cyclopropyl analogs XI–XXI. The receptor binding data is presented in two parts (A and B) due to the overlap in binding between these compounds. flask was cooled in an ice water bath and a 33–50% aqueous sodium hydroxide solution (sodium hydroxide–chloroform, 2:1) was added dropwise while the mixture was magnetically stirred. After the addition was completed, the ice bath was removed and stirring continued for 6–120 hr. The dark mixture was diluted with excess water and the aqueous layer was separated and extracted three times with chloroform. The chloroform extracts were combined, washed three times with water, dried over anhydrous magnesium sulfate, and filtered to remove the drying agent. The chloroform was removed under reduced pressure, yielding a dark liquid or solid which was purified as described in Table I. PMR ($CDCl_3$): XI, 7.13 (q, 8H), 3.80 (s, 6H), 3.05 (s, 1H), 1.40 (s, 3H); XII, 7.13 (q, 8H), 3.82 (s, 6H), 1.40 (s, 6H); XIII, 7.37 (s, 10H), 3.17 (s, 1H), 1.43 (s, 3H); XIV, 7.32 (s, 10H), 1.40 (s, 6H); XV, 7.13 (m, 10H), 2.85 (s, 1H), 1.80 (s, 3H); XVI, 7.33 (m, 10H), 1.77 (s, 6H).

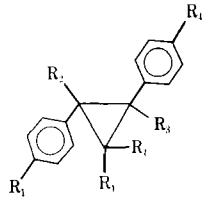
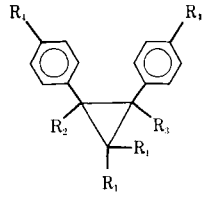
General Method for the Preparation of Cyclopropyl Analogs XVII–XXI (Table II)—The method of Gassman and Pape (16) was modified. *gem*-Dichloro intermediates XI–XVI and tetrahydrofuran were added to a 100-ml flask fitted with a reflux condenser. This solution was stirred by means of a magnetic stirrer and sodium metal was cut in small pieces and added to the solution followed by *tert*-butyl alcohol. The mixture was stirred and heated at reflux for 12 hr. The unreacted sodium was consumed with methanol and then water was added. The aqueous layer was separated and extracted twice with ether. The ether extracts were combined, dried over anhydrous magnesium sulfate, filtered, and the solvent removed under reduced pressure yielding a solid or liquid which was purified as described in Table II. PMR ($CDCl_3$): XVII, δ 7.04 (m, 8H), 3.70 (s, 6H), 2.23 (m, 3H), 1.18 (m, 3H); XVIII, δ 7.10 (q, 8H), 3.80 (s, 6H), 1.10 (s, 2H), 1.00 (s, 6H); XIX, δ 7.41 (m, 10H), 2.33 (m, 1H), 1.29 (m, 2H), 1.03 (s, 3H); XX, δ 7.35 (s, 10H), 1.18 (s, 2H), 1.03 (s, 6H); XXI, δ 7.16 (m, 10H), 2.60 (m, 2H), 1.93 (m, 1H), 1.36 (m, 3H).

Uterotropic Assay for Estrogenic and Antiestrogenic Activity—The assay for estrogenic activity was a modification (1) of the original uterotropic method of Rubin *et al.* (17) using Swiss-Webster mice. Each cyclopropyl analog was examined over a dosage range of 1–25 μg (total dose).

The uterotropic assay also was used to evaluate the antiestrogenic activity of the test compounds which did not produce an estrogenic response in the previous assay. The antiestrogenic assay was conducted as described for estrogenic activity, except that each animal in the cyclopropyl analog treatment groups received a standard stimulating dose of estradiol (0.04 μg). The test compounds and estradiol were administered separately at different injection sites to minimize possible physical interaction or reduced absorption of either compound. Antiestrogenic activity was measured as a decrease in estradiol-stimulated uterotropic response in groups which received both the test compound and estradiol as compared to a group that received estradiol alone.

Table III—Receptor Binding Assay



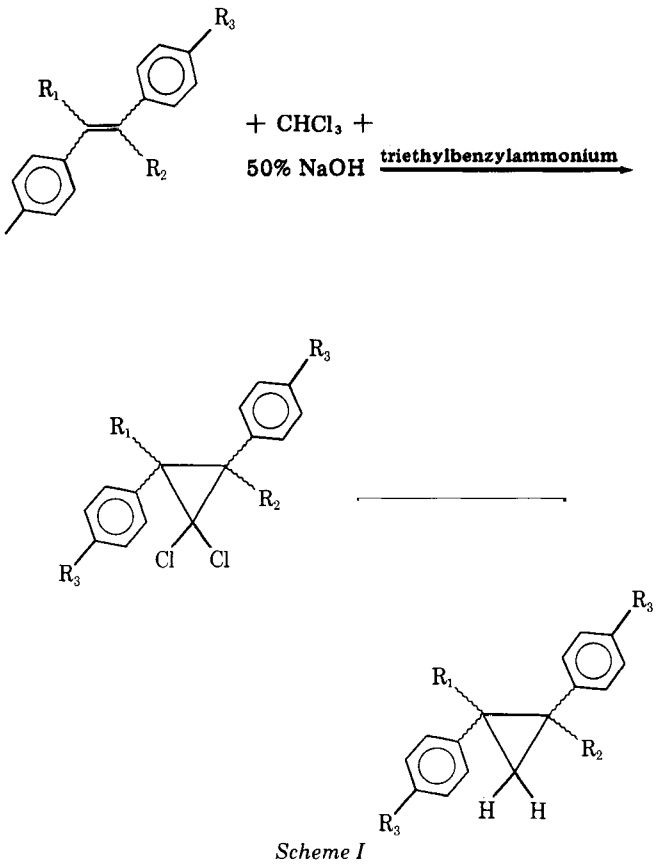


Compound No.	Configuration	R_1	R_2	R_3	R_4	Relative Binding Activity[a] (Estradiol Response, %)
Estradiol						100
XI	*trans*	Cl	CH_3	H	O—CH_3	8.3×10^{-5}
XII	*trans*	Cl	CH_3	CH_3	O—CH_3	5.9×10^{-4}
XIII	*trans*	Cl	CH_3	H	H	5.3×10^{-4}
XIV	*trans*	Cl	CH_3	CH_3	H	5.1×10^{-4}
XV	*cis*	Cl	CH_3	H	H	6.3×10^{-4}
XVI	*cis*	Cl	CH_3	CH_3	H	5.5×10^{-4}
XVII	*trans*	H	CH_3	H	O—CH_3	7.3×10^{-4}
XVIII	*trans*	H	CH_3	CH_3	O—CH_3	2.2×10^{-3}
XIX	*trans*	H	CH_3	H	H	1.5×10^{-4}
XX	*trans*	H	CH_3	CH_3	H	1.1×10^{-4}
XXI	*cis*	H	CH_3	H	H	8.0×10^{-4}

[a] $\frac{\text{Concentration of estradiol that displaced 50\% [}^3\text{H]estradiol}}{\text{Concentration of analog that displaced 50\% [}^3\text{H]estradiol}} \times 100$.

Receptor Binding Assay—A modification (1) of the competitive receptor binding assay method of Korenman (18) was used in this study. Uteri from mature (250 g) female Sprague-Dawley rats were used to prepare the cytosol receptor agent for this assay. Each test compound was assayed at three concentrations over a range of 10^{-4} to 10^{-6} *M* for the cyclopropyl analogs and 10^{-7} to 10^{-9} *M* for the estradiol standard. The test compounds were dissolved in ethanol, and in all cases the final concentration of ethanol was <2% of the total incubation volume.

The [^{3}H]estradiol displacement curve for each test compound was determined by linear regression analysis and plotted graphically. The relative receptor binding activity of each analog was determined using the ratio (concentration of unlabeled estradiol producing 50% displacement of [^{3}H]estradiol/concentration of cyclopropyl analog producing 50% displacement of [^{3}H]estradiol) × 100. Parallelism between the curve produced by each of the analogs and the unlabeled estradiol standard (an index of assay displacement specificity) was determined according to the method of Bliss (19).



Scheme I

RESULTS AND DISCUSSION

Chemistry—Scheme I illustrates the method of Dehmlow and Schonefeld (13) used for the synthesis of the *gem*-dichloropropanes (Table I) in this study. This is a phase transfer reaction catalyzed by triethylbenzylammonium chloride using chloroform and concentrated aqueous sodium hydroxide solution (33%) to generate a dichlorocarbene. The carbene adds stereospecifically across the double bond in the starting olefins, thus, generating the desired *gem*-dichlorocyclopropyl intermediate (Table I). This reaction was easily carried out and provided yields between 50 and 70%; however, analog XVI was obtained in only 37% yield, and XI and XII yielded dark mixtures before purification. The method of Gassman and Pape (16) was modified to remove the *gem*-dichloro groups from the cyclopropyl ring, and is illustrated in Scheme I. This modified reaction involved the use of the dichloro intermediate, sodium metal, and *tert*-butyl alcohol in refluxing tetrahydrofuran. The dehalogenated cyclopropyl analogs (Table II) were isolated in 60–80% yields.

Pharmacology—All cyclopropyl analogs prepared were tested for estrogenic and antiestrogenic activity in a concentration range of 1–25 μg (total dose) using the immature mouse uterotropic assay (17). None of the test compounds produced an estrogenic response (increase in uterine weight) or an antiestrogenic response (antagonism of estradiol-induced increase in uterine weight) within the dosage range used in this assay system.

Each test compound produced a significant displacement of [^{3}H]estradiol in the rat uterine receptor binding assay (Table III, Figs. 1A and 1B) with analog XVIII displaying the greatest binding affinity and compound XI the lowest. However, the binding affinity of most of the test compounds was similar and in the order of 10^{-3} to 10^{-5}% of 17β-estradiol on a molar basis. Accordingly, receptor binding curves were illustrated in two separate figures due to the significant overlap in analog-induced [^{3}H]estradiol displacement activity.

Since substituents play an important role in the receptor recognition of substrates, it was of interest to look at the nature of the substituent and its contribution to the binding processes. Consequently, the structure–affinity relationships exhibited by this substituted *cis*- and *trans*-diphenylcyclopropane series (Table III) are discussed briefly.

Structural modifications restricted to monomethyl (R_2) and dimethyl (R_2 and R_3) substitutions in *gem*-dichloro-*cis*- and *trans*-2,3-diphenylcyclopropanes (XIII–XVI) did not alter binding activity. The additional methyl group (R_3) in dimethyl substitution does appear, however, to increase activity when in combination with *p*-methoxyphenyl substituents (XII *versus* XI and XVIII *versus* XVII). *gem*-Dichloro substitution (R_1 = Cl) in monomethyl *trans*-diphenylcyclopropanes (XIX *versus*

XIII) and dimethyl analogs (XX *versus* XIV) generally produced a small increase in binding affinity. *p*-Methoxy groups increased activity in the dehalogenated cyclopropyl analogs (XIX *versus* XVII and XX *versus* XVIII) with the greatest receptor binding affinity found in compound XVIII. The *cis*-isomer XXI displayed greater receptor affinity than the *trans*-isomer XIX, but there were no apparent differences in the *gem*-dichloro analogs (XV *versus* XIII and XVI *versus* XIV).

When the receptor binding activities of these analogs were compared to the present compounds (1), it was found that the monomethyl and dimethyl substituents at R_2 and R_3 (Table III) in the hydrophobic cyclopropyl skeleton led to a reduction in receptor binding affinity of the derivatives, while diethyl substitution increased receptor binding ability.

Moment Analysis for the Separation of Mean *In Vivo* Disintegration, Dissolution, Absorption, and Disposition Time of Ampicillin Products

YUSUKE TANIGAWARA ˣ, KIYOSHI YAMAOKA, TERUMICHI NAKAGAWA, and TOYOZO UNO

Received September 28, 1981, from the *Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto 606, Japan.* Accepted for publication December 18, 1981.

Abstract □ The *in vivo* disintegration, dissolution, absorption, and disposition processes of ampicillin products are separated by means of moment analysis. This method is model-independent, that is, any specific model is not assumed. The mean residence time (MRT), mean absorption time (MAT), mean dissolution time (MDT), and mean disintegration time (MDIT) are calculated for several dosage forms of ampicillin. The fraction of dose absorbed (F) is also separated into several fractions corresponding to these *in vivo* processes. Bioavailability and bioequivalence are discussed in terms of the zero and first moments. The flip-flop behavior of ampicillin is proved by the fact that the MRT following intravenous injection is less than the MAT of any oral dosage form. Absorption of released ampicillin is proved to be a rate-determining step, since the MRT of released ampicillin in the GI tract is the greatest of all MRT corresponding to the *in vivo* processes. Moment analysis is compared with classical compartment theory, and a new component concept is introduced.

Keyphrases □ Ampicillin—moment analysis, *in vivo* disintegration, dissolution, absorption, disposition time □ Disintegration—ampicillin, moment analysis, *in vivo* dissolution, absorption, disposition time □ Dissolution—ampicillin, moment analysis, *in vivo* disintegration, absorption, disposition time □ Absorption—ampicillin, moment analysis, *in vivo* disintegration, dissolution, disposition time

In recent years moment analysis has been developed in the pharmacokinetic field as a method to comprehend drug behavior in the body, that is, absorption, distribution, metabolism, and excretion (1–10)[1]. Since statistical moments are characteristic of the shape of the statistical distribution curves such as plasma concentration–time curve or urinary excretion rate–time curve, they are only dependent on the observed time course data and are independent of the pharmacokinetic compartment model. Zero moment represents the area under the plasma concentration–time curve (AUC) or the total amount of drug excreted in urine, which is widely used as a model-independent parameter. The first moment, which is defined as the mean residence time (MRT), gives significant information with respect to kinetic features of the process which a drug undergoes in the GI tract and the body (1).

The absorption of a drug from its oral preparation involves a process too complex to be described by a simple mathematical equation. Therefore, a model-independent approach has been undertaken to evaluate the absorption rate (1–3, 11–13). These methods are based on deconvolution. The mean absorption time (MAT) is the useful index of the rate of bioavailability (1–3). The *in vivo* drug absorption involves disintegration and dissolution steps

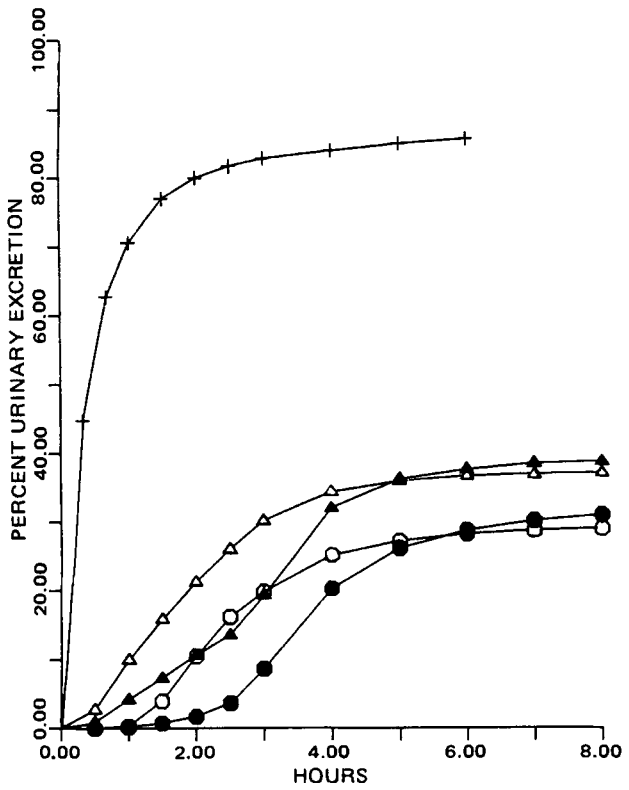

Figure 1—*Cumulative urinary excretion of ampicillin after intravenous and oral administrations to Subject 2. Key: (+) intravenous injection; (△) solution; (▲) Powder A; (●) Capsule A; (○) Capsule B.*

prior to absorption of released drug. The evaluation of *in vivo* disintegration and dissolution of a drug product is necessary for the development of a drug delivery system. It is also necessary to know the rate-determining step in these *in vivo* processes.

Recently the mean dissolution time (MDT) was defined as the magnitude of *in vivo* dissolution rate (3). In this article, moment analysis using urinary excretion data is carried out to separate four *in vivo* steps from administration of an ampicillin product through urinary excretion, that is, disintegration, dissolution, absorption, and disposition steps. The rate-determining step is specified by comparing the mean residence time intrinsic to each step. The extent and rate of bioavailability of the anhydrate and trihydrate forms of ampicillin are estimated in terms of the zero and first moments. Bioequivalence is discussed from the results for the urinary recovery and the mean residence time.

EXPERIMENTAL

Procedure—Four healthy male volunteers, 25–32 years of age, weighing 62–76 kg participated in this study. The subjects were fasted overnight before each dosage and were permitted to eat no food until 3 hr after dosing except for intravenous administration. No other drugs were taken for at least 1 week prior to and during the study. All subjects received single doses of ampicillin in five different dosage forms (*a–e*). Each dosage was separated by at least 1 week:

(a) *Intravenous injection*—A 2.5-ml injectable ampicillin[2] solution containing 125 mg (as potency) was intravenously administered in 1 min.

(b) *Solution*—A solution of 500-mg (as potency) of ampicillin sodium[2] dissolved in 100 ml of water was orally administered.

(c) *Powder* A—The contents of a 500-mg (as potency) ampicillin trihydrate capsule[3] were removed and orally administered with 100 ml of water.

(d) *Capsule* A—One 500-mg (as potency) capsule[3] was orally administered with 100 ml of water. The ampicillin was in trihydrate form.

(e) *Capsule* B—One 500-mg (as potency) ampicillin anhydrate capsule[4] was orally administered with 100 ml of water.

The maximum plasma concentration after intravenous injection is much higher than that after oral administration of the same dose. Therefore, a quarter of the oral dose was used for the intravenous dose in order to avoid saturation in drug disposition.

Urine samples were collected immediately before and at 0.5, 1, 1.5, 2, 2.5, 3, 4, 5, 6, 7, and 8 hr after oral dosing, or at 20 and 40 min and 1, 1.5, 2, 2.5, 3, 4, 5, and 6 hr after intravenous dosing. After the urine volume was measured, a portion was frozen until assayed.

Assay of Ampicillin—The antibiotic concentration was determined by reversed-phase high-pressure liquid chromatography (HPLC). The chromatograph[5] was equipped with a UV detector[6] adjusted at 220 nm. The stationary phase was octadecylsilane chemically bonded on totally porous silica gel (particle size 5 μm), packed in a 150-mm stainless steel column[7] (4-mm i.d.). The mobile phase was a mixture of methanol–0.0167 *M* phosphate buffer (pH 7.0, 1:2 v/v). The flow rate was 0.6 ml/min and column oven temperature was set at 28°. Peak area was used for quantitation[8].

Evaluation of Moments and Statistical Analysis—The urinary recovery, *f*(percent), and the mean residence time, MRT(hour), were evaluated from the time course data for the urinary excretion by means of the linear trapezoidal integration and extrapolation (1). The statistical evaluation of the differences in MRT and *f* values between dosage forms and subjects was achieved by two-way ANOVA. The subsequent pairing test was carried out when significant differences were found ($p < 0.05$).

Table I—Mean Residence Time, MRT(hr), of Ampicillin Products

Dosage Form	Subject 1	2	3	4	Mean ± *SD*
Intravenous injection	0.766	0.752	0.816	0.752	0.772 ± 0.026
Solution	2.53	2.00	2.78	2.10	2.35 ± 0.32
Powder A	3.18	2.95	2.88	2.56	2.89 ± 0.22
Capsule A	3.40	3.98	3.33	2.23	3.24 ± 0.63
Capsule B	3.08	2.73	2.51	2.24	2.64 ± 0.31

Table II—Percent Urinary Recoveries, *f*(%), of Ampicillin at Infinite Time

Dosage Form	Subject 1	2	3	4	Mean ± *SD*
Intravenous injection	83.4	86.9	64.1	77.5	78.0 ± 8.7
Solution	39.0	37.2	37.8	52.5	41.6 ± 6.3
Powder A	45.2	38.9	39.0	45.8	42.2 ± 3.3
Capsule A	40.9	31.9	30.7	42.2	36.4 ± 5.2
Capsule B	38.7	29.2	26.1	31.2	31.3 ± 4.6

RESULTS

Mean Residence Time and Urinary Recovery—Figure 1 shows the time courses for the cumulative urinary excretion of ampicillin administered to Subject 2 in various dosage forms. The MRT and *f* values are listed in Tables I and II. In calculating the moments, the contributions of the extrapolated area to MRT and *f* values were evaluated. The increases of MRT and *f* by extrapolation to infinite time were <1%, which demonstrates that the urinary time courses were measured in an adequate period of time. The differences in MRT and *f* values among the dosage forms were statistically significant at the 0.01 level by ANOVA. The MRT and *f* values after intravenous injection are very different from those after any other oral dosage forms. For example, ampicillin is retained in the

[2] Pentrex for injection, Banyu Pharmaceutical Co. Ltd., Tokyo, Japan.

GI tract and the body for ~3 hr when the trihydrate capsule (Capsule A) is orally administered, whereas only 46 min of residence time follows intravenous injection. The differences in MRT values are insignificant at the 0.05 level between Powder A and Capsule A, between Solution B and Capsule B, and between Powder A and Capsule B. The differences in f values are insignificant at the 0.05 level between Powder A and Capsule A, between Solution A and Powder A, between Solution A and Capsule A, and between Capsule A and Capsule B. Therefore, from the viewpoint of extent and rate of bioavailability, it follows that Powder A and Capsule A are bioequivalent, but that any other pairs are not bioequivalent at the 0.05 level.

Mean Absorption Time and Extent of Absorption—The following discussions are based on the assumptions (1) that the pharmacokinetic system is linear, and the oral response is given by the convolution of weight functions which correspond to each step, such as disintegration, dissolution, absorption, and disposition.

The mean absorption time, MAT, and the fraction of dose absorbed, F, for a drug administered orally have been defined as (1, 2):

$$MAT = MRT_{po} - MRT_{iv} \quad \text{(Eq. 1)}$$

$$F = f_{po}/f_{iv} \quad \text{(Eq. 2)}$$

where po and iv reveal oral and intravenous bolus administrations, respectively. MAT expresses the mean overall time since a drug is administered until it enters into the systemic circulation. Table III lists the MAT (hour) and F (percent) for four ampicillin dosage forms. The MAT values are estimated by the subtraction of the average of MRT_{iv} from that of MRT_{po}. Absorption rate from the solution is the fastest of all oral dosage forms. Absorption from Capsule B, which contains ampicillin anhydrate is as fast as that from the solution, but absorption from Capsule A, which contains the trihydrate form, is clearly slower than that from the solution. Difference in MAT values between these two capsules is 0.60 hr (36 min). The fact that the MRT_{iv} is less than the MAT of any oral dosage form shows that the pharmacokinetic profile of ampicillin is flip-flop (14).

Mean Disintegration Time and Mean Dissolution Time—Though the discussion below can be applied to tablets and sustained-release preparations, the case of capsules is considered here as a representative example. Prior to the absorption of released drug through the GI wall, a drug administered as a capsule undergoes *in vivo* disintegration of the capsule shell and subsequent dispersion of drug powder, and dissolution of the dispersed drug into GI fluid. Therefore, the MAT for capsules was separated into three steps as follows (Scheme I):

Table III—MAT, MDT, F, and F_{rel} of Orally Administered Ampicillin Preparations

	Solution	Powder A	Capsule A	Capsule B
MAT (hr)	1.58	2.12	2.47	1.87
MDT (hr)	—	0.54	0.89	0.29
F (%)	53.3	54.1	46.7	40.1
F_{rel} (%)	—	101.4	87.5	75.2

$$MAT_{capsule} = T_1 + T_2 + T_3 \quad \text{(Eq. 3)}$$

where T_1 is the mean time for the disintegration of a capsule, T_2 is the mean time for the dissolution of dispersed drug powder, and T_3 is the mean time for the absorption of the released drug. Accordingly, it is possible to estimate the *in vivo* mean time of each step by comparing the MAT values for several different dosage forms. When a drug is administered as a solution:

$$MAT_{solution} = T_3 \quad \text{(Eq. 4)}$$

When a drug is administered as a powder (or suspension):

$$MAT_{powder} = T_2 + T_3 \quad \text{(Eq. 5)}$$

The mean *in vivo* dissolution time, MDT, was defined (3):

$$MDT_{capsule} = MAT_{capsule} - MAT_{solution} \quad \text{(Eq. 6)}$$

In the same manner, we define the mean *in vivo* disintegration time, MDIT, as follows:

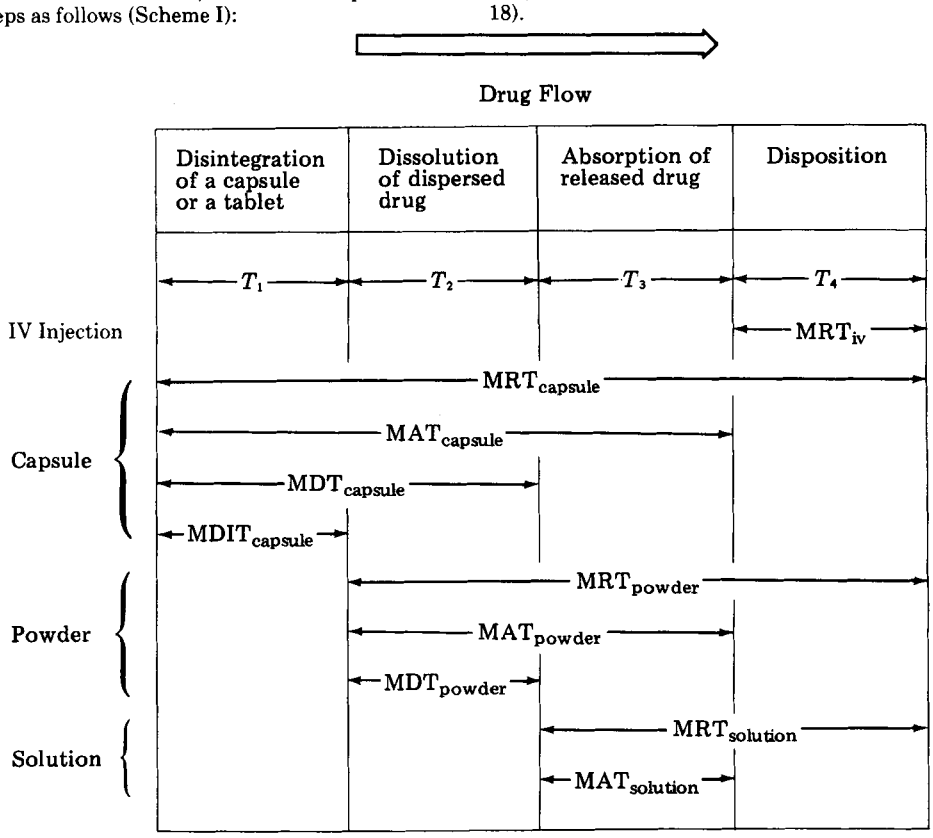
$$MDIT_{capsule} = MAT_{capsule} - MAT_{powder} \quad \text{(Eq. 7)}$$

Substitution of Eq. 1 into Eqs. 6 and 7 yields:

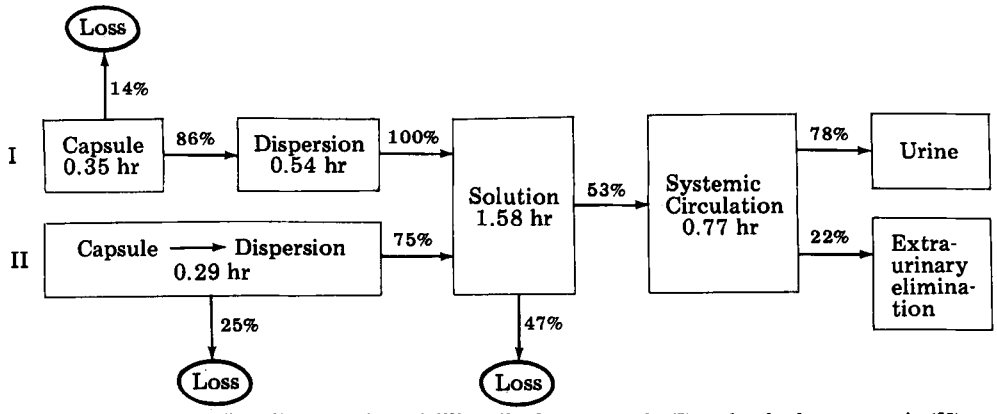
$$MDT_{capsule} = MRT_{capsule} - MRT_{solution} \quad \text{(Eq. 8)}$$

$$MDIT_{capsule} = MRT_{capsule} - MRT_{powder} \quad \text{(Eq. 9)}$$

Table III lists the MDT values for three solid dosage forms. The MDIT of Capsule A is 0.35 hr which is statistically negligible, and it means that the disintegration of capsule shell in the GI tract is a very rapid process. The MDT of Capsule A is greater than that of Capsule B, which coincides with the previously reported fact that the *in vitro* dissolution rate of anhydrous ampicillin is faster than that of the trihydrate form (15–18).



Scheme I—Illustration of the meanings of the MRT, MAT, MDT, and MDIT.



Scheme II—Drug flow diagram of ampicillin trihydrate capsule (I) and anhydrate capsule (II).

The zero moment of each step for a capsule can be separated as:

$$F_{capsule} = F_1 \cdot F_2 \cdot F_3 \qquad \text{(Eq. 10)}$$

where F_1, F_2, and F_3 reveal the ratio of ampicillin amount which transfers as an intact form from step to step. The zero moments for solution and powder thus become:

$$F_{solution} = F_3 \qquad \text{(Eq. 11)}$$

$$F_{powder} = F_2 \cdot F_3 \qquad \text{(Eq. 12)}$$

Corresponding to MDT, the relative extent of absorption, F_{rel}, is defined as:

$$F_{rel} = F_{capsule\ (or\ powder)}/F_{solution} \qquad \text{(Eq. 13)}$$

The F and F_{rel} values are listed in Table III.

Drug Flow Diagram of Ampicillin Products—Scheme II depicts the drug flow diagram summarizing the drug flow after oral administration of two kinds of ampicillin capsules. The intrinsic MRT, which is a time component related to each step in the total MRT, is given in the box and the transfer ratio from step to step is written on the arrow. It should be noted that this box exhibits a quite different concept from the classical compartment. We call the box a component. This is very similar to the strong component concept (19). The detailed discussion is given later.

The absorption kinetics of some ampicillin products were compared by means of a previous method (20), but that report did not give a clear explanation for the incomplete absorption of orally administered ampicillin. Scheme II clearly shows that some portions of ampicillin are lost before entering the systemic circulation. This may be due to incomplete disintegration of a capsule or incomplete dissolution or degradation to an unavailable form. In the case of the trihydrate form, the loss in the disintegration process is 14%, but the dissolution of the dispersed drug is perfect, whereas the loss of the anhydrate form in the dissolution process is 25%.

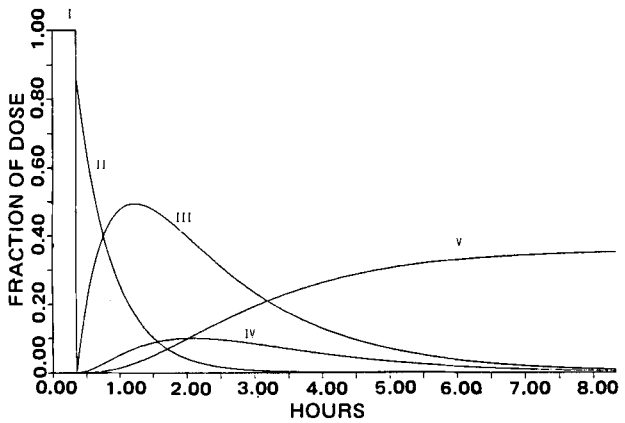


Figure 2—*Computer simulations of ampicillin amount* versus *time curves in five components for the trihydrate form. The drug levels are simulated by a convolution method. Key: (I) capsule form; (II) dispersed drug; (III) released drug in the GI tract; (IV) drug amount in body; (V) amount of urinary excreted drug.*

The interesting observation is that the intrinsic MRT of released drug in the GI tract is the greatest of all time components, and it means that the absorption of released ampicillin is the rate-determining step. Therefore, the dissolution rate does not appreciably affect the plasma peak levels. Besides, the transfer ratio from solution to systemic circulation is the lowest (53%) of all transfer ratios. It is suggested that the pharmaceutical improvement of absorption in the released state (esterification, *etc.*) is more effective than that of dissolution in order to obtain high plasma peak levels.

Simulations of Ampicillin Levels in Each Component—To simulate the ampicillin levels in each component shown in Scheme II, the following approximation was adopted. It was assumed that all the steps except for disintegration were expressed by the monoexponential equations, and that the disintegration step was represented by the lag time, because the collapse of a capsule is expected to occur abruptly. Actually the lag time was observed in the experimental time course data for a capsule form. The weight function of each step except for disintegration is represented by:

$$G_i = \frac{F_i}{T_i} \times \exp\left(-\frac{t}{T_i}\right) \qquad i = 2, 3, \text{ and } 4 \qquad \text{(Eq. 14)}$$

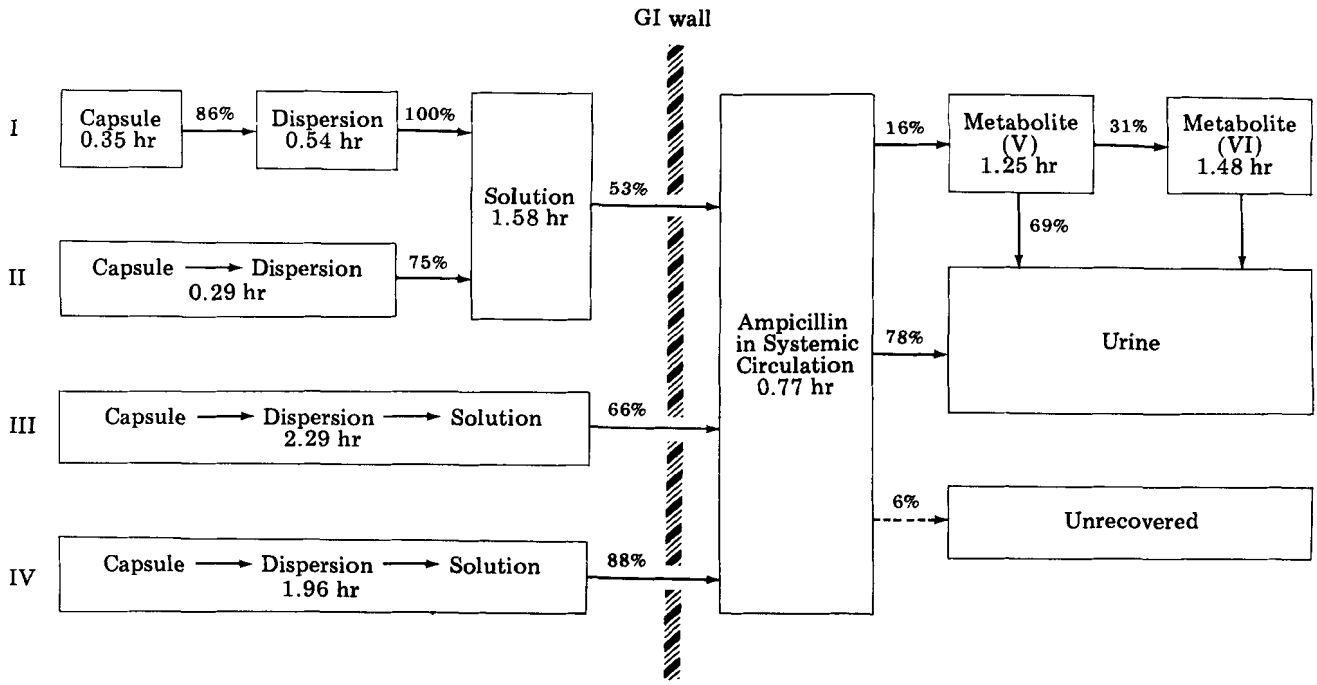
where 2, 3, and 4 reveal the dissolution, absorption, and disposition processes, respectively. It is noted that the zero and first moments of G_i *versus* time curve just become F_i and T_i, respectively.

Figure 2 shows ampicillin fraction *versus* time curves in five components after oral administration of trihydrate capsules. Drug levels in the body are much less than those in the GI tract, and the area under the curve (*AUC*) of body levels (Curve IV) is only 25% of released drug (Curve III).

DISCUSSION

Bioavailability is defined as the rate and extent of absorption of a drug from its dosage form (21). The absolute bioavailability is determined by a comparison of the measured characteristics after oral and intravenous administration, so long as instantaneous and complete bioavailability is assumed for intravenous injection. The zero moment (*AUC* or urinary recovery) expresses the amount profile, and the first moment (MRT) expresses the time profile. Therefore, the rate of absolute bioavailability is represented by the MAT, and the extent of absolute bioavailability is the fraction of dose absorbed (F). The relative bioavailability is determined by comparing the absorption behavior of a test preparation of a drug with that of its standard preparation. Thus, the MDT or MDIT is the indication of the rate of relative bioavailability, when solution or powder is specified as the reference standard. The extent of relative bioavailability is expressed by F_{rel}.

The absorption time of pharmaceutical alternatives can be compared by using MAT. Though MAT is a useful index of the overall absorption time of several drug products, the intravenous administration is not always possible because of toxicity or hydrophobicity of a drug. The MDT and MDIT can be useful in that case. Pharmaceutical equivalents, which lead to the identical resolved state in the GI tract, are compared in terms of MDT. In the case of poorly soluble drugs, the use of semiaqueous solutions, *e.g.*, polyethylene glycol–water solution, has been proposed as the reference standards in estimating MDT (3). However, since polyethylene glycol can have an effect not only on the dissolution process but also on the GI wall as an adjuvant, the latter effect could interfere in estimation of MDT. Hence, the MDIT is a useful indicator for relative bioavailability of very poorly soluble drugs.



Scheme III—Drug flow diagram of ampicillin and its prodrugs. Key: (I) ampicillin trihydrate; (II) ampicillin anhydrate; (III) hetacillin potassium; (IV) talampicillin hydrochloride; (V) α-aminobenzyl penicilloic acid; (VI) α-aminobenzyl penamaldic acid.

It is of interest to correlate *in vitro* tests with *in vivo* bioavailability. Because MDT and MDIT are just the extracted characteristics of *in vivo* dissolution and disintegration from a complicated biopharmaceutical process, the *in vitro* dissolution and disintegration tests can be directly correlated to these quantities.

The component is a concept that should be distinguished from the classical compartment. The compartment is related to the pharmacokinetic model which is expressed by simultaneous ordinary differential equations. The complete mixing or the steady state is assumed in a certain compartment. The number of compartments in a system is determined according to the number of exponential terms in a pharmacokinetic equation that fits well to the experimental time course data. In contrast, the component is derived from the moment analysis, which is a model-independent method. A component specifies a biological or physicochemical state of a drug, that is, in a capsule, in intestinal fluid, in plasma, as a prodrug, or as a metabolite. The drug flow diagram constructed by components gives the intuitive information about rate and extent profiles of a drug in the GI tract and systemic circulation. The diagram can be more detailed as the experimental information increases. For example, Scheme III shows the more detailed flow diagram of four ampicillin preparations. This diagram was prepared by combining the data in this article with those reported previously (8). Six percent of absorbed ampicillin was unrecovered as shown by the dotted arrow. This process is not yet confirmed and another disposition route is possible.

Sequential Electrochemical Reduction, Solvent Partition, and Automated Thiol Colorimetry for Urinary Captopril and its Disulfides

HAROLD KADIN ˣ **and RAYMOND B. POET**

Received June 8, 1981, from the *Squibb Institute for Medical Research, New Brunswick, NJ 08903.* Accepted for publication December 10, 1981.

Abstract □ Analysis of urinary captopril was necessary for dosage form bioavailability and dose titration studies. The necessity for long-term storage of samples prior to analysis and the presence of an oxidation-prone thiol of captopril required development of an acid-chelate stabilization method for urinary captopril. An electrochemical reduction released disulfide-conjugated captopril for thiol colorimetry. Of several rugged reduction cells evaluated, one with a porous glass disk separating the anode and the mercury pool cathode was preferred. Methylene chloride partitions from acidified salt-saturated urines, before and after reduction, allowed the measurement of free and disulfide-conjugated captopril. The drug partitioned into the solvent, whereas the aqueous phase retained acid protonated, amino group-bearing thiols like cysteine. Subsequent solvent evaporation volatilized other potential colorimetric interferences. An automated thiol colorimetry of 25 samples/hr was developed for analysis of the aqueous reconstitutes. Results were confirmed by a subsequently developed HPLC method with electrochemical detection.

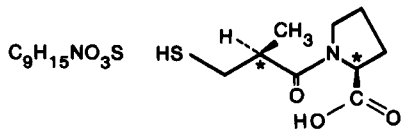
Captopril, 1-(3-mercapto-2-D-methyl-1-oxopropyl)-L-proline (*S,S*)



MW 217.29

is the first clinically potent oral hypotensive agent designed for highly selective inhibition of the angiotensin-converting enzyme (1). Captopril has been found effective for treatment of hypertension and congestive heart failure (2–4).

BACKGROUND

Captopril[1] is readily oxidized in human urine. Acidification minimizes excessive oxidation for only 1–2 days. However, an anticipated large sample load required storage for several weeks before analysis. This provided the impetus for a urinary captopril stability study to determine sample stability under various storage conditions prior to analysis. Satisfactory stabilization was attained by acidification, trace metal removal, and quick refrigeration. A very simple, direct automated colorimetry of pre- and postdosage urines, developed first, appeared adequate. Attempts were made to minimize the predosage urine blank by automating additional thiol colorimetries. These included the alkaline nitroprusside (5) and *S*-nitroso-Bratton–Marshall (6) colorimetries. An automated version of the reaction of Ellman and Lysko (7) gave the lowest blanks.

This simple, direct analysis was quickly found to lack sensitivity by comparison with thin-layer radiochromatographic analysis (8, 9) performed on divided samples from subjects dosed with radioactive captopril. Consequently, the direct colorimetry was preceded by a solvent partition clean-up. To assay for total captopril, which includes captopril, its disulfide, and captopril mixed disulfides (*e.g.*, captopril–cysteine), the urine sample was electrochemically reduced prior to solvent extraction.

The present method, intended as an interim method until development of an HPLC–electrochemical detection (ECD) procedure (10), offers an alternative to laboratories not equipped for HPLC-ECD.

EXPERIMENTAL

Reagents and Apparatus—The reagents included captopril, captopril disulfide, captopril–cysteine disulfide, 8% diethylenetriamine pentaacetic acid (I) in 0.8 *N* NaOH (refrigerate), 10.5% citric acid monohydrate in 6.3% oxalic acid dihydrate, acid-chelating mixture of 0.4% I and 1.05% citric acid monohydrate in 0.63% oxalic acid dihydrate (constituted from the preceding concentrates), freshly water washed methylene chloride, sodium sulfate (anhydrous, fine, granular, or ball milled for rapid dissolution), 1.86% disodium ethylenediaminetetraacetic acid dihydrate (II) plus 0.02% polyoxyethylene sorbitan monooleate[2] in 20% triethanolamine (III)[3], 0.08% 5,5′ dithio-bis(2-nitrobenzoic acid) (Ellman's reagent) in 50% methanol–50% 0.01 *M* sodium acetate–acetic acid buffer[3] (pH 4.7), 0.1 *N* HCl[3], 10% mercuric chloride in 1 *N* HCl, aqueous saturated sodium chloride, and 0.5 *M* Na_2CO_3. In constituting Ellman's reagent, refrigerated buffer was used to minimize heat generated on dilution of the methanol, since heat hydrolyzes the reagent to produce the same yellow color characteristic of its colorimetric reaction with thiols. Since it is also sensitive to light, the reagent was dispensed from an amber container. To further minimize yellow background the triethanolamine used was water-white rather than the yellow of amines stored for long periods of time. Water referred to in this report is distilled water.

The apparatus included centrifuge tubes (50-ml round-bottom, screw capped, with flat polytetrafluoroethylene[4] or polyethylene cone liners), nitrogen evaporation assembly with a 40° bath, ultrasonic bath, plastic caps[5], and an autoanalysis system[6] as illustrated in Fig. 1. The system included an automatic sampler[7] equipped with a 50-2/1 cam. The cam facilitates 50 sample transfers per hour, with samplings twice as long as intermediate washes. The asterisks in Fig. 1 identify solvent resistant tubing[8], whereas the other tubing[9] was not required to be solvent resistant. The peristaltic pump transferred Ellman's reagent, the II–III mixture, and other solutions as indicated in Fig. 1 and in the *Reagents* section.

Colorimetric Standards—Exactly 25.0 mg of captopril was accurately weighed into a 100-ml volumetric flask, dissolved, and diluted to volume with the acid-chelating mixture. Ten-milliliter portions of this primary standard were transferred to 25-, 50-, and 100-ml volumetric flasks. Each flask was diluted to volume with the acid-chelating mixture. These secondary working standard solutions contained 100, 50, and 25 μg of captopril/ml. The primary standard solution was refrigerated up to 1 week. Fresh secondary working standards were prepared daily.

Sample Collection—Five milliliters of I concentrate was added to each subject's plastic, urine collection container. Subjects voided into these containers and the contents were mixed by swirling. The total volume was immediately measured and recorded. Without delay, each

sample was then poured into central, plastic storage vessels (one for each subject), containing 100 ml of cold citric–oxalic concentrate. The solutions were mixed by swirling and the sample rapidly chilled to about refrigerator temperature (3–5°). Each subject's urine voided during a desired collection period was treated as described and collected in that individual's central storage vessel. The volume of urine plus stabilizers in the central storage vessel was measured and recorded. About 50 ml of the settled, measured urine was transferred to a suitably labeled tube. All such tubes were refrigerated during storage or transportation pending assay. The collections for each subject included a predosage control urine.

Electrochemical Reduction Cell—The cell in Fig. 2 was a scale-up from that of previous study (11), and was used for most of the studies. The 5.05 × 1.85-cm i.d. tube contained a magnetically stirred mercury pool in electrical contact with a platinum wire extending to the exterior of the tube. An inverted U side arm (3.5-mm i.d.) was attached ~2 cm from the bottom of the tube. The latter contained a saturated sodium chloride 2% agar bridge constituted and maintained as described previously (12). The agar salt bridge isolates the negative reductive mercury pool cathode from the positive oxidative platinum anode. The anode is positioned at the tip of the bridge in a small container of saturated sodium chloride. The cells were connected in series with miniature alligator clip jumper leads through a 0–5 milliammeter and a power supply[10] capable of supplying 2.5 mA/hr. The integrity of the agar bridge was maintained optimally by storage with saturated sodium chloride solution at both

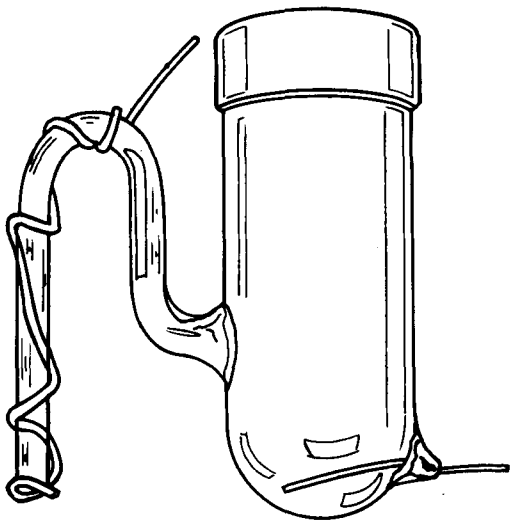

Figure 2—*Saetre-Rabenstein (see Ref. 11) agar bridged electrochemical reduction cell.*

[10] Power Supply No. 6212A, Hewlett-Packard Co., Palto Alto, Calif.

ends. During electrolysis the mercury pool–urine interface was magnetically stirred[11] minimizing vortexing or dispersed mercury droplets. Two cells were stirred over each stirrer. As many as 12 cells were operated in series. To minimize chlorine generation at the anode the saturated sodium chloride electrolyte was made alkaline, as recommended previously (13). Five to six drops of 0.5 *M* Na_2CO_3 were mixed in 9 ml of the anode electrolyte, and the reduction assembly was operated in a hood to sweep chlorine away. The alligator clips were placed well away from the anodic electrolyte to minimize corrosion by chlorine. To minimize chlorine retention in the gel, the bridge tip was removed from the electrolyte soon after a run. Near quantitative disulfide reduction was obtained without widely recommended (13–18) nitrogen blanketing of the cathode compartment. Almost complete sulfhydryl recovery was ensured by l-citric–oxalic thiol stabilization, slight electrolytic hydrogen generation, and a minimum headspace beneath a pinhole vented plastic cap.

Electrochemical Reduction of Sample—Prior to analysis, the saturated sodium chloride and three subsequent water washes were aspirated from the mercury in each cell. The wet mercury and stirring bar were then poured into a 100-ml beaker containing a generous piece of filter paper on the bottom. The mercury was cleaned and dried by swirling it several times over the paper. The mercury and stirring bar were returned to the cell. The cell was then clamp mounted over a magnetic stirrer with its salt bridge exit tip immersed in a small container of alkaline saturated sodium chloride. Washed, dried, and mounted cells were filled with urine samples, leaving minimal headspace beneath the pinhole vented plastic caps[5]. Moderate magnetic stirring was initiated. The cells were securely connected in series to the milliammeter and power supply with the miniature alligator clip jumper leads as follows. The black negative terminal of the power supply was attached with a clip lead to the platinum–mercury cathode of the first cell, then its positive salt bridge platinum anode was clip attached to the platinum–mercury cathode of the next cell in the series. This series clip lead connection between adjoining cells was continued until the last platinum salt bridge anode was connected to the red positive terminal of the power source through the milliammeter. The power supply current was adjusted to 2.5 mA. The voltage across each cell was measured to locate those with abnormally high voltage drops due to a high resistance, deteriorated agar bridge. When a cell had a voltage drop greater than 5 V it was replaced. The electrolysis proceeded for 1 hr with adjustment of the 2.5-mA current, if required. The reduced urine samples were solvent partitioned as subsequently described.

Cells were prepared for the next electrolysis by first shutting off the power supply and stirrers. The urine and three successive, briefly stirred water washes were aspirated. Saturated sodium chloride was added to each cell. The electrolysis as just described for urine samples was performed for 30 min. After 30 min, the electrolysis leads at the power supply terminals were reversed for 10 sec. The power source was then turned off. Leads were disconnected. Cells were demounted for storage in large covered beakers with salt bridges moistened with saturated sodium chloride at both ends.

Solvent Partition—This was performed on reduced urine (section above) to determine free plus disulfide conjugated captopril and on nonreduced urines to determine free captopril. To prepare for the solvent partition 1.0 ± 0.1-g portions of the fine, granular, anhydrous sodium sulfate were weighed into screw-capped 50-ml round bottom tubes. In addition, methylene chloride was freshly water washed (250 ml of methylene chloride washed with 3 × 150 ml of water).

Reduced urine samples were handled as follows: the electrolysis was allowed to proceed while exactly 5.0 ml of the urine was removed by pipet then gradually and vigorously swirled into the sodium sulfate in the 50-ml screw-capped tube to effect salt dissolution[12]. Nonreduced urine samples were likewise transferred to other sodium sulfate containing tubes. Ten milliliters of the washed methylene chloride was gradually added to each tube over the surface of the aqueous phase. Each tube was firmly capped. A pair of tubes was gently rocked to effect emulsion-free extraction[13]. The tubes were centrifuged for ~2 min at ~2500 rpm. With tissue-wiped

[11] Micro V magnetic stirrers, Cole-Parmer Instrument Co., Chicago, Ill.

[12] This was done with a vigorous, circular motion to prevent refractory caking. This vigorous swirling was successively repeated down a line of tubes to effect a gradual salt dissolution. To aid the dissolution the lower portion of the tubes was agitated in the active portion of an ultrasonic bath immediately after the initial swirling.

[13] The extraction was effected by enclosing a pair of tubes within both hands. The tubes were gently rocked 3× within 60° from the horizontal then placed vertically in a rack for at least 30 sec to allow maximum phase separation. The rocking extraction-standing sequence was then repeated two more times. This gentle rocking technique was developed when ordinary shaking oxidized captopril and yielded very stable emulsions.

Table I—Percent Recovery of Captopril [a] in Pooled, Refrigerated, and Frozen Human Urine

Storage Time, days	Stabilized by: Citric–Oxalic-I pH 2 Refrig	Citric–Oxalic-I pH 2 Frozen	Perchloric Acid pH 1 Refrig	Perchloric Acid pH 1 Frozen

63	84.3	—	—	—

[a] 25 and 50 μg/ml.

10-ml pipets and using a pipet filler all of the possible lower phase was carefully transferred to another 50-ml screw-capped tube. Two additional extractions were performed. The combined extracts were evaporated under nitrogen at 40°. Residues were reconstituted in 5.0 ml of the acid chelating mixture, sonicated, and vortexed briefly to dissolve any particles. The tubes were then centrifuged for 5 min at ~2500 rpm. Automated colorimetry with associated blanking was then performed as described.

Automated Colorimetry—Figure 1 shows the apparatus for automated colorimetry. The centrifuge clarified samples were transferred to sample cups[6] by careful decantation[14]. The filled cups were then placed in sampler turntable slots with each sample cup bracketed by full washout water cups. In the same manner single cups containing the acid chelating mixture (reagent blank) and duplicate cups containing 25-, 50-, and 100-μg/ml standards were placed in the turntable prior to and after the sample sequence. The automated analysis was allowed to proceed while preparing the mercuric treated samples as follows. Two milliliters of the above clarified urine sample and reagent blanks was transferred into suitable test tubes containing 0.2 ml of mercuric chloride solution. These were capped, mixed, then centrifuged to optical clarity. Each supernate was carefully transferred[14] (to avoid disturbing sediment) into a sample cup. These were placed on the sampler, bracketed by water cups, following the second set of standards. Five sample cups containing the primary standard dilution followed the mercuric blanked samples. The latter solutions were used to remove trace, potential sulfhydryl blocking mercuric ion from the autoanalysis system (absorbance data were discarded).

Calculations—Percent dose voided = $[100\,(X - B)\,SV]/(1000\,D) = [(X - B)\,SV]/(10\,D)$, where X is absorbance of sample minus the reagent blank, B is 1.1 (absorbance of mercuric treated sample minus the mercuric treated reagent blank), where 1.1 is the mercuric solution sample dilution factor, S is average of three standards calculated as (micrograms per milliliter)/(absorbance of standard), V is urine + stabilizers volume, ml, D is captopril dose, in milligrams.

RESULTS AND DISCUSSION

Urinary Captopril and Its Disulfides—This method was used to analyze captopril in 8-hr postdosage urine of normal subjects before and after electrochemical reduction. Results with 10 subjects expressed as percent of dose (100 mg) were:

$$\text{Free Captopril} - 30.3 \pm 7.74\ SD$$

$$\text{Captopril + Disulfides} - 54.9 \pm 14.6\ SD$$

Thin-layer radiochromatography (8) indicated that human urinary captopril was primarily free (unchanged) and, in almost equal proportion, disulfide conjugated with cysteine. Relatively small amounts of captopril disulfide were observed. Consequently, the present results suggest that ~25% of the dose in the 8-hr urine is principally captopril–cysteine.

Urinary Captopril Stabilization—Long-term urinary captopril stabilization studies were performed by the simple, direct automated analysis on pooled human urine in screw-capped tubes containing 25 and 50 μg of captopril/ml at room, refrigerator, and freezer temperatures. Direct automated analysis of the unfortified pooled urine served as a blank. Data obtained are presented in Table I.

Note that long-term freezing seemed to enhance degradation relative to refrigeration storage particularly with perchloric acid acidified urine. Acid–chelate stabilized urine freezing did not seem to increase stabilization, and in the long-term slightly enhanced degradation.

The stabilization attained by the acid–chelate mixture was attributed to efficient (19) trace metal binding by I at the pH of human urine (pH 5–6), acidification, and refrigeration.

Selectivity, Recovery, Precision, Sensitivity—Selectivity was shown by analysis of predosage 8-hr urines collected from 34 individuals. All yielded essentially zero colorimetric response. Interference from occasionally extracted urinary pigments is obviated by subtracting the colorimetric response of the mercuric blank from that of the sample (see Calculations). Mercuric ion added to a portion of the sample (reconstituted from the methylene chloride extract–nitrogen evaporation residue) prevents captopril colorization of Ellman's reagent by formation of thiol mercaptides. This allows measurement and correction for nonsulfhydryl color.

Pooled predosage and postdosage urines from six individuals were fortified with captopril at 25 and 50 μg/ml, respectively. In two experiments the recoveries with predosage urine were 96.4 and 98.8%. The analysis of the unfortified postdosage pool was subtracted from that fortified to 50 μg/ml to yield a recovery for added captopril of 96.6%. The precision and sensitivity were evaluated by pooling blank urine from 12 subjects. Six replicate assays of this pool determined the apparent micrograms of captopril per milliliter. The pooled urine was fortified with captopril at ~46 μg/ml. Two chemists each performed eight replicate assays of thiol content as described.

Chemist 1 achieved a mean of 45.1 ± *SD* 0.26 with an *RSD* of 1.2. Chemist 2 obtained 45.4 ± *SD* 0.72 with an *RSD* of 2.0. The apparent micrograms per milliliter of captopril in the blank pooled urine was 0.24. The average blank value (subtracted for the recovery data) was calculated from absorbances of 0.002–0.003. Zero and negative absorbance values in this range were frequently obtained and were considered essentially zero blanks. The sensitivity of this method is conservatively estimated at 0.5 μg/ml, which is approximately twice the average blank found in this precision study.

Solvent Partition—To reduce the large predosage blank obtained in direct colorimetry of the urine, the multiple methylene chloride extraction and evaporation was performed, as described in *Experimental* section. Solvent partition of highly polar captopril required salting out from the acidic urines. Appreciable captopril oxidation was observed when using sodium chloride as a salting out agent instead of sodium sulfate. This oxidation was attributed to chlorine from metal catalyzed, solvent mediated air oxidation of chloride (20). Attempts were made to substitute a column solvent partition in which the acidified urine–sodium sulfate was held by a column of polar stationary phase (*e.g.*, diatomaceous earth, silica gel, or cellulose) and a readily evaporated mobile phase (*e.g.*, ethyl acetate, methylene chloride, or 10% isopropanol in methylene chloride) percolates through the column to efficiently perform continuous, multiple extractions. If successful, this column partition would have considerably decreased operator time. However, incomplete recoveries (60–80%), possibly attributable to irreversible adsorption and/or oxidation, were obtained. Attempts at a reversed-phase partitioning into particulate polystyrene divinylbenzene[15] or octadecylsilane bonded to silica particles[16] followed by solvent elution also resulted in recoveries of 85–90%, short of the goal of 95% or better.

Automated Colorimetry—In the design of the colorimetry from a preexisting manual colorimetry (7), the sequence of adding Ellman's reagent before the alkali was reversed to maintain solubility of the reagent within the autoanalysis system. In addition, methanol and acidic aqueous buffer were added to Ellman's reagent to enhance both solubility and stability.

Electrochemical Reduction—The electrical characteristics of the cell included the resistance across the agar bridge of 1600–1700 ohms, a voltage drop across the cell of 3–4 V, and a cathode voltage, *versus* silver–silver chloride, of −0.9 to −1.0 V. These characteristics allowed efficient disulfide reduction by minimizing parasitic reductions of hydrogen ion, oxalic acid (14), and I–metal complexes.

Part of a pool of five normal human urine, stabilized with I–citric–oxalic acids, was fortified with captopril disulfide at 50 μg/ml. Table II presents results of a time and current study of the electrochemical re-

[14] When commercially available pasteur pipets were used to transfer the reconstituted acid captopril solutions to autoanalyzer cups, the first transfer yielded appreciably lower results than the second transfer with the same pipet. This was not encountered when previously washed and dried volumetric pipets or decantation transfers were made.

Table II—Effect of Time and Current on Reduction of Captopril Disulfide [a] in Normal Human Urine Pool

Min	Percent Recovery at Current, mA		
	2	2.5	5
20	53.4	—	68.7
40	84.4	—	92.0
60	97.3	99.3, 98.1, 100.1	93.0

[a] 50 μg/ml.

duction of this fortified urine followed by the extraction analysis. The unfortified human urine pool (control) reduced electrochemically at 2.5 mA for 1 hr yielded a colorimetric response, through the extraction analysis, of 0.003 absorbance units. This is equivalent to a blank (see preceding discussion on sensitivity of the solvent partition).

Table II indicates a possible fall off of reduction at 5 mA. Subsequently, a current of 2.5 mA for 1 hr was used with the encouraging results indicated. Whereas a 1-hr reduction was necessary here, Saetre and Rabenstein (11, 13) reported a complete 10-min reduction with cystine and the penicillamine and the glutathione disulfides. Possibly the amino groups of the latter three disulfides facilitate disulfide reduction by shifting electrons from the disulfide linkage in a manner described previously (21). The 1-hr electrochemical reduction was also valid for captopril–cysteine disulfide. However, a time–current study comparable to that in Table II was not done with the mixed disulfide.

In view of the agar bridge fragility in routine use, several substitutes were considered including a sturdy polyacrylamide gel (22), sintered glass disks (17), tightly rolled paper wads in each end of a glass U tube containing the saturated sodium chloride[17], and 4-mm porous glass[18] disks[19]. The porous (pore diameter 4 μm) glass[18] acts as a semipermeable membrane providing ultra-low liquid leakage rates and minimum IR drop through the tip (23). A rather simple porous glass[18] disk bridge[19] (Fig. 3) had the same resistance as the agar bridge and gave captopril analyses very comparable to that with the agar bridge. It is considered a preferable substitute for the agar bridge. Incorporating the porous glass[18] disk at its end, a tapered glass tube enters a hole in the previously needle-punctured plastic cap (from a 5-ml plastic container)[5] at the top of the cell illustrated. The 4 × 2.9 mm (diameter × width) porous glass disk in heat shrink polytetrafluoroethylene tubing[19] was previously slipped over the glass taper. The heat shrink tubing, well away from the porous glass[18] disk, was then heat shrunk with a heat gun. The assembly was completed with a platinum electrode clipped to the wide top of the glass tube, which contained saturated aqueous sodium chloride. The electrochemical reduction was chosen over other disulfide reduction procedures since it is performed at an acid pH which stabilizes the sulfhydryl. It adds no reducing agents (dithiothreitol, mercaptoethanol, or sulfite) which colorize Ellman's reagent. It is not toxic as is the highly effective disulfide reductant tributylphosphine (24). Finally, several reports (13–16) indicated that borohydride and zinc-acid reductions yielded incomplete reduction or reoxidations in biological samples, whereas electrochemical reductions were quantitative.

Table III—Analysis of Captopril and Its Disulfides in 0–4 Hr Predosage Urine by HPLC–ECD and the Present Method [a]

Subject No.	μg/ml			
	Captopril		Captopril Plus Disulfides	
	HPLC-ECD	PM	HPLC-ECD	PM
2D	13.7	14.7	22.0	23.4
3B	30.6	32.5	47.0	49.3
4A	32.0	33.1	50.5	51.3
5C	25.1	33.5	39.4	32.9
6C	29.7	28.7	52.6	50.7
7B	45.6	43.3	74.2	73.5
8B	34.4	33.2	58.1	59.6

[a] Present method = PM.

The reported electrochemical reduction utilizes a meter, a relatively sophisticated power supply, and an integrated reduction cell. It should be pointed out that simpler versions using a battery, a variable resistor, beakers, and detached agar U-bridges have been implemented (18).

Confirmatory Analysis *via* HPLC–Electrochemical Detection (ECD)—Analysis performed by the presently reported method and the subsequently developed HPLC method (10) are compared in Table III. Agreement is very satisfactory. The assay conformity appears more remarkable when it is learned that the HPLC–ECD assays were performed on samples stored for 90–120 days after their colorimetric analyses.

Intestinal Absorption of Amino Acid Derivatives: Importance of the Free α-Amino Group

G. L. AMIDON *[x], M. CHANG, D. FLEISHER, and R. ALLEN

Received August 14, 1981, from the *School of Pharmacy, University of Wisconsin, Madison, WI 53706.* Accepted for publication December 18, 1981. *Present Address: INTER$_x$ Research Corporation, Lawrence KS 66044.

Abstract ■ The intestinal absorption of L-lysine-*p*-nitroanilide, L-alanine-*p*-nitroanilide, and glycine-*p*-nitroanilide was studied in the presence of competitive inhibitors in a perfused rat intestine. It was observed that L-lysine-*p*-nitroanilide absorption was inhibited by L-lysine methyl ester and L-arginine-β-naphthylamide but not by N_α-acetyl-L-lysine methyl esters. L-Alanine-*p*-nitroanilide absorption was inhibited by L-alanine methyl ester but not by β-alanine methyl ester. It was further observed that N_α-benzoyl-L-arginine-*p*-nitroanilide and N_α-succinyl-L-phenylalanine-*p*-nitroanilide were poorly absorbed. It was concluded that the peptidase in the brush border region that serves as the hydrolysis site requires a free α-amino group (an aminopeptidase), and that passive absorption of these compounds occurs only to a small extent.

Keyphrases □ Absorption, intestinal—amino acid derivatives, importance of the free α-amino group □ Amino acid derivatives—intestinal absorption importance of the free α-amino group □ α-Amino groups—importance of the free α-amino group in the intestinal absorption of amino acid derivatives

Recent investigations have demonstrated that brush border hydrolysis of soluble derivatives of insoluble drugs may significantly increase the absorption rate of the drug (1). Since the approach is based on enzymatic hydrolysis, the specificity of the hydrolytic enzymes in the brush border region must be investigated. While many enzymes have been reported to be present in this region (1), the aminopeptidases represent a likely site for reconversion of compounds previously studied (2–4). Furthermore, a free amino group on the substrate is required for aminopeptidase activity. The objective of this study was to determine the importance, for absorption, of a free α-amino group in amino acid derivatives of drugs.

EXPERIMENTAL

Materials—α-*N*-Benzoyl-DL-arginine-*p*-nitroanilide, *n*-succinyl-L-phenylalanine-*p*-nitroanilide, L-lysine-*p*-nitroanilide, L-lysine methyl ester, N_α-acetyl-L-lysine methyl ester, L-arginine-β-naphthylamide, L-alanine-*p*-nitroanilide, L-alanine methyl ester, β-alanine-*p*-nitroanilide, L-lysine methyl ester, β-alanine methyl ester, glycine-*p*-nitroanilide[1], and glycine methyl ester were used as received.

[1] U.S. Biochemical Corp., Cleveland, Ohio.

Perfusion Experiments—Drug absorption was measured in a perfused rat intestine segment as previously reported (1, 5). The inlet (C_o) and exit (C_m) concentrations were measured spectrophotometrically for the *p*-nitroanilide derivatives. The free *p*-nitroanilide was released by overnight (12 hr) hydrolysis of the syringe and perfusate samples after addition of sodium hydroxide (pH 11–12). A three-point analysis of the spectrum (350, 375, and 400 nm) was used in order to subtract the usually small protein background at these wavelengths.

THEORETICAL

The method of data analysis is the same as previously reported (1, 6). The method is appropriate as long as the boundary condition is linear:

$$J_w = -D\left.\frac{dc}{dr}\right|_{r=R} = P_w C_w \qquad \text{(Eq. 1)}$$

where J_w is the flux at the wall, P_w the wall permeability, and C_w the wall concentration. The dimensionless wall permeability (P_w*) is:

$$P_w^* = \frac{P_w R}{D} \qquad \text{(Eq. 2)}$$

where R is the radius of the intestine and D the solute diffusivity. The wall permeability ($^\circ P_w$*) is calculated using the measured ratio of exit to inlet concentrations (C_m/C_o) and the Graetz number (Gz) where $Gz = \pi DL/2Q$ and where L is the length of the intestinal segment and Q the fluid flow rate. The calculations follow the method previously reported (6). Diffusion coefficients are given in Table I. Analysis is based on the uncorrected $^\circ P_w$* values since the correction is small (6).

For the test compounds used in the present report (*e.g.*, L-lysine-*p*-nitroanilide) it is assumed that hydrolysis at the wall provides the driving force for transport to the wall, with the released *p*-nitroanilide being taken up by the wall (1). The wall permeability is, consequently, a heterogeneous reaction rate constant. The general case has been discussed (1) and gives:

$$P_w = \alpha D \operatorname{Tanh}(\alpha\delta_E) \qquad \text{(Eq. 3)}$$

or

$$P_w^* = \alpha R \operatorname{Tanh}(\alpha\delta_e) \qquad \text{(Eq. 4)}$$

where

$$\alpha^2 = k/D \qquad \text{(Eq. 5)}$$

where k is the first-order reaction rate constant, and δ_E is the (unknown) thickness of the enzyme layer. Two special cases of Eq. 4 are:

High reactivity ($\alpha\delta_e > 1$):

$$P_w^* = \alpha R \qquad \text{(Eq. 6)}$$

[1] U.S. Biochemical Corp., Cleveland, Ohio.

Perfusion Experiments—Drug absorption was measured in a perfused rat intestine segment as previously reported (1, 5). The inlet (C_o) and exit (C_m) concentrations were measured spectrophotometrically for the *p*-nitroanilide derivatives. The free *p*-nitroanilide was released by overnight (12 hr) hydrolysis of the syringe and perfusate samples after addition of sodium hydroxide (pH 11–12). A three-point analysis of the spectrum (350, 375, and 400 nm) was used in order to subtract the usually small protein background at these wavelengths.

THEORETICAL

The method of data analysis is the same as previously reported (1, 6). The method is appropriate as long as the boundary condition is linear:

$$J_w = -D\left.\frac{dc}{dr}\right|_{r=R} = P_w C_w \qquad \text{(Eq. 1)}$$

where J_w is the flux at the wall, P_w the wall permeability, and C_w the wall concentration. The dimensionless wall permeability (P_w*) is:

$$P_w^* = \frac{P_w R}{D} \qquad \text{(Eq. 2)}$$

where R is the radius of the intestine and D the solute diffusivity. The wall permeability ($^\circ P_w$*) is calculated using the measured ratio of exit to inlet concentrations (C_m/C_o) and the Graetz number (Gz) where $Gz = \pi DL/2Q$ and where L is the length of the intestinal segment and Q the fluid flow rate. The calculations follow the method previously reported (6). Diffusion coefficients are given in Table I. Analysis is based on the uncorrected $^\circ P_w$* values since the correction is small (6).

For the test compounds used in the present report (*e.g.*, L-lysine-*p*-nitroanilide) it is assumed that hydrolysis at the wall provides the driving force for transport to the wall, with the released *p*-nitroanilide being taken up by the wall (1). The wall permeability is, consequently, a heterogeneous reaction rate constant. The general case has been discussed (1) and gives:

$$P_w = \alpha D \operatorname{Tanh}(\alpha\delta_E) \qquad \text{(Eq. 3)}$$

or

$$P_w^* = \alpha R \operatorname{Tanh}(\alpha\delta_e) \qquad \text{(Eq. 4)}$$

where

$$\alpha^2 = k/D \qquad \text{(Eq. 5)}$$

where k is the first-order reaction rate constant, and δ_E is the (unknown) thickness of the enzyme layer. Two special cases of Eq. 4 are:

High reactivity ($\alpha\delta_e > 1$):

$$P_w^* = \alpha R \qquad \text{(Eq. 6)}$$

Table I—Diffusion Coefficients

Compound	D, × 10^6, cm^2/sec
Lysine-*p*-nitroanilide	6.7
Alanine-*p*-nitroanilide	7.0
Glycine-*p*-nitroanilide	7.4

Low reactivity ($\alpha\delta_E < 1$):

$$P_w^* = \alpha^2\delta_E \qquad \text{(Eq. 7)}$$

Assuming Michaelis-Menten kinetics at the wall and limiting substrate concentration to the first-order region, the first-order reaction rate constant (k) (Eq. 5) becomes:

$$k = V_{max}/K_m \qquad \text{(Eq. 8)}$$

where V_{max} (moles/liter/second) is the maximal velocity and K_m (moles/liter) is the Michaelis constant. In the presence of a competitive inhibitor[2] (*e.g.*, lysine-*p*-nitroanilide in the presence of lysine methyl ester) Eq. 8 becomes:

$$k = V_{max}/\left(1 + \frac{I}{K_I}\right)K_m \qquad \text{(Eq. 9)}$$

where I is the inhibitor concentration (in the enzyme layer) and K_I the inhibition constant. Combining Eqs. 5, 6, 7, and 9 gives:

High reactivity case:

$$P_w^{*2} = (V_m R^2/DK_m)[1/(1 + I/K_I)] \qquad \text{(Eq. 10)}$$

Low reactivity case:

$$P_w^* = (V_m \delta_E/DK_m)[1/(1 + I/K_I)] \qquad \text{(Eq. 11)}$$

Both Eqs. 10 and 11 can be linearized, but this aspect is not explored in this report. The main point of Eqs. 10 and 11 is that P_w^* is reduced in the presence of a competitive inhibitor. This investigation uses as substrates the *p*-nitroanilide derivatives and the remaining compounds as competitive inhibitors.

Rough estimates of the inhibition constants (K_I) can be made on the basis of this model. From Eqs. 6–11 the following relationships can be obtained:

High reactivity:

$$K_I = I/\{[P_w^*(S)/P_w^*(I)]^2 - 1\} \qquad \text{(Eq. 12)}$$

Low reactivity:

$$K_I = I/\{[P_w^*(S)/P_w^*(I)] - 1\} \qquad \text{(Eq. 13)}$$

where $P_w^*(S)$ is the (dimensionless) substrate permeability and $P_w^*(I)$ is the substrate permeability in the presence of the inhibitor. The inhibitor concentration, $[I]$, would be the concentration in the enzyme layer which is unknown. However, using as $[I]$ its value in the profusing solution allows the calculation of an apparent K_I.

RESULTS AND DISCUSSION

The experimental C_m/C_o ratios and Graetz numbers (Gz), along with the calculated dimensionless wall permeabilities ($^\circ P_w^*$), are presented in Tables II–XIV. Figure 1 presents a summary of the results.

Figure 2 is a graph of the data in Table II where the lysine-*p*-nitroanilide permeability was studied as a function of concentration. The results do not provide any evidence of saturation. While saturation would be expected at some point, it apparently would require concentrations above the 0.8 mM used in these studies. All subsequent studies were done using a lysine-*p*-nitroanilide concentration of 4×10^{-5} M. At this concentration the enzymatic reaction at the wall is in the apparent first-order region, and the analysis in the theoretical section would apply.

The results for the L-lysine-*p*-nitroanilide permeability in the presence of the competitive inhibitors L-lysine, L-lysine methyl ester, N_α-acetyl-L-lysine methyl ester, and arginine-β-naphthylamide are given in Tables IV–VII and Fig. 1. L-Lysine and N_α-acetyl-L-lysine methyl ester did not reduce the L-lysine-*p*-nitroanilide permeability at concentrations of 4×10^{-4} M. L-Lysine methyl ester and arginine-β-naphthylamide did significantly (t test) reduce the L-lysine permeability. These results are consistent with the hydrolysis site being an enzyme of the aminopeptidase type, *i.e.*, requiring a free α-amino group. The fact that L-lysine itself is not a good competitive inhibitor is probably related to the fact that it is the product of the enzymatic reaction. The surface enzyme responsible for hydrolysis apparently does not show significant product inhibition[3].

[2] Compounds used are actually competitive substrates, but since the assay is specific for only one of the substrates, the other acts as a competitive inhibitor (7).

The results for the L-alanine-*p*-nitroanilide permeability in the presence of L-alanine methyl ester and β-alanine methyl ester (Tables VIII–X) are also consistent with the hydrolysis site being an enzyme of the aminopeptidase class. The β-alanine methyl ester, with the primary amino group on the β-carbon rather than the α-carbon, is not a good competitive inhibitor. This is consistent with structural specificity of an aminopeptidase enzyme.

The results for N_α-benzoyl-arginine-*p*-nitroanilide and N_α-succinyl-phenylalanine-*p*-nitroanilide, (Tables XI and XII) provide direct evidence for the importance of a free α-amino group. Both compounds are poorly absorbed as evidenced by their very low permeabilities. The

fact that L-arginine-β-naphthylamide is a good competitive inhibitor for L-lysine-*p*-nitroanilide, while the N_α-benzoyl-arginine-*p*-nitroanilide is not absorbed well at all, further illustrates the importance of a free α-amino group. In addition, the low permeabilities for N_α-benzoyl-arginine-*p*-nitroanilide and N_α-succinyl-phenylalanine-*p*-nitroanilide suggest that passive absorption for both compounds is very small. This is expected since both compounds are ionized at pH 7.4. It further suggests that passive permeation of the other compounds studied is not significant, providing further evidence (in addition to the observed competition) that the absorption mechanism is through membrane hydrolysis (1).

The results for glycine-*p*-nitroanilide and glycine methyl ester (Tables XIII and XIV) do not fit with the above results. That is, it would be expected that glycine methyl ester would be a competitive inhibitor for glycine-*p*-nitroanilide. This suggests that glycine derivatives may be absorbed by a different mechanism (*e.g.*, passive diffusion) or that the enzyme binding constants for the glycine derivative are small. Peptide absorption studies on glycine peptides (*e.g.*, Gly-Gly) indicate that the peptide is taken up intact and is not a good substrate for the brush border peptidases (3, 8). Studies with peptide transport inhibitors need to be

done to further establish the absorption mechanism for glycine-*p*-nitroanilide.

Using Eqs. XII and XIII, rough estimates of a k_I value can be made where significant inhibition is observed. For L-arginine-β-naphthylamide and L-lysine methyl ester respective values of 0.7×10^{-4} and 1.0×10^{-4} *M* are obtained for the high reactivity case, while respective values of 2.5×10^{-4} and 3.3×10^{-4} *M* are obtained for the low reactivity case. The values for L-alanine methyl ester are 0.6×10^{-4} and 2.2×10^{-4} *M* for the high and low reactivity cases, respectively. Since the inhibitor concentration in the enzyme layer is certainly lower than that in the perfusing solutions, these values would represent upper limits on the estimate.

Studies on the intestinal absorption of *p*-nitroanilide derivatives of the amino acids, L-lysine and L-alanine, in the presence of various competitive inhibitors have shown that only those compounds with a free α-amino group are good competitive inhibitors, *i.e.*, reduce the wall permeability, $°P_w*$. This suggests a free α-amino group is essential for good brush border peptidase activity. The fact that N_α-benzoyl-arginine-*p*-nitroanilide and N_α-succinyl-phenylalanine-*p*-nitroanilide are poorly absorbed is also consistent with this inference.

Determination of Sulfadiazine and N^4-Acetylsulfadiazine in Biological Fluids by Liquid Chromatography on Silica Gel with an Aqueous Buffer as Mobile Phase

DOUGLAS WESTERLUND ˣ **and AGNETA WIJKSTRÖM**

Received June 8, 1981, from the *Astra Läkemedel AB, Research and Development Laboratories Analytical Chemistry, S-151 85 Södertälje, Sweden.* Accepted for publication December 15, 1981.

Abstract □ Sulfadiazine and N^4-acetylsulfadiazine were determined in biological fluids by the direct injection (plasma after protein precipitation and urine after dilution 100 times) of 20 μl on a silica gel column. The mobile phase was an aqueous citrate buffer (pH 4.0) and UV detection was at 264 nm. Chromatographic selectivity was optimized by the silica gel surface and pH of the mobile phase. Detection limits were ~0.4 μg/ml for sulfadiazine in plasma and ~5 and 7 μg/ml for sulfadiazine and N^4-acetylsulfadiazine in urine, respectively. In quantitations by peak heights relative to an internal standard (sulfamerazine), within-run precisions ($s_{rel\%}$) for sulfadiazine were 1.7 and 4.0% at 40 and 2 μg/ml, respectively, in plasma and 0.76 and 1.7% at 750 and 25 μg/ml, respectively, in urine.

Keyphrases □ Sulfadiazine—N^4-acetylsulfadiazine, determination in biological fluids by liquid chromatography □ Biological fluids—determination of sulfadiazine and N^4-acetylsulfadiazine by liquid chromatography □ Liquid chromatography—determination of sulfadiazine and N^4-acetylsulfadiazine in biological fluids

It has been demonstrated recently that the antibacterial (1) and pharmacokinetic (2–4) properties of sulfadiazine indicate that it is a suitable sulfonamide for combination with trimethoprim in order to utilize optimally the synergistic antibacterial effect that is exerted by such a composition.

Sulfonamides have been determined by tradition in biological material by the colorimetric Bratton–Marshall technique (5) or modifications that partly overcome its lack of specificity. The most important of these was developed by Rieder (6). Recently, the Bratton–Marshall reaction has been automated for determination of sulfisoxazole and sulfamethoxazole in biological fluids (7). Sulfasalazine could be determined in biological samples by direct spectrophotometric measurement at 455 nm (8). Sulfamethoxazole has been determined in serum by spectrofluorometry after extraction with *n*-butyl chloride (9). There have also been published methods in which gas chromatography with both flame ionization (10) and electron capture detection (11), thin-layer chromatography with spectrophotometric scanning (12, 13), and spectrofluorimetric scanning after derivatization with fluorescamine (14), have been used.

Most new methods have utilized HPLC as the separation tool, either after a preliminary extraction (15–17), or by the direct injection of the biological fluid after a preliminary precipitation of proteins and/or dilution (18–24). Nonpolar bonded phases have been used mainly as the support, but underivatized silica gel (15), amino-bonded (18) and cyano-bonded (20) reversed-phase materials have also been utilized. Thus far, no method has been published for determination of sulfadiazine and its main metabolite, N^4-acetylsulfadiazine, in biological material by HPLC. To study in detail the pharmacokinetics of sulfadiazine, the desired limit of determination should be ~1 μg/ml for plasma and ~10 μg/ml in urine.

The present method relies on the direct injection of biological fluid: either plasma after precipitation of proteins or urine after dilution onto the chromatographic column. The support was silica gel with a large specific surface area, and the chromatogram was developed with an aqueous buffer as the mobile phase. The UV absorbance was recorded at 264 nm.

EXPERIMENTAL

Apparatus—The chemicals were weighed on analytical[1] or microanalytical[2] balances. Samples were vortexed[3], and precipitated proteins and tissue were removed by centrifugation[4] at 1000×*g*. The pH was measured[5] when necessary. For column packing a constant pressure gas amplifier pump[6] was used connected to a 30-ml reservoir[7].

The liquid chromatograph consisted of a reciprocating piston pump[8], an injection valve[9] equipped with a 20-μl loop, and a variable wavelength UV detector[10,11] monitored at 264 nm by a recorder[12].

Chemicals—Sulfadiazine[13], N^4-acetylsulfadiazine[13] and sulfamerazine[13] were from approved batches. The buffer substances, citric acid[14], phosphoric acid[14], sodium dihydrogen phosphate[14], and sodium hydroxide[15], were of analytical quality. From stock solutions of the sulfonamides (0.5 mg/ml in 0.01 *M* NaOH), suitable dilutions were made with deionized and doubly distilled water, which also was used for preparation of the chromatographic mobile phases.

Chromatographic Technique—A spherical silica gel[16] with a mean particle diameter of 5 μm and a specific surface area of 500 m^2/g was packed into a precision bore stainless steel column[17] (150 × 4.0 mm) by an upwards slurry packing technique (25). The slurry (1.5-g support in 25 ml of methyl isobutyl ketone[18]) was sonicated[19] for 5 min and forced into the column by methylene chloride at 400 bars. After packing, the column was washed with methanol and water (100 ml each), and the mobile phase was deaerated by vacuum. Equilibrium was obtained after the passage of ~25 ml of mobile phase at a flow rate of 0.85 ml/min. The column void volume (~1.3 ml) was determined by the injection of potassium nitrate.

Sample Preparation—*Plasma*—A 0.5-ml sample of plasma containing sulfadiazine and 125 μl of sulfamerazine (internal standard) solution (1.0 μg/μl) were acidified by the addition of 25 μl of hydrochloric acid. The proteins were precipitated by the addition of 1 ml of 45% ammonium sulfate solution, mixing, and keeping at room temperature for 0.5 hr. After centrifugation at 1000×*g* for 10 min, the clear supernatant was transferred by a Pasteur pipet, equipped with a piece of cotton at the

tip, to another tube, and 20 μl of the filtrate was injected onto the column. A standard curve (2–40 μg/ml) was obtained by treating 0.5 ml of pooled plasma, 100 μl of sulfadiazine standard solution (0.01–0.20 μg/μl), and 25 μl of sulfamerazine solution (0.5 μg/μl) in the same way as the samples.

Urine—Urine (containing sulfadiazine) (0.5 ml) and 200 μl of sulfamerazine solution (0.5 μg/μl) were diluted to 50.0 ml with water, and 20 μl was injected onto the column after careful mixing. A standard curve (25–750 μg/ml) was obtained by adding 25–750 μl of sulfadiazine and N^4-acetylsulfadiazine solutions (0.5 μg/μl) to 0.5 ml of pooled urine portions, which were treated equivalently to the samples.

Chromatography—Plasma and urine samples were run with the same mobile phase, citric acid buffer (pH 4.0; ionic strength = 0.1; 70 ml of 1 *M* citric acid–83 ml of 1 *M* NaOH were diluted to 1000 ml with water). The flow rate was 0.8–0.9 ml/min and the UV absorbance was recorded at 264 nm. After continuous running the chromatographic performance slowly changed (decreasing capacity ratios and efficiencies), probably because of the adsorption of endogenous compounds onto the support. For column maintenance after each working day, the column was washed first with water (50 ml), then overnight with methanol at a low flow rate (0.1 ml/min), and again just before use with 50 ml of water. By treating in this way, a column could be used for routine analysis (300 plasma or urine samples per week) giving reproducible results for several months.

RESULTS AND DISCUSSION

Chromatography—Sulfadiazine is an amphoteric polar compound which is difficult to extract quantitatively into an organic phase. It is possible to achieve such an extraction, but this necessitates the use of a strongly polar organic medium and/or the addition of ion-pairing counter ions. As a consequence, the obtained extract will contain many coextracted endogenous compounds that may disturb the chromatogram when nonselective UV detection is used. Under such circumstances the introduction of an extraction step only means an unnecessary and roundabout way and time loss in the analytical method. The method was developed to avoid extractions and design the necessary selectivity within the chromatographic system to allow for the direct injection of biological fluids. Preliminary experience with a conventional reversed-phase system (LiChrosorb RP-8 with an acidic methanolic mobile phase) showed significant chromatographic interferences that were hard to control, especially within the retention times for N^4-acetylsulfadiazine.

Underivatized silica gel has been used successfully with aqueous mobile phases for forensic purposes (26, 27) for the determination of the new antidepressant, zimelidine (28), and in studies on ion-pair retention mechanisms (29). A system of this kind was tried for the sulfonamides. It was found at an early stage during the method development that the addition of even small amounts (2%) of organic modifier (*e.g.*, methanol) to the aqueous mobile phase causes the compounds to elute with the front, so neat aqueous buffer solutions had to be used for optimization of the chromatographic system. The actual sulfonamides are only slightly retained by the support in systems of this kind, and it is important to use supports with the largest possible effective surface area. The capacity ratios of sulfadiazine, N^4-acetylsulfadiazine, and sulfamerazine were nearly linearly related to the nominal specific surface area of three different commercial supports (Fig. 1); a citrate buffer (pH 4) was used as the mobile phase in all cases. The pore diameter of the supports decrease with increasing surface area, and this may account for the retentions obtained for the support with the largest area, since all the area may not be available to the comparatively large eluates in this case.

The chromatographic performance of the 800-m^2/g support was, however, not acceptable, giving low efficiency and tailing peaks. Furthermore, it gave coincident retention times for sulfadiazine and sulfamethoxazole, as well as for their N^4-acetylated metabolites. Therefore, the 500-m^2/g support was utilized for further studies.

There is not a marked dependence of the retention on pH (Fig. 2). The capacity ratios are generally somewhat larger at higher pH, but a retention reversal between sulfamerazine and N^4-acetylsulfadiazine occurs with an acidic mobile phase. Crommen (29) has shown that in this kind of chromatography the support seems to work as the more unpolar phase relative to the aqueous mobile phase, and demonstrated that the addition of counterions gave an ion-pair effect similar to that obtained in conventional reversed-phase liquid chromatography. It was found that a large hydrophobic counterion (tetrahexylammonium) was required to give an ion-pair effect in this system. At pH 6.5 the capacity ratios increased about three times in the presence of this counterion, but the time needed for column stabilization was long (~15 hr). Later experience also showed

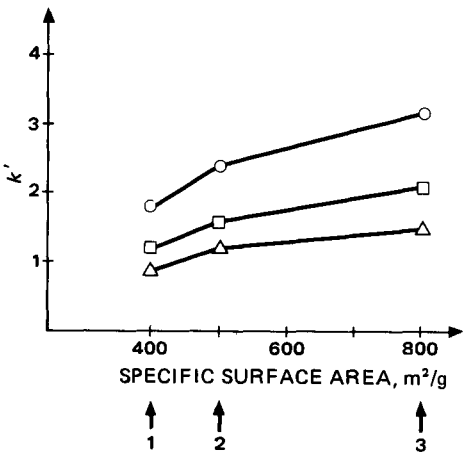

Figure 1—*The dependence of capacity ratios on the support surface area. Mobile phase: citrate buffer (pH 4, μm = 0.1) Column packings: (1) Partisil 5; (2) Nucleosil 50-5;(3) Spherosil XOA-800. Key: (○) sulfamerazine; (□) N^4-acetylsulfadiazine; (△) sulfadiazine.*

that in blank chromatograms from body fluids, endogenous compounds, whose retention times also were influenced by the hydrophobic counterion, interfered with the sulfonamides.

The chromatographic efficiency is typically in the range of 35–45 μm (HETP), while the asymmetry factor (back/front at 10% of peak height) normally is in the range of 1.3–1.8.

The selectivity against trimethoprim is high for all three sulfonamides (α = 2.2) at pH 4 which is used in the bioanalysis, but with this mobile phase it is not as satisfactory relative to other sulfonamides. N^4-Acetylsulfadiazine almost coelutes with sulfamethoxazole (α = 1.07) and N^4-acetylsulfamethoxazole interferes with sulfamerazine (α = 1.05). Changing the pH of the mobile phase, however, will also change the selectivity, since the retentions in this system are dependent on the pKa values of the compounds.

Analysis in Biological Material—The only useful parameter remaining for optimization of the mobile phase for bioanalytical work is pH. The result of such a procedure for urine is demonstrated in Fig. 2. Sulfadiazine is severely interfered with by endogenous compounds at most pH values, but at pH 4 all three actual eluates are resolved from the main interfering compounds. An equivalent optimization for plasma determinations resulted in the same mobile phase pH as for urine. Unfortunately, however, endogenous compounds severely disturbed the N^4-acetylsulfadiazine peak and prevented quantitative determination in plasma by the present method at the very low concentrations of this

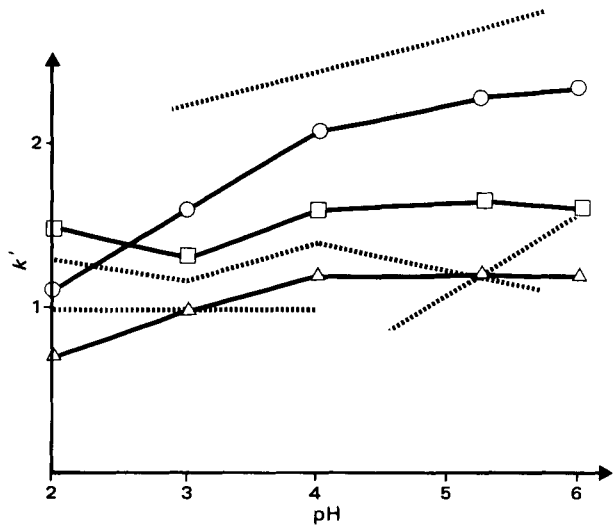

Figure 2—*Optimization of mobile phase pH for urine determinations. Mobile phase: pH ≥4 citrate buffer (μm = 0.1); pH <4 phosphate buffer (μm = 0.1). Key: (△) sulfadiazine; (□) N^4-acetylsulfadiazine; (○) sulfamerazine (internal standard); (·····) endogenous peaks.*

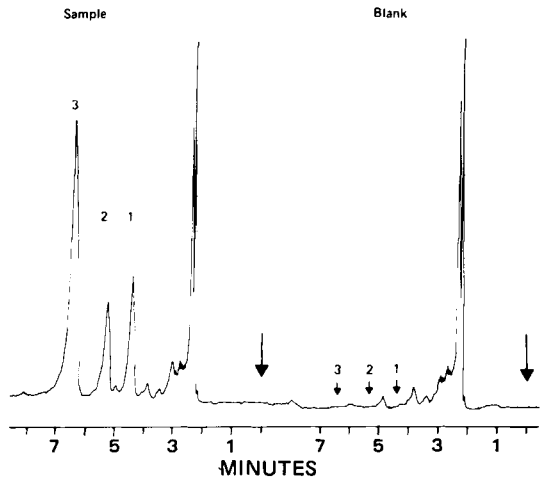

Figure 3—*Chromatograms for determinations in urine (column: 200 × 3.8 mm). Spiked with: (1) sulfadiazine (100 μg/ml); (2) N^4-acetylsulfadiazine (100 mg/ml); (3) sulfamerazine (400 μg/ml). See text for experimental details.*

compound that normally are encountered in most volunteers and patients. Representative chromatograms from spiked urine and plasma samples are shown in Figs. 3 and 4, respectively.

For plasma determinations, the proteins are precipitated by the addition of ammonium sulfate followed by acidification; this procedure was found to give reasonably clean blank chromatograms and acceptable recoveries. The addition of acetonitrile or methanol for this purpose is not possible, since the chromatographic performance (decreased retention times, the appearance of double peaks, *etc.*) is affected by the presence of an organic solvent in the injected sample. A comparison of peak heights of sulfadiazine (1–15 μg/ml) obtained from plasma samples after protein precipitation by the adopted method and from pure buffer samples, respectively, indicated that the absolute recovery from pooled plasma samples is ~76%. A similar comparison of peak height ratios of sulfadiazine and sulfamerazine, the internal standard, gave congruent standard curves (1–15 μg/ml) from pure mobile phase and plasma, respectively, showing that the recovery of sulfamerazine from plasma is of the same magnitude as for sulfadiazine.

The concentrations of sulfadiazine and N^4-acetylsulfadiazine in human urine are high after the recommended dose (0.82 g × 1 or × 2), even after

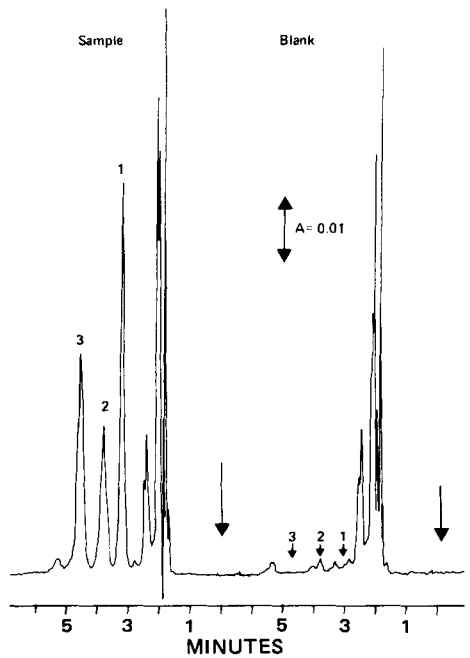

Figure 4—*Chromatograms for determinations in plasma. Spiked with: (1) sulfadiazine (25 μg/ml) in plasma; (2) N^4-acetylsulfadiazine (15 μg/ml) in plasma; (3) sulfamerazine (20 μg/ml) in plasma. See text for experimental details.*

Table I—Studies on Quantitative Determinations and Within-Run Precisions

	Added μg/ml of Plasma	$s_{rel\%}$	Mode[a]
Plasma[b]			
Sulfadiazine	40	1.68	IS
	40	2.85	NIS
Sulfadiazine	2	3.97[c]	IS
	2	3.74	NIS
Urine[d]			
Sulfadiazine	750	0.76	IS
	750	2.12	NIS
N^4-Acetylsulfadiazine	750	0.69	IS
	750	1.73	NIS
Sulfadiazine	25	1.67	IS
	25	3.42	NIS
N^4-Acetylsulfadiazine	25	2.46	IS
	25	4.16	NIS

[a] IS, with internal standard; NIS, without internal standard. [b] Internal standard: 25 μg of sulfamerazine/ml of plasma (n = 10). [c] Change of detector sensitivity during the run. [d] Internal standard: sulfamerazine 500 μg/ml and 200 μg/ml, respectively (n = 8).

a single dose, so that a simple dilution of the urine 100 times and the injection of 20 μl of the resultant solution is an adequate procedure for quantitative determinations. The limits of detection for sulfadiazine and N^4-acetylsulfadiazine are ~5 and 7 μg/ml, respectively, under these conditions, corresponding to the injection of 1–1.4 ng of the compounds. It was observed, however, that the selectivity of the chromatographic system may differ between different batches of the support. In some cases the N^4-acetylsulfadiazine peak was interfered with by endogenous compounds also in the urine determinations. In plasma determinations the detection limit for sulfadiazine is ~0.4 μg/ml, *i.e.*, an injected amount of 2.4 ng.

For characterization of the methods, some repeatability studies were performed where the results were calculated in two ways on the same sample: by peak height measurements of sulfadiazine (*i.e.*, no internal standard involved in the calculations) and by peak height ratio calculations (Table I). In accordance with some earlier studies (30, 31), the incorporation of an internal standard, structurally related to the compounds of interest, significantly improves the within-run precisions of the method, presumably by the compensation for the slight changes in chromatographic performance of the column that occur during a working day, and by the elimination of deviations due to small differences in volume between the samples.

Binding of Selected Phenol Derivatives to Human Serum Proteins

JOSEPH JUDIS

Received March 10, 1981, from the *College of Pharmacy, The University of Toledo, Toledo, OH 43606.* Accepted for Publication December 17, 1981.

Abstract □ The binding of phenol and four of its derivatives to whole human serum and several human serum proteins was investigated. ^{14}C-labeled derivatives were utilized and binding was studied by either equilibrium or dynamic dialysis. Phenol itself was bound least to most of the serum proteins as compared to the derivatives and albumin, and whole human serum exhibited the highest percent binding of the proteins used. Percent binding to albumin and serum paralleled molecular weights of the derivatives, but no definite pattern was observed in ranking the percent binding of the other derivatives to the other serum proteins. Binding constants (K_1, K_2, n_1 and n_2) were determined from Scatchard plots for all the derivatives except *p*-chloro-*m*-xylenol. Phenol was found to have the highest association constant (K_1) and *p-tert*-amylphenol, the lowest. For the entire group of five derivatives and albumin as the protein, a direct, statistically significant correlation was found between percent binding and Hansch π values. No correlation could be found with Hammett σ values. It is concluded that binding of the phenol derivatives to albumin involves primarily hydrophobic bonds.

Keyphrases □ Binding—selected phenol derivatives, human serum proteins ■ Phenol—selected derivatives, binding, selected human serum proteins □ Serum—human, binding of selected phenol derivatives to proteins ■ Derivatives—phenol, selected, binding to human serum proteins

Since the discovery of phenol in 1834 and its introduction to antiseptic surgery by Lister in 1867 (1), both phenol and many of its derivatives have become firmly established as germicidal agents (2, 3). Phenol derivatives, unlike many other germicides, have been shown to be less active in the presence of organic matter (2–4). Blood is a common organic contaminant in materials to be sterilized. Preliminary investigations of the binding of phenol derivatives to human serum proteins were carried out as part of the work in this study on the mechanism of action of phenol derivatives (5, 6). These preliminary studies were expanded to include individual major human serum proteins, percent binding to each, and binding parameters for human serum albumin for a selected group of phenol derivatives.

EXPERIMENTAL

Materials—The phenol derivatives used were obtained with carbon-14 labels[1]. The compounds used and specific activities were as follows: [^{14}C]phenol, 1.57 mCi/mmole; [2,4-^{14}C]dichlorophenol, 0.68 mCi/mmole; [2,4,6-^{14}C]trichlorophenol, 0.68 mCi/mmole; [^{14}C]*p-tert*-amylphenol, 0.27 mCi/mmole; [^{14}C]*p*-chloro-*m*-xylenol, 0.0027 mCi/mmole. Phenol stock solutions were made in distilled water and those of the other derivatives were made with 0.1% NaOH as the solvent. Crystalline human serum albumin and the other human serum proteins were obtained commercially[2] and the whole human serum was of tissue culture quality[3]. All other chemicals used were of reagent grade.

Methods—Dialysis methods (equilibrium and dynamic) were carried out as previously described (7). Radioactivity was determined in a liquid scintillation system using techniques previously described (7, 8). Estimates of binding parameters were calculated using the method of Sandberg (8) and standard Scatchard techniques. All averages were based on a minimum of three replicates.

Table I—Binding of [^{14}C]Phenol and [^{14}C]-*p-tert*-Amylphenol to Human Serum Proteins [a]

Serum Proteins		Ligands Percent Bound[b]	
Fraction	Concentration[c], mg/ml	Phenol	*p-tert*-Amylphenol
Albumin	40.0	48.7 (0.68)	89.1 (0.74)
α Globulin IV-1	1.0	7.9 (0.47)	28.5 (1.92)
α Globulin IV-4	5.0	23.0 (0.63)	46.5 (1.60)
β Globulin III	7.0	3.13 (0.14)	35.2 (0.60)
γ-Globulin II	11.0	8.21 (0.63)	13.0 (0.69)
Human serum	—	52.7 (1.16)	95.3 (0.18)

[a] Each system contained a total of 1.00×10^{-7} mole of [^{14}C]phenol or 1.86×10^{-7} mole of [^{14}C]*p-tert*-amylphenol. [b] The values in parentheses are standard deviations. Data obtained using equilibrium dialysis method. [c] Concentrations used approximate those normally found in human serum.

RESULTS AND DISCUSSION

The values obtained for percent binding to whole human serum and the several serum proteins for the five derivatives studied are listed in Tables I and II. Weakest binding was found with phenol and the latter was bound primarily to albumin. Although phenol was bound to the other serum proteins, the extent was <10% except for α-globulin IV-4. The addition of alkyl groups or halogens to the phenol molecule has been found to increase the latter's germicidal activity (9). It would appear from the results in Tables I and II that alkylation and/or halogenation of phenol also increases the latter's binding affinity for serum proteins. The addition of a tertiary amyl group to phenol increased percent binding of phenol almost twofold (Table I) for albumin and whole human serum and

[a] Each system contained a total of 1.56×10^{-7} mole of [2,4-^{14}C]dichlorophenol, or 2.21×10^{-7} mole of [2,4,6-^{14}C]trichlorophenol or 2.04×10^{-7} mole of [^{14}C]*p*-chloro-*m*-xylenol. [b] The values in parentheses are standard deviations. Data obtained using equilibium dialysis method.

Table III—Binding Parameters [a] (Albumin) of Phenol, 2,4-Dichlorophenol, 2,4,6-Trichlorophenol, and *p-tert*-Amylphenol

Ligand [b]	Percent Binding	K_1 [c]	n_1	K_2	n_2
Phenol	48.7	67,200,000	0.0487	16,020	0.186
2,4-Dichlorophenol	87.7	1,010,000	0.1930	71,900	0.345
p-tert-Amylphenol	89.1	64,600	0.3670	21,500	0.714
2,4,6-Trichlorophenol	94.1	30,200,000	0.2940	1,470,000	0.323

[a] Data obtained by dynamic dialysis method. [b] Initial number of moles added to each system: phenol, 1.03×10^{-6}; *p-tert*-amylphenol, 9×10^{-7}; 2,4-dichlorophenol, 9.2×10^{-7}; 2,4,6-trichlorophenol, 9.95×10^{-7}. Dynamic dialysis method was used to obtain data. [c] Liters per mole.

Table IV—Ranking of Phenol Derivatives [a] in Order of Percent Binding to Various Serum Proteins

Serum Protein	Ranking by Percent Binding
Whole human serum	III > IV > II > V > I
Human serum albumin	III > IV > II > V > I
α-Globulin IV-1	IV > V > II > III > I
α-Globulin IV-4	II > III > IV > I > V
β-Globulin III	IV > V > II > III > I
γ-Globulin II	V > IV > I > II > III
Ranking on basis of molecular weight	III > IV > II > V > I

[a] Phenol derivatives above are: phenol, I; 2,4-dichlorophenol, II; 2,4,6-trichlorophenol, III; *p-tert*-amylphenol, IV; and *p*-chloro-*m*-xylenol, V.

also substantially for the other serum proteins. Again, the serum protein showing the highest percent binding was albumin, and α-globulin IV-4 also exhibited substantial binding (46.5%).

Halogenation of phenol also caused a great increase in binding with whole serum and the serum proteins. 2,4,6-Trichlorophenol was found to be bound to a higher percent to whole serum and albumin than 2,4-dichlorophenol ($p < 0.05$), but binding to the other serum proteins did not show a similar pattern. The derivative that was both a halogenated and alkylated derivative of phenol, *p*-chloro-*m*-xylenol, exhibited a higher percent binding to whole serum and most of the serum proteins than phenol itself, but not higher than the two halogenated derivatives for albumin and human serum.

The Scatchard plot for *p-tert*-amylphenol and albumin is shown in Fig. 1. Data for Scatchard plots were limited, in this study, to albumin as the protein, because all of the derivatives showed the highest percent binding to albumin. The plots for phenol, 2,4-dichlorophenol, and 2,4,6-trichlorophenol were similar, differing only in values for the axes. It can be seen that the curve is not a straight line as would be expected for a single binding system. It appears that the curve has two distinct segments indicative of two binding systems. The binding parameters calculated are given in Table III[4]. The two derivatives exhibiting the highest percent binding to whole serum and albumin, did not yield the largest K_1 association constants. Phenol itself had the highest calculated association constant (K_1) and *p-tert*-amylphenol's constant (K_1) was the lowest of all. All of the *n* values, the number of binding sites, were fractional. Values for $n < 1$ have been reported in other studies (10–12) and present difficulties in interpretation in terms of a physical model.

The ranking by percent binding of the several phenol derivatives to the protein fractions studied is illustrated in Table IV. The only obvious pattern is that ranking of the phenols with respect to binding to albumin or whole human serum is exactly the same as ranking by molecular weight. No clearcut pattern is apparent for the other proteins. Hansch (13–15), in his studies of the relationships between structure and biological activity, found correlation of the latter with partition coefficients expressed as the constant, π. An additional constant, σ, was developed by Hammett (16) to express the electronic activity of the substituents on an organic molecule. Thus, π is an expression of the degree of lipophilicity of a compound and σ is the electronic (polar) nature of a compound. The Hansch equation attempts to take into account the contribution of both lipophilic and electronic properties of a compound with respect to its biological activity. The latter is usually represented as the log of the reciprocal of the measure of biological activity.

The π and σ values for the phenol derivatives were determined, either from literature values reported (15) or calculated on the basis of the sum of the values of substituent groups (14–17). The log of the reciprocal of percent binding to each protein was analyzed by regression analysis with the π and σ values to search for possible correlations. The results obtained are listed in Table V. For those values (π or σ values and log of 1/percent bound) yielding a correlation coefficient of at least 0.900 ($p \leq 0.05$), correlation coefficients are listed. A direct relationship with π values would indicate that the percent binding increased with an increase in lipophilic properties. Significant correlation with σ values would suggest increased binding with more polar properties if the relationship was direct

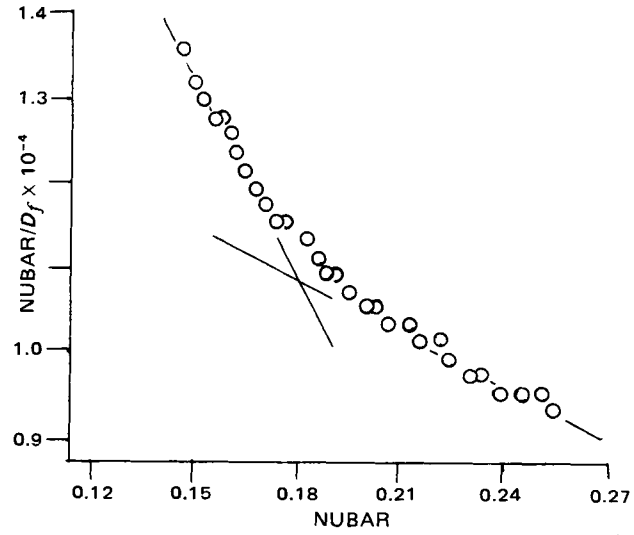

Figure 1—*Scatchard plot of data for binding of* p-tert-*amylphenol to human serum albumin, determined by dynamic dialysis. A total of 9.3* $\times 10^{-7}$ *moles of* p-tert-*amylphenol were added at the beginning of the run and albumin concentration in the bag (5 ml volume) was* 5.797×10^{-4} *M (40 mg/ml). Nubar is equal to total bound moles of ligand divided by moles of albumin in the system and* D_f *is the molar concentration of unbound ligand.*

[4] It was not possible to obtain binding parameters for *p*-chloro-*m*-xylenol because a sufficient quantity of the labeled compound was not available.

Table V—Relationships Between Percent Binding of Phenol Derivatives to Various Serum Proteins and π or σ Values or Molecular Weights of Phenol Derivatives

Phenol Derivative[a] Groups	Serum Protein	Relationship[b] π[c] Values	σ Values	Molecular Weight
I–V	Albumin	Direct (0.963)	—	Direct (0.964)
II–V	α-Globulin IV-1	—	Inverse (−0.964)	—
	β-Globulin III	—	Inverse (−0.954)	—
I–III	Albumin	Direct (0.98)	Direct (0.979)	Direct (0.98)
	α-Globulin IV-4	Direct (0.924)	Direct (0.920)	Direct (0.924)
I, IV, V	Albumin	Direct (0.979)	—	Direct (1.0)
	α-Globulin IV-1	Direct (.997)	—	Direct (1.0)
	β-Globulin III	Direct (0.998)	—	Direct (0.966)
	γ-Globulin II			Direct (0.931)

[a] Phenol derivatives above are: I, phenol; II, 2,4-dichlorophenol; III, 2,4,6-trichlorophenol; IV, *p*-chloro-*m*-xylenol; V, *p*-*tert*-amylphenol. [b] Figures in parentheses are coefficients of correlation. [c] π Values for I–V, respectively, were 1.46, 3.0, 3.69, 3.27, and 3.59. σ Values, respectively, were −0.36, 0.10, 0.33, −0.47, and 0.85.

and the reverse, if inverse. For the entire group of five phenol derivatives, correlation was direct with increasing molecular weight (as pointed out previously) and with increasing π values. The relationship with σ values was not statistically significant.

It would appear that for the entire group of five derivatives, the more lipophilic the molecule, the higher the binding to albumin. Other statistically significant relationships were found when the phenol derivatives were divided into other groups. Namely, either the halogenated phenols plus phenol or the alkylated phenols (including *p*-chloro-*m*-xylenol) and phenol. The data in Table V also suggest something about the hydrophilic–hydrophobic properties of several of the proteins. Albumin appears to have both hydrophobic and polar binding sites in that there was a direct relationship between binding and π values and also with σ values for the more polar derivatives (Group 3). On the other hand, α-globulin IV-1 had a direct relationship with π values and an inverse relationship with σ values for the more polar derivatives (Group 2.) suggesting capability for a polar binding primarily. Like albumin, α-globulin IV-4 appears to have both nonpolar and polar binding sites as indicated by the direct relationship with both π and σ values for the more polar derivatives.

In one form of the Hansch equation (17):

$$\log 1/C = a\pi + b\sigma + c \qquad \text{(Eq. 1)}$$

where C represents the measure of biological activity. The values a, b, and c are constants characteristic of the system, while π is the Hansch constant and σ is the Hammett constant. It was possible to fit this equation with statistical significance ($p = 0.05$) only in the cases of binding of the five phenols to either albumin or human serum. The constants obtained were:

For albumin:

$$\log 1/\text{percent binding} = -0.13\pi + 0.016\sigma - 1.51 \qquad \text{(Eq. 2)}$$

For human serum:

$$\log 1/\text{percent binding} = -0.12\pi + 0.0091\sigma - 1.56 \qquad \text{(Eq. 3)}$$

In studies of the toxicity of phenol derivatives to two microorganisms (18) the Hansch equations calculated suggested that the σ value was of little consequence. This would also appear to be true in the equations describing the binding of the phenol derivatives to either albumin or human serum in that the coefficient for the σ term is relatively small.

In conclusion, it would appear from the data obtained that for the derivatives of phenol studied, serum protein binding is significant, especially to whole human serum and albumin and that binding is related to molecular weight and Hansch π values. Binding to albumin apparently involves primarily hydrophobic bonds rather than polar bonding. This conclusion would be consistent with the findings of Teresi (19) that treatment of bovine serum albumin to remove epsilon-amino positive charges had little effect on binding of 2,4-dichlorophenolate (pH 7.6). In addition, Scholtan (20) concluded that nonspecific hydrophobic binding to human serum albumin is the major mechanism for a wide variety of organic molecules.

Determination of Bacmecillinam, an Amdinocillin Prodrug, in Human and Canine Whole Blood by Reversed-Phase Liquid Chromatography

DOUGLAS WESTERLUND ˣ, BODIL PETTERSSON, and JAN CARLQVIST

Received June 8, 1981, from the *Astra Läkemedel AB, Research and Development Laboratories, Analytical Chemistry, S-151 85 Södertälje, Sweden.* Accepted for publication December 15, 1981.

Abstract □ Bacmecillinam is an amdinocillin prodrug designed to be easily hydrolyzed in biological materials, so special procedures were developed for the collection of blood specimens. Whole blood was collected in tubes containing bacampicillin as an adsorption inhibitor and kept at −70°; the extracting solvent, hexane–methylene chloride (9:1, v/v), was added to the cold tubes, and the extraction was performed during the thawing of the samples. The organic phase was partially evaporated before a reextraction to a small volume of acidic aqueous phase was made. The separation was performed on a microparticulate C_{18}-alkyl bonded silica packed in glass-lined stainless steel columns. Mobile phase was a buffer (pH 6)–acetonitrile mixture containing *N*-hexyl-*N*-methylamine as an adsorption inhibitor. The detection limit was 600 pg/ml of whole blood, and the within-run precision ($s_{rel\%}$) was ~8% at the 5-ng/ml level.

Keyphrases □ Bacmecillinam—determination in biological fluids by reversed-phase liquid chromatography □ Biological fluids—determination of bacmecillinam by reversed-phase liquid chromatography □ Reversed-phase liquid chromatography—determination of bacmecillinam in biological fluids

Amdinocillin, a 6β-amidinopenicillanic acid, is a relatively new antibiotic agent for which a synergistic effect *in vitro* and *in vivo* has been demonstrated, in combination with β-lactam antibiotics, against many strains of Gram-negative bacteria. Since amdinocillin is poorly absorbed after oral administration, prodrugs such as amdinocillin pivoxil and bacmecillinam have been developed in order to enhance the oral drug absorption efficiency. Bacmecillinam, the 1′-ethoxycarbonyloxyethyl ester, is rapidly hydrolyzed by endogenous esterases in blood and tissues releasing ethanol, acetaldehyde, and carbon dioxide. Recently (1), the superior pharmacokinetic properties of bacmecillinam compared with amdinocillin pivoxil were demonstrated in studies on healthy volunteers, resulting in statistically significant differences regarding areas under the curve, urinary excretion, and peak plasma concentrations.

During the evaluation of the toxicological and clinical properties of the drug, a need for the determination of the intact prodrug, bacmecillinam, arose. This report presents such a method for the quantitative determination of the compound in whole blood and bile. Since the compound is very unstable in the presence of biological fluids, special precautions in sample handling had to be developed. At the very low concentration levels encountered, severe adsorption tendencies of the compound had to be overcome by careful handling of the sample. An extraction procedure comprising a base extraction and a reextraction to an acidic aqueous phase precedes the chromatographic step which relies on reversed-phase liquid chromatography and UV detection. Amdinocillin pivoxil was utilized as the internal standard.

EXPERIMENTAL

Apparatus—Chemicals were weighed on analytical[1] or microanalytical[2] balances; a shaker[3] was used for extraction, speed control 6.5; and the extraction tubes were centrifuged at 300×*g*[4] (Step 1 in the extraction) or at 650×*g*[5] (Step 2). The equipment for liquid chromatography was comprised of a dual reciprocating piston pump[6], an injection valve[7] equipped with a 20- or 200-μl loop, an injection syringe[8] with a total volume of 1 ml, a variable UV detector[9] monitored at 230 nm, and a recorder[10] with an input of 10 mV and a paperspeed of 40 cm/hr.

Chemicals—Bacampicillin[11], bacmecillinam[11], and amdinocillin pivoxil[12] were from released batches. *N*-Hexyl-*N*-methylamine[13] of pure quality, phosphoric acid (85%)[14] of analytical quality, and acetonitrile[13] of HPLC quality were used for preparation of the mobile phases. Methylene chloride[13] of HPLC quality and *n*-hexane[14] of spectroscopic quality were used in the extractions. The water was deionized.

Standard Solutions—Solution S consisted of 5 mg of bacmecillinam/250 ml of water in a polypropylene flask[15]; Solution I: amdinocillin pivoxil, internal standard, 1.25 mg/250 ml of water in a polypropylene flask; Solution A: bacampicillin, adsorption inhibitor, 100 mg/100 ml of water in a polypropylene flask. Solutions S, I, and A were divided into 1-ml portions and stored at −70° in tubes[16]. Each day of analysis, appropriate amounts were thawed, and out of Solution S, a series of seven twofold dilutions (S_1–S_7), containing 10–0.156 μg/ml, were made in tubes[16].

Solution IA was made by mixing 1.0 ml of I and 0.5 ml of A in a tube[16] and Solution ID was made by mixing 1.0 ml of I and 0.5 ml of water in a tube[16]. Solvent for extraction (Solvent E): methylene chloride (50.0 ml) was added by pipet into a 500-ml flask and *n*-hexane was added to the mark. Solution S_4 (200 μl), 300 μl of Solution IA, and 3500 μl of 0.01 *M* H_3PO_4 were mixed to make the chromatographic test solution.

Control of Standards—Two independent weighings for the preparation of standard solutions were made. The solutions were diluted with an equal volume of deionized water and the absorbances at 220 nm were measured on a spectrophotometer. If the absorbances agreed within 2%, one of the standard solutions was prepared and stored according to the described procedure. If the absorbances deviated, new sets of dilutions were prepared and the control performed once more. If disagreement still persisted, new weighings had to be made.

Instrument Control—The performance of the HPLC instrumentation was controlled each day of operation by the injection of two standard solutions (S_2 and S_5). The slope of this standard curve was calculated, and the baseline noise level was observed. If data were in accordance with previously reported data (results within ±10% of established data) the instrument performance was approved.

Sample Collection—*Whole Blood*—Whole blood (0.25–2 ml) was collected by means of a cannula[17] in 5-ml tubes[18], containing 10–100 μl

of Solution A, diluted 10 times, with each dilution containing 10 μg of bacampicillin. Care was taken to avoid blood coming into contact with the stopper. The content was then rapidly poured into preweighed centrifuge glass tubes, which were placed in a carbon dioxide–ethanol bath in order to rapidly freeze the content. The whole procedure had to be performed within 10 sec.

Bile—Bile from dogs was collected directly in preweighed centrifuge tubes, containing ~10 μg of bacampicillin as an adsorption inhibitor, and kept in a carbon dioxide–ethanol bath, which was isolated[19] to prevent the freezing of the bile in the tube coming from the dog.

Sample Preparation—For preparation of standards, 2.00 ml of human whole blood or 1.00 ml of canine whole blood or bile was added by pipet into 14 centrifuge tubes and the tubes were chilled in an ice bath. A 20 μl volume of Solutions S_1–S_7 was added to the standard tubes, each solution to two tubes leaving two tubes as blanks; the tubes were mixed for 5 sec and put in a carbon dioxide–ethanol bath (~−70°) in a fast and reproducible manner. All sample handling from then on was performed by keeping the samples cold in the carbon dioxide–ethanol bath. The sample tubes were weighed on an analytical balance and put in the freezing mixture. Solution IA (30 μl) was added to all standard tubes, and 30 μl of Solution ID was added to all sample tubes.

Extraction—While keeping the tubes at −70°, 5.00 ml of Solvent E/ml of sample was added to each tube. The stoppers were sealed by rubber bands and the tubes were put in the shaker horizontally for 20 min. After loosening the stoppers, the tubes were centrifuged[4] for 10 min. The organic phase was carefully transferred to new glass centrifuge tubes (10-ml volume) and evaporated to 4 ml under a gentle stream of air or nitrogen at room temperature, 400 μl of 0.01 *M* H_3PO_4 was added, the stoppers were sealed by rubber bands, and the tubes were put in the shaker horizontally for 15 min. After centrifugation[5] for 5 min the organic phase was removed carefully by a Pasteur pipet and remaining traces were evaporated by compressed air. The aqueous phase (200 μl) was injected into the chromatographic column.

Chromatography—The support[20] was packed in glass-lined stainless steel columns[21] (100 × 4-mm, i.d.) by an upwards slurry packing technique (2) with methylene chloride as solvent. Mobile phase was pH 6 phosphate buffer (ionic strength = 0.05)–acetonitrile (6:4, v/v) containing *N*-hexyl-*N*-methylamine (10^{-4} *M*); the mixture was degassed for 2 hr by magnetic stirring before use. The chromatographic procedure was as follows. The column was equilibrated with the mobile phase for ~1 hr before starting the analysis. Samples (200 μl) were injected in the following order: (*a*) 0.01 *M* H_3PO_4 for control of chromatographic purity; (*b*) chromatographic test solution; (*c*) extract from a whole blood blank sample; (*d*) Standard S_1, (*e*) sample; (*f*) Standard S_2 and so on from there. (This sequence of injections is not critical to the outcome of the analysis but is recommended in order to get as reliable results as possible from the quantitations.) The standard injecting frequency depended on the number of samples and was distributed as evenly as possible among the samples. Finally, the injections were concluded by another sample of the chromatographic test solution, and its chromatographic appearance was compared with the first sample injected in order to confirm the column retention throughout the study.

For quantitation a standard curve was constructed by plotting the peak height ratio of sample–internal standard against the concentration of bacmecillinam in the standards.

RESULTS AND DISCUSSION

Sample Handling—Bacmecillinam as a prodrug is designed to be unstable in biological material, and the compound is rapidly hydrolyzed in whole blood as demonstrated in Fig. 1 (~30% of the compound is lost within 1 min at 37°). The enzyme systems responsible for the degradation are not identified, but similar studies on other prodrugs, amdinocillin pivoxil, talampicillin, and bacampicillin (3), have revealed that blood, plasma, and serum, as well as homogenates from liver, gastric, and duodenal mucosa from humans, dogs, and rats, are capable of efficiently hydrolyzing these types of prodrugs. A fast procedure for collection of samples, involving an immediate freezing of the sample to −70° and subsequent storage at this temperature, therefore, is an essential step in the method.

In bile the compound was more stable: after 10 min at 23° and 37°, ~4.0 and 6.5%, respectively, was lost.

Table I—Stability of Bacmecillinam in Canine Biological Fluids[a]

Day of Analysis	Mean, ng/ml	*s*, ng/ml	Confidence Interval[b]	*n*
Whole Blood				
1	7480	—	—	2
42	7310	134	7090–7520	4
1	89	—	—	2
42	83	6.2	73–92	4
Bile				
1	105	4.8	93–117	3
42	100	1.7	97–103	4

[a] At −70°. [b] $p = 0.05$.

Bacmecillinam is stable both in canine whole blood and bile (Table I) at −70° for at least 40 days; although, the mean values of the analyses indicate a small decrease in concentration after this time, it is not statistically significant.

Extraction—The extraction was optimized by mixing a nonpolar organic solvent, *n*-hexane, with a more polar one, methylene chloride. Preliminary experiments gave log $k_d \times K'_s = 6.3$ and 2, respectively, for the two solvents (k_d is the partition coefficient, K'_s is the acid dissociation constant = $10^{-6.83}$ at 21° and ionic strength = 0.1[22]). The extraction yield was optimized at pH 7.4, ionic strength = 0.5 (equal to the plasma pH) to eliminate the need of buffer addition to the whole blood. Under these conditions the percent extraction from buffer increased from 92 to 97% (Fig. 2) by adding 10% methylene chloride. It can be calculated that with a phase ratio (V_{org}/V_{aq}) equal to three, a quantitative extraction (99%) is achieved with such an organic phase, compared to $V_{org}/V_{aq} = 9$ required with pure *n*-hexane. In extractions from biological fluids, a phase ratio of five was used in order to compensate for the influence of biological material on the extraction.

For a quantitative reextraction of bacmecillinam to an aqueous phase, 0.01 *M* H_3PO_4 was used. It was found empirically that even with $V_{org}/V_{aq} = 20$, the compound is completely reextracted onto the aqueous phase. In the analytical procedure, the initial organic extract is partially evaporated to about half the volume prior to extraction resulting in $V_{org}/V_{aq} = \sim 12$.

In extractions from bile using a mechanical shaker, a heavy emulsion was obtained. It could be decreased by mixing the phases more gently in a rotating device[23], but to break up the emulsion completely, it was necessary to freeze the samples to −25° after a preliminary centrifugation

(900×*g* for 5 min), followed by another identical centrifugation. Bacmecillinam also has a tendency to adsorb at certain interfaces. This was first observed in studies on extraction properties of the compound during method development when nonreproducible results initially were obtained. Silanization of glassware or use of plastic (polypropylene) tubes did not improve the results; only by the addition of a comparatively large excess (100–5000 times) of a related prodrug, bacampicillin, the results became reproducible. The adsorption of bacmecillinam to glass surfaces was further illustrated in an experiment (Table II) where whole blood containing bacmecillinam was transferred by Pasteur pipets. The recovery in the transferred samples was ~57% (median value), and with a large variation, the difference was statistically significant compared with controls.

Considering the facts on hydrolysis and absorption, the blood is collected in sampling tubes which contain an aqueous solution of the adsorption inhibitor, bacampicillin. The content is then rapidly poured into preweighed centrifuge tubes of glass placed in a freezing bath. The whole procedure must be performed within 10 sec to avoid significant hydrolysis of the compound.

Chromatography—Nucleosil C_{18} (5 μm) has been found suitable for the chromatography of hydrophobic amines (4) and was chosen as the support in this study. Initial experiments indicated that bacmecillinam

Table II—Adsorption of Bacmecillinam onto Pasteur Pipets [a]

Treatment	Range Found, ng/g	Median, ng/g	Median Recovery, %
Not transferred	20.7–32.0	27.6	99.3
Transferred	0.5–16.8	15.8	56.8

[a] Procedure: From five centrifuge tubes with 4 ml of whole blood, each containing bacmecillinam (27.8 ng/g), ~2 ml was transferred to new centrifuge tubes by Pasteur pipets during 30 sec maximally. The tubes were then immediately frozen to −70° and later analyzed by HPLC.

Table III—Adsorption of Bacmecillinam onto Glass-Lined Stainless Steel Columns [a]

Mobile Phase	Amount Injected, ng	Peak Height Range, mm	Peak Height Median, mm	*n*
Without *N*-hexyl-*N*-methylamine	23	30–68	61	7
With *N*-hexyl-*N*-methylamine	20	78–80	79	6

[a] Procedure: Bacmecillinam was dissolved in water and analyzed by HPLC with and without the addition of *N*-hexyl-*N*-methylamine (10^{-4} *M*) to the mobile phase.

gave unacceptable asymmetric peaks ($As_{10\%}$ = 2.4–3.0) when the support was packed in conventional stainless steel columns and run with phosphate buffer (pH 7; ionic strength = 0.05)–acetonitrile (3.5–4.0—6.5–6.0, v/v) as mobile phase. With glass-lined stainless steel columns, however, the peaks were symmetrical ($As_{10\%}$ = 1.0–1.2) and had equally good efficiencies (h ~ 5: h = reduced plate height; HETP/dp; dp = support particle diameter). With this system, however, nonreproducible peak heights were obtained, although other chromatographic parameters were unaffected. The phenomenon was interpreted as being due to adsorption of the compound to the glass walls, similar to the problems encountered during the development of the described extraction procedure, and the effect could be avoided by the addition of a secondary amine (*N*-hexyl-

Table IV—Repeatability in Quantitative Determinations of Bacmecillinam [a]

Added, ng/ml	Found, %	*CV*, %
4.7	100.4	8.3
18.6	95.7	4.1

[a] Four samples were analyzed as described in *Experimental* relative to five standards in the range of 3.3–53 ng/ml.

N-methylamine) as an adsorption inhibitor (Table III). The chromatographic parameters (efficiency, peak symmetry, and capacity ratio) were virtually unaffected by the amine addition. Later experiments with stainless steel columns indicate that peak asymmetries observed initially, and described above, were also eliminated by the presence of *N*-hexyl-*N*-methylamine in the mobile phase.

The capacity factor of bacmecillinam was optimized by varying the pH of the mobile phase while keeping the volume ratio between buffer and acetonitrile constant (4:6, v/v) (Fig. 3). At pH 6 the retention time is suitable and the chromatographic efficiency is acceptable, while at pH 5 the capacity ratios are too low and the efficiencies are about half of those at higher pH. The compound used as the adsorption inhibitor for the extraction, bacampicillin, is almost nonretained at the chosen conditions and elutes near the front of the chromatogram. Amdinocillin, the antibiotically active compound, also elutes near the front in this chromatographic system, and the compound, furthermore, is not extracted to a significant amount in the extraction step. The quantitative determination of amdinocillin in biological fluids still requires the methodology described earlier (5).

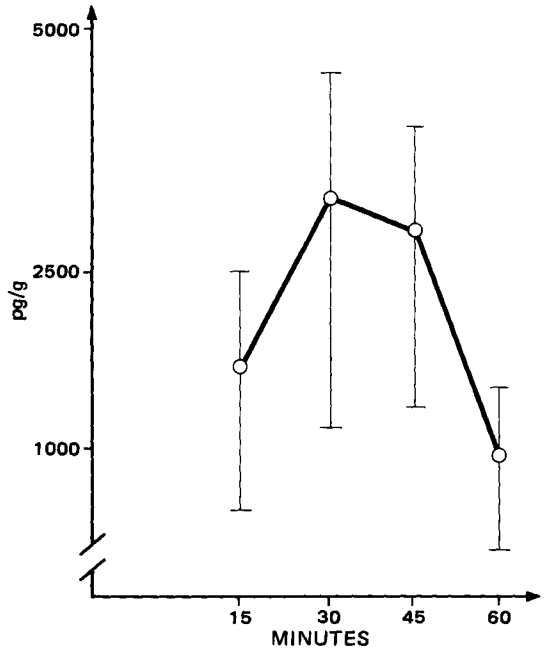

Figure 5—*Mean levels of bacmecillinam from three volunteers. Dose: 244 mg of bacmecillinam hydrochloride orally.*

Representative blank and sample chromatograms from whole blood (Fig. 4) illustrate that the chosen conditions are suitable for the analysis of bacmecillinam, and that the internal standard, amdinocillin pivoxil, elutes largely unaffected by blank disturbances.

The injected sample differs in composition from the mobile phase, and some of the small peaks that appear in the chromatogram originate from the resulting composition disturbance and not from the biological sample. Late in the chromatogram, after ~2 hr, an additional broad composition disturbance peak elutes and has to be taken into account in routine determinations in order to avoid interferences. This kind of disturbance can be reduced by the injection of smaller sample volumes. Some preliminary experiments have indicated the possibility of reextracting and injecting a volume 10 times smaller (*i.e.*, 20 μl instead of 200 μl).

Quantitative Determinations—The limit of detection, defined as a signal equal to twice the background noise level of the baseline, is ~600 pg/ml of whole blood. The repeatability of the method (Table IV) is ~8% (*CV*) at the level of 5 ng/ml, and it is estimated that at 1–2 ng/ml, the precision still is acceptable (*i.e.*, 15–20%, *CV*) for quantitative determinations.

Mean levels from three volunteers receiving 244 mg of bacmecillinam as a single dose are in the range of 1–3 ng/g of whole blood (Fig. 5).

The method has also been applied to determination of the compound in canine portal and peripheral whole blood as well as bile.

Biotransformation and Excretion of Nitromethaqualone in Rats and Humans

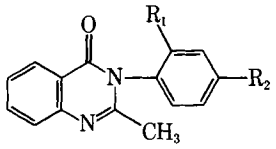
M. VAN BOVEN and P. DAENENS ˣ

Received April 27, 1981, from the *Laboratory of Toxicology, University of Louvain, Louvain, Belgium.* Accepted for publication December 23, 1981.

Abstract □ The metabolic disposition of ^{14}C-labeled nitromethaqualone was investigated in rats. Unlabeled nitromethaqualone was used for studies on humans. Nitromethaqualone was eliminated from the body after most of it had undergone biotransformation. Both humans and rats reduced the nitro group of nitromethaqualone to the corresponding amino derivative, which was partially transformed to the corresponding acetylated form. Cleavage of the quinazolinone nucleus resulting in 2-methoxy-4-nitroaniline was also observed in humans. In rats additional major metabolites arose from the oxidation of the 2-methyl group into hydroxymethyl resulting in 2-hydroxymethyl-3-(2′-methoxy-4′-nitrophenyl)-4(3*H*)-quinazolinone and concomitant *in vivo* reduction of the latter resulting in 2-hydroxymethyl-3-(2′-methoxy-4′-aminophenyl)-4(3*H*)-quinazolinone. Both metabolites were also excreted as glucuronides. In rats fecal excretion accounted for 55–60% of the administered dose, while 24–27% was excreted in the urine. Protracted excretion in both humans and rats indicated an extensive enterohepatic circulation.

Keyphrases □ Biotransformation—excretion, nitromethaqualone in rats and humans, metabolism □ Nitromethaqualone—biotransformation and excretion in rats and humans, metabolism □ Metabolism—biotransformation and excretion of nitromethaqualone in rats and humans

Nitromethaqualone[1] (I) or 2-methyl-3-(2′-methoxy-4′-nitrophenyl)-4(3*H*)-quinazolinone has been available in Europe since 1967 as a nonbarbituric hypnotic of the quinazolinone series, which includes methaqualone [2-methyl-3-*o*-tolyl-4(3*H*)-quinazolinone (II)] and mecloqualone [2-methyl-3-(2′-chlorophenyl)-4(3*H*)-quinazolinone (III)].



$R_1 = OCH_3$, $R_2 = NO_2$ (Nitromethaqualone, I)
$R_1 = CH_3$, $R_2 = H$ (methaqualone, II)
$R_1 = Cl$, $R_2 = H$ (mecloqualone, III)

The abuse of methaqualone (1–3) and mecloqualone (4) has been reported previously. Both drugs are metabolized extremely well in humans and animals (5–12), with detection of the unchanged drug in the urine being difficult when therapeutic amounts have been ingested. Detection in urine samples is usually done by means of the metabolites (13, 14).

Neither the metabolism of nitromethaqualone nor its analysis in urine samples has been established previously.

The present report deals with the metabolism of nitromethaqualone in humans and rats, along with the detection of the drug in urine samples for clinical and medicolegal practice. The excretion in rats was studied with [2-^{14}C]2-methyl -3- (2′-methoxy-4′-nitrophenyl)-4(3*H*)-quinazolinone.

EXPERIMENTAL

Synthesis of [2-^{14}C]2-Methyl-3-(2′-methoxy-4′-nitrophenyl)-4(3*H*) - quinazolinone—[2-^{14}C]2-Methyl-3-(2′-methoxy-4′-nitrophenyl)-4(3*H*)-quinazolinone was synthesized as shown in Scheme I by condensation of labeled *N*-acetylanthranilic acid with 2-methoxy-4-nitroaniline in toluene in the presence of phosphorus trichloride according to a procedure described previously (15). Labeled *N*-acetylanthranilic acid was prepared by refluxing 1 mmole of anthranilic acid in toluene with 1 mmole of [1-^{14}C]acetyl chloride (specific activity, 5.0 mCi/mmole) until no more hydrochloric acid was liberated. The reaction mixture was cooled to 70°. 2-Methoxy-4-nitroaniline (1 mmole) was added followed by the addition of phosphorus trichloride in toluene over a 10-min period (Scheme I). The mixture then was mixed thoroughly and refluxed for 2 hr in an oil bath. Toluene was evaporated under vacuum and the yellow residue was shaken with 10% aqueous sodium carbonate and extracted twice with 50 ml of chloroform. After evaporation of the solvent, the residue was taken up in benzene and purified on a 10-g column[2]. The column was eluted with 1 liter of benzene. Benzene was removed under vacuum and the residue recrystallized from methanol–water.

The specific activity determined by liquid scintillation counting was 5.0 mCi/mmole. The purity of the prepared compound was tested by TLC using two different solvents: chloroform–acetone–ammonia (50:50:1) and cyclohexane–chloroform–diethylamine (70:20:10). In both solvent systems only one spot could be detected accounting for the complete radioactivity with an R_f value identical to a standard of unlabeled nitromethaqualone. The radioactive spots were localized with a thin-layer scanner[3].

Animal Experiments—A single 2-mg dose of [^{14}C]nitromethaqualone with an activity of 5 μCi/mg suspended in medicinal oil was introduced directly into the stomach of two male Wistar rats, 260 and 312 g, respectively. The rats were housed in metabolic cages; urine and feces were collected separately at 12-hr intervals over 6 days. Urine samples were counted without any treatment; feces samples were counted as described under quantification of radioactivity. Two other rats were each given 30 mg of unlabeled nitromethaqualone. Urine was collected during 6 days and examined for metabolites.

Clinical Study—Two male volunteers were administered single 25-mg nitromethaqualone tablets[1]. Urine was collected at 2–4-hr intervals on the first day and 12-hr specimens were sampled over the next 6 days.

Quantification of Radioactivity—The isotope disintegration rates of all specimens were determined by liquid scintillation spectrometry[4]. Counting mixtures were prepared as follows: 2-ml urine samples were taken up in 15 ml of scintillation liquid[5]; 20- to 40-mg feces samples were rehydrated for 2 hr with 200 μl of water in plastic counting vials and 1 ml of tissue solubilizer[6] was added. The mixtures were incubated for 5 hr

[a] Solvent A: benzene–*n*-propanol–ammonia (80:20:1); Solvent B: chloroform–acetone–ammonia (50:50:1); Solvent C: cyclohexane–chloroform–diethylamine (70:20:10). [b] OV-17/QF, (1.5%); 260°.

at 60°. After cooling to room temperature, 0.5 ml of isopropanol was added followed by 0.2 ml of hydrogen peroxide (30%) for bleaching. The mixtures were kept at room temperature for 4 hr until transparent.

Finally, 15 ml of a mixture of 9 parts scintillation liquid[5] and 1 part 0.5 *N* HCl was added and the sample counted. Counting efficiency was determined by the internal standard method with ^{14}C-labeled toluene. Efficiency of the different urine samples examined varied between 85 and 99% and of the feces between 65 and 90%. Silica gel zones scraped from thin-layer chromatograms were suspended in 15 ml of scintillation fluid. Solvent extracts were measured following evaporation of the solvent and dissolution of the residue in 15 ml of scintillation liquid[7].

Extraction and Fractionation of Drug Components from Urine Samples—Urine samples were extracted on prepacked kieselguhr columns[8]. Twenty-milliliter samples were poured onto the columns, the aqueous solution was distributed as stationary phase on the chemically inert support, and then eluted with 100 ml of extraction solvent consisting of a mixture of dichloromethane–*n*-propanol (85:15). In this way the lipophilic substances were extracted from the aqueous phase into the organic phase, the aqueous phase remaining on the support (16, 17). The solvent was evaporated under vacuum and the residue taken up in 100 μl of methanol for TLC, GC, and GC–MS examination.

For the study of glucuronides, urine samples were extracted with chloroform at pH 3.0 followed by an extraction with ethyl acetate at pH 9.0. The remaining aqueous phases were submitted to an enzymatic hydrolysis. Therefore, 5 ml of the previously extracted samples were adjusted to pH 5.2 and incubated for 24 hr at 37° with 0.1 ml of β-glucuronidase[9]. The treated samples were handled on columns as described for the direct extraction. TLC examination of radioactive extracts was performed on precoated silica gel plates[10].

The presence of intact [^{14}C]nitromethaqualone was determined by one-dimensional TLC of extracts[8] using System C (Table I). For metabolites, Systems A and B (Table I) were used. Measurements of the isotope disintegration rates of the silica gel areas were carried out as described. For nonradioactive extracts, different metabolites were located by spraying the plates with different reagents specific for definite chemical functions. Aromatic amino functions were detected by the Bratton–Marshall reaction. The plates were sprayed first with a 1:1 mixture of 1% sodium nitrite in water and 1 *N* HCl followed by a solution of 200 mg of *N*-(1-naphthyl)ethylenediamine dihydrochloride in methanol.

Aromatic acetyl amino functions were detected in the same way as described for the aromatic amino functions following acid hydrolysis on the TLC plate to the free amino function. Plates were first sprayed with 2 *N* H_2SO_4 and put in an oven at 130° for 15 min. After cooling, the plates were sprayed as described earlier. Aromatic nitro functions were first reduced to an aromatic amino function by spraying the plates with a 1% titanium trichloride solution. After drying with warm air, the aromatic amino function was detected as described. Phenols were detected by the Folin–Ciocalteu reagent.

The metabolites present in the extracts from human urine samples were isolated by preparative TLC. Silica gel plates (20 × 20 cm, 250-μm thick[11]) were used. The extracts were applied as a band across the plate. Following development with Solvent System B, the separated zones were scraped off and eluted in minicolumns with 10 ml of methanol. The solvent was evaporated under a stream of nitrogen. The residues were then analyzed by GC and GC–MS.

Metabolite Characterization—Metabolites were identified by comparing their mass spectra and chromatographic data (TLC and GLC) with those of synthesized metabolites. The structure of the synthesized nitromethaqualone was confirmed by comparing the obtained physicochemical data with those of the literature (18). The structure of the synthesized metabolites was proved by NMR and mass spectrometry.

The mass spectra were recorded on a single-focusing apparatus[12] operated at 8-kV accelerating voltage, 100-μA trap current, and 70-eV ionization energy. The spectra were recorded either by the direct inlet method for isolated metabolites or synthesized products or by coupling the gas chromatograph to the mass spectrometer.

Optimal GC conditions were as follows: mixed phase, 1.5% OV-17-1.5% QF_1 on 80–100 mesh Gaschrom Q (180 cm × 2-mm i.d.) at 260° or with temperature programming (4°/min from 100 to 260°). The carrier gas was either helium at 60 ml/min (GC–MS) or nitrogen at 30 ml/min (GC).

Products were detected with a nitrogen-phosphorus detector for conventional GC. Identity of the proposed structures from the metabolites were confirmed by synthesis, and NMR spectra[13] were recorded in deuterochloroform as a solvent and tetramethylsilane as an internal standard.

Synthesis of Metabolites—*2-Methyl-3-(2′-hydroxy-4′-nitrophenyl)-4(3H)-quinazolinone*—Acetylanthranilic acid was condensed with 2-hydroxy-4-nitroaniline (15). White crystals with mp 225° were obtained.

2-Methyl-3-(2′-methoxy-4′-nitrophenyl)-4(3H)-quinazolinone (Nitromethaqualone)—The previous product was dissolved in methanol and a solution of diazomethane in ether added in excess. After 30 min the solvents were evaporated and the residue was crystallized. Light yellow crystals with mp 193° were obtained. The structure was identical with the product isolated from commercial nitromethaqualone tablets and confirmed by mass spectrometry and NMR (18). Nitromethaqualone was also prepared by direct condensation of acetylanthranilic acid with 2-methoxy-4-nitroaniline, yield 70%.

2-Methyl-3-(2′-methoxy-4′-aminophenyl)-4(3H)-quinazolinone—Nitromethaqualone (0.5 g) was dissolved in 200 ml of warm 0.2 *N* NaOH; 1 g of sodium dithionite was added and the mixture kept at 80° for 10 min, then it was cooled and extracted twice with a mixture of chloroform–1-propanol (85:15). The solvent was evaporated under vacuum and the yellow residue recrystallized from ethanol. White crystals (mp 205–206°) were obtained, yield 80%. The NMR spectrum of the synthesized compound showed a broad singlet integrating for two protons at $\delta = 4.9$ proving the presence of an amino group. The latter gave a positive reaction with the Bratton–Marshall reagent proving its aromatic nature. The mass spectrum (Table II) confirmed the proposed structure.

of acetic anhydride was added, and the mixture refluxed for 30 min. The reaction mixture was allowed to cool then neutralized and extracted with ether. The extract was dried on anhydrous sodium sulfate and evaporated. The residue was recrystallized from methanol. White crystals (mp 256°) were obtained, yield 82%. The NMR spectrum showed a singlet at δ = 2.15 integrating for three protons proving the presence of an acetyl group in the molecule. The mass spectrum from this compound (Table II) confirmed the proposed structure.

Anal.—Calc. for $C_{18}H_{17}N_3O_3$: C, 66.86; H, 5.30; N, 13.00. Found: C, 66.91; H, 5.21; N, 13.09.

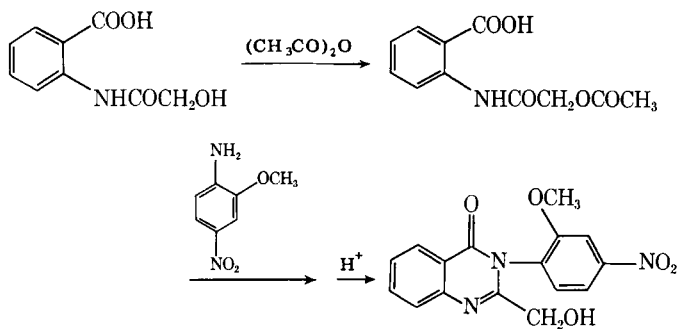
2-Hydroxymethyl-3-(2′-methoxy-4′-nitrophenyl)-4(3H)-quinazolinone—The synthesis of an analogous methaqualone metabolite (Scheme II) was carried out using a procedure described previously (19). Glycolic acid was taken up in an excess of thionyl chloride and the mixture kept at room temperature for 25 hr. The excess thionyl chloride was then evaporated and the residue taken up in dry toluene, along with an equivalent amount of anthranilic acid, and refluxed for 1 hr. The solvent was evaporated under vacuum, and the residue was taken up in acetic acid and treated with sodium acetate and acetic anhydride in slight excess [1.5 mole of both for 1 mole of *N*-(hydroxyacetyl)anthranilic acid]. The mixture was heated to 100° for 2 hr and then concentrated *in vacuo*. The residue was taken up in chloroform and washed with 5% sodium carbonate. The chloroform was evaporated under vacuum and the resulting *N*-(acetoxyacetyl)anthranilic acid condensed with 2-methoxy-4-nitroaniline in the usual way (15).

The obtained ester was dissolved in a 100:25 mixture of dioxane–5 *M* HCl. The mixture was boiled for 10 min then cooled and the hydrochloride filtered off. The base was isolated by dissolving the hydrochloride in chloroform and adding 0.2 *N* NaOH. The chloroform was evaporated and the residue crystallized from methanol–water. White crystals with mp 169–170° were obtained, yield 10%. The NMR spectrum of this compound showed a singlet at δ = 4,2 integrating for two protons replacing the singlet at δ = 2,2 integrating for three protons in nitromethaqualone. An additional broad singlet integrating for one proton was observed at δ = 3,4 corresponding to an hydroxyl proton.

Anal.—Calc. for $C_{16}H_{13}N_3O_5$: C, 58.72; H, 4.00; N, 12.84. Found: C, 58.62; H, 3.94; N, 12.77.

2-Hydroxymethyl-3-(2′-methoxy-4′-aminophenyl)-4(3H)-quinazolinone—This compound was prepared by alkaline reduction of 2-methyl-3-(2′-methoxy-4′-nitrophenyl)-4(3*H*)-quinazolinone in alkaline medium with sodium dithionite. The reaction product was extracted with a mixture of chloroform–2-propanol (85:15). White crystals (mp 290°, dec.) were obtained, yield 92%. The NMR spectrum of the compound showed an additional broad singlet at δ = 4,9 in comparison to the starting compound proving the presence of an amino group. The last gives a positive Bratton–Marshall reaction proving its aromatic nature. The mass spectrum (Table II) confirms the proposed structure.

Anal.—Calc. for $C_{16}H_{15}N_3O_3$: C, 64.64; H, 5.09; N, 14.13. Found: C, 64.69; H, 5.13; N, 14.22.



Scheme II—Synthesis of 2-hydroxymethyl-3-(2′-methoxy-4′-nitrophenyl)-4(3H)-quinazolinone.

RESULTS

Rat Experiments—*Identification of Urinary Metabolites*—After counting the individual urine samples, the residual collected samples were pooled and extracted on columns[8], and 21–25% of the total urinary radioactivity was extracted. TLC of the extract using Solvent System C separated a compound with R_f = 0.30 (Metabolite I). The remaining radioactivity was located at the start of the chromatogram. Intact [^{14}C]nitromethaqualone (R_f = 0.6) could not be detected. The same plate was now run with Solvent System B allowing the detection of two additional radioactive zones with R_f = 0.7 (Zone II) and 0.61 (Zone III). This made it possible to locate on a plate the corresponding zones of metabolites in urine extracts of rats treated with unlabeled nitromethaqualone. The latter were applied in 10-cm bands across the plates. One centimeter of this band was overspotted with the extract from [^{14}C]nitromethaqualone-treated rats and the plates run in Solvent System B. After localizing the radioactive zones, the corresponding nonradioactive zones were scraped off and extracted with methanol. The solvent was evaporated and the residue examined by GC and GC–MS.

Metabolite I—The metabolite isolated from Zone I appeared to consist of one single spot on TLC with all solvent systems, A, B, and C. GC of the product, however, showed a broad peak of two maxima with R_t = 13.4 and 13.6 min, respectively. Following silylation with trimethylsilylimidazole[14], only one homogeneous peak was observed. The mass spectrum of the product recorded *via* solid probe (Table II,A) was different from the product recorded by GC–MS indicating that the metabolite decomposed under the described gas chromatographic conditions. The mass spectrum of Metabolite I recorded by the direct inlet method indicated a molecular ion at *m/z* 327 representing an addition of one oxygen to nitromethaqualone. The mass spectrum of the trimethylsilyl derivative (Table II,B) showed one silylated function, indicating the presence of an hydroxyl group in the molecule. This, however, is not located on one of the phenyl nuclei as could be shown from the fragmentation pattern of both silylated and underivatized metabolites. This metabolite proved to be identical with the synthesized 2-hydroxymethyl-3-(2′-methoxy-4′-nitrophenyl)-4(3*H*)-quinazolinone.

Metabolites II, III, and IV—The product isolated from Zone II was examined by GC and showed one homogeneous peak with an R_t value of 12.8 min (Metabolite II). The mass spectrum obtained with GC–MS (Table II,C) revealed a molecular ion at *m/z* 281 and a fragment ion at *m/z* 250 indicating the loss of a methoxy fragment. The metabolite showed a positive Bratton–Marshall reaction. All those characteristics

[14] Pierce Eurochemie NV, Rotterdam, Holland.

Table IV—Percent of [^{14}C]Nitromethaqualone and Metabolites Present in the Direct Extracts from Rat Urine

Drug and Metabolites	Recovered Radioactivity (Extract, %)[a]
Nitromethaqualone	0
Metabolite[b] I	8
Metabolite II	40
Metabolite III	19
Metabolite IV	14
Not identified	19

[a] The values are averages of results on two rats. [b] Symbols correspond to metabolites given in the text.

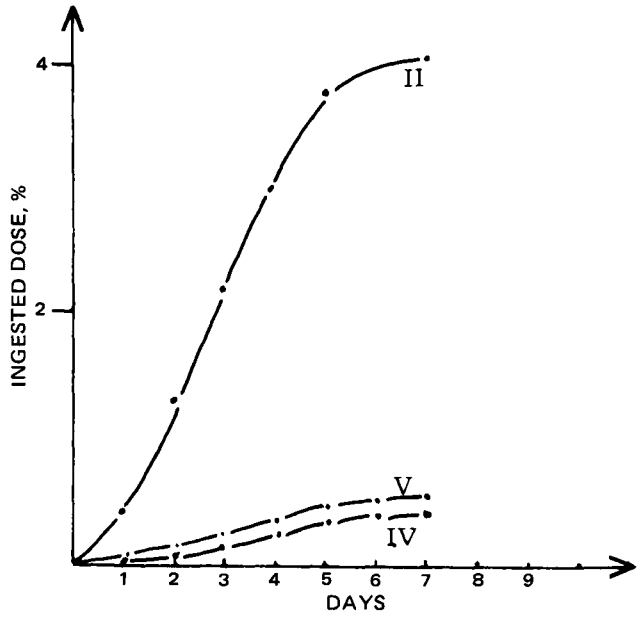

Figure 1—*Cumulative excretion graph of nitromethaqualone Metabolites II, IV, and V in humans.*

were identical with those of synthesized 2-methyl-3-(2′-methoxy-4′-aminophenyl)-4(3*H*)-quinazolinone.

Zone III, isolated with Solvent System B, was reexamined with Solvent System A and consisted of two distinct products with R_f values of 0.45 and 0.52. In this way both compounds of Zone III were separated on a preparative scale and examined separately with GC and GC–MS. The zone with R_f = 0.52 on GC showed different peaks when analyzed without derivatization. Following silylation with trimethylsilylimidazole, one homogeneous peak eluted with R_t = 16.6 min. The mass spectrum of this product obtained with the direct inlet method indicated a molecular ion at *m/z* 297 (Table II,E). The silylated derivative showed one silylated hydroxyl function (Table II,D). Fragmentation patterns of both the underivatized metabolite and silylated derivative showed that this is not located on one of the phenyl nuclei of the molecule. The metabolite showed also a positive Bratton–Marshall reaction. These characteristics suggest 2-hydroxymethyl-3-(2′-methoxy-4′-aminophenyl)-4(3*H*)-quinazolinone as a possible structure for this metabolite. This structure was confirmed by synthesis of the expected metabolite (Metabolite III). The zone with an R_f value of 0.45 in Solvent System A showed one homogeneous peak with an R_t value of 43 min on GC (Metabolite IV).

The mass spectrum recorded by GC–MS indicated a molecular ion at *m/z* 323 (Table II,F). The transition *m/z* 292 to *m/z* 250 proved by the presence of a metastable peak corresponds to the loss of ketene and indicates the presence of an acetyl group in the molecule. The metabolite showed only a positive Bratton–Marshall reaction on the plate following acid hydrolysis, indicating the presence of an aromatic acetylamino group. Those characteristics suggest that Metabolite IV is the acetylated form of Metabolite II. The structure could be confirmed by synthesis of the metabolite. Table I represents the TLC and GC data of nitromethaqualone and its metabolites.

Quantitation of the Metabolites—The cumulative urinary and fecal excretion of nitromethaqualone after a single oral dose of 10-μCi [^{14}C]-nitromethaqualone is given in Table III. Within 6 days, 55–60% of the dose is excreted in the feces while 25–27% is excreted in the urine.

Aliquots of the collected urine samples were extracted on kieselguhr columns. In this way 21 and 25%, respectively, of the radioactivity present in the urine of the two rats could be extracted.

The concentrated extracts were chromatographed on silica gel plates using the described solvent. The radioactive zones were scraped off and counted as described. The quantitative amounts of the different metabolites present in definite areas are given in Table IV. Metabolite II is the major metabolite (40%). Unchanged nitromethaqualone could not be detected. The measured radioactivity (19%) remained at the start of the chromatogram and was not further examined. From the kieselguhr columns used for extraction, remaining polar metabolites, probably consisting of glucuronides, could not be eluted. Following enzymatic hydrolysis with β-glucuronidase of urine samples previously extracted with chloroform and ethyl acetate at pH 3.0 and 9.0, only Metabolites I and III could be identified in the same way as described above, proving their excretion as conjugates with glucuronic acid. No quantitative data, however, could be obtained due to the instability of the amino compound during the reaction procedure.

Human Studies—The metabolism in humans was studied only with unlabeled nitromethaqualone. Aliquots of the different urine samples were pooled and extracted as described. The extracts were examined by analytical and preparative TLC as for the study on urine from rats. Solvent System C was used for detecting unchanged nitromethaqualone and the hydroxymethyl derivative (Metabolite I). Neither nitromethaqualone nor Metabolite I could be detected in human urine. TLC with Solvent System B resulted in three spots showing a positive Bratton–Marshall reaction corresponding to R_f values of 0.90, 0.70, and 0.16 and one additional spot at R_f = 0.61 reacting positively only following acid hydrolysis on the plate. Preparative TLC allowed isolation of all four metabolites. The zone with R_f = 0.90 showed on GC one single homogeneous peak at 170°. The mass spectrum (Table II,G) revealed a molecular ion at *m/z* 168. Loss of 31 indicates the presence of an intact methoxy group.

Furthermore, a positive Bratton–Marshall reaction indicates the presence of an aromatic amino group. The spectrum is compatible with 2-methoxy-4-nitroaniline as a possible structure of this metabolite (Metabolite V). This product could be obtained from a commercial source[15] and proved to be identical with the isolated metabolite. The zone

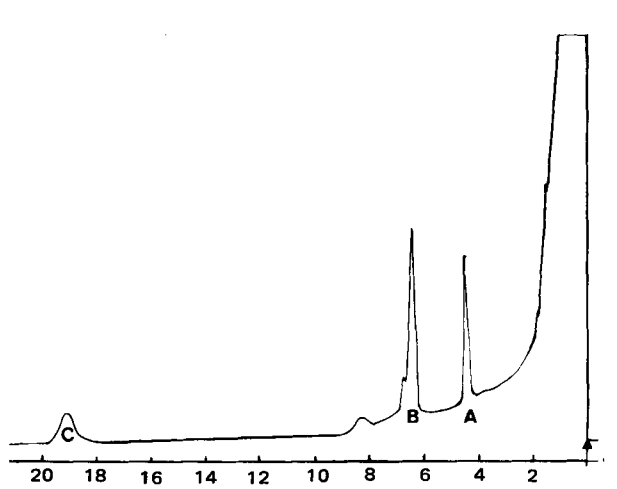

Figure 2—*Typical gas chromatogram from a urine extract. Key: (A) internal standard; (B) Metabolite III; (C) Metabolite IV.*

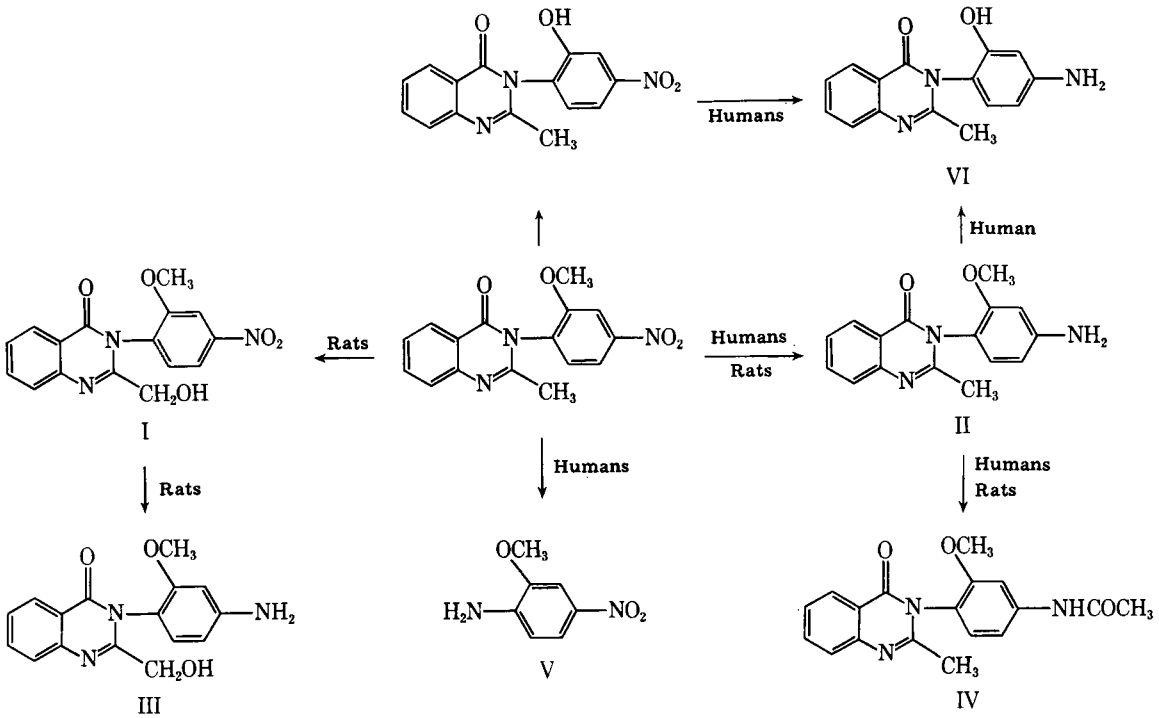
[15] Riedel-de-Haën AG, Seelze, Hannover, West Germany.



Scheme III—Metabolic pathways of nitromethaqualone in humans and rats.

with an R_f value of 0.70 showed one peak on GC at 260°. The mass spectrum proved to be identical with the spectrum of Metabolite II already identified in the urine of treated rats. Likewise, the zone with R_f = 0.61 appeared to be identical with Metabolite IV. The zone with R_f = 0.16 reacts not only positively with the Bratton–Marshall reagent but also with the Folin–Ciocalteu reagent. The product could only be analyzed by GC following methylation with diazomethane. The resulting peak showed the R_f value of Metabolite II along with an identical mass spectrum. The most important fragment ions of the mass spectrum of the metabolite prior to methylation are represented in Table II,H. The molecular ion shows at m/z 267. All these characteristics suggest 2-methyl-3-(2′-hydroxy-4′-aminophenyl)-4(3*H*)-quinazolinone as a possible structure (Metabolite VI). This structure was proved to be correct by synthesis. After enzymatic hydrolysis with β-glucuronidase, Metabolite VI could be detected in the extract. No quantitative data could be obtained, since the metabolite was not stable in the course of the reaction.

Cumulative excretion curves (Fig. 1) in humans were established for Metabolites II, IV, and V. Therefore, following administration of nitromethaqualone, urine samples were collected at regular intervals and the metabolite concentration per milliliter determined. Upon multiplication by the volume of urine excreted during the collecting period, the amount of metabolites was obtained. The additive amounts excreted for each collecting period were then plotted *versus* time of collecting intervals.

Metabolites II and IV were determined by GC. Therefore, 20-ml urine samples, to which 2-methyl-3-(4′-nitrophenyl)-4(3*H*)-quinazolinone had been added as an internal standard, were extracted as described above. The concentrated extracts were injected on a mixed phase 1.5% OV-17, 1.5% QF_1 column at 260° and detected with a nitrogen-phosphorus detector. Figure 2 shows a typical gas chromatogram of a urine extract. Metabolite V was determined by TLC. The violet color of the spots following a Bratton–Marshall reaction was measured on the plate in comparison with known amounts of the reference compound.

DISCUSSION

Nitromethaqualone is eliminated from rats and humans by biotransformation. No unchanged drug can be detected in urine samples. In both rats and humans, 2-methyl-3-(2′-methoxy-4′-aminophenyl)-4(3*H*)-quinazolinone is quantitatively the most important unconjugated metabolite. Both species excrete this metabolite partially in the acetylated form. In rats but not in humans, oxidation of the 2-methyl group to 2-hydroxymethyl-3-(2′-methoxy -4′ -nitrophenyl)-4(3*H*)-quinazolinone along with reduction of the nitro function of the latter to 2-hydroxymethyl-3-(2′-methoxy-4′-aminophenyl)-4(3*H*)-quinazolinone represents two other important metabolites, both being excreted also as conjugates with glucuronic acid. The slow urinary excretion along with the protracted fecal excretion of carbon 14 in the rats suggests an extensive enterohepatic circulation. In addition, human subjects excrete 2-methoxy-4-nitroaniline indicating cleavage of the quinazolinone nucleus. *O*-Demethylation followed by reduction of the nitro group is a minor metabolic pathway in humans (Scheme III). The slow urinary excretion in the urine of the formed metabolites in humans may be related to a continuous reabsorption of the biliary fraction. The method, as described for the extraction and analysis of urine extracts, using Solvent System B and the reagents for the Bratton–Marshall reaction, makes it possible to demonstrate nitromethaqualone intake even in a therapeutic dose. For legal practice, a GC–MS examination for the presence of the major metabolite in humans [2-methyl-3-(2′-methoxy-4′-aminophenyl)-4(3*H*)-quinazolinone] should confirm the TLC results.

Guinea Pig Ear as a New Model for *In Vivo* Percutaneous Absorption

H. Y. ANDO ˣ, E. T. SUGITA, R. L. SCHNAARE, and L. BOGDANOWICH

Received October 29, 1981, from the *Department of Pharmacy, Philadelphia College of Pharmacy and Science, Philadelphia, PA 19104.* Accepted for publication December 29, 1981.

Abstract □ A new animal model for *in vivo* percutaneous absorption utilizing the hairless, relatively thick skin of the guinea pig ear is proposed. Topical absorption studies were carried out with [^{14}C]hydrocortisone and [^{14}C]testosterone. Systemic studies were also conducted to correct for incomplete urinary excretion. In addition, a single stratum corneum correction factor was developed from published data to enable the guinea pig ear skin to be directly compared with human forearm skin. A comparison of human percutaneous absorption with the corrected guinea pig ear absorption shows a high correlation for both hydrocortisone and testosterone. The effects of ambient changes in relative humidity are also discussed with respect to *in vivo* percutaneous absorption.

Keyphrases □ Guinea pig ear—model for *in vivo* percutaneous absorption, hydrocortisone, testosterone □ Absorption—percutaneous, guinea pig ear, *in vivo* model, hydrocortisone, testosterone □ Hydrocortisone—guinea pig ear, model for *in vivo* percutaneous absorption, testosterone □ Testosterone—guinea pig ear, model for *in vivo* percutaneous absorption, hydrocortisone

Various animal species have been used to study percutaneous absorption *in vivo*. Percutaneous absorption rates of common laboratory rodents such as rats and rabbits have been studied (1). These studies have shown that the back skin of these animals absorb a selected number of substances much more rapidly than the ventral surface of the human forearm (2, 3). Higher species of mammals including hairless dogs (4), rhesus monkeys (5), and miniature swine (1) have also been studied. Of these species, it has been concluded (6) that the rhesus monkey and the miniature swine percutaneous absorption characteristics correlated best with human penetration. The obvious disadvantage of using swine and monkeys include cost and the need for special animal facilities.

One important determinant of percutaneous absorption is the thickness of the stratum corneum. If two areas of skin are sufficiently similar, then one would expect percutaneous absorption to be inversely proportional to the number of stratum corneum layers in the skin. The percutaneous absorption of hydrocortisone from a number of different anatomical sites in humans has been determined previously (7). The number of stratum corneum layers at these sites has also been determined (8). If a proportional relationship between thickness and absorption can be established in humans, this provides a rationale to correct animal model data for thickness. However, the problem with most animal models is that skin with fur generally has a thin stratum corneum (9). Consequently, changes of one or two layers could cause corrections as much as 50% if the stratum corneum is very thin. An ideal animal surface would have to be relatively large and essentially hairless. The guinea pig ear appeared to meet the desired criteria.

EXPERIMENTAL

Male albino guinea pigs, 250–300 g, were individually acclimated for 1 day in metabolism cages[1]. Water and guinea pig chow were given *ad libitum*. For topical application of [^{14}C]hydrocortisone (I) or [^{14}C]testosterone (II), the animals were lightly anesthetized in a bell jar with methoxyflurane[2]. One ear of an animal was sandwiched with medium pressure between two halves of Karush-type dialysis chambers without caps[3]. A 4 μg/cm^3 volume of one of the ^{14}C-labeled compounds reconstituted in acetone was applied in a 40-μl volume to a 1.77-cm^2 area with a flat tip 50-μl syringe[4] to the dorsal surface of the ear. After the acetone had evaporated, the dialysis chambers were removed, and the animals were returned to their metabolism cages. For systemic administration, the ^{14}C-compounds were solubilized first in 50 μl of ethanol and then in 1 ml of sterile saline. The animals were then dosed intraperitoneally with a 0.5-ml volume.

Urine samples were collected daily. The urine was acidified with glacial acetic acid to a pH of 5 to solubilize the magnesium and calcium phosphate precipitates. A 1-ml aliquot was counted on a liquid scintillation counter[5] using 10 ml of liquid scintillation cocktail[6]. The internal standard method using [^{14}C]toluene[7] was used to correct for quench. Relative humidity readings were taken daily using a wet–dry thermometer.

RESULTS

Thickness of the Stratum Corneum and Absorption—Table I presents the determination of:

$$N \times A = K \qquad \text{(Eq. 1)}$$

where N is the number of cell layers in the stratum corneum (8), A is the percent of drug absorbed in 5 days (7), and K is the inverse proportionality constant. These results from human data show that K (forearm) differs from K (back) by only 9.8%. It would be desirable to have more data to confirm this result for different compounds besides hydrocortisone in humans. Nevertheless, one form of verification would be to use a single correction factor to relate guinea pig ear data to the human forearm for a number of different compounds. If Eq. 1 holds, then this

correction factor would be determined from the relation:

$$A_h = (N_g/N_h)\, A_g \qquad \text{(Eq. 2)}$$

where the subscripts h and g refer to the human forearm and the guinea pig ear, respectively. The values, N_g is 11 and N_h is 21.9, have been determined previously (8, 10). The correction factor, N_g/N_h, is therefore 0.502.

Guinea Pig Ear Absorption—Table II shows the recovery of ^{14}C-labeled compound following intraperitoneal and topical administration of hydrocortisone and testosterone for a 5-day period. The intraperitoneal data were used to correct the topical studies for incomplete excretion. Equation 2 was also used to correct the topical studies for stratum corneum thickness. Figure 1 shows a comparison of the corrected percent of topical hydrocortisone not absorbed for humans (2) and for the guinea pig ear. Similarly, Fig. 2 shows a comparison for testosterone between humans (2), rats (1), rabbits (1), and the guinea pig ear. In Fig. 3, the corrected percent of the dose absorbed is shown for hydrocortisone and testosterone on days 1 and 5. On day 1, the ratio of guinea pig ear to human forearm absorption is nearly 1, whereas by day 5, this ratio is nearly 2.

Effect of Ambient Relative Humidity—In Fig. 4, the corrected percent of drug absorbed by the guinea pig ear is shown for hydrocortisone and testosterone over a 10-day period. Each point is plotted

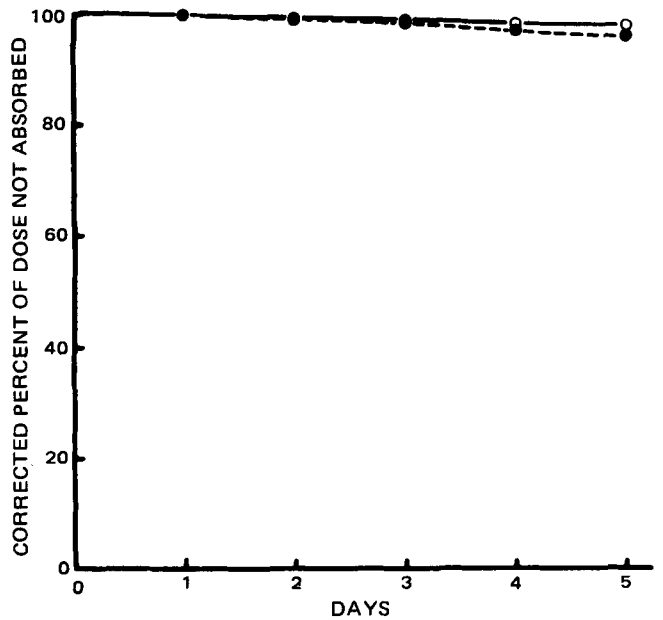

Figure 1—*Percutaneous absorption of hydrocortisone in humans and guinea pig ear. Key: (○) human (2); (●) guinea pig. All data are corrected for recovery following systemic administration. Guinea pig ear data are also corrected for thickness using Eq. 2.*

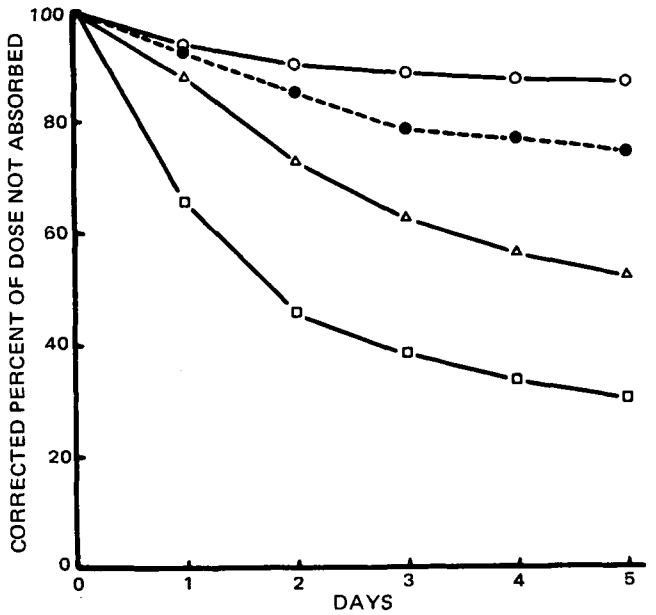

Figure 2—*Percutaneous absorption of testosterone in humans, rats, rabbits, and guinea pig ear. Key: (○) human (2); (●) guinea pig; (△) rat (1); (□) rabbit (1). All data are corrected for recovery following systemic administration. Guinea pig ear data are also corrected for thickness using Eq. 2.*

at the end of its respective 24-hr collection period. Figure 5 shows the relative humidity at the time of urine collection for the hydrocortisone and testosterone experiments. Note in Fig. 4 the drop in the testosterone curve on day 4 and the rise in the hydrocortisone curve on day 5. Corresponding changes in relative humidity can be seen in Fig. 5. It appears that these countertrend changes in percutaneous absorption reflect changes in the ambient relative humidity. Moreover, these changes in relative humidity are also reflected in the volume of urine excreted (Fig.

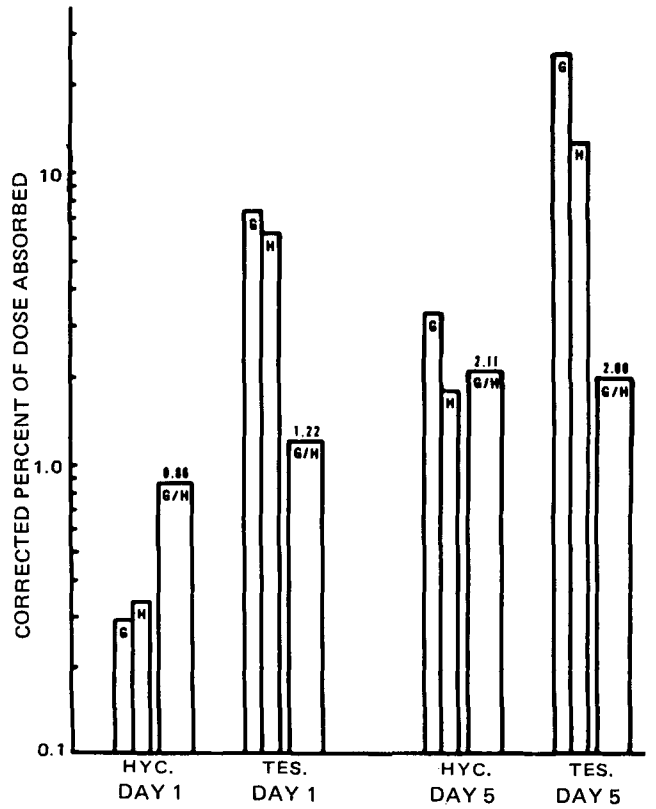

Figure 3—*Comparison of percutaneous absorption in guinea pig ear and humans (2) 1 day and 5 days following topical application. Key: (G) guinea pig; (H) humans.*

6) and in the urine color quench (Fig. 7). This can be seen by comparing Fig. 5 with Figs. 6 and 7.

DISCUSSION

To be useful, an animal model should correlate with the desired parameter, and it should be accessible to a large number of researchers. Use of the guinea pig ear as a model for human percutaneous absorption may meet these criteria.

The animal is relatively inexpensive to acquire and house, its ears each have an area of ~3 cm^2, and are essentially hairless. Hairless guinea pig ear skin, as in humans, would be expected to have a thicker stratum corneum than back skin with hair because it must adapt to greater mechanical and temperature stress (1).

Human stratum corneum is on the average of 15 cells thick with a viable layer of 6–10 cells (9, 10). The guinea pig ear skin compares favorably with human skin, having a viable thickness of 7–8 cell layers and a stratum corneum thickness of 10–12 cells (12, 13). In addition, the correlation between epidermal thickness and turnover time (maturation) for human and guinea pig ear epidermises are nearly identical (14). This is important, since the structural organization of normal stratum corneum is dependent upon a slow rate of cell maturation (14).

Percutaneous absorption studies presented here using the guinea pig ear show that for hydrocortisone and testosterone the initial 24-hr period of absorption is comparable to human absorption if a correction is made for differences in stratum corneum thickness. Five-day cumulative absorption in this model is twice as great as in humans. This might be attributed to three possible factors. First, in the human studies (2, 3), the subjects were allowed to wash the application site after the first 24 hr. Thus, some material could have been removed. Second, in our studies no attempt was made to prevent exfoliation of the stratum corneum. It is possible that radioactive squama contamination could have elevated the urine counts. We did not attempt to prevent this because almost any attempt to prevent exfoliation would most likely increase the local moisture content of the stratum corneum. As the relative humidity studies have shown, this can increase absorption. Finally, there may be physical differences between human stratum corneum and guinea pig squama as there may be human differences (15).

In a recent study (16), the guinea pig back skin was used as a model for percutaneous absorption; the much thicker and hairless skin of the guinea pig ear was used as a model in this study. A comparison of the 1-day guinea pig back skin to human forearm absorption ratio (G/H) for hydrocortisone and testosterone (0.30 and 2.23, respectively) showed a much larger variation than the ratios of 0.86 and 1.22, respectively, obtained with the ear model in this report. Similarly, the G/H for the 5-day absorption studies for hydrocortisone and testosterone (1.33 and 3.83, respectively) also showed a much greater variation than the ratios of 2.11 and 2.00, respectively, obtained in this study with the guinea pig ear. The ear skin model would be expected to be a superior model compared to the back skin because the stratum corneum is thicker in accordance with the inverse relationship between stratum corneum thickness and hairiness (9) and the ear is hairless so that no depilation is necessary as it is for the furred back skin.

Hydrocortisone and testosterone were chosen for this study because these compounds are among the slowest and the fastest steroids absorbed by humans. If further studies show that the ratio between the guinea pig ear model and human percutaneous absorption remain constant as they do for these steroids, the guinea pig ear model may prove to be an inexpensive, accessible model for human percutaneous absorption.

Improved High-Pressure Liquid Chromatographic Method for the Analysis of Erythromycin in Solid Dosage Forms

KIYOSHI TSUJI ˣ **and MICHAEL P. KANE**

Received September 18, 1981, from the *Control Analytical Research and Development, The Upjohn Company, Kalamazoo, MI 49001.* Accepted for publication December 23, 1981.

Abstract □ A stability-indicating high-pressure liquid chromatographic (HPLC) method for the assay of erythromycin in enteric film-coated tablets was developed. The method used a reversed-phase column at 70° with a mobile phase of acetonitrile–methanol–0.2 *M* ammonium acetate–water (45:10:10:35) at pH 7.0. The column effluent was monitored at 215 nm. Several reversed-phase columns were evaluated for the analysis of erythromycin. The HPLC method was also applicable for the analysis of salts and esters of erythromycin. The linearity and precision of the HPLC assay method for erythromycin in the solid dosage form were examined by spiking erythromycin into a tablet placebo at 60–120% of the label. The recovery of erythromycin was 99.9% with a relative standard deviation of <1%. The correction factors to express the results of HPLC in terms of antimicrobial bioequivalency against *Staphylococcus aureus* ATCC 6538P for erythromycins A, B, and C were determined to be 1.0, 0.92, and 0.48, respectively. Eight lots of tablets were assayed by the HPLC method, and the results, expressed in terms of erythromycin bioequivalency, showed no statistically significant difference from those of the microbiological assay method.

Keyphrases □ High-pressure liquid chromatography—improved method for the analysis of erythromycin in solid dosage forms □ Dosage forms—improved high-pressure liquid chromatographic method for the analysis of erythromycin □ Erythromycin—solid dosage forms, improved high-pressure liquid chromatographic method for analysis

Erythromycin, a macrolide antibiotic, is normally administered orally and is marketed in several forms. These include the free base, salts such as the stearate, and esters such as ethyl succinate and 2′-*O*-propionyl. Erythromycin free base is formulated as an enteric coated tablet to protect erythromycin from acid degradation and to allow absorption in the intestinal tract.

High-pressure liquid chromatographic (HPLC) methods for the determination of erythromycin free base and an ester of erythromycin, erythromycin ethyl succinate, have been reported (1–4). The HPLC assay method for erythromycin ethyl succinate uses an elevated column temperature at 70° to minimize peak tailing and to improve peak resolution (4). This HPLC method was adopted for monitoring the clinical blood level of erythromycin and erythromycin ethyl succinate by use of a postcolumn extraction and derivatization technique for fluorimetric detection (5).

Since the HPLC method reported for the assay of erythromycin uses ambient column temperature (1), considerable peak tailing and lack of peak resolution have been experienced. The method reported in this paper uses elevated column temperature for optimum peak resolution and minimum peak tailing for the assay of erythromycin in a solid dosage form.

EXPERIMENTAL

Apparatus—A modular liquid chromatograph equipped with a variable wavelength detector at 215 nm[1], a high-pressure pump[2], and a 100-μl fixed loop injector[3] were used. A reversed-phase HPLC column[4] was water jacketed and maintained at 70° with a circulating water bath[5]. The peak area was electronically determined by use of an electronic integrator[6].

Reagent—All the solvents used were distilled in glass and were UV grade[7]. Ammonium acetate used was analytical reagent grade. The mobile phase composed of acetonitrile–methanol–0.2 *M* ammonium acetate–water (45:10:10:35) was filtered through a membrane filter[8]. The flow rate of the mobile phase was ~1.0 ml/min.

The 0.2 *M* ammonium acetate was prepared by weighing 15.5 g of ammonium acetate[9] into a 1-liter graduated cylinder and adding water to volume.

Reference Standard Solution—USP erythromycin reference standard was dried at 60° for 3 hr under <5-mm Hg pressure. The dried bottle was capped and placed in a desiccator to cool. Approximately 10 mg of the reference standard was weighed accurately using an electronic balance[10] and placed in a 10-ml volumetric flask. The standard was dissolved and diluted to volume with the internal standard solution.

Internal Standard Solution—A sufficient quantity of megestrol acetate was dissolved in the mobile phase to give a final concentration of ~0.025 mg/ml.

Sample Preparation—Approximately 10 mg of erythromycin powder was accurately weighed into a 10-ml volumetric flask. The powder was dissolved and diluted to volume with the internal standard solution.

To assay solid dosage forms, 10 tablets were accurately weighed to compute an average tablet weight. Tablets were ground to a fine powder using a laboratory mill[11] with a 40-mesh screen. Approximately 18 mg of the ground tablet, or an equivalent quantity of the powder to contain ~10 mg of erythromycin, was accurately weighed using an electronic balance[10] into a 10-ml volumetric flask. The internal standard solution was added to the flask, sonicated for ~1 min, and shaken briefly to facilitate dissolution. The suspension was then centrifuged at 2000 rpm for ~2 min to remove tablet excipients.

Calculation—The erythromycin content in a tablet was calculated using:

$$\text{Erythromycin (mg/tablet)} = \frac{Pa + 0.9Pb + 0.5Pc}{Ta + 0.9Tb + 0.5Tc} \times \frac{W_t}{W_p} \times \frac{I_t}{I_p} \times F_1 \times \frac{F_2}{1000} \quad \text{(Eq. 1)}$$

where Pa is the peak area of erythromycin A of the sample; Pb is the peak area of erythromycin B of the sample; Pc is the peak area of erythromycin C of the sample; Ta is the peak area of erythromycin A of the reference standard; Tb is the peak area of erythromycin B of the reference standard; Tc is the peak area of erythromycin C of the reference standard; W_t is the weight of the reference standard in milligrams per milliliter; I_t is the peak area of the internal standard in the reference standard; I_p is the peak area of the internal standard of the sample; W_p is the weight of the sample in milligrams per milliliter; F_1 is an average tablet weight in milligrams per tablet; F_2 is the assigned potency of the reference standard in micrograms per milligram; and 1000 is a factor to convert the potency of the reference standard to a fraction.

Microbiological Assay Method—The turbidimetric assay method using *Staphylococcus aureus* ATCC 6538P as the test microorganism as described in the Code of Federal Regulations (6) was used to assay erythromycin.

RESULTS AND DISCUSSION

Chromatographic Conditions—The effect of mobile phase composition and pH on the chromatographic behavior of erythromycins A, B, and C have been reported (1). Increasing the concentration of acetonitrile or methanol or decreasing the pH of the mobile phase was found to reduce the retention times of erythromycins A, B, and C. The selection of pH for the mobile phase was determined by the type of sample under investigation, with pH 6.2 for the bulk drug and pH 7.8 for biological extracts.

Increase in the column temperature was found to significantly improve column performance for the assay of erythromycin. The effects of column temperature on the height equivalent to theoretical plate (HETP) for LiChrosorb RP-18[4] and μ-Bondapak C_{18}[12] columns are presented in Fig. 1. The HETP for the μ-Bondapak C_{18} column was significantly smaller than that of the LiChrosorb RP-18 at a column temperature <50°. However, lines of two-column performance intersected at ~70°. The HETP for the LiChrosorb RP-18 was slightly smaller than that of μ-Bondapak C_{18} at the column temperature of 80°. Although column performances increased up to 80°, 70° was selected for the assay of erythromycin. The 70° temperature represents a compromise between column performance and column stability. Most column manufacturers recommend that the column not exceed 70°. The HPLC column was stable for more than 1 month when operated at 70° if the mobile phase was saturated with silica.

Increase in temperature has been shown to increase the rate of mass transfer or diffusion of the solute to the stationary phase (7). This most likely has resulted in improved column efficiency.

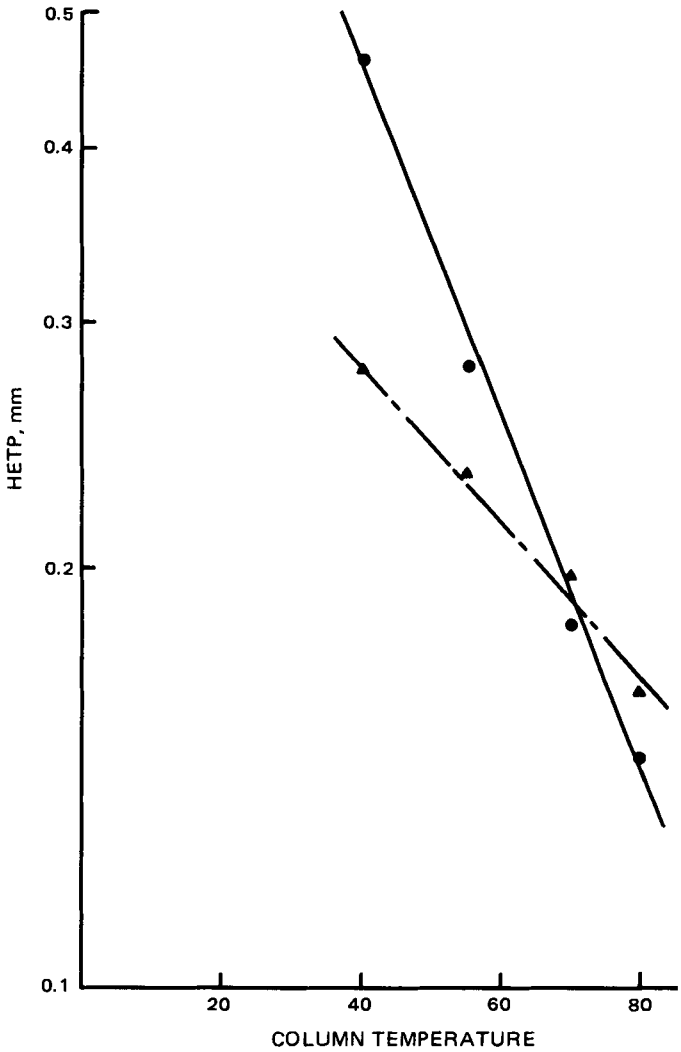

Figure 1—*Effect of column temperature on HETP. Key: (●) LiChrosorb RP-18; (▲) μ-Bondapak C_{18}.*

Selection of Column—Several HPLC columns were evaluated for analysis of erythromycin using the mobile phase composed of acetonitrile–methanol–0.2 *M* ammonium acetate–water (45:10:10:35) at pH 7.0. This pH was selected as a compromise between shorter retention times and better resolution. The following HPLC columns were evaluated: LiChrosorb RP-18[4], μ-Bondapak C_{18}[12], Spherisorb RP-18[13], Partisil ODS[14], Partisil ODS-3[14], and Zorbax ODS[15]. Erythromycin A eluted in 8–10 min from LiChrosorb RP-18, Partisil ODS, and Partisil ODS-3 columns. However, it was found necessary to increase the acetonitrile concentration to 60% to obtain comparative retention time for the erythromycin A peak from Spherisorb RP-18 and Zorbax ODS columns. These latter columns are packed with spherical particles.

The columns were evaluated on the basis of HETP, tailing factor for the erythromycin A peak, and the peak resolution between erythromycins A and C. The data are presented in Table I. The LiChrosorb RP-18 and μ-Bondapak C_{18} columns were judged to give good overall performance for the analysis of erythromycin. A typical chromatogram of erythromycin powder using the LiChrosorb RP-18 column is shown in Fig. 2.

The relative retentions of erythromycins A, B, and C, as well as various impurities and degradation products on the LiChrosorb RP-18 column, are listed in Table II. Although the relative retentions of these compounds were slightly different from those reported previously using a μ-Bondapak C_{18} column at room temperature (1), the order of elution was not affected.

A peak which frequently appears on GLC chromatograms using an

Erythromycin B	1.46
Dihydroerythromycin A	1.74
8,9-Anhydro-6,9-hemiketal erythromycin	2.20

[a] LiChrosorb RP-18 at 70°; mobile phase: acetonitrile–methanol–0.2 *M* ammonium acetate–water (45:10:10:35), pH 7.0.

OV-225 column and tentatively reported as an acid hydrolyzed erythromycin (8) was identified as 8,9-anhydro-6,9-hemiketal erythromycin (9). Although this compound is often inherently present in erythromycin powder, additional amounts can easily be formed from erythromycin under the silylation conditions employed for the GLC assay method. This was not a problem for this HPLC method.

Megestrol acetate, selected as the internal standard for the LiChrosorb RP-18 column, eluted between erythromycin B and 8,9-anhydro-6,9-hemiketal erythromycin peaks (Fig. 3). Calusterone, which elutes immediately after the erythromycin peak, would be suitable as an internal standard when a μ-Bondapak C_{18} column is used (Fig. 4).

Antimicrobial Activity—Since erythromycins A, B, and C differ in both peak response and antimicrobial activity, correction factors must be applied to each of these biologically active compounds so that the total antimicrobial potency of a sample as determined by HPLC correlates with that of the microbiological assay method. The correction factors for

Table IV—Relative Retention of Erythromycin Ethyl Succinate and Impurities[a]

Compound	Relative Retention
Erythromycin A	0.45
Anhydroerythromycin A	0.56
Erythromycin C ethyl succinate	0.69
8,9-Anhydro-6,9-hemiketal erythromycin A	0.78
Erythromycin A ethyl succinate	1.0
Erythromycin B ethyl succinate	1.4
Anhydroerythromycin ethyl succinate	1.7
8,9-Anhydro-6,9-hemiketal erythromycin ethyl succinate	2.2

[a] LiChrosorb RP-18 at 70°; mobile phase: acetonitrile–0.2 *M* ammonium acetate–water (60:10:30), pH 7.4.

erythromycins A, B, and C are 1.0, 0.92, and 0.48, respectively, when tested turbidimetrically using *S. aureus* ATCC 6538P (6) (Table III). These values were obtained by comparison of the relative chromatographic area responses and antimicrobial activities of erythromycins B and C with the erythromycin A reference standard. The relative response factors for erythromycins A, B, and C of 1.0, 0.5, and 0.4, respectively, reported previously were obtained by use of less pure samples of erythromycins B and C and a different test microorganism, *S. aureus* ATCC 9144 (8). Differences in the strain of *S. aureus* could account for the difference in the relative responses of erythromycin B and erythromycin A.

Assay of Erythromycins—Versatility of the HPLC method for the analysis of esters and salts of erythromycin has been demonstrated. HPLC chromatograms of erythromycin estolate, erythromycin ethyl-

to differentiate an ester of erythromycin, erythromycin ethyl succinate, from its impurities. The peaks, EES-C1 and EES-C2, reported previously (2) have been identified as erythromycin C ethyl succinate and 8,9-anhydro-6,9-hemiketal erythromycin A. For quantification of erythromycin, the HPLC response was linear over a concentration range of 0.5–1.3 mg of erythromycin/ml with a correlation coefficient of 0.9999. Six individually weighed and prepared samples were analyzed at an erythromycin concentration of 0.9 mg/ml. The relative standard deviation (*RSD*) of the assay was 0.8% (Table V).

Enteric film coated tablets were then examined for erythromycin content by HPLC. No interference from placebo was experienced. Linearity of recovery was studied by spiking erythromycin into placebo at ~60–120% of label. The average recovery was 99.9% (*RSD* 0.9%). The correlation coefficient for linearity was 0.9996 with the slope of 0.9999 (Table VI). The precision of the HPLC assay for tablets was determined by analyzing six replicate samples prepared at 100% of the label requirements. The average recovery was 99.7% (*RSD* 0.9%) (Table VII).

Table VIII—Comparison of HPLC and Microbiological Assay Methods for the Determination of Erythromycin in Enteric Film Coated Tablets

Lot Number	Erythromycin Content, mg/tablet	
	HPLC (bioequivalency)	Microbiology (potency)
A	263	257
B	261	250
C	267	250
D	262	260
E	251	251
F	263	246
G	335	347
H	328	347

Eight lots of tablets were assayed. The results of HPLC were expressed in terms of bioequivalency using the correction factors described earlier. The results of the HPLC and the microbiological assay methods are shown in Table VIII. No statistically significant difference was noted between the HPLC and the microbiological assay methods.

Bioavailability of Griseofulvin from Tablets in Humans and the Correlation with its Dissolution Rate

NOBUO AOYAGI ˣ, HIROYASU OGATA, NAHOKO KANIWA, MASANOBU KOIBUCHI †, TOSHIO SHIBAZAKI, and AKIRA EJIMA

Received July 31, 1981, from the *Division of Drugs, National Institute of Hygienic Sciences, 18-1, Kamiyoga 1-chome, Setagaya-ku, Tokyo 158, Japan.* †Deceased. Accepted for publication December 30, 1981.

Abstract □ Dissolution rates of 10 commercial microsize griseofulvin tablets and one ultramicrosize griseofulvin tablet were preliminarily determined in 18 liters of pH 7.2 phosphate buffer and in 900 ml of 40% dimethylformamide as test media. Addition of dimethylformamide affected the dissolution behavior of the formulations. The products, three microsize and one ultramicrosize, were selected for further studies on the bioavailability in humans and dissolution. Significant differences among the formulations were found in serum levels, C_{max}, and $AUC_{47.5\ hr}$, but not in AUC_{∞} and t_{max}. The maximum difference of C_{max} was ~40%. The ultramicrosize product showed lower C_{max} and serum levels at earlier sampling times than two microsize products. The dissolution rates determined under sink and nonsink conditions without pretreatment significantly correlated with the serum level at 1 hr but not with the other *in vivo* parameters. Only the dissolution rate determined by the sink method with pretreatment with a small quantity of water (1.0 ml) and plastic beads significantly correlated with serum levels at 3 and 5 hr, C_{max}, and $AUC_{47.5\ hr}$.

Keyphrases □ Bioavailability—griseofulvin from tablets in humans, correlation with dissolution rate □ Dissolution, rates—correlation with bioavailability of griseofulvin from tablets in humans □ Griseofulvin—bioavailability from tablets in humans, correlation with dissolution rate

The absorption of a poorly water soluble drug is considered to be dissolution rate limited. Griseofulvin used as an antifungal agent is a practically insoluble compound. The *in vivo* availability is enhanced by increasing the dissolution rate by means of reduction of particle size of the crystals (1–6). A good correlation between the bioavailability and dissolution rate was found for griseofulvin tablets (7, 8). However, fine particles may not necessarily produce the expected dissolution rate and bioavailability due to their aggregation and agglomeration (4, 9). A microsize griseofulvin powder has been widely used in commercial tablets, and now a new formulation, an ultramicrosize griseofulvin tablet, can be obtained, which has been formulated with the drug dispersed in polyethylene glycol 6000 (10–12) and has been shown to have better bioavailability than microsize products (11, 12). However, recently lower absorption of the drug from an ultramicrosize than from a microsize formulation was shown (13).

The present investigation was undertaken to study the dissolution rate and bioavailability in humans for commercial microsize griseofulvin tablets and an ultramicrosize griseofulvin tablet, and to clarify the relation between the *in vitro* and *in vivo* findings.

EXPERIMENTAL

Formulation—Ten commercial microsize griseofulvin tablets available in Japan and one ultramicrosize griseofulvin tablet[1] were used for the preliminary dissolution test. Each tablet contained 125 mg of griseofulvin. Based on preliminary dissolution data, four formulations, including an ultramicrosize formulation, were selected to provide a broad range of dissolution rates with the expectation that those formulations would show a wide variation in their bioavailabilities.

Table I—t_{50} for Griseofulvin Tablets [a]

Tablet	Method	
	Beaker[b]	Paddle[c]
1 (A)	13.8	8.3
2	25.4	24.7
3	102.6	9.1
4	80.3	10.6
5 (B)	8.1	11.0
6	73.9	37.0
7	85.0	6.0
8 (D)	211.0	38.8
9 (C)	107.8	9.0
10	86.8	—
11	66.0	29.5

[a] Time (t_{50}) in minutes. [b] 18 liters of pH 7.2 phosphate buffer. [c] 40% Dimethylformamide (900 ml).

Solubility—The solubility of griseofulvin in water [pH 7.2 sodium phosphate buffer (0.01 *M*) and 40% dimethylformamide] was determined at 37° spectrophotometrically after filtration of the equilibrated solution of griseofulvin through a 1.0-μm membrane filter.

Disintegration Time—Disintegration times of the griseofulvin formulations were determined with six tablets in pH 7.2 sodium phosphate buffer (0.01 *M*) according to Japanese Pharmacopeia IX specifications (30 strokes/min, 37°). The time when there were no particles of tablets or only a trace amount of soft residue on the screen was selected as the disintegration time.

Dissolution Rate—The dissolution rate of the drug from each dosage form was determined at 37° in pH 7.2 sodium phosphate buffer (0.01 *M*) unless otherwise specified. Hydrochloric acid solution (pH 1.2) and 40% dimethylformamide were also used as solvents. The amount of the drug dissolved was monitored spectrophotometrically by passing the solution through a glass filter stick (porosity G-3) to a flow cell and was expressed as a percentage of the labeled amount. An average dissolution rate was obtained after three dissolution runs. The dissolution rate was represented as t_5, t_{30}, and t_{50}, which indicate, respectively, the time required for 5, 30, and 50% of the drug to be dissolved. Polysorbate 80[2] and diastase (Japanese Pharmacopeia IX grade) were used to investigate their effects on the dissolution.

Method II	—	1.8	1.9	6.6	3.3	2.7	3.2	17.3	6.4

Sink Method—*Nonpretreatment Method*—The beaker method consisted of agitating the solution with a three-bladed screw-type impeller (5.0-cm i.d., stirring rate: 512 rpm) in the middle of the solvent (18 liters) in a 20-liter flat-bottom beaker (29.0-cm i.d.).

The basket method consisted of placing a tablet in a cylindrical basket (1.7-cm i.d. × 2.3 cm) of 80-mesh stainless steel cloth. This basket was placed in a basket (Apparatus 1) as used in USP XX. The basket was held ~10 cm below the surface of the solvent and rotated at 400 rpm, ~7 cm from the wall of the beaker. The dissolution medium was agitated with a three-bladed impeller as described for the 18-liter beaker method.

With the paddle method (USP XX), 900 ml of 40% dimethylformamide was used as a solvent and was stirred at 120 rpm.

Pretreatment Method—Method I: A tablet was put into a 100-ml round bottle containing 1.0 ml of water and was gently shaken for 1 min. After standing for 5 min, 20 g of plastic beads (8-mm i.d.)[3] was added to the bottle. The bottle was fixed at an angle of 5° and was rotated at 3.8 rpm in a water bath (37°) for 15 min. The contents then were poured into 18 liters of the solvent with 100 ml of water for washing through a sieve to remove the plastic beads. Then the dissolution rate was determined according to the 18-liter beaker method procedure.

Method II: A tablet was gently shaken in 20 ml of water contained in a 50-ml round bottle for 5 min, and then 27 g of the plastic beads used in Method I was added. The subsequent procedure was the same as method I.

Nonsink Method—A 900 ml volume of the solvent was used in each experiment. The following procedures were used:

1. Rotating basket method (USP XX): The basket was rotated at 120 rpm.
2. Paddle method (USP XX): The stirring rate was 120 rpm.
3. Beaker method: A three-bladed screw-type impeller (5.0-cm i.d.) used as a stirring device was rotated at 2.5 cm from the bottom of the beaker which was used for the paddle method at 120 rpm.

Bioavailability—Twelve healthy male volunteers who participated in a Latin square crossover study were randomly assigned to one of four groups of equal size. The subjects ranged in age from 22 to 51 years (22, 22, 22, 22, 23, 24, 30, 32, 37, 37, 50, and 51; mean 31), in height from 160 to 180 cm (mean 170), and in weight from 53 to 69 kg (mean 60). Before the studies the participants were given a clinical examination to ensure they were healthy. All of the subjects were prohibited from taking medicines and alcoholic beverges from 3 days before the drug administration to the end of the test. Each subject took a test tablet orally with 200 ml of water at 9:00 am after fasting overnight. No foods or liquids were allowed until 4 hr after ingestion of the tablet. Blood samples (5 ml) were obtained at 1, 3, 5, 8, 23.5, 33, and 47.5 hr after administration of a tablet and the serum samples were kept frozen at −15° until assayed. The experiments were repeated every 2 weeks according to the dosage schedule. The following parameters were statistically subjected to ANOVA, and the differences among the treatments were examined by Tukey's test:

1. Serum levels at each sampling time.
2. Peak serum level (C_{max}).
3. Time to reach peak serum level (t_{max}).
4. Area under serum concentration–time curves from zero to the time t (AUC_t) calculated by the trapezoidal rule

The AUC_∞ was calculated by the method of Wagner (14).

Dose–Bioavailability Relation—A single tablet and one-half tablet of Formulation B, corresponding to 125 and 62.5 mg of griseofulvin, respectively, were given orally to three subjects according to a crossover design. The sampling times were the same as described in the bioavailability study.

Assay—The serum griseofulvin concentration was determined by the GLC method described previously (15). To a 0.5-ml aliquot of serum were added 0.5 ml of saturated sodium chloride solution and 5 ml of ether. After shaking for 10 min, a 4-ml aliquot of the ether phase was taken and evaporated to dryness *in vacuo*. The residue was dissolved with 0.4 ml of benzene containing 1.1 μg of clothiapine as internal standard, and 5 μl of the solution was taken for the GLC assay. GLC conditions: column, glass column (3-mm i.d. × 70 cm) packed with 5% OV-17 on 60–80 mesh Chromosorb W; injection temperature, 260°; detector temperature, 260°.

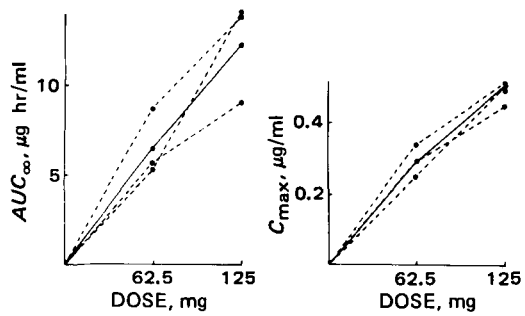

Figure 2—*Relations of griseofulvin dose with* AUC_∞ *and peak concentration after oral administration of the drug. Key: (- - -) responses of the individual subjects; (—) the average response.*

[3] Sartorius-Membranfilter GmbH.

RESULTS

Dissolution Rate—The solubilities of griseofulvin at 37° in water, pH 7.2 buffer, and 40% dimethylformamide were 31.8, 32.2, and 482.1 μg/ml, respectively; therefore, the preliminary dissolution tests were carried out with 18 liters of the aqueous medium (18-liter beaker method) and 900 ml of 40% dimethylformamide (paddle method) in order to get a sink condition. Figure 1 shows the dissolution profiles with the 18-liter beaker method. Relatively large differences were observed among the microsize griseofulvin formulations. The ultramicrosize formulation (A) showed rapid dissolution. Table I lists t_{50} in 18 liters of aqueous solvent and in 40% dimethylformamide. Addition of the organic solvent to aqueous medium altered the dissolution behavior of griseofulvin; however, the use of a partially alcoholic medium was described for the dissolution test of water insoluble drugs (16). On the basis of the *in vitro* data, four formulations (A, B, C, D), including an ultramicrosize formulation, were selected for further investigations concerning their dissolution rates and bioavailabilities.

Table II lists the dissolution rates (t_{30} and t_{50}) of these formulations determined under the sink condition. With the 18-liter beaker method

[a] The figures indicate means ± standard errors. [b] NS: not significant. [c] Formulations underlined by a common line did not differ significantly; $p < 0.05$.

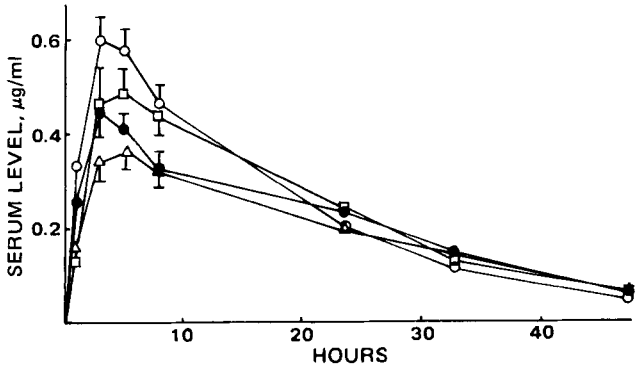

Figure 3—*Mean serum griseofulvin concentration after oral administration of 125-mg griseofulvin tablets to humans. Key: (●) Tablet A; (○) Tablet B; (△) Tablet C; (□) Tablet D. The vertical lines indicate standard errors.*

at either pH 7.2 or 1.2 without additives, the drug rapidly dissolved from Formulations A and B due to their rapid disintegration into fine particles. It slowly dissolved, however, from Formulations C and D due to the large particles resulting from disintegration. Polysorbate 80 and diastase, which was used to investigate the digestive action on the starch widely employed in tablets as the disintegrant or excipient, enhanced the dissolution from Formulation D, and in the presence of diastase its dissolution rate was faster than that from Formulation C. This can be attributed to a wetting action of the surfactant and a digestive one of the diastase. The dissolution rates were not enhanced by an increase of agitation intensity, but the dissolution from Formulation D was specifically facilitated with the basket method in which its deaggregation into fine particles seemed to be promoted due to being rubbed against the sieve wall of the basket as it was rotated. This suggests that deaggregation, especially for Formulation D, must be more accelerated by mechanical forces than by the flow of the dissolution medium. This was further ascertained by the pretreatment methods in which the dissolution of the drug, especially from Formulation D, was greatly enhanced. This is probably due to the strong deaggregation effects of the plastic beads.

The volume of water used in the pretreatment affected the dissolution, especially from the ultramicrosize formulation (A). It formed a pastelike agglomerate and showed slower dissolution when a small quantity of water (1.0 ml) was used (Method I) than when 20 ml of water was employed. In the latter case the formulation rapidly disintegrated into fine particles.

Table V—Power Analysis with $\alpha = 0.05$ and $\beta = 0.2$

Parameter	Time, hr	Subjects for 20% difference	Minimum Detectable Difference, %
Serum level	1	76	53
	3	28	30
	5	24	28
	8	20	26
	23.5	20	25
	33	44	39
	47.5	60	47
C_{max}		20	24
t_{max}		216	90
$AUC_{47.5}$		12	17
AUC_∞		16	21

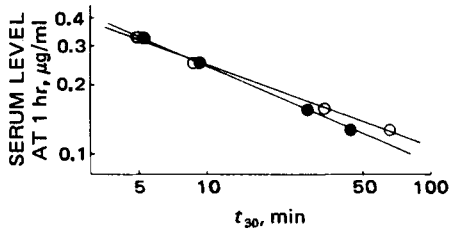

Figure 4—*Log–log plots of serum level of griseofulvin at 1 hr against t_{30} determined by the beaker method at pH 7.2 without an additive (○) and in the presence of polysorbate 80 (●).*

The initial dissolution rates (t_5) determined under the nonsink condition are shown in Table III. The results were similar to those determined with nonpretreatment methods under the sink condition, which suggests that by using the initial dissolution rates, the dissolution under the sink condition can be predicted.

Disintegration Time—The mean disintegration times of Formulations A, B, C, and D were 9.3, 12.5, 0.4, and 2.4 min, respectively. Contrary to the disintegration findings, the slow dissolution of the drug from Formulations C and D led to the conclusion that the resultant particulate state after disintegration is more important for the dissolution of griseofulvin than the disintegration time.

Bioavailability—The relations of griseofulvin dose with AUC_∞ and C_{max} are shown in Fig. 2. The nearly linear relationships of dose–AUC_∞ ($r = 0.829$) and dose–C_{max} ($r = 0.944$) indicate that linear pharmacokinetics can be applied to the serum level of griseofulvin within the dose ranges studied.

Figure 3 shows the mean serum concentration–time curves of griseofulvin in humans after oral administration of four formulations. Table IV lists the mean values of each parameter for these formulations. The rank order of serum level at 1 hr was B>A>C>D, but the serum levels during 3–8 hr, C_{max} and $AUC_{47.5}$, were B>D>A>C. The lowest peak

concentration (Formulation C) was only 60% of the highest one (Formulation B). Significant differences were found among the formulations; however, there were no significant differences in AUC_∞, which suggests that the four formulations were equivalent in the extent of bioavailability.

The mean peak times did not show significant differences, though the maximum difference (3.6–7.9 hr) was relatively large. This can be attributed to the large variations in the parameter which will be due in some degree to a few peak times of 23.5 hr, which occurred with all formulations except B. It may have been artificially caused by the long interval of the sampling time from 8 to 23.5 hr. The power analysis was employed to estimate the minimum detectable difference between the formulations which would be statistically significant ($\alpha = 0.05$, $\beta = 0.2$) or the number of subjects required for a 20% difference to be significant (Table V). The results of this analysis indicate considerably low detectability of t_{max} compared with the other parameters; only 90% of the minimum difference could be detected in this study, and >200 subjects would have been required for a 20% difference to be significant. The parameters of $AUC_{47.5}$ and AUC_∞ provided better detectabilities, which must be due to the small variabilities in the parameters.

The ultramicrosize formulation (A) did not show good bioavailability, which is coincident with previous results (13), though absorption of the drug from the formulation was reported to be approximately twice that from microsize formulations (11, 12).

Correlation Between Dissolution Rate and Bioavailability—The correlation coefficients between the *in vivo* and *in vitro* parameters (t_{30} and t_5 determined by sink and nonsink methods, respectively) are shown in Tables VI and VII. The t_{30} determined by sink methods without pretreatment correlated significantly with the serum level at 1 hr in normal–reciprocal and log–log regressions but not with the other *in vivo* parameters. Similar relations were found between t_5 determined by nonsink methods and the *in vivo* parameters. The t_{30} determined by Method I with pretreatment with 1.0 ml of water was significantly correlated with serum levels at 3–5 hr and C_{max} in normal–reciprocal regression and even with $AUC_{47.5}$ in log–log regression. Those determined by Method II using 20 ml of water, however, did not correlate significantly with any of the *in vivo* parameters. Figures 4 and 5 illustrate the log–log regression lines that were significantly correlated between *in vivo* and *in vitro* findings.

DISCUSSION

The *in vivo* and *in vitro* findings for griseofulvin formulations suggest the complex dissolution behavior of the drug from its dosage forms in the GI tract in humans. The serum levels 1 hr after administration of the formulation correlated well with the dissolution rates determined under sink and nonsink conditions without pretreatment, which leads to the conclusion that initial absorption is mainly controlled by relatively simple dissolution behavior as shown artificially in the dissolution tests without pretreatment. However, the serum levels during 3–5 hr and C_{max} did not correlate well with these dissolution rates, which is probably due to the unexpectedly low values for Formulation A and high values for D for the *in vivo* parameters. It may be considered that for a drug having as low solubility in water or biological fluids as griseofulvin, the *in vivo* disintegration and dissolution must be affected more by physiological factors in the GI tract than those of a drug having high solubility, because the former drug must stay in the GI tract longer. The *in vitro* pretreatment, which decreases the sizes of aggregates or particles available from dissolution with plastic beads, markedly increased the dissolution, especially from Formulation D. The resulting dissolution rates highly correlated with the serum levels at 3 and 5 hr, C_{max}, and $AUC_{47.5}$. These findings suggest a strong deaggregation action on the aggregates and/or particles while the drug having low solubility stays in the GI tract.

A previous report on sugar-coated tablets of chloramphenicol also suggested the violent destructive force on the formulations *in vivo* (17). Therefore, the absorption of a drug having low solubility from its dosage forms seems to be correlated more with the dissolution rates determined under the conditions of vigorous agitation and destructive intensities than under mild conditions, though the absorption of a drug having high solubility such as aspirin may be correlated more with the dissolution rates determined under the latter conditions (18, 19).

Formulation A showed rapid dissolution under sink and nonsink conditions without pretreatment, which is probably due to the original ultramicrosize particulate state of the drug. But the rapid dissolution did not contribute to the *in vivo* absorption. Formulation A formed a pastelike agglomerate when treated with a small quantity of water (1.0 ml). Such an agglomerate may be also produced in the GI tract after rapid gastric emptying and rapid absorption of water coadministered with the formulation and may be responsible for slower dissolution and the resulting lower absorption of the drug.

Abstract □ The bioavailability of four griseofulvin tablets in beagle dogs, including an ultramicrosize tablet used previously in a human bioavailability study, was investigated on the basis of the plasma 6-demethylgriseofulvin concentration. The relations with the *in vivo* findings in humans and the *in vitro* dissolution rates also were examined. Contrary to the lower bioavailability of the ultramicrosize formulation in humans, it provided the best bioavailability in beagles. The microsize griseofulvin formulations showed similar *in vivo* results to those in humans. Poor correlation of *in vivo* parameters between humans and beagles was attributed to the discrepancy of the availability of the ultramicrosize formulation between the two species. The dissolution rates determined by the pretreatment method using plastic beads were correlated more with the *in vivo* findings than those determined by the other methods. Beagles were a useful animal model for bioavailability studies of certain griseofulvin formulations but not ultramicrosize ones.

Keyphrases □ Bioavailability—griseofulvin from tablets in beagle dogs, correlation with dissolution rate and bioavailability in humans □ Dissolution rates—bioavailability of griseofulvin from tablets in beagle dogs, bioavailability in humans □ Griseofulvin—bioavailability from tablets in beagle dogs, dissolution rate and bioavailability in humans

The bioavailabilities for four lots of griseofulvin tablets in humans have been reported previously, and the relations with *in vitro* dissolution rates have been discussed (1).

Beagle dogs are often used as an animal model for bioavailability studies, but their suitability has not been clarified sufficiently. A good relation of penicillin bioavailability between humans and dogs was reported (2). Previous studies on bioavailability of diazepam formulations in humans and beagles revealed no good relations between the results from both species. The discrepancy was considered to be due to the differences of physiological states of the GI tract, especially of gastric emptying rate and GI transition time (3).

In the present study the bioavailability of griseofulvin from tablets in beagles was studied, and the relations with *in vivo* results in humans and *in vitro* dissolution rates were investigated.

[a] The figures indicate means ± standard error. [b] NS: not significant. [c] Formulations underlined by a common line did not differ significantly ($p < 0.05$).

lation was an ultramicrosize griseofulvin tablet (A); the others were commercial microsize griseofulvin tablets (B, C, D).

Dissolution Rate—The methods to determine the dissolution rates were carried out as reported previously (1). Sink methods included nonpretreatment (18-liter beaker method and basket method) and pretreatment (Methods I and II). The dissolution rate was expressed as t_{30} the time taken for 30% of the drug to dissolve.

Bioavailability—Twelve beagles (12.0–14.0 kg; mean 12.9) were randomly divided into four groups according to a Latin square crossover design. The beagles, having fasted for 20 hr, were given a test tablet and then forced to take 30 ml of water. The beagles were not given any food until 10 hr after drug administration. Blood samples were taken at 0.5, 1, 2, 3, 4, 6, 8, 10, and 24 hr after administration, and the plasma samples were frozen and stored until assay. The experiments were repeated every week according to the dosage schedule. The bioavailability for each formulation was evaluated from the plasma concentrations of 6-demethylgriseofulvin, a metabolite of griseofulvin, at each sampling time, peak plasma concentration (C_{max}), time to C_{max} (t_{max}), and area under plasma concentration–time curves from 0 to the sampling time t (AUC_t). The value for AUC_∞ was calculated by the method of Wagner (4).

[a] With 30 and 200 ml of water. [b] NS: not significant. [c] Mean ± standard error.

Dose–AUC_∞ Relation—Three beagles were fasted overnight and given one and two tablets of Formulation C, corresponding to 125 and 250 mg of griseofulvin, respectively. The other procedures were the same as described for the bioavailability test.

Effects of Volume of Water Coadministered—Three formulations, including the ultramicrosize formulation, were used. Eight beagles were given a tablet with 30 and 200 ml of water in a crossover design. The other procedures were the same as described for the bioavailability test.

Assay—Griseofulvin and 6-demethylgriseofulvin in plasma were determined by GC (5).

RESULTS

Plasma Levels of Griseofulvin and 6-Demethylgriseofulvin—Table I shows the mean plasma griseofulvin and 6-demethylgriseofulvin concentrations after oral administration of Formulation A. The plasma griseofulvin concentrations were below one-fifth of those of 6-demethylgriseofulvin, and only a trace of griseofulvin was detected at 24 hr after administration of the drug. This can be attributed to the greater clearance of griseofulvin in dogs than in humans (6, 7), and hence, a considerable fraction of the dose administered orally will be converted to 6-demethylgriseofulvin by first-pass metabolism before reaching the blood circulation (8). The great clearance of griseofulvin probably leads to the greater coefficients of variation found in the plasma levels of griseofulvin than those of 6-demethylgriseofulvin. Considering the findings, the bioavailability of griseofulvin in beagles was estimated on the basis of the plasma level of 6-demethylgriseofulvin.

Bioavailability—The relation of the griseofulvin dose and the AUC_∞ of 6-demethylgriseofulvin is shown in Fig. 1. Large differences in the AUC_∞ values among the beagles were found. With the high dose, the unabsorbed fraction of the drug may increase by being not fully dissolved in the GI tract.

Figure 2 shows the mean plasma level–time curves of 6-demethylgriseofulvin following oral administration of four formulations. Table II lists their mean values for *in vivo* parameters. The plasma levels of 6-demethylgriseofulvin at 24 hr were very low, so the AUC_{24} can be considered as AUC_∞. Although the ultramicrosize formulation (A) showed relatively low bioavailability in humans (1), this formulation showed the highest values in the plasma concentrations, C_{max} and AUC_{24}, in beagles. The ratios of C_{max} and AUC_{24} of the ultramicrosize formulation to those of Formulation B, which showed the highest availability of all microsize formulations, were 132 and 127%, respectively. Significant differences were found between Formulation A and two microsize formulations (C and D) in the plasma levels at earlier sampling times, C_{max} and AUC_{24}.

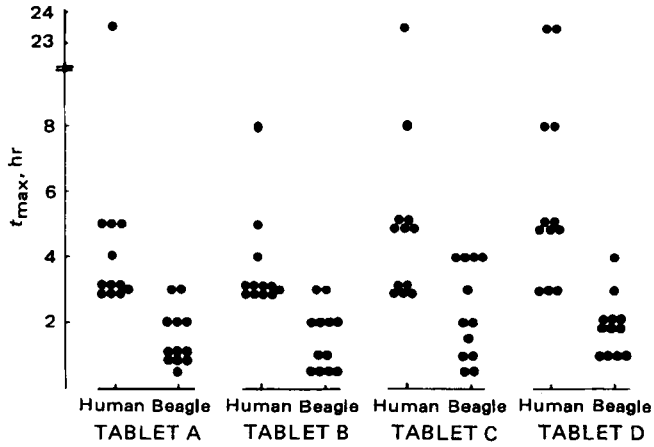

Figure 4—*Individual t_{max} values in beagles and humans after oral administration of four griseofulvin formulations.*

For microsize formulations, the *in vivo* results were similar to those in humans: Formulation B had the best bioavailability as expected from the *in vitro* dissolution rate and Formulation D showed better bioavailability than Formulation C. A significant difference was found in C_{max} between Formulations B and C but not in plasma levels and AUC_{24}. The t_{max} values in beagles, which seemed shorter than those in humans (3.6–7.9 hr), did not show significant differences among the formulations.

Effects of Volume of Water Coadministered—Thirty milliliters of water was given to beagles; however, 200 ml was used in the human bioavailability study (1). The large volume of water enhanced the *in vivo* absorption of erythromycin stearate and amoxicillin which are poorly soluble in water (9). The different volumes of water used in the human and beagle tests might lead to a discrepancy in the *in vivo* results, especially for the ultramicrosize formulation. To clarify this, the bioavailabilities were tested with 30 and 200 ml of water. As shown in Table III, the fluid volume did not significantly affect the bioavailabilities, which leads to the conclusion that the discrepancy of bioavailabilities between humans and beagles is not due to the difference of the volume of water administered. As another explanation, the physiological differences in the GI tract between the two species may be considered.

Correlation Between the Bioavailability and Dissolution Rates—The correlation coefficients between the *in vivo* parameters and *in vitro* dissolution rates (t_{30}) determined by sink methods are shown in Table IV. The *in vivo* parameters are correlated more in the log–log and normal–reciprocal regressions with t_{30} determined by Method II (Table IV), in which the tablets were treated in 20 ml of water with plastic beads before the determination of dissolution rates.

Correlation Between Humans and Beagles—As shown in Table V, low correlation coefficients were found between humans and beagles. The poor relations are attributed mainly to the discrepancy of the ultramicrosize formulation (A) between them. Figure 3 shows that the microsize formulations (B, C, D) showed a good relation (r = 0.976) in C_{max} values between humans and beagles, which suggests that the bioavailabilities of microsize formulations can be evaluated in beagles instead of humans.

DISCUSSION

The *in vivo* findings in beagles did not correlate well with those in humans. The ultramicrosize formulation provided the best availability

[a] C_t shows the plasma or serum concentration at time t.

in beagles contrary to its lower absorption in humans. Considering the insignificant effects of the volume of water on the bioavailability, the ultramicrosize formulation discrepancy may be attributed to the physiological differences in the GI tract. None of the *in vitro* dissolution methods indicated such a superiority of the ultramicrosize formulation in beagles. These findings suggest that this formulation may disintegrate into the original ultramicrosize particulate state of the drug and allow rapid dissolution in the GI tract in beagles beyond the expectation from the *in vitro* dissolution findings.

The t_{max} values in beagles for different formulations were smaller than those in humans (Fig. 4). This suggests rapid transition of the drug to the absorption site, namely, fast gastric emptying of the drug in beagles. The good bioavailability of the ultramicrosize formulation may be related to the rapid gastric emptying of the drug which leads to dissolution of the drug in the small intestinal tract.

Formulation D provided higher C_{max} and plasma levels at earlier sampling times than Formulation C as observed in the human test. The *in vitro* dissolution rate of the drug from Formulation D was enhanced over that from Formulation C by pretreatment with plastic beads. These findings suggest that in beagles and humans there is a strong intensive deaggregation action on the particles or aggregates of the drug during their transition into the GI tract.

Although there was no significant difference in AUC_∞ values among the formulations in humans, the AUC_{24} (considered as AUC_∞) of Formulations C and D were significantly lower than that of Formulation A in beagles. This suggests their incomplete dissolution during passage through the GI tract and also suggests the short absorption site and/or fast transition of the drug in the GI tract in beagles as previously shown for the bioavailability of diazepam in beagles (3).

Although the *in vivo* findings of the ultramicrosize formulation in beagles did not agree with those in humans, the bioavailabilities of the microsize formulations showed good agreement. Considering this, beagles may serve as a useful animal model for bioavailability studies of certain griseofulvin tablet formulations, but not ultramicrosize ones.

NOTES

Antibradykinin Active Material in *Aloe saponaria*

AKIRA YAGI *x, NOBUO HARADA ‡, HIDENORI YAMADA *, SHUICHI IWADARE ‡, and ITSUO NISHIOKA *

Received October 27, 1981, from the **Faculty of Pharmaceutical Sciences, Kyushu University, Maidashi, Higashi-ku, Fukuoka, Japan*, and the ‡*Banyu Pharmaceutical Co., Ltd., Nihonbashi honcho, Chuo-ku, Tokyo, Japan.* Accepted for publication December 31, 1981.

Abstract □ A material having antibradykinin activity on isolated guinea pig ileum was partially purified from the nondialysate of the pulp of *Aloe saponaria* by repetition of gel chromatography using a hydrophilic polyvinyl gel and dextran gels. From the results of amino acid and carbohydrate analyses, the antibradykinin-active material was estimated to be a glycoprotein. It was found that this material catalyzes the hydrolysis of bradykinin at pH 7.4. The results of peptide analysis using reversed-phase high-performance liquid chromatography coupled with amino acid analysis indicate that this glycoprotein cleaves the Gly^4-Phe^5 and Pro^7-Phe^8 bonds of the bradykinin molecule.

Keyphrases □ Antibradykinin—active material in *Aloe saponaria*, guinea pig ileum, glycoprotein, high-performance liquid chromatography □ Glycoprotein—antibradykinin active material in *Aloe saponaria*, high-performance liquid chromatography, guinea pig ileum □ *Aloe saponaria*—antibradykinin active material, glycoprotein, high-performance liquid chromatography, guinea pig ileum

Cardiac stimulant action of the constituents in the dialysate of the pulp from *Aloe saponaria*[1] on isolated cardiac muscles has been reported (1). Antibradykinin activity of the nondialysate of the pulp has been examined here to obtain pharmacological evidence for its anti-inflammatory action (2). In this report, the results of partial purification of material having antibradykinin activity from *A. saponaria* on isolated guinea pig ileum and its proteolytic property against bradykinin are presented.

EXPERIMENTAL

Materials—The following materials were purchased from suppliers: dextran gel[2,3], hydrophilic polyvinyl gel[4], dialysis membrane[5], synthetic bradykinin[6], and bromelain[7]. The gel filtrations were performed at room temperature at a flow rate of 21 ml/hr using a microtube pump[8].

Methods of Analysis—Protein and carbohydrate contents in samples

were determined colorimetrically by a previously reported method (3) and the phenol–sulfuric acid method (4), respectively. Elution of materials through gel filtration was monitored by absorbance of effluents at 260 nm[9]. Paper electrophoresis[10] was carried out with a buffer solution of pyridine–acetic acid–water (1:10:489, pH 3.5) at 600 V for 2 hr. Paper chromatography was performed by developing the paper[10] with the solvent of butanol–pyridine–water (6:4:3). Peptide separation was accomplished by reversed-phase[11] high-performance liquid chromatography (HPLC)[12]. Peptides were applied to a column (4 × 250 mm), and the column was eluted with a linear gradient of ethanol concentration from 1% (40 ml) to 50% (40 ml), both containing 0.1% concentrated HCl at a flow rate of 0.4 ml/min (5). Peptide elution was monitored by absorbances of effluents at 210 and 260 nm[13]. The elution volume of bradykinin was 48 ml. For amino acid analysis the sample was hydrolyzed in 6 *N* HCl at 110° for 20 hr in evacuated sealed tubes. At the end, the hydrolysates were evaporated to dryness, dissolved in 0.02 *N* HCl, and analyzed with an amino acid analyzer[14]. Ultracentrifugation was performed on an analytical ultracentrifuge with an optical system[15] in a single sector at 20° and 56,000 rpm.

Assay Method for Antibradykinin—Antibradykinin activity was estimated by the biological assay on the guinea pig ileum by a previously described method (6). Briefly, a strip from 2 to 3 cm of guinea pig ileum was suspended in 10 ml of magnesium ion-free Tyrode solution which was oxygenated with oxygen–carbon dioxide (95:5) in an organ bath at 30°. The contractile responses of various concentrations of bradykinin were measured with a mechanoelectric transducer[16] equipped with a recorder[17] for 45 sec after injection. At the beginning of the assay, responses to a series of four doses of bradykinin (usually 25, 50, 75, and 100 ng dissolved in 1 ml of 10 m*M* phosphate buffer at pH 7.4) were checked, and each of them was repeated two or three times to obtain a standard dose–response curve. For measurement of anti-bradykinin activity, 0.2 ml of bradykinin solution (1 μg/ml) was incubated with 0.2 ml of a sample for 5 min at 30°, and the contractile response by 0.2 ml of this mixture (100 ng bradykinin equivalent) was measured. When the activity of a sample was so potent that >70% of bradykinin was inactivated, the sample was diluted with the same buffer to give at least 30 ng of bradykinin remaining after 5 min of incubation.

Extraction and Purification of Antibradykinin Active Material from *A. saponaria*—*Water Extraction*—The fresh leaves of *A. saponaria*[18] were harvested from the green house of the herbal garden of Kyushu University in September or December, 1979. The leaves (7 kg) were cut in half and colorless gelatinous pulp was separated carefully by scraping the green cortical layer containing yellow phenolics. The homogenized pulp (3 kg) was centrifuged at 10,000 rpm for 30 min. The supernatant was dialyzed with cellulose tubing[5] against distilled water for 48 hr. The nondialyzable fraction was lyophilized to yield colorless, soft crude Extract A (obtained from the leaves harvested in September, 5.8 g) or B (obtained from the leaves harvested in December, 7.0 g). No considerable difference between crude Extracts A and B in antibradykinin activity was observed (Table I).

Ammonium Sulfate Precipitation—Ammonium sulfate was added to a solution of crude Extract A (5.8 g) in distilled water (200 ml) to make 35% saturation, and after standing overnight it was centrifuged at 10,000 rpm for 30 min. The precipitate was dissolved in distilled water, dialyzed against distilled water for 48 hr, and then lyophilized to yield ammonium sulfate fraction (1.2 g).

Gel Filtration on Hydrophilic Polyvinyl Gel and Dextran Gels—Ammonium sulfate fraction (0.1 g) dissolved in 0.3 *M* NaCl (6 ml) was applied to a column of hydrophilic polyvinyl gel[4] (20 × 690 mm), and the column was eluted with the same solution. The eluate (108 ml) was dialyzed against distilled water followed by lyophilization to give polyvinyl gel fraction (50 mg). The fraction (50 mg) was subjected to filtration through a column of dextran gel[2] (20 × 790 mm) using 0.3 *M* NaCl as a solvent, and the eluate from the column was fractionated to three portions. Each portion was dialyzed against distilled water followed by lyophilization to yield gel filtration Fractions A (20 mg), B (10 mg), and C (negligible amount). Fraction B (120 mg) was further chromatographed through a column of dextran gel[3] (16 × 880 mm) using distilled water as a solvent followed by lyophilization to give Fraction D (26.3 mg).

Table I—Antibradykinin Activity of Fractions on Isolated Guinea Pig Ileum

Sample	Protein, %	Carbohydrate, %	Unit/g[a]	Ratio
Crude Extract A	1.7	66[b]	6.34	1.00
Crude Extract B	1.9	63	8.94	1.41
Ammonium sulfate precipitate	2.4	68	27.9	4.40
Gel filtration Fraction A	—	72	6.0	0.94
Gel filtration Fraction B	7.2	63	85.4	13.47
Bromelain			1114.0	175.70

[a] One kininase unit was defined as the amount of enzyme preparation that could degrade 1 μg of bradykinin for 1 min, at 30°, pH 7.4. For statistical purposes 3–5 guinea pigs were used for each assay. [b] The measured content of carbohydrate and protein does not account for 100% of the material. This may reflect the presence of water, since a polymer is extremely hygroscopic.

RESULTS AND DISCUSSION

Extraction and Concentration of Antibradykinin Active Material from *A. saponaria*—The pulp of *A. saponaria* leaves was extracted with water and the extract was dialyzed against distilled water. The nondialyzable fraction (crude extract) showed antibradykinin activity when assayed on the inhibition of the contractile response on isolated guinea pig ileum. As can be seen in Table I, no considerable difference in antibradykinin activity was observed between crude Extracts A and B, which were obtained from the leaves harvested in September and December, respectively. Crude Extract A was precipitated with ammonium sulfate at 35% saturation. The precipitate gained 4.4 times the increased specific activity compared with crude Extract A (Table I). Several attempts to increase the specific activity by means of dextran gel chromatographies were unsuccessful, because the material was too viscous to obtain a practical flow rate. Thus, the chromatography over hydrophilic polyvinyl gel[4] was performed first to remove viscous material from the antibradykinin active material, which was then chromatographed on dextran gel[2] to give three fractions (A–C). As shown in Table I, Fraction A having low specific activity is composed of only carbohydrate, while Fraction B with 13.5 times higher specific activity than crude Extract A is composed of carbohydrate and a low content of protein. Fraction C was not analyzed because of its low yield. To remove contaminated salts completely, Fraction B was chromatographed over dextran gel[3] using distilled water as an eluting solvent to yield Fraction D. Further purification was not continued because of shortage of the sample (total yield, 0.003%). As a positive control, bromelain containing ~2% carbohydrate was employed for the assay and extremely potent antibradykinin activity was observed (7).

Characterization of Antibradykinin Active Material—To clarify the nature of the antibradykinin active material, the pH-dependency of antibradykinin activity and the thermal stability were studied using crude Extract A. Each solution of crude Extract A (10 mg) in 0.067 *M* phosphate buffer (1.0 ml) at various pH values (4.5, 5.0, 6.0, 7.0, 8.0, and 8.5) was kept standing at 30° for 1 hr.

After the dialysis, followed by lyophilization, antibradykinin activity of crude Extract A at each pH was estimated and expressed as percent of the activity at pH 7.4. The results showed that crude Extract A is comparably active at pH 5.0–7.0, but <20% of antibradykinin activity was observed at pH 4.5, 8.0, or 8.5. Antibradykinin activity was completely lost when crude Extract A was treated at 90° for 10 min. These results suggest that the antibradykinin active material may be a protein or a glycoprotein having enzymatic activity rather than a small molecule such as norepinephrine (8).

To ascertain this speculation, the purest material obtained here, Fraction D, was subjected to an ultracentrifugation experiment, uv spectral absorption measurement, amino acid analysis, and carbohydrate analysis. Fraction D in 0.3 *M* NaCl was analyzed by ultracentrifugation with an optical system[15] for determination of the sedimentation coefficient. Since Fraction D (10 mg/ml of 0.3 *M* NaCl) indicated a single peak having $S_{20,w}$ = 0.79 *S*, it appeared to be homogeneous in size. The UV absorption spectrum of Fraction D in 0.3 *M* NaCl indicated the presence of an absorption band with a maximum at 260 nm. On acid hydrolysis of Fraction D, only D-mannose was observed as sugar moiety on paper chromatography, and Asp, Thr, Ser, Glu, Gly, Ala, Val, Ile, Leu, Phe, Lys,

Arg, and Pro as amino acid moieties were observed on amino acid analysis. All of these results support the theory that the antibradykinin active material is a protein or a glycoprotein.

Action of the Antibradykinin Active Material Against Bradykinin Molecule—Bradykinin (0.5 mg) in 10 m*M* phosphate buffer (0.7 ml, pH 7.4) was incubated with 1.0 mg of Fraction D at 30° for 2 hr. The lyophilized mixture was subjected to paper electrophoresis with acetate–pyridine buffer (pH 3.5) to afford two ninhydrin positive spots of fast and slow moving ones compared with that of bradykinin which migrates towards the cathode. These two spots were not observed in the blank experiments without bradykinin or Fraction D.

The fast moving spot was eluted from unstained paper strips and the extract was subjected to amino acid analysis. The fast moving spot was confirmed to be a peptide composed of Arg, Pro, and Gly in the ratio of 1:2:1, which was consistent with the residues 1–4 (Arg^1-Pro^2-Pro^3-Gly^4) of bradykinin, indicating that Fraction D cleaved the bond between Gly^4 and Phe^5 in bradykinin and, therefore, had a kininase activity. The slow moving spot, however, was not clearly separated from the spot due to bradykinin on paper electrophoresis.

The incubation mixture after lyophilization was subjected to HPLC on a reversed-phase column. Three major peaks were observed at an elution volume of 6, 38, or 48 ml in HPLC, and each peak was collected and subjected to amino acid analysis to afford the following amino acid composition, respectively: Arg, Pro, Gly (1:2:1); Arg, Pro, Gly, Phe, Ser (1:3:1:1:1); and Arg, Pro, Gly, Phe, Ser (2:3:1:2:1).

Each composition was consistent with the structures Arg^1-Pro^2-Pro^3-Gly^4, Arg^1-Pro^2-Pro^3-Gly^4-Phe^5-Ser^6-Pro^7, and Arg^1-Pro^2-Pro^3-Gly^4-Phe^5-Ser^6-Pro^7-Phe^8-Arg^9 (bradykinin), respectively. All of these results indicate that the antibradykinin active material in *A. saponaria* has a kininase activity and cleaves the peptide bonds at *N*-terminuses of two phenylalanine residues in bradykinin.

As a kininase from plant origin, bromelain, papain, and ficin are known to cleave Gly^4-Phe^5 and Phe^5-Ser^6 bonds of the bradykinin molecule, while both shimejikininase (9) from mushroom, *Tricholoma congluobatum*, and kinonase AI (10) from microbes, *Streptomyces* species, cleave Gly^4-Phe^5 and Pro^7-Phe^8 bonds of the bradykinin molecule. Thus, the action of the glycoprotein obtained here is similar to that of shimejikininase and kinonase AI.

As one of the pharmacological evidences for anti-inflammatory activity of *A. saponaria*, the presence of an antibradykinin active glycoprotein was confirmed here. Further study on the anti-inflammation effect is in progress.

Cardiotonic Principles of Ginger (*Zingiber officinale* Roscoe)

N. SHOJI *, A. IWASA *, T. TAKEMOTO *, Y. ISHIDA ‡ and Y. OHIZUMI ‡x

Received May 12, 1981, from the **Faculty of Pharmacy, Tokushima-Bunri University, Tokushima-shi, Tokushima 770, Japan* and ‡*Mitsubishi-Kasei Institute of Life Sciences, Machida-shi, Tokyo 194, Japan.* Accepted for publication December 9, 1981.

Abstract □ Crude methanol extracts of the rhizome of ginger (*Zingiber officinale* Roscoe) showed potent, positive inotropic effects on the guinea pig isolated left atria. The extract of this rhizome has been fractionated, monitored by the cardiotonic activity, to yield gingerols as active principles.

Keyphrases □ Ginger (*Zingiber officinale* Roscoe)—cardiotonic principles, gingerols, □ Cardiotonic principles—ginger (*Zingiber officinale* Roscoe), gingerols □ Gingerols—cardiotonic principles of ginger (*Zingiber officinale* Roscoe)

The rhizome of ginger (*Zingiber officinale* Roscoe) has been used not only as a seasoning spice but also as an important medicine in Japan and China. It is considered to possess stomachic, carminative, stimulant, diuretic, bechic, and antiemetic properties (1). Chemical studies on the pungent principles of ginger have been carried out by a number of investigators (2–8). Recently, gingerols have been isolated from ginger as pungent substances (3).

It was found that the crude methanol extract of ginger had a powerful positive inotropic effect on the guinea pig isolated atria. The present report describes the isolation of cardiotonic principles from ginger and determination of their chemical structures.

EXPERIMENTAL[1]

Isolation—The dried rhizome (580 g) of ginger (*Z. officinale* Roscoe), zingiberis rhizoma, was crushed mechanically and soaked in methanol at room temperature. The mixture was filtered and the filtrate was evaporated *in vacuo*. The residue (106 g) was partitioned between water and ethyl acetate. The ethyl acetate layer was evaporated *in vacuo* and the residue (30 g) was dissolved in methanol and extracted with *n*-hexane. The pharmacologically active methanol fraction was again evaporated *in vacuo*. The residue (25.4 g) was dissolved in a small amount of benzene,

[1] Melting points were obtained on a Yanagimoto micro melting point apparatus and are uncorrected. Optical rotation was recorded on a Jasco ORD/UV-5 spectrometer with a circular dichroism attachment. UV spectra were obtained with a Hitachi 200-20 spectrophotometer. IR spectra were obtained on a Shimadzu LKB-9000B. PMR spectra were recorded on a Varian XL-100A spectrometer. CMR spectra were recorded on a Hitachi R-22 spectrometer.

0022-3549/82/01000-1174$01.00/0

Arg, and Pro as amino acid moieties were observed on amino acid analysis. All of these results support the theory that the antibradykinin active material is a protein or a glycoprotein.

Action of the Antibradykinin Active Material Against Bradykinin Molecule—Bradykinin (0.5 mg) in 10 m*M* phosphate buffer (0.7 ml, pH 7.4) was incubated with 1.0 mg of Fraction D at 30° for 2 hr. The lyophilized mixture was subjected to paper electrophoresis with acetate–pyridine buffer (pH 3.5) to afford two ninhydrin positive spots of fast and slow moving ones compared with that of bradykinin which migrates towards the cathode. These two spots were not observed in the blank experiments without bradykinin or Fraction D.

The fast moving spot was eluted from unstained paper strips and the extract was subjected to amino acid analysis. The fast moving spot was confirmed to be a peptide composed of Arg, Pro, and Gly in the ratio of 1:2:1, which was consistent with the residues 1–4 (Arg^1-Pro^2-Pro^3-Gly^4) of bradykinin, indicating that Fraction D cleaved the bond between Gly^4 and Phe^5 in bradykinin and, therefore, had a kininase activity. The slow moving spot, however, was not clearly separated from the spot due to bradykinin on paper electrophoresis.

The incubation mixture after lyophilization was subjected to HPLC on a reversed-phase column. Three major peaks were observed at an elution volume of 6, 38, or 48 ml in HPLC, and each peak was collected and subjected to amino acid analysis to afford the following amino acid composition, respectively: Arg, Pro, Gly (1:2:1); Arg, Pro, Gly, Phe, Ser (1:3:1:1:1); and Arg, Pro, Gly, Phe, Ser (2:3:1:2:1).

Each composition was consistent with the structures Arg^1-Pro^2-Pro^3-Gly^4, Arg^1-Pro^2-Pro^3-Gly^4-Phe^5-Ser^6-Pro^7, and Arg^1-Pro^2-Pro^3-Gly^4-Phe^5-Ser^6-Pro^7-Phe^8-Arg^9 (bradykinin), respectively. All of these results indicate that the antibradykinin active material in *A. saponaria* has a kininase activity and cleaves the peptide bonds at *N*-terminuses of two phenylalanine residues in bradykinin.

As a kininase from plant origin, bromelain, papain, and ficin are known to cleave Gly^4-Phe^5 and Phe^5-Ser^6 bonds of the bradykinin molecule, while both shimejikininase (9) from mushroom, *Tricholoma congluobatum*, and kinonase AI (10) from microbes, *Streptomyces* species, cleave Gly^4-Phe^5 and Pro^7-Phe^8 bonds of the bradykinin molecule. Thus, the action of the glycoprotein obtained here is similar to that of shimejikininase and kinonase AI.

As one of the pharmacological evidences for anti-inflammatory activity of *A. saponaria*, the presence of an antibradykinin active glycoprotein was confirmed here. Further study on the anti-inflammation effect is in progress.

Abstract □ Crude methanol extracts of the rhizome of ginger (*Zingiber officinale* Roscoe) showed potent, positive inotropic effects on the guinea pig isolated left atria. The extract of this rhizome has been fractionated, monitored by the cardiotonic activity, to yield gingerols as active principles.

Keyphrases □ Ginger (*Zingiber officinale* Roscoe)—cardiotonic principles, gingerols, □ Cardiotonic principles—ginger (*Zingiber officinale* Roscoe), gingerols □ Gingerols—cardiotonic principles of ginger (*Zingiber officinale* Roscoe)

put on a silica gel[2] column packed with benzene, and eluted with a mixture of benzene–ethyl acetate (9:1). Each fraction was monitored using TLC[3] with a mixture of benzene–acetonitrile (9:1) as a developing solution. Fractions showing the bioactivity were combined and rechromatographed five times on silica gel to afford three active substances, I–III:

Compound I—$C_{17}H_{26}O_4$, mp 30–32°, $[\alpha]_D$ = +27.8° (*C*, 1.0 chloroform); UV (ethanol): 284 nm (ϵ 2700); IR (neat): 1700 cm^{-1} (C=O); mass spectrum: *m/z* 294 (M^+, 61.8%), 137 (100), PMR (deuterochloroform): δ 0.88 (3H, broad t, J = 7 Hz, —$(CH_2)_4$—CH_3), 1.06–1.62 [8H, m, —$(CH_2)_4$—CH_3], 2.42–2.61 (2H, m, —CO—CH_2—CHOH—), 2.61–2.95 (4H, m, —CH_2—CH_2—CO—), 3.07 (1H, broad s, —*OH*), 3.84 (3H, s, —OCH_3), 3.86–4.16 (1H, m, —CH_2—*CH*OH—), 5.82 (1H, broad s, —*OH*), 6.54–6.86 (3H, m, aromatic H); CMR (deuterochloroform): δ 14.02 (q), 22.61 (t), 25.19 (t), 29.31 (t), 31.78 (t), 36.59 (t), 45.45 (t), 49.50 (t), 55.89 (q), 67.83 (d), 111.29 (d), 114.72 (d), 120.85 (d), 132.75 (s), 144.23 (s), 146.77 (s), 211.50 (s).

Compound II—$C_{19}H_{30}O_4$, mp 28–30°, $[\alpha]_D$ = +26.2° (*C*, 1.0 chloroform); UV (ethanol): 284 nm (ϵ 2700); IR (KBr): 1700 cm^{-1} (C=O); mass spectrum: *m/z* 322 (M^+, 13.9%), 137 (100); PMR (deuterochloroform): δ 0.88 [3H, broad t, J = 7 Hz, —$(CH_2)_6$—CH_3], 1.06–1.55 [12H, m, —$(CH_2)_6$—CH_3], 2.43–2.62 (2H, m, —CO—CH_2—CHOH—), 2.62–2.92 (4H, m, —CH_2—CH_2—CO—), 2.89 (1H, broad s, —*OH*), 3.86 (3H, s, —OCH_3), 3.88–4.16 (1H, m, —CH_2—*CH*OH—), 5.71 (1H, s, —*OH*), 6.56–6.88 (3H, m, aromatic H); CMR (deuterochloroform): δ 14.06 (q), 22.65 (t), 25.50 (t), 29.27 (t) × 2, 29.54 (t), 31.82 (t), 36.63 (t), 45.41 (t), 49.46 (t), 55.85 (q), 67.83 (d), 111.33 (d), 114.76 (d), 120.81 (d), 132.71 (s), 144.23 (s), 146.81 (s), 211.46 (s).

Compound III—$C_{21}H_{34}O_4$, mp 42–43°, $[\alpha]_D$ = +19.8 (*C*, 1.0 chloroform); UV (ethanol): 284 nm (ϵ 3100); IR (KBr): 1700 cm^{-1} (C=O); mass spectrum: *m/z* 350 (M^+, 13.4%), 137 (100); PMR (deuterochloroform): δ 0.80 (3H, broad t, J = 7 Hz, —$(CH_2)_8$—CH_3), 1.20 (16H, broad s, —$(CH_2)_8$—CH_3), 2.39–2.54 (2H, m, —CO—CH_2—CHOH—), 2.54–2.84 (4H, m, —CH_2—CH_2—), 2.91 (1H, broad s, —*OH*), 3.78 (3H, s, —OCH_3), 3.82–4.08 (1H, m, —CH_2—*CH*OH—), 5.63 (1H, broad s, —*OH*), 6.48–6.82 (3H, m, aromatic H); CMR (deuterochloroform): δ 14.09 (q), 22.69 (t), 25.50 (t), 29.35 (t) × 4, 29.62 (t), 31.93 (t), 36.63 (t), 45.45 (t), 49.46 (t), 55.89 (q), 67.83 (d), 111.25 (d), 114.68 (d), 120.85 (d), 132.75 (s), 144.19 (s), 146.73 (s), 211.50 (s).

Guinea Pig Isolated Left Atria—Bioassay of the fraction being tested was performed on the isolated left atria of guinea pigs. Guinea pigs (300–400 g) were sacrificed by cervical dislocation. The atrium was separated from the rest of the heart and mounted vertically in 50 ml of tissue bath containing Krebs-Ringer bicarbonate solution of the following

Rhizhome of ginger (580 g)
↓ extracted with methanol
Methanol extract (106 g)(+)
↓ partitioned with ethyl acetate and water

Ethyl acetate soluble portion (30 g)(+) — Water soluble portion (76 g)(−)
↓ partitioned with n-hexane and methanol

Methanol soluble portion (25.4 g)(+) — n-Hexane soluble portion (4.4 g)(−)
↓ chromatographed over silica gel
eluted with benzene-ethyl acetate (9:1)

(7.19 g)(−) | (7.29 g)(+) | (8.30 g)(−)
↓ chromatographed five times over silica gel
eluted with benzene-ethyl acetate (9:1)

Substance I (4.14 g)(+) | Substance II (0.62 g)(+) | Substance III (1.08 g)(+)

Scheme I—Procedure of the isolation of the cardiotonic principles from ginger (Z. officinale Roscoe); (+) active, (−) inactive.

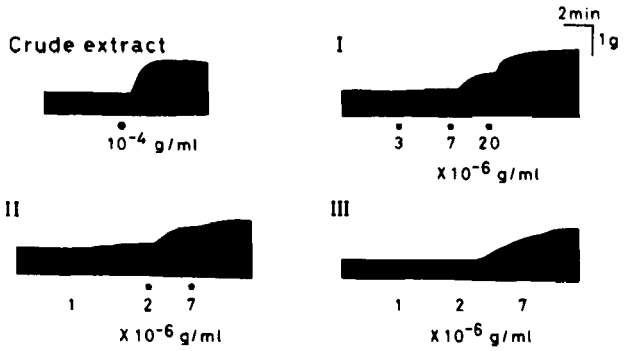

Figure 1—*The inotropic effect of the crude methanol extract of ginger (Z. officinale Roscoe) and gingerols on the guinea pig isolated left atria. Crude extract and gingerols were cumulatively added at (●). (I) [6]-gingerol; (II) [8]-gingerol; (III) [10]-gingerol.*

composition (in millimoles): sodium chloride, 120; potassium chloride, 4.8; calcium chloride, 1.2: magnesium sulfate, 1.3; potassium dihydrogenphosphate, 1.2; sodium hydrogen carbonate, 25.2; and glucose, 5.8; pH 7.4. The solution was bubbled with a gas mixture of oxygen–carbon dioxide (95:5) and maintained at 30°. A resting tension of 800 mg was applied to each strip. Tissues were driven by an electrical stimulator[4] at a frequency of 2 Hz with square-wave pulses of 5 msec at 4–5 V. Isometric contractions were measured by the force-displacement transducer and recorded on a polygraph. Four preparations from different animals were used for one sample being tested.

RESULTS AND DISCUSSION

The methanol extract (6×10^{-5}–3×10^{-4} g/ml) of rhizome of ginger caused a dose-dependent positive inotropic effect on the guinea pig isolated atria. A representative pattern of a positive inotropic effect of the methanol extract (10^{-4} g/ml) is shown in Fig. 1. In order to isolate the cardiotonic principles from ginger, fractionation of the methanol extract of ginger was performed, being monitored by the positive inotropic action as shown in Scheme I. Active fractions, 37–117, eluted with benzene–ethyl acetate (9:1) from the silica gel column, contained three components. The mixture was chromatographed five times over silica gel to give three active substances, I–III. Their yields were 0.71, 0.11, and 0.19%, respectively. Each substance tasted pungent, suggesting that they might be known pungent principles of ginger. Their physicochemical properties confirm that substances I–III are [6]-, [8]-, and [10]-gingerol, respectively, which had been isolated previously as pungent constituents (9).

As shown in Fig. 1, treatment with [6]-, [8]-, and [10]- gingerol of the atria induced a dose-dependent positive inotropic action. The minimum effective doses were 10^{-5}, 10^{-6}, and 3×10^{-5} g/ml for [6]-, [8]-, and [10]-gingerol, respectively. The activity appears to be in the decreasing order: [8]-gingerol > [10]-gingerol > [6]-gingerol.

On the basis of the present results, it is concluded that ginger has a powerful positive inotropic effect on the guinea pig isolated atria and that cardiotonic principles of ginger were identified as [6]-, [8]-, and [10]-gingerol.

Lipid-Soluble Inhibitors of Dihydrofolate Reductase III: Quantitative Thin-Layer and High-Performance Liquid Chromatographic Methods for Measuring Plasma Concentrations of the Antifolate, 2,4-Diamino-6-(2,5-dimethoxybenzyl)-5-methylpyrido-[2,3-*d*]pyrimidine

ROBERT G. FOSS and CARL W. SIGEL ˣ

Received November 20, 1981, from the *Department of Medicinal Biochemistry, Wellcome Research Laboratories, Research Triangle Park, NC 27709.* Accepted for publication January 4, 1982.

Abstract □ Specific methods using high-performance liquid chromatography (HPLC) and thin-layer chromatography (TLC) for the analysis of the potent antifolate, 2,4-diamino-6-(2,5-dimethoxybenzyl)-5-methylpyrido-[2,3-*d*]pyrimidine (I) in plasma were developed. The HPLC system employed paired-ion chromatography using a mobile phase of water–acetonitrile (65:35, v/v) in conjunction with a reversed-phase C-1 column and detection by UV absorbance measurement. The TLC system utilized a scanning densitometer operating in the reflectance mode with detection of I by fluorescence measurement. The lower limits of detection for the HPLC and TLC methods were ~0.005 μg/ml. The coefficients of variation for the measurement of drug concentrations over the range of 0.04–1.0 μg/ml of plasma were 5 and 6%, respectively.

Keyphrases □ Dihydrofolate reductase—quantitative thin-layer chromatographic and high-performance liquid chromatographic methods for measuring plasma concentrations of antifolate □ Antifolate—thin-layer chromatographic and high-performance liquid chromatographic methods for measuring concentrations of plasma, lipid-soluble inhibitors of dihydrofolate reductase □ High-performance liquid chromatography—method for measuring concentrations of an antifolate, lipid-soluble inhibitors of dihydrofolate reductase

2,4-Diamino-6-(2,5-dimethoxybenzyl)-5-methylpyrido-[2,3-*d*]pyrimidine (I)[1] is a new lipid-soluble folate antagonist for the treatment of neoplastic diseases (1, 2). Methods using high-performance liquid chromatography (HPLC) and quantitative TLC for assaying this drug in plasma were developed and compared. For the measurement of I by HPLC, a reversed-phase C-1 column coupled with UV detection at 254 nm was employed; the TLC method fluorescence was measured after chromatography on conventional §silica gel plates. Chromatographic analyses were facilitated by the use of a microcomputer-based system for the acquisition and reduction of data (3).

BACKGROUND

In contrast to some other antifolate drugs, I exhibits activity comparable to methotrexate against mammalian dihydrofolate reductase, while minimally inhibiting the catabolism of histamine *via* histamine-*N*-methyltransferase (2, 4). The moderate lipophilicity [log *P* (octanol–water) = 1.73] of I facilitates cellular entry of the drug by diffusion, thus avoiding the dependence on the reduced folate facilitated transport system (2, 5). The short half-life of the drug (0.38 hr in the rat) and its response to calcium leucovorin rescue alleviate the problems of cumulative toxicity to normal cells (2, 6). Studies *in vivo* of the effect of I on solid W256 carcinoma in the rat resulted in reductions in mean tumor volumes of 70–90%, relative to tumorous control animals (1, 2).

The encouraging properties of I prompted development of specific analytical methods that could be used for measuring I in biological samples for chemotherapy, disposition, and toxicological studies. HPLC and TLC methods were evaluated and found to be comparable with respect to the analytical precision and net recovery of I.

EXPERIMENTAL

Reagents—Acetonitrile[2], chloroform[2], methylene chloride[2], methanol[2], 2-propanol[2], ammonium hydroxide[3], sodium bicarbonate[3], and sodium hydroxide[3] were reagent grade. The ion-pairing reagent[4] was used as received. Distilled water was filtered through a 0.45-μm membrane filter[5] prior to use.

Apparatus—A liquid chromatograph[6] equipped with a valve-loop injector[7], strip-chart recorder[8], and a microcomputer-based data system was used with a commercially packed 25 cm × 4.6-mm i.d. column[9] containing 6-μm C-1 reversed-phase packing. A precolumn[10] filled with C-18 pellicular packing[11] was also used.

A motor-driven multispotter[12] was used to spot 20 × 20-cm nonfluorescing 0.25-mm layer thickness silica gel 60 TLC plates[13]. The plates were quantified using a scanning densitometer[14] interfaced with a microcomputer.

Standard Solutions—A stock solution of I was prepared in methanol that was diluted with either methanol or chloroform–methanol (90:10, v/v) to produce standard solutions for liquid and thin-layer chromatography, respectively.

Reference solutions of I for HPLC analyses were prepared at concentrations of 0.25, 1.0, and 4.0 ng/μl; those for TLC analyses were prepared at concentrations of 1.0 and 5.0 ng/μl. No apparent degradation of stock

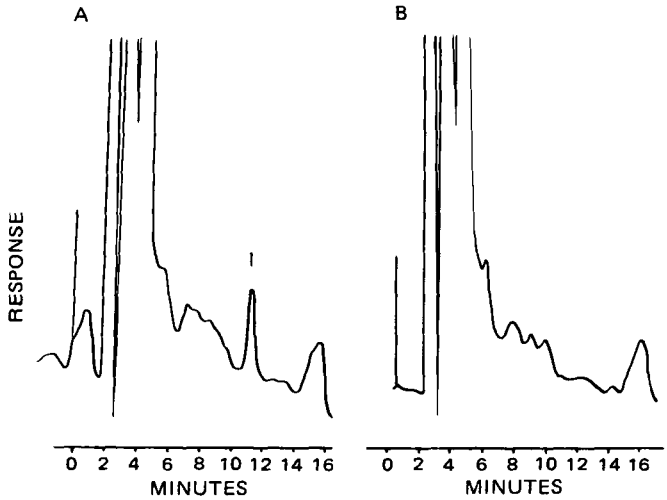

Figure 1—*Typical HPLC chromatograms of extracts from plasma (1 ml) (A) containing 0.040 μg of I and from blank plasma (1 ml) (B).*

0022-3549/82/01000-1176$01.00/0

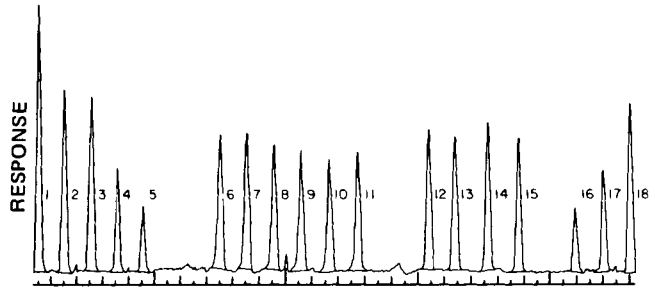

Figure 2—*Typical TLC chromatogram of extracts from plasma (1 ml) and I. Peaks corresponding to known amounts of I are as follows: 1, 0.080 μg; 2, 0.050 μg; 3, 0.050 μg; 4, 0.030 μg; 5, 0.020 μg; 16, 0.020 μg; 17, 0.030 μg; 18, 0.050 μg. Peaks 6–11 are the extracts from replicate plasma (1 ml) samples, each containing 0.040 μg of I. Peaks 12–15 are 20% of the extracts from replicate plasma (1 ml) samples, each containing 0.20 μg of I.*

or standard solutions was observed over a period of 6 months, when stored at −15°.

Sample Preparation—To a 12-ml culture tube[15], fitted with a polytef[16]-lined screw cap, was added 1.0 ml of plasma. The pH of the plasma was adjusted with 1.0 ml of pH 10 bicarbonate buffer and vortex mixed[17] for 5 sec. The basified plasma was extracted by addition of 4.0 ml of methylene chloride and rotary mixing[18] for 10 min. The organic phase was transferred and retained. A second 4.0-ml portion of methylene chloride was used to extract the aqueous phase, as above, and the organic extracts were combined and concentrated at ~40° to 1.0 ml using a gentle stream of dry nitrogen. Extraneous material was separated from I by passing the concentrated extract through a disposable silica gel cartridge[19] that was preeluted sequentially with 25 ml of methanol and 15 ml of methylene chloride. Ten milliliters of methylene chloride was passed through the silica cartridge and discarded. A 6.5-ml eluate of methanol was collected and evaporated at ~55° with nitrogen. The residue was reconstituted, using methanol for HPLC analysis or chloroform–methanol (90:10, v/v) for TLC analysis, to a final volume dependent on the expected concentration of I in the plasma. For both analyses, if low levels (5–200 ng) of I were anticipated, sample tubes were washed with two 40-μl portions of the appropriate solvent, which were drawn into a 100-μl syringe; for higher levels, residues were dissolved in 250–1000 μl of solvent and a suitable volume (10–100 μl) was drawn into a syringe.

Analytical Procedure for HPLC—The mobile phase, filtered distilled water containing 0.005 *M* 1-octane sulfonic acid–acetonitrile (65:35, v/v), was degassed by agitation under reduced pressure. The C-1 column was operated isocratically with an eluent flow rate of 1.5 ml/min and a column inlet pressure of 2500 psi. The retention time for I was ~11 min. Volumes of reference solution (20–100 μl) were injected to bracket expected amounts of I in the samples. The column effluent was monitored by UV absorbance measurement at 254 nm. Chromatograms were obtained in an analog form using a recorder with a chart speed of 0.5 cm/min and in a digital form using a microcomputer[20] with a data sampling rate of 1 point/sec. The use of a microcomputer in this laboratory as an adjunct to the acquisition and reduction of chromatographic data has been described previously (3).

Analytical Procedure for TLC—A motor-driven multispotter was used to spot gradually the extracts and reference solutions onto a nonfluorescing silica gel plate. Volumes of reference solution (10–100 μl), containing a sufficient quantity of I to bracket expected amounts in the sample residues, were drawn into 100-μl syringes for deposit on the TLC plate. Warm air from a 460-watt hair dryer[21] was blown across the plate to hasten evaporation of the solvent and to minimize spot diffusion. Plates were developed to 10 cm with chloroform–2-propanol–concentrated ammonium hydroxide (25:20:01, v/v). The plate was air dried in a hood for 30 min, then the fluorescence of I was measured using a scanning densitometer operated in the single-beam reflectance mode at 340 nm excitation wavelength with a 400-nm cutoff interference filter. Plates that were spotted with quantities of I at the low end of the concentration range were stored overnight and scanned the next day after the intensity of the fluorescence of I had increased.

Table I—Recovery of I from Spiked Plasma

Compound I, μg/ml	HPLC			TLC		
	N	Recovery, %	*CV*	*N*	Recovery, %	*CV*
0.040	4	84	6	10	95	7
0.200	4	80	0	10	89	5
1.00	4	86	5	10	93	5
Composite	12	84	5	30	92	6

Identification and Quantification of I in Plasma—Programmable microcomputers were interfaced with the HPLC and TLC equipment to provide for ready assessment of chromatograms (3). The microcomputers monitored either the output of the HPLC absorbance detector or the output of the TLC scanning densitometer.

The chromatographic peak corresponding to I in samples was identified by comparison of retention time or R_f value with those for reference solutions containing I. Quantification was achieved by calculating the ratio of the peak area of I in the sample to the peak areas of varying amounts of external reference I as determined by least-squares regression fit. Although peak heights were also available, calculations based on peak areas were found to provide more reliable results (3).

RESULTS

High-Performance Liquid Chromatography—Typical chromatograms of the entire extracts from 1.0 ml of control (blank) plasma and 1.0 ml of plasma to which was added 0.040 μg of I are presented in Fig. 1. At a capacity factor (k') of 6, the linear calibration range for I was 0.010–0.320 μg. A correlation coefficient of 0.999 was obtained for a typical regression analysis, $y = 0.2134x - 0.0008$, where y is the peak area and x is the peak amount in micrograms. At a signal-to-noise ratio of 2.5, the HPLC limit of detection for I in plasma was 0.005 μg/ml. The mean recovery of I in plasma over the range of 0.04–1.0 μg/ml was 84% with a coefficient of variation (CV) of 5% ($n = 12$) (Table I).

Thin-Layer Chromatography—Using the chromatographic conditions indicated, I had an R_f of 0.35. A microcomputer-generated plot of peaks obtained for I by scanning an entire TLC plate is presented in Fig. 2. No peaks corresponding to the drug were found in control samples. A typical TLC calibration curve was linear over the range of 0.004–0.300 μg with a correlation coefficient of 0.997 for the line $y = 1.167x + 0.0128$, where y is the peak area and x is the peak amount in micrograms. The limit of detection for plasma extracts, at a signal-to-noise ratio of 2.5, was 0.004 μg/ml. The mean recovery of I over the range of 0.040–1.0 μg/ml of plasma was 92% with a CV of 6% ($n = 30$) (Table I).

DISCUSSION

Concentration-dependent variations in the extraction efficiency of BW 301U were observed over the measured range when a one-step methylene chloride extraction procedure was utilized; consequently, a two-step extraction procedure was investigated. Although this refinement did decrease the variability to an acceptable level, an excessive amount of endogenous material was extracted also. The coextractives resulted in considerable streaking from the origin to the solvent front of TLC silica gel plates, deforming the spots of compound I. Silica gel cartridges were used to remove these relatively nonpolar materials. Prior to use, the cartridges were eluted with methanol to reduce plate streaking and to remove a contaminant, R_f of ~0.85, that fluoresced when exposed to long wavelength (366 nm) UV radiation. Once the sample extract was loaded, the cartridge was eluted with methylene chloride to remove the sample components responsible for the streaking. Compound I, strongly retained on silica gel, was not eluted until methanol was passed through the cartridge.

Immediately after removal of the TLC plate from the developing chamber the fluorescence of I was most intense, but it diminished markedly to a minimum within 20 min. Plates could be analyzed at that time; however, for increased sensitivity, plates were retained for 24 hr before scanning to permit the fluorescence of I to increase to an intensity that was comparable to that observed initially. The change in fluorescence intensity did not require the presence of light. Following this initial interval, the enhanced fluorescence was stable for at least 1 month.

The substances responsible for the streaking of TLC silica gel plates initially did not appear to adversely affect HPLC chromatograms; however, the silica gel cartridges and a C-18 guard column were used to maximize column longevity, providing a useful column life in excess of several months.

The tendency of I to exhibit fluorescence in solution is potentially useful for analysis by HPLC. However, this fluorescence is readily quenched in aqueous solutions, thereby hindering its use in many reversed-phase liquid chromatographic systems. Normal-phase liquid chromatography does not appear promising due to the strong affinity of I for silica gel columns, resulting in asymmetric peak shapes and excessive capacity factors. Thus, paired-ion reversed-phase chromatography in conjunction with detection by UV absorbance is used for the analysis of I by HPLC. The parameters chosen provided good peak shape, a moderate retention time, and analytical sensitivity comparable to that obtained by fluorescence detection.

The selection of one procedure in preference to the other for the analysis of plasma samples from clinical studies is a matter of available equipment and efficiency. TLC is used preferentially to HPLC in this laboratory for the rapid analysis of limited numbers of samples (typically 1–20). Larger numbers of samples may be analyzed more efficiently by HPLC using an auto-injector to provide for unattended operation. The chromatographic equipment is interfaced with microcomputers to facilitate quantification, thereby achieving high levels of precision and accuracy.

NMR Determination of Isosorbide Dinitrate and β-Adrenergic Blocking Agents in Tablets

SILVIA N. CHIARELLI, MABEL T. ROSSI, MARÍA T. PIZZORNO, and SEM M. ALBONICO ˣ

Received August 26, 1981, from the *Universidad de Buenos Aires, Faculdad de Farmacia y Bioquímica, 1113 Buenos Aires, Argentina.* Accepted for publication January 11, 1982.

Abstract □ An NMR spectroscopic method for the determination of isosorbide dinitrate, alone or together with alprenolol or propranolol, is described. Spectra are determined in dimethyl sulfoxide-d_6 containing maleic acid or 1,4-dinitrobenzene as internal standards. Both synthetic mixtures and commercial formulations were assayed, and the results were compared using compendial procedures.

Keyphrases □ Isosorbide dinitrate—NMR determination, β-adrenergic blocking agents in tablets □ β-Adrenergic blocking agents—NMR determination of isosorbide dinitrate, tablets □ NMR spectroscopy—determination of isosorbide dinitrate and β-adrenergic blocking agents in tablets

Isosorbide dinitrate (I) is a member of the group of vasodilator drugs, having a nitrite or nitrate function, that are used particularly in the treatment of angina pectoris and ischemia of skeletal muscle (1). It is used alone or together with β-adrenergic blocking agents such as propranolol (II) (2) or alprenolol (III) (3).

Several methods for the analysis of I, II, and III have been described. The official compendia describe a polarographic titration (4) or a colorimetric reaction with *p*-phenolsulfonic acid (5) for isosorbide dinitrate and a spectrophotometric assay for alprenolol (6) and propranolol (7). However, their application for the quantitative determination of I in tablets is laborious and time consuming. The present report describes a new quantitative method for the determination of I alone or together with II or III by ^{1}H-NMR spectroscopy. Furthermore, it allows the simultaneous analysis of II or III.

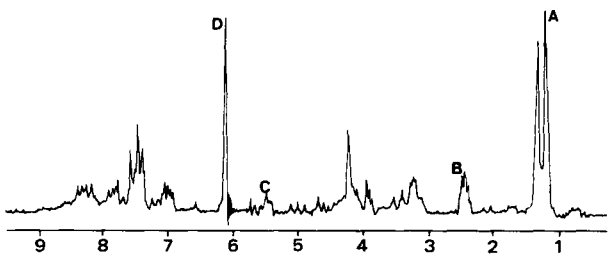

Figure 1—*NMR spectrum of a typical I and II mixture analysis in dimethyl sulfoxide-*d_6. *Key: (A) methyl protons of II; (B) solvent impurity; (C) protons on* C_2 *and* C_5 *of I; (D) single signal of IV.*

EXPERIMENTAL[1]

Materials—Standard isosorbide dinitrate (I), propranolol hydrochloride (II), and alprenolol hydrochloride (III) were purified by recrystallization from ethanol–water, *n*-propanol, and ethyl acetate, respectively.

Maleic acid (IV) was used as internal standard after recrystallization from water, mp 130–131°; 1,4-dinitrobenzene (V) (8), also used as internal standard, was purified by sublimation, mp 173–174°. Dimethyl sulfoxide-d_6 (VI) was used as the solvent and tetramethylsilane was the internal standard.

Samples—Tablets from two batches of each brand locally obtained were used.

Isosorbide Dinitrate Tablets—Twenty tablets were weighed and a sample equivalent to 50 mg of I was dissolved in 10 ml of 2% sodium bicarbonate solution and extracted from methylene chloride (3 × 7 ml). The solution was evaporated in a Craig tube, and 75 mg of IV was added. The mixture was dissolved in 1.0 ml of VI, and ~0.4 ml of the solution was transferred to an NMR tube where the spectrum was obtained (Table I).

Isosorbide Dinitrate and Propranolol Hydrochloride Tablets—The same procedure as just described was used with a sample equivalent

[1] A Perkin-Elmer R12 NMR spectrometer, 60 MHz was used. All spectra were scanned at a probe temperature of 35°.

to 50 mg of I and 200 mg of II using 75 mg of IV as the internal standard (Table II).

Isosorbide Dinitrate and Alprenolol Hydrochloride Tablets—The same procedure as described for isosorbide dinitrate was used, with a sample equivalent to 20 mg of I and 100 mg of III using 60 mg of V as the internal standard (Table III).

Calculations—The amount of I was calculated as follows:

$$\frac{\text{I, mg}}{\text{tablet}} = \frac{EW_I}{EW_{ST}} \times \frac{A_I}{A_{ST}} \times \frac{ST, \text{mg}}{W_S} \times ATW$$

Where EW_I is the molecular weight of I divided by the number of protons in the signal chosen, EW_{ST} is the molecular weight of the internal standard divided by the number of protons in its signal, A_I is the integral value of the signal representing I, A_{ST} is the integral value of the signal representing the internal standard, W_S is the weight of the sample in milligrams, and ATW is the average tablet weight.

The amount of II and III was calculated by a similar procedure.

RESULTS AND DISCUSSION

All the drugs and internal standards were soluble in dimethyl sulfoxide. Its impurity appeared at 2.5 ppm and it did not interfere with the signals chosen. The stability of the drugs in this solvent during testing was ensured by running the spectra twice.

Maleic acid was selected as the internal standard because it provides a signal at 6.2 ppm, which is near the signal chosen for the analysis; therefore, the error due to drift is small. Furthermore, it has an equivalent of 58, larger than the equivalent of most internal standards. For the analysis of III, V was used due to the overlapping of the signals of III and IV.

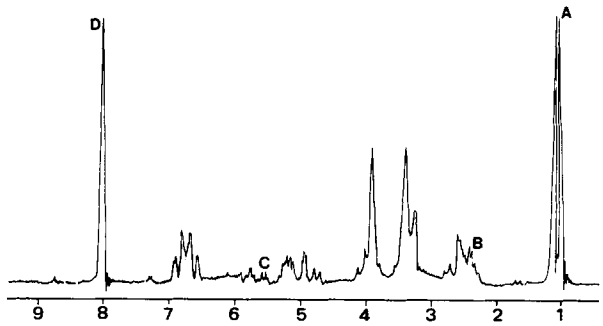

Figure 2—*NMR spectrum of a typical I and III mixture analysis in dimethyl sulfoxide-*d_6. *Key: (A) methyl protons of III; (B) solvent impurity; (C) protons on* C_2 *and* C_5 *of I; (D) single signal of V.*

Table V—Analysis of Standard Mixtures of Isosorbide Dinitrate and Alprenolol Hydrochloride

Standard Mixture	Internal Standard, mg	Alprenolol Hydrochloride			Isosorbide Dinitrate		
		Added, mg	Found, mg	Recovery, %	Added, mg	Found, mg	Recovery, %

8	91.5	258.5	266.0	102.9	62.0	63.0	101.6
				Mean = 101.6			Mean = 99.7
				%SD = ±1.78			%SD = ±3.18

The signal chosen for the analysis of I was the multiplet at 5.5 ppm due to the protons on C_2 and C_5. The presence of this signal at low fields is due to the electronegativity of the nitrate ester group as in 1,4:3,6-dianhydro-D-glucital. In this compound both diacetoxy and dimesyloxy derivatives have their C_2 and C_5 protons shifted to lower fields (9).

The doublet at 1.25 ppm due to both methyl groups was chosen for II. The signal given by the same group in III, a doublet at 1.30 ppm, was selected for III. The singlets at 6.2 ppm for IV and 8 ppm for V were used for the internal standards.

The results of the analysis of a group of known standard mixtures of I and II and I and III are summarized in Tables IV and V (Figs. 1 and 2). The method is accurate and precise, with an $SD \pm 3.06$ for I. The standard deviation is ±1.80 and ±1.78 for II and III, respectively, for the standard mixtures.

This procedure was also applied to commercial lots of tablets from three companies containing I and its mixtures with II and III.

The results obtained are in agreement with those obtained using the official USP procedure for I (4) and the BP procedures for II (6) and III (7).

Ion-Specific Electrode Study of Copper Binding to Serum Albumins

P. MOHANAKRISHNAN and C. F. CHIGNELL[x]

Received October 26, 1981, from the *Laboratory of Environmental Biophysics, National Institute of Environmental Health Sciences, Research Triangle Park, NC 27709.* Accepted for publication December 23, 1981.

Abstract □ The binding of copper to bovine, human, rabbit, rat, and porcine albumin has been studied using a cupric ion-specific electrode. The results were analyzed in terms of Scatchard expression assuming two classes of independent binding sites. The high-affinity constants for copper binding to the albumin show the same trend as the first association constants for nickel binding, namely, rabbit > human > rat > pig. Despite the similarity in the primary amino acid sequence for human and bovine serum albumin, the former has only one high-affinity site for copper, while the latter has more than three sites.

Keyphrases □ Binding—copper to serum albumin, ion-specific electrode study, bovine, human, rabbit, rat, porcine □ Serum albumin—bovine, human, rabbit, rat, porcine, ion-specific electrode study, copper binding □ Ion-specific electrode—copper binding to serum albumin, bovine, rabbit, human, rat, porcine

Serum copper levels play a dual role in several pathological conditions, both in humans and experimental animals (1, 2). Anti-inflammatory properties are associated with several salts and chelates of copper (3–9). On the other hand, increased copper levels have been observed in several diseases such as tuberculosis and pneumonia (10), rheumatoid arthritis (11, 12), and ankylosing spondilitis (13). In serum the weakly bound form of copper is associated with the transport protein, albumin. Sequence analysis studies have shown that the first three amino acids at the *N*-terminal constitute a high-affinity copper binding site in bovine (14–16), human, and rat albumin (17). Nickel, which has been implicated as a carcinogen in humans and experimental animals (18), also binds to this *N*-terminal site.

There have been several previous attempts to measure the binding of copper to serum albumins from different animal species. In an early study (19) the thermodynamics of copper binding to bovine serum albumin using absorption spectroscopy were examined. However, the insensitivity of the spectroscopic method necessitated the use of high protein concentrations, which precluded the determination of the high-affinity binding constants. A later study (20) estimated the number of copper binding sites on bovine and human albumin but the relative affinity constants were not determined. A more recent study (21)

8	91.5	258.5	266.0	102.9	62.0	63.0	101.6
				Mean = 101.6			Mean = 99.7
				%SD = ±1.78			%SD = ±3.18

The signal chosen for the analysis of I was the multiplet at 5.5 ppm due to the protons on C_2 and C_5. The presence of this signal at low fields is due to the electronegativity of the nitrate ester group as in 1,4:3,6-dianhydro-D-glucital. In this compound both diacetoxy and dimesyloxy derivatives have their C_2 and C_5 protons shifted to lower fields (9).

The doublet at 1.25 ppm due to both methyl groups was chosen for II. The signal given by the same group in III, a doublet at 1.30 ppm, was selected for III. The singlets at 6.2 ppm for IV and 8 ppm for V were used for the internal standards.

The results of the analysis of a group of known standard mixtures of I and II and I and III are summarized in Tables IV and V (Figs. 1 and 2). The method is accurate and precise, with an $SD \pm 3.06$ for I. The standard deviation is ±1.80 and ±1.78 for II and III, respectively, for the standard mixtures.

This procedure was also applied to commercial lots of tablets from three companies containing I and its mixtures with II and III.

The results obtained are in agreement with those obtained using the official USP procedure for I (4) and the BP procedures for II (6) and III (7).

Ion-Specific Electrode Study of Copper Binding to Serum Albumins

P. MOHANAKRISHNAN and C. F. CHIGNELL[x]

Received October 26, 1981, from the *Laboratory of Environmental Biophysics, National Institute of Environmental Health Sciences, Research Triangle Park, NC 27709.* Accepted for publication December 23, 1981.

Abstract □ The binding of copper to bovine, human, rabbit, rat, and porcine albumin has been studied using a cupric ion-specific electrode. The results were analyzed in terms of Scatchard expression assuming two classes of independent binding sites. The high-affinity constants for copper binding to the albumin show the same trend as the first association constants for nickel binding, namely, rabbit > human > rat > pig. Despite the similarity in the primary amino acid sequence for human and bovine serum albumin, the former has only one high-affinity site for copper, while the latter has more than three sites.

Keyphrases □ Binding—copper to serum albumin, ion-specific electrode study, bovine, human, rabbit, rat, porcine □ Serum albumin—bovine, human, rabbit, rat, porcine, ion-specific electrode study, copper binding □ Ion-specific electrode—copper binding to serum albumin, bovine, rabbit, human, rat, porcine

Serum copper levels play a dual role in several pathological conditions, both in humans and experimental animals (1, 2). Anti-inflammatory properties are associated with several salts and chelates of copper (3–9). On the other hand, increased copper levels have been observed in several diseases such as tuberculosis and pneumonia (10), rheumatoid arthritis (11, 12), and ankylosing spondilitis (13). In serum the weakly bound form of copper is associated with the transport protein, albumin. Sequence analysis studies have shown that the first three amino acids at the *N*-terminal constitute a high-affinity copper binding site in bovine (14–16), human, and rat albumin (17). Nickel, which has been implicated as a carcinogen in humans and experimental animals (18), also binds to this *N*-terminal site.

There have been several previous attempts to measure the binding of copper to serum albumins from different animal species. In an early study (19) the thermodynamics of copper binding to bovine serum albumin using absorption spectroscopy were examined. However, the insensitivity of the spectroscopic method necessitated the use of high protein concentrations, which precluded the determination of the high-affinity binding constants. A later study (20) estimated the number of copper binding sites on bovine and human albumin but the relative affinity constants were not determined. A more recent study (21)

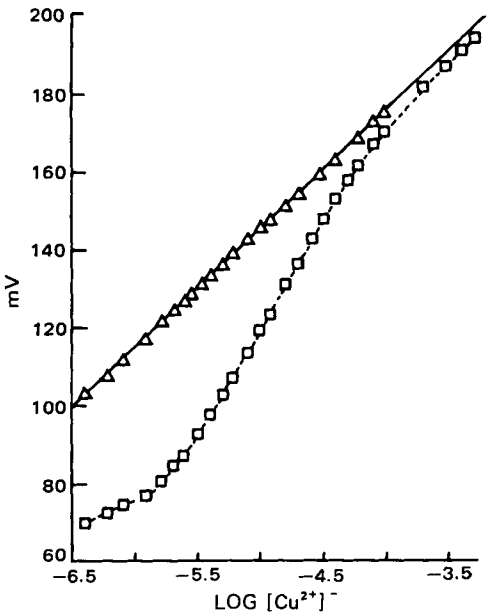

Figure 1—*Response of the electrode to the addition of Cu^{2+} Cu^{2+} was added in microliter quantities to a stirred solution of 0.1 M KNO_3 (50 ml) in the absence (△) and in the presence (□) of human serum albumin, and the change in potential was measured after each addition.*

employed a cupric ion-specific electrode to determine the copper binding parameters of bovine serum albumin. In this report the copper binding parameters for bovine, human, rat, porcine, and rabbit albumins have been estimated using a cupric ion-specific electrode. The sensitivity of this technique is such that it permits the determination of the association constant of copper for the high-affinity primary albumin binding site(s).

EXPERIMENTAL

Materials—Crystallized bovine, human, and rabbit serum albumins[1] were used without further purification. Rat serum albumin[1] (Fraction V) was extensively dialyzed against large volumes of 5 m*M* edetic acid and deionized water, freeze-dried, and stored at 4° until use. Porcine Fraction V[2] was decolorized with charcoal at pH 3 and eluted with 0.2 *M* NaCl over a cross-linked dextran gel column (100 × 3.5 cm). The albumin fractions from the column were concentrated by ultrafiltration[3], dialyzed against large volumes of 5 m*M* edetic acid, lyophilized after dialysis against large volumes of deionized water, and stored cold (4°). The monomer and higher oligomers were pooled together before use. Human and bovine albumin concentrations in the solutions were estimated from their respective absorbances at 279 nm (22, 23). Other albumin solutions were prepared by dissolving a known amount of protein in a desired volume of 0.1 *M* KNO_3 solution. Typically, the titration solutions contained 10–40 μ*M* albumin. Stock solutions of 2 and 100 m*M* $CuSO_4$ were prepared and their concentrations were estimated by atomic absorption spectroscopy.

Titration Experiments—The titrations were carried out with a cupric ion-specific electrode[4] and a single-junction electrode[5] both connected to a digital pH/mV meter and dipped in a 0.1 *M* KNO_3 solution (with or without albumin). Aliquots of the copper sulfate solution (first 2 and later 100 m*M*) were added to the albumin solutions (20–50 ml) using a microsyringe such that the logarithm of the cupric ion concentration in the medium increased linearly with each addition. The corresponding potential as shown by the pH/mV meter was noted after each addition. The parameters of the electrode (the slope and the intercept) were determined from control (no protein) titrations in each case. All titrations were performed at room temperature (23–25°). The pH of the solution at the beginning and end of each titration was 5.2–5.4.

Table I—Parameters of Cu^{2+} Binding to Serum Albumins [a]

Source	n_1	$K_1 \times 10^{-6}, M^{-1}$	n_2	$K_2 \times 10^{-3}, M^{-1}$
Bovine	3.68	3.14	12.73	20.15
	3.0[b]	3.0[b]	16.0[b]	20.0[a]
Human	1.13	2.33	4.5	67.54
Rabbit	3.9	2.83	15.14	7.52
Rat	2.62	1.85	26.4	4.34
Porcine	1.86	0.41	18.01	5.76

[a] The values represent the computer analysis of the results of three or more titration experiments. The values are the best fit for both *R versus C* and *(R/C) versus R* Scatchard analysis. The standard deviation was <8% for the computer fittings. [b] Taken from Reference 21.

It is known that above pH 4 at the concentrations employed in this study, the Cu^{2+} ion begins to hydrolyze and precipitates as the oxide or hydroxide soon thereafter (24). Although a more physiological pH of 7.4 would have been the ideal choice, the sensitivity of the electrode may decrease above pH 6 because of the formation of both soluble and insoluble hydroxo–oxo complexes under experimental conditions. Hence, no pH adjustments were made before each titration.

Data Analysis—The titration data were analyzed in terms of the Nernst equation to find the concentration of free and bound copper in solution. Since the resultant Scatchard plots exhibited considerable curvature, the assumption was made that there were two sets of independent binding sites and the data were fitted to the expression (25):

$$r = \frac{n_1 K_1 C}{1 + K_1 C} + \frac{n_2 K_2 C}{1 + K_2 C}$$

where r is the number of Cu^{2+} bound per mole of protein, n_1 and n_2 are the number of binding sites, K_1 and K_2 are the corresponding constants[6], and C the molar concentration of free Cu^{2+}. The curve fitting was performed using a modeling program[7] (26) running on a computer[8,9].

RESULTS AND DISCUSSION

A typical titration curve is shown in Fig. 1. Figure 2 is a computer-fitted Scatchard plot for human serum albumin. The binding parameters determined in this study for albumins from different species are listed in Table I. Also listed in Table I are the binding parameters for bovine serum albumin reported previously (21) for comparison. It can be seen that the results of the present study are in reasonable agreement with previous results (21).

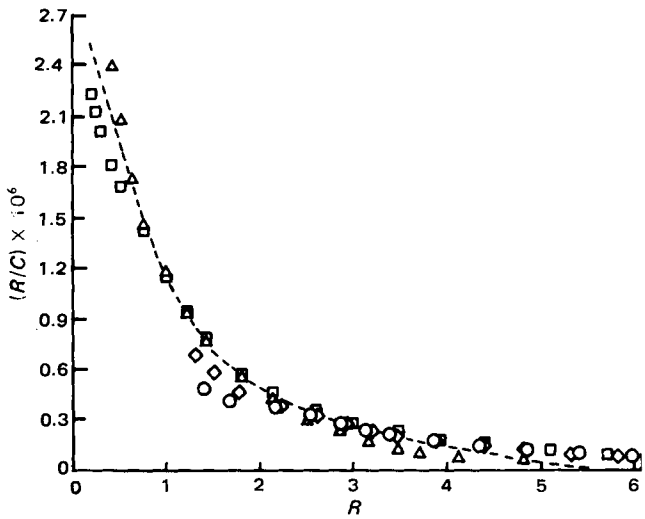

Figure 2—*Scatchard analysis of Cu^{2+} binding to human serum albumin. R and C are the number of Cu^{2+} ions bound per mole of albumin and the molar concentration of free Cu^{2+}, respectively. The figure is the result of a computer fit of the results from four different (○,△,□,◇) titration experiments.*

[6] K_1 and K_2 above are defined for the equilibrium: albumin + n Cu^{2+} ⇌ (albumin-n Cu^{2+}).

The trend in the high-affinity association constants, namely, rabbit > human > rat > pig, parallels that observed for nickel binding to the same albumins as determined previously (27). While it was not possible to obtain consistent values for copper binding to dog serum albumin, the results seemed to indicate that the primary binding sites for canine albumin had a lower affinity than those found in porcine albumin. Again, this is the case for nickel binding (27). If both Cu^{2+} and Ni^{2+} occupy the same albumin binding sites and form complexes of the same geometry type, then one would expect the same trend for both copper and nickel binding. This suggests that the *N*-terminal Cu^{2+}-binding site may also constitute the primary binding site for nickel. The relatively lower binding constants for dog and pig albumins are probably due to the absence of a histidine at the third amino acid position from the *N*-terminal end of these proteins (26).

The number of high-affinity sites for human albumin is less than that for bovine (Table I). From a comparison of the proposed primary structures of these proteins (28, 29), and based on the assumption that the geometry at the additional sites should be comparable to that at the *N*-terminal site, two extra high-affinity sites in bovine albumin may be provided by the amino acid sequences of Glu^{16}–Glu–His^{18} near the *N*-terminal and Asp^{373}–Lys–Leu–Lys–His–Leu–Val–Asp^{380} between the second and the third domains. However, it should be pointed out that this assignment is only tentative and needs to be further substantiated experimentally. It is our experience that the extrinsic circular dichroism spectra of bound copper are not the same for human and bovine albumins[10]. Obviously, there must be some significant differences in both the number and the nature of the copper binding sites for these two types of albumin.

Effect of Dose Size on the Pharmacokinetics of Oral Hydrocortisone Suspension

ROGER D. TOOTHAKER *‡, **WILLIAM A. CRAIG** §, and **PETER G. WELLING** *x

Received September 1, 1981, from the *School of Pharmacy, University of Wisconsin, Madison, WI 53706 and the §Veterans Administration Hospital, Madison, WI 53705. Accepted for publication December 31, 1981. ‡Present address: School of Pharmacy, University of Washington, Seattle, WA 98195.

Abstract □ The pharmacokinetics of hydrocortisone were examined following single doses of 5-, 10-, 20-, and 40-mg hydrocortisone suspensions to healthy male volunteers. Endogenous hydrocortisone was suppressed by giving 2 mg of dexamethasone the night before hydrocortisone administration. Plasma samples obtained serially for 12 hr after hydrocortisone administration were assayed by reversed-phase high-pressure liquid chromatography using a fixed-wavelength (254 nm) UV absorbance detector. Drug absorption was rapid, with mean maximum plasma hydrocortisone concentrations occurring within 60 min of dosing. Subsequent drug elimination was monophasic with mean elimination half-lives increasing from 1.2 hr for the 5-mg dose to 1.7 hr for the 40-mg dose. Increases in *AUC* and C_{max} with increasing dose were linear but not directly proportional to dose size. This was attributed to dose-dependent absorption or to loss of drug during the first-pass through the liver.

Keyphrases □ Hydrocortisone—effect of dose size on pharmacokinetics of oral suspension, absorption, elimination □ Pharmacokinetics—oral hydrocortisone suspension, absorption, elimination, effect of dose size □ Absorption—oral hydrocortisone suspension, elimination, effect of dose size on pharmacokinetics □ Suspension—oral hydrocortisone, absorption, elimination, effect of dose size on pharmacokinetics

Hydrocortisone was designated by the U.S. Food and Drug Administration as a drug whose different brands and dosage forms should be examined for bioequivalence (1). A series of studies was initiated to examine the pharmacokinetics of hydrocortisone and to assess the feasibility of conducting bioequivalence studies on commercial products.

In a previous study (2), dexamethasone was shown to

0022-3549/82/01000-1182$01.00/0

The trend in the high-affinity association constants, namely, rabbit > human > rat > pig, parallels that observed for nickel binding to the same albumins as determined previously (27). While it was not possible to obtain consistent values for copper binding to dog serum albumin, the results seemed to indicate that the primary binding sites for canine albumin had a lower affinity than those found in porcine albumin. Again, this is the case for nickel binding (27). If both Cu^{2+} and Ni^{2+} occupy the same albumin binding sites and form complexes of the same geometry type, then one would expect the same trend for both copper and nickel binding. This suggests that the *N*-terminal Cu^{2+}-binding site may also constitute the primary binding site for nickel. The relatively lower binding constants for dog and pig albumins are probably due to the absence of a histidine at the third amino acid position from the *N*-terminal end of these proteins (26).

The number of high-affinity sites for human albumin is less than that for bovine (Table I). From a comparison of the proposed primary structures of these proteins (28, 29), and based on the assumption that the geometry at the additional sites should be comparable to that at the *N*-terminal site, two extra high-affinity sites in bovine albumin may be provided by the amino acid sequences of Glu^{16}–Glu–His^{18} near the *N*-terminal and Asp^{373}–Lys–Leu–Lys–His–Leu–Val–Asp^{380} between the second and the third domains. However, it should be pointed out that this assignment is only tentative and needs to be further substantiated experimentally. It is our experience that the extrinsic circular dichroism spectra of bound copper are not the same for human and bovine albumins[10]. Obviously, there must be some significant differences in both the number and the nature of the copper binding sites for these two types of albumin.

suppress endogenous hydrocortisone plasma levels from normal values of 40–200 ng/ml to 6–14 ng/ml for at least 21 hr, thus permitting accurate measurement of circulating exogenous hydrocortisone with negligible interference by endogenous compounds. A reversed-phase high-pressure liquid chromatographic (HPLC) assay for hydrocortisone in plasma, capable of measuring concentrations as low as 5 ng/ml, was used to determine the pharmacokinetics from 10-, 30-, and 50-mg doses of hydrocortisone given as oral tablets to healthy male volunteers (3). Results obtained in this study suggested that hydrocortisone pharmacokinetics may be dose-dependent, and that increases in circulating levels may not be dose-proportional. Similar results to these were observed following oral doses of cortisone acetate (4). A subsequent study, in which 5-, 10-, 20-, and 40-mg doses of hydrocortisone sodium succinate were given intravenously, demonstrated dose-proportional hydrocortisone levels and dose-independence of most pharmacokinetic values (5). Dose-nonproportionality following oral doses was thus attributed either to tablet effects or to nonlinear absorption or first-pass metabolism.

In the present study, hydrocortisone pharmacokinetics were examined in healthy male volunteers following oral doses of 5, 10, 20, and 40 mg of hydrocortisone suspension.

EXPERIMENTAL

Materials—Chemical standard hydrocortisone[1] and internal standard Δ^4-pregnen-17α,20β,21-triol-3,11-dione[1] were analytical grade. Reagent grade methylene chloride[2] was distilled prior to use. All other solvents and chemicals were reagent grade and were used as supplied. Plasma for construction of standard curves was obtained from healthy volunteers between 7 and 9 am subsequent to administration of 2 mg of dexamethasone at 11 pm the previous day.

Subjects—After giving informed consent, eight male volunteers (age 22–39 years, height 170–183 cm, weight 64–77 kg) underwent physical examinations including blood and urine analyses. Vital signs and laboratory values for all subjects were normal.

Protocol—Each subject received 5-, 10-, 20-, and 40-mg doses of hydrocortisone as an oral suspension[3] at least 1 week apart in a randomized block design. Subjects were fasted from 10 pm on the day prior to dosing until 12 noon the next day. All subjects received 2 mg of dexamethasone[4] together with 180 ml of water at 11 pm hr on the day before dosing. Hydrocortisone suspension (0.1–0.8 ml) was mixed with 60 ml of orange juice immediately before dosing. The orange juice–hydrocortisone mixture was swallowed, rapidly followed by three 40-ml rinses of orange juice. Dosing containers were assayed for residual hydrocortisone and contained 0.41 ± 0.25% (*SD*) of the dose; this was considered negligible. Subjects were permitted to ingest no other liquid until 4 hr after dosing.

Blood samples (10 ml) were taken from a forearm vein into heparinized vacuum tubes immediately before and then serially from 15 min to 12 hr after hydrocortisone administration. Blood samples were centrifuged immediately and the plasma was stored at −20° until assayed. Subjects were ambulatory during blood sampling.

Assay—The HPLC assay used in this study was described previously (3). Hydrocortisone and added internal standard were extracted from 1 ml of plasma into methylene chloride. The residue from the evaporated organic layer was reconstituted in the liquid chromatographic mobile phase (60% aqueous methanol), and 30 μl was injected onto the column. Components were detected at 254 nm, and concentrations of hydrocortisone were calculated by peak height ratio. Separate standard curves were run with each batch of samples. Suppressed hydrocortisone concentrations obtained just before hydrocortisone administration were subtracted from all concentrations obtained after dosing for each subject.

Data Analysis—Model-independent estimates of areas under plasma hydrocortisone concentration curves from zero to infinite time (AUC) were calculated by trapezoidal rule, with end correction where necessary (6). Elimination rate constants were calculated by regression analysis of the postabsorption phase of hydrocortisone plasma profiles.

Pharmacokinetic parameters were examined by ANOVA for crossover design. Differences between individual doses were analyzed using Tukey's test (7).

RESULTS

Mean plasma hydrocortisone concentrations, corrected for endogenous hydrocortisone, are shown for all four dose levels in Fig. 1. Drug absorption was rapid, with maximum drug concentrations occurring within 1 hr of dosing. Drug levels then declined monoexponentially in all cases. Mean hydrocortisone levels resulting from the 10-, 20-, and 40-mg doses were slightly elevated at the last sampling times, suggesting the possibility of a more prolonged terminal elimination phase. However, the drug levels at these times approached the lower sensitivity limit of the assay, so that their significance is uncertain. This effect was not noted following the 5-mg dose. Exclusion of the terminal data points did not significantly affect the calculated drug half-lives. Hydrocortisone concentrations were above predose suppressed values for up to 8 hr following the 5- and 10-mg doses, and up to 12 hr following the 20- and 40-mg doses.

Pharmacokinetic parameters and statistical analysis are presented in Table I. Mean peak levels of hydrocortisone increased from 119 ng/ml following the 5-mg dose, to 389 ng/ml following the 40-mg dose. The time of peak levels was independent of dose. The elimination half-life was affected by dose size, increasing from a mean value of 1.2 hr following the 5-mg dose to 1.7 hr following the 40-mg dose. The area under the hydrocortisone plasma curve, and also the area corrected for variance in the elimination rate constant, $AUC\ k_{el}$, both increased with increasing dose. However, the increases in both the area and C_{max} values were not dose-proportional. Doubling the dose at 5, 10, and 20 mg resulted in mean area increases of 1.5-, 1.9-, and 1.6-fold, respectively, while the value of C_{max} increased 1.5-fold with each two-fold increase in dose.

The nonproportional relationship between AUC, C_{max}, and dose size is shown graphically in Fig. 2. Linear regression analysis resulted in positive y-intercepts which were significantly >0 ($p < 0.05$). When $AUC\ k_{el}$ and C_{max} values were corrected for dose size (Table I) the resulting values significantly decreased between each incremental dose of hydrocortisone.

DISCUSSION

In this study, the pharmacokinetics of hydrocortisone have been described following 5-, 10-, 20-, and 40-mg oral suspension doses to healthy

volunteers. The plasma profiles, and also the values of pharmacokinetic parameters, obtained under these conditions are generally consistent with values reported elsewhere (8–12). The drug is absorbed rapidly into the circulation, achieving peak plasma concentrations within 1 hr. Plasma levels then decline with a half-life of 1.2–1.7 hr. The plasma levels of hydrocortisone obtained in this study are comparable to those obtained previously when a tablet dosage form was used (3). The only dose size that was common to both studies, 10 mg, yielded almost identical C_{max} and *AUC* values.

Increases in circulating levels of hydrocortisone have thus been shown not to be proportional to increasing doses following both tablet (3) and suspension dosage forms. An overall five-fold increase in the tablet dose (10–50 mg) resulted in a 2.1-fold increase in mean C_{max}, and a 3.3-fold increase in *AUC* values. In the present study an overall eight-fold increase in the suspension dose (5–40 mg) resulted in a 3.3-fold increase in C_{max} and a 4.6-fold increase in *AUC*. The somewhat greater increase in *AUC* compared to C_{max} with increasing dose in both studies is due to the somewhat slower absorption and elimination of hydrocortisone at higher doses resulting in flatter and somewhat more prolonged drug profiles.

A number of explanations was originally proposed to account for the nonproportional relationship between circulating hydrocortisone levels and the size of the oral dose (3). These included changes in the binding characteristics of hydrocortisone to plasma proteins, limited tablet dissolution, saturable absorption, and an increased first-pass effect following higher doses. Of these, changes in binding characteristics appear unlikely as plasma levels of hydrocortisone have been shown to be dose-proportional following those intravenous doses that yielded similar circulating drug levels to those obtained following the oral doses (5). Limited tablet dissolution at higher doses is also an unlikely explanation as similar effects occurred with both tablet and suspension dosages.

It is difficult to distinguish the other possibilities, limited absorption and greater first-pass metabolism, from the present data. Previous studies have indicated that hydrocortisone is well-absorbed from the small intestine (13), and absorption appears not to be saturable at dosages used in the present study (14). Dividing the mean *AUC* values obtained following the suspension dose by those obtained after equivalent intravenous doses (5) shows that the systemic availability of hydrocortisone is 71, 57, and 56% from the 5-, 10-, and 20-mg doses, respectively. Similar

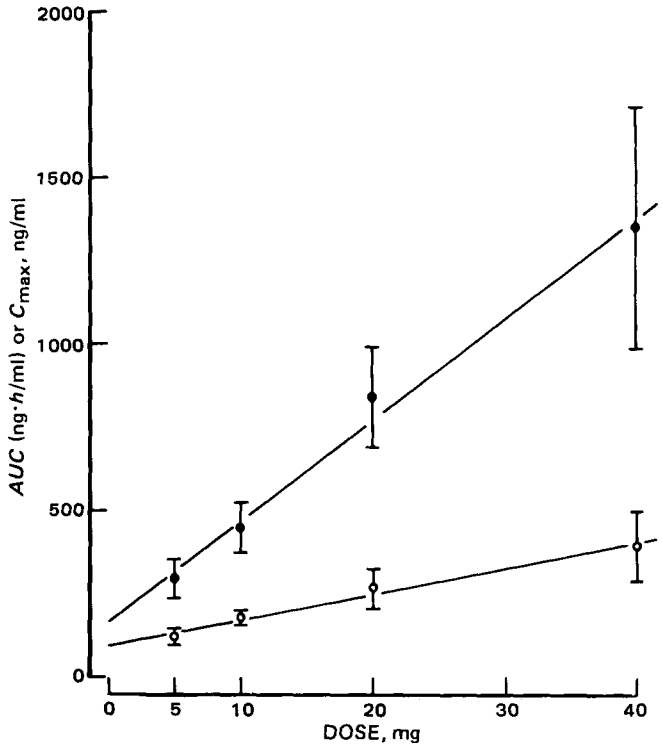

Figure 2—*Relationship between mean (±1 SD) AUC and C_{max} values, and oral hydrocortisone dose (n = 8). Key: (●) AUC; (○) C_{max}.*

comparison of the tablet dose data indicates that systemic availability of hydrocortisone was 60% from a 10-mg dose, and 40% from 30- and 50-mg doses.

In the absence of additional information, the most likely cause of the apparent dose dependency of hydrocortisone absorption is that of increased first-pass metabolism at higher doses. The rapid absorption of hydrocortisone from the GI tract will give rise to transient, high drug levels in the splanchnic circulation. These levels are likely to exceed the binding capacity of the high-affinity, low-capacity binding protein transcortin (15), resulting in a large proportion of drug passing through the liver during the first-pass either loosely bound to the low-affinity, high-capacity protein albumin or in free form. The percentage of drug that is in the loosely bound or unbound form during the first-pass will increase, while the percentage of drug tightly bound to transcortin will decrease, as the size of the dose increases. An increased free fraction during the first-pass is likely to permit greater hepatic clearance, and to decrease the overall systemic availability of unchanged drug. While this hypothesis is attractive, further studies are needed to identify the intrinsic relationships between the protein binding and hepatic clearance of hydrocortisone.

The results obtained in the present study have confirmed that plasma levels of oral hydrocortisone are not proportional to the administered dose. However, as peak plasma levels and *AUC* are approximately linearly related to dose size within the dosage range studied (Fig. 2), we conclude that meaningful bioavailability comparisons can be made for hydrocortisone at therapeutic dose levels.

The Effect of Thermal History on the Transition Temperature of Citric Acid Glass

Keyphrases □ Transition temperature—effect of thermal history, citric acid glass □ Citric acid glass—effect of thermal history on the transition temperature

To the Editor:

Glass is a noncrystalline solid which does not exhibit long-range order of its molecules and has a characteristic temperature where its physical state changes from a rigid, brittle material to a flexible, rubbery material. In addition, glass is not thermodynamically stable and will readily revert to the crystalline state under the proper environmental conditions (1, 2). As a result of these characteristics, materials capable of glass formation have been suggested as vehicles for solid dispersion systems, because it has been theorized that they should exhibit more rapid dissolution than their crystalline counterparts (3–5).

One compound often mentioned as a potential vehicle is citric acid (6–12). In the crystalline state, this material is highly hydrogen bonded (13), a property that apparently is responsible for its glass formation, because it has been reported that hydrogen bonding tendency helps prevent crystallization from occurring when a liquid melt is cooled below its liquidus temperature (14–16).

Recently, there has been a reported discrepancy in the transition temperature (T_g) of citric acid glass. This discrepancy was explained (17) to be due to residual moisture contamination in the samples. These studies (7–10) utilized citric acid monohydrate, while another study (12) employed anhydrous citric acid.

We do not dispute this explanation of the discrepancy. However, we thought it would be helpful to future investigators if the effect of thermal history of the melt and the presence of impurities on the T_g of citric acid glass was reported.

Anhydrous citric acid[1] was used in this study in order to eliminate possible effects of residual moisture contamination. The procedures used for sample preparation and determination of the T_g of a glass by differential scanning calorimetry (DSC) have already been discussed in detail (12). In examination of the effect of the thermal history of the molten citric acid on the T_g of citric acid glass, the DSC procedure was modified such that after heating the citric acid to melting, the molten citric acid was raised to the desired temperature and held isothermally for a specified time before rapidly being cooled.

[a] Average of at least duplicate determinations. [b] Material discolored, not able to detect a T_g from −60 to 200°.

Table I shows the effect of thermal history on the T_g of citric acid glass. Results indicate that the higher the temperature and the longer the exposure time at a given temperature, the lower the T_g value of citric acid glass. Accompanying this decrease in the T_g value was a progressive discoloration of the molten citric acid from a clear transparent liquid to a yellowish brown liquid.

Aconitic acid[2], a dehydration decomposition product of citric acid, degrades upon melting. By adding the material to citric acid in varying proportions and then preparing glass dispersions of the mixture, it is possible to simulate the effect of degradation product impurities on the T_g of citric acid glass. Figure 1 shows that as the level of impurities increases, the T_g of citric acid glass decreases.

The thermal stability of citric acid has been of concern to previous solid dispersion investigators (6–10, 12). Available thermal analysis literature on citric acid is limited. One study (18) suggests that citric acid may begin to decompose at ~185°, while another study (19) states that thermal degradation of citric acid does not begin to occur until 200–225°. The data presented in this communication indicate that citric acid does exhibit some degree of thermal instability. However, thermal degradation does not appear to begin immediately upon initial melting but only

on prolonged exposure of molten citric acid to temperatures above its melting temperature. It has been shown previously that the sample preparation techniques used in this study did not adversely affect citric acid (12). In addition, the data also imply that low levels of impurities (<5% w/w) cannot be readily detected by DSC.

In preparation of citric acid glass, care should be taken to use the minimum amount of heat necessary to melt the citric acid, to avoid prolonged heating at temperatures of its melting point, and to employ a procedure in which there is some means of temperature control. Although these suggestions for the preparation of citric acid glass may make this material unsuitable for use in the commercial preparation of solid dispersion systems, it should not eliminate the use of this glassy vehicle as a tool for the examination of the compatability, miscibility, and stabilization of the glassy states of materials.

Dose-Dependent Decrease in Heparin Elimination

Keyphrases □ Heparin—dose-dependent pharmacokinetics □ Pharmacokinetics—dose-dependent decrease in heparin elimination

To the Editor:

Studies on the pharmacokinetics of heparin have revealed dose-dependent (1–4), time-dependent (5), and assay-dependent (4) characteristics. The mechanisms underlying these characteristics are unknown but are likely to reside in the heterogeneity of heparin. Heparin is a natural mammalian glycosaminoglycan consisting of polymeric constituents arranged linearly, with different chain length and chemical composition and with a molecular weight ranging from 3000 to 45,000 (6–8). Recent studies have demonstrated that the antithrombin-III binding site of heparin, which is necessary for its pharmacological action, appears to reside in an oligosaccharide segment of the molecule that has a specific sequence of four to eight monosaccharides, *i.e.*, iduronic and glucuronic acids and glucosamines, with *N*-sulfate, *O*-sulfate, and *N*-acetyl groups being required at specific sites (9–11). The metabolism of heparin is not well understood. Although the metabolic processes involved are thought to include depolymerization and desulfation, the relationship between different metabolic processes and the decline in anticoagulant activity is unclear.

The biologic half-life of heparin increases with increasing dose in humans and animals (1–4). This dose-dependence is without any indication of Michaelis-Menten type kinetic characteristics (3, 4) and recently has been demonstrated in humans to be due to a dose-dependent decrease in the total clearance of the anticoagulant (4). The total clearance of heparin in humans usually is reported to be between 0.5 and 2 ml/min/kg, while the apparent volume of distribution is usually reported to be between 40 and 100 ml/kg (2, 4, 12–14). However, reported values for both of these pharmacokinetic parameters vary widely

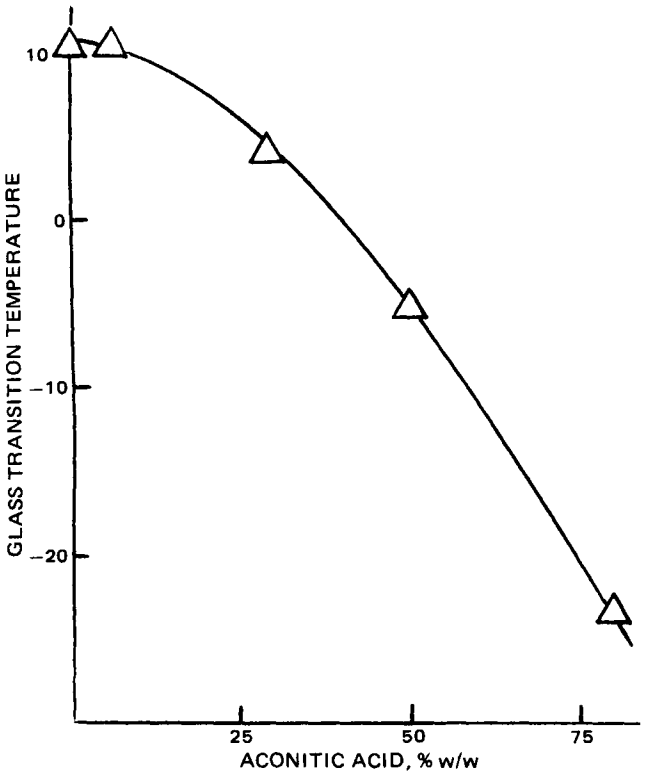

Figure 1—*The effect of aconitic acid on the transition temperature of citric acid glass.*

on prolonged exposure of molten citric acid to temperatures above its melting temperature. It has been shown previously that the sample preparation techniques used in this study did not adversely affect citric acid (12). In addition, the data also imply that low levels of impurities (<5% w/w) cannot be readily detected by DSC.

In preparation of citric acid glass, care should be taken to use the minimum amount of heat necessary to melt the citric acid, to avoid prolonged heating at temperatures of its melting point, and to employ a procedure in which there is some means of temperature control. Although these suggestions for the preparation of citric acid glass may make this material unsuitable for use in the commercial preparation of solid dispersion systems, it should not eliminate the use of this glassy vehicle as a tool for the examination of the compatability, miscibility, and stabilization of the glassy states of materials.

Dose-Dependent Decrease in Heparin Elimination

Keyphrases □ Heparin—dose-dependent pharmacokinetics □ Pharmacokinetics—dose-dependent decrease in heparin elimination

To the Editor:

Studies on the pharmacokinetics of heparin have revealed dose-dependent (1–4), time-dependent (5), and assay-dependent (4) characteristics. The mechanisms underlying these characteristics are unknown but are likely to reside in the heterogeneity of heparin. Heparin is a natural mammalian glycosaminoglycan consisting of polymeric constituents arranged linearly, with different chain length and chemical composition and with a molecular weight ranging from 3000 to 45,000 (6–8). Recent studies have demonstrated that the antithrombin-III binding site of heparin, which is necessary for its pharmacological action, appears to reside in an oligosaccharide segment of the molecule that has a specific sequence of four to eight monosaccharides, *i.e.*, iduronic and glucuronic acids and glucosamines, with *N*-sulfate, *O*-sulfate, and *N*-acetyl groups being required at specific sites (9–11). The metabolism of heparin is not well understood. Although the metabolic processes involved are thought to include depolymerization and desulfation, the relationship between different metabolic processes and the decline in anticoagulant activity is unclear.

The biologic half-life of heparin increases with increasing dose in humans and animals (1–4). This dose-dependence is without any indication of Michaelis-Menten type kinetic characteristics (3, 4) and recently has been demonstrated in humans to be due to a dose-dependent decrease in the total clearance of the anticoagulant (4). The total clearance of heparin in humans usually is reported to be between 0.5 and 2 ml/min/kg, while the apparent volume of distribution is usually reported to be between 40 and 100 ml/kg (2, 4, 12–14). However, reported values for both of these pharmacokinetic parameters vary widely

0022-3549/82/01000-1186$01.00/0

among studies. Although this variability in part may be due to the nonlinearity in the elimination kinetics of heparin, it is in part due to differences in heparin assay methods used, since recent studies in humans have shown that there are significant differences among values of individual pharmacokinetic parameters obtained, depending on heparin assay methodology (4). This applies primarily to total clearance and apparent volume of distribution, both of which were on the average ~1.5- to twofold larger when based on hexadimethrine bromide[1] neutralization assay of heparin than when based on bioassays using the coagulation tests activated partial thromboplastin time and thrombin clotting time. However, no significant differences were noted in values of biologic half-life. The immediate practical consequences of the assay-dependent pharmacokinetics of heparin are that when summarizing published pharmacokinetic parameters for heparin, the assay methods have to be specified, and only data obtained by the same heparin assay can be treated together. This becomes particularly important when exploring relationships between dose and individual pharmacokinetic parameters of heparin. Two studies have been published on heparin pharmacokinetics in normal subjects using heparin assays based on thrombin-induced clotting times, with doses ranging from 50 to 400 U/kg (1, 4). Therefore, it was of interest to use data from these two studies to explore relationships between dose and pharmacokinetic parameters of heparin, particularly since one of the studies had not provided values for the latter.

The subjects studied in these two studies were four healthy males, ages 27–35 years, who received intravenous injections of heparin of 50 and 75 U/kg body weight each (4), and six healthy males and seven healthy females, ages 19–45 years, who received intravenous injections of heparin of either 100 (five subjects), 200 (four subjects), or 400 (four subjects) U/kg body weight (1). Multiple blood samples were collected after each dose, and plasma heparin activity was determined by bioassays based on thrombin clotting time. These assays are described in detail elsewhere (4, 15). They involve first establishing the relationship between the thrombin-induced clotting times and heparin added to plasma *in vitro*, and then deriving the plasma heparin activity in the samples obtained after the dose from the observed clotting times. One of these assays uses addition of bovine plasma to the plasma sample (15). While this will attenuate intersubject differences in the relationship between clotting time and added heparin, it will not affect the determination of heparin activity in plasma. It should be noted that the relationship between thrombin-induced clotting times and heparin activity in plasma is log linear (4, 15, 16).

The pharmacokinetic parameters, biologic half-life ($t_{1/2}$), total clearance (Cl), and apparent volume of distribution (V_d), were calculated as described previously (4). As is shown in Fig. 1, the biologic half-life of heparin increases with increasing dose. The average ($\pm SD$) $t_{1/2}$ values for the 50, 75, 100, 200, and 400 U/kg doses were 42 ± 5, 49 ± 15, 57 ± 8, 96 ± 10, and 153 ± 10 min, respectively. The positive relationship between the biologic half-life and dose of heparin is statistically highly significant ($p < 0.001$).

[1] Polybrene.

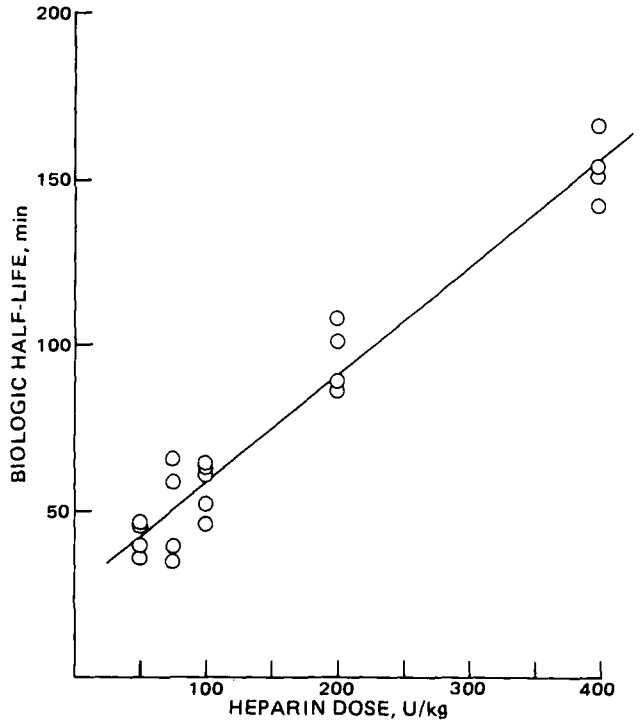

Figure 1—*Relationship between biologic half-life and dose of heparin in humans when heparin activity in plasma is determined by a bioassay based on thrombin-induced clotting times. (Data are from Refs. 1 and 4). The line represents the best-fitted line for the relationship between these parameters (intercept, 26.2 min; slope, 0.323 min kg U^{-1}; r^2 = 0.952).*

Figure 2 shows that there is also a statistically highly significant positive linear relationship between the biologic half-life and total clearance of heparin ($p < 0.001$). The

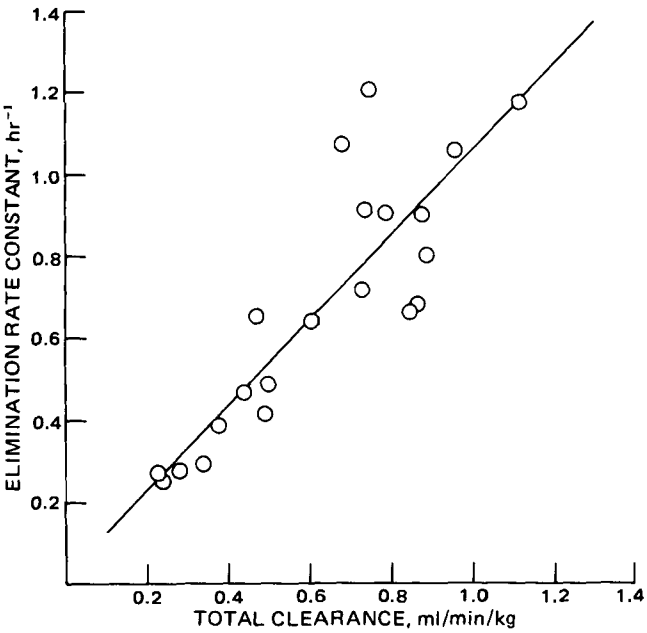

Figure 2—*Relationship between the elimination rate constant and total clearance of heparin in humans when heparin activity in plasma is determined by a bioassay based on thrombin-induced clotting times. (Data are from Refs. 1 and 4.) The line represents the best-fitted line for the relationship between these parameters (intercept, 0.030 hr^{-1}; slope, 1.025 t ml^{-1} kg^{-1}, where t is a time unit correction factor; r^2 = 0.739).*

total clearance of heparin ranged from 0.23 to 1.12 ml/min/kg for the 400 and 50 U/kg doses, respectively, representing about a fivefold variation in total clearance for eightfold difference in dose. The reason for this linear positive relationship is that the apparent volume of distribution of heparin changes only very modestly with dose. The average ($\pm SD$) V_d was 58 ± 11 ml/kg body weight over the entire dose range, with small but statistically insignificant changes in V_d when it was evaluated with respect to dose (intercept, 55 ml/kg; slope, 0.018 ml/kg/U; r^2 = 0.046).

The results presented in this report are in support of and extend recent findings that the dose-dependent increase in the biologic half-life of heparin in humans is due to a dose-dependent decrease in the total clearance of the anticoagulant (4). In humans, there is no significant increase in the apparent volume of distribution of heparin with dose. This is in contrast to findings in rats and dogs, which have shown a dose-dependent increase in V_d with dose (2, 3). While the mechanism underlying the nonlinear pharmacokinetics of heparin in humans is presently not understood, however, the linear relationship between dose and dose-dependent pharmacokinetic parameters is noteworthy.

Renal Excretion of *R*- and *S*-Epimers of Moxalactam in Dogs

Keyphrases □ Stereoisomers—arylmalonylamino 1-oxacephem, renal clearance, dog, plasma protein binding □ Renal clearance—arylmalonylamino 1-oxacephem, comparison between stereoisomers, relation to plasma protein binding □ Protein binding—dog plasma, arylmalonylamino 1-oxacephem, comparison between stereoisomers, relation to renal clearance

To the Editor:

Moxalactam[1] (latamoxef[2], I) is a mixture of *R* (II) and *S* (III) epimers, and both forms are usually eliminated unchanged by the kidney (1, 2). Studies with humans (3) show that the biological half-life of the *R*-epimer is shorter than that of the *S*-epimer. To obtain a better understanding of the elimination kinetics, we studied the renal clearance and binding of moxalactam epimers to plasma protein in beagle dogs.

Two male beagle dogs were anesthetized with sodium pentobarbital (30 mg/kg iv). After a tracheotomy was performed, an incision was made in the left flank. The retroperitoneal space was explored and the left ureter was cannulated. Urine was collected through the cannula (4). After completion of the operation, 20 mg of sodium *p*-aminohippurate/kg and 100 mg of creatinine/kg were injected as the priming dose into the axillary vein. As the sustaining dose, a solution containing 15% mannitol, 0.9% NaCl, 0.25% creatinine, and 0.1% sodium *p*-aminohippurate was injected at the rate of 5 ml/min/10 kg. Moxalactam[3] was injected at a priming dose of 10 mg/kg followed by a sustaining dose of 5.0 mg/kg/hr. Approximately 1 hr after beginning the infusion, the urinary output was stabilized at 3–5 ml/min and urine samples were collected three or four times from the left ureter at 3-min intervals. Blood samples were taken at the middle point of each clearance period. The same procedure was repeated in the presence of probenecid (30 mg/kg iv). Collected urine and plasma samples were analyzed for creatinine (5), *p*-ami-

Table I—Renal Clearance (ml/min/kidney) of *R*- and *S*-Epimers of Moxalactam in Anesthetized Male Beagle Dogs

	Dog 1		Dog 2	
	Control phase[a]	Probenecid phase[b]	Control phase[a]	Probenecid phase[a]
Apparent clearances				
R-epimer, total	16.29 ± 0.68[a]	10.81 ± 0.17[b]	17.32 ± 1.18	15.90 ± 0.58
S-epimer, total	9.21 ± 0.52	6.97 ± 0.85[b]	10.48 ± 0.43	10.76 ± 0.25
Clearance ratio *R*/*S*, I	1.81 ± 0.11	1.59 ± 0.19[b]	1.66 ± 0.10	1.48 ± 0.07
Corrected clearances				
R-epimer, 23.7% binding	21.73 ± 0.74	14.19 ± 0.20[b]	22.57 ± 1.55	20.01 ± 0.26
S-epimer, 44.9% binding	16.68 ± 0.95	12.67 ± 1.56[b]	19.03 ± 0.82	19.52 ± 0.44
Clearance ratio *R*/*S*, II	1.32 ± 0.09	1.16 ± 0.14[b]	1.19 ± 0.07	1.07 ± 0.05
Statistical differences[c] of *R*/*S* values between I (total) and II (unbound)	$p < 0.05$	NS	$p < 0.01$	$p < 0.01$
Glomerular filtration rate (Creatinine clearance)	18.16 ± 0.19	14.33 ± 0.88[b]	18.67 ± 0.37	17.04 ± 0.44

[a] Value represents mean ± *SE* (number of samples: $n = 4$). [b] Number of samples: $n = 3$. [c] Student's t test.

nohippuric acid (6), and moxalactam (7). The ratios of *R*- to *S*-epimer in plasma and urine were determined using high-performance liquid chromatography (8). The fractions of the *R*- and *S*-epimers of moxalactam bound to dog plasma were determined at 37° by an ultrafiltration method[4].

The renal clearances of the moxalactam epimers in Table I were calculated by dividing the urinary excretion (micrograms per milliliter) by the total (bound and unbound) concentrations of the epimers. Clearance of the *R*-epimer was 1.4–1.8 times that of the *S*-epimer. The clearance ratios of *R*- and *S*-epimers to creatinine were less than unity. Since only unbound moxalactam would have been available for glomerular filtration, the clearance value based on the total concentration of the epimer in plasma may be underestimated. To determine the actual glomerular filtration, the protein binding of moxalactam epimers was determined at concentrations of 25, 50, and 100 μg/ml of dog plasma. The mean percentage of the bound fraction calculated from these values was 23.7 ± 1.6% *SEM* ($n = 3$) for the *R*-form and 44.9 ± 0.4% ($n = 3$) for the *S*-form.

As indicated in Table I, the data were corrected for the binding of the *R*- and *S*-epimers, *e.g.*, the clearances were calculated by dividing the urinary excretion (micrograms per minute) by the concentrations of the unbound epimers. The calculated renal clearances of the epimers were nearly equal to the glomerular filtration rate (creatinine clearance) and the *R*-epimer/*S*-epimer clearance ratio was closer to unity. When probenecid was given to Dog 1, the *p*-aminohippurate clearance decreased from 55.3 ± 0.6 to 17.0 ± 1.0 ml/min/kidney (mean ± standard error, $n = 3$), but the *R*- or *S*-epimer/creatinine clearance ratio was not affected.

Stereospecific differences in protein binding have been reported for other drugs (9–12) and vary from one animal species to another (3, 13). Our findings indicate that in the dog, both epimers of moxalactam are excreted by glomerular filtration, and the striking difference in renal clearance of the *R*- and *S*-epimers is due mainly to differences in binding to plasma protein.

Table I—Renal Clearance (ml/min/kidney) of *R*- and *S*-Epimers of Moxalactam in Anesthetized Male Beagle Dogs

	Dog 1		Dog 2	
	Control phase[a]	Probenecid phase[b]	Control phase[a]	Probenecid phase[a]
Apparent clearances				
R-epimer, total	16.29 ± 0.68[a]	10.81 ± 0.17[b]	17.32 ± 1.18	15.90 ± 0.58
S-epimer, total	9.21 ± 0.52	6.97 ± 0.85[b]	10.48 ± 0.43	10.76 ± 0.25
Clearance ratio *R*/*S*, I	1.81 ± 0.11	1.59 ± 0.19[b]	1.66 ± 0.10	1.48 ± 0.07
Corrected clearances				
R-epimer, 23.7% binding	21.73 ± 0.74	14.19 ± 0.20[b]	22.57 ± 1.55	20.01 ± 0.26
S-epimer, 44.9% binding	16.68 ± 0.95	12.67 ± 1.56[b]	19.03 ± 0.82	19.52 ± 0.44
Clearance ratio *R*/*S*, II	1.32 ± 0.09	1.16 ± 0.14[b]	1.19 ± 0.07	1.07 ± 0.05
Statistical differences[c] of *R*/*S* values between I (total) and II (unbound)	$p < 0.05$	NS	$p < 0.01$	$p < 0.01$
Glomerular filtration rate (Creatinine clearance)	18.16 ± 0.19	14.33 ± 0.88[b]	18.67 ± 0.37	17.04 ± 0.44

[a] Value represents mean ± *SE* (number of samples: $n = 4$). [b] Number of samples: $n = 3$. [c] Student's t test.

nohippuric acid (6), and moxalactam (7). The ratios of *R*- to *S*-epimer in plasma and urine were determined using high-performance liquid chromatography (8). The fractions of the *R*- and *S*-epimers of moxalactam bound to dog plasma were determined at 37° by an ultrafiltration method[4].

The renal clearances of the moxalactam epimers in Table I were calculated by dividing the urinary excretion (micrograms per milliliter) by the total (bound and unbound) concentrations of the epimers. Clearance of the *R*-epimer was 1.4–1.8 times that of the *S*-epimer. The clearance ratios of *R*- and *S*-epimers to creatinine were less than unity. Since only unbound moxalactam would have been available for glomerular filtration, the clearance value based on the total concentration of the epimer in plasma may be underestimated. To determine the actual glomerular filtration, the protein binding of moxalactam epimers was determined at concentrations of 25, 50, and 100 μg/ml of dog plasma. The mean percentage of the bound fraction calculated from these values was 23.7 ± 1.6% *SEM* ($n = 3$) for the *R*-form and 44.9 ± 0.4% ($n = 3$) for the *S*-form.

As indicated in Table I, the data were corrected for the binding of the *R*- and *S*-epimers, *e.g.*, the clearances were calculated by dividing the urinary excretion (micrograms per minute) by the concentrations of the unbound epimers. The calculated renal clearances of the epimers were nearly equal to the glomerular filtration rate (creatinine clearance) and the *R*-epimer/*S*-epimer clearance ratio was closer to unity. When probenecid was given to Dog 1, the *p*-aminohippurate clearance decreased from 55.3 ± 0.6 to 17.0 ± 1.0 ml/min/kidney (mean ± standard error, $n = 3$), but the *R*- or *S*-epimer/creatinine clearance ratio was not affected.

Stereospecific differences in protein binding have been reported for other drugs (9–12) and vary from one animal species to another (3, 13). Our findings indicate that in the dog, both epimers of moxalactam are excreted by glomerular filtration, and the striking difference in renal clearance of the *R*- and *S*-epimers is due mainly to differences in binding to plasma protein.

Effect of Ascorbic Acid on Renal Excretion of Lead in the Rat

Keyphrases □ Ascorbic acid—effect on renal excretion of lead, rats □ Lead—effect of ascorbic acid on renal excretion, rats □ Renal excretion—effect of ascorbic acid, lead, rats

To the Editor:

Lead poisoning is currently treated by chelation therapy using edetate disodium and dimercaprol, both of which have serious side effects. Few studies have been carried out

0022-3549/82/01000-1189$01.00/0

on the use of natural compounds such as ascorbic acid to remove heavy metals from the body, and these few studies and anecdotal observations have not provided any direct evidence for ascorbic acid on the excretion of lead from the body (1–4).

In the present communication we report a direct effect of ascorbic acid on the excretion profile of lead in the rat. The control group of rats (weight 300–450 g) were given demineralized water for 4 weeks; the treatment group received 4% ascorbic acid (pH 7.4) as drinking water. Food was given *ad libitum* to both groups ($n = 16$). Lead was administered as lead acetate solution in 5% dextrose intravenously at a dose of 0.637 μg of lead/g of body weight. The treatment group also received a bolus dose of ascorbic acid (1 mg/g of body weight) following administration of lead acetate solution. This was followed by 0.25 mg of ascorbic acid/g of body weight given subcutaneously every 6 hr. The blood samples were collected from the tail vein periodically for up to 163 hr, and urine samples were collected in 24-hr pools for up to 1 week. All samples were analyzed for total lead using a flameless atomic absorption spectrophotometer with graphite furnace[1].

The initial blood levels in the treatment group were higher than the control in accordance with previous findings (3). The urinary clearance of lead was calculated from the plots of blood concentration (C_b) against the urinary excretion (X_u) rate:

$$\text{Control: } \frac{dX_u}{dt} = 0.0049 + 0.1932\ C_b \quad (r > 0.92) \qquad \text{(Eq. 1)}$$

$$\text{Treatment: } \frac{dX_u}{dt} = -0.02089 + 0.4261\ C_b \quad (r > 0.99) \qquad \text{(Eq. 2)}$$

[1] Atomic Absorption Spectrophotometer model 503, Perkin-Elmer, Norwalk, Conn.

The good linear correlation coefficient signifies the relationship between blood concentration and the urinary excretion according to clearance principles; the slopes of Eqs. 1 and 2 were statistically different ($p < 0.05$). An increase of almost 120% in the urinary clearance of lead was recorded as a result of treatment with ascorbic acid. This finding was also reflected in a similar increase in the total amount of lead excreted in the urine (6.5 *versus* 12.8%) within 1 week (difference significant at $p < 0.05$).

Despite the complications involved in the disposition kinetics of lead in the body, such direct observation of the effect of ascorbic acid attests to the many anecdotal uses of ascorbic acid in the treatment and prevention of lead poisoning.

BOOKS

REVIEWS

The International Pharmacopoeia, Third Edition, Vol. 2: Quality specifications, Health and Biomedical Information Programme, World Health Organization, 1211 Geneva 27, Switzerland. 1981. 342 pp. 16 × 24 cm. Price 36 Sw fr.

By virtue of a resolution of the Third World Health Assembly, the *International Pharmacopoeia* is published to improve the quality control of all drugs and pharmaceutical substances. The quality specification establishment and revision process was carried out with the help of members of the World Health Organization's Expert Advisory Panel on the International Pharmacopoeia and Pharmaceutical Preparations and other specialists.

The present (third) edition of the *International Pharmacopoeia* will appear in five volumes. This volume, the second, contains quality specifications for 126 individual drugs widely used in health care. The first volume was published in 1979 and describes 42 general methods of analysis and should be used along with the general notices given in the present volume. The remaining three volumes will contain further specifications.

Specifications included in the second edition of the *International Pharmacopoeia* have been subjected to thorough revision. For other substances, no international quality specifications have been previously issued. While these specifications have no legal status in any country, unless expressly introduced into the national legislation, they are intended to serve as references for national authorities; it is expected that they will be applied by many developing countries for pharmaceuticals used by their health systems.

As for the monographs themselves, for substances used in more than one form (*e.g.*, anhydrous and hydrated, or noninjectable and sterile) the requirements for the relevant forms have been put together in a single monograph, but separate tests have been provided, as required, for each specific form. Also, IR spectra are mentioned in a number of monographs; however, a separate publication containing reproductions of such spectra will be issued at a later date.

Solving the Orphan Drug Problem

"Motherhood, the Flag, and apple pie" need to move over to make room for another revered entity. "Orphan drugs" constitute the newest member of this select group.

Every government official, every drug firm, every consumer representative, and every health care organization seemingly has a policy position or other means of indicating their support for research, development, and marketing of drugs of little commercial value, otherwise popularly known as "orphan drugs."

Moreover, various bills on the subject have been introduced in the U.S. Congress; the Food and Drug Administration has established a separate unit within the Commissioner's Office on Orphan Product Development; the Pharmaceutical Manufacturers Association has set up a blue-ribbon Commission on Drugs for Rare Diseases; and there has been a host of other activities ranging from congressional hearings to lay audience-prime time television shows.

Indeed, things seemed to be moving along in fine fashion insofar as solving the "orphan drugs" problem. The PMA's Commission wasted no time in getting itself off and running. In mid-June it announced that it had made its first selection: *"At its recent meeting on June 10, 1982, the PMA Commission on Drugs for Rare Diseases unanimously recommended further development of L-5-hydroxytryptophan (L-5HTP) in the treatment of post-hypoxic myoclonus."* Accompanying the announcement was an array of impressive information disclosing the scientific and medical considerations that went into the selection process, the expertise of consultants who participated, and the importance of the drug chosen and its value in treatment of the disease involved.

Moreover, the regulatory wheels over at FDA also seemed to be moving with rather unaccustomed speed. A statement from the FDA's office of Orphan Products Development outlining the NDA approval requirements was released simultaneously with the PMA Commission's announcement. Finally, a summary report was included that described the disease, myoclonus, and the reasons why the group felt that this disease and this drug clearly were their first choice in launching what we might refer to as "the war on orphan drugs."

So far, so good. We all had reason to believe that a great start had been made and concrete progress would be right around the corner.

But not so.

An "Orphan Drug Update" newsletter, published by the National Coalition for Rare Disorders, carried in its September 1982 issue an article entitled **"L-5HTP NOT ADOPTED!!"** The article described the situation as follows:

"However, despite the (PMA) Commission's massive effort to publicize the need for a sponsor of L-5HTP (more than 2,000 announcements were distributed by PMA), not one PMA member has stepped forward *to give hope to people with Myoclonus . . . A small generic manufacturer is interested (not a PMA member), but a final commitment has not been made by the manufacturer.*

"Consumers must question why none of the multi-million dollar pharmaceutical corporations stepped forward to adopt L-5HTP. Why would a small manufacturer, who has much more to lose, offer to adopt this drug? At press time, we are still in doubt as to the future of L-5HTP, and people with Myoclonus are suffering needlessly. Since the government and industry claim they will both solve the orphan drug dilemma 'voluntarily,' why are people with Myoclonus without their therapy? In this instance, HHS, FDA, NIH and the PMA have all failed to live up to their promises! In the absence of a legislative mandate, the Coalition feels that the saga of L-5HTP will be repeated again and again by other drugs for a great variety of orphan diseases."

More recent information appears to confirm that Bolar Laboratories—which has been described in the pharmaceutical press as a small, generic, non-PMA member drug company—is *"assuming the responsibility for financing clinical trials on the product (L-5HTP) and the administrative role of shepherding an NDA through FDA."*

Hence, it appears that a fairy godmother, or godfather, has been found for this particular agent. But although this immediate crisis has passed, what about the second orphan drug selected? and the third? and the next after those? What firm, if any, will step forward to undertake the financially unrewarding, but humanely necessary, task of sponsoring those agents through the drug approval process?

When the cry went up for patient information on prescribed drugs, FDA responded by proposing mandatory Patient Package Inserts (PPIs). But that proposed regulation was withdrawn because the health professions—and pharmacy and medicine particularly—moved decisively to embrace voluntary systems of patient education and information regarding prescribed and dispensed drugs.

Similarly, it appears to us that the drug industry now is faced with comparable options. Everyone else, including the industry's own trade association (PMA), has done all they can do to solve the orphan drugs problem. Whether the voluntary approach will work depends on individual drug companies making the necessary financial commitment.

If individual companies fail to respond in a positive fashion, legislation—and with it regulations, government intrusion, red tape, and all the other things that run contrary to the free enterprise system—is bound to ensue. But is the industry, on a company-by-company basis, willing to pay the relatively small price of voluntary service in order to retain its freedom of operation in this area?

In Vitro Adsorption–Desorption of Fluphenazine Dihydrochloride and Promethazine Hydrochloride by Microcrystalline Cellulose

ROBERT M. FRANZ * and GARNET E. PECK ˣ

Received December 26, 1980, from the *Industrial and Physical Pharmacy Department, School of Pharmacy and Pharmacal Sciences, Purdue University, West Lafayette, IN 47907.* Accepted for publication January 29, 1982. *Present Address: The Upjohn Co., Kalamazoo, MI 49001.

Abstract □ Fluphenazine dihydrochloride and promethazine hydrochloride were adsorbed *in vitro* from suspensions of the tableting excipient, microcrystalline cellulose. Studies were undertaken to determine how this adsorption phenomenon was affected by the type of phenothiazine derivative, the type of microcrystalline cellulose, and pH and ionic strength adjustment. The smaller the microcrystalline cellulose particle size, the more drug was adsorbed. Changes in the pH, the ionic strength, and the valency of the cation used to adjust the ionic strength all had a major effect on the extent of adsorption. The adsorption process was rapidly and completely reversed *in vitro* at gastric pH and ionic strength values.

Keyphrases □ Fluphenazine dihydrochloride—*in vitro* adsorption-desorption by microcrystalline cellulose, promethazine hydrochloride □ Promethazine hydrochloride—*in vitro* adsorption-desorption by microcrystalline cellulose, fluphenazine dihydrochloride □ Adsorption—*in vitro* desorption of fluphenazine dihydrochloride and promethazine hydrochloride by microcrystalline cellulose

Microcrystalline cellulose has been extensively used as a tablet diluent, disintegrant, and dry binder in tablet formulations prepared by direct compression. More recently it has been used as a tablet excipient in formulations prepared by wet granulation (1). This process often involves dissolving the active ingredient or ingredients in the granulating liquid. When the active ingredient is dissolved, the possibility of its being adsorbed by microcrystalline cellulose or other tablet excipients is increased due to the greater number of drug molecules available for interaction with the sorbent surface.

Cellulose derivatives and their adsorption properties have been studied extensively in the textile and paper industries. These studies have often involved dye and surfactant adsorption (2–7). Cellulose, including microcrystalline cellulose, has also been used to coat TLC plates for use in the separation of various chemical and biological agents (8, 9). The adsorptive properties of cellulose cannot be disputed. Even so, very few studies have been undertaken to determine if drug substances (*i.e.*, phenothiazines) adsorb to the insoluble cellulose derivatives that are used as excipients in the manufacture of tablets (10).

This study was undertaken to characterize the interaction, if any, between the phenothiazine derivatives, fluphenazine dihydrochloride (I) and promethazine hydrochloride (II), and two different grades of microcrystalline cellulose. It was hoped that by understanding the basic principles of drug–microcrystalline cellulose interactions a greater insight into the formulation of phenothiazine tablets could be gained.

EXPERIMENTAL

Materials—Fluphenazine dihydrochloride[1], promethazine hydrochloride[2], and all other chemicals used in this study were either USP, NF, or reagent grade. All water was doubled distilled, deionized, and degassed. Microcrystalline cellulose, in both a medium grade (III)[3] and a fine grade (IV)[4] was obtained directly from the supplier and was used without further modification. Actinic glassware was used to avoid photodecomposition of the phenothiazines.

Methods—The analytical procedure used for determining drug concentrations in solutions or suspension supernatants was a 3-point UV spectrophotometric technique (11) subsequently adopted for phenothiazine analysis (12, 13). This method was used in order to remove linear background absorbance due to UV absorbing trace substances released into the suspension media by the microcrystalline cellulose. Wavelengths used for the adsorption measurements are shown in Table I.

Table I—Wavelengths Used for UV Absorption Measurements

Compound	Wavelengths, nm		
	WL^{a}_{short}	WL^{b}_{max}	WL^{c}_{long}
I	234	256	268
II	225	250	260

[a] Wavelength shorter than WL_{max}. [b] Wavelength of maximum absorption. [c] Wavelength longer than WL_{max}.

The accuracy of the assay was determined at different drug concentrations, as well as at the different ionic strengths and pH values used in this study. The range of measured drug concentrations was 97.60–105.17% of the theoretical drug concentrations. The appropriate pH and ionic strength adjusted solution was used in the reference cell.

Adsorption *versus* pH—The preparation of a series of drug–cellulose suspensions involved the addition of 100 ml of distilled water to a 250-ml actinic glass flask containing 3 g of the appropriate grade of microcrystalline cellulose. The suspensions were then shaken or placed in a bath-type sonifier[5] for 30 sec to ensure dispersion. To each suspension was added 1.3 ml of a 1 mg/ml stock solution of the appropriate drug. The pH of these suspensions was adjusted to 2.1, 3.0, 4.0, 5.0, or 6.1, using 0.1 *N* HCl or 0.009 *N* KOH, while the added[6] ionic strengths were adjusted to 0.0107 or 0.107 using 2 *N* KCl. The pH and ionic strengths of the suspensions were adjusted by the addition of ~95% of the total 2 *N* KCl necessary for ionic strength adjustment (determined by a trial run), followed by pH adjustment using 0.1 *N* HCl or 0.009 *N* KOH, and finally the addition of enough 2 *N* KCl to bring the added ionic strengths to the desired level. This was necessary since the initial addition of 2 *N* KCl caused a significant drop in the pH of the suspensions. The final small addition of 2 *N* KCl to bring the added ionic strength to the desired level caused no significant pH change. A final small dilution with distilled water brought the total volume of the suspensions to 120 ml. The pH was monitored using a combination hydrogen ion electrode[7] and pH meter[8].

Preliminary experiments indicated no significant drug degradation took place at the pH values used in this study, nor in the presence of

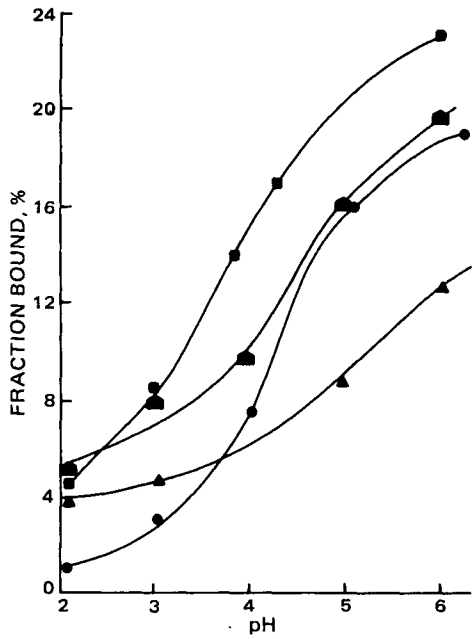

Figure 1—*Effect of pH on the percent fraction of fluphenazine dihydrochloride bound to 3 g of microcrystalline cellulose (1.3 mg of drug/120 ml of external phase). Key: (●) III, added ionic strength (μ′) = 0.0107; (■) IV, μ′ = 0.0107; (▲) III, μ′ = 0.107; (▲) IV, μ′ = 0.107.*

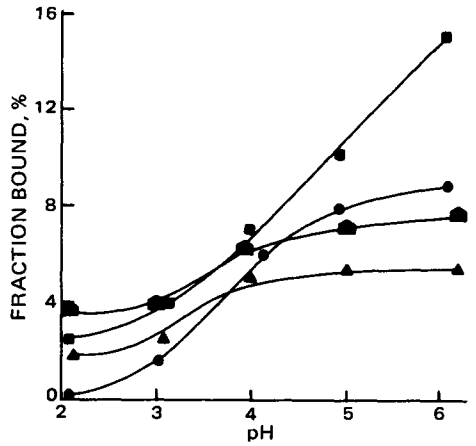

Figure 2—*Effect of pH on the percent fraction of promethazine hydrochloride bound to 3 g of microcrystalline cellulose (1.3 mg of drug/120 ml of external phase). Key: (●) III, μ′ = 0.0107; (■) IV, μ′ = 0.0107; (▲) III, μ′ = 0.107; (▲) IV, μ′ = 0.107.*

microcrystalline cellulose. Blanks were prepared at the same drug concentrations, pH, and added ionic strengths as the samples, but they contained no microcrystalline cellulose. The suspensions and blanks were equilibrated for 1 hr at 23 ± 0.5° on a mechanical shaker water bath[9]. Preliminary experiments performed over a 24-hr period indicated that equilibrium between the adsorbates and adsorbents was reached in <30 min. The suspensions were then centrifuged for 20 min at 23 ± 0.5° on a refrigerated centrifuge[10] at 15,100 rpm. The supernatants were decanted and recentrifuged for an additional 20 min at the same temperature and rpm. The supernatants and blanks were then assayed by the previously described UV spectrophotometric technique. Two separate readings were performed on each sample, and the average was used in the final calculations. The pH values of the final supernatants were monitored and they did not differ by > ±2% of the original adjusted value. The percent fraction of drug bound was calculated as:

$$\% \text{ Fraction Bound} = \frac{[\text{Drug}]_B - [\text{Drug}]_S}{[\text{Drug}]_B} \times 100\% \qquad \text{(Eq. 1)}$$

where $[\text{Drug}]_B$ was the concentration of drug found in the blank and $[\text{Drug}]_S$ was the concentration of drug found in the suspension supernatant. Throughout this study it was assumed that only a minimal amount of water was adsorbed by the microcrystalline cellulose. Even so, the uptake of water by the adsorbent will alter slightly the actual drug concentrations in the suspension supernatants. For this reason, the adsorption discussed throughout this work is actually the apparent adsorption and includes the effect of water uptake by microcrystalline cellulose.

Adsorption Isotherms—Adsorption isotherms were determined for suspensions where the external medium was distilled water (*i.e.*, no pH or ionic strength adjustment), as well as for pH and ionic strength adjusted suspensions. The suspensions were prepared as previously described, with only the drug concentrations being different. For the un-

adjusted suspensions, the initial drug concentration ranged from 2.5×10^{-3} to 3.33×10^{-2} mg/ml, while for the pH and ionic strength adjusted suspensions the initial concentration of drug was between 2.5×10^{-3} and 1.67×10^{-2} mg/ml. The pH values of the adjusted suspensions were held at 2.1 and 6.1, while the added ionic strengths were held at 0.0107 and 0.1070. The pH values were considered to approximate gastric and intestinal conditions. Blanks were prepared at the same drug concentration, pH, and added ionic strength as the appropriate suspension, only containing no microcrystalline cellulose. The suspensions and blanks were adjusted to the above-mentioned pH and added ionic strength values, equilibrated, and assayed as described previously. The amount of drug adsorbed to the microcrystalline cellulose was determined by the difference in drug concentrations between the suspension supernatant and the appropriate blank. The amount of drug adsorbed in milligrams per gram of microcrystalline cellulose was calculated.

Adsorption *versus* Electrolyte Addition—Suspensions and blanks were prepared at constant pH values of 2.1 and 6.1 exactly as described in the Adsorption *versus* pH section except the added ionic strengths were adjusted. Only III was used. Suspensions prepared at pH 6.1 were adjusted to added ionic strengths of 0, 0.000107, 0.00107, 0.0107, 0.107, and 1.070. Appropriate dilutions were made in a 2 *N* KCl solution so that measurable volumes could be added to the suspensions for ionic strength adjustment. At pH 2.1 the suspensions were adjusted to added ionic strength values of 0.0107, 0.107, and 1.07, using 2 *N* KCl. The suspensions and blanks were equilibrated and assayed as previously described. The percent fraction of drug adsorbed was calculated usng Eq. 1.

Adsorption *versus* Ionic Species—Individual suspensions were prepared by adding 100 ml of distilled water to 250-ml actinic glass flasks containing 3 g of III. Compound III was dispersed, and 1 ml of the appropriate 1-mg/ml drug solution was added. Blanks were prepared containing no adsorbent. Enough sodium chloride, potassium chloride, magnesium chloride, or calcium chloride was added to make the suspensions and blanks 9.804×10^{-4} *M* in added electrolyte. All salt solutions used were 0.1 *N*. These electrolytes were selected due to their frequency of occurrence in the GI tract. Another group of suspensions and blanks were adjusted to a constant added ionic strength of 9.804×10^{-4} using the same salts. Total volume was kept constant at 102 ml, and no pH adjustments were made. The suspensions and blanks were equilibrated, centrifuged, and assayed as previously described. The percent fraction of drug adsorbed was calculated using Eq. 1, and the supernatant pH was monitored.

Desorption *versus* Elution—Individual adsorption complexes were prepared by the addition of 39 ml of distilled water to 50-ml plastic centrifuge tubes containing 1 g of III or IV. The adsorbent was dispersed by shaking. To these suspensions was added 1 ml of a 1-mg/ml solution of the appropriate drug. Blanks were prepared without III or IV. The suspensions and blanks were then equilibrated, centrifuged, and assayed as previously described. Preliminary experiments performed over a 24-hr period indicated that desorption equilibrium was attained in <30 min.

The amount of drug adsorbed to III or IV in the suspension sediment was calculated as the difference between the total drug concentration in the blank and the total drug concentration in the supernatant. This adsorbed amount was considered to be 100% of the possible drug that could be desorbed during an elution. After carefully decanting the supernatant, the remaining drug–microcrystalline cellulose sediment was eluted with either distilled water, or medium adjusted to pH values of 2.1 or 6.2 and added ionic strengths of 0.0107 or 0.1070. The pH and added ionic strength adjustments were performed as previously described after the addition of 35 ml of distilled water to resuspend the sediment. The total volume of elution medium was kept constant at 40 ml. Sediment and elution media were equilibrated, centrifuged, and assayed as described previously, and the elution procedure was repeated a maximum of five times on each drug–microcrystalline cellulose sediment. The pH values of the supernatants were determined and they did not differ significantly from the original adjusted pH values. The cumulative percent desorbed was calculated after each elution using the following equation:

$$\text{Cumulative \% Desorbed} = \frac{[\text{Drug}]_C - \sum_{i=1}^{m} [\text{Drug}]_i}{[\text{Drug}]_C} \times 100\% \qquad \text{(Eq. 2)}$$

where $i = 1, 2, 3, \ldots m$ elutions, $[\text{Drug}]_C$ is the total amount of drug initially adsorbed in the drug–microcrystalline cellulose adsorption complex, and $[\text{Drug}]_i$ is the total amount of drug found in the supernatant after the ith elution. Each elution was performed on two separate samples and the values were averaged.

RESULTS AND DISCUSSION

Effect of pH on Adsorption—Figures 1 and 2 illustrate the effect of pH on the adsorption of fluphenazine dihydrochloride and promethazine hydrochloride from suspensions of microcrystalline cellulose adjusted to two different added ionic strengths. Both figures show that at a given added ionic strength and pH, IV always adsorbs a greater amount of drug than does III. This is probably due to the greater total surface area of IV when compared with an equal weight of III. The average particle size of III is 50 μm, while the average particle size of IV is 20 μm (1).

0.0107	16.83	8.77
0.107	13.50	5.28
1.07	11.99	5.84

[a] At a fixed pH of 6.1.

As the pH increases from 2.1 to 6.1, the amount of drug adsorbed by the microcrystalline cellulose also increases (Figs. 1 and 2). This is most likely due to the ionization of carboxyl groups on the cellulose surface. These carboxyl groups are formed by oxidation of the hydroxy groups on individual anhydro-glucose units (14–16). The pKa of these carboxyl groups is ~4.0 (14). As the pH values of the suspensions are increased from 2.1 to 6.1, the number of negatively charged carboxylate groups on the surface of the microcrystalline cellulose particles increases. The increased number of anionic surface sites leads to increased adsorption of the predominantly positively charged drugs at the surface of the particles. The pKa values of these weakly basic drugs are 3.90 and 8.05 for fluphenazine dihydrochloride and 9.08 for promethazine hydrochloride (13).

The possibility also exists that these hydrophobic drugs are adsorbed from solution as the nonprotonated free bases. As the pH values of the suspensions approach the highest pKa values of the phenothiazines, more free base will be found in solution. The free base could then be removed from solution by adsorption to the microcrystalline cellulose surface. As free base is removed from solution, new free base will replace it from the

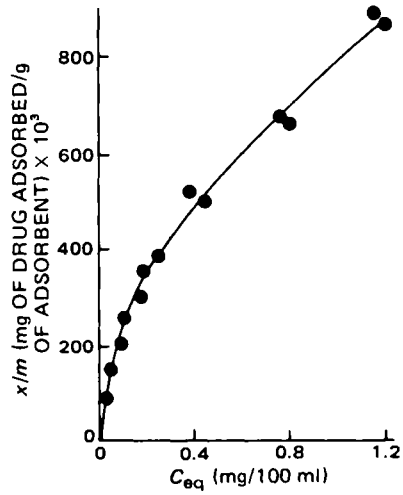

Figure 7—*Adsorption isotherm of fluphenazine dihydrochloride on III in distilled water.*

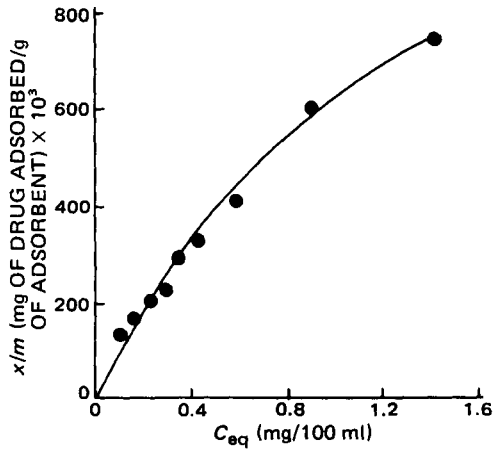

Figure 8—*Adsorption isotherm of promethazine hydrochloride on III in distilled water.*

protonated excess. This will continue until an equilibrium is established between the free base in solution and the base adsorbed to the cellulose surface. This explanation does not seem as likely as the one previously described since pH levels are kept two or more units below the highest pKa of the drugs, and there is an abundance of literature describing the negative surface of microcrystalline cellulose (14, 17–19) as well as other cellulosic materials (2, 15, 20).

Increasing the added ionic strength has different effects on the extent of adsorption depending on the pH of the suspension (Figs. 1 and 2). At high pH values (*i.e.*, pH 6.1), an increase in added ionic strength caused a decrease in the amount of drug adsorbed. This is most likely caused by increased competition between positively charged drug molecules and potassium and hydrogen ions for the negatively charged microcrystalline cellulose surface.

At low pH values (*i.e.*, pH 2.1), where the cellulose carboxy groups are predominantly in their nonionized form, an increase in the added ionic strength causes a slight increase in the amount of drug adsorbed by a particular type of microcrystalline cellulose (Figs. 1 and 2). This could be due to the increased surface activity of these phenothiazines at higher ionic strengths (21). The increased surface activity of these drugs at higher ionic strengths could be caused by the suppression of adsorbed drug–drug electrical repulsions due to the screening effect of the added ions. This would allow more drug to be adsorbed to the cellulosic surface. At higher pH values, where the surface of the microcrystalline cellulose is predominantly negative, this suppression effect may be absent or hidden by the attraction between oppositely charged particles. There is also a possibility that these drugs adsorb by different mechanisms depending on the pH of the suspension and the interrelated surface charge of the microcrystalline cellulose.

The experimental results of this adsorption study give only indirect evidence for the mechanism of adsorption. Further experiments using IR spectroscopy and X-ray diffraction would be needed to determine the exact adsorption mechanism (22, 23).

Calcium chloride	9.5	4.90	15.4	5.30

Adsorption Isotherms—Adsorption isotherms prepared from suspension data where the pH and ionic strength were adjusted to fixed values adhered to the theoretical Langmuir equation, while those prepared from distilled water conformed to the empirical Freundlich equation (24–26). Fit to one or the other type of isotherm was based solely on the comparison of R^2 values obtained from the linear plots (using least squares) of the respective isotherms.

Drug aggregates often exist below the apparent critical micelle concentration for surface active agents such as the phenothiazines (27). The apparent critical micelle concentration will change with varying pH and ionic strength levels (28). Adsorption of aggregates of drug molecules (*i.e.*, ion-pair adsorption) has been reported in the literature (2). This type of phenomenon is often accompanied by a drastic increase in adsorption as the drug concentration approaches its apparent critical micelle concentration (2). No such changes in the adsorption isotherms were observed during this study. It was felt that this fact, coupled with the low concentrations of drugs used, indicated that adsorption was predominantly occurring at a monomolecular level.

The linear form of the Langmuir adsorption isotherm is given by:

$$\frac{C_{eq}}{x/m} = \frac{1}{k_1 k_2} + \frac{C_{eq}}{k_2} \qquad \text{(Eq. 3)}$$

where C_{eq} is the concentration of drug remaining in the suspension supernatant in mg/100 ml after equilibrium adsorption is obtained, x/m is the amount of drug adsorbed in milligrams per gram of microcrystalline cellulose, and k_1 and k_2 are constants. The constant k_2 is the limiting adsorptive capacity. It is the maximum amount of adsorbate, in milligrams, that can be adsorbed by 1 g of adsorbent. Due to the lack of data points at extremely low drug concentrations (*i.e.*, infinite dilution), k_1k_2, instead of k_1, is often used as a measure of the relative affinity of the adsorbate for the adsorbent (13, 29, 30). Typically, calculated k_1k_2 values have been shown to be subject to some error (31). Figures 3 and 4 are typical examples of the isotherms obtained from pH and ionic strength adjusted suspensions. Figures 5 and 6 are the linear plots of these same Langmuir adsorption isotherms.

Adsorption isotherms determined for the phenothiazine–microcrystalline cellulose suspensions where the external phase was distilled water conformed to the Freundlich equation given in the linear form as:

$$\log \frac{x}{m} = \log K + N \log C_{eq} \qquad \text{(Eq. 4)}$$

where x/m and C_{eq} are defined as before and K and N are constants. According to Adamson, the constant K gives a rough measure of the relative adsorbent capacity for a given drug, while N gives a general idea of the affinity of the adsorbate for the adsorbent (32). Typically, the

Table VII—Summary of Desorption *versus* Elution Data for Fluphenazine Dihydrochloride

Elution 4									37.7	39.0
Elution 5									44.3	45.4

constants k_1 and k_2 (Langmuir constants) are not compared to the constants K or N (Freundlich constants) since they are determined from different types of isotherms (*i.e.*, theoretical *versus* empirical). Figures 7 and 8 are typical examples of the isotherms obtained from suspensions where the external medium was distilled water. Figures 9 and 10 are the linear plots of these same Freundlich adsorption isotherms.

Tables II and III show the constants obtained from the different isotherms, as well as the squared correlation coefficients of the linear plots for fluphenazine dihydrochloride and promethazine hydrochloride, respectively. Comparison of isotherms determined from suspensions in which the external medium was distilled water (Figs. 7 and 8) to isotherms where the external medium was pH and ionic strength adjusted (Figs. 3 and 4) indicates that the electrolyte concentration of the suspension has a major effect on the extent of adsorption.

Effect of Added Electrolyte—Tables IV and V show how changes in the added ionic strength of the suspensions affects the percent fraction of drug adsorbed at constant pH values of 6.1 and 2.1, respectively.

Effect of Ionic Species—The results shown in Table VI indicate that divalent cations have a major effect on the extent of promethazine hydrochloride adsorption by III at both constant electrolyte molarity and added ionic strength. There seems to be little difference in the fraction of drug bound when comparing cations with equal valences. Divalent cations seem to cause a major decrease in the amount of drug adsorbed to III, as compared with monovalent cations. This could be due to divalent cations neutralizing twice as much negative charge on the surface of the microcrystalline cellulose as monovalent cations, which would decrease the number of anionic surface sites available for the protonated drug molecules to interact with, and therefore less drug would be adsorbed. The divalent cations may also have a greater affinity for the surface of III than the monovalent cations and, therefore, less drug would be adsorbed due to increased competition for the negative surface of the microcrystalline cellulose.

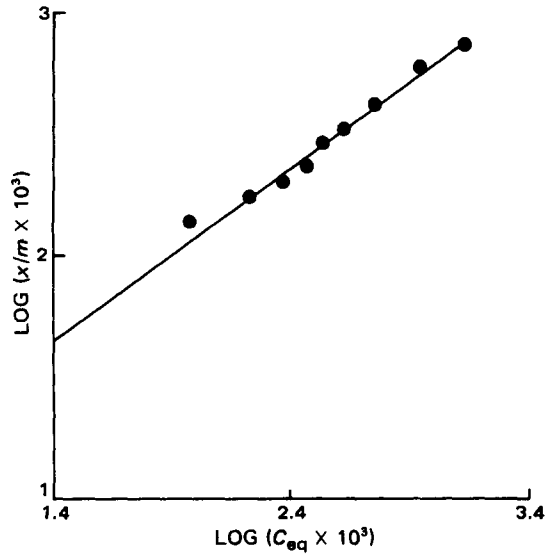

Figure 10—*Freundlich plot for the adsorption of promethazine hydrochloride on III in distilled water.*

Even though the above are hypothesized mechanisms, they seem likely due to the fact that oxidized celluloses, such as microcrystalline cellulose (14, 18), have been shown to adsorb inorganic cations (16, 20, 33). The pH values of the final supernatants were approximately the same after the addition of potassium chloride, sodium chloride, magnesium chloride, and only slightly lower for calcium chloride, indicating that pH was not the reason for the differences seen in the fraction of drug adsorbed.

Desorption—Preliminary experiments indicated that desorption equilibrium was attained in <30 min. Tables VII and VIII show the results of the desorption experiments for fluphenazine dihydrochloride and promethazine hydrochloride, respectively. These results demonstrate the importance that electrolytes play in the desorption phenomenon. It would appear that the inorganic cations in the elution medium have an affinity for the negative surface of the microcrystalline cellulose and, therefore, displace the adsorbed drugs into the external media. This is evidenced by small amounts of the drugs being desorbed from microcrystalline cellulose after five elutions with distilled water, as compared with almost 100% being desorbed with pH and ionic strength adjusted media after three or less washes (Tables VII and VIII). The pH values of the elution supernatants of samples washed with distilled water were close to the adjusted elution pH of 6.2. This indicates that the added electrolytes in the adjusted elution samples must cause the increased desorption, not differences in pH.

The results of these *in vitro* desorption studies indicate that the adsorption of these drugs by microcrystalline cellulose should be rapidly and completely reversed at gastric and intestinal pH values and ionic strengths.

Isolation, Identification, and Synthesis of the Major Sulpiride Metabolite in Primates

J. J. BRENNAN *[x], A. R. IMONDI [‡], D. G. WESTMORELAND [§], and M. J. WILLIAMSON [‡]

Received March 27, 1981, from the *Corporate Health & Safety Department, Rohm and Haas Co., Bristol, PA 19007;* the [‡]*Adria Laboratories, Inc., Columbus, OH 43216;* and the [§]*Rohm and Haas Company, Research Laboratories, Spring House, PA 19477.* Accepted for publication January 6, 1982.

Abstract □ The major metabolite of sulpiride, *N*-[(1-ethyl-2-pyrrolidinyl)methyl]-5-sulfamoyl-2-anisamide (I), in the monkey is *N*-[(1-ethyl-5-oxo-2-pyrrolidinyl)methyl]-5-sulfamoyl-2-anisamide (II). It is also a metabolite in other laboratory animal species and possibly at very low levels in humans. Treatment of the urine from a monkey dosed orally with ^{14}C-I by dry column chromatography and high-pressure liquid chromatography (HPLC) produced the major metabolite in pure form. Characterization of the purified ^{14}C-radiolabeled metabolite by proton NMR, TLC, HPLC, and chemical ionization mass spectroscopy, along with subsequent comparison of a synthetically prepared sample, gave unequivocal structural confirmation.

Keyphrases □ Sulpiride—isolation, identification, and synthesis of major metabolites, monkeys □ High-pressure liquid chromatography—analysis, major sulpiride metabolites, monkeys □ Metabolites—sulpiride, isolation, identification, and synthesis, monkeys

Sulpiride (I) is a structurally unique antipsychotic drug. Studies utilizing ^{14}C-labeled I indicated that, while this drug is metabolized to a very small extent in humans, the monkey produces a major metabolite which accounts for 10–30% of a single dose (1). Column chromatography on a strong cation exchange resin, with dilute acid, rapidly eluted this major metabolite, whereas I was retained. This behavior suggested that the metabolite was rendered less basic than the parent drug by a metabolic change on the pyrrolidine ring.

There are several model chemical compounds that possess a pyrrolidinyl moiety either as a fused five-membered ring or as the saturated heterocyclic structure analogous to I. Among these are mazindol (III), prolintane (IV), and tremorine (V).

One of the major biotransformations of these chemical models (Structures II, III–V) in analogous animal species is the oxidation of the alpha position of the five-membered ring to the lactam structures (VI, VII, and VIII). These metabolic changes suggest that I would be similarly biotransformed. It has been reported (2) that the metabolite oxytremorine (VI) is physiologically active and provided

further impetus for identification, synthesis, and biological evaluation of this suspected metabolite.

EXPERIMENTAL

Isolation of the Metabolite by Dry Column Chromatography—Urine from a male monkey (*Macaca mulatta*) which had been dosed orally with [^{14}C]3,4-pyrrolidine sulpiride (I) was dissolved in Solvent System I [1-butanol-acetic acid–water (2:2:1)] and placed on a nylon column (25-mm flat width × 280-mm flat length) packed with dry silica gel[1] to a height of 250 mm. When the elution was complete, the column was divided into 11 segments (25 mm each), excluding the upper and lower portions of the column which were discarded. The segments were slurried with absolute methanol (25 ml) and 10-μl aliquot portions were collected, diluted with 10 ml of scintillation cocktail[2], and counted in liquid scintillation counter. The results are plotted in Fig. 1. Fractions from segments II–V were slurried with methanol, filtered (0.5-μm filter), and concentrated under dry nitrogen. The residue was dissolved in Solvent System V [5 ml of propanol–NH_4OH (9:1)] and eluted with the same size column used for Solvent System I. When the elution was complete, the column was treated as above; the data are plotted in Fig. 2. Fractions 6–8 were diluted further, filtered, and concentrated under dry nitrogen. The residue was extracted with methylene chloride (25 ml), and two aliquot portions (50 μl) were removed and counted. The results showed that 239 μg of crude metabolite had been isolated.

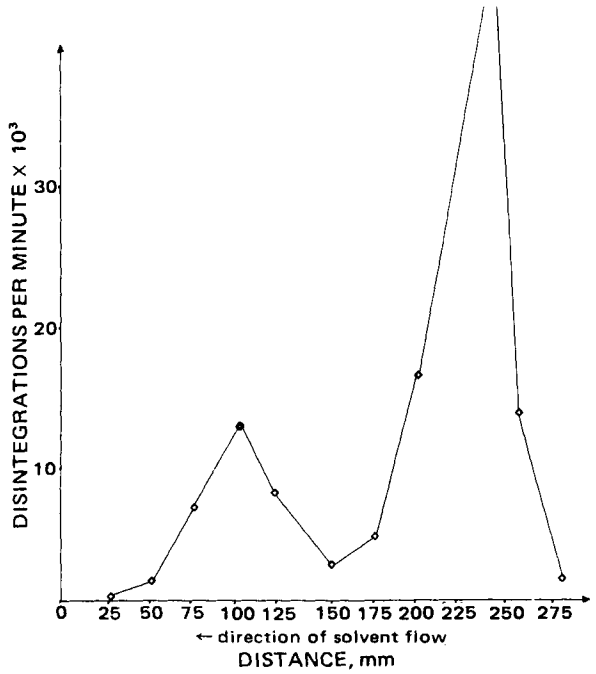

Figure 1—*Radiolabeled sulpiride and the metabolite.*

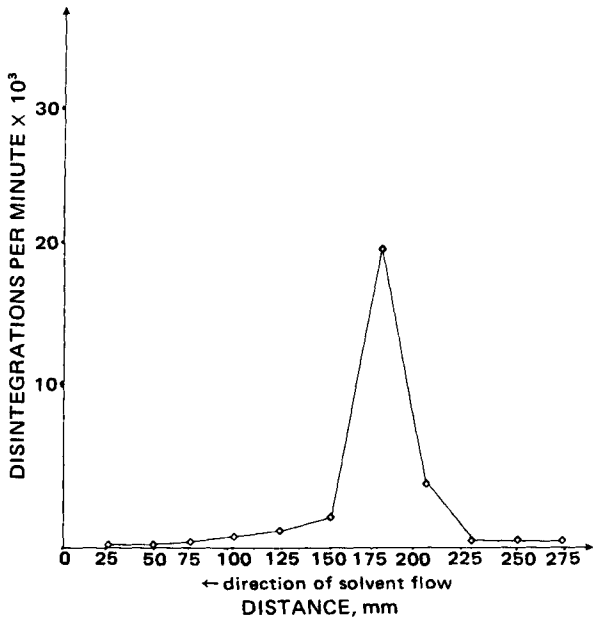

Figure 2—*Radiolabeled metabolite.*

Purification of the Metabolite by HPLC—The methylene chloride solution containing ~239 μg of radioactive material was concentrated to ~1.2 ml under nitrogen and filtered through a 0.5-μm filter. The filtered solution was loaded into a high-pressure liquid chromatographic (HPLC) injection assembly and the solvent overflow was collected and counted; it contained no detectable radioactivity. At zero time, the sample was injected on a preparative HPLC column[3] and the program initiated. A 50-min concave program from 100% water to 100% acetonitrile at 2.8 ml/min and with UV detection at 290 nm was used. The fractions were collected at 5-min intervals or when necessary by elution of a peak. Aliquots of up to 0.5 ml were taken from each vial for liquid scintillation counting. After four runs, it was determined by UV absorption and liquid scintillation counting that three vials (Fig. 3) contained ~77, 17, and 7 μg, respectively, of radioactive material. The vial with the highest radioactivity was concentrated under nitrogen and examined by ^{1}H-NMR.

Identification—*NMR Analysis of the Metabolite*—The sulpiride metabolite sample which had been purified by dry column chromatography and HPLC was dried in a conical vial. The vial was placed under a nitrogen blanket (water free), and 6 μl of dimethyl sulfoxide[4] was added

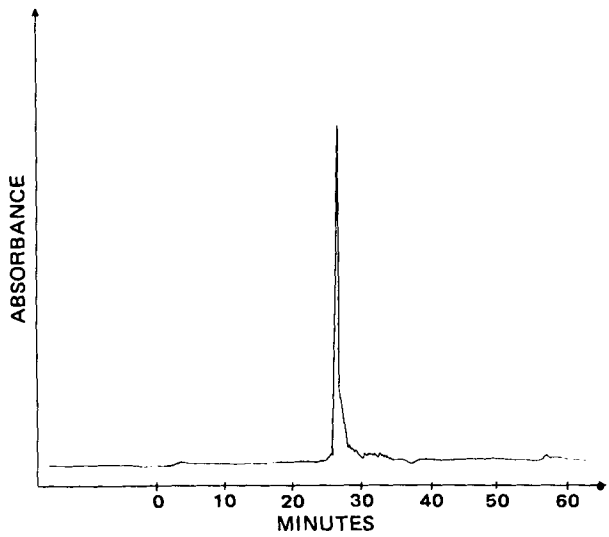

Figure 3—*Isolation of the radiolabeled metabolite by HPLC.*

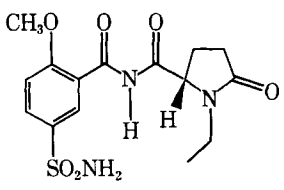
to the vial. When the material had dissolved, the solution was transferred *via* capillary action to a 1-mm glass tube and the ends sealed with corks. The tube was removed from the nitrogen blanket and sealed immediately with a torch. The 100 MHz ^{1}H-NMR spectrum was obtained using Fourier transform spectroscopy. The time average of 4872 free induction decays (collected with a 1-sec acquisition time) yielded the following spectrum: δ 0.98 (triplet, J = 7 Hz, CH_3), 1.75–2.26 (multiplet, $2CH_2$), 2.87–3.59 (multiplet, CH, $2CH_2$), 3.88 (singlet, CH_3), 7.21 (singlet, NH_2), and 7.29–8.31 (multiplet, 3 aromatic). Analysis of this spectrum compared to that of sulpiride suggested that the metabolite had the structure of II. The ^{1}H-NMR spectrum of synthetic II was obtained at a later date in a similar manner and was essentially identical to that of the metabolite.

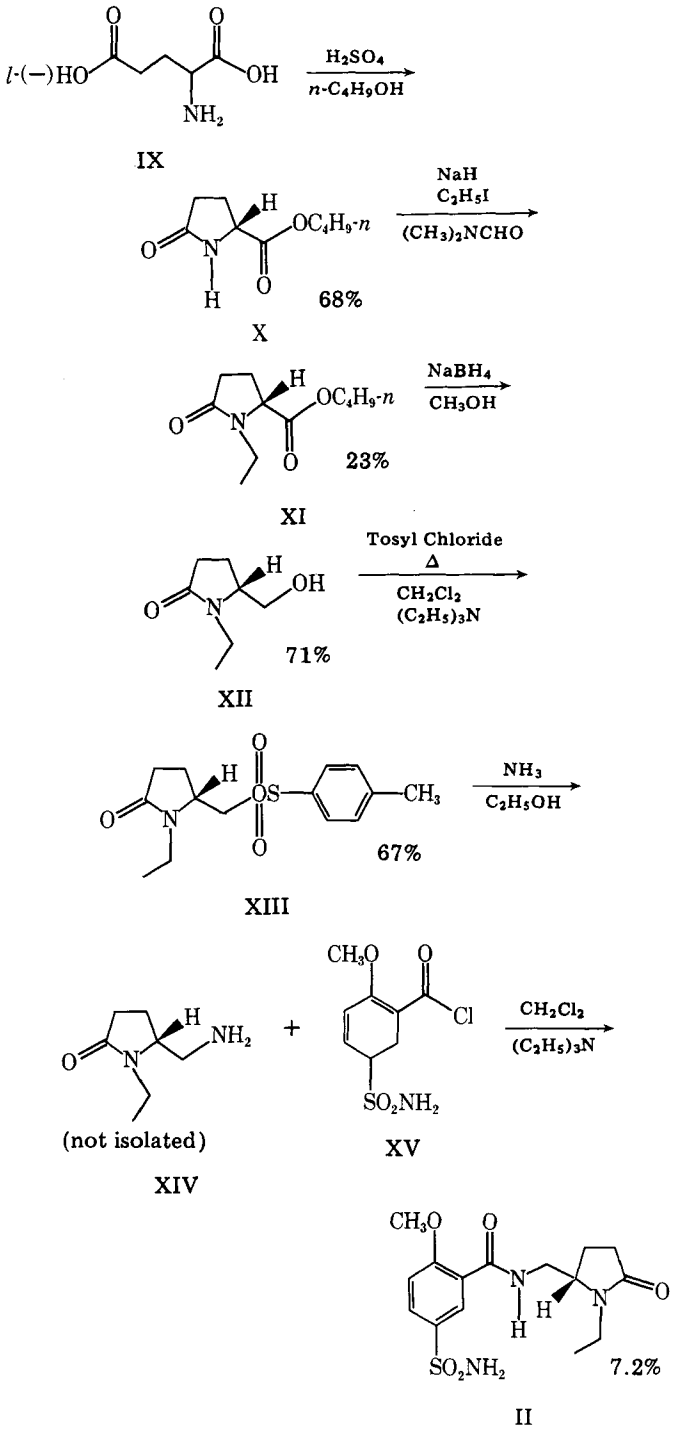
Chemical Ionization Mass Spectral Analysis of the Metabolite and the Synthetically Prepared Material—The data for the purified metabolite sample were of good quality, probably because of the higher purity. The methane chemical ionization mass spectrum shows the protonated molecular ion of the α-pyrrolidinone derivative at mass spectrum 356 and also association ion peaks for $(M+, C_2H_5)^+$ at 384 and $(M+, C_3H_5)^+$ at 396. However, a second component was also observed with peaks at 370 and 398, implying a molecular weight of 369. The amount of this component cannot be estimated from the chemical ionization mass spectroscopic data, but is probably <10% of II, since it was not readily observed in the ^{1}H-NMR data. This second component was probably a derivative of sulpiride which was oxidized at two positions on XVI.
A mass spectral scan of synthetic II showed a multitude of ions and could not be readily interpreted. Evidently the impurities in the preparation were masking the major component, perhaps due to higher volatility or stability.

HPLC Analysis of the Metabolite—A high-pressure liquid chromatograph equipped with a valve-loop injector (10 μl), an amino column[5], and a variable wavelength detector set at 240 nm was used. The mobile phase was prepared by adding 15 ml of concentrated ammonium hydroxide to a 400-ml mixture of 97.5 acetonitrile–2.5% water. This mixture was pumped through the column at 1 ml/min. Using this system I eluted at 3.3 min, with an internal standard of *p*-toluenesulfonamide eluting at 1.0 min (Fig. 4).



XVI

[5] Varian Micropak-NH_2.



Scheme I—Synthetic route to II.

A solution of 1.8 mg of II in 5 ml of acetonitrile was prepared. A 10-μl aliquot was injected and a retention time of 1.9 min measured (Fig. 5A). A sample of the radioactive metabolite was dissolved in 1 ml of acetonitrile, and a 5-μl aliquot was injected. The retention time by UV absorption and collected radioactivity was found to be 1.9 min (Fig. 5B), identical to that of the synthetic material. The two chromatograms are shown in Fig. 5.

Synthesis of Metabolite II—*Butyl-5-oxopyroglutamate (X)*—Scheme I shows the synthesis of II: A 2-liter flask containing *l*(−)-glutamic acid (IX) (147 g, 1.0 mole) and 1-butanol (625.0 g, 8.45 moles) was stirred at room temperature. The suspension was treated with concentrated sulfuric acid (125.0 g, 1.27 moles) in portions and gave a clear solution. The reaction was heated at reflux with the removal of water for 25 hr and the pH adjusted to 4.5 with 1 *N* Na_2CO_3 and concentrated *in vacuo*. The viscous oil obtained was stirred with benzene (500 ml) while adjusting the pH to 9.5 with 2 *N* NaOH. The organic layer was separated,

and the aqueous layer was further extracted with benzene (2 × 250 ml). The organic layers were combined, washed with saturated sodium chloride solution, and concentrated to give a lightly colored oil. The oil was distilled (160–165°, 1.7 mm) to give 126.0 g (68%) of a colorless product.

Butyl-N-ethyl-5-oxopyroglutamate (XI)—A 500-ml flask equipped with a mechanical stirrer, reflux condenser, thermometer, and funnel was used. Compound X (37.0 g, 0.2 mole) was dissolved in dimethylformamide (200 ml, previously dried over 4-Å molecular sieves for 24 hr). Sodium hydride (9.5 g of 50% dispersion, 0.2 mole) was added in portions, the reaction exothermed to 50°, and the solution became amber. The reaction was maintained at 50° for 1 hr and then cooled. Ethyl iodide (31.2 g, 0.2 mole) was then added dropwise at a rate sufficient to maintain a temperature of 50°. After the addition was complete, the reaction was heated at 50° for 2 hr and stirred to room temperature overnight. The reaction mixture was poured into water (1000 ml), extracted with carbon tetrachloride (3 × 600 ml), dried over magnesium sulfate, filtered, and concentrated to give 35.5 g of crude product. The crude material was distilled (136°, 0.75 mm) to give 18.7 g (44%) of pure product.

N-Ethyl-5-hydroxymethyl-2-pyrrolidinone (XII)—A 250-ml flask equipped with a magnetic stirrer, reflux condenser, thermometer, and funnel was used. Compound XI (25.0 g, 0.12 mole) was added dropwise to a solution of absolute methanol (120 ml) containing sodium borohydride (11.4 g, 0.30 mole) at room temperature. The addition of the ester caused an exotherm and the reaction temperature was maintained below 50° with ice. When the addition was complete, the reaction was heated at reflux overnight. The reaction mixture was concentrated, the viscous oil slurried with a minimum amount of anhydrous ethanol, then chromatographed on a glass column (58 mm × 600 mm) which had been packed with slurried silica gel[1]. The product was eluted with ethanol, concentrated, and the oil obtained was extracted into benzene, dried over magnesium sulfate, filtered, and concentrated to give 12.2 g (71.2%) of pure product.

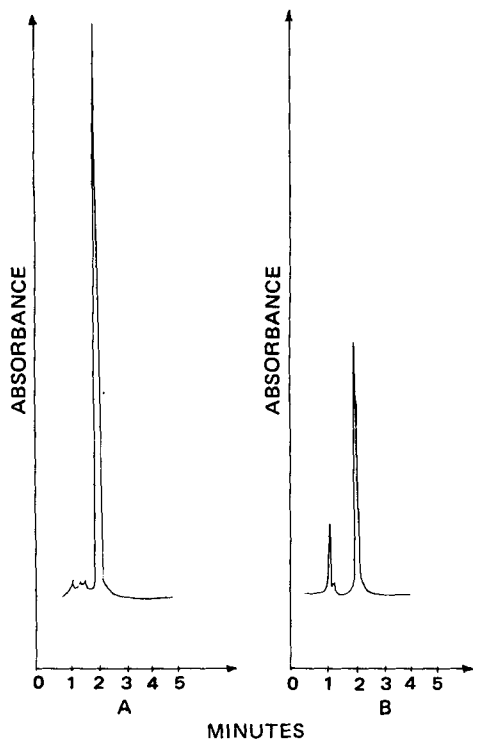

Figure 5—*Comparison of the elution times of the synthetic (A) and radiolabeled metabolite (B).*

N-Ethyl-5-tosylmethyl-2-pyrrolidinone (XIII)—A 100-ml flask equipped with a reflux condenser and drying tube was used. Compound XII (7.24 g, 50.77 mmoles), 4-toluenesulfonyl chloride (19.1 g, 100.0 mmoles), and triethylamine (10.1 g, 100.0 mmoles) were dissolved in methylene chloride (50 ml) and heated overnight. The rection mixture was poured into dilute sodium bicarbonate solution (10 ml of a saturated solution was diluted to 100 ml), the layers were separated, and the organic layer was extracted with 0.1 *N* HCl (2 × 100 ml), dried over magnesium sulfate, filtered, concentrated, and refrigerated, overnight. The tan solid obtained was stirred with heptane (5 × 100 ml), filtered, and air dried to give 10.15 g of product (mp 80–82°). The product was crystallized from ethyl acetate–heptane (1:1) (mp 84–85°, 67% yield).

N-Ethyl-α-aminomethyl-2-pyrrolidinone (XIV)—A 300-ml stainless steel autoclave equipped with a pressure gauge (1 × 10^3 psi) was employed. Ethanol (200 proof, 100 ml) was cooled and saturated with ammonia for 1.5 hr. *N*-Ethyl-5-tosylmethyl-2-pyrrolidinone (XIII) (5.0 g, 16.9 mmoles) was added and the solution was stirred and heated at 80° overnight. The resulting amber solution was diluted with water (30 ml) and then the ethanol was removed *in vacuo*. The remaining aqueous solution was cooled and the pH adjusted to 14 with solid potassium hydroxide. The resulting alkaline solution was extracted with ethyl acetate (3 × 100 ml) and the aqueous solution was readjusted to pH 14 and further extracted with ethyl acetate (2 × 100 ml). The organic layers were combined and concentrated to a minimum volume and further extracted with 1 *N* HCl (30 ml). The acid solution was made alkaline to litmus, extracted with ethyl acetate (3 × 300 ml), dried over magnesium sulfate, filtered, and concentrated to give 220 mg of an amber oil (9.3% yield).

N-[(1-Ethyl-2-pyrrolidinyl)methyl-5-oxo]-5-sulfamoyl-2-anisamide (II)—A 100-ml single-neck flask equipped with a magnetic stirrer, reflux condenser, and drying tube was used. Thionyl chloride (50 ml, 0.68 mole) and 2-methoxy-5-sulfamoyl-benzoic acid (7.0 g, 26.6 mmole) were mixed, pyridine (4 drops) was added, and the reaction was heated at reflux overnight. The thionyl chloride was removed *in vacuo*, and benzene (2 × 50 ml) was added and removed *in vacuo* to remove the final traces of thionyl chloride.

α-Aminomethyl-*N*-ethyl-2-pyrrolidinone (XIV) (220 mg, 1.55 mmoles) and triethylamine (160 mg, 1.58 mmoles) were dissolved in 10 ml of chloroform in a 50-ml flask equipped with a magnetic stirrer and a reflux condenser, and cooled in ice. A chloroform solution (3.5 ml) containing 2-methoxy-5-sulfamoyl-benzoyl chloride (402 mg, 1.61 mmoles) was added dropwise (a slight exotherm was observed). The reaction was stirred to room temperature and then heated at reflux for 3.5 hr. The mixture was cooled, concentrated, and the resulting gummy black tar was triturated with water and allowed to stand. A gray solid formed, which was filtered and air dried, to yield 40 mg of the desired product. Further trituration of the solid with absolute methanol followed by filtering and air drying gave a gray solid (mp 228° with decomposition, 7.2%).

The melting points were obtained on a melting point apparatus[6] and are uncorrected. The elemental analyses for these compounds are given in Table I.

[6] Thomas–Hoover.

DISCUSSION

The major metabolite of sulpiride in monkeys was obtained by isolation from urine followed by chromatographic purification. The chromatogram in Fig. 3 represents the sample that was submitted for identification by ^{1}H-NMR, chemical ionization mass spectroscopy, and HPLC. Comparison for the ^{1}H-NMR spectra of the metabolite and sulpiride showed that some biotransformation had occurred to the pyrrolidine ring, where it appeared that alpha oxidation had taken place similar to the model compounds, VI–VIII.

This conclusion was further supported by the fact that sulpiride is retained on a cation exchange column, while metabolite II can be eluted with an acidic solvent system. The different chemical behavior of these two species was attributed to the differences in the basicity of the sulpiride pyrrolidine ring nitrogen, which was a tertiary amine prior to biotransformation and subsequently was converted into a cyclic amide of lesser basicity. The synthesis of compound II by an unambiguous route (Scheme I) and analysis by ^{1}H-NMR of the synthetic material gave unequivocal evidence that alpha oxidation had occurred. In addition, a sample of the radiolabeled metabolite and the synthetically prepared sample were compared by HPLC and found to have identical retention times (Fig. 5).

Previous attempts to obtain a mass spectrum on II by electron impact had failed, probably due to the presence of impurities. Subsequently, chemical ionization mass spectral data were obtained on the same sample that had been subjected to ^{1}H-NMR. The spectrum was of good quality and demonstrated that II has a molecular weight of 355. A compound of molecular weight 369 ($\simeq$10%) was also observed. Although its structure has not been identified, it has undergone oxidation at two methylene groups and may be the compound shown by XVI.

Isolation of the metabolite by column chromatography and purification by HPLC with subsequent identification by Fourier transform-NMR, chemical ionization mass spectroscopy, HPLC, and unambiguous chemical synthesis has shown that the structure of the major metabolite of sulpiride is II.

Potential Radiosensitizing Agents III: 2-Nitro-4-Acetylimidazole Analogs

RAJ K. SEHGAL and KRISHNA C. AGRAWAL ˣ

Received November 2, 1981, from the *Department of Pharmacology, Tulane University School of Medicine, New Orleans, LA 70112.* Accepted for publication, December 31, 1981.

Abstract □ New analogs of 2-nitroimidazole have been synthesized in an effort to minimize the toxicity and increase selective sensitization of hypoxic mammalian cells toward lethal effects of ionizing radiation. 2-Nitro-4(5)-acetyl-5(4)-methylimidazole was synthesized from the corresponding 2-amino analog and then reacted with oxiranes to produce the corresponding 1-substituted 2-propanol and 3-methoxy-2-propanol derivatives. The biological results of radiosensitizing activity of these agents against Chinese hamster cells (V-79) indicated that the 3-methoxy-2-propanol derivative was a more effective radiosensitizer than misonidazole *in vitro*. Evaluation of the acute toxicity of these agents as determined by LD_{50} demonstrated no significant difference between these agents and misonidazole suggesting that the 3-methoxy-2-propanol analog may possess a therapeutic advantage over misonidazole.

Keyphrases □ Radiosensitizing agents, potential—2-nitro-4-acetylimidazole analogs □ 2-Nitro-4-acetylimidazole—analogs, potential radiosensitizing agents □ Analogs—2-nitro-4-acetylimidazole, potential radiosensitizing agents

In a continuing effort to develop new effective radiosensitizers to sensitize selectively the relatively resistant hypoxic tumor cells toward radiotherapy, an additional electron affinic acetyl function has been incorporated into the 2-nitroimidazole nucleus. A direct correlation between the sensitizing efficiency and electron affinity of the radiosensitizers has been demonstrated (1). Initially, a series of 2,4-dinitroimidazoles were synthesized in an effort to increase the electron affinity of the 2-nitroimidazole nucleus (2, 3). The 1-(2-hydroxy-3-methoxypropyl)-2,4-dinitroimidazole was found to be the most effective radiosensitizer of this series (4). However, the 2,4-dinitroimidazole derivatives were found to be generally more toxic than misonidazole (5), an agent currently under clinical trials for evaluation as a radiosensitizer. It was deemed desirable to study the effect of another electron affinic group other than the nitro function at the 4-position of the 2-nitroimidazole nucleus. Accordingly, 4-acetyl substituted 2-nitroimidazole analogs have been synthesized. This modification was thought to be of interest in view of the report that 1-methyl-2-nitroimidazole-5-carboxaldehyde sensitized the hypoxic Chinese hamster cells *in vitro* to ionizing radiation at much lower concentrations (25 μM) than misonidazole (1).

BACKGROUND

It is obvious that an aldehyde function is a metabolically unstable group, and perhaps in addition to high electron affinity, lack of an hydroxyl group in the side chain at the 1-position may have contributed toward enhanced cytotoxicity of this agent. Therefore, the synthesis of 4-acetyl analogs of 2-nitroimidazole with a 2-hydroxypropyl side chain at the 1-position was undertaken. The molecular design of agents described in this report was also related to the structure of metronidazole, a known but less potent radiosensitizer than misonidazole, in that the functional groups at 2- and 5-positions were reversed to provide a 2-nitro-5-methyl analog, since 2-nitroimidazoles have been reported to be more effective radiosensitizers (6).

The synthesis of the required intermediate 2-amino-4(5)-acetyl-5(4)-methylimidazole (III) was accomplished by the known mononuclear 1,2,4-oxadiazole imidazole rearrangement with minor modification of utilizing sodium methoxide in dimethylformamide rather than sodium ethoxide as a base (7). The starting material 3-amino-5-phenyl-1,2,4-oxadiazole, readily obtained from hydrolysis of the *N,O*-dibenzoyl hydroxyguanidine (8), was condensed with an equimolar amount of acetylacetone in anhydrous toluene in the presence of *p*-toluenesulfonic acid

DISCUSSION

The major metabolite of sulpiride in monkeys was obtained by isolation from urine followed by chromatographic purification. The chromatogram in Fig. 3 represents the sample that was submitted for identification by ^{1}H-NMR, chemical ionization mass spectroscopy, and HPLC. Comparison for the ^{1}H-NMR spectra of the metabolite and sulpiride showed that some biotransformation had occurred to the pyrrolidine ring, where it appeared that alpha oxidation had taken place similar to the model compounds, VI–VIII.

This conclusion was further supported by the fact that sulpiride is retained on a cation exchange column, while metabolite II can be eluted with an acidic solvent system. The different chemical behavior of these two species was attributed to the differences in the basicity of the sulpiride pyrrolidine ring nitrogen, which was a tertiary amine prior to biotransformation and subsequently was converted into a cyclic amide of lesser basicity. The synthesis of compound II by an unambiguous route (Scheme I) and analysis by ^{1}H-NMR of the synthetic material gave unequivocal evidence that alpha oxidation had occurred. In addition, a sample of the radiolabeled metabolite and the synthetically prepared sample were compared by HPLC and found to have identical retention times (Fig. 5).

Previous attempts to obtain a mass spectrum on II by electron impact had failed, probably due to the presence of impurities. Subsequently, chemical ionization mass spectral data were obtained on the same sample that had been subjected to ^{1}H-NMR. The spectrum was of good quality and demonstrated that II has a molecular weight of 355. A compound of molecular weight 369 ($\simeq$10%) was also observed. Although its structure has not been identified, it has undergone oxidation at two methylene groups and may be the compound shown by XVI.

Isolation of the metabolite by column chromatography and purification by HPLC with subsequent identification by Fourier transform-NMR, chemical ionization mass spectroscopy, HPLC, and unambiguous chemical synthesis has shown that the structure of the major metabolite of sulpiride is II.

Potential Radiosensitizing Agents III: 2-Nitro-4-Acetylimidazole Analogs

RAJ K. SEHGAL and KRISHNA C. AGRAWAL ˣ

Received November 2, 1981, from the *Department of Pharmacology, Tulane University School of Medicine, New Orleans, LA 70112.* Accepted for publication, December 31, 1981.

Abstract □ New analogs of 2-nitroimidazole have been synthesized in an effort to minimize the toxicity and increase selective sensitization of hypoxic mammalian cells toward lethal effects of ionizing radiation. 2-Nitro-4(5)-acetyl-5(4)-methylimidazole was synthesized from the corresponding 2-amino analog and then reacted with oxiranes to produce the corresponding 1-substituted 2-propanol and 3-methoxy-2-propanol derivatives. The biological results of radiosensitizing activity of these agents against Chinese hamster cells (V-79) indicated that the 3-methoxy-2-propanol derivative was a more effective radiosensitizer than misonidazole *in vitro*. Evaluation of the acute toxicity of these agents as determined by LD_{50} demonstrated no significant difference between these agents and misonidazole suggesting that the 3-methoxy-2-propanol analog may possess a therapeutic advantage over misonidazole.

Keyphrases □ Radiosensitizing agents, potential—2-nitro-4-acetylimidazole analogs □ 2-Nitro-4-acetylimidazole—analogs, potential radiosensitizing agents □ Analogs—2-nitro-4-acetylimidazole, potential radiosensitizing agents

In a continuing effort to develop new effective radiosensitizers to sensitize selectively the relatively resistant hypoxic tumor cells toward radiotherapy, an additional electron affinic acetyl function has been incorporated into the 2-nitroimidazole nucleus. A direct correlation between the sensitizing efficiency and electron affinity of the radiosensitizers has been demonstrated (1). Initially, a series of 2,4-dinitroimidazoles were synthesized in an effort to increase the electron affinity of the 2-nitroimidazole nucleus (2, 3). The 1-(2-hydroxy-3-methoxypropyl)-2,4-dinitroimidazole was found to be the most effective radiosensitizer of this series (4). However, the 2,4-dinitroimidazole derivatives were found to be generally more toxic than misonidazole (5), an agent currently under clinical trials for evaluation as a radiosensitizer. It was deemed desirable to study the effect of another electron affinic group other than the nitro function at the 4-position of the 2-nitroimidazole nucleus. Accordingly, 4-acetyl substituted 2-nitroimidazole analogs have been synthesized. This modification was thought to be of interest in view of the report that 1-methyl-2-nitroimidazole-5-carboxaldehyde sensitized the hypoxic Chinese hamster cells *in vitro* to ionizing radiation at much lower concentrations (25 μM) than misonidazole (1).

BACKGROUND

It is obvious that an aldehyde function is a metabolically unstable group, and perhaps in addition to high electron affinity, lack of an hydroxyl group in the side chain at the 1-position may have contributed toward enhanced cytotoxicity of this agent. Therefore, the synthesis of 4-acetyl analogs of 2-nitroimidazole with a 2-hydroxypropyl side chain at the 1-position was undertaken. The molecular design of agents described in this report was also related to the structure of metronidazole, a known but less potent radiosensitizer than misonidazole, in that the functional groups at 2- and 5-positions were reversed to provide a 2-nitro-5-methyl analog, since 2-nitroimidazoles have been reported to be more effective radiosensitizers (6).

The synthesis of the required intermediate 2-amino-4(5)-acetyl-5(4)-methylimidazole (III) was accomplished by the known mononuclear 1,2,4-oxadiazole imidazole rearrangement with minor modification of utilizing sodium methoxide in dimethylformamide rather than sodium ethoxide as a base (7). The starting material 3-amino-5-phenyl-1,2,4-oxadiazole, readily obtained from hydrolysis of the *N,O*-dibenzoyl hydroxyguanidine (8), was condensed with an equimolar amount of acetylacetone in anhydrous toluene in the presence of *p*-toluenesulfonic acid

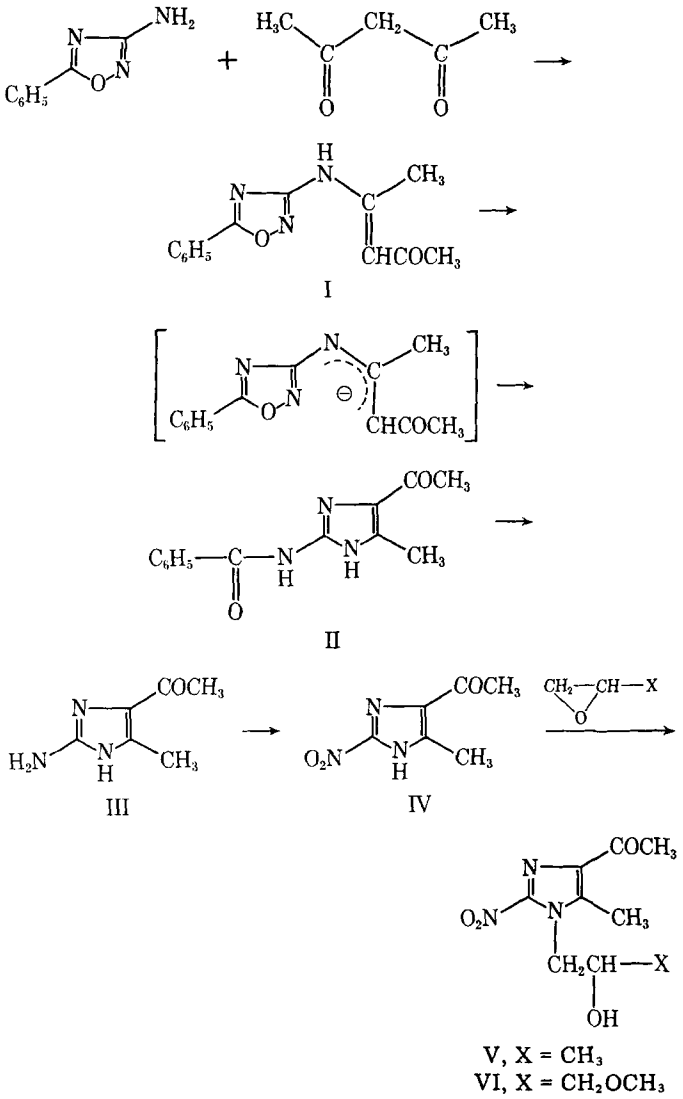

Scheme I

as a catalyst, removing azeotropically the reaction water to give the enaminoketone I (Scheme I). Treatment of I with a molar equivalent amount of sodium methoxide in anhydrous dimethylformamide caused isomerization to the anticipated 2-benzoylaminoimidazole (II). Acid hydrolysis of II afforded the 2-aminoimidazole analog (III). 2-Nitro-4(5)-acetyl-5(4)-methylimidazole (IV) was prepared from the corresponding 2-aminoimidazole derivative (III) by diazotization in fluoroboric acid followed by the reaction of the diazonium salt with nitrous acid in the presence of copper sulfate. Treatment of IV with propylene oxide in absolute ethanol, in the presence of a catalytic amount of sodium hydroxide, afforded Alcohol V. Reaction of IV with 1,2-epoxy-3-methoxypropane during 16 hr at 80° under reflux afforded alcohol VI. In each case the reaction with oxiranes produced the corresponding 4-acetyl analog and not the 5-acetyl isomer, suggesting that the reaction mechanism may be similar to the reaction of 2,4(5)-dinitroimidazoles with oxiranes as reported earlier (4).

EXPERIMENTAL

IR spectra were recorded on a spectrophotometer[1] as potassium bromide pellets. PMR spectra were recorded on a 90-MHz spectrometer[2] using tetramethylsilane as the internal reference. Electron-impact mass spectra were run on a spectrometer[3] at 70 eV ionization potential using direct inlet injection. The elemental analyses[4] were within ±0.4% of the theoretical values. Melting points were determined on glass cover slips[5] and are uncorrected. Analytical TLC was performed on plastic plates coated with a 0.25-mm layer of silica gel[6] GF_{254} and the compounds were detected by visual examination under UV light (254 nm).

4(5)-Acetyl-5(4)-methyl-2-nitroimidazole (IV)—4(5)-Acetyl-5(4)-methyl-2-aminoimidazole (III) (0.556 g, 4 mmoles) (7) was dissolved in a mixture containing 10 ml of water, 0.5 ml of sulfuric acid, and 3.5 ml of 50% fluoroboric acid. The solution was then cooled to −20° in an ice–salt bath and a solution of sodium nitrite (2.76 g, 40 mmoles) in 5 ml of water was added dropwise to the cooled 2-aminoimidazolium sulfate solution. The mixture was stirred at −10° for 1 hr and then added to a solution of copper sulfate (19.97 g, 80 mmoles) in 150 ml of water. An additional 2.76 g of sodium nitrite was added to this mixture and stirred at room temperature overnight. The pH of the mixture was then adjusted to ~2.0 with dilute nitric acid. The mixture was repeatedly extracted with ethyl acetate (8 × 30 ml), dried over sodium sulfate, and the solvent removed under reduced pressure to leave a yellow residue, which was recrystallized (ethyl ether–hexane) to afford 210 mg (31%): mp 155–156°; IR (KBr) 1652 (CO) 1540 and 1342 (NO_2) cm^{-1}; NMR ($CDCl_3$) δ 2.68 [s, CH_3CO (CH_3)], 2.72 [s, $CH_3(CH_3CO)$]; MS, *m/z* 169 (M^+), 154 (M—CH_3), 122 [M—(NO_2+H)], 108 [M—(NO_2+CH_3)].

Reaction of 4(5)-Acetyl-5(4)-methyl-2-nitroimidazole (IV) with 1,2-Epoxy-3-methoxypropane—A solution of IV (0.169 g, 1 mmole) in 2.5 ml of 1,2-epoxy-3-methoxypropane was initially stirred at room temperature for 8 hr. The reaction was found to be negligible as followed by TLC in ethyl acetate; however, it was completed upon further heating the solution to 80° under reflux for 16 hr. The excess oxirane was removed under diminished pressure to leave a residual oil, which was recrystallized (ethyl ether) to afford 148 mg (58%) of VI: mp 126–127°; IR (KBr) 3367 (OH), 1667 (CO), 1540 and 1350 (NO_2) cm^{-1}; NMR ($CDCl_3$) δ 2.64 [s, $CH_3CO(CH_3)$], 2.76 [s, $CH_3(CH_3CO)$], 4.28 (m, NCH_2), 4.64 (m, CHO), 3.60 (d), and 3.51 (s, CH_2OCH_3): MS, *m/z* 257 (M+), 242 (M—CH_3), 240 (M—OH), 211 (M—NO_2).

Anal.—Calc. for $C_{10}H_{15}N_3O_5$: C, 46.69; H, 5.84; N, 16.34. Found: C, 46.75; H, 5.62; N, 16.41.

Biological Studies—The cytotoxicity studies were carried out by employing asynchronous monolayer cultures of Chinese hamster cells (V-79). The techniques used for culturing and handling this cell line were followed as previously reported (2). To determine differential cytotoxicity between the oxic and hypoxic cells, ~200 cells were plated in petri dishes[7] (60 × 15 mm) containing 3 ml of minimum essential medium with 15% fetal calf serum and allowed to attach for 2 hr. The medium was then removed by aspiration and replaced by the medium containing an appropriate concentration of the compound under study. The cells were exposed to a range of concentrations of each compound for intervals of 2, 4, and 8 hr at 37° in air or in hypoxia. The hypoxia was achieved by placing the open petri dishes in sealed containers and then purging with nitrogen–carbon dioxide (95:5). The gas mixture was bubbled through a flask containing sterile water before entering the sealed containers to maintain humidity inside the chambers. At the end of the specific time interval, the medium containing the drug was removed and replaced with 3 ml of fresh medium. Cultures were incubated for 6 days at 37° in an atmosphere of air–carbon dioxide (95:5); the resulting colonies were fixed in absolute ethanol, stained with methylene blue, and counted.

The radiosensitization studies were carried out by irradiating the cells inside the sealed containers under hypoxia by employing a cobalt 60 source at a dose rate of ~240 rad/min. Complete survival curves were obtained for each compound at radiation doses of 400–3000 rad under oxic and hypoxic conditions. The D_0 values were calculated for the hypoxic control cells and for the hypoxic cells treated with the drug. The ratio of these two D_0 values provided the sensitizer enhancement ratio of the corresponding agent.

Partition Coefficients—The compounds were dissolved in phosphate buffer (0.1 *M*, pH 7.4) and were then stirred with an equal volume of octanol at room temperature for 1 hr. The concentration of the nitroimidazoles in the aqueous phase was determined spectrophotometrically at 320 nm.

Table I—Sensitizer Enhancement Ratios, LD_{50} Values, and Partition Coefficients of 2-Nitro-4-acetylimidazole Analogs

Compound	SER[a]	LD_{50}[b], mg/kg	PC[c]
V	2.1	1,200	2.46
VI	1.9	1,400	1.07
Misonidazole	1.9	1,300	0.43

[a] Sensitizer enhancement ratio determined by dividing the D_0 value for the control hypoxic cells with the D_0 value obtained for the cells irradiated in the presence of the sensitizer. [b] LD_{50} values were determined in C57BL mice by the standard procedures. [c] Partition coefficients.

RESULTS AND DISCUSSION

Both Compounds V and VI were essentially nontoxic to the Chinese hamster cells up to a concentration of 5 m*M* when exposed to a maximum period of 8 hr under oxic conditions. However, when the cells were exposed to various drug concentrations under nitrogen, Compounds V and VI were differentially more toxic to the hypoxic cells, and the toxicity increased as a function of time with increased concentration (Figs. 1 and 2, respectively). Similar differential cytotoxicity has been reported for other nitroimidazoles (9) and has been related to the metabolic reduction of the drug under hypoxia, causing the production of the reduced intermediates that are toxic to the cells (10). Compound V was comparatively more toxic to the hypoxic Chinese hamster cells than VI. The hypoxic toxicity increased with time and drug concentration. Compound V, although nontoxic, at 1.0 m*M* concentration upon 2 hr of exposure, caused >50% inhibition by 8 hr (Fig. 1). Compound VI did not show significant differential cytotoxicity up to a concentration of 1 m*M* and required higher concentrations and increasing incubation time for hypoxic cytotoxicity (Fig. 2).

The radiosensitizing efficiency of these agents was assessed from the radiation survival curves of hypoxic Chinese hamster cells (Fig. 3). These experiments were conducted at a nontoxic concentration of 1 m*M*, and the sensitizer enhancement ratios were calculated by dividing the D_0 value for the control hypoxic cells with the D_0 value obtained for the cells irradiated in the presence of the radiosensitizer under nitrogen. The enhancement ratios for Compounds V and VI were found to be 2.1 and 1.9, respectively (Table I). Misonidazole, under similar conditions, produced an enhancement ratio of 1.9 at 1 m*M* concentration, suggesting that V is, comparatively, a more effective radiosensitizer.

Although 2,4-dinitroimidazole derivatives have been shown to be more efficient radiosensitizers than 2-nitroimidazoles *in vitro* (4), the powerful electron withdrawing group at the 4-position also causes an increase in

[7] Permanox, Lux Scientific Corp.

cytotoxicity (5). In attempts to develop radiosensitizers relatively less toxic than misonidazole, the results obtained upon introducing an acetyl function at the 4-position of 2-nitroimidazole have been described in this report. The acetyl function, although relatively less powerful than the nitro group with respect to the electron withdrawing capacity, has been reported to possess radiosensitizing properties (11). It was contemplated that the insertion of an acetyl function in the 2-nitroimidazole molecule may provide analogs which are comparatively less toxic than the 2,4-dinitroimidazoles. The *in vivo* acute toxicity of these agents was assessed by determining the LD_{50} in C57BL mice. Compounds V and VI were found to have an LD_{50} of 1.2 and 1.4 g/kg, respectively (Table I). These values are similar to misonidazole, which had an LD_{50} of 1.3 g/kg but are greater than the LD_{50} of 2,4-dinitroimidazoles (5). These agents are relatively less toxic than the corresponding dinitroimidazoles as expressed by the doses required for acute toxicity. The partition coefficients of these agents were determined in an octanol–phosphate buffer (pH 7.4) mixture. Compounds V and VI are more lipophilic than misonidazole (Table I), a property that would be expected to be favorable for *in vivo* diffusion into the hypoxic region of the tumors. This work has demonstrated that an additional electron affinic group could be inserted in the misonidazole molecule without significantly increasing the acute toxicity and yet enhancing the sensitizing efficiency. Thus, V may possess a therapeutic advantage over misonidazole as a radiosensitizer.

The Hydrolysis of Spirohydantoin Mustard

K. P. FLORA, J. C. CRADOCK, and J. A. KELLEY ˣ

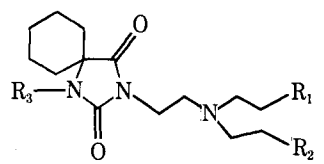
Received July 23, 1981, from the *Pharmaceutical Resources Branch, and the Laboratory of Medicinal Chemistry and Biology, Division of Cancer Treatment, National Cancer Institute, National Institutes of Health, Bethesda, MD 20205.* Accepted for publication January 13, 1982.

Abstract □ Spirohydantoin mustard (I) is a rationally designed antitumor agent with substantial *in vivo* activity against intracranially implanted tumors in mice. However, hydrolysis of I was much faster than that of mechlorethamine hydrochloride or melphalan, two parenterally administered mustards. The hydrolysis products of I were identified by GC–MS of their silylated derivatives. The decomposition of I (at 25° in 10% dimethylacetamide at pH 4–6), as monitored by GLC was pseudo first-order. The half-life of I ranged from 20 min at pH 4.0 to 14 min at pH 6.0. Nonionic surfactants enhanced the stability of I, but this effect was diminished at lower pH, presumably due to decreased solubility of I in the micelle as more drug was protonated. Several dilute parenterally suitable solvents exhibited no marked effect on the hydrolysis of I. The drug was most stable in a 10% fat emulsion system where the time for 10% decomposition of I was 49 ± 5 min. Plots of the concentration of I *versus* time were linear indicating the disappearance was zero order in the 10% fat emulsion system.

Keyphrases □ Spirohydantoin mustard—hydrolysis, antitumor agent, mechlorethamine hydrochloride, melphalan, mice □ Hydrolysis—spirohydantoin mustard, antitumor agent, mechlorethamine hydrochloride, melphalan, mice □ Antitumor agents—hydrolysis of spirohydantoin mustard, mice

Spirohydantoin mustard (I) (NSC-172112), 3-[2-[bis(2′- chloroethyl)amino] - ethyl] - 5,5 - pentamethylenehydantoin, is a potential antitumor agent that has been designed specifically for use against central nervous system tumors. Compound I has demonstrated significant antitumor activity against L-1210 leukemia, P-388 leukemia, B-16 melanoma, and ependymoblastoma when administered in an aqueous suspension by the intraperitoneal route (1). Compound I was designed to incorporate a mustard alkylating function coupled to a substituted hydantoin carrier to provide an overall optimum partition coefficient for crossing the blood–brain barrier (1). A preliminary pharmacological study in dogs indicates that I does enter the central nervous system, although actual concentrations in cerebrospinal fluid are low (2).

As is often the case with nitrogen mustard derivatives, solution decomposition problems are evident. The aqueous stability of I and related compounds is such that octanol–water partition coefficients could not be determined (1). Preliminary chloride titration data also indicate that the decomposition of I in aqueous solution is rapid. In fact, the decomposition of I is more rapid than the hydrolysis of either of two clinically useful mustards, melphalan or mechlorethamine hydrochloride. In addition, the aqueous solubility of I is limited (<10 μg/ml) (3). Dissolution in concentrated acid with subsequent dilution is possible (1.25 mg/ml); however, the upward adjustment of pH usually results in precipitation of the drug. Likewise, I has



I $R_1 = R_2 = -Cl$; $R_3 = -H$
Ia $R_1 = R_2 = -Cl$; $R_3 = -$Trimethylsilyl or $-Si(CH_3)_3$
II $R_1 = -Cl$; $R_2 = -OH$; $R_3 = -H$

The Hydrolysis of Spirohydantoin Mustard

K. P. FLORA, J. C. CRADOCK, and J. A. KELLEY ˣ

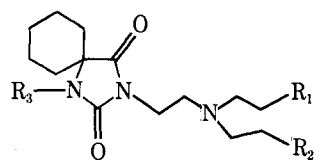
Received July 23, 1981, from the *Pharmaceutical Resources Branch, and the Laboratory of Medicinal Chemistry and Biology, Division of Cancer Treatment, National Cancer Institute, National Institutes of Health, Bethesda, MD 20205.* Accepted for publication January 13, 1982.

Abstract □ Spirohydantoin mustard (I) is a rationally designed antitumor agent with substantial *in vivo* activity against intracranially implanted tumors in mice. However, hydrolysis of I was much faster than that of mechlorethamine hydrochloride or melphalan, two parenterally administered mustards. The hydrolysis products of I were identified by GC–MS of their silylated derivatives. The decomposition of I (at 25° in 10% dimethylacetamide at pH 4–6), as monitored by GLC was pseudo first-order. The half-life of I ranged from 20 min at pH 4.0 to 14 min at pH 6.0. Nonionic surfactants enhanced the stability of I, but this effect was diminished at lower pH, presumably due to decreased solubility of I in the micelle as more drug was protonated. Several dilute parenterally suitable solvents exhibited no marked effect on the hydrolysis of I. The drug was most stable in a 10% fat emulsion system where the time for 10% decomposition of I was 49 ± 5 min. Plots of the concentration of I *versus* time were linear indicating the disappearance was zero order in the 10% fat emulsion system.

Keyphrases □ Spirohydantoin mustard—hydrolysis, antitumor agent, mechlorethamine hydrochloride, melphalan, mice □ Hydrolysis—spirohydantoin mustard, antitumor agent, mechlorethamine hydrochloride, melphalan, mice □ Antitumor agents—hydrolysis of spirohydantoin mustard, mice

Spirohydantoin mustard (I) (NSC-172112), 3-[2-[bis(2′- chloroethyl)amino] - ethyl] - 5,5 - pentamethylenehydantoin, is a potential antitumor agent that has been designed specifically for use against central nervous system tumors. Compound I has demonstrated significant antitumor activity against L-1210 leukemia, P-388 leukemia, B-16 melanoma, and ependymoblastoma when administered in an aqueous suspension by the intraperitoneal route (1). Compound I was designed to incorporate a mustard alkylating function coupled to a substituted hydantoin carrier to provide an overall optimum partition coefficient for crossing the blood–brain barrier (1). A preliminary pharmacological study in dogs indicates that I does enter the central nervous system, although actual concentrations in cerebrospinal fluid are low (2).

As is often the case with nitrogen mustard derivatives, solution decomposition problems are evident. The aqueous stability of I and related compounds is such that octanol–water partition coefficients could not be determined (1). Preliminary chloride titration data also indicate that the decomposition of I in aqueous solution is rapid. In fact, the decomposition of I is more rapid than the hydrolysis of either of two clinically useful mustards, melphalan or mechlorethamine hydrochloride. In addition, the aqueous solubility of I is limited (<10 μg/ml) (3). Dissolution in concentrated acid with subsequent dilution is possible (1.25 mg/ml); however, the upward adjustment of pH usually results in precipitation of the drug. Likewise, I has



I $R_1 = R_2 = -Cl$; $R_3 = -H$
Ia $R_1 = R_2 = -Cl$; $R_3 = -$Trimethylsilyl or $-Si(CH_3)_3$
II $R_1 = -Cl$; $R_2 = -OH$; $R_3 = -H$
IIa $R_1 = -Cl$; $R_2 = -OSi(CH_3)_3$; $R_3 = -Si(CH_3)_3$
III $R_1 = R_2 = -OH$; $R_3 = -H$
IIIa $R_1 = R_2 = -OSi(CH_3)_3$; $R_3 = -Si(CH_3)_3$
IV $R_1 = -OH$; $R_2 = -OCOCH_3$; $R_3 = -H$
IVa $R_1 = -OSi(CH_3)_3$; $R_2 = -OCOCH_3$; $R_3 = -Si(CH_3)_3$

considerable solubility in some organic solvents (*e.g.*, >300 mg/ml in dimethylacetamide); however, dilution with aqueous solutions usually causes the drug to precipitate.

The purpose of this study was to investigate the effect of pH and the presence of various excipients on the hydrolysis of I with emphasis on impeding degradation. Successful approaches would be applied to the development of a parenteral dosage form suitable for clinical trial.

EXPERIMENTAL

Materials—Dimethylacetamide[1], polysorbate 20[2], polysorbate 80[2], two polyoxyethylated castor oils[3,4], stearylcetyl alcohol ethoxylate[5], propylene glycol[6], bovine albumin[7], thymol[8], thymol blue[8], gelatin[9], spirohydantoin mustard (I)[10] (NSC-172112), mechlorethamine hydrochloride[10] (NSC-762), and melphalan (NSC-8806) were used as received. Compound III[10] was twice recrystallized from isopropanol–benzene (1:50) before use. All other chemicals were reagent grade. Citrate buffers (pH 3–6) were prepared by dilution of a 0.42 *M* stock solution of citric acid with subsequent addition of sodium hydroxide to the desired pH.

Hydrolysis Studies—Due to the limited solubility of I, studies of the hydrolysis at various pHs were conducted in 10% dimethylacetamide in citrate or ammonium acetate buffer (4.2×10^{-2} *M*), or under pH stat control. All reported pH values are in fact apparent pH values unless otherwise indicated. The mustard I was weighed, dissolved in dimethylacetamide, and then diluted with thermally equilibrated (25 ± 0.1°) water, buffer, or buffer plus excipient. Final drug concentration was 0.35 mg/ml unless otherwise indicated. All hydrolysis studies were run at 25 ± 0.1°.

Chloride Titration—The concentration of chloride ion was determined by the coulometric–amperometric titration[11] of aliquots of the hydrolysis mixture. A 0.5- or 1.0-ml aliquot was removed and diluted with 3.0 ml of 0.1 *N* nitric acid–10% acetic acid reagent. When a 0.5-ml aliquot was used, 0.5 ml of distilled water was added to keep the titration volume consistent at 4.0 ml. Four drops of a gelatin reagent containing 6.0 mg/ml of gelatin, 0.1 mg/ml of thymol blue, and 0.1 mg/ml of thymol were added prior to each titration. The titration was performed only if a red color, indicating that the mixture was sufficiently acidic (pH ~ 1.2), was present. The titrator was calibrated at the low titration rate using standard sodium chloride solutions. Blanks and standards were prepared to be of identical composition to the hydrolysis solution in terms of the buffers and excipients present.

Disappearance of I by GLC—Preliminary studies at pH 4.0 indicated that the efficient and simultaneous extraction of I, II, and III from sodium citrate or sodium acetate buffers was impractical, presumably because of the low pH. Extraction of I, II, and III could be avoided by using an ammonium acetate buffer which could be removed by freeze-drying the hydrolysis mixture. However, in this case, small peaks corresponding to acetate esters of III were detected within 90 min. Therefore, a bufferless system, which also required no extractive cleanup, was employed by using a titrator[12] operating in the pH stat mode. Sodium hydroxide (0.05 *M*) was used as the titrant. This system was capable of maintaining the pH of the solution at ±0.1 pH units during the course of the experiment.

In these hydrolysis studies a 2-ml aliquot of the hydrolysis mixture initially containing I at a concentration of 0.15 mg/ml and internal standard (phenytoin) was removed at appropriate times and immediately

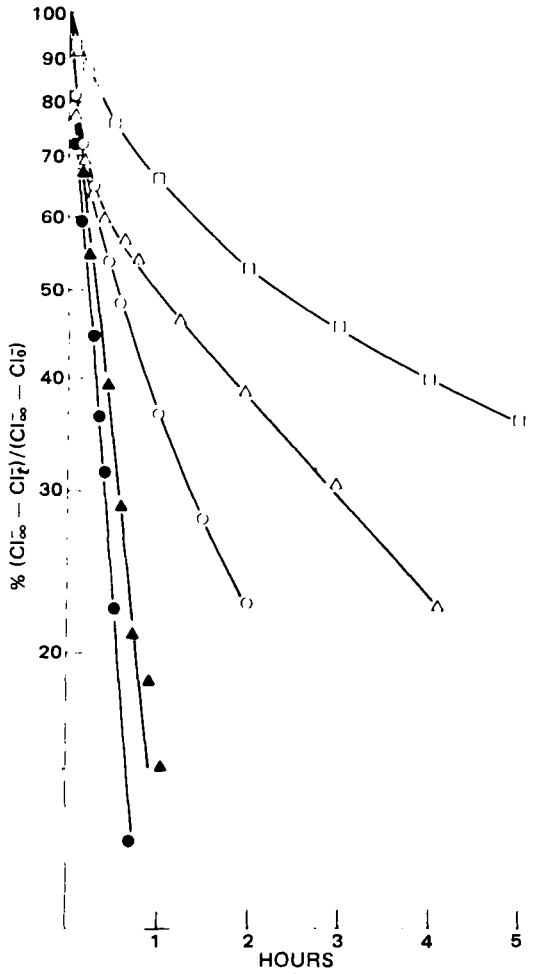

Figure 3—*The effect of pH on the hydrolysis of I (0.35 mg/ml) as determined by chloride titration. All pHs (apparent) are with sodium citrate buffer (4.2×10^{-2} M). Key: (□) pH 3.0; (△) pH 3.5; (○) pH 4.0; (▲) pH 5.0; (●) pH 6.0.*

frozen in glass vials (37.4 ml) prechilled on dry ice. Appropriate standards of I and III plus internal standard were similarly frozen. All samples were then placed on a prechilled shelf and freeze-dried[13]. The freeze-dried samples and standards were derivatized by reaction with 0.30 ml of a mixture of *N,O*-bis(trimethylsilyl)trifluoroacetamide[14]–acetonitrile (1:2) at room temperature for a minimum of 30 min. Shaking and sonication were employed to effect solution and reaction of the freeze-dried samples. Aliquots (4.0 μl) of the trimethylsilylation reaction mixture were analyzed by GLC[15] on a 1.83-m × 2-mm i.d. glass column packed with 3% SE-30 100/120 mesh Gas-Chrom Q[14] and installed for on-column injection. The gas chromatograph was temperature programmed from 210 to 240° at 2°/min after an initial delay of 3 min. Other operating parameters were: helium carrier gas flow, 30 ml/min; hydrogen, 30 ml/min; air, 300 ml/min; injector port, 255°; and flame ionization detector (FID), 260°. Samples were analyzed interspersed with standards so that standard curves of the peak area ratios of both I and III to internal standard were prepared for each hydrolysis experiment. The direct quantitation of I and III allowed II to be calculated by difference as well as a calculation of chloride ion so that a direct comparison with the coulometric–amperometric titrations could be made. A typical chromatogram is presented in Fig. 1.

GC–MS Analysis—Representative hydrolysis mixtures were also analyzed by GC–MS[16] under data system[17] control to identify the hydrolysis products. GC analysis parameters were identical to those used above, while the mass spectrometer operating conditions were: transfer line and jet separator, 255°; ion source, 260°; electron energy, 75 eV; ionizing current, 250 μamps; accelerating voltage, 1.6 kV; and scan speed, 2 sec/decade.

Table I—Comparison of Percent Total Chloride Liberated from I after Hydrolysis at pH 4.0 (apparent) in 0.042 *M* Ammonium Acetate Calculated from GLC and by Titration

Minutes	Percent Total Chloride Liberated: Calculated from GLC Data	Percent Total Chloride Liberated: Determined by Direct Titration
5	12.3	10.3
10	16.2	16.6
20	31.7	29.8
30	39.3	38.2
60	52.1	53.0

Stability in 10% Fat Emulsion by GLC—The disappearance of I in 10% fat emulsion[18] was monitored by GLC[19]. A measured volume of 10% fat emulsion (49.4 ml) was placed in a 50-ml flint serum vial which was closed with a butyl rubber stopper and an aluminum seal. The vial was secured to a mechanical mixer with tape. The mixer was started, and a solution of I in dimethylacetamide (50 mg in 0.6 ml) was injected directly into the emulsion using a 1-ml glass syringe equipped with an 8.89-cm, 22-gauge needle. The solution of I was injected at ~1 ml/min while the vigorous mixing continued. Duplicate 2-ml aliquots were drawn at designated times, placed in glass screw-capped vials (149.6 ml each) and were immediately frozen in a dry ice–acetone bath. A series of standards corresponding to 0.2, 0.5, 0.7, 1.0, and 1.5 mg/ml of I were prepared by adding appropriate amounts of I in ethyl acetate to the emulsion. Samples were immediately frozen. All samples and standards were freeze-dried in a shelf-type unit[13]. The freeze-dried residue was extracted with 5.0 ml of ethyl acetate containing 40 mg/ml tetraphenylethylene as an internal standard. Aliquots (2 μl) of the samples and standards were analyzed by GLC on a 1.83-m × 2-mm i.d. glass column packed with 3% OV-17 on 80/100 mesh Chromosorb WHP[20] and installed for on-column injection. The gas chromatograph was operated isothermally at 230°. Other operating parameters were: helium carrier gas flow, 22 ml/min; hydrogen, 28 ml/min; air, 350 ml/min; injector port, 240°, and FID, 250°. Samples were analyzed interspersed with standards. Quantitation was accomplished by an internal standard method using the ratio of peak heights of I to tetraphenylethylene. A typical chromatogram is seen in Fig. 2.

Antitumor Activity—The antitumor activity of I in an experimental formulation (5% dimethylacetamide in 10% fat emulsion[18]) was evaluated against a suspension of bulk I in the P-388 tumor. Studies were conducted according to standard National Cancer Institute protocols (4). The tumor inoculum was injected intraperitoneally. Drug treatment began the following day and continued for a total of 9 daily intraperitoneal injections.

RESULTS AND DISCUSSION

Chloride titrations of the bulk drug I used as received indicated no free chloride was present. Hydrolysis mixtures that were allowed to proceed

to completion yielded, by titration, the theoretical amount of chloride ion. The hydrolysis products, II and III, were identified as their trimethylsilyl derivatives (IIa and IIIa) by GC–MS analysis of a typical hydrolysis mixture.

Stability *Versus* pH by Chloride Titration—The hydrolysis of I in 10% dimethylacetamide and sodium citrate buffer (4.2×10^{-2} *M*) as a function of pH between pH 3.0 and pH 6.0 is shown in Fig. 3. The percent of chlorine remaining covalently bound in I and II is calculated based on the percent of the theoretical amount of chloride that has been liberated at a given time.

The liberation of chloride from I is a function of pH of the media as seen in Fig. 3. The rate of hydrolysis increases as the pH increases. The slower rate at lower pH may be due to the protonation of the nitrogen of the alkylating function which inhibits the formation of the postulated aziridinium ion intermediate (Scheme I). Over the pH range studied (3.0–6.0) the rate of hydrolysis is too rapid for practical application.

Stability *Versus* pH by GLC—Table I compares the percentage of total chloride liberated from I in 0.042 *M* ammonium acetate buffer at pH 4.0 as determined by immediate direct titration and as calculated on the basis of the amounts of I, II, and III present determined by GLC analysis. These data indicate that the required manipulations prior to GLC analysis (freezing, freeze-drying, and derivatization) did not produce additional hydrolysis of I. Similar data demonstrate the comparability of the two methods in the pH stat controlled experiments. However, in this instance, it was necessary to apply corrections to the titration data to compensate for chloride bleed from the pH electrode.

The concentrations of I, II, and III *versus* time at pH 4.0 (pH stat control) as determined by GLC are seen in Fig. 4. Trimethylsilylation was essential for forming volatile derivatives with good GC properties from the degradation products of I. Combined GC–MS analysis showed that the hydantoin nitrogen as well as any free hydroxyl groups were derivatized by *N,O-bis*(trimethylsilyl)trifluoroacetamide. Table II lists the isothermal retention indexes of these derivatives and summarizes their mass spectral fragmentation patterns. The predominant mode of fragmentation was cleavage at bonds α to the mustard nitrogen with charge retention on this nitrogen. When the ethylene moiety between the hydantoin ring and mustard nitrogen was cleaved, Fragment A resulted as a major ion. Cleavage of the other C—C bonds α to the mustard nitrogen resulted in loss of substituted methyl radicals to form abundant ions such as *m/z* 358 in IIa, *m/z* 412 in IIIa, and *m/z* 382 in IVa. Cleavage of the bond adjacent to the mustard nitrogen and charge retention on the hydantoin moiety produced Fragment B at *m/z* 267, which was found in the MS of every derivative. The presence or absence and number of chlorine atoms was also evident from the distinctive isotopic pattern of this element. This information, plus an indication of the molecular weight from the molecular ion and fragmentation due to neutral losses (*e.g.*, $M-CH_3$, M−HCl), was more than sufficient to determine the identity of these derivatives.

The disappearance of I was pseudo first-order as indicated by the linearity ($r > 0.998$) of plots of the log of concentration of I *versus* time at pH 4.0, 5.0, and 6.0 (pH stat control). Pseudo first-order rate constants (k_1) at pH 4.0, 5.0, and 6.0 were 0.0336, 0.0472, and 0.0492/min, respectively. This pH–hydrolysis rate relationship demonstrates the same trend seen with the chloride titration data (Fig. 3). If the hydrolysis of I is

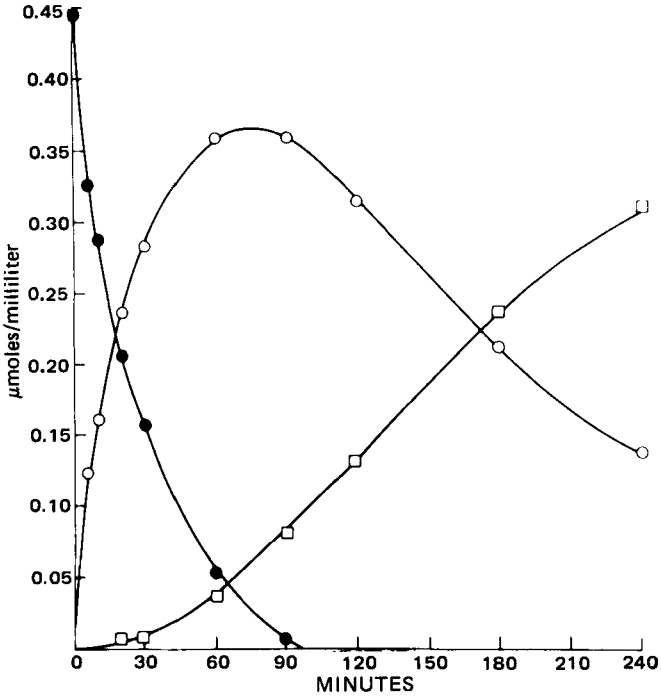

Figure 4—*Concentration* versus *time curves at pH 4.0 (apparent) and 25 ± 0.1°. Key: (●) I; (○) II; (□) III.*

represented by a mechanism comprised of consecutive pseudo first-order reactions (*i.e.*, $k_1 \gg k_{-1}$, $k_1 \ll k_2$, and $k_3 \gg k_{-3}$, $k_3 \ll k_4$),

$$I \xrightarrow{K_1} II \xrightarrow{k_3} III$$

where k_1 and k_3 are pseudo first-order rate constants, and it is possible to obtain estimates of k_3 by a method using dimensionless parameters and variables (5, 6). Application of this method gave $k_3 = k_1/14.0$ at pH 4.0 and $k_3 = k_1/1.9$ at pH 6.0.

Interpretation of Chloride Titration Data at Various pHs—The decomposition of I as a function of solution pH (Fig. 3) as determined by the titration of chloride ion shows a significant deviation from linearity in plots of percent chloride remaining $[\%(Cl_\infty^- - Cl_t^-)/(Cl_\infty^- - Cl_0^-)]$ *versus* time at ≤pH 4.0. To investigate any relationship these deviations might have with the protonation of I, II, or III, it was necessary to have information regarding their pKa values. The instability and limited solubility of I rendered pKa measurements impractical. However, it was possible to estimate by potentiometric titration with 0.05 *N* HCl a pKa of 6.4 for III. A spectrophotometric estimation of the pKa value for the dialcohol hydrolysis product of aniline mustard (NSC-18429) by a standard method (7) is 4.3. A published pKa for aniline mustard is 2.2 (8) indicating a 2.1-U difference between the pKa values of aniline mustard and its final hydrolysis product. If the aniline mustard–dialcohol model is roughly analogous the pKa of I may be ~4.3. The rate of hydrolysis of I or II decreases as pH decreases, presumably due to the protonation of the alkylating function nitrogen which inhibits aziridinium ion formation (an intermediate in the hydrolytic cleavage). A decrease in the rate of hydrolysis of I as pH decreases is reflected in the GLC data at pH 6.0, 5.0, and 4.0. If the pKa of II is taken to be intermediate between I and III the value would be 5.3. At pH 4.0 Compound II would be >95% protonated, which should significantly affect the hydrolysis rate (k_3) when compared to the rate at pH 6.0. This is supported by the data which indicate a sevenfold decrease in k_3 between pH 6.0 and 4.0. The decrease in the hydrolysis of I (k_1) between pH 6.0 and 4.0 is less dramatic, because with a pKa of 4.3 significant amounts of I remain unprotonated even at pH 4.0. The shape of the decomposition curves based on the release of chloride ion (Fig. 3) at ≤pH 4.0 are consistent with the lower rate (k_3) at which II releases chloride at low pH. The effect of various values of k_3/k_1 on the linearity of theoretical chloride ion plots have been described (9). It has also been shown (10) that an inverse relationship exists between hydrolysis rate and degree of protonation of a nitrogen mustard.

Chloride titration, although lacking specificity, is a useful tool in the investigation of the hydrolysis of nitrogen mustards. This is particularly true when used in a screening context (*e.g.*, to evaluate the effect of various solvent mixtures and other excipients on the hydrolysis rate).

Table III—Comparison of Stability of I to Melphalan and Mechlorethamine at 25°

Drug[a]	pH (apparent)	Time, Liberation of 50% Theoretical Cl^-, hr[b]
I	5.0	0.3
Melphalan	5.0	9.0
Mechlorethamine hydrochloride	5.0	8.4

[a] All drugs were 1×10^{-3} *M* in 10% dimethylacetamide–citrate buffer (4.2×10^{-2} *M*). [b] Determined graphically from a plot of log $(Cl_\infty^- - Cl_t^-)/(Cl_\infty^- - Cl_0^-)$ *versus* time.

However, particular care must be taken in the interpretation of chloride ion titration data derived from the hydrolysis of nitrogen mustards at pH near or between the pKa values for the intact mustard and its hydrolysis products. Since the titration of chloride is not a specific method (*i.e.*, the disappearance of I is not measured independently), the rate of chloride ion release measures the combined effect of both chloride generating reactions. Therefore, it is important to be aware of the effect of the relative magnitudes of k_1 and k_3 when interpreting such data.

Comparisons to Other Mustards—A comparison of the rates of hydrolysis as indicated by the liberation of chloride at pH 5.0 of I and two clinically useful mustards, mechlorethamine hydrochloride (NSC-762) and melphalan (NSC-8806), is presented in Table III. Compound I is much less stable than either of these mustards. The aromatic nitrogen mustards (melphalan and the aromatic hydantoin mustards described previously) (11) are inherently more stable due to the decreased basicity of the alkylating function nitrogen when attached to an aromatic ring. The apparent superior stability of mechlorethamine hydrochloride relative to I (Table III) is probably because of the fact that its more stable hydrochloride salt is formed (the formation of the aziridinium ion intermediate is blocked) and can be administered at a pharmaceutically acceptable pH (3.0–5.0 for the reconstituted USP product) (12). In contrast, the hydrochloride salt of I could be isolated only at pH <1 and upon storage was unstable[21]. Salt formation was effective for increasing solubility only at very low, pharmaceutically unacceptable pH values. Subsequent upward adjustment of pH caused precipitation of I.

Attempts to Stabilize I—The stability of I in the presence of a chemically diverse group of additives is seen in Table IV. Significant increases in the stability of some aromatic nitrogen mustards in the presence of surface active agents has been shown (13). Several surfactants slowed the hydrolysis of I (Table IV) with the best, stearylcetyl alcohol ethoxylate[5], increasing the half-life of I six- to sevenfold at pH 5.0. The increases in the stability of I appear to parallel the lipophilicity of the surface active agents. At lower pH (3.0 and 4.0) in the presence of 5% polyoxyethylated castor oil[3] the relative increases in stability of I are less. This diminished effect is probably due to a decreased solubility of I in the micelle as more drug is protonated. Solutions of up to 30% ethanol or 50% propylene glycol have no significant effect on the hydrolysis of I. Some mustards were found to be more stable in the presence of albumin (13, 14). However, the hydrolysis of I was very rapid in the presence of 5% albumin.

The disappearance of I as monitored by GLC at pH 4.0 in the presence of 0.15 *M* NaCl demonstrates the inhibitory effect of chloride ion on the hydrolysis of I. The pseudo first-order rate constant for the disappearance of I under these conditions is 0.00925/min. This reduced hydrolysis rate is not unexpected, since it has been shown previously with other nitrogen mustards using specific assay procedures (15, 16). None of these approaches has dramatically increased the stability of I.

10% Fat Emulsion System—The 10% fat emulsion system combines two approaches which have increased the stability of I (*i.e.*, isolation of I from the aqueous component of the vehicle as with the surfactants and inhibition by the presence of chloride ion).

The stability of I in a 10% fat emulsion was determined by GLC. Attempts to extract I directly from the 10% fat emulsion with ethyl acetate for GLC analysis were erratic with the recovery varying from 80 to 37% in the 1.0–0.2 mg/ml concentration range. Other extraction solvents gave similar results. However, the extraction of I with ethyl acetate from the residue remaining after freeze drying the 10% fat emulsion was more consistent. An extraction efficiency of 89.4 ± 3.3% was observed over the 1–0.15 mg/ml concentration range. Compounds II and III were not extracted under these conditions. The relative standard deviation for the overall extraction GLC procedure was 5.0% on the basis of 10 extracted samples (0.7 mg/ml of I). Determination of the concentration of I by GLC in the emulsion system with subsequent filtration through a 0.45-μm filter and reassay indicated that the drug does not precipitate at 1 mg/ml. However, at 2 mg/ml considerable precipitation had occurred.

[21] J. S. Driscoll, Laboratory of Medicinal Chemistry and Biology, National Cancer Institute, personal communication, 1979.

Table IV—Stability of I in Various Media at 25 ± 0.1°

pH (apparent)	Media[a]	Time, Liberation of 50% Theoretical Cl^-, hr[b]

[a] In addition to the component listed, each solution contained 10% dimethylacetamide and sodium citrate buffer 4.2×10^{-2} *M*. [b] Graphically estimated from a plot of log $(Cl_\infty^- - Cl_t^-)/(Cl_\infty^- - Cl_0^-)$ *versus* time. [c] Tween 20. [d] Tween 80. [e] Cremophor El. [f] Siponic E-7. [g] Emulphor EL-719.

The disappearance of I in 10% fat emulsion was monitored by GLC. Plots of the concentration of I *versus* time were linear ($r > 0.99$). The release of I from the fat component of the emulsion may be the rate-limiting step.

A fat emulsion identical to the one used in this report has been used as a vehicle for another unstable antitumor agent (17). Also, large volumes of the fat emulsion alone have been used clinically as a nutritional source (17, 18). A projected human dose for I derived by the application of equivalent surface area dosage conversion factors described previously (19) to the mouse antitumor data would indicate a dose of 6–48 mg for a 60-kg human. This would require the administration of 6–48 ml of the 10% fat emulsion formulation (1 mg/ml of I). A formulation of another antitumor agent in 10% fat emulsion has been given at 1 ml/min with no adverse effects (17). At the time of use, a vial containing I produced by low temperature vacuum drying (20) would be dissolved in dimethylacetamide with the resulting solution being added to the fat emulsion as described in the Experimental section. Administration of appropriate doses of the formulation of I could be accomplished by an infusion at 1 ml/min or slightly faster. This would allow the entire dose to be administered before unacceptable decomposition (≥10%) occurred.

Biological Activity—The antitumor activity of I in the emulsion formulation was compared with a suspension of I *versus* intraperitoneally implanted P-388 leukemia cells in three experiments. The antitumor response of I in both emulsion and suspension preparations was comparable.

Summary—The hydrolysis of I is quite rapid. Several attempts (Table IV) to increase the stability of I have provided less than dramatic results. Although the 10% fat emulsion system has significantly stabilized I, the decomposition rate remains rather rapid resulting in a formulation that is only marginally acceptable. It is unfortunate that I exhibits poor solubility in addition to the instability. Other nitrogen mustards are inherently more stable, such as the aromatic mustards (*e.g.*, melphalan) or they are more soluble allowing for more rapid administration in a small volume (*e.g.*, mechlorethamine).

The Use of *N,N*-Diethyl-*m*-Toluamide to Enhance Dermal and Transdermal Delivery of Drugs

JOHN J. WINDHEUSER *, JOHN L. HASLAM ˣ, LARRY CALDWELL, and RICHARD D. SHAFFER

Received October 16, 1981, from the *INTERx Research Corporation, Lawrence, KS 66044.* Accepted for publication January, 11, 1982. *Present address: Luitpold-Werk, Munich, West Germany.

Abstract □ A dermal penetration enhancer has been found which improves the dermal delivery of a wide variety of drugs and at the same time has a history of low toxicity for human dermal application. *N,N*-Diethyl-*m*-toluamide (I) has been shown to improve the delivery of many drugs through hairless mouse skin in an *in vitro* diffusion cell model. A topically applied steroid, hydrocortisone, has been used to demonstrate the *in vivo* effectiveness of I on human skin. The degree of pallor produced on human skin by the corticosteroids was used as a measure of the relative delivery of hydrocortisone from formulations with and without I.

Keyphrases □ *N,N*-Diethyl-*m*-toluamide—enhancement of dermal and transdermal drug delivery, hydrocortisone □ Hydrocortisone—enhancement of *N,N*-diethyl-*m*-toluamide on drug delivery, dermal and transdermal delivery □ Delivery, drug—dermal and transdermal, *N,N*-diethyl-*m*-toluamide enhancement, hydrocortisone

Improved dermal delivery of drugs has been the focus of pharmaceutical research worldwide for many years. The goal in most cases has been to find a substance of low toxicity which is nonirritating and will deliver a wide variety of compounds effectively.

Efforts to improve dermal delivery of drugs have included traditional formulation approaches and studies on the effects of surfactants, fatty acids, and glycols (1, 2). Although these approaches attained some degree of success, in no case was the enhancement of drug delivery spectacular. In contrast, dimethyl sulfoxide has been shown to greatly enhance dermal and transdermal delivery of a wide variety of drugs (3–11). Unfortunately, the use of this substance has been limited in humans to the treatment of interstitial cystitis by intravesical instillation. Dimethylacetamide has been found to enhance the delivery of a number of drugs for the treatment of skin diseases (12–14). However, the lack of long-term safety information has limited the use of this compound.

In the present study, the effects of *N,N*-diethyl-*m*-toluamide (I) on skin permeability was examined for a wide variety of drugs. Formulations of I have been used extensively as insect repellents. The compound was first reported to be an effective insect repellent in 1954 (15) and has been applied *ad libitum* to the skin in concentrations ranging from 10 to 100%. Despite prolonged and widespread use in humans, major side effects due to the penetration enhancer itself have not been encountered.

EXPERIMENTAL

Reagents and Drugs—Hydrocortisone[1], hydrocortisone acetate[1], hydrocortisone 17-butyrate[2], and hydrocortisone 17-valerate[3] were among the compounds used. Also used were dibucaine[1], benzocaine[4], indomethacin[1], ibuprofen[5], erythromycin[6], tetracycline hydrochloride[7], griseofulvin[8], mycophenolic acid[9], and methyl salicylate[10]. Triethanolamine salicylate was prepared by adding equal molar amounts of

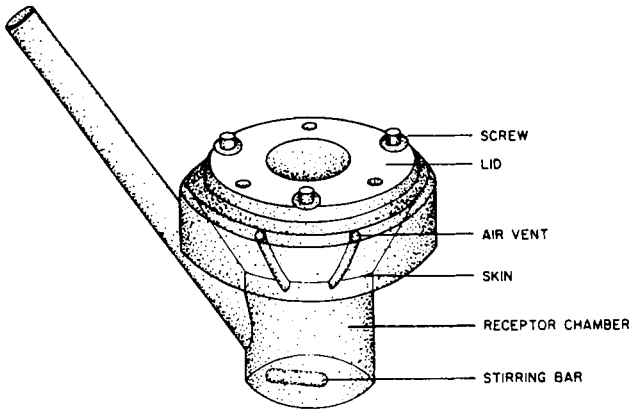

Figure 1—*Plexiglass diffusion cell with polytef lid.*

triethanolamine[11] and salicylic acid[12]. Idoxuridine[13], petrolatum USP, mineral oil[14], isopropyl myristate[1], *N,N*-diethyl-*m*-toluamide (I)[1], polyoxyethylene (2) stearyl ether[15], and polyoxyethylene 40 stearate[15] were additional compounds used. Other chemicals were reagent grade.

Procedure for Hairless Mouse Skin Diffusion Model—Transdermal drug delivery rates were determined using an *in vitro* diffusion cell procedure. Diffusion cells consisted of a plexiglass receptor chamber with a side arm to allow receptor phase sampling and a polytef lid[16] (Fig. 1). A polytef-coated stirring bar was used for receptor mixing. Female hairless mice[17] were sacrificed by cervical dislocation and the dorsal skin was removed in one piece. The skin was placed over the lower opening of the polytef lid and secured with a neoprene rubber gasket. The lid was then secured on the chamber. The exposed epidermal surface measured 8.0 cm^2. The receptor fluid was 45 ml of buffer solution consisting of 1.5×10^{-1} *M* NaCl, 5.0×10^{-4} *M* NaH_2PO_4, 2.0×10^{-4} *M* Na_2HPO_4, and 200 ppm gentamicin sulfate adjusted to pH 7.2 with sodium hydroxide or hydrochloric acid. In most cases, test formulations were applied in the amount of 0.1 ml (~100 mg/cell). The cell was placed in a thermostated chamber maintained at 32 ± 1°. The reservoir was stirred by a magnetic stirrer at 2.5 Hz. After 24 hr, a sample of the receptor fluid was withdrawn by a pipet through the side arm and emptied into a test tube. The test tube was then capped and frozen. The concentration of applied drug in the receptor fluid was measured using high-pressure liquid chromatography (HPLC). The results reported for each experiment were the average values from three replicate diffusion cells.

Procedures for Human Blanching Studies—Test formulations were applied to test areas (2 × 2 cm) on the lower backs of healthy human volunteers. Each formulation was applied to four or more test areas per subject and the results were averaged. All test areas were exposed to air (nonoccluded) for 3.5 hr after application. Any remaining formulation was then wiped off with ethanol. Blanching was evaluated at 5, 6, 7, and 8 hr postapplication. The blanching at each test area was visually appraised on a scale of 0–4, where 0 is no blanching, 1 is barely discernible blanching, and 4 is maximum blanching. Individual values for each formulation were averaged (n = 8–10). This value became the basis for comparisons.

Chromatographic Analysis—Samples of the *in vitro* receptor fluid were analyzed for the drug substance in each experiment by HPLC. The chromatographic components included pump[18], injector[19], detector[20], and recorder[21] coupled with a microparticulate column. The column type, mobile phase, and detection wavelength used for each drug substance are detailed in Table I.

Table I—HPLC Conditions for Analysis

Compound	Mobile Phase	Detection Wavelength, nm
Hydrocortisone[a]	35% acetonitrile–65% water	254

Petrolatum	0.3
5% I-petrolatum	0.8
Cream	0.5
5% I cream	1.5

[a] One hundred milligrams (~0.1 ml, containing 1 mg of hydrocortisone) of the formulation was applied.

RESULTS AND DISCUSSION

In the *in vitro* diffusion experiments, hairless mouse skin was used as the barrier membrane. The data were generally reproducible allowing for comparisons between the relative rates of penetration of a wide variety of drugs. These diffusion cell results are not necessarily applicable to skin *in vivo*, but they do provide an indication of the relative penetration enhancement. Literature references suggest that a correlation between human and hairless mouse skin can be expected for some drugs (16, 17). Table II contains diffusion results for various drugs dissolved in pure Compound I and allowed to diffuse through the hairless mouse skin at 32° for 24 hr. All the drugs in I were solutions; however, griseofulvin required warming to obtain a solution rapidly. The I formulation was compared to a commercial product whenever possible. Where no comparable product was available, the drug was dispersed in petrolatum USP. It should be noted, however, that both ibuprofen and methyl salicylate dissolve in petrolatum, while the others are suspensions. From the results presented in Table II, it is apparent that enhancement of drug delivery is dramatic when I is present in the formulation.

The amount of pure I which diffused through the barrier membrane was also measured. Over 90% of the sample of I diffused across the hairless mouse skin in 24 hr. In an investigation (18) studying the evaporation of I from human skin *in vivo*, it was found that ~50% of the applied amount of I (25 $\mu g/cm^2$) could be recovered by evaporation, skin wiping, and skin stripping after 30 min. The remaining 50% of I, therefore, appeared to have been absorbed or associated with nonstripped skin.

Although solution preparations dissolved in I were used in the *in vitro* studies, they are less commonly used for topical application *in vivo*. Creams and ointments are the more conventional mode. To investigate enhanced drug delivery with I *in vivo*, hydrocortisone cream and ointment formulations were prepared. Hydrocortisone was chosen as the model drug due to the blanching effect it causes on human skin. The amount of skin blanching due to local vasoconstriction occurring after corticosteroid application was used as a relative measure of drug penetration.

As a preliminary experiment to examine hydrocortisone delivery, the following formulations were prepared: 1, 1% hydrocortisone in petrolatum; 2, 1% hydrocortisone in petrolatum plus 5% I; 3, 1% hydrocortisone cream; and 4, 1% hydrocortisone cream plus 5% I. These formulations differed only in that 2 and 4 contained 5% I. These preparations were examined in the hairless mouse skin diffusion test, the results of which are shown in Table III.

The hydrocortisone preparations were then applied to humans as described in the *Experimental* section. Figures 2 and 3 show the results obtained from two subjects. A large increase in the blanching response was observed for Formulations 2 and 4 relative to 1 and 3. Control experiments demonstrated that I alone does not cause skin blanching. Therefore, the increase in the blanching response clearly indicates enhanced dermal delivery of hydrocortisone effected by the presence of I in the hydrocortisone formulations. It is interesting to note that hydrocortisone delivery is improved with as little as 5% I, whereas studies with other dermal penetration enhancers such as dimethyl sulfoxide appear to require higher concentrations.

Esters of Nipecotic and Isonipecotic Acids as Potential Anticonvulsants

A. MICHAEL CRIDER *x, TERENCE T. TITA *, J. D. WOOD ‡, and CHRISTINE N. HINKO *

Received September 24, 1981, from the **College of Pharmacy, University of Toledo, Toledo, OH 43606* and the ‡*Department of Biochemistry, University of Saskatchewan, Saskatoon, Saskatchewan.* Accepted for publication January 11, 1982.

Abstract □ A variety of esters of nipecotic and isonipecotic acids were synthesized and evaluated for anticonvulsant activity. The ester group was varied in terms of lipophilicity and reactivity toward hydrolysis. The esters were screened against seizures induced by electroshock, pentylenetetrazol, and the putative γ-aminobutyric acid antagonist, bicuculline. The most significant activity was demonstrated by the *p*-nitrophenyl esters of nipecotic and isonipecotic acids against bicuculline-induced seizures. Esters of nipecotic acid were tested for *in vitro* inhibition of γ-aminobutyric acid and L-proline uptakes into mouse whole brain minislices. The *p*-nitrophenyl, *n*-octyl, and succinimidyl esters were the most potent inhibitors of γ-aminobutyric acid uptake. The uptake of γ-aminobutyric acid by the ester derivatives appeared to involve specific and nonspecific mechanisms.

Keyphrases □ Anticonvulsants—potential, esters of nipecotic and isonipecotic acids, mice □ Nipecotic acid—esters, isonipecotic acid, potential anticonvulsants, mice □ Isonipecotic acid—esters, nipecotic acid, potential anticonvulsants, mice

Over the past several years evidence has been accumulated to implicate γ-aminobutyric acid as a major central nervous system (CNS) inhibitory neurotransmitter (1, 2). Impairment of γ-aminobutyric acid neurotransmission may cause a variety of neurological disorders such as epilepsy and certain psychiatric conditions (2, 3). As a result, considerable research has been directed toward the search for compounds that act as agonists, uptake inhibitors, or inhibitors of the metabolizing enzymes of γ-aminobutyric acid (4). The hope has been that agents that potentiate γ-aminobutyric acid neurotransmission could be potentially useful anticonvulsants.

BACKGROUND

(±)-Nipecotic acid (I*a*) was shown to be a potent inhibitor of neuronal γ-aminobutyric acid uptake into rat cerebral cortex (5) and mouse whole brain minislices (6). Additional studies found that the *R*-(−) enantiomer was more active as a γ-aminobutyric acid uptake inhibitor than the *S*-(+) enantiomer (7).

Due to its polarity, nipecotic acid does not readily penetrate the blood–brain barrier (8). However, it was previously shown (9) that (+)-ethyl nipecotate, when administered intraperitoneally, protected mice against audiogenic seizures. Furthermore, it was found (10) that (−)-ethyl nipecotate raised the threshold for convulsions induced by electroshock in mice. These same investigators also demonstrated that (−)- and (+)-ethyl nipecotate significantly elevated the threshold for clonic convulsions induced by pentylenetetrazol. (−)-Nipecotic acid had no effect in these anticonvulsant tests when administered intraperitoneally.

Recently, it was found that (*R*)-ethyl nipecotate given intramuscularly in mice resulted in a dose-dependent increase in γ-aminobutyric acid levels in the synaptosomes (11). The speculation was that such an increase in γ-aminobutryic acid levels in the nerve endings possibly could bring about an anticonvulsant effect.

During the final stages of this work, the anticonvulsant activity of a series of esters of the γ-aminobutyric acid agonist, isoguvacine, was reported (12). Most of the esters exhibited weak anticonvulsant activity against seizures induced by bicuculline or isoniazid. However, a good correlation existed between the onset of electroshock activity and the rates of *in vitro* enzymatic hydrolysis.

Isonipecotic acid (I*b*) was shown to be a potent and specific γ-aminobutyric acid agonist in the [^{3}H]γ-aminobutyric acid-binding assay procedure (13, 14). As in the case of nipecotic acid, isonipecotic acid was also too polar to penetrate the blood–brain barrier.

The purpose of this investigation was to prepare and evaluate the anticonvulsant activity of ester derivatives of nipecotic and isonipecotic acids. The ester group was varied in terms of lipophilicity and reactivity toward hydrolysis. Since the amino acids (I*a* and I*b*) are too polar to penetrate the CNS, it was anticipated that the ester derivatives would enter the brain and be hydrolyzed to yield the respective amino acids.

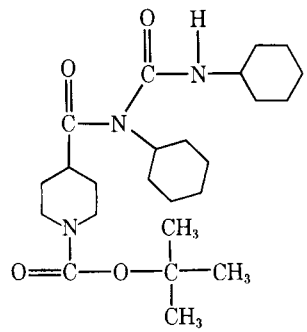
The synthesis and anticonvulsant activity of the ester derivatives of nipecotic and isonipecotic acids are described in the present report. Additionally, γ-aminobutyric acid and L-proline uptake studies into mice whole brain minislices by the ester derivatives of nipecotic acid are reported.

RESULTS AND DISCUSSION

Chemistry—Esterification of carboxylic acids can be accomplished by the use of dehydrating agents such as dicyclohexylcarbodiimide, provided an acid catalyst is present (15). Although *N*-hydroxysuccinimide and *p*-nitrophenol are acidic enough to furnish a proton, the aliphatic alcohols are not. As a result, the reaction between 1-(*tert*-butoxycarbonyl)piperidine-4-carboxylic acid (II*b*) and *n*-hexanol initially gave a thermally unstable *O*-acylisourea (16), which rearranged to the more stable *N*-acylurea (III). The alkyl esters (IV*a–f*) were successfully synthesized by Fischer esterification of the piperidine carboxylic acids (I*a* and I*b*) with an appropriate alcohol in the presence of dry hydrogen chloride. The remaining esters were conveniently prepared by standard procedures (Scheme I). The physical properties of these derivatives are given in Tables I and II.

Biological Testing—In initial investigations[1], three of the piperidinyl esters showed some activity against the subcutaneous pentylenetetrazol seizure test. The octyl ester (IV*f*) exhibited an ED_{50} of 165 mg/kg in the subcutaneous pentylenetetrazol seizure test at the time of peak effect (4 hr). However, IV*f* showed considerable toxicity (TD_{50} = 178 mg/kg) when evaluated in the rotorod test at 4 hr after administration of the compound. Compounds II*a* and VI*a* protected one out of four animals when administered 0.5 hr before pentylenetetrazol in doses of 600 and 300 mg/kg, respectively. Although no neurotoxicity was reported for II*a*, compound VI*a* produced deficiency in rotorod performance in two out of four animals when administered in a dose of 300 mg/kg.

The subcutaneous pentylenetetrazol test was repeated in the laboratory with three of the esters, which were administered 1 hr prior to the con-



III

[1] All compounds were tested for anticonvulsant activity by the Antiepileptic Drug Development Program, Epilepsy Branch, Neurological Disorders Program, National Institutes of Health, Bethesda, MD 20225.

0022-3549/82/1100-1214$01.00/0

vulsant by subcutaneous injection in an attempt to reduce peripheral hydrolysis that might occur with the intraperitoneal route. The results are shown in Table III. Sodium phenobarbital (25 mg/kg sc), the reference compound, completely protected the mice tested from clonic and tonic seizure. Esters VIII*a*, VIII*b*, and VI*a*, in 150-mg/kg doses, all significantly lengthened the onset time for myoclonic activity as compared to the saline-treated control animals. The succinimidyl ester (VI*a*) was most active, protecting three out of the eight animals from clonic convulsions. All three esters protected the animals tested from tonic seizure and death. These results, however, are difficult to interpret since only 2 of the 16 control animals died after exhibiting tonic convulsions, and pentylenetetrazol is most commonly used for its ability to produce threshold or minimal (clonic) seizures (17). Neurotoxicity was not observed with any of the three esters at the 150-mg/kg dose.

These three compounds were also evaluated for their ability to protect against bicuculline-induced convulsions. The results are shown in Table IV. Each of the three esters at a 150-mg/kg dose significantly prolonged the onset time of clonic seizures when administered by subcutaneous injection. The *p*-nitrophenyl ester (VIII*a*) was most active against bicuculline, protecting four out of eight animals from any clonic activity and completely protecting all eight mice from tonic seizure and death. These results are especially significant when compared to the controls where bicuculline produced clonic and tonic seizures and resulted in fatality in 100% of the saline-treated mice. The *p*-nitrophenyl ester (VIII*b*), although not as effective as VIII*a*, protected three out of eight mice from clonic seizure and seven out of eight from tonic convulsions and death. The succinimidyl ester (VI*a*), which showed activity against pentylenetetrazol produced no protection from myoclonus and only minimal protection (two out of eight mice) from tonic seizures. Four out of eight animals, however, were protected from fatality. Additional experiments were performed in an attempt to maximize the anticonvulsant activity of VI*a*. However, increasing the dose to 225 mg/kg and varying the pretreatment time did not alter its effects. The reference compound, diazepam (10 mg/kg ip), prevented bicuculline-induced seizure activity in all animals tested.

The results of the uptake studies of the esters of nipecotic acid, with respect to γ-aminobutyric acid and L-proline into mouse whole brain minislices, are given in Table V. Although all esters showed appreciable inhibition of γ-aminobutyric acid uptake, IV*c*, VI*a*, and VIII*a* were the most potent. In order for the esters to exhibit inhibition of γ-aminobutyric acid uptake, hydrolysis to the parent amino acid (I*a*) is necessary. Thus, it is not surprising that VI*a* inhibited γ-aminobutyric acid uptake in a manner identical to nipecotic acid. NMR analysis of VI*a* indicates that the ester is hydrolyzed very rapidly to the parent amino acid. (±)-ethyl nipecotate demonstrated moderate inhibition (47%) as contrasted with an earlier report (7) indicating that the (−)-isomer was inactive.

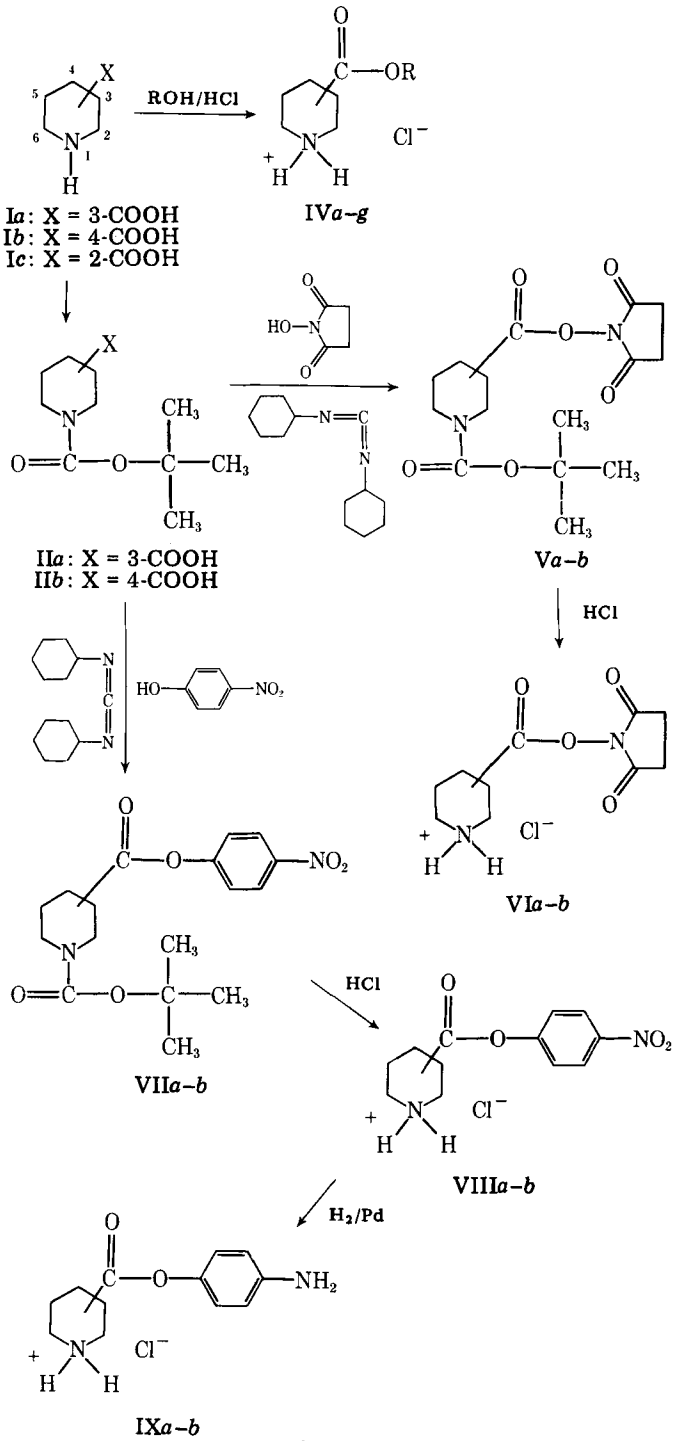
In all probability, the octyl ester (IV*c*) is acting as a nonspecific inhibitor of γ-aminobutyric acid uptake. In comparison with I*a*, IV*c* is a much more potent inhibitor of L-proline (99 *versus* 21% inhibition). The octyl ester (IV*c*) may well be exerting its inhibitory activity by a nonspecific detergent-like effect. Compound IV*c* probably interrupts all types of membrane functions, causing γ-aminobutyric acid and L-proline inhibition.

Compound VIII*a* presents a different case than IV*c*. Although VIII*a* seems to exhibit nonspecificity, as evidenced by its 70% inhibition of L-proline uptake at 1×10^{-3} *M*, it does not inhibit L-proline as potently as IV*c*. Dilution of VIII*a* does not decrease the γ-aminobutyric acid uptake inhibition as drastically as that for IV*c*.

One possible explanation for these results is that the observed effects of IV*c* and VIII*a* are the summation of two different types of inhibition, specific and nonspecific. The nonspecific effect is due to the intact ester, while the specific effect is caused by hydrolysis of IV*c* and VIII*a* to nipecotic acid. Support for this hypothesis can be obtained by noting that at 1×10^{-3} *M*, both IV*c* and VIII*a* are more potent than I*a* in the γ-aminobutyric acid uptake assay. Furthermore, pipecolic acid is a much weaker inhibitor of γ-aminobutyric acid uptake than I*a* (Table V). However, the octyl esters (IV*c* and IV*g*) of the amino acids were equal in potency as γ-aminobutyric acid uptake inhibitors. These results suggest that IV*c* and IV*g* are not hydrolyzed under the assay conditions, and that their inhibition is due to a nonspecific cationic detergent effect.

If this hypothesis is correct, the nonspecific mechanism appears to assume a greater role in the case of IV*c* than VIII*a*. Support for this can be gathered by noting that VIII*a* did not inhibit L-proline to the extent of IV*c*. Furthermore, the inhibition of L-proline by VIII*a* was always much less than that of IV*c*.

Further studies are in progress to define more accurately the anti-



Scheme I

convulsant activity of VIII*a* as well as to determine the effect of VIII*a* on the γ-aminobutyric acid content of nerve endings using a synaptosomal model.

EXPERIMENTAL[2]

Nipecotic Acid (I*a*)—Compound I*a* was prepared by the method of Freifelder (18) in 62% yield, mp 258–260° [lit. (19) mp 260–261°].

1-(tert-Butyloxycarbonyl)piperidine-3-carboxylic Acid (*II*a)—A solution of I*a* (10.0 g, 0.077 mole) in 50 ml of water was treated with tri-

[2] Melting points were determined on a Fisher-Johns melting point apparatus and are uncorrected. IR spectra were recorded as potassium bromide pellets with a Perkin-Elmer 137 spectrophotomer. NMR spectra were recorded on a Varian EM 360A spectrometer. Chemical shifts are reported in parts per million (δ) relative to tetramethylsilane (1%) or in the case of D_2O (1%) sodium 2,2-dimethyl-2-silapentane-5-sulfonate.

N,N′-*Dicyclohexyl*-N-(1-tert-*butyloxycarbonyl-4-piperidinocarbonyl)urea* (III)—A solution of II*b* (2.50 g, 0.011 mole) and *n*-hexanol (1.10 g, 0.011 mole) in 155 ml of acetonitrile was treated in one portion with 2.30 g (0.011 mole) of dicyclohexylcarbodiimide. The reaction mixture was stirred overnight, filtered, and the filtrate was concentrated under reduced pressure. The resulting oil was triturated with diethyl ether to afford after recrystallization from hexane 1.30 g (28%) of white solid, mp 166–168°; IR (KBr): 3350 (NH), 1700 (C=O, amide) and 1670 (C=O, carbamate and urea) cm^{-1}; NMR ($CDCl_3$): δ 1.30 [s, 9H, $C(CH_3)_3$], 1.40–1.80 (broad m, 26H, CH_2NCH_2 and cyclohexyl overlap), 2.20–2.60 (broad m, 3H, CHNCH and CHCO overlap), 4.0 (m, 2H, CHNCH), and 6.15 (d, 1H, NH) ppm.

Anal.—Calc. for $C_{24}H_{41}N_3O_4$: C, 66.16; H, 9.50; N, 9.65. Found: C, 65.91; H, 9.49; N, 9.44.

n-*Alkyl Piperidinecarboxylate Hydrochlorides* (*IV*a–g)—The synthesis of *n*-butyl 4-piperidinecarboxylate hydrochloride (IV*d*) was representative of the general method. A suspension of isonipecotic acid in 20 ml of *n*-butanol was saturated with dry hydrogen chloride and refluxed for 2 hr. The resulting solution was cooled, diluted with ether, and washed with four 50-ml portions of water. The aqueous phase was washed with 50 ml of ether, basified with sodium bicarbonate to pH 8, and extracted with four 50-ml portions of chloroform. The combined chloroform layer was dried (sodium sulfate) and evaporated to give a colorless oil. The oil was dissolved in anhydrous chloroform and was saturated with hydrogen chloride at 0°. Recrystallization of the hydrochloride from ethyl acetate gave 2.3 g (67%) of white crystalline solid, mp 113–115°; IR (KBr): 2500 (NH_2^+), 1760 (C=O), and 1225 (C—O) cm^{-1}; NMR ($CDCl_3$): δ 0.90 (t, 3H, CH_3), 1.50 (m, 4H, CH_2CH_2), 2.15 (t, 4H, CH_2CHCH_2), 2.50 (m, 1H, CH), 3.20 (m, 4H, $CH_2NH_2^+CH_2$), 4.1 (t, 2H, OCH_2), and 8.50–9.30 (broad s, 1H, NH_2^+).

Anal.—Calc. for $C_{10}H_{20}ClNO_2$: C, 54.16; H, 9.11; N, 6.32. Found: C, 54.31; H, 9.27; N, 6.18.

Preparation of *tert*-Butyloxycarbonyl Esters V*a–b* and VII*a–b*)—The synthesis of *p*-nitrophenyl-1-(*tert*-butyloxycarbonyl)-4-piperdinecarboxylate (VII*b*) is representative of the general procedure. A mixture of II*b* (2.5 g, 0.011 mole) and *p*-nitrophenol (1.50 g, 0.011 mole) in 115 ml of acetonitrile was treated with dicyclohexylcarbodiimide (2.30 g, 0.011 mole). Immediately, a white precipitate of dicyclohexylurea formed. Stirring was continued overnight and the precipitated dicyclohexylurea was filtered, and the filtrate was concentrated. Recrystallization of the solid from absolute ethanol gave 2.30 g (60%) of white crystalline solid, mp 91–93°; IR (KBr): 1790 (C=O, ester) and 1700 (C=O, carbamate) cm^{-1}; NMR ($CDCl_3$): δ 1.40 [s, 9H, $C(CH_3)_3$], 1.80 (m, 4H, CH_2CHCH_2), 2.80 (m, 3H, CHNCH and CH), 4.0 (m, 2H, CHNCH), 7.20–8.20 (m, 4H, ArH).

Anal.—Calc. for $C_{17}H_{22}NO_6$: C, 58.27; H, 6.34; N, 8.00. Found: C, 58.29; H, 6.24; N, 8.19.

Removal of the *tert*-Butyloxycarbonyl Group from V*a–b* and VII*a–b*—p-*Nitrophenyl 4-Piperidinecarboxylate Hydrochloride* (*VIIIb*)—Synthesis of VIII*b* is typical of the general method. A solution of VII*b* (2.70 g, 0.008 mole) in 100 ml of chloroform was saturated with hydrogen chloride at 0–5° for 1 hr. The solvent was evaporated and the resulting solid was recrystallized from ethanol–water to afford 1.70 g (78%) of a white crystalline solid, mp 215–217°; IR (KBr): 2500 (NH_2^+), 1750 (C=O, ester), and 1180 (C—O) cm^{-1}; NMR (D_2O): δ 2.45 (m, 4H, CH_2CHCH_2), 3.10–3.65 (broad m, 5H, CH_2NCH_2 and CH overlap), and 7.45–8.35 (m, 4H, ArH).

Anal.—Calc. for $C_{12}H_{15}ClN_2O_4$: C, 50.26; H, 5.28; N, 9.77. Found: C, 50.03, H, 5.09; N, 10.01.

p-*Aminophenyl 3-Piperidinecarboxylate Hydrochloride* (*IX*a)—A suspension of VIII*a* (1.40 g, 0.0049 mole) and 0.2 g of 10% palladium on carbon in 250 ml of ethanol was hydrogenated on a hydrogenator[3] at an initial pressure of 3 atm. After 1 hr, the theoretical amount of hydrogen had been absorbed. The mixture was warmed gently to dissolve the product, filtered, and evaporated under reduced pressure. The solid product was recrystallized twice from ethanol to yield 0.92 g (73%) of a brown crystalline solid, mp 217–219°; IR (KBr): 3550 and 3450 (NH_2), 2500 (NH_2^+), 1780 (C=O, ester), and 1220 (C—O) cm^{-1}; NMR (D_2O): δ 1.90 (m, 4H, CH_2CH_2CH), 2.70–3.70 (broad m, 5H, $CH_2NH_2^+CH_2CH$) and 6.85 (s, 4H, ArH).

Anal.—Calc. for $C_{12}H_{17}ClN_2O_2$: C, 56.13; H, 6.69; N, 10.91. Found: C, 55.96; H, 6.62; N, 10.77.

p-*Aminophenyl 4-Piperidinecarboxylate Hydrochloride* (*IX*b)—Compound IX*b* was prepared from VIII*b* (1.50 g, 0.005 mole), 0.2 g of 10% palladium on carbon in 250 ml of ethanol in the same manner as described for the synthesis of IX*a*. Recrystallization of the product from ethanol gave 0.89 g (66%) of analytically pure product, mp 237–239°; IR (KBr): 3550 and 3400 (NH_2), 2500 (NH_2^+), 1750 (C=O, ester), and 1190 (C—O) cm^{-1}; NMR (D_2O): δ 2.20 (m, 4H, CH_2CHCH_2), 2.80–3.50 (broad m, 5H, $CH_2NH_2^+CH_2$ and CH overlap) and 6.90 (s, 4H, ArH).

Anal.—Calc. for $C_{12}H_{17}ClN_2O_2$: C, 56.13; H, 6.69; N, 10.91. Found: C, 55.90; H, 6.51; N, 10.78.

Biological Testing—Initial evaluation for anticonvulsant activity was done by an antiepileptic drug development program[1] using the test systems as previously described (19). The testing included the maximal electroshock seizure test, the subcutaneous pentylenetetrazol seizure threshold test, and the rotorod test to evaluate neurotoxicity. In these

[a] GABA = γ-aminobutyric acid. [b] Uptake measured in mouse whole brain minislices. [c] All values are mean ± *SEM* for six samples except where indicated and for the control group where 18 samples were used. [d] Mean ± *SEM* for five samples.

tests the compounds being evaluated were administered by intraperitoneal injection.

Based on the data obtained from the initial screening, additional tests were performed on the piperidinyl esters using male Sprague-Dawley mice[4]. To assess the activity of these compounds against convulsions induced by the putative γ-aminobutyric acid antagonist, bicuculline, the experimental animals received a subcutaneous injection of 3 mg/kg of bicuculline in a volume of 0.01 ml/g. The bicuculline solution was freshly prepared on the day of the experiment by dissolving the solid in 0.1 *N* HCl and adjusting to pH 5 with 0.1 *N* NaOH solution (20). The compounds evaluated against bicuculline-induced seizures were administered by intraperitoneal or subcutaneous injection prior to challenge with the convulsant. Diazepam, dissolved in a 40% propylene glycol–10% ethanol solution, was used as a reference compound in these studies.

The mice were divided into groups of four to eight animals, with Group 1 receiving injection of 0.9% NaCl solution (0.01 ml/g sc); Group 2, an injection of the diazepam solvent (0.01 ml/g ip); Group 3, 10 mg/kg ip of diazepam by injection; and Group 4, 150 mg/kg sc of the ester by injection. The incidence of clonic and tonic convulsions induced by bicuculline was determined at 0.5, 1.0, and 4.0 hr after administration of the test compound. A clonic convulsion was defined as a single episode of clonic spasms of at least a 5-sec duration. A tonic seizure was defined as a brief period of hindlimb flection followed by a prolonged period of hindlimb extension.

In addition, the piperidinyl esters were reevaluated for their ability to protect against pentylenetetrazol-induced seizures. In the initial evaluation, the test compounds were administered by intraperitoneal injection. It was theorized that subcutaneous administration might increase anticonvulsant activity by preventing the peripheral hepatic hydrolysis of the esters that might occur with intraperitoneal dosing. Therefore, experimental animals received a subcutaneous injection of 85 mg/kg of pentylenetetrazol in a 0.01-ml/g volume. Sodium phenobarbital dissolved in saline was used as a reference compound. Groups of four to eight mice were used to determine the anticonvulsant activity, with Group 1 receiving a subcutaneous injection of 0.9% NaCl solution (0.01 ml/g); Group 2, 25 mg/kg sc of sodium phenobarbital by injection; and Group 3, 150 mg/kg sc of the ester by injection. The incidence of clonic and tonic convulsions induced by pentylenetetrazol was determined as described for bicuculline.

[4] Obtained from Harlan Sprague-Dawley, Madison, Wis.

Uptake of Amino Acids—The uptakes of [^{3}H]γ-aminobutyric acid and tritiated L-proline were carried out according to described procedures (6, 21).

Simultaneous Determination of Hydrocortisone and Benzyl Alcohol in Pharmaceutical Formulations by Reversed-Phase High-Pressure Liquid Chromatography

ALBERT REGO ˣ **and BRETT NELSON**

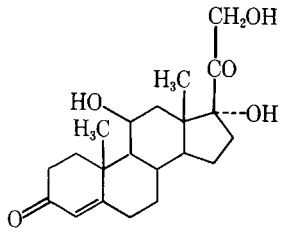
Received May 13, 1981, from the *Analytical Development Group, Allergan Pharmaceuticals, Inc., Irvine, CA 92713.* Accepted for publication January 12, 1982.

Abstract □ An accurate, reproducible, and specific reversed-phase high-pressure liquid chromatographic (HPLC) procedure that simultaneously determines hydrocortisone and benzyl alcohol in a variety of pharmaceutical formulations is presented. Cream, gel, ointment, and solution formulations containing varying hydrocortisone and benzyl alcohol concentrations can be analyzed with only minor modifications in sample preparation. To provide optimum accuracy and reproducibility, phenethyl alcohol is used as an internal standard. The specificity of the procedure allows for the quantitative determination of hydrocortisone and benzyl alcohol in the presence of their degradation products and without interference from the phenethyl alcohol. The determinations can be performed with an analysis time of 10–13 min/sample.

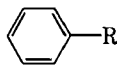
Keyphrases □ Hydrocortisone—simultaneous determination with benzyl alcohol, pharmaceutical formulations, reversed-phase high-pressure liquid chromatography □ Benzyl alcohol—simultaneous determination with hydrocortisone, pharmaceutical formulations, reversed-phase high-pressure liquid chromatography □ High-pressure liquid chromatography, reversed-phase—hydrocortisone, simultaneous determination with benzyl alcohol, pharmaceutical formulations

Hydrocortisone (I) has gained wide acceptance as a topical agent for the relief of inflammatory manifestations of corticosteroid-responsive dermatoses (1). Benzyl alcohol (II) is commonly used as an antimicrobial agent in a variety of topical formulations (2).

Various methods have been used for the determination of hydrocortisone, including TLC, polarography, colorimetry, GC, and high-pressure liquid chromatography (HPLC). TLC, though somewhat specific, lacks precision and short analysis time (1, 3–6). Polarographic determinations can be erroneous due to interferences, and they can



I



II: R = CH_2OH
III: R = CH_2CH_2OH

be nonspecific in that a variety of similar steroids can elicit the same reduction potential for the same functional groups (7–10). Colorimetric methods include reaction with aldehyde–sulfuric acid (11), ammonium molybdate (12), and 4,5-dimethyl-*o*-phenylenediamine (13). These methods lack specificity, because degradation products may provide a colorimetric response not indicative of actual steroid concentration. Numerous GC methods are available (14–18); however, most steroids cannot be directly analyzed but must be initially derivatized. The complexity of steroids precludes the direct formation of a single derivative (19). The USP methods for hydrocortisone formulations were recently changed from a colorimetric reaction with tetrazolium blue (1, 20–23) to HPLC procedures (1). Recently, literature on hydrocortisone analysis *via* HPLC has been published (19, 24–29). While these methods may be specific, the sample preparation and analysis time can be prohibitive to a rapid assay. Benzyl alcohol can be determined by spectrophotometry and GC. Spectrophotometric methods have the inherent problems of nonspecificity and formulation base interferences. GC methods, including the USP compendial method, are specific and efficient (2). However, these methods may have interferences due to longer retained compounds from the formulation base[1].

The described procedure allows for the simultaneous determination of hydrocortisone and benzyl alcohol in cream, gel, ointment, and solution formulations with a general sample preparation. The procedure incorporates phenethyl alcohol (III) as an internal standard to achieve optimum accuracy and reproducibility with an analysis

time of 10–13 min/sample. Phenethyl alcohol cannot be used as an internal standard for those formulations containing methylparaben, as these compounds elute at the same time. Benzyl alcohol could be used as an internal standard for those formulations containing methylparaben and propylparaben. The procedure is shown to be specific for hydrocortisone and benzyl alcohol in the presence of their degradation products in these formulations.

EXPERIMENTAL

Materials—Hydrocortisone[2], benzyl alcohol[3], methylparaben[4], propylparaben[4], and phenethyl alcohol[5] were used as standards. HPLC grade acetonitrile[6] and distilled, deionized water were used as reagents.

The HPLC system consisted of a pump[7], an automatic injector[8], a 254-nm detector[9], a radial compression module[10], and a reversed-phase octadecylsilane cartridge[11] fitted with a 2-μm precolumn filter and a recorder[12]. All peaks were electronically integrated with the laboratory data system[13].

The system was operated at ambient temperature, and the detector sensitivity was 0.1 or 0.2 aufs, depending on the hydrocortisone concentration. The chromatographic parameters include a 10-μl loop, an analysis time of 10 min, and a chart speed of 0.25 cm/min. After the baseline had stabilized, replicate standards were run to ensure reproducibility.

Mobile Phase—The mobile phase was 22.5% (v/v) acetonitrile in distilled, deionized water. Prior to use, the mobile phase was filtered through a 3.0-μm filter[14] and degassed with a water aspirator. A flow rate of 6.0 ml/min was used with a cartridge pressure of 1500–2000 psi.

Internal Standard Preparation—The stock phenethyl alcohol internal standard solution was prepared as 1.0% (w/v) in acetonitrile.

Standard Preparations—The hydrocortisone reference standard and benzyl alcohol reference standard were diluted to give the required working standard concentration levels. To provide accuracy and reproducibility, 25.0 ml of the phenethyl alcohol internal standard solution

was added before the diluted standards were brought to 100 ml final volume with acetonitrile. The diluted working standard concentrations included 0.125 mg/ml, 0.250 mg/ml, and 0.625 mg/ml of hydrocortisone (equivalent to 0.5, 1.0, and 2.5% hydrocortisone on a product basis) and 0.250 and 0.500 mg/ml of benzyl alcohol (equivalent to 1.0 and 2.0% benzyl alcohol on a product basis).

Sample Preparation for Hydrocortisone and Benzyl Alcohol Determinations—*Cream and Gel Formulations*—Five-hundred milligrams of the sample was weighed into a 30-ml screw-capped culture tube. Acetonitrile (15.0 ml) and 5.0 ml of phenethyl alcohol internal standard solution, were accurately added and tightly capped. The tube was vigorously shaken by hand to disperse the sample and shaken for an additional 30 min on a mechanical shaker. The sample was centrifuged for 20 min, and the injector vial was filled with the clear supernatant. An aliquot (10 μl) was injected onto the liquid chromatograph.

Ointment Formulations—Five-hundred milligrams of the sample was accurately weighed into a 30-ml screw-capped culture tube. HPLC mobile phase (15.0 ml) and 5.0 ml of the phenethyl alcohol internal standard solution were accurately added, then tightly capped. The sample was then placed into a constant temperature (60–65°) water bath for 30 min and shaken by hand at 5-min intervals. The solution was then cooled to room temperature and centrifuged for 20 min. An aliquot was injected onto the liquid chromatograph following the procedure used for cream and gel formulations.

Solution Formulations—Five-hundred milligrams of the sample was accurately weighed into a 30-ml screw-capped culture tube. Acetonitrile (15.0 ml) and 5.0 ml of the phenethyl alcohol internal standard solution were accurately added and tightly capped. The sample was then shaken for 20 min on a mechanical shaker. The solution was injected as described in the previous two preparations.

RESULTS AND DISCUSSION

Linearity—To determine the linearity of the detector response, separate calibration curves for hydrocortisone (0.5, 1.0, and 2.5% product level) and benzyl alcohol (1.0 and 2.0% product level) were obtained. Each curve contained points equivalent to 50 and 150% of label claim and three intermediate points. In all cases, the component concentration was plotted *versus* the ratio of component peak area over internal standard peak area. The internal standard was held constant throughout the study. A composite hydrocortisone calibration curve passed through zero and was linear from 0.050 to 1.008 mg/ml with a correlation coefficient of 0.999. A composite benzyl alcohol calibration curve passed through zero and was linear from 0.129 to 0.854 mg/ml with a correlation coefficient of 0.999.

Recovery Studies—Each formulation was received with the appropriate placebo base. Each base was prepared and analyzed by HPLC to ensure that no UV absorbing peaks were present in the regions of benzyl alcohol, phenethyl alcohol, and hydrocortisone. To determine method accuracy, each placebo was spiked a minimum of three times with benzyl alcohol to the appropriate levels (1.0 and 2.0% on a product basis). A second placebo series was spiked a minimum of three times with hydrocortisone to the appropriate levels (0.5, 1.0, and 2.5% on a product basis). The samples were prepared and subjected to HPLC analysis. In all cases, satisfactory recoveries were obtained (Table I).

Reproducibility Studies—The reproducibility of the HPLC procedure was determined by the criteria of day-to-day reproducibility and operator-to-operator reproducibility. The following scheme was applied to each formulation: Day 1, Operator 1; Day 2, Operator 1; and Day 2, Operator 2 (Table II).

Limit of Detection—The limit of detection, defined here as an acceptable signal to noise level of >2:1 was performed by diluting the working standard 1–100 with acetonitrile and performing the analysis at 0.01 aufs. In all cases, benzyl alcohol, phenethyl alcohol, and hydrocortisone were easily detected and within acceptable limits.

Specificity Studies—It is known that benzyl alcohol degrades *via* oxidation to yield benzoic acid and benzaldehyde[15]. As confirmation of method specificity, a sample was spiked with benzoic acid and benzaldehyde and analyzed. The two peaks were noted and did not create any interference problems (Fig. 1).

The degradation of a steroid, such as hydrocortisone, is complex and involves hydrolysis, oxidation, and possible transesterification (19). Each formulation and formulation base placebo was artificially degraded by adjusting the sample to ~pH 12 with 50% NaOH and also by heating a second series of samples at 100° for 1 hr.

The four base formulation placebos, with or without benzyl alcohol depending on the formulation, were analyzed by the HPLC procedure. In all cases, no interfering peaks were noted in the area of benzyl alcohol, phenethyl alcohol, or hydrocortisone.

Further work demonstrated that degradation products of hydrocor-

[15] The degradation products benzaldehyde and benzoic acid were verified by GC using 1.83-m × 0.318-cm stainless steel Porapak P column (Waters Associates, Milford, Mass.). Chromatographic parameters include gas flow of 45 ml/min, nitrogen, 220° oven temperature, and a flame ionization detector.

Table III—Stability Study[a]

Age, Days	Percent Hydrocortisone Found[b] Lot A	Lot B	Lot C	Percent Benzyl Alcohol Found[b] Lot A	Lot B	Lot C
0	0.517	0.527	0.528	1.06	1.06	1.05
36	0.517	0.519	0.518	1.02	1.04	1.04
49	0.472	0.476	0.480	1.05	1.07	1.06
86	0.467	0.470	0.464	1.06	1.07	1.04
119	0.391	0.390	0.393	1.00	0.99	1.00

[a] Claim was 0.525% hydrocortisone and 1.0% benzyl alcohol. [b] Each result represents the mean of four values.

tisone do not interfere with benzyl alcohol or the internal standard phenethyl alcohol. An artificially degraded gel formulation, not containing benzyl alcohol or phenethyl alcohol, gave a similar pattern of degradation peaks as noted in Fig. 2 with no benzyl alcohol or phenethyl alcohol interferences.

As a final test, a tube of a sample stored at 45° for >300 days was analyzed. The hydrocortisone level was 72% of label claim, substantially below the allowed lower specification limit. The chromatogram revealed a variety of peaks, none of which interfere with the benzyl alcohol, phenethyl alcohol, or hydrocortisone (Fig. 3). To ensure that there were no extraneous peaks under the hydrocortisone peaks, the sample was injected onto the HPLC coupled with a UV-visible spectrophotometer[16].

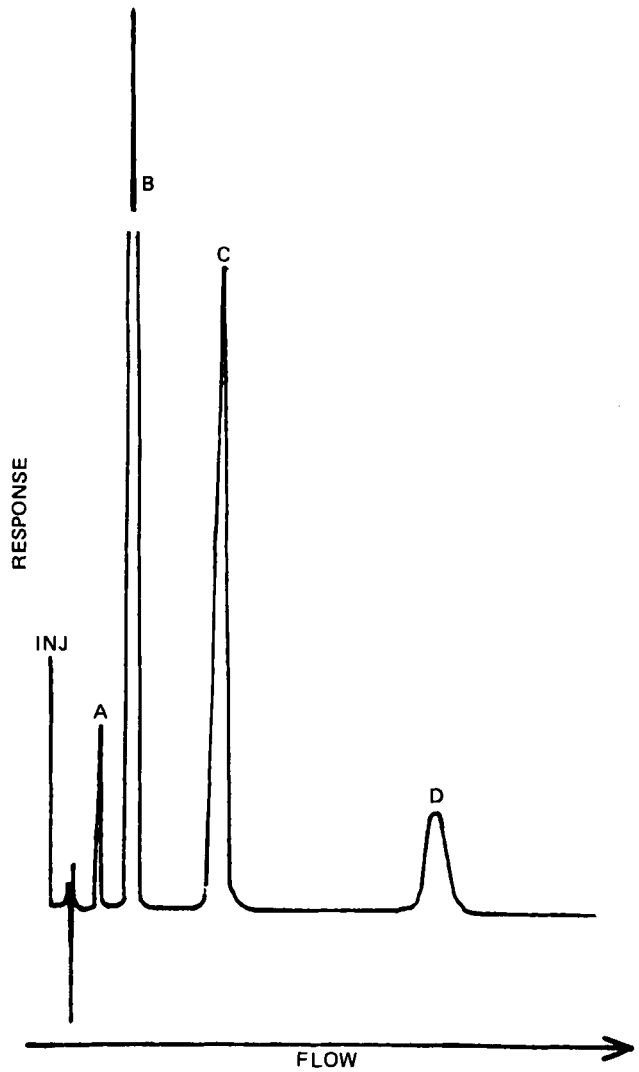

Figure 4—*A chromatogram showing the separation of preservatives and hydrocortisone. Key: (A) benzyl alcohol; (B) methylparaben; (C) intact hydrocortisone; (D) propylparaben.*

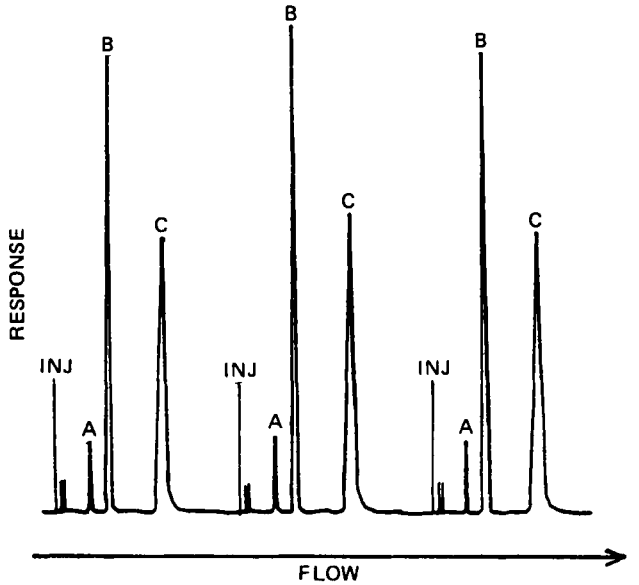

Figure 5—*A typical chromatogram of an experimental formulation. Key: (A) benzyl alcohol; (B) phenethyl alcohol; (C) hydrocortisone.*

As the hydrocortisone peak eluted, a UV scan was taken every 3 sec. These 14 scans were compared to a standard hydrocortisone UV scan. No differences were noted during the elution of the peak. As a further check, the first derivatives of the peak segments were subtracted from the first derivative of the hydrocortisone standard. In all cases, the predicted waveform was noted, indicating there are no UV absorbing interferences at the location of hydrocortisone. No attempt was made to identify the peaks associated with the degradation of hydrocortisone.

Phenethyl alcohol was used as a chromatographically pure reagent for all studies and was not subjected to a simulated degradation.

Stability Study—Actual data were generated with this procedure (Table III). The samples were a 0.5% hydrocortisone experimental formulation stored at 45° for accelerated stability studies for 120 days. The data for hydrocortisone revealed the expected downward trend and demonstrated the method could easily detect changes in hydrocortisone concentration. The data for benzyl alcohol revealed no significant loss throughout the study. Note that specificity was previously established to confirm the validity of the data.

Paraben Study—The methylparaben reference standard and propylparaben reference standard were diluted to 0.005 and 0.016 mg/ml, respectively. The hydrocortisone reference standard was added equivalent to 0.125 mg/ml to the diluted paraben standard. The three components are completely resolved. The methylparaben would interfere with the phenethyl alcohol. A second injection showed benzyl alcohol does not interfere with the parabens (Fig. 4). In formulations containing parabens the benzyl alcohol could be utilized as the internal standard in place of phenethyl alcohol.

The principal goal of any analytical separation procedure is to achieve maximum resolution in minimum time. Initial studies were conducted with a reversed-phase stainless steel column[17] and a 25% (v/v) acetonitrile solution in distilled, deionized water mobile phase pumped at 2.0 ml/min. Under these conditions, 15–25 min were required to achieve baseline to baseline resolution of the benzyl alcohol, phenethyl alcohol, and hydrocortisone, as well as the total elution of the degradation products. In comparison, the radial compression system with the modified mobile phase pumped at 6.0 ml/min achieved the same analysis in 10–13 min. The time factor was of obvious importance in the choice of this approach, allowing for the analysis of a large number of samples in a short period of time (Fig. 5).

An efficient feature of this procedure is the general sample preparation scheme and analysis parameters. The sample weights, sample dilution volumes, and internal standard concentration are constant. There are only two minor variations in sample preparation. The first is the centrifugation step for the cream, gel, and ointment formulations (relative to the solution) prior to injection. The second is the heating of the ointment formulation in the HPLC solvent prior to centrifugation. With this

[17] μ Bondapak C-18, 30 cm × 3.9-mm i.d. (10-μm particles), Waters Associates, Milford, Mass.

general scheme, the analysis parameters do not require solvent modification, variable injection volumes, or a change in analysis time. The only chromatographic variation is an attenuation change from 0.1 to 0.2 aufs for the 2.5% hydrocortisone formulations.

A variety of hydrocortisone formulations may contain methylparaben and propylparaben as preservatives. Though methylparaben interferes with phenethyl alcohol, benzyl alcohol could be substituted as the internal standard and yield satisfactory chromatographic separation.

Synthesis and Evaluation of an ^{111}In-labeled Porphyrin for Lymph Node Imaging

RICHARD VAUM *, NED D. HEINDEL *‡ˣ, H. DONALD BURNS *, JACQUELINE EMRICH*, and NATALIE FOSTER‡

Received October 20, 1981, from the **Department of Radiation Therapy and Nuclear Medicine, Hahnemann Medical College and Hospital, Philadelphia, PA 19102* and the ‡*Center for Health Sciences, Lehigh University, Bethlehem, PA 18015.* Accepted for publication January 18, 1982.

Abstract □ ^{111}In-labeled tetra(4-*N*-methylpyridyl)porphyrin was investigated as a possible lymph node imaging agent. A clinically feasible method for the preparation of this radioactive pharmaceutical was developed from experiments with the synthesis and characterization of the unlabeled complex. The *in vivo* distribution of the compound in Wistar rats was determined as a function of time. Favorable lymph node–blood, lymph node–muscle, and specific lymph node–surrounding tissue ratios were obtained.

Keyphrases □ Porphyrin—^{111}In-labeled, synthesis and evaluation, biodistribution, lymph node imaging, rats □ Imaging, lymph node—^{111}In-labeled porphyrin, synthesis and evaluation, biodistribution, rats □ Biodistribution—^{111}In-labeled porphyrin, synthesis, lymph node imaging, evaluation, rats

The diagnostic imaging methods now being used for evaluating disease in the lymphatic system, oil lymphography and technetium Tc 99m antimony trisulfide colloid lymphoscintigraphy, possess significant inherent limitations. These methods image only those nodal groups that drain the subcutaneous injection site, and thus, require patent lymphatic vessels between the injection site and the nodes to be imaged (1–3). An intravenously administered radiopharmaceutical agent that allows the visualization of all nodal groups with a single injection would be an improvement in the diagnosis of lymph node involvement in malignancy.

BACKGROUND

It has been known since the 1940s that many porphyrins and metalloporphyrins display an affinity for lymphatic and neoplastic tissues when injected intravenously (4, 5). These early studies, however, depended solely upon differential fluorescence to detect the presence of the porphyrin in the target tissue and, consequently, were of limited diagnostic utility. A method is available for introducing indium, an electronic isostere of iron, into porphyrins (6). Two nuclides of that element, indium 111 and indium 113m, would be clinically acceptable from the viewpoint of decay energies, gamma-emission, and half-life for use in *in vivo* diagnostic radiopharmaceuticals. Furthermore, it has been shown that several porphyrins can transport β-emitting nuclides (cobalt 58, zinc 65, and palladium 109) to nodal tissue where their ionizing radiation results in selective nodal ablation and diminished rejection rate for skin homographs in dogs dosed with these radio porphyrins (7–9). It has also been demonstrated that an intravenously administered cobalt 57 derivative of a water-soluble porphyrin developed a tumor–blood ratio of 44:1 at 5 days postdosing in the TCT-4904 rat bladder tumor (10). Sufficient precedent exists to indicate that a soluble indium-labeled porphyrin might be nodal specific. This study reports a facile synthesis for radioactive [^{111}In]tetra(4-*N*-methylpyridyl)porphyrin (I) whose biodistribution in rats illustrates its potential as a radiodiagnostic agent for major nodal systems.

0022-3549/82/1100-1223$01.00/0

general scheme, the analysis parameters do not require solvent modification, variable injection volumes, or a change in analysis time. The only chromatographic variation is an attenuation change from 0.1 to 0.2 aufs for the 2.5% hydrocortisone formulations.

A variety of hydrocortisone formulations may contain methylparaben and propylparaben as preservatives. Though methylparaben interferes with phenethyl alcohol, benzyl alcohol could be substituted as the internal standard and yield satisfactory chromatographic separation.

The diagnostic imaging methods now being used for evaluating disease in the lymphatic system, oil lymphography and technetium Tc 99m antimony trisulfide colloid lymphoscintigraphy, possess significant inherent limitations. These methods image only those nodal groups that drain the subcutaneous injection site, and thus, require patent lymphatic vessels between the injection site and the nodes to be imaged (1–3). An intravenously administered radiopharmaceutical agent that allows the visualization of all nodal groups with a single injection would be an improvement in the diagnosis of lymph node involvement in malignancy.

BACKGROUND

It has been known since the 1940s that many porphyrins and metalloporphyrins display an affinity for lymphatic and neoplastic tissues when injected intravenously (4, 5). These early studies, however, depended solely upon differential fluorescence to detect the presence of the porphyrin in the target tissue and, consequently, were of limited diagnostic utility. A method is available for introducing indium, an electronic isostere of iron, into porphyrins (6). Two nuclides of that element, indium 111 and indium 113m, would be clinically acceptable from the viewpoint of decay energies, gamma-emission, and half-life for use in *in vivo* diagnostic radiopharmaceuticals. Furthermore, it has been shown that several porphyrins can transport β-emitting nuclides (cobalt 58, zinc 65, and palladium 109) to nodal tissue where their ionizing radiation results in selective nodal ablation and diminished rejection rate for skin homographs in dogs dosed with these radio porphyrins (7–9). It has also been demonstrated that an intravenously administered cobalt 57 derivative of a water-soluble porphyrin developed a tumor–blood ratio of 44:1 at 5 days postdosing in the TCT-4904 rat bladder tumor (10). Sufficient precedent exists to indicate that a soluble indium-labeled porphyrin might be nodal specific. This study reports a facile synthesis for radioactive [^{111}In]tetra(4-*N*-methylpyridyl)porphyrin (I) whose biodistribution in rats illustrates its potential as a radiodiagnostic agent for major nodal systems.

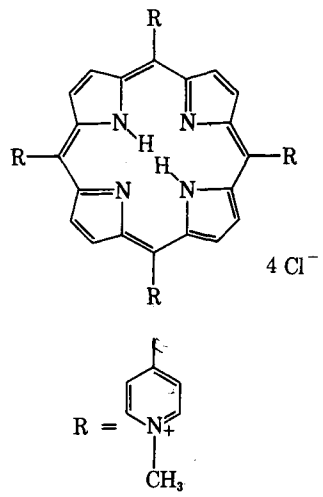
EXPERIMENTAL

The reactants, indium chloride[1], [^{111}In]indium chloride[2], and tetra(4-*N*-methylpyridyl)porphyrin tosylate salt[3], were obtained commercially. The tosylate salt of the porphyrin was converted to the chloride by passage through an anion-exchange column in the chloride form and the tetra(4-*N*-methylpyridyl) porphyrin chloride (II) used in all subsequent syntheses. UV spectra were obtained on a UV-visible spectrophotometer[4] in aqueous solution. Combustion analyses were performed by a microanalytical laboratory[5].

Synthesis of Indium Tetra(4-*N*-methylpyridyl)porphyrin—Indium chloride (66.0 mg, 0.30 mmole) was dissolved in 2.0 ml of 0.05 *N* HCl. In a 3.0-ml capped vial, 0.02 ml of this solution was evaporated to dryness under nitrogen in a 115° oil bath. Tetra(4-*N*-methylpyridyl)-porphyrin chloride (II) (25.0 mg, 0.03 mmole) was dissolved in 1.0 ml of distilled water and added to the indium chloride residue. This reaction mixture was stirred in a capped vial in a 115° oil bath for 1 hr. The visible spectra of both this reaction mixture and the starting ligand (II) were obtained. The majority of the reaction mixture was retained for elemental analysis. The aliquot portion of the mixture was applied to a 1.0 × 19.0-cm cation exchange column, which had been pretreated by eluting it with 10 ml of 5×10^{-5} *N* HCl. This column was then eluted sequentially with 10 ml of 5×10^{-5} *N* HCl, 30 ml of 5×10^{-4} *N* HCl, 10 ml of 5×10^{-3} *N* HCl, and 100 ml of 5×10^{-2} *N* HCl. The eluate was collected in 180 0.8-ml fractions.



A sample of the porphyrin ligand (II) was passed through an identically prepared column in the same manner. Visible spectra were obtained of representative samples of the colored eluate fractions from both indium tetra(4-*N*-methylpyridyl)porphyrin and the ligand (II) columns. Tubes (130–160 fractions) inclusive from the complex's eluate were then combined, the pH of the resulting solution adjusted to neutrality, and a visible spectrum obtained.

The portion of the original reaction mixture, retained for analysis, was solubilized in 2.5 ml of distilled water and treated with 5 ml of 4 *M* lithium perchlorate. The perchlorate salt precipitated. It was vacuum filtered with a fine frit, washed with cold water, dried under 0.5 torr, transferred carefully with a porcelain spatula (similar perchlorate salts have been reported to explode when rubbed or heated), and a portion subjected to combustion analyses. Chemical yields of the precipitated perchlorates were always in excess of 90% of theoretical. No defined melting point could be observed.

Anal.—Calc. for $C_{44}H_{36}N_8In(ClO_4)_5$: C, 41.12; H, 2.80; N, 8.72. Found: C, 41.28; H, 3.01; N, 8.87.

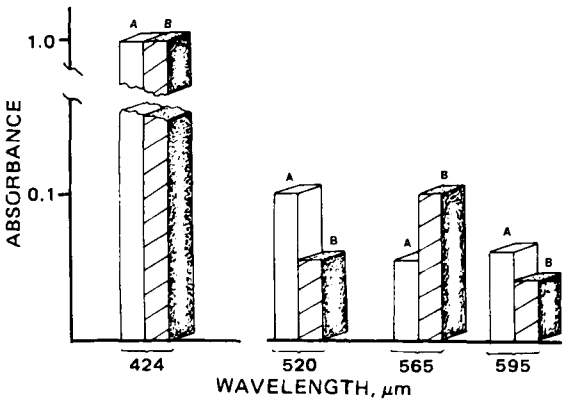

Figure 2—*UV and visible absorption spectra of free porphyrin ligand (II) and of the indium complex of II. Key: (A) indium complex; (B) porphyrin ligand.*

Synthesis of [^{111}In]tetra(4-*N*-methylpyridyl)porphyrin (I)—[^{111}In]indium chloride (3.8×10^{-6} mg, 1.7×10^{-8} mmoles, 1.57 mCi) in 0.05 *N* HCl was evaporated to dryness as described previously for nonradioactive indium chloride. Carrier indium chloride (3.8×10^{-4} mg, 1.7×10^{-6} mmoles) was added to the residue in 100 μl 0.05 *N* HCl, which was once again evaporated to dryness. The ligand (II) (0.14 mg, 1.7×10^{-4} mmoles) in 1.0 ml distilled water was added, and the reaction vial was stirred in a 115° oil bath for 1 hr. The cooled reaction mixture was applied to a cation exchange column prepared identically to those previously described and eluted in the same manner, and the activity of each 0.8-ml fraction was determined. Fractions 130–160 inclusive were combined, and the pH of the resulting solution was adjusted to neutrality by the addition of dilute sodium hydroxide. The neutralized solution was evaporated to a volume appropriate for the animal studies. The effective specific activity of I prepared in this manner was ~9 Ci/mmole as determined by dividing the total indium 111 activity used (1.57 mCi) by the total ligand (II) used (1.7×10^{-4} mmoles).

One microcurie of [^{111}In]indium chloride (2.39×10^{-9} mg, 1.08×10^{-11} mmoles) in 1.0 ml of distilled water was applied to a cation exchange column as previously described for I and was eluted in an identical manner. The activity of every one-tenth fraction plus a tube containing the contents of the eluted column was determined (Fig. 1).

Biodistribution Studies—Biodistribution studies using Wistar rats, average age 6.5 months and average weight 500 g, were carried out over a 4-day period. The animals were sacrificed in groups of 5 at four time periods: 1, 4, 24, and 48 hr. Each rat was injected with 0.2 ml of a 10-μCi/ml concentration of the neutralized solution of I in a caudal vein while under ether anesthesia. Just prior to the end of each time period each rat was again anesthetized with ether and a cardiac puncture was performed. Each rat was then sacrificed by cardiac removal and autopsied. The organs and tissues listed in Table I were removed, weighed, and counted in the gamma scintillation counter. The data for each organ or tissue have been normalized for a rat weighing 500 g, and the percentage of the total injection dose per gram weight has been calculated. The technique for tissue sampling and animal weight normalization has been described previously (11).

RESULTS AND DISCUSSION

Elemental analysis of the indium tetra(4-*N*-methylpyridyl)porphyrin correlated well with the calculated values. Since the amount of I synthesized for this study was too small to be characterized by the same method, another technique for its identification in solution was sought. When II was dissolved in distilled water the resulting solution was dark brown; after being heated with the indium chloride for 1 hr the reaction mixture turned violet in color. This color change was further manifested by a major difference in the visible spectral properties of the complex *versus* the porphyrin ligand. The spectra are compared at equimolar concentrations in Fig. 2. The change in the peak height ratios was used as a convenient tool to detect the complex in the presence of unreacted porphyrin. Cation exchange chromatography was used to isolate I from the crude reaction mixture. This method was capable of demonstrating small quantities of the radioactive complex in the presence of both unlabeled complex and free radioindium. Both the labeled and the unlabeled complexes were shown to elute from the column in the same elution volume (fractions 130–160): the former being demonstrated by a sharp rise in total counts per sample when each tube was examined in a gamma counter (Fig. 1), and the latter being demonstrated by the characteristic color which appeared only in those 30 fractions, and which possessed a visible spectrum identical to that of the complex prior to passing through the column.

Table II—Significant Lymph Node–Background Ratios

	1 hr	4 hr	24 hr	48 hr
Average node–bone	2.0:1	3.5:1	7.3:1	16.3:1
Average node–muscle	8.2:1	21.4:1	48.5:1	72.2:1
Thoracic nodes–heart	1.7:1	3.1:1	9.5:1	16.6:1
Thoracic nodes–blood	1.2:1	2.5:1	37.0:1	63.7:1
Superior mesenteric nodes–intestine	4.0:1	4.4:1	11.5:1	14.0:1

The identification of the labeled complex was considered conclusive when [^{111}In]indium chloride was placed on an identically prepared column, and no counts significantly over the background tissue were detected in the eluate, while the substance of the column was shown to retain all the counts that were applied as the radioactive indium chloride. The final manipulation of I was to neutralize the eluate that contained it with dilute sodium hydroxide before injection. This procedure was examined with the unlabeled complex and was shown to have no effect on the visible spectrum of that compound.

The distribution of I in rats as a function of time is presented in Table I. The percentage of the total injected dose per gram in the lymph nodes is surpassed only by that of the kidneys. More importantly, some node–surrounding tissue ratios, which would be pertinent for imaging both abdominal and thoracic nodal groups, have been expressed in Table II and show considerable prominence of the nodes over background tissue. The nodal groups in these areas are among the most difficult, if not impossible, to image by the best existing techniques, which depend on drainage of the injection site by the lymphatics of the nodes in question.

Earlier studies that reported the node ablation with β-emitting metalloporphyrins did not indicate, however, any property unique to porphyrins which causes their affinity for lymphatic tissue (7–10). It has been theorized in one report that porphyrins and metalloporphyrins are concentrated by tissues with a high mitotic index (4). Bone marrow and duodenal mucosa are two tissues with extremely high turnover rates, and yet in one quantitative study, it was noted that lymph node activity was 16.7 times that of duodenal mucosa and 7.5 times that of bone marrow (7). These data tend to indicate that some quality other than a high mitotic index may be required to explain the localization of these complexes in lymph nodes. It is possible that the complexes localize in the lymph nodes by the mechanism recently proposed for particulate antigens (12). This study showed that colloidal carbon was concentrated in lymph nodes in the region of the high endothelial venules. These unique vessels have been extensively examined (13), and this work suggests that the highly permeable nature of these venules, coupled with the intricate system of hemodynamic controls inherent in the nodal microvasculature, could provide functional lymph node–venous communications. Further study, however, will be required before the porphyrin localization mechanism can be clearly identified.

The potential of I as a diagnostic imaging agent is apparent. The intravenous route of administration would provide an easy and reproducible clinical procedure superior to oil lymphography and to technetium Tc 99m–antimony sulfide lymphoscintigraphy, while the possibility of examining abdominal and thoracic nodal groups by a relatively noninvasive technique would be an invaluable aid in monitoring both neoplastic metastasis and alterations in the immune system in response to a host of other pathologies. Further study of this compound is currently in progress.

Simultaneous Self-Association and Diffusion of Phenol in Isooctane

J. B. DRESSMAN *§, **K. J. HIMMELSTEIN** *‡§x, **and T. HIGUCHI** *

Received June 11, 1981, from the *Department of Pharmaceutical Chemistry, ‡Department of Chemical and Petroleum Engineering, University of Kansas, Lawrence, KS 66045. Accepted for publication January 8, 1982. §Present Address: INTER$_x$ Research Corp., Lawrence, KS 66044

Abstract □ The impact of self-association on mass transport was studied. The model system chosen was the diffusion of phenol through an immobilized layer of isooctane. In the theoretical development, self-associated phenol contributed to diffusion, with the fluxes being interdependent because of the self-association equilibrium. Predictions from theory were then compared with experimental results. It was shown that self-association can significantly affect flux of diffusing species.

Keyphrases □ Phenol—self-association and diffusion in isooctane □ Isooctane—simultaneous self-association and diffusion of phenol □ Diffusion—phenol in isooctane, simultaneous self-association

Associative interactions are of interest to those concerned with pharmaceutics for two reasons. First, associative interactions affect many processes such as dissolution, partitioning, and diffusion, all of which are vitally important to drug delivery. Second, most drugs contain at least one interactive functional group and, thus, are able to participate in associative interactions with many substances found in dosage forms and in the body.

The effects of association and related processes on various aspects of drug delivery have been examined in several studies. Dissolution rate is known to be altered significantly when dissociation reactions (1, 2) or complexation (3) occur within the dissolution layer. It has also been observed that when a diffusing species self-associates (4) or forms micelles (5) there is a pronounced effect on the rate of transport of that substance. Another study (6) has indicated that in a self-associating system, where diffusion of the self-associated species is blocked by its inability to penetrate the membrane used, the observed mass transport behavior can be accounted for by assuming that the compound is transported only in its monomeric form.

Where simultaneous self-association and diffusion occur, the direct application of Fick's laws fails to predict the diffusion rates observed. In the current study, a more comprehensive approach to the theoretical analysis of diffusion under such circumstances is presented. It is postulated that (*a*) by taking into account the interdependence of the fluxes of the associated and unassociated species arising from associative equilibrium within the diffusional layer, (*b*) by applying Fick's laws to each kind of species present, and (*c*) by numerically solving the differential equations derived on this basis, it is possible to predict the mass transport behavior of self-associating systems.

The model system used to test this postulate was one in which phenol was allowed to diffuse from a donor phase of isooctane, through an immobilized layer of isooctane which served as the diffusion layer, into an aqueous receptor phase. Phenol is known to self-associate significantly (>50%) at high concentrations in isooctane (7). This interaction was expected to cause the rate of mass transport into the aqueous phase to deviate markedly from that predicted by simply applying Fick's laws to the overall concentration of phenol present. Using the scheme outlined above, the diffusional behavior of phenol in the model system was predicted mathematically. The predicted results were then compared with the experimental data obtained.

THEORETICAL

Previous studies have shown that when phenol self-associates in isooctane, the dominant species formed is probably the pentamer[1] (7). The equilibrium expression for this interaction has been reported as:

$$5\,P_m \rightleftharpoons P_5$$

where P_m represents monomeric phenol and P_5 represents the pentameric species. The equilibrium constant for this interaction is $K_{1\text{-}5} = 6300\ M^{-4}$ at 25° in isooctane. This model appears to provide an adequate description of self-association of phenol over a wide range of concentrations.

In the present investigation a silanized sintered glass filter with a presilanization pore size range of 4.5–5.5 μm was used to form a diffusional barrier between the donor isooctane and the receptor aqueous phases. Because of the large pore size and equilibration of the filter with the donor phase prior to each experiment, the barrier actually consisted of a layer of isooctane immobilized within the sintered glass filter. Figure 1—*Interactions of phenol in the silanized sintered glass filter system.*

shown in Fig. 1, self-association would be expected to occur within the diffusional layer as well as in the donor phase. Over the time span of the experiment, phenol concentrations remained sufficiently low in the aqueous phase to allow the assumption that self-association in that phase was negligible.

Consider an infinitesimal element within the diffusion layer. Expressions for the net flux of the monomer and pentamer species into the element can be obtained assuming that the self-association equilibrium between the two species is established very quickly compared to the rate of diffusion, and Fick's laws can be applied to the diffusion of each species within the element. Influx of the monomer can be represented as:

$$\left(\frac{\partial P_m}{\partial t}\right)_{IN} = -D_m\left(\frac{\partial P_m}{\partial h}\right) \qquad \text{(Eq. 1)}$$

where D_m is the diffusivity of the phenol monomer, h is distance, and t is time. The efflux of the monomer from the element can be written as:

$$\left(\frac{\partial P_m}{\partial t}\right)_{OUT} = -D_m\left[\left(\frac{\partial P_m}{\partial h}\right) + \frac{\partial}{\partial h}\left(\frac{\partial P_m}{\partial h}\right)\right] \qquad \text{(Eq. 2)}$$

The net flux of the monomer into the element is given by the difference between the influx and efflux of the monomer from the element:

$$\left(\frac{\partial P_m}{\partial t}\right) = \left(\frac{\partial P_m}{\partial t}\right)_{IN} - \left(\frac{\partial P_m}{\partial t}\right)_{OUT} = D_m\frac{\partial}{\partial h}\left(\frac{\partial P_m}{\partial h}\right) \qquad \text{(Eq. 3)}$$

as given by Fick's second law. Similarly, the following expression is obtained for the net flux of the pentamer:

$$\left(\frac{\partial P_5}{\partial t}\right) = D_5\left(\frac{\partial^2 P_5}{\partial h^2}\right) \qquad \text{(Eq. 4)}$$

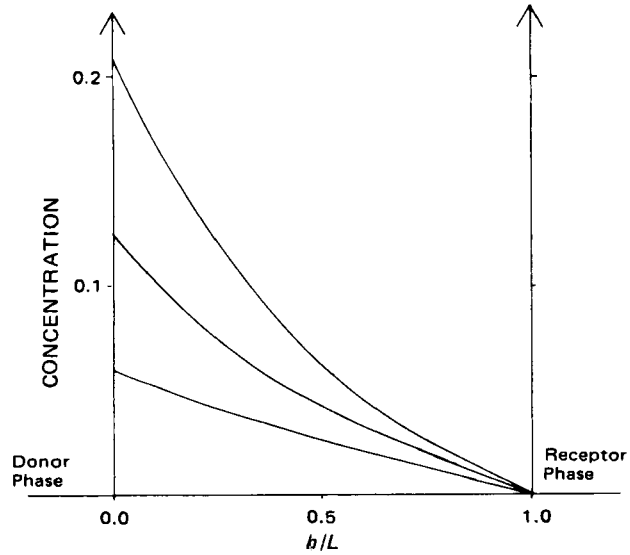

Figure 2—*Profile of total concentration of phenol in the immobilized layer of isooctane constituting the diffusion layer, calculated from Eqs. 9 and 15 for three donor phase concentrations of phenol: 0.2063, 0.1226, and 0.0432* M, *under steady-state and sink conditions.*

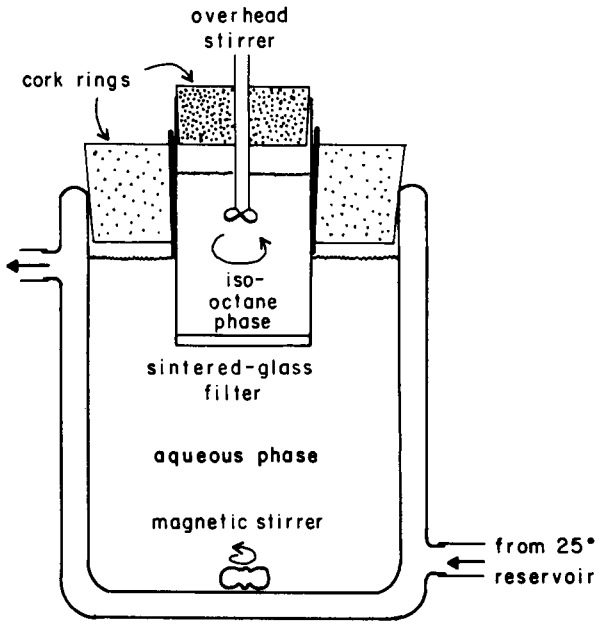

Figure 3—*Apparatus for diffusion studies.*

where D_5 is the diffusivity of the pentamer species. Given that P_T is the total concentration of phenol present, one can write:

$$P_T = P_m + 5P_5 \qquad \text{(Eq. 5)}$$

The expressions for the flux of the monomer and pentamer can therefore be combined into one expression as follows:

$$\left(\frac{\partial P_T}{\partial t}\right) = D_m\left(\frac{\partial^2 P_m}{\partial h^2}\right) + 5D_5\left(\frac{\partial^2 P_5}{\partial h^2}\right) \qquad \text{(Eq. 6)}$$

Using the equilibrium expression:

$$P_5 = K_{1-5}P_m^5 \qquad \text{(Eq. 7)}$$

it can be shown then by repeated application of the chain rule that:

$$\left(\frac{\partial^2 P_5}{\partial h^2}\right) = 20K_{1-5}P_m^3\left(\frac{\partial P_m}{\partial h}\right)^2 + 5K_{1-5}P_m^4\left(\frac{\partial^2 P_m}{\partial h^2}\right) \qquad \text{(Eq. 8)}$$

By substituting Eq. 7 into Eq. 5 one obtains the expression:

$$P_T = P_m + 5K_{1-5}P_m^5 \qquad \text{(Eq. 9)}$$

Taking the derivative of both sides of Eq. 9 with respect to time it can be shown that:

$$\left(\frac{\partial P_T}{\partial t}\right) = \left(\frac{\partial P_m}{\partial t}\right)(1 + 25K_{1-5}P_m^4) \qquad \text{(Eq. 10)}$$

Then, by substituting Eqs. 8 and 10 into Eq. 6 one can produce a partial differential equation in terms of the monomer concentration only:

$$\left(\frac{\partial P_m}{\partial t}\right)(1 + 25K_{1-5}P_m^4) = \left(\frac{\partial^2 P_m}{\partial h^2}\right)(D_m + 25D_5K_{1-5}P_m^4) + \left(\frac{\partial P_m}{\partial h}\right)^2 100D_5K_{1-5}P_m^3 \qquad \text{(Eq. 11)}$$

Steady-State Solution Under Sink Conditions—At steady state there is no net accumulation of either form of phenol at any point within the diffusion layer, so there is no net flux into any element, *i.e.*, $\partial P_T/\partial t = 0$. Applying this condition to Eq. 11 one finds that:

$$\left(\frac{\partial P_T}{\partial t}\right) = \left(\frac{\partial^2 P_m}{\partial h^2}\right)(D_m + 25D_5K_{1-5}P_m^4) + \left(\frac{\partial P_m}{\partial h}\right)^2 100K_{1-5}K_5P_m^3 = 0 \qquad \text{(Eq. 12)}$$

Letting $y = (dP_m/dh)$ in the above expression and then separating the variables and integrating, one obtains:

$$\left(\frac{dy}{y}\right) = -\left(\frac{100K_{1-5}D_5P_m^3}{D_m + 25K_{1-5}D_5P_m^4}\right)dP_m$$

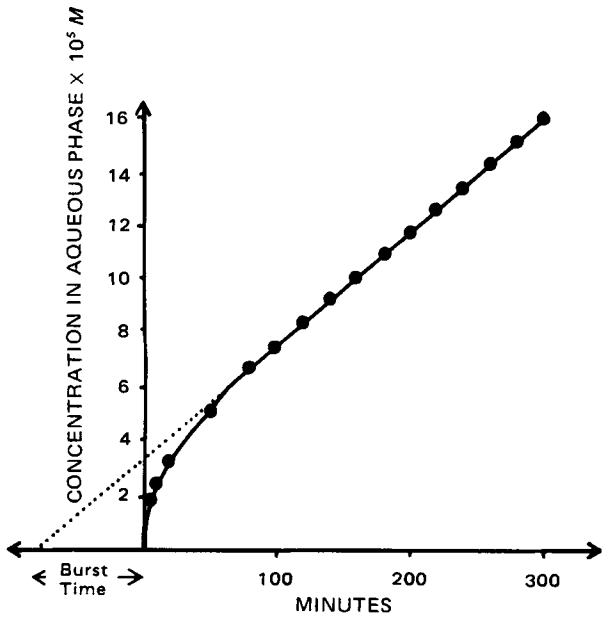

Figure 4—*Cumulative concentration of phenol in the aqueous phase* versus *time for diffusion through a sintered glass filter from a 0.1403* M *solution of phenol in isooctane. Key: (●) experimental data; (—) results obtained by numerical solution of Eq. 11.*

which leads to:

$$y = \left(\frac{dP_m}{d\,h}\right) = \frac{C_1}{D_m + 25\,K_{1\text{-}5}\,D_5 P_m^4} \qquad \text{(Eq. 13)}$$

where C_1 is the first constant of integration. Separating variables and integrating again gives the equation:

$$D_m P_m + 5\,K_{1\text{-}5}\,D_5 P_m^5 = C_1\,h + C_2 \qquad \text{(Eq. 14)}$$

where C_2 is the second constant of integration.

Appropriate boundary conditions can then be applied to solve for the constants of integration. Since the concentration in the bulk of the donor phase remains effectively constant during the course of the experiment, one can write:

$$P_m = P_0 \text{ at } h = 0$$

The second constant of integration C_2 can be found by substituting this condition into Eq. 14 to give:

$$C_2 = D_m\,P_0 + 5\,K_{1\text{-}5}\,D_5\,P_0^5$$

If sink conditions are assumed to hold at the aqueous interface, *i.e.*, $P_m = 0$ at $h = L$ where L is the distance across the diffusion barrier, this condition can be used in conjunction with the expression for C_2 in Eq. 14 to obtain the first constant of integration, which is thus given by:

$$C_1 = \frac{-D_m\,P_0 - 5\,K_{1\text{-}5}\,D_5\,P_0^5}{L}$$

Substituting for C_1 and C_2 in Eq. 14 gives the expression:

$$\frac{h}{L} = \frac{D_m(P_0 - P_m) + 5\,K_{1\text{-}5}\,D_5\,(P_0^5 - P_m^5)}{D_m\,P_0 + 5\,K_{1\text{-}5}\,D_5 P_0^5} \qquad \text{(Eq. 15)}$$

Equation 15 can be used to find the concentration of monomer and total phenol at any point in the diffusion layer at steady state, under sink conditions. Using Eq. 9 and the monomer concentration obtained using Eq. 15, the total concentration profile can be calculated. Figure 2 shows the total concentration profiles at three representative donor phase concentrations of phenol. These plots show that at higher concentrations of phenol where the self-associated species accounts for a large percentage of phenol present, the concentration profile is predicted to deviate from linearity in a pronounced manner. The values of D_m and D_5 were 5.5×10^{-6} and 2.0×10^{-6} cm²/sec, respectively. They were obtained initially from the Stokes–Einstein equation and then adjusted to give a reasonable representation of the experimental data. Filter tortuosity characterization with a substance with a known diffusion coefficient would have allowed a more accurate determination of D_m, at least at low concentrations.

Nonsteady-State Solution—To determine whether the self-association model can be used to successfully predict the data obtained for the cumulative amount of phenol in the aqueous phase over the course of the experiment and subsequently to predict burst time and steady-state flux data, it was necessary to obtain solutions to Eq. 11 for both presteady-state and steady-state behavior under nonsink conditions.

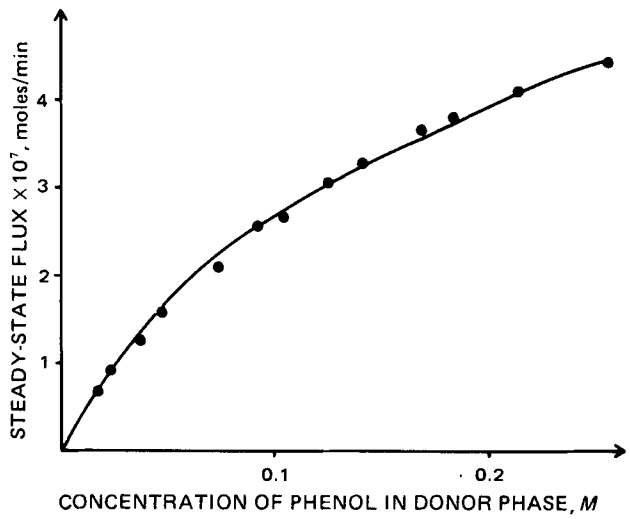

Figure 5—*Steady-state flux (moles per minute) over the entire diffusion layer surface area* versus *total concentration of phenol in the donor phase. Key: (●) mean of the experimental data at a given concentration of phenol; (—) results obtained by numerical solution of Eq. 11.*

Equation 11 is a nonlinear second-order partial differential equation and cannot be conveniently solved analytically under the required conditions. Therefore, it was necessary to transform the equation into an approximate algebraic expression that could be solved numerically. The derivatives were expressed as finite differences using the central and backward difference formulas outlined in a previous report (8) for use in implicit solution methods. The square term in the first derivative of P_m with respect to distance was handled by splitting it into two parts: a constant coefficient calculated on the previous time step and a backward difference expression for the derivative calculated on the current time step. This enabled a set of linear equations to be established for each time step, the coefficients of which were arranged in a tridiagonal matrix. This matrix system was then solved using a Gaussian elimination method as described previously (8). The nonlinear elements of the equation could then be updated from the solution obtained. The entire procedure was repeated until the solution obtained did not differ from the assumed elements by more than a predetermined tolerance. However, it was found that the first approximation used for the nonlinear elements was within the desired tolerance and the iterative solution was not employed subsequently.

Burst Time—Burst time methodology was employed because of the apparatus design. That is, the glass filter initially contained phenol at the same concentration as the bulk isooctane phase. As with the more commonly used lag time, the burst time should be independent of the donor phase concentration in a system where only one species is responsible for the total observed rate of diffusion. This can be shown by following the derivation presented in a previous report (9) and applying boundary and initial conditions appropriate for burst effect conditions to obtain:

$$t_{\text{burst}} = \frac{-L^2}{3.1\,D} \qquad \text{(Eq. 16)}$$

where L is the distance across the diffusion layer and D is the diffusivity (10). Deviation from this relationship was predicted in the current study as it was postulated that more than one species contributed to the overall rate of diffusion.

EXPERIMENTAL

Materials—Phenol[2] (Analytical reagent grade) was fractionally distilled under vacuum to remove the preservative and other contaminants, then stored under nitrogen in a desiccator. Certified ACS isooctane (2,2,4-trimethylpentane)[3] was used without further purification.

[a] Number of experiments.

The single sintered glass filter (pore size 4.5–5.5 μm; 2-mm thick; 30-mm radius) was obtained commercially[4] and silanized by soaking overnight in a solution of dichloromethylsilane in toluene. Excess silanizing agent was later removed with a solution of acetic acid in hexane.

Analytical Method—Two-milliliter samples were removed from the aqueous phase at suitable time intervals up to 300 min. At the conclusion of the experiment the UV absorbance at 269 nm, the wavelength of maximum absorbance for phenol in the UV region, was determined for each sample[5]. Deoxygenated, distilled water was used as the reference solution. In the aqueous solution with ~pH 6 ionization was >99.9% suppressed.

Diffusion Apparatus and Study—The experimental apparatus is depicted in Fig. 3. Five hundred milliliters of freshly deoxygenated distilled water was placed in a water-jacketed beaker connected to a controlled-temperature reservoir which was used to maintain the temperature of the system at 25°. A magnetic stirrer was used to keep the aqueous phase well mixed. Fifty milliliters of a solution of phenol in isooctane was poured into the tube containing the silanized sintered glass filter and allowed to sit for 3 min. The lower side of the filter was then wiped dry and the tube placed in the aqueous phase in such a position that bulging of the isooctane phase down into the aqueous phase was avoided. Silanization of the filter prevented the hydrostatic pressure of the aqueous phase forcing any water up into the filter. Cork rings fitted above both phases prevented evaporation. The isooctane phase was stirred from above. Optimal stirring rates for the isooctane and aqueous phases were used to ensure even mixing without vortexing problems. This allowed the assumption to be made that the boundary layers in the bulk isooctane and aqueous phases were a negligible barrier to diffusion compared to the immobilized isooctane layer in the sintered glass filter. Thus, the principal barrier to diffusion was the layer of isooctane immobilized in the sintered glass filter.

At suitable time intervals, 2-ml samples were removed from the aqueous phase and the volume replaced with deoxygenated distilled water. The samples were analyzed by UV spectroscopy at the conclusion of each experiment on the same day, so that chemical stability was not a problem.

RESULTS AND DISCUSSION

Phenol was diffused from a donor phase solution in isooctane (at concentrations ranging from 0.0123 to 0.255 M) through a layer of isooctane immobilized within a sintered glass filter into an aqueous phase. The concentration of phenol was determined in the aqueous phase at times up to 300 min. Figure 4 shows a typical plot of the data obtained. For all donor phase concentrations studied, the plot became linear for times >100 min as the system reached a pseudo steady state. Data for these points were analyzed by linear regression to determine the steady-state flux and burst time values. Results from runs in which the correlation coefficient was <0.999 were discarded to minimize uncertainty in calculations of steady-state flux. Extrapolation of the best-fitting linear relationship to zero phenol concentration in the aqueous phase provided the burst time measurement. The slope of the line was used to calculate the steady-state flux in moles per minute over the entire surface area of the diffusion layer (7.069 cm^2) after adjusting the units from molarity per minute by using the aqueous phase volume. Table I summarizes steady-state flux and burst time values obtained.

Steady-State Flux—The experimentally observed relationship between steady-state flux and total concentration in the donor phase obtained in these studies is shown in Fig. 5. This relationship may be compared with classical behavior predicted from Fick's laws. Fick's first law is given by:

$$J = -D\frac{\partial C}{\partial h} \qquad \text{(Eq. 17)}$$

$$J \approx -D\left(\frac{C_0 - C_L}{h}\right) \qquad \text{(Eq. 18)}$$

where J is the flux across the diffusion layer, D is the diffusivity, C_0 is the concentration at $h = 0$ (the donor phase interface), C_L is the concentration at $h = L$ (the receptor phase interface), and h is distance. Provided the receptor phase concentration remains low, *i.e.*, $C_L \approx 0$, the flux can be written as:

$$J \propto C_0 \qquad \text{(Eq. 19)}$$

Under these conditions, one would expect the steady-state flux to increase linearly with increasing concentration in the donor phase. Figure 5 shows, however, that steady-state flux is not directly proportional to donor phase concentration, since the plot deviates significantly from linearity. Anomalous behavior of this type has also been noted for diffusion of phenol through high-density polyethylene membranes by

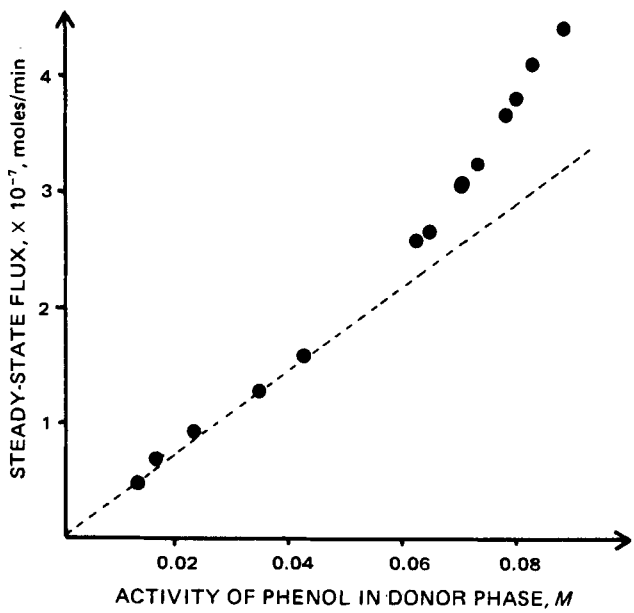

Figure 6—*Steady-state flux (moles per minute) over the entire diffusion layer surface area* versus *activity of phenol (concentration of monomeric phenol) in the donor phase. Figure 7—*Burst time (minutes)* versus *total concentration of phenol in the donor phase. Key: (O) experimental data points; (—) obtained from the numerical solution of Eq. 11.*

Mikkelson *et al.* (6) who were subsequently able to obtain a linear relationship by plotting the steady-state flux *versus* activity of phenol present. For that system it was suggested that only the monomeric phenol could partition into the membrane and, hence, contribute to the observed rate of flux. The steady-state flux data for the sintered glass filter system used in the current study was replotted *versus* activity of phenol (defined as the concentration of monomeric phenol) as shown in Fig. 6. The plot exhibits pronounced positive deviation from linearity which indicates that the monomeric portion of the phenol was not solely responsible for the transport of phenol into the aqueous phase in this system. The fraction of phenol present as monomer is ~0.35 at a total phenol concentration of 0.255 *M* as compared to >0.99 at 0.0132 *M*.

On the basis of the pentamer model for self-association of phenol in isooctane, it was proposed that both the monomer and the pentamer species of phenol contribute to the overall observed flux according to Eq. 11. This equation was solved numerically as outlined in the *Theoretical* section and the results compared with the experimental data. For both the individual plots of cumulative concentration in the aqueous phase *versus* time (Fig. 4) and the overall plot of steady-state flux *versus* total concentration of phenol on the donor phase (Fig. 5), the numerical solution is in good agreement with the observed results, indicating that the pentamer species was able to form in the diffusion layer and, hence, contribute proportionately to the flux into the aqueous phase.

Transient Behavior—A second way to study the effect of self-association on diffusion is to analyze the transient (burst time) data. The burst time for a single diffusing species should be independent of the concentration in the donor phase when the diffusion of one species accounts for the observed flux. Burst time data for the system under study are presented in Table I. Figure 7 shows a plot of measured burst time *versus* concentration in the donor phase. The burst time increased with increasing concentration rather than being entirely concentration independent. Since burst time is inversely proportional to diffusivity, the apparent diffusivity appears to have become smaller as the concentration in the donor phase increased. This type of behavior has also been noted for solutions of phenol in carbon tetrachloride (11).

An explanation can be offered for this behavior by considering the monomer–pentamer equilibrium. As the total concentration of phenol increased in the donor phase, the percentage present in the self-associated form increased. Since diffusivity is inversely related to the size of the diffusing species, one would expect that when the pentamer accounts for a large percentage of the phenol present, the apparent diffusivity would be lower, and thus, the burst time would be longer than at low concentrations where the much smaller monomer species accounts for virtually all of the phenol in solution.

The solid line in Fig. 7 represents burst time values calculated from the computer-generated data by applying linear regression analysis to predicted steady-state cumulative concentrations of phenol in the aqueous phase and extrapolating back to zero phenol concentration. Although there is considerable scatter in the experimental data, they appear to follow the same trend as the results derived from Eq. 11. In most instances the observed burst time tends to be greater than the theoretical value. This is probably due to a small amount of phenol solution on the lower face of the glass filter when it was positioned into the aqueous phase. This would have caused the immediate release of phenol into the aqueous phase by nondiffusive means, which in turn would result in falsely high observed values for the cumulative amount in the aqueous phase and, therefore, for the burst time.

The burst time and the steady-state flux data both support the conclusion that the apparent deviation of the diffusion characteristics of phenol in isooctane from Fick's laws can be entirely accounted for by considering the self-association equilibrium of phenol in isooctane. From Eq. 11 one can note that the diffusion of each species, monomer and pentamer, fundamentally obeys Fick's laws and that the diffusivity of each species is constant. The apparent diffusivity, as reflected in the burst time, only changes because of the variation with concentration of the relative proportions of the monomer and pentamer present.

CONCLUSIONS

In these studies it has been shown that the apparent deviation from classical behavior of the diffusion of phenol through an immobilized solution of isooctane can be explained by the specific interaction effects rather than needing to resort to an empirical description in terms of the apparent diffusivity of the overall system. This approach to describe concomitant self-association and mass transport can be used to help predict delivery rates of drugs for which diffusion is the rate-controlling step in release from the dosage form or in the absorption process, and self-association occurs under physiological conditions. Caffeine (4) and some analgesics and antihistamines (12–17) have been shown to self-associate at high concentrations in aqueous solution.

The rate of transport of these drugs across the dissolution layer when they are released from solid dosage forms, therefore, may be affected by the self-association interaction. Other substances such as alcohols and carboxylic acids are known to self-associate in organic solvents (18). Absorption through lipoidal membrane barriers or release from dosage forms which are coated with polymeric films are examples of steps in the drug delivery process at which self-association of drugs containing such groups may significantly affect the rate of transport.

Factors Affecting Survival of *Pseudomonas cepacia* in Decongestant Nasal Sprays Containing Thimerosal as Preservative

B. T. DECICCO *x, E. C. LEE *, and J. V. SORRENTINO ‡

Received July 6, 1981, from the **Department of Biology, The Catholic University of America, Washington, DC 20064*, and ‡*Vick Health Care Division, Richardson-Vicks, Inc., Wilton, CT 06897.* Accepted for publication January 18, 1982.

Abstract □ Strains of *Pseudomonas cepacia*, isolated from packages of nasal spray preserved with thimerosal, showed a high degree of resistance to the organomercurial, as compared to low and moderate resistance of standard laboratory strains or isolates from water. The product isolates were shown to degrade the thimerosal to metallic mercury which volatilized from the product or assay medium. The addition of organic nutrient was essential for survival of unadapted cells in the product. However, when cells were first grown in diluted product containing added nutrient and then inoculated into the full-strength product, survival and growth occurred even in the absence of added nutrient. The time required for growth to occur was inversely related to the amount of added nutrient. At low nutrient concentrations, ~99.9% of the inoculated cells were killed rapidly, but after a lag time of 7–12 days, the few survivors began to increase in numbers and eventually attained high cell concentrations. These findings should be useful in planning production and testing programs with thimerosal-preserved products.

Keyphrases □ Thimerosal—preservative, factors affecting survival of *Pseudomonas cepacia* in decongestant nasal sprays □ *Pseudomonas cepacia*—factors affecting survival in decongestant nasal sprays containing thimerosal as preservative □ Decongestants—nasal sprays containing thimerosal as preservative, factors affecting survival

Although generally considered nonpathogenic, *Pseudomonas cepacia* can cause severe and sometimes fatal infections, especially when accidently introduced directly from contaminated materials into wounds, blood vessels, or the urinary tract (1–9). Recently, it has been implicated as the cause of contamination of decongestant nasal sprays produced by two different companies. In one case the affected products contained the cationic surfactant benzalkonium chloride as the preservative, while in the other instance, the products contained the organomercurial, thimerosal. The present report describes studies with organisms isolated as contaminants in the latter products.

BACKGROUND

The bacterium, *P. cepacia*, was first reported as the causative agent of yellow rot in onions (10) and was given the species name on the basis of that ability. A taxonomic study of the genus *Pseudomonas* described an organism which was versatile nutritionally (11); based on that characteristic it was named *P. multivorans*. It was suggested that this species, which can utilize over 150 different organic compounds as sources of carbon and energy, had not been described earlier because of its geographic restriction, but it is now known to occur widely in soil and water. The two species, *P. cepacia* and *P. multivorans*, plus a third, *P. kingii*, have since been shown to be identical, and the designation *P. cepacia* has been adopted (12, 13).

In addition to its nutritional versatility, *P. cepacia* possesses the ability to grow in distilled water without added nutrients (14), and most isolates are highly resistant to antibiotics and other antibacterial agents (15, 16). This combination has led to numerous nosocomial problems due to its presence in water reservoirs, hospital aqueous solutions, and disinfectants (17–22). Like some of the other pseudomonads, *P. cepacia* has been isolated from numerous commercial products and rivals *P. aeruginosa* as to its presence and persistance in various pharmaceuticals.

In 1978, pseudomonads were isolated from several lots of both the regular and long-acting formulations of nasal sprays. The regular formulation contains phenylephrine hydrochloride while the long-acting variety contains xylometazoline as the adrenergic component. Both formulations contain 10 ppm of thimerosal as a preservative. Cetylpyridinium chloride also is present in the regular formulation but not in the long-acting brand. A number of separate bacterial isolates from both formulations were identified as *P. cepacia* of several different biotypes[1].

The occurrence of resistance to high levels of thimerosal and other organomercurials has been demonstrated in numerous bacterial species including the pseudomonads, *P. cepacia* and *P. aeruginosa*, and, although the mechanism of resistance varies with the microbial strain and the type of mercurial compound, with organomercurials it normally involves plasmid-determined inducible enzymes which hydrolyze the carbon–mercury linkage and then reduce the released Hg^{+2} to volatile metallic mercury (Hg°) (23, 24).

In this report some physiological characteristics of strains of *P. cepacia* isolated from products containing thimerosal are described. They are compared with strains from other sources, and the conditions under which successful contamination may or may not occur are examined.

EXPERIMENTAL

The bacterial strains employed in these studies were obtained from various sources, as shown in Table I.

Thimerosal sensitivity assays were performed in test tubes containing 7.5 g/liter (one-fourth strength) trypticase soy broth[2] plus various concentrations of thimerosal[3] ranging from 0 to 10,000 ppm in a final volume of 6.0 ml. Tubes were inoculated to cell densities of $\sim 5 \times 10^6$ organisms/ml using 0.05 ml of inocula grown in 7.5 g/liter trypticase soy broth, and were incubated with slow shaking at 30°. The highest concentration yielding growth, as indicated by visible turbidity, was noted. In the thimerosal sensitivity assay, turbidity was always present by Day 5 if growth was to occur. Negative tubes were verified to be free of viable cells by streaking onto trypticase soy agar[2] plates.

Chemical analyses for thimerosal were performed by determining mercury contents using atomic absorption spectrophotometry (25).

Microbiological assays for thimerosal were performed on trypticase soy agar and Mueller–Hinton agar plates using a sensitive strain of *Staphylococcus aureus* as the indicator organism. Filter paper disks were 12.5 mm in diameter. The plates were incubated at 35° and read at 24 hr. Challenge testing of the product was performed by growing test organisms in trypticase soy broth at 30 or 35° and inoculating the product to concentrations ranging from 1.5×10^5 to 2.4×10^7 organisms/ml. In some instances a second challenge was performed with the same organism. Both types of nasal spray were employed and were either freshly prepared or were from commercial lots of different ages.

Tests to determine the ability of the isolates to utilize product components as sole sources of carbon and energy were performed using a mineral salts basal medium. The mineral medium consisted of the following components per liter of distilled water: 80 mg K_2HPO_4, 200 mg NaH_2PO_4, 100 mg $(NH_4)_2SO_4$, 14 mg $MgSO_4 \cdot 7H_2O$, and 2 mg $Fe(NH_4)_2 \cdot 6H_2O$. Organic components of the nasal sprays were tested separately by adding them to the mineral medium to final concentrations of 0.1 and 1.0 g/liter. Thimerosal could not be tested as a carbon and energy source, since in mineral salts medium it was lethal to all strains at concentrations >5 ppm. Inocula for these studies were grown overnight on mineral salts agar containing 1 g/liter monosodium glutamate. Cells were transferred to sterile distilled water and shaken overnight, then

diluted in distilled water to yield the desired inoculum size, which was calculated to be $\sim 1 \times 10^{2}$ cells/ml. The actual number of cells present at the time of inoculation and at daily intervals for 5 days was determined by spreading samples onto trypticase soy agar plates.

When adapted cultures were employed, they were prepared by growing inocula in a fourfold dilution of product (diluted with deionized water) containing 300 ppm of phytone[2] (soy peptone). In this medium organisms reached visible turbidity in 1–2 days.

In those experiments where nutrient supplementation of the product was employed, individual substances or complex media were prepared at concentrations of 120 g/liter (or lower if solubilities did not permit the higher levels), sterilized by membrane filtration, and added to tubes containing product to yield the desired range of concentrations. As with assays for thimerosal resistance, growth was noted by observing tubes for turbidity. Tubes showing no turbidity were checked periodically for viable cells by streaking or spreading aliquots onto trypticase soy agar plates.

RESULTS AND DISCUSSION

The thimerosal sensitivities of a number of well-characterized bacterial strains, as well as some water and product isolates, are shown in Table I. A difference in resistance is evident between the ATCC strains (growth up to 10 ppm) and the product isolates, which grew in the presence of 300–1000 ppm of thimerosal. No organism was isolated from the product which was not resistant to high levels of thimerosal. Thus, resistance to thimerosal appeared to be essential for survival in the product. Strains of *Pseudomonas* isolated from city water entering the production site had resistance levels intermediate between the laboratory strains and the product isolates. The effect of inoculum size also can be seen in Table I. When strain CXN was inoculated at concentrations 100- and 10,000-fold below the standard level of 5×10^{6} organisms/ml, the highest thimerosal concentration yielding survival and growth fell slightly, but even with the lowest inoculum of 500 cells/ml, the organisms still grew in 100 ppm of thimerosal. A similar effect was noted when strain CWJ was inoculated directly from a contaminated bottle into assay tubes to produce an inoculum level ~100-fold below the standard level (growth was to 500 ppm).

Table II—Microbiological and Chemical Assays[a] for Thimerosal in Uninoculated Samples and in Media Inoculated with Resistant Strains of *P. cepacia*

[a] Both uninoculated and inoculated samples were assayed after 4-days incubation at 30°. [b] Not assayed. [c] Trypticase soy broth.

Table II shows the results of chemical and microbial assays for thimerosal using various solutions containing thimerosal, both uninoculated and after growth of two resistant strains. Comparison of thimerosal in deionized water with 4-day-old uninoculated trypticase soy–thimerosal tubes, using the microbiological assay, showed that the one-fourth strength trypticase soy medium had no neutralizing effect on thimerosal. Tubes inoculated with *P. cepacia* strain CXN showed the absence of detectable thimerosal by microbial assay, even when the initial concentration was 100 ppm and even though this assay easily detected 1-ppm concentration in the uninoculated deionized water and in trypticase soy broth controls. Chemical analyses for thimerosal mercury confirmed the inactivation of thimerosal by strains CXN and B7L. Since the chemical assay determines mercury levels, it can be assumed that strains B7L and CXN are resistant to thimerosal by virtue of enzymes which liberate metallic mercury from the media. This also was observed by chemical determination of mercury levels in numerous contaminated and uncontaminated packages of nasal spray. The analyses showed that 1-year-old uncontaminated packages all contained the expected levels of 6.8–7.4 ppm of thimerosal, whereas contaminated packages from the same lots and cases contained 0.1–1.5 ppm. Thus, when the contaminating organisms survived and grew in the product, the thimerosal was degraded.

When strains CWO and CXN were used to challenge both the regular and the long-acting product at levels of 1.5×10^{5}–2.4×10^{7} organisms/ml, no viable organisms could be recovered after 1 hr. In all, over 70 challenge tests were performed with uniformly negative results. This was true whether the products were freshly prepared in the laboratory or were uncontaminated packages taken from cases that contained one or more contaminated packages. Thus, no differences were noted between old and fresh product or between regular and long-acting product with regard to survival of *P. cepacia* strains isolated from the product. Since the long-acting product does not contain cetylpyridinium chloride, while the regular product does, the absence of cetylpyridinium chloride did not allow for survival of the challenge organisms.

It was assumed that the contaminating strains of *P. cepacia* were capable of utilizing some component(s) of the nasal sprays as a source of carbon and energy. To explore this assumption, each component was individually tested for its ability to support growth of *P. cepacia* strains CWO, B7L, and 25416. Within 72 hr, inoculum levels increased from between 40 and 200 organisms/ml to $\sim 2 \times 10^{6}$ organisms/ml in the presence of each tested component. However, the same increase in cell

[a] Growth to $>10^7$ cells/ml. [b] No viable cells present.

population occurred in the mineral salts medium without added substances. When acid-washed glassware and ultrapure reagents were employed, cell yields between 9×10^5 and 1.2×10^6 organisms/ml still were obtained both in mineral salts alone and with product components. When cells were passed repeatedly in sterile distilled water obtained from a quartz element glass still-fed from a deionizer unit, cell densities between 4 and 5×10^5 were maintained. Thus, the addition to water of usable organic nutrient is not necessary for the survival and growth of the product isolates. Growth of *P. cepacia* previously has been reported in mist therapy unit water and commercial distilled water (14).

An explanation was needed for the apparent contradiction between the observed high degree of thimerosal resistance of the product isolates as measured by tube or plate assay in trypticase soy media and the failure of the isolates to survive when introduced back into products similar to those from which they were originally isolated. Since none of the product ingredients stimulated growth of the isolates in minimal media, and since the absence of cetylpyridinium chloride did not enhance survival, two other factors were studied for their effect on survival of the isolates in the product: the addition of nutrient and adaptation of the isolates to the product.

Since the product isolates all showed high levels of thimerosal resistance in the trypticase soy tube assays, this complex medium was employed as a source of nutrient. As shown in Table III, when trypticase soy broth was added to the regular nasal spray formulation at concentrations ≥3200 ppm, survival and growth to visible turbidity was observed. When the organic components of trypticase soy broth (trypticase, phytone, dextrose) were tested individually, phytone (soy peptone) was most effective and supported growth in the regular product at concentrations ≥1200 ppm. Since the concentrations of nutrient required to support growth were higher than the nutrient levels present in the treated water or other components used in formulating the product, organic substances other than those present in trypticase soy broth were also tested in an attempt to find a more efficacious stimulator of successful contamination. The test substrates included the amino acids glutamine, glutamate, asparagine, and aspartate; the organic acids acetate, pyruvate, and benzoate; proteose peptone and yeast extract as complex nutrients; and starch and maltose as nonutilizable organics (for *P. cepacia*). As shown in Table III, none of these compounds was as effective as phytone in allowing survival of *P. cepacia* strain CWO. Of the single substrates, only dextrose and glutamate supported contamination of the product and neither of these was effective in concentrations that were comparable to those yielding growth when the complex nutrients were used. Since the tested organic substrates spanned a variety of utilizable and nonutilizable compounds, it seemed unlikely that a more effective supporter of survival would be found.

Since an alternative explanation was necessary to account for the survival of the contaminant organisms in the product in the absence of high quantities of nutrient, the effect of cultivating strain CWO in diluted product and then inoculating this adapted culture into undiluted commercial product containing a range of phytone concentrations was determined.

The effect of adaptation on the ability of thimerosal-resistant organisms to survive in the product is shown in Table IV. The inocula for these studies were grown in a fourfold dilution of product (regular formulation) containing 300 ppm of phytone, as contrasted with the unadapted inocula employed for the data shown in Table III, which were grown in trypticase soy broth. Table IV shows three significant effects. First, the adapted cells were able to survive and proliferate in the product in the absence of any added nutrient. Second, the time required for growth and turbidity to be evident was inversely related to the added nutrient concentration. Third, at low nutrient levels (0–120 ppm) the number of viable cells declined dramatically from the initial concentration of 1×10^6 cells/ml to between 1 and 15×10^2 cells/ml and remained at the lower levels for up to 2 weeks before an increase in viable cells was noted. The third effect was observed by periodically plating calibrated loops (0.01 ml) of culture from those tubes which showed no turbidity on day 5. These were the tubes containing the four lowest concentrations of phytone. Samples were plated on days 5, 7, and 12. The numbers of viable cells were low and remained stable for at least 7 days in the tubes containing the three lowest concentrations of nutrients (0, 60, and 120 ppm of phytone) (Table IV). The tube containing 240 ppm of phytone, which was not yet turbid on day 5, contained $\sim 10^5$ cells/ml at the time and became turbid on day 7. In the two tubes that became turbid on days 14 and 17 (0 and 120 ppm), increases in cell numbers were evident on day 12. The tube that became turbid on day 19 (60 ppm of phytone) still showed no increase in viable cells on day 12. Thus, inoculation into the product containing low concentrations of extraneous organic matter led to the death of most resistant cells, but the survivors persisted and eventually grew. A similar effect was noted by Pinney when a strain of *P. aeruginosa* resistant to thimerosal was inoculated into a minimal medium containing glucose as the energy source (26).

As expected, the turbidy attained in each tube was related to the level of nutrient present; when survival and growth occurred in the absence of added organic nutrient, the cultures were barely turbid. Similar levels were observed when strain CWO was inoculated into laboratory deionized water containing no added components. Thus, none of the organic components of the nasal spray need serve as a nutrient source in order to allow survival and growth of certain bacteria.

The data shown in Table IV were obtained using the product taken

Table IV—Persistence and Growth of *P. cepacia*[a] in Nasal Spray with Various Concentrations of Nutrient

Days Post Inoculation	Concentration of Soy Peptone, ppm: 0	60	120	240	360	480

12	200	3	260	TNTC	TNTC	TNTC
Day on which culture became turbid	17	19	14	7	3	2

[a] Inoculum was adapted in diluted product (see text) and was adjusted to yield initial concentrations of 1×10^6 cells/ml. [b] Number of colonies present on trypticase soy agar after plating 0.01 ml of product. [c] Too numerous to count.

from commercial polyethylene containers. That product contained thimerosal levels of 8.0–8.5 ppm, which is the usual concentration present several months after manufacture due to the absorption of some thimerosal by the container. When similar challenges were performed with product formulated in glass containers containing thimerosal at 10 ppm, the same inverse relationship between nutrient concentrations and lag time was observed, except that with 10 ppm of thimerosal, cultures in the product containing low nutrient levels took up to 37 days to become turbid. Under these circumstances, low numbers of cells persisted for as long as 1 month before growth occurred. It is likely that during these long lag periods, small numbers of surviving cells were producing thimerosal-inactivating enzymes, which then reduced the thimerosal concentration to a level which allowed growth. The greater enhancement of survival and growth of resistant cells by peptone mixtures as compared with single carbohydrates or amino acids probably was due to the utilization of the peptone amino acids for efficient and rapid synthesis of the thimerosal-inactivating enzymes.

When the product containing thimerosal levels >10 ppm was tested, strain CWO survived and grew only when nutrient was added. The required nutrient levels increased with increasing thimerosal, *e.g.*, at 60 ppm of thimerosal; survival and subsequent growth of adapted cells required the presence of 1000 ppm of phytone. It is suspected that in the presence of thimerosal, the levels of inactivating enzymes are related to the amount of phytone present. Thus, high phytone levels are necessary for survival at higher thimerosal concentrations. At lower thimerosal concentrations, higher phytone levels and, consequently, greater levels of inactivating enzymes more quickly reduce thimerosal below the inhibitory level with the resultant shorter lag time.

One concern emanating from this study results from the long lag period which may precede growth. Thus, samples of the product which are tested microbiologically shortly after manufacture may contain only small numbers of viable organisms, yet if those organisms are resistant strains, eventual growth to high levels may occur. Some measures that would reduce the risk of such an occurrence are as follows:

1. Composite samples must not be made except in neutralizing solutions, since reduction or elimination of resistant cells can occur upon mixing with additional product.
2. Vegetative cells isolated from the product, even in very small numbers, should be checked for resistance to the preservative if the isolates are of a suspect species, especially one of the Gram-negative nonfermentative bacilli.
3. If low counts of an organism are obtained and the organism is shown to be resistant to the preservative by tube or plate testing, the product should be retested at intervals to determine whether counts are increasing. It is preferable to encode and hold individual packages for this purpose. With thimerosal preserved products, if viable vegetative cells are recovered after several days, eventual increases in counts are likely.
4. Challenge testing of product with suspected contaminants may give false assurance if the inocula for the challenges are grown in the absence of preservative. A 10- or 20-fold dilution of the product in water is a useful medium for growth of challenge organisms. In many cases it is not necessary to add additional nutrient to allow growth of Gram-negative organisms. Survival of adapted organisms in the full-strength product then can be compared with unadapted inocula grown in the usual culture media.

Water Vapor Sorption and Desorption by Human Callus I: Anomalous Diffusion

DALE E. WURSTER [x] **and KIN-HAI YANG** *

Received September 1, 1981, from the *College of Pharmacy, University of Iowa, Iowa City, IA 52242.* Accepted for publication January 18, 1982. * Present address: School of Pharmacy and Allied Health Sciences, University of Montana, Missoula, MT 59812.

Abstract □ The rates of sorption and desorption of water in membranes of varying thickness of excised human callus were determined for several relative vapor pressures and temperatures. Under the conditions studied, the diffusion of water in these membranes was interpreted as non-Fickian in nature. It was concluded that at low water concentration this type of membrane exists in the glassy state. The effect of the relative vapor pressure on the water sorption rates was examined in the context of the free volume theory.

Keyphrases □ Diffusion—anomalous, water vapor sorption and desorption by human callus □ Sorption—water vapor, by human callus, anomalous diffusion □ Desorption—water vapor, by human callus, anomalous diffusion

The hydration of the skin has been found to increase the percutaneous absorption rates of several substances in humans (1). *In vivo* studies have demonstrated this effect for salicylate esters (2) and methyl ethyl ketone (3); whereas, an *in vitro* study has shown the same effect for sarin (4). The transport of water itself in skin is affected similarly (5–7). In an early study (8), water was shown to plasticize human callus when the concentration was ~10%. Since the glass transition temperature of stratum corneum is reported as 53° (9), it might be anticipated that non-Fickian diffusion of water in stratum corneum would occur below this temperature. The purpose of this study was to study the rates of water vapor sorption and desorption, to elucidate the nature of the diffusional process, and to provide a theoretical basis for the above observations.

THEORETICAL

The experimental system can be defined as consisting of water in the vapor state in equilibrium with sorbed water in a membrane of human callus. The rate of sorption to attain the equilibrium amount (Q_e), however, is considered to be controlled by the rate at which water molecules diffuse in the membrane. For isothermal diffusion in a two-component system, the rate of diffusion is governed by Fick's second law:

$$\partial C/\partial t = \partial/\partial x\,[D(C)(\partial C/\partial x)] \qquad \text{(Eq. 1)}$$

where C is the concentration of the diffusing molecules in the system at time t and distance x, and $D(C)$ is the mutual diffusion coefficient of the system, assuming that diffusion is one-dimensional and the diffusion coefficient depends on concentration only. The initial and boundary conditions assumed for sorption are:

$$C(x, 0) = 0, 0 < x < L \qquad \text{(Eq. 2)}$$

$$C(0, t) = C(L, t) = C_e, t > 0 \qquad \text{(Eq. 3)}$$

and for desorption:

$$C(x, 0) = C_e, 0 < x < L \qquad \text{(Eq. 4)}$$

$$C(0, t) = C(L, t) = 0, t > 0 \qquad \text{(Eq. 5)}$$

where L is the thickness of the membrane, and C_e is the equilibrium concentration at given temperature (T) and pressure (p). Solution of Eq. 1, subject to Eqs. 2–5, indicates (10) that the fractional uptake, $Q(t)/Q_e$, should theoretically increase linearly with $t^{1/2}$ during the initial period for both sorption and desorption, and the initial slope, $K(C_e)$, of the plot of $Q(t)/Q_e$ *versus* $t^{1/2}$ is given by (11):

$$K(C_e) = 4\bar{D}^{1/2}(C_e)/\pi^{1/2}L \qquad \text{(Eq. 6)}$$

In this instance, $Q(t)$ is the amount sorbed or desorbed at time t and $\bar{D}(C_e)$ is the mean value of the mutual diffusion coefficient over the concentration range taken. Thus, the slope will vary with C_e for any given membrane. It was also shown that for $D(C)$ increasing with C, $K(C_e)$ for sorption is always greater than $K(C_e)$ for desorption, the difference being an indication of how strongly $D(C)$ depends on C for the given concentration range. For D independent of C, it can be seen from Eq. 6 that for a given membrane, the slope K will be independent of C_e and identical for both sorption and desorption. It can also be seen that when $Q(t)/Q_e$ is plotted against $t^{1/2}/L$, the slope should be independent of L.

Deviations from these theoretical predictions for the conditions considered, however, have been observed in many polymer–diluent systems (12–14). These deviations generally implicate the role of slow relaxation processes for glassy polymers (14, 15).

To meet the conditions imposed on the mathematical representation of the system, thin membranes of callus devoid of lipid were used. Since kinetic data for the initial period were emphasized and studies were limited to the relative vapor pressures below unity, any swelling effect on the membrane thickness was considered negligible. Thus, from measurements of $Q(t)$ as a function of time for varied relative vapor pressures and thicknesses at constant temperatures, the nature of the diffusion process for the membrane–water system can be examined.

EXPERIMENTAL

Sorption–Desorption System—The system, constructed of glass[1], consists of a sorption tube connected to a manifold leading to both the vapor source and the vacuum system. A sensitive quartz spring[2] was placed inside the sorption tube. The entire sorption system was enclosed in a thermostated chamber and the temperature was controlled to within ±0.05°. A two-stage mercury-vapor diffusion pump[3] backed by a two-stage mechanical forepump[4] provided a base vacuum of $<10^{-4}$ torr. For measuring the extension of the spring, a precision cathetometer[5], which

Table II—Physical Constants of the Test Membranes

Membrane	Weight, mg	Diameter, mm	Thickness, μm	Density, g/ml, 25°
1	1.364 ± 0.005	4.85 ± 0.05	57.3 ± 1.6	1.288 ± 0.005
2	0.786 ± 0.005	4.585 ± 0.007	37.0 ± 0.5	
3	0.826 ± 0.005	5.032 ± 0.007	32.3 ± 0.4	
4	1.152 ± 0.005	4.941 ± 0.007	46.7 ± 0.5	

reads to 0.01 mm, was used. Thus, with a spring sensitivity of 20 mm/mg, a change in weight of 0.5 μg could be detected. This system was similar in principle to the one employed by Prager and Long (16).

The quartz springs were calibrated with small standard weights which were weighed to 0.1 μg on an electrobalance[6]. Four quartz springs (A, B, C, and D) having calibrated sensitivities of 9.36, 9.59, 18.73, and 17.60 mm/mg, respectively, were used.

Conventional salt solutions were employed to obtain the relative water vapor pressures in the system. The relative vapor pressures of these salt solutions (17, 18) are shown in Table I.

Membrane Preparation and Physical Measurements—Human callus was used as a convenient and readily available model for stratum corneum in an attempt to study water sorption, desorption, and the influences on the water transport mechanism in skin. Excised human callus tissue was microtomed to thin membranes of different thicknesses and delipidized in anhydrous ether as reported (4). To prepare a test membrane, the membrane was first partially hydrated and then cut with a 4.76-mm punch. The diameter of each test membrane was measured with a filar eyepiece micrometer[7] attached to an optical micrometer[8], which was calibrated with a micrometer disk[9]. The weights of the test membranes were obtained using an electrobalance[6]. All test membranes were dried over Drierite to constant weight. The thickness of the membrane was calculated from its diameter, weight, and density (19).

The weights, diameters, and calculated thicknesses of the membranes used in this study are given in Table II.

Sorption–Desorption Studies—For the sorption studies, the test membrane was attached to the quartz spring and kept at base vacuum at the given temperature until constant weight was reached. The membrane was then exposed to a given vapor pressure. The amount of water absorbed was followed by measuring the change in extension, $Q(t)$, of the spring with the cathetometer as a function of time until Q remained constant for a period of 24 hr. This value was taken as $Q_e(T,p)$. Upon the completion of the sorption run, the sorption tube was switched to the vacuum to initiate the desorption experiment. At that time $Q(t)$ represented the amount of water desorbed at the time t when Q was measured. Sorption and desorption rates were measured at relative vapor pressures of 0.32, 0.52, 0.67, 0.75, 0.84, and 0.91 and temperatures of 21, 28, 32, and 39°. The membrane thicknesses were 32.3, 37.0, 46.7, and 57.3 μm.

RESULTS AND DISCUSSION

Repeated experiments with the described system showed good reproducibility of the experimental procedure. A typical example showing the reproducibility of the experimental data is given in Fig. 1.

Effect of Relative Vapor Pressure—The rates of sorption and desorption were determined for various relative vapor pressures ($p/p°$) at 28° using Membrane 4. Paired sorption and desorption curves obtained for $p/p°$ = 0.91, 0.67, and 0.32 are shown in Figs. 2–4, respectively. The sorption curves obtained for four different relative vapor pressures are compared in Fig. 5. Similar results were obtained with test Membrane 1. Thus, the possibility of a constant, D, for the concentration range studied here does not seem plausible. Also, from the sigmoidal shape of the sorption curves and the relative positions of the sorption and desorption curves, it can be seen that the sorption and desorption of water vapor by the membranes are non-Fickian in nature. This would suggest that under the conditions studied, these membranes behave like glassy polymers, and some slow relaxation processes are taking place concurrently with the diffusion process when sorption occurs. The glass transition temperature of the callus was estimated to be ~55° (20). Thus, at 28° all experiments were started with a test membrane which was in a glassy state. At low water concentrations, for which the relaxation effect may be expected to be small, the rates of sorption or desorption could be essentially diffusion-controlled. This has been shown to be the case for a cellulose–water system (21), a wool–water system (22), and also appears to be true for the human callus–water system (Fig. 4). The sorption curve in Fig. 4, however, still exhibits the sigmoidal shape, which indicates that

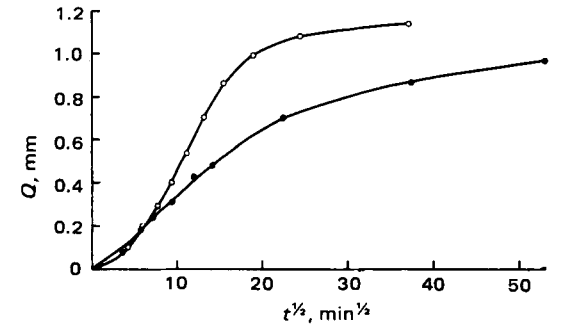

Figure 4—*Sorption and desorption of water vapor in human callus (Membrane 4) at 28°, p/p° = 0.32. Key: (○) sorption, (●) desorption, Spring C; Q_e (sorption) 1.14 mm.*

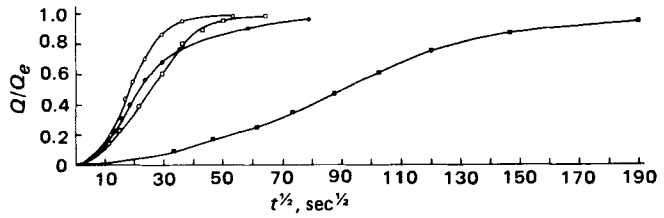

Figure 5—*Sorption of water vapor in human callus (Membrane 4) at 28°, p/p° = 0.32. (■); 0.67 (□); 0.84 (○); 0.91 (●).*

some relaxation effects are still present and cannot be totally ignored. For a cellulose–water system (21), this was previously attributed to a time-dependent surface concentration which approaches its equilibrium value shortly after the start of the experiment. A similar explanation could be suggested for the present system at $p/p° = 0.32$, which corresponds to an equilibrium water concentration of ~5% (w/w). It has been shown (12, 23, 24) that sigmoidal sorption curves can be obtained from the solution of Eq. 1 subject to the boundary condition of a variable surface concentration, $C_s(t)$. Both the theoretical consideration (25) and experimental evidence (23) for $C_s(t)$ have been utilized by others.

At high water concentrations, relaxation effects became more obvious (Figs. 2 and 3) and are not likely to be limited only to the surface region. A further complication may also arise. Since the glass transition temperature of the system is a function of the diluent concentration (26), these membranes may undergo transition from the glassy state to a rubbery state as sorption proceeds at the higher relative vapor pressures. Following Frisch (27), the glass transition temperature of the callus containing x (g/g) water can be estimated from the equation (28) based on the free volume theory:

$$T_g = T_g^\circ - (\beta/\alpha)x \qquad \text{(Eq. 7)}$$

where T_g is the glass transition temperature of the system, T_g° is the glass transition temperature of the callus, x is the water concentration (g/g), α is the difference between the thermal expansion coefficient above and below the glass transition temperature, and β is a parameter representing the contribution of water to the increase in free volume of the system. The value of β was found to be 0.16 for both collagen–water and wool–water systems (29). It also was shown (28) that for a limited range, β is independent of C and T. Using this same value for the present system and the suggested value of $\alpha = 4.8 \times 10^{-4}$ (deg^{-1}) for polymeric systems (30), T_g was calculated to be ~38° for $x = 0.05$ ($p/p° = 0.32$), and 15° for $x = 0.12$ ($p/p° = 0.60$). At $p/p° = 0.67$, which corresponds to an equilibrium water concentration of 0.16 g/g, the lowering of T_g will be even greater. Thus, at 28° and $p/p° = 0.67$, the callus membrane, initially in a glassy state, becomes rubbery whenever the concentration reaches its equilibrium value or lower, as long as it is sufficient to lower the T_g to <28°. This is in contrast to the absorption at 28° and the low $p/p° = 0.32$, where the membrane will remain in essentially the glassy state throughout the entire experiment.

While the exact shapes of the sorption curves in Fig. 5 reflect the total effect of both the relaxation and diffusion processes, in general they are in agreement with the presented analysis. In Fig. 5 the curves for $p/p°$ = 0.32, 0.67, and 0.84 all have an extended portion centered around $Q/Q_e = 0.5$, which is linear within the experimental error. The slopes of these linear portions are in order in accordance with an apparent diffusion coefficient increasing monotonically with the concentration. The slope of the curve for $p/p° = 0.91$, however, is smaller than that of the curve for $p/p° = 0.84$, indicating that the apparent diffusion coefficient decreases as the concentration increases above that corresponding to $p/p°$ = 0.84. A similar trend was confirmed with Membrane 1. The existence

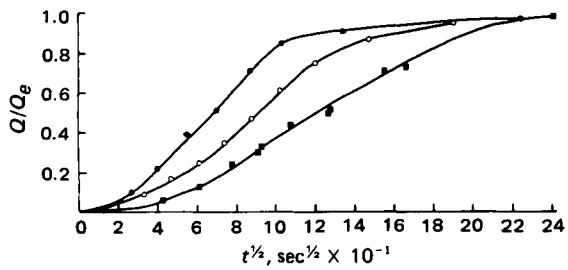

Figure 6—*Sorption of water vapor in human callus (Membrane 4) at p/p° = 0.32 and T = 21°. (■); 28° (○); 39° (●).*

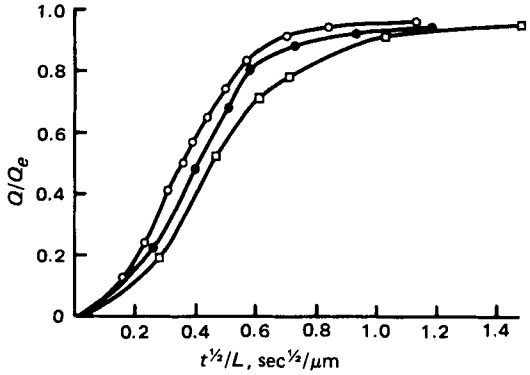

Figure 7—*Sorption of water vapor in human callus. Key: Membranes 1 (○) 57.3 μm; 2 (●) 37.0 μm; 3 (□) 32.4 μm at 28°; p/p° = 0.84.*

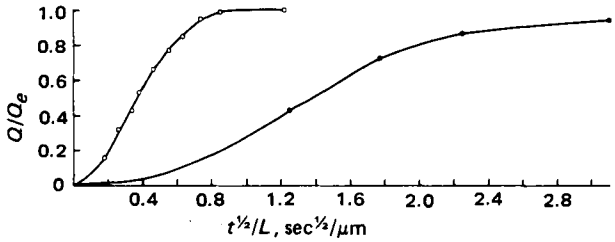

Figure 8—*Sorption of water vapor in human callus; Membrane 1. (○) 57.3 μm; and a human stratum corneum membrane (●) 9.7 μm at 28° and p/p° = 0.75.*

of a limiting value of the diffusion coefficient was also noted in a wool–water system (31). Thus, as absorption proceeds at 28° and $p/p° = 0.91$, not only is there a transition from glassy state to rubbery state for the callus–water system, but also a change in the functional dependence of D on C. This can be seen by the shapes of the curves for $p/p° = 0.84$ and 0.91 in Fig. 5.

The observation made by Blank (8) that the callus tissue became soft and pliable at 23° when it contained 10% water now can be understood. At this concentration, T_g of the system is effectively lowered to ~22°. Also, the same amount of water will not be sufficient to soften or plasticize the tissue at lower temperatures. The general effect of hydration on percutaneous absorption rates can be understood in the same context. The diffusion coefficients of organic vapors in glassy polymers are $\leq 10^{-10}$ cm^2/sec, while in the rubbery polymers they are in the order of 10^{-6} cm^2/sec (27).

Effect of Temperature—Absorption data obtained at 21, 28, and 39° for $p/p° = 0.32$ are compared in Fig. 6. The slopes of the linear portions of the curves increase as the temperature increases, which indicates that the apparent diffusion coefficient increases with the temperature, as would be expected. Since the relaxation time will also decrease as the temperature increases, the general effect of increasing the temperature to 39° was to reduce the role of the relaxation processes. The shape of the upper curve in the figure reflects this effect. A similar trend was seen for $p/p° = 0.67$ at these temperatures.

Effect of Thickness—In an attempt to confirm the non-Fickian mechanism, membranes of different thicknesses were used for the measurements of the rates of absorption under otherwise identical conditions. Results obtained at 28° and $p/p° = 0.84$ with Membranes 1–3 are compared in Fig. 7 in plots of Q/Q_e *versus* $t^{1/2}/L$. For a Fickian mechanism, the curves as plotted should be superimposable, but they are not. Repeated experiments for $p/p° = 0.75$ gave similar results. Such behavior was noted in a wool–water system (31) and a methylene chloride–polystyrene system (32). In both cases they were attributed to the time-dependence of D and/or C_s. The trend shown in Fig. 7 indicates that the apparent diffusion coefficient of the system studied depends on the membrane thickness which is smaller with the thinner membrane. Similar results are shown in Fig. 8 where a membrane, 1, of human callus having a 57.3-μm thickness is compared with a stratum corneum membrane of 9.7 μm at 28° and $p/p° = 0.75$. In the present report it appears that little difference other than thickness exists between these two different membrane types; however, this requires experimental verification.

Pharmacokinetics of Probenecid Following Oral Doses to Human Volunteers

ARZU SELEN, G. L. AMIDON, and P. G. WELLING ˣ

Received November 23, 1981, from the *School of Pharmacy, University of Wisconsin, Madison, WI 53706.* Accepted for publication January 19, 1982.

Abstract □ The pharmacokinetics of probenecid were examined following single 0.5-, 1.0-, and 2.0-g oral doses to healthy male volunteers. Doses were administered following overnight fast, according to a randomized design. Plasma levels of probenecid were determined by high-pressure liquid chromatography (HPLC), using sulfamethazine as the internal standard. Mean peak probenecid levels of 35.3, 69.6, and 148.6 μg/ml were obtained at 3–4 hr following the 0.5-, 1.0-, and 2.0-g doses, respectively. Probenecid levels from the 0.5- and 1.0-g doses declined in apparent monoexponential fashion, with mean elimination half-lives of 4.2 and 4.9 hr. Interpretation of the 2.0-g data by a kinetic model incorporating first-order elimination resulted in a plasma drug half-life of 8.5 hr. When first-order elimination was replaced by a Michaelis–Menten-type function, the mean value of the resulting V_m/K_m ratios was 0.20, equivalent to a plasma drug half-life [$0.693/(V_m/K_m)$] of 3.8 hr. Plasma probenecid curves from all three dosages were successfully fitted to the saturable elimination model using nonlinear regression and numerical integration routines. The results suggest that probenecid elimination may be saturable at therapeutic dose levels.

Keyphrases □ Probenecid—pharmacokinetics following oral doses to humans, high-pressure liquid chromatography, elimination □ Pharmacokinetics—probenecid following oral doses to humans, high-pressure liquid chromatography, elimination □ High-pressure liquid chromatography—probenecid following oral doses to humans, pharmacokinetics

Probenecid is used for the treatment of gout and gouty arthritis and also as an adjuvant in therapy to prolong the plasma levels of other compounds, particularly the β-lactam antibiotics (1).

Although it has been used clinically for several years, the pharmacokinetics of probenecid are not well documented. It is efficiently absorbed after oral doses (2–4) with peak plasma concentrations occurring at 1–5 hr. Probenecid is 83–95% bound to plasma proteins at concentrations of 20–176 μg/ml (3). It is cleared from the body predominantly by metabolism, which occurs mainly by side-chain oxidation and glucuronide conjugation (3, 5). Only 5–11% of orally dosed probenecid is excreted in unchanged form in urine (6, 7).

The rate at which probenecid is cleared from plasma was shown to be dose-dependent in dogs (8) and humans (3). In the latter study, the plasma half-life of probenecid increased from 3–8 hr following a 0.5-g iv dose, to 6–12 hr following a 2.0-g iv dose in three subjects.

Since probenecid is extensively metabolized, dose-dependent elimination may be due to saturation of one or more metabolic pathways. However, a subsequent study demonstrated an unchanged pattern of urinary metabolites from oral doses of 0.5, 1.0, and 2.0 g of probenecid (6).

In view of the uncertainty regarding the nature and possible dose-dependency of probenecid pharmacokinetics, this study was undertaken to examine plasma levels of probenecid following 0.5-, 1.0-, and 2.0-g oral doses to healthy male volunteers.

EXPERIMENTAL

Protocol—Five healthy male volunteers (20–39 years, 53–86 kg), whose weight–height relationships were within ±10% of normal (9), participated in the study after giving informed consent. Subjects were instructed to take no other medication for 1 week before the study and during the study. Subjects received single doses of 0.5, 1.0, and 2.0 g of probenecid[1] on three separate occasions, at least 1 week apart, according to a randomized design. Doses were administered with 250 ml of water at 8 am following an overnight fast. The tablets were swallowed whole. Food and water were withheld until 4 hr postdose, then normal eating and drinking were resumed.

Blood samples (~10 ml) were taken from a forearm vein into heparinized evacuated tubes[2] immediately before and then serially to 48 hr postdose. Plasma was separated by centrifugation and stored at −20° until assayed. No deterioration of samples was observed during storage.

Assay—Probenecid concentrations in plasma were determined by a modification of a previously described high-pressure liquid chromatographic (HPLC) procedure (10). Plasma (1 ml), pH 4 phosphate buffer (1 ml), sodium chloride (1 g), 0.1–0.3 ml of methanol containing 25–75 μg/ml sulfamethazine as internal standard, and ether (8 ml) were combined in a 15-ml centrifuge tube, vortex mixed for 15 sec, and shaken for 30 min on a horizontal shaker. After centrifuging at 3000×*g* for 10 min, 5 ml of the ether layer was transferred to a clean tube, and evaporated to dryness in a water bath at 40° under nitrogen. The residue was reconstituted in 1.0 ml of chromatographic mobile phase by vortex mixing for 30 sec, and 20 μl of this was injected onto the column.

The chromatographic system consisted of a solvent pump[3], a fixed-volume (20 μl) sample injection valve[4], a 10-μm particle size reversed-phase octadecyl column (4.6 mm × 250 mm)[5], and a fixed-wavelength (254 nm) UV detector[6]. All chromatograms were recorded at a chart speed of 10 cm/hr.

The mobile phase was 27.5% acetonitrile in 0.01 *M* phosphate buffer, at pH 6, and the flow rate was 1 ml/min. Under these conditions, the retention times of probenecid and sulfamethazine were 9 and 6 min, respectively. There was no interference from endogenous substances. Concentrations of probenecid were determined by peak height ratios. Standard curves using each individual's predose plasma were run together with each batch of postdose plasma samples.

The extraction efficiency of probenecid in this system was 94.3 ± 5.8% *SD* ($n = 20$). The chromatographic assay was linearly responsive to probenecid concentrations between 1 and 200 μg/ml, and assay reproducibility was within 10% of the mean in this concentration range. Probenecid metabolites, all of which are more polar than the parent compound, do not interfere with the assay for probenecid under these assay conditions (10).

Reagents—Human plasma for assay development was purchased[7]. Probenecid[8] and sulfamethazine[9] were of reference standard quality. All other chemicals and solvents were analytical reagent grade and were used as received.

Data Analysis—Individual probenecid profiles in plasma resulting from the three doses were examined using two different pharmacokinetic models. The first of these was a one-compartment kinetic model with first-order appearance of drug into and loss of drug from plasma and an absorption lag time. With this model, plasma concentrations of probenecid were fitted to Eq. 1 in which F is the fraction of the oral dose (D) which is absorbed into the systemic circulation, V_d is the apparent homogenous distribution volume for probenecid, k_a and k_{el} are first-order rate constants for appearance and loss of drug, respectively, and t_0 is the absorption lag time (11):

$$C = \frac{FD}{V_d}\left(\frac{k_a}{k_a - k_{el}}\right)\left(e^{-k_{el}(t-t_0)} - e^{-k_a(t-t_0)}\right) \qquad \text{(Eq. 1)}$$

Initial estimates of parameter values were obtained by standard graphical procedures. Final estimates were obtained by nonlinear regression analysis using the program NREG (12) on a digital computer[10].

The second model, which was investigated primarily as a result of the plasma data resulting from the 2.0-g dose of probenecid, is different from the first in that the elimination phase is described in terms of a saturable Michaelis–Menten-type term. The rate equation for time-dependent change in probenecid plasma levels with this model is:

$$\frac{dc}{dt} = \frac{FDk_a}{V} e^{-k_a(t-t_0)} - \frac{V_m C}{K_m + C} \qquad \text{(Eq. 2)}$$

where V_m and K_m are Michaelis–Menten-type functions describing the maximum rate of probenecid elimination and the drug concentration when the rate of elimination is one-half the maximum value, respectively, and all other parameters are as described for Eq. 1. This rate equation cannot be solved analytically, and nonlinear regression analysis was done by coupling the program NREG with the numerical integration program DGEAR (13). Initial estimates of the values of V_m and K_m were obtained graphically by a previous method (14). Final computer estimates of values for k_a and FD/V_d from Eq. 1 were used as initial estimates for these parameters when fitting data to Eq. 2.

[a] The model-dependent parameter values were obtained by fitting plasma data to Eq. 1. [b] Differences between doses are significant if $p < 0.05$. [c] Observed maximum concentration of probenecid in plasma. [d] A = 0.5-g dose, B = 1.0-g dose, and C = 2.0-g dose. [e] Time of C_{max}. [f] No significant differences. [g] Area under plasma–probenecid curve (0–48 hr), calculated by trapezoidal rule. [h] Area normalized for administered dose. [i] Calculated from $t_{1/2(el)} = \ln 2/k_{el}$. [j] Fraction of the dose absorbed, expressed as a concentration in its volume of distribution. [k] FD/V_d normalized for administered dose. [l] Coefficient of determination, $r^2 = (\Sigma obs^2 - \Sigma dev^2)/\Sigma obs^2$.

Statistical analysis of plasma levels, and also pharmacokinetic parameter values, resulting from the three doses were examined by ANOVA for crossover design. Significant effects between specific doses were examined by Tukey's test (15). Differences between pharmacokinetic parameter values, and also coefficients of determination, obtained by nonlinear regression analysis of plasma data using the first-order and saturable kinetic models were examined by paired *t*-test.

RESULTS

The mean plasma levels of probenecid obtained from the three doses are given in Table I, and the data are summarized graphically in Fig. 1. Some model-independent pharmacokinetic parameter values and also pharmacokinetic constants obtained after fitting individual data sets to Eq. 1 are given in Table II.

Following the 0.5-g dose, plasma probenecid levels reached a mean peak value of 35.3 μg/ml at 3 hr and then declined in apparent monoexponential fashion. Probenecid could be detected in all subjects up to 24 hr postdose. Following the 1.0-g dose, the mean peak probenecid level increased twofold to 69.6 μg/ml and occurred at 4 hr postdose. Drug levels again declined in apparent monoexponential fashion and could be detected in all subjects up to 30 hr postdose.

Individual plasma probenecid profiles following the 2.0-g dose were different from those resulting from the lower doses. The mean peak level was again doubled, compared with that from the 1.0-g dose, to 148.6 μg/ml and occurred at 3.5 hr. After peak levels had been reached from this dose, plasma levels of probenecid declined initially at a slower rate compared with the lower doses, and the rate of decline in the logarithm of plasma levels *versus* time during this period was curvilinear. It was not until 24–30 hr after dosing, when probenecid plasma levels had fallen to similar values to those obtained from the 0.5- and 1.0-g doses, that the rate of loss of probenecid from plasma became log-linear, with a similar rate to that obtained from the lower doses. Following the 2.0-g dose, probenecid could be detected in the plasma of all subjects at 36 hr, and in three of the five subjects at 48 hr, postdose.

Table III—Pharmacokinetic Parameter Values (±1 *SD*) Obtained by Analyzing Plasma Probenecid Levels from the 2.0-g Dose According to First-order or Saturable Kinetic Models

Parameter	Value First-Order Model[a]	Saturable Model[b]	Statistic[c]
k_a (hr^{-1})	0.66 ± 0.29	0.63 ± 0.26	NS[d]
t_0 (hr)	0.56 ± 0.32	0.40 ± 0.52	NS
k_{el} (hr^{-1})	0.082 ± 0.504	—[e]	
$t_{1/2(el)}$ (hr)	8.5 ± 0.4[f]	3.8 ± 1.1[g]	S[h]
V_m (μg/ml·hr)	—	8.6 ± 2.1	
K_m (μg/ml)	—	46.6 ± 26.5	
V_m/K_m (hr^{-1})	—	0.20 ± 0.06	
FD/V_d	176 ± 30	160 ± 19	NS

[a] Data was fitted to Eq. 1. [b] Data was fitted to Eq. 2 with numerical integration. [c] Data compared using a paired *t* test. [d] Not significant ($p > 0.05$). [e] Does not apply. [f] Calculated from $t_{1/2(el)} = \ln 2/k_{el}$. [g] Calculated from $t_{1/2(el)} = \ln 2/(V_m/K_m)$. [h] Significant ($p < 0.05$).

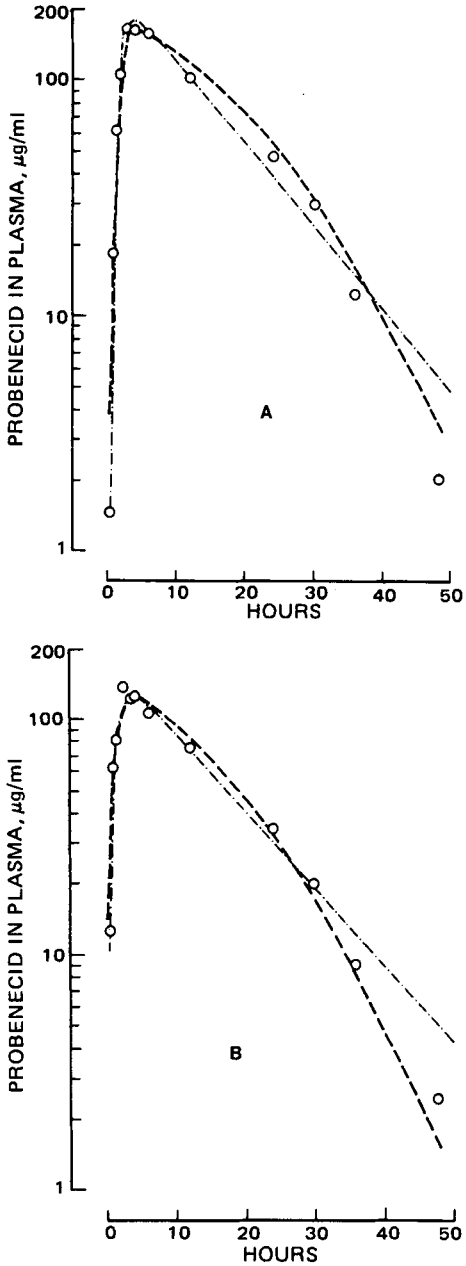

Figure 2—*Plasma levels (○) of probenecid in two subjects and nonlinear regression curves obtained from Eq. 1 (·--) and Eq. 2 (---). Key: (A) subject 1; (B) subject 2.*

Although the value of C_{max} was dose-proportional between the three dosages of probenecid, the 0–48-hr area under the plasma curve, $AUC^{0\rightarrow 48\ hr}$, increased 2.6-fold between the 0.5- and 1.0-g doses, and 2.9-fold between the 1.0- and 2.0-g doses. When the areas were normalized for the administered dose, there appeared to be a progressive increase in the values with increasing dose, and the value for the 2.0-g dose was significantly larger than those from the other two doses.

While the increases in area values were greater than expected with increasing dose size, the opposite effect was observed in the values of FD/V_d, which is a rate-independent measure of drug availability to the systemic circulation. The value of this parameter increased 2.2-fold between the 0.5- and 1.0-g doses, but only 1.5-fold between the 1.0- and 2.0-g doses. Normalizing this value for the administered dose resulted in a somewhat lower F/V_d value for the 2.0-g dose compared with the other two doses, but only the difference between the 2.0- and 1.0-g doses reached the 95% significance level.

No significant differences were observed in the lag times or in the absorption rate constants between doses. The elimination rate constant was

similar for the 0.5- and 1.0-g doses, yielding mean plasma half-lives of 4.2 and 4.9 hr, respectively. Following the 2.0-g dose, however, the elimination half-life of probenecid was significantly increased to a mean value of 8.5 hr. The coefficient of determination for nonlinear regression analysis of data using Eq. 1 was slightly lower following the 2.0-g dose compared to the other two doses, but differences in this value between treatments were not significant.

The discrepancies observed in the $AUC^{0\rightarrow 48}/D$ values between the 2.0-g dose and the 0.5- and 1.0-g doses, and the similar dose-dependency of the value of k_{el} and $t_{1/2(el)}$, prompted the analysis of the 2.0-g data in terms of Eq. 2. The results obtained using this equation are compared with those using Eq. 1 in Table III. No significant differences were observed in the values of k_a, t_0, or FD/V_d calculated by the two methods. The coefficient of determination r^2 was also similar, indicating that neither equation described the overall data significantly better than the other. However the ratio V_m/K_m, which is analogous to k_{el} at low drug concentrations, of 0.20 yielded a drug half-life in plasma of 3.8 hr. This value is less than one-half the value calculated using Eq.1, and is not statistically different from the values obtained from the two lower doses.

Although the saturable elimination model did not provide a better fit to the 2.0-g data compared to the first-order elimination model, it did provide a superior fit to the elimination phase of each drug profile. This is clearly demonstrated for two subjects in Fig. 2. The mean coefficient of determination between observed and predicted probenecid levels for all subjects during the 12–48-hr sampling period was 0.973 when Eq. 2 was used for nonlinear regression analysis. This value was significantly higher than the value of 0.953 obtained when the data were fitted by means of Eq. 1.

To determine whether Eq. 2 also described the probenecid data resulting from the 0.5- and 1.0-g doses, nonlinear regressions were carried out on these data using k_a, t_0, and FD/V_d values obtained from the analysis using Eq. 1, and V_m and K_m values obtained from the 2.0-g dose data for each individual. The mean coefficients obtained by this method were 0.96 and 0.97 for the 0.5- and 1.0-g doses, respectively. These values were not significantly different from those obtained when these data were fitted to Eq. 1.

DISCUSSION

The data generated in this study provide evidence that the elimination of probenecid from plasma is saturable at therapeutic dose levels. Following the 0.5- and 1.0-g oral doses of probenecid, plasma curves could be described adequately by a kinetic model incorporating first-order absorption and elimination. Although a satisfactory description of probenecid plasma levels following the 2.0-g dose was obtained also with this model, the probenecid elimination half-life obtained was twice that following the lower doses. When saturable elimination of probenecid from the 2.0-g dose was assumed, however, the terminal elimination half-life of probenecid was similar for all three dosages. Also a more satisfactory description of the elimination phase of probenecid plasma levels following the 2.0-g dose was obtained by incorporating a saturable component in the kinetic model.

These observations are consistent with previous suggestions that the elimination of probenecid is dose-dependent (3, 8), the drug half-life increasing with increasing dose size. In this respect probenecid behaves similarly to salicylate (16, 17), phenytoin (18), theophylline (19, 20), and alcohol (21); all of which exhibit saturable elimination kinetics at drug levels below those considered to be toxic.

An alternative explanation for the prolonged probenecid profiles in plasma following the 2.0-g dose, and to a smaller extent following the 1.0-g dose (Fig. 1), involves drug absorption rather than elimination. This argument, which was used previously in this context (6), is based on the low aqueous solubility of probenecid, and proposes that slow dissolution of the drug in the GI tract from larger doses may give rise to prolonged absorption. While the data obtained in the present study do not preclude this possibility, the similar absorption rate constants, absorption lag times, and times that maximum drug concentrations occur in plasma from the three dosages make it unlikely. Also, dose-dependent elimination of probenecid was previously demonstrated in humans following intravenous doses (3). Although the value of F/V_d from the 2.0-g dose was statistically smaller than that from the 1.0-g dose (Table II), it cannot be determined from the present data whether this is due to a change in drug absorption or in drug distribution at the higher dose.

The plasma levels at which Michaelis–Menten-type elimination became evident in this study, 40–50 μg/ml, are in excellent agreement with the observation (3) that probenecid levels measured in the 50–220-μg/ml range declined at slower rates than levels in the 10–55-μg/ml range. The higher levels in that study were obtained following a 2.0-g iv dose, while the lower levels were obtained following a 0.5-g dose. Unfortunately, the plasma sampling in that study was not extended for a sufficient time following the 2.0-g dose to monitor plasma levels in the lower concentration range.

The mechanism causing slower elimination of probenecid at high circulating levels is uncertain. Altered renal clearance is unlikely. Probenecid is actively secreted into the kidney tubules, but it is efficiently reabsorbed into the peritubular capillaries, and only a small fraction of the drug is cleared by this route. Probenecid is extensively metabolized, the principal metabolites involving side-chain oxidation (~70%) and glucuronide conjugation (~20%) (1). The dose-dependency of the amounts of these metabolites formed in two individuals has been investigated (6), and relative urinary recoveries of unchanged drug, probenecid acyl glucuronide, and the mono-*N*-propyl, carboxylic acid, and secondary alcohol metabolites from 0.5-, 1.0-, and 2.0-g doses were obtained. The investigators concluded that no individual metabolic pathway was saturated at high probenecid levels as this would have altered the relative amounts of the different metabolites that were formed. However, some of the side-chain oxidation metabolites of probenecid may be formed through a single intermediate, *i.e.*, an epoxide. Saturation of this common step may lead to a reduced rate of metabolism without affecting the ratio of formation of some of the major metabolites (22). One also cannot exclude product inhibition by one or more of the metabolites formed or saturation of a transport step governing access of probenecid to the site(s) of metabolism, causing clearance of drug from plasma to be delayed. More studies are needed to identify the rate-limiting process(es), and also the possible influence of other drugs on the saturable elimination of probenecid.

While attempting to describe plasma probenecid data in terms of Eq. 2, the authors are aware of the problems inherent in applying this type of equation to drug–concentration profiles, and also to the uncertainty regarding the numerical values assigned to the parameters V_m and K_m (23). However, notwithstanding these limitations, use of the saturable model is felt to be justified in terms of the similarity of the pharmacokinetic parameters which were common to the saturable and first-order models from the different doses, the realistic values of V_m and K_m obtained, and also the close agreement between the drug elimination half-lives obtained from the V_m/K_m ratios and from k_{el}.

The clinical significance of saturable probenecid elimination is uncertain. In view of the profound effect that saturable elimination may have on the degree of drug accumulation with repeated doses (24), it is likely that probenecid levels may increase with repeated dosing to an extent greater than might be predicted if first-order elimination is assumed. The clinical implication of saturable probenecid elimination may be further complicated, as the uricosuric potency of the oxidized metabolites has been shown to be approximately the same as the parent drug in experimental animals (25, 26).

Purity Profiles of Pteroylglutamate Reference Substances by High-Performance Liquid Chromatography

L. V. FEYNS ˣ, K. D. THAKKER, V. D. REIF, and L. T. GRADY

Received October 5, 1981, from the *Drug Research and Testing Laboratory, United States Pharmacopeia, Rockville, MD 20852.* Accepted for publication January 21, 1982.

Abstract □ High-performance liquid chromatography (HPLC) in the reversed-phase mode was used for the purity analysis of three pteroylglutamic acid-type reference substances (folic acid, leucovorin calcium, and methotrexate). The influence of the pH of the mobile phase on the separation of an artificial mixture of six pteroylglutamic acid derivatives and three potential impurities was studied. Results of purity analysis of current lots of USP reference standards are reported. A better separation of methotrexate from its major impurities was achieved by using a standard buffer, rather than an ion-pairing mobile phase. A separation of methotrexate and its biologically inactive 7-isomer is reported.

Keyphrases □ Pteroylglutamate—purity profiles, reference substances, high-performance liquid chromatography, methotrexate □ High-performance liquid chromatography—pteroylglutamate, purity profiles, reference substances, methotrexate □ Methotrexate—pteroylglutamate, purity profiles, reference substances, high-performance liquid chromatography

Three USP drug substances, available as USP reference standards, belong to the class of pteroylglutamic acid derivatives: folic acid (I), methotrexate (II), and leucovorin calcium (III) (authentic substance as calcium formyltetrahydrofolate). This class of compounds exhibits high hydrolytic and oxidative reactivity. High-performance liquid chromatography (HPLC) has proved to be the method of choice for purity analysis in this laboratory because of similarities of structure within this series. Additional purity profile data were gained from 5 to 8 collateral determinations, but are not reported here as these results are independent of chromatographic purity.

Almost all the HPLC techniques have been used for the separation and analysis of this class of compounds. Anion-exchange columns were used first in 1973 for the separation of folic acid from a mixture of water-soluble vitamins (1) and then for the separation of folic acid and its reduced and N^5- and N^{10}-substituted derivatives (2). Anion-exchange chromatography alone, or coupled with an amine column operated in the reversed-phase mode, has also been used for the analysis and quantitative determination of methotrexate (3).

An extensive study (4) resulted in the development of a reversed-phase HPLC assay and purity analysis method for folic acid. The assay was made the object of a collaborative study (5), and it has been adopted into the folic acid monograph in the USP (6).

For the reversed-phase chromatographic analysis of methotrexate, mixtures of methanol or acetonitrile with the following buffers have been suggested as mobile phases: pH 3.5, 0.005 *M* ammonium formate (7); pH 5, 0.005 *M* ammonium acetate (7); pH 6.7, 0.1 *M* KH_2PO_4 (8); pH 6.8, 2-amino-2-hydroxymethyl-1,3-propanediol (tris) (9); pH 7.2, 0.05 *M* KH_2PO_4[1]; pH 6, 0.1 *M* citric acid–0.2 *M* Na_2HPO_4[2]. The latter is used in the assay of methotrexate in USP XX–NF XV (10). Mobile phases consisting of pH 5 phosphate buffer–acetonitrile (9) and pH 4 citrate buffer–dioxane (11) were recommended for the analysis and assay of leucovorin calcium. The effect of pH on the retention behavior of pteroyloligo-glutamates in reversed-phase HPLC has also been reported (12).

A third technique, ion-pair chromatography, separated 21 UV-absorbing impurities in a clinical sample of methotrexate (13) and has also been utilized in the separation of folic acid and its dihydro- and tetrahydro derivatives (14).

The object of this investigation was to study the influence of the pH of the mobile phase on the chromatographic separation of some pteryolglutamic acid derivatives and to determine optimum conditions for the purity analysis of the USP reference standards by HPLC.

EXPERIMENTAL

Apparatus—An isocratic high-performance liquid chromatograph[3] with a 254-nm detector and a gradient chromatograph[4] equipped with a variable wavelength UV detector[5] were used. The instruments were

Purity Profiles of Pteroylglutamate Reference Substances by High-Performance Liquid Chromatography

L. V. FEYNS ˣ, K. D. THAKKER, V. D. REIF, and L. T. GRADY

Received October 5, 1981, from the *Drug Research and Testing Laboratory, United States Pharmacopeia, Rockville, MD 20852.* Accepted for publication January 21, 1982.

Abstract □ High-performance liquid chromatography (HPLC) in the reversed-phase mode was used for the purity analysis of three pteroylglutamic acid-type reference substances (folic acid, leucovorin calcium, and methotrexate). The influence of the pH of the mobile phase on the separation of an artificial mixture of six pteroylglutamic acid derivatives and three potential impurities was studied. Results of purity analysis of current lots of USP reference standards are reported. A better separation of methotrexate from its major impurities was achieved by using a standard buffer, rather than an ion-pairing mobile phase. A separation of methotrexate and its biologically inactive 7-isomer is reported.

Keyphrases □ Pteroylglutamate—purity profiles, reference substances, high-performance liquid chromatography, methotrexate □ High-performance liquid chromatography—pteroylglutamate, purity profiles, reference substances, methotrexate □ Methotrexate—pteroylglutamate, purity profiles, reference substances, high-performance liquid chromatography

Three USP drug substances, available as USP reference standards, belong to the class of pteroylglutamic acid derivatives: folic acid (I), methotrexate (II), and leucovorin calcium (III) (authentic substance as calcium formyltetrahydrofolate). This class of compounds exhibits high hydrolytic and oxidative reactivity. High-performance liquid chromatography (HPLC) has proved to be the method of choice for purity analysis in this laboratory because of similarities of structure within this series. Additional purity profile data were gained from 5 to 8 collateral determinations, but are not reported here as these results are independent of chromatographic purity.

Almost all the HPLC techniques have been used for the separation and analysis of this class of compounds. Anion-exchange columns were used first in 1973 for the separation of folic acid from a mixture of water-soluble vitamins (1) and then for the separation of folic acid and its reduced and N^5- and N^{10}-substituted derivatives (2). Anion-exchange chromatography alone, or coupled with an amine column operated in the reversed-phase mode, has also been used for the analysis and quantitative determination of methotrexate (3).

An extensive study (4) resulted in the development of a reversed-phase HPLC assay and purity analysis method for folic acid. The assay was made the object of a collaborative study (5), and it has been adopted into the folic acid monograph in the USP (6).

For the reversed-phase chromatographic analysis of methotrexate, mixtures of methanol or acetonitrile with the following buffers have been suggested as mobile phases: pH 3.5, 0.005 *M* ammonium formate (7); pH 5, 0.005 *M* ammonium acetate (7); pH 6.7, 0.1 *M* KH_2PO_4 (8); pH 6.8, 2-amino-2-hydroxymethyl-1,3-propanediol (tris) (9); pH 7.2, 0.05 *M* KH_2PO_4[1]; pH 6, 0.1 *M* citric acid–0.2 *M* Na_2HPO_4[2]. The latter is used in the assay of methotrexate in USP XX–NF XV (10). Mobile phases consisting of pH 5 phosphate buffer–acetonitrile (9) and pH 4 citrate buffer–dioxane (11) were recommended for the analysis and assay of leucovorin calcium. The effect of pH on the retention behavior of pteroyloligo-glutamates in reversed-phase HPLC has also been reported (12).

A third technique, ion-pair chromatography, separated 21 UV-absorbing impurities in a clinical sample of methotrexate (13) and has also been utilized in the separation of folic acid and its dihydro- and tetrahydro derivatives (14).

The object of this investigation was to study the influence of the pH of the mobile phase on the chromatographic separation of some pteryolglutamic acid derivatives and to determine optimum conditions for the purity analysis of the USP reference standards by HPLC.

[g] Eluted at the same retention time as an authentic sample of aminopterin. [h] Eluted at the same retention time as an authentic sample of 4-amino-4-deoxy-N^{10}-methylpteroic acid. [i] Poorly resolved from Peak 5.

pH 6.0, 0.1 *M* citric acid–0.2 *M* Na_2HPO_4 (37:63, Buffer A); 0.05 *M* KH_2PO_4 brought to either pH 3.0 or 4.0 with 85% H_3PO_4 and to pH 5.0, 6.0, 7.0, 7.2, and 7.5 with 1 *N* NaOH (Buffers P-3–P-7.5, respectively); and pH 7.2, 0.05 *M* KH_2PO_4–0.25 *M* $NaClO_4$ (Buffer B).

As an ion-pairing mobile phase a 0.005 *M* solution of tetrabutylammonium bromide in pH 7.5, 0.05 *M* KH_2PO_4 buffer was used.

Sample Solutions—Mixtures of 0.25–4 mg of compound/ml of mobile phase were sonicated for 15–20 min and filtered through a 5-μm membrane filter prior to injection[14]. Fresh solutions were prepared daily.

RESULTS AND DISCUSSION

Analysis—In Table I and Fig. 1 the results are presented both as absolute values of the retention times (obtained from chromatograms of individual compounds) and as their ratios to the retention time of methotrexate (α_{II}). The quantitative data were calculated by area normalization. Unless otherwise mentioned, all the analyses were run in duplicate.

Influence of Buffer pH—Only a few of the impurities typical of commercial production of compounds in this class have been identified. To gain information on the influence of buffer pH on the chromatographic behavior, a synthetic mixture of Compounds I–IX was prepared and the separation has been studied over a pH range limited by the stability of the packing material (3.0–7.5). Buffers of 0.05 *M* KH_2PO_4 were prepared in this range in increments of whole pH units, and the amount of methanol in the mobile phase was adjusted to keep the retention time of the methotrexate peak between 9 and 10 min at a flow rate of 2 ± 0.2 ml/min.

[14] Fluoropore membrane filter, Millipore Corp., Bedford, Mass.

No attempts were made to obtain baseline separation of all nine compounds, since their simultaneous presence in any one specimen is unlikely. The results are presented in Table I and Fig. 1.

A few aspects of the strong influence of the pH value of the buffer on the separation and order of elution of the peaks can be outlined as follows:

1. The α_{II} values for methopterin, aminopterin, folic acid, and leucovorin calcium increase with the decrease of pH value of the buffer. The most pH-sensitive is the methopterin peak. At pH 7.5 it elutes before the aminopterin peak; at pH 7.0 this order is reversed; at pH 4.0 it overlaps the methotrexate peak; and at pH 3.0 it is eluted after both methotrexate isomers.
2. At pH 3.0, methotrexate elutes before the 7-isomer; at pH 4.0 the two peaks overlap and the order of elution is reversed at all pH values above 4.0.
3. A reversal in the elution order of the folic acid and aminopterin peaks takes place at a pH value between 4.0 and 5.0.
4. The retention time of Compound VII reaches a maximum at pH 5.0. For practical reasons (long analysis time) it is probably better to avoid the use of this pH value in the analysis of mixtures containing VII.

The change in the order of elution is illustrated by the chromatograms at pH 3.0 and 7.5 (Fig. 2).

It is apparent that in this class of compounds the pH value of the buffer is the most powerful parameter in adjusting the separation of any given combination of components in a mixture, with optimization of a particular separation making use of other capabilities of HPLC such as selection of a percentage of the organic solvent or gradient elution.

Purity Analysis—*Folic Acid*—Using Buffer B and UV detection at 254 nm, the chromatographic purity of the current lot of USP folic acid RS (J) was found to be 99.8%. Four minor impurities were separated (three before the main peak, one after), none of them at the locus of formyltetrahydrofolate, which as calcium salt is used as an internal standard in the USP assay of folic acid.

Leucovorin Calcium—A 2-year-old sample was recently reanalyzed using two mobile phases. With Buffer B–methanol mixtures a 95.6% chromatographic purity was obtained, eight impurities being separated before the main peak and one after it.

Using a mobile phase recommended in the literature, pH 5.0, 0.05 *M* KH_2PO_4–acetonitrile (95:5) (9), a chromatographic purity of 95.8% was obtained (average of seven injections, 10 impurities separated).

Methotrexate—From the data in Table I, it appears that the best separation of methotrexate from closely related compounds takes place in the pH range of 6.0–7.5. A comparison between the pH 6.0 citrate buffer and the pH 7.5 phosphate buffer in the purity analysis of a 2-year-old sample (C) shows that the same number of impurities (13) was separated. Quantitation by area normalization indicated a chromatographic purity of 92.7% with either pH 6.0 or 7.5 mobile phases.

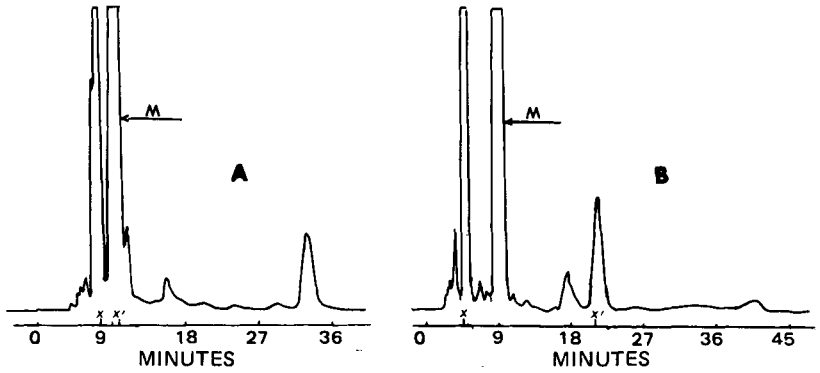

Figure 3—*High-pressure liquid chromatogram of methotrexate Sample B. Key: (A) ion-pairing mobile phase; (B) mobile phase–citrate buffer A: acetonitrile 10:1; (M) methotrexate peak; (X) retention time of an authentic sample of methopterin; (X′) retention time of an authentic sample of VII.*

To compare the pH 6.0 citrate buffer and the ion-pairing mobile phases, two methotrexate samples (A and B) were analyzed for chromatographic purity by the two procedures. The results are shown in Table II. The two methods separate the same number of major impurities, but there are significant advantages for the citrate buffer method:

1. The resolution between the peaks corresponding to methotrexate and methopterin (the major degradation product) is considerably larger using the citrate buffer. The average ratio of the retention times of the two peaks is 2.1 for the citrate buffer method and 1.3 for the ion-pair method. As a result, the resolution of the two peaks by the ion-pair method is acceptable at rather low concentrations of methopterin (V) (Sample A, <1%), but the peaks overlap at a 6% concentration (Sample B) (Fig. 3A). In Reference 13, although the methotrexate peak has a retention time of >40 min, V still elutes as a shoulder on the main peak. The better separation of the two peaks by the citrate buffer method is illustrated in the chromatogram of Sample B (Fig. 3).

2. Another potential impurity in methotrexate is 4-amino-4-deoxy-N^{10}-methylpteroic acid (VII). Again, the citrate buffer provided better separation. In the reported ion-pair chromatography[13], VII is well separated from methotrexate ($t_{R,VII}$ = 18 min, $t_{R,II}$ > 40 min). However, in conditions that, for practical purposes, bring the retention time of the methotrexate peak <10 min, the two peaks overlap ($t_{R,VII}$ = 8.4 min; $t_{R,II}$ = 8.5–8.6 min), and VII could not be identified by spiking a methotrexate sample. Using the citrate buffer mobile phase, with the methotrexate peak eluting between 8 and 10 min, the retention time of VII was ~20 min.

3. The ion-pairing procedure did not separate methotrexate and its 7-isomer. Without giving baseline resolution, the citrate buffer method allowed the detection of 0.2% of the 7-isomer in a spiked sample of methotrexate.

The ion-pairing method proved to be an excellent tool for biochemical studies on methotrexate and its metabolites, but from the previously mentioned considerations it may be concluded that standard buffers should be used as mobile phases for the purity analysis of methotrexate.

The chromatogram of the candidate lot for USP methotrexate reference standard is presented in Fig. 4. Additional chromatograms with mobile phases containing 5–20% acetonitrile ascertained the absence of late-eluting peaks or of potential impurities overlapping the main peak in Fig. 4. The chromatographic purity by area normalization with UV detection at 302 nm was 98.8%.

Separation of the 6- and 7-Isomers of Methotrexate—The formation of 6- and 7-pteridyl isomers in the reaction between 4,5-diaminopyrimidines and polyfunctional 3-carbon compounds is well known (15, 16). Isomerically pure 6- and 7-methotrexate have been synthesized and it was found that the position of the side chain is mainly a function of the pH of the reaction mixture in the pteridine ring closing step and that 7-methotrexate is biologically inactive (17). The two isomers have similar physical chemical characteristics, differing significantly only in the NMR spectra. By TLC or paper chromatography they could be separated only after a preliminary hydrolysis and oxidation to the 2-hydroxy-pteridine-6-carboxylic acid and 2-hydroxy-pteridine-7-carboxylic acid (17).

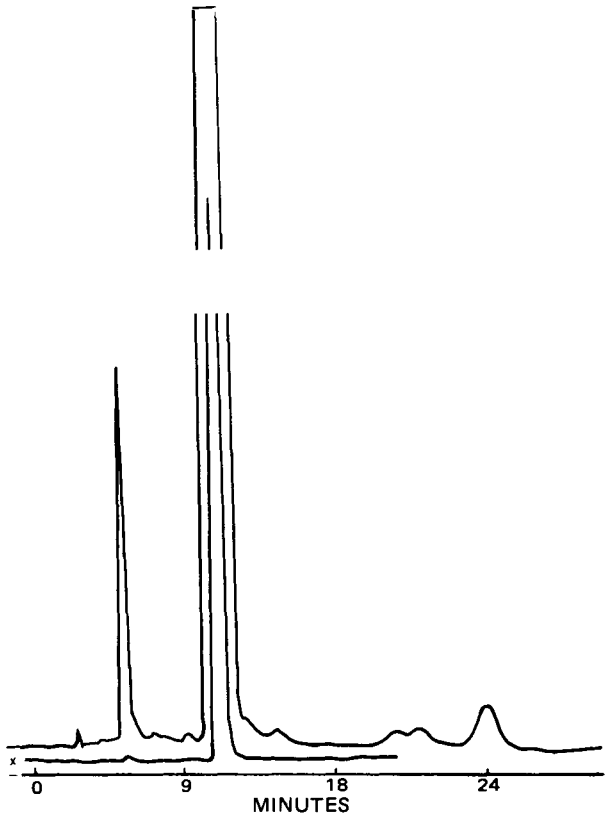

Figure 4—*High-pressure liquid chromatogram of a candidate lot for USP methotrexate reference standard. Mobile phase–Buffer A: acetonitrile 10:1, flow rate 1 ml/min. Key: (X) attenuation 32.*

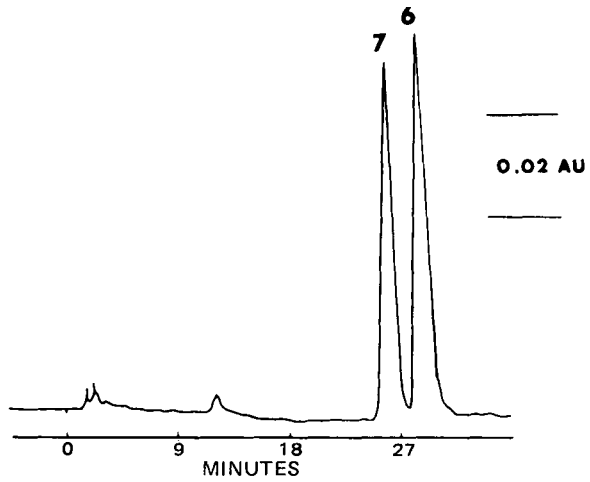

Figure 5—*HPLC separation of the 6- and 7-isomers of methotrexate. Mobile phase–Buffer P-7–CH_3OH; initial 100:5; final 100:12.5; sweep time 15 min, flow rate 2 ml/min. Sample 0.25 mg each/ml.*

Reversed-phase HPLC has been used for the separation of 6- and 7-methyl- (and-methanol-)2,4-diaminopteridines (9).

A nearly baseline separation of 6- and 7-methotrexate (R = 1.4) was obtained using a gradient elution system illustrated in Fig. 5.

Microbial Transformations of Natural Antitumor Agents XVIII: Conversions of Vindoline with Copper Oxidases

FRANCES ECKENRODE, WANDA PECZYNSKA-CZOCH, and JOHN P. ROSAZZA ˣ

Received November 20, 1981, from the *Division of Medicinal Chemistry and Natural Products, College of Pharmacy, The University of Iowa, Iowa City, IA 52242.* Accepted for publication January 22, 1982.

Abstract □ Vindoline occurs structurally intact in the clinically important *Vinca* alkaloids vinblastine and vincristine. It is oxidized by human ceruloplasmin and fungal and plant laccases into a reactive intermediate which undergoes intramolecular cyclization to an enamine which ultimately dimerizes. Transformations of vindoline by these copper oxidases are enhanced when enzyme incubations are performed with cofactors such as chlorpromazine. The role of copper oxidases in alkaloid metabolic interconversions and the possible implications of these reactions in *Vinca* alkaloid toxicity are discussed.

Keyphrases □ Vindoline—microbial transformations, natural antitumor agents, conversions with copper oxidase, *Vinca* alkaloids □ Alkaloids, *Vinca*—vindoline, microbial transformations, natural antitumor agents, conversions with copper oxidase □ Antitumor agents—vindoline, microbial transformations, natural antitumor agents, conversions with copper oxidase, *Vinca* alkaloids

Vincristine (II) and vinblastine (I) are widely used dimeric antitumor alkaloids obtained from species of *Catharanthus rosea*. These compounds differ structurally only in the oxidation state of one carbon atom which is attached to the dihydroindole nitrogen atom of the *Aspidosperma* portion of the molecule. Studies concerned with the metabolism of I and II are intended to reveal pathways of metabolic transformations which might ultimately be implicated in mechanism(s) of action and/or the toxicities associated with their use. Several attempts have been made to date (1–5) to study the metabolism of *Vinca* alkaloids, but no metabolites of these compounds have been isolated and fully identified. Low amounts of metabolites produced, very low doses of compounds employed, high molecular weights, and structural complexities probably rendered the identification of presumed metabolites difficult in previous studies.

Copper oxidases are widely occurring enzymes found in mammals, plants, and microorganisms. Enzymes from these different sources possess different physical characteristics including molecular weight, the number and oxidation states of copper, and the nature of copper ligands at presumed active sites (6, 7). Recognized similarities also exist among these enzymes, and direct comparisons between the catalytic capabilities of ceruloplasmin and laccases have been made previously (8, 9). The enzymes achieve the oxidation of substrates by the direct removal of substrate electrons and protons with the subsequent transfer of electrons to molecular oxygen *via* copper (6, 7, 10, 11). True substrates interact directly with copper oxidase enzymes to yield products, while pseudosubstrates require substances capable of interfacing between them and the enzyme during oxidations (6). The requirement for such cofactors has been noted primarily in work with ceruloplasmin in the oxidation of xenobiotics such as arylamines, phenols, and some centrally acting drugs and their analogs (6).

It was discovered that vindoline, a dihydroindole monomer found in the structure of I undergoes oxidation in the presence of copper oxidase enzymes including human ceruloplasmin, fungal, and plant laccases. This report describes the types of chemical transformations of vindoline catalyzed by the copper oxidases which result

Vincristine (II) and vinblastine (I) are widely used dimeric antitumor alkaloids obtained from species of *Catharanthus rosea*. These compounds differ structurally only in the oxidation state of one carbon atom which is attached to the dihydroindole nitrogen atom of the *Aspidosperma* portion of the molecule. Studies concerned with the metabolism of I and II are intended to reveal pathways of metabolic transformations which might ultimately be implicated in mechanism(s) of action and/or the toxicities associated with their use. Several attempts have been made to date (1–5) to study the metabolism of *Vinca* alkaloids, but no metabolites of these compounds have been isolated and fully identified. Low amounts of metabolites produced, very low doses of compounds employed, high molecular weights, and structural complexities probably rendered the identification of presumed metabolites difficult in previous studies.

Copper oxidases are widely occurring enzymes found in mammals, plants, and microorganisms. Enzymes from these different sources possess different physical characteristics including molecular weight, the number and oxidation states of copper, and the nature of copper ligands at presumed active sites (6, 7). Recognized similarities also exist among these enzymes, and direct comparisons between the catalytic capabilities of ceruloplasmin and laccases have been made previously (8, 9). The enzymes achieve the oxidation of substrates by the direct removal of substrate electrons and protons with the subsequent transfer of electrons to molecular oxygen *via* copper (6, 7, 10, 11). True substrates interact directly with copper oxidase enzymes to yield products, while pseudosubstrates require substances capable of interfacing between them and the enzyme during oxidations (6). The requirement for such cofactors has been noted primarily in work with ceruloplasmin in the oxidation of xenobiotics such as arylamines, phenols, and some centrally acting drugs and their analogs (6).

It was discovered that vindoline, a dihydroindole monomer found in the structure of I undergoes oxidation in the presence of copper oxidase enzymes including human ceruloplasmin, fungal, and plant laccases. This report describes the types of chemical transformations of vindoline catalyzed by the copper oxidases which result

I: R = CH_3
II: R = CHO

in the formation of a reactive enamine intermediate which dimerizes.

EXPERIMENTAL

Compounds—Vindoline (III)[1] was fully characterized (melting point, NMR, UV,and IR spectra) before being used in these experiments (12). Dihydrovindoline ether (IV) and the enamine dimer (V) were authentic standards from previous work (12, 13). These compounds were previously characterized by high resolution mass spectral, carbon-13 and proton NMR analyses.

General—IR spectra[2] were determined using potassium bromide disks, UV spectra[3] were measured in alcohol solution, proton NMR spectra[4] were obtained using deuterochloroform as the solvent and tetramethylsilane as an internal standard, and low resolution mass spectra[5] were obtained using a direct inlet probe.

Chromatography—TLC was performed on 0.25-, 0.50-, or 1.0-mm thick layers of silica gel GF_{254}[6] on glass plates. Prior to use, TLC plates were activated at 120° for 30 min. Solvent systems employed were: A, ethyl acetate–methanol (3:1); B, ethyl acetate–benzene (3:1); C, ethyl acetate–benzene (1:1); and D, ethyl acetate 100%. Compounds were detected on developed chromatograms by fluorescence quenching <254- or 365-nm UV light and were later visualized by spraying with cerium (VI) ammonium sulfate (1% in 50% H_3PO_4, v/v). Column chromatography was performed with silica gel[7] activated for 30 min at 120° prior to use. Columns were packed wet by slurrying silica gel in developing solvent. High-performance liquid chromatography (HPLC) was performed using a reversed-phase column[8] (0.4 × 30 cm), a septumless injector[9], a solvent delivery system consisting of a dual-piston pump[10], and a dual fixed wavelength 254-nm UV absorbance detector[11]. Separations were best achieved using acetonitrile and 0.1% $(NH_4)_2CO_3$–water (50:50) at an average flow rate of 1 ml/min, and an operating pressure of 2000 psi. Authentic standards were injected singly to establish individual retention volumes, and mixtures of metabolites were well-resolved. The identities of individual metabolite peaks were confirmed by spiking with analytical standards. Retention volumes of various compounds were: III, 6.59 ml; IV, 7.78 ml; and V, 23.95 ml.

Enzymes—Methods used in the production, isolation, and analysis of *Polyporus anceps* laccase enzyme were described previously (14). Laccase enzyme activities were determined using a simple colorimetric assay procedure based on the oxidation of syringaldazine (14–16). For these assays, a standard laccase unit was defined as the amount of enzyme catalyzing the oxidation of 1 μmole of syringaldazine to its quinone form (ϵ = 65,000 at 526 nm)/min at 25° in pH 5.0, 0.2 *M* phosphate (K_2HPO_4–KH_2PO_4) (14).

Rhus vernicifera laccase[12] enzyme activities were determined in pH 7.5, 0.1 *M* phosphate buffer using the syringaldazine method.

The purity of ceruloplasmin (human, type III)[13] was ascertained by determining the ratio of absorbances at 610/280 nm, which was measured at 0.046. Pure crystalline enzyme was reportedly measured at A_{610}/A_{280} of 0.047 (17). Enzyme concentrations were calculated from the 610-nm absorption (ϵ = 10,900/*M*) (18) based on a molecular weight of 132,000 (19). Ceruloplasmin activity was standardized in terms of international units according to a previous procedure (20). A single variation of this procedure was the use of the sulfate rather than the oxalate salt of *N*,*N*-dimethyl-*p*-phenylenediamine for this determination. Based on these measurements, human ceruloplasmin contained a specific activity of 123 U/mg of protein. Ceruloplasmin activity was significantly lower at 25°, providing a measured specific activity of only 29 U/mg of protein.

Enzyme Incubation Procedures—Most incubations were conducted in 50-ml flasks which were shaken at 250 rpm[14].

Laccase incubations of *P. anceps* were conducted at 27°. Incubation mixtures were prepared by adding 2 mg (4.39×10^{-6} moles) of vindoline in 0.1 ml of methanol to 7 ml of phosphate buffer (pH 5.0, 0.2 *M*) containing 1.05 U of laccase.

Incubations with *R. vernicifera* laccase were also conducted at 27°, and incubation mixtures were prepared by adding 2 mg of vindoline in 0.1 ml of methanol to 5.2 ml of phosphate buffer (pH 7.0, 0.1 *M*) containing 0.019 U of *Rhus* laccase.

Incubations with human ceruloplasmin were conducted at 37°. These were prepared by adding 2 mg of vindoline in 0.1 ml of methanol to 7.05 ml of acetate buffer (0.2 *M*, pH 5.5) containing 54 U of ceruloplasmin activity.

Several cofactors were also employed in enzyme incubation mixtures. Where used, they were employed in molar ratios of 1:1 and 3:1 *versus* the substrate vindoline. Cofactors examined in this work were 3-hydroxy-4-methoxyphenethylamine; harmine; harmol hydrochloride; histamine; levodopa; syringaldazine; hydroquinone; *N*,*N*-dimethyl-*p*-phenylendiamine; and chlorpromazine. Cofactors were added to incubation mixtures in 0.1 ml of methanol.

Controls consisted of incubations containing enzyme alone, mixtures containing only substrates plus cofactors, and complete incubations containing boiled enzymes. No reactions were observable when boiled enzymes were used or when no enzymes were present in incubation mixtures.

Rates of enzyme reactions were determined by measuring oxygen uptake with an electrode[15] connected to a stirred, water-jacketed reaction chamber 3.73 ml in volume (21). Incubations were conducted as described before using 54 U of ceruloplasmin, and 0.25 U of *P. anceps* laccase. Vindoline (1.02 mg, 2.24×10^{-6} moles) was added to incubations in 0.05 ml of methanol, and chlorpromazine (9.4 mg, 2.65×10^{-6} moles) was added as a cofactor for most incubations.

Analyses of enzyme incubation reactions were also performed by withdrawing samples of 1.0 ml at various time intervals. Reaction samples were adjusted to pH 10 with 58% NH_4OH and extracted with 1 ml of ethyl acetate. Extracts were examined by TLC using solvent systems A and B or by HPLC.

Preparative Scale Production of the Dimer (V) Using *P. anceps* Laccase—Vindoline (300 mg) dissolved in 25 ml of dimethylformamide was added to 300 ml of pH 5.0, 0.2 *M* phosphate buffer containing 66 units of *P. anceps* laccase enzyme and 3.2 mg of syringaldazine added in 2 ml of methanol. This mixture was incubated for 24 hr at room temperature to ensure a complete bioconversion reaction before being adjusted to pH 10 with 58% NH_4OH and extracted four times with equal portions of ethyl acetate. The extracts were dried over anhydrous sodium sulfate and concentrated to a red oil (0.635 g). The oil was dissolved in 1 ml of ethyl acetate, applied to a silica gel column (3 × 33 cm, 100 g) and eluted with solvent system C at a flow rate of 2 ml/min while 10-ml fractions were collected. Fractions 269–300 contained the major reaction product, and these were combined, dried over anhydrous sodium sulfate, and concentrated to a brown solid (143 mg). This material was further purified by dissolving in 1 ml of acetone and applying to a 0.5-mm silica gel preparative layer TLC plate which was developed in solvent system B. The band at R_f 0.39 was scraped from the plate, mixed with 10-ml portions of acetone (4X), stirred, and filtered. Evaporation of the combined filtrates yielded 81 mg of pure V as an amorphous glass.

Trapping a Reactive Enamine Intermediate (VI) by Reduction to IV with Sodium Borohydride—Two milligrams of III dissolved in 0.1 ml of methanol was added to 7 ml of 0.2 *M* phosphate buffer, pH 6.5,

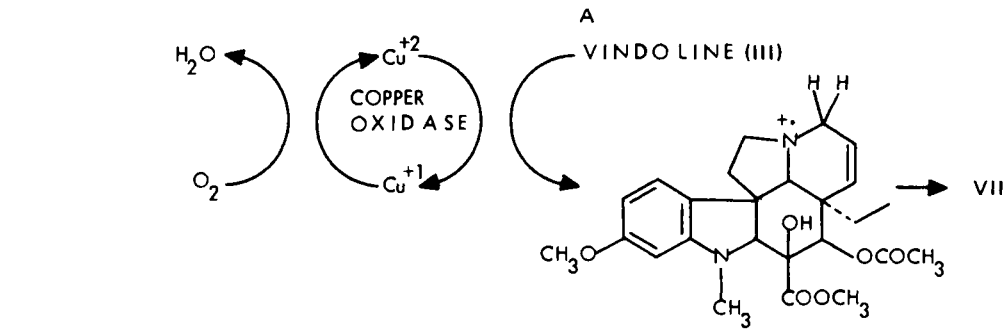

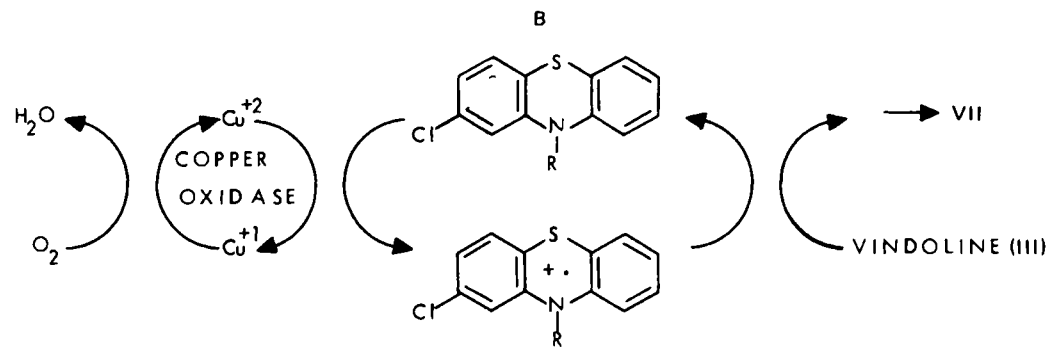

***Scheme II**—Pathways for the flow of electrons in the oxidation of vindoline by the copper oxidases.*

containing 1.2 units of *P. anceps* laccase. The mixture was incubated for 2.5 hr before being adjusted to pH 9.6 with 58% NH_4OH and extracted with 7 ml of ethyl acetate. TLC of the crude extract on silica gel plates (solvent system A) *versus* authentic standards revealed the presence of III R_f 0.7, V R_f 0.82, and the presumed enamine VI, R_f 0.9. The extract was evaporated to dryness, redissolved in 1 ml of methanol and treated with 10 mg of sodium borohydride. After 30 min, this reaction mixture was evaporated to 1 ml, quenched with 5 ml of water and extracted with ethyl acetate. This extract was evaporated to dryness and TLC examination on silica gel GF_{254} (solvent system A) revealed the presence of a substance with chromatographic mobility of R_f 0.25, identical to known dihydrovindoline ether (IV). The extract was dissolved in ethyl acetate, applied to a preparative 0.5-mm silica gel plate, and developed with solvent system A. The band at R_f 0.25 was removed and extracted from silica gel with acetone. TLC and HPLC (retention volume of 7.78 ml) determined that the eluted compound was identical to authentic IV.

RESULTS AND DISCUSSION

The monomeric *Vinca* alkaloid III has been the subject of a previous metabolic study. This compound is the most abundant and available of the alkaloids of *C. rosea*, and it is found essentially intact in the dimeric structures of I and II. Enzymatic transformations observed with III also might be expected to occur in the appropriate functionalities of the dimeric alkaloids like I and II.

Early work with microorganisms as metabolic tools (22) resulted in the elaboration of a unique vindoline metabolic pathway (Scheme I) (12, 13). *Streptomyces griseus* whole cells oxidized vindoline to V and IV, both of which accumulated in incubation media in high yield. A reactive enamine VI was identified as a key intermediate in transformations of III (13). Although the enzyme systems of *S. griseus* responsible for the biotransformation reactions remain unknown, it is possible to postulate four different pathways by which III might undergo initial oxidation to VI (Scheme I). The first pathway involves initial *N*-oxidation of III to VIII, conjugation through the *N*-oxide and elimination of ROH to form VII; and subsequent intramolecular cyclization to VI. This pathway would represent a biochemical equivalent to the modified Polonovsky reaction observed in the chemical treatment of these alkaloids (12). A second path involves direct oxidation of vindoline to VII by the removal of two electrons and a proton. The third possibility would invoke a direct hydroxylation of vindoline at position 3 to form a carbinolamine (IX) which provides VII by elimination of a hydroxide ion. Finally, and perhaps least likely, initial epoxidation of the 14,15-double bond followed by intramolecular etherification and subsequent dehydration could also provide VI. The need to elaborate the precise steps involved in oxidations of III has stimulated a search for more highly defined enzyme systems such as the copper oxidases.

Since crude fungal laccase could be reproducibly obtained in relatively large amounts, it was employed in preparative scale incubations designed to afford sufficient amounts of metabolites for isolation and structure elucidation. Incubations of III with *P. anceps* laccase (14) produced two metabolites with similar TLC mobilities to III derivatives VI and V (12, 13). The major and stable metabolite produced by *P. anceps* laccase was obtained by column and preparative layer chromatography in 27% yield from 300 mg of III. This metabolite was identified as V by spectral and chromatographic comparison with an authentic sample of the dimer (12). Pertinent spectral properties included the UV spectrum in ethanol with λ_{max} values at 252 nm (log ϵ, 4.13) and 309 (log ϵ, 3.84). Highly characteristic NMR signals were also obtained for the metabolite and included the following: ppm, 0.8 (6H, m, 2 overlapping 18H), 1.9 (3H, s, $COCH_3$), 2.0 (3H, s, $COCH_3$), 2.65 (3H, s, NCH_3), 2.75 (3H, s, NCH_3), 3.75 (12H, s, two overlapping CO_2CH_3 and OCH_3 groups), 4.05 (1H, m, 15′H), 4.2 (1H, s, 15H), 5.35 (2H, d, J = 2 Hz, overlapping 17H), 5.99 (2H, d, J = 2 Hz, overlapping 12H), 6.05 (1H, s, 3H), 6.25 (2H, q, overlapping 10H), 6.9 (2H, dd, overlapping 9H). Confirmation of the structure of the major and stable laccase metabolite as V is a significant finding, because the mechanism of copper oxidase reactions is reasonably well understood.

It was mechanistically important to confirm the involvement of the enamine (VI), in copper oxidase transformations of vindoline. The second and unstable laccase metabolite possessed similar TLC mobility to VI previously obtained from *S. griseus* incubations. Since the presumed enamine intermediate was considerably more stable at pH values near neutrality, enzyme incubations were conducted at pH 6.5 to favor its accumulation. Extracts of laccase incubation mixtures were concentrated, and reduced with sodium borohydride to convert the enamine to the known dihydrovindoline ether IV. This technique was employed earlier as a means of stabilizing and identifying the enamine VI (12, 13). Chromatographic (HPLC, retention volume 7.78 ml; TLC, R_f 0.25) analysis of the reduced laccase extract clearly demonstrated the presence of IV. Thus, it has been shown that the copper oxidase oxidations of III result in the formation of VI as well as V.

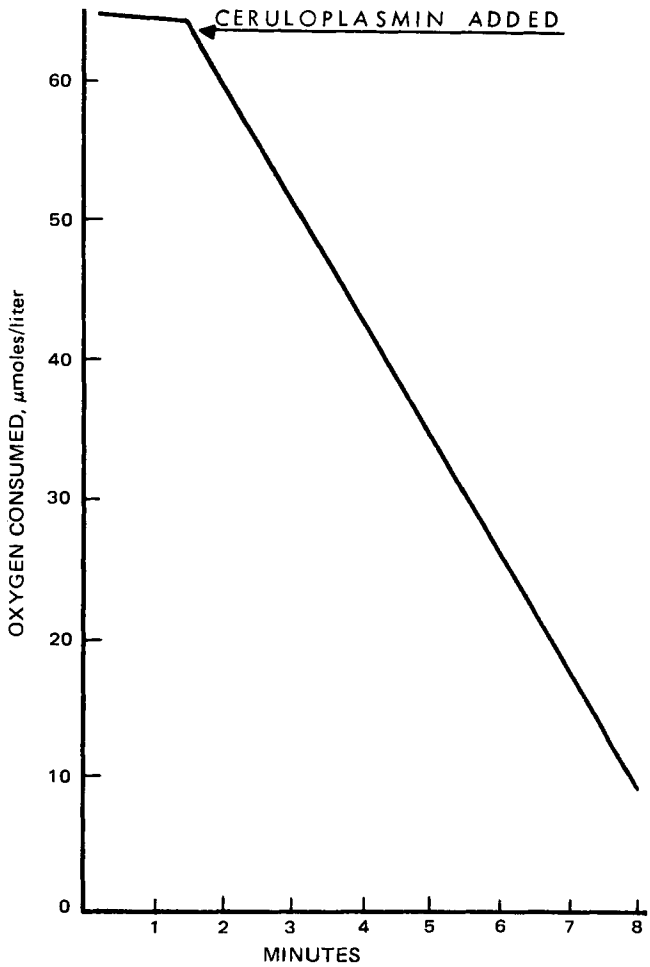

***Figure 1**—Rate of oxidation of vindoline by ceruloplasmin as shown by the uptake of molecular oxygen using a Clark oxygen electrode.*

The involvement of chlorpromazine and other cofactors in copper oxidase oxidations of III is illustrated in Scheme II. When III is a true substrate for ceruloplasmin, it is directly oxidized by the transfer of electrons through the copper oxidase enzyme to molecular oxygen (A). With chlorpromazine and syringaldazine, III is a pseudosubstrate which is oxidized directly by a chlorpromazine radical species which serves as a cycling intermediate between it and ceruloplasmin (Scheme IIB) (23). The oxidation of chlorpromazine to a radical species by ceruloplasmin has been associated with the formation of a red pigment with an absorption maximum at 529 nm by simultaneous optical-absorption, electron paramagnetic resonance measurements (23). With both laccase and ceruloplasmin, chlorpromazine forms a visible red pigment with an absorption maximum at 529 nm. Similar radical intermediates have been implicated in other oxidation reactions catalyzed by ceruloplasmin (23–26).

Human ceruloplasmin and *R. vernificera* laccase also oxidized III to the dimer (V). As with *P. anceps* laccase, III was an apparent true substrate for serum ceruloplasmin, forming products in the absence of added cofactors. However, reaction rates were increased sixfold when an ~1-mole equivalent of chlorpromazine was added to the reaction mixtures. A similar effect was observed when III was incubated with laccase alone or in the presence of laccase plus chlorpromazine. Results obtained using the oxygen electrode illustrate the rate enhancements obtained when chlorpromazine was added to enzyme incubation mixtures, and these are shown in Fig. 1. No reactions were observed at all with *Rhus* laccase unless cofactors were present.

Chlorpromazine clearly enhanced oxidation rates with all of the copper oxidases examined. Of the other cofactors examined, only syringaldazine, a known substrate for laccase (14), increased *Rhus* and *P. anceps* laccase oxidations. However, this compound had no measurable effect with ce-

ruloplasmin. Other substrates listed in the *Experimental* section had no effect on copper oxidase reactions. This was surprising since these compounds had previously been shown to facilitate oxidations of biogenic amine substrates with ceruloplasmin (23, 24, 27, 28).

This is the first report of any type of metabolic conversion of a *Vinca* alkaloid by mammalian enzymes, and the first demonstrating the oxidation of a nitrogen heterocycle of the *Aspidosperma* class of alkaloid by copper oxidases. It is an excellent example of the principle of microbial models for mammalian drug metabolism (22), and it clearly demonstrates the similarities with which microbial and mammalian enzymes achieve xenobiotic transformations. By their nature, copper oxidases most likely cause the elimination of two electrons and a proton from III as the first step in the biotransformation pathway. It appears that protons at position 3 of III are activated toward copper oxidase oxidations by virtue of their allylic nature and their proximity to the heterocyclic nitrogen atom. It can be expected that similar functionalities in other substrates will also be oxidized by the copper oxidases. While *N*-oxides, carbinolamines, and epoxides may be ruled out as possible intermediates in copper oxidase-mediated transformation of the *Vinca* alkaloids, it is possible that derivatives such as VIII and IX may be formed as a result of oxidation catalyzed by other types of enzymes such as the mixed function oxygenases found in mammalian liver (29–31).

This work provides a biochemical basis for understanding possible interactions of drugs like chlorpromazine and perhaps others with compounds like vindoline (III) and other copper oxidase substrates. The presence of cofactors that enhance conversions of their alkaloids and their congeners to chemically reactive species may have profound toxicological implications. The potential for chemically reactive imminium and enamine species to partake in reactions of pharmacological significance is enhanced by virtue of the stabilities of these substances in aqueous media (12, 13), which would allow for their facile distribution throughout the body. In this connection, ceruloplasmin levels are elevated in individuals afflicted with various types of cancer (32, 33). Further studies designed to elaborate enzymatic transformations of *Iboga* alkaloids representing the other half of dimers such as I and *Vinca* dimers themselves are in progress.

Determination of Captopril in Human Blood and Urine by GLC–Selected Ion Monitoring Mass Spectrometry after Oral Coadministration with Its Isotopomer

ALLEN I. COHEN ˣ, RICHARD G. DEVLIN, EUGENE IVASHKIV, PHILLIP T. FUNKE, and TERRENCE McCORMICK

Received September 17, 1981, from the *Departments of Analytical Research and Clinical Pharmacology, The Squibb Institute for Medical Research, New Brunswick, NJ 08903.* Accepted for publication January 26, 1982.

Abstract □ A modified electron-impact GLC-selected ion monitoring mass spectrometric method for captopril is described. Positive chemical ionization GLC-selected ion monitoring and direct chemical ionization confirms the specificity of this procedure for captopril and establishes the chemical ionization techniques as potential analytical methods. This procedure has been adapted to the simultaneous measurement of captopril and its isotopomer. The results of a pilot oral bioavailability study of four subjects receiving either 100 mg of captopril as a direct compression tablet or a solution concomitantly with a 100-mg solution of isotopomer is discussed.

Keyphrases □ Captopril—determination in human blood and urine, GLC-selected ion monitoring mass spectrometry, oral coadministration with isotopomer □ GLC-selected ion monitoring mass spectrometry—determination of captopril in human blood and urine, oral coadministration with isotopomer □ Urine, human—determination of captopril in urine blood, GLC-selected ion monitoring mass spectrometry, oral coadministration with isotopomer

Captopril (I) is an orally active inhibitor of the angiotensin-converting enzyme (1, 2). A specific determination of I was performed by GLC–selected ion monitoring mass spectrometry (3). The succinimide (I*a*) was formed in whole blood by the addition of *N*-ethylmaleimide (IV), which was then adsorbed onto XAD-2 resin, eluted, methylated, and measured as the ester (I*b*). The collaborative studies obtained by the GLC selected ion monitoring and radiometric-TLC methods (4) established a high degree of specificity for the determination of the administered compound, in the presence of other captopril biotransformation products (5). Other recent assays for captopril in blood and urine employ GC (6) and high-performance liquid chromatography (HPLC) (7, 8).

BACKGROUND

Based on the experience gained from the analysis of blood samples from more than 200 normotensive subjects, a number of modifications of the method (3) evolved to achieve more ease and reliability in processing samples as well as increased precision in making measurements. Currently, 1000 samples, typically collected in one multiple crossover bioavailability study, are processed monthly.

This highly specific and precise analytical method has shown the variability that exists in the disposition of the drug by individual subjects. Using the statistical criteria, a significant subject population is required to demonstrate bioequivalence of formulations. A number of investigators have successfully employed the coadministration of a drug with an isotopomeric formulation in absolute (9) and relative bioavailability (10–15) studies with fewer subjects and at a substantial savings in expense and time. Use of coadministered formulations places more emphasis on a comparison of intra- and intersubject variabilities and at the same time provides data better suited to the evaluation of pharmacokinetic parameters (16).

EXPERIMENTAL

Reagents—Captopril (I, 1-[*S*(2)-mercapto-2-methylpropionyl]-L-proline, CAS registry 62571-86-2), its heptadeutero-isotopomer(II) and 1-[(*S*,4*S*)-4-fluoro-1-(D-3-mercapto-2-methyl -1- oxopropyl)]-L-proline (III) were pharmaceutical grade materials[1] used with additional purification. Methanol, *N*-ethylmaleimide (IV), hydrochloric acid, sodium bicarbonate, diethylenetriaminetetraacetic acid[2] (V), citric acid, oxalic acid dihydrate, sodium phosphate dibasic ($Na_2HPO_4 \cdot 7H_2O$), ammonium phosphate dibasic, instant methanolic hydrochloric acid kit[3], 80–200 mesh Brockman Activity 1 neutral alumina, and sodium chloride were used without purification. Purified XAD-2 resin[3] was conditioned as previously described (3). Ethyl acetate was purified immediately before use by passing 600 ml through a neutral alumina 2.5 × 40-cm column to remove oxidizing impurities (3). Preparation of the phosphate buffer (pH 7.0) and methanolic hydrochloric acid have been previously described (3).

The solutions used for processing urine samples were prepared by a previous method (17). The 0.8% V solution was prepared by dissolving 4 g of V in 500 ml of 0.08 *M* NaOH, sonicated for ~30 min in an ultrasonic bath. The 0.08 *M* NaOH solution was prepared by dissolving 3.2 g in 1 liter of distilled water. The citric acid–oxalic acid solution was prepared by dissolving 105 g of citric acid monohydrate and 63 g of oxalic acid in 1 liter of distilled water.

Blood and Urine Collection—From 12 to 15 ml of blood was drawn[4] and processed as previously described (3) by the addition of 75 mg of IV to each sample. Frozen citrated whole blood was used for calibration and control samples. Urine samples were collected according to a previous

procedure (17) for the colorimetric determination of captopril. The urine for each subject was collected over the prescribed time period, and 5 ml of refrigerated solution was added to the temporary container. Each subject's sample was swirled and added to the permanent container which contained 100 ml of citric acid–oxalic acid solution. The permanent container was returned to a 5° refrigerator, and at the end of the collection period the pH was tested with pH 2–4 paper. An additional 100 ml of citric acid–oxalic acid solution was added if the pH exceeded 2. Each volume of urine and citric acid–oxalic acid solution added to the container was measured and recorded, and 50–100 ml of this solution was transferred to a smaller container for storage in a refrigerator.

Before an elapsed time of 48 hr, 0.2 ml of a solution of IV (5 g/ml in acetone) was added to 5 ml of refrigerated urine sample, followed by 5 ml of ammonium phosphate dibasic solution (250 g/liter in water). After standing for 15 min, the solution was sampled for analysis or frozen if the analysis was to be performed at a later date.

Extraction of Blood Samples—The extraction procedure remained essentially the same (3), except that the samples were processed in batches of 11 plus one control. For samples containing the isotopomer, 2.5 μg of III was added as an internal reference to each 5-ml aliquot of blood sample, while 2.5 μg of II was added as the internal reference for the measurement if only captopril was administered. For coadministration studies, the control was composed of 5 μg each of I and II and 2.5 μg of the internal reference III. For the single administration samples, the control sample was 5 μg of I and 2.5 μg of the internal reference II. The samples were methylated after extraction, and just prior to measurement they were reconstituted with 20 μl of acetone.

642.0	621.0	21.0

Extraction of Urine Samples—Urine samples collected just prior to and 4 hr after administration were processed in the same manner as the blood samples (3). To each 3-ml aliquot, 0.1 ml of the fluoro internal reference III containing 2.5 μg was added.

Samples collected during the first 4 hr after administration, were processed by adding 0.1 ml of internal reference containing 25 μg of internal reference III to a 2-ml aliquot of urine sample. The control urine sample contained 50 μg each of I and II and 25 μg of III. To each 150-mm screw-capped culture containing the urine sample, 2 g of sodium chloride and 2 ml of 6 N H_3PO_4 were added, the tubes covered with caps, and agitated on a shaker for 5 min. Five milliliters of purified ethyl acetate was added, the tubes were shaken for 5 min, and then centrifuged at 2000 rpm for 5 min. Five-tenths milliliter of the ethyl acetate layer (top) was then transferred to a 1-ml reaction vial[5] and the solvent was evaporated under nitrogen[6]. The contents of the reaction vials were then further dried under vacuum at room temperature for 15 min in an oven or dessicator. The samples were then methylated as described (3) and stored in a freezer. Just prior to measurement, the samples were dissolved in 20 μl of acetone.

Calibration and Preparation of Control Blood and Urine Samples—Varying amounts of I (and an equal amount of II for simultaneous measurements) were added to 5 ml of citrated blood (containing 25 mg of IV, in a 150-mm screw-capped culture tube), to yield blood concentrations of 0–1500 ng/ml. For the simultaneous measurements of captopril and its isotopomer, 0.1 ml of solution containing 2.5 μg of internal reference III was added, while an equivalent amount of internal reference II was added if only I was to be measured. The control sample represents the calibration point of 1000 ng of analyte(s) and 500 ng of internal reference per milliliter of blood.

The standard curve for the low-concentration urine samples was prepared from 3-ml urine samples containing 0–7.5 μg of I and II and 2.5 μg of internal reference III, which were processed as described for urine samples collected during the first 4 hr after administration. Control urines, containing either 5 or 50 μg of analytes I and II and 50% of internal reference III were processed for either low or high concentrations of captopril.

Table IV—Statistical Evaluation of Captopril Blood Calibration Data

Ratio ng Captopril I / ng Isotopomer II[a]	$Int_{m/z\ 230}/Int_{m/z\ 237}$ Mean[b]	Standard Deviation (s)	s/Mean
0.0	0.01915	0.002783	0.145
0.0625	0.09775	0.01099	0.112
0.125	0.19146	0.02515	0.131
0.25	0.34287	0.01893	0.055
0.50	0.68678	0.02410	0.035
1.0	1.3050	0.04248	0.033
2.0	2.5694	0.1344	0.052
3.0	3.8928	0.1659	0.043

[a] 2500 ng internal reference standard added. [b] Based on nine measurements.

The ratio of the maximum peaks heights, R_n, was plotted *versus* the respective nanogram ratio R'_n:

n	R_n	R'_n
1	$I_{m/z\ 230}/I_{m/z\ 237}$	1/2
2	$I_{m/z\ 230}/I_{m/z\ 248}$	1/3
3	$I_{m/z\ 237}/I_{m/z\ 248}$	2/3

The intercept, I_n, is the ratio R_n for the blank extract ($R'_n = 0$). Linear regression:

$$R_n = I_n + k_n R'_n \qquad \text{(Eq. 1)}$$

establishes the slopes, k_n, and the intercepts I_n for Eq. 1 (Table I).

Selected Ion Monitoring—From 1 to 2 μl of solution, added to the tip of a GLC solids injector[7], was allowed to evaporate. The appropriate ion profiles (m/z 230.1, m/z 237.1, m/z 248.1) were obtained by selected ion monitoring. The maximum peak heights were measured using a program written especially for the batch processing of the data[8]. The program selects the baseline-corrected maximum peak heights of the requested ions. The mean ratio, R''_n, and standard deviation for three to five injections of the control sample bracketing the samples were determined for subsequent use to correct the data for differences in response from the calibration slope, k_n. The adjustment factor, A, is related to the calibration slope and the measured ratio of the control, R''_n, by Eq. 2:

$$A = \frac{R''_n}{I_n + 2k_n} \qquad \text{(Eq. 2)}$$

The measured ratio of the sample, R^*_n, is related to R_n by Eq. 3:

$$R_n = R^*_n/A \qquad \text{(Eq. 3)}$$

which is then used to calculate the ng (or μg) ratio of analyte to internal reference, R'_n:

$$R_n = R^*_n/A = I_n + k_n R'_n \qquad \text{(Eq. 4)}$$

The concentration of analyte, C_x, is calculated from Eq. 5:

$$C_x = R'_n(F/M) \qquad \text{(Eq. 5)}$$

where C_x is the concentration of analyte in nanograms per milliliter (blood) or micrograms per milliliter (urine), F is the quantity of internal reference (ng for blood; μg for urine) added to M milliliters of sample, and R'_n is the ratio of analyte to internal reference calculated from Eq. 1.

Instrumental Procedure—The combined GLC–MS with data system[9] was operated under selected ion monitoring mode. The instrument was tuned[10] for electron-impact (EI) MS from 69 to 502 Daltons using perfluorotributylamine at an ionization voltage of 70 eV and at an emission of 300 μA. The ion source was controlled at a constant temperature of 200°.

A septum guide[11] was attached to the GLC injector. The analyses were carried out on an 80- cm × 2-mm i.d. silanized glass column packed with 3% OV-101[12] which was connected through a single-stage jet separator.

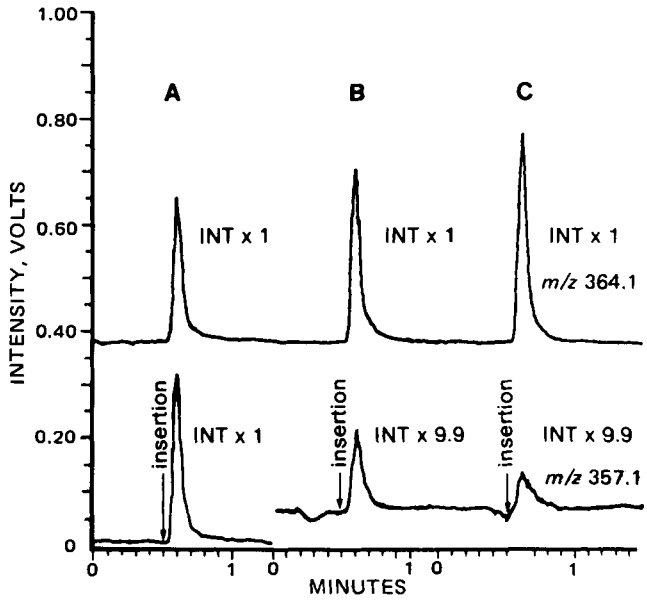

Figure 1—*Direct chemical ionization of captopril blood samples containing 500 ng/ml of internal reference as IIb and (A) 442, (B) 13.8, and (C) 2.5 ng/ml of captopril as Ib*

The separator and transfer line were maintained at 275° while the column was kept at an isothermal temperature of 260° and the injector was heated to 290°. A typical retention time of 0.6 min was obtained at a helium flow rate of 30 cm³/min. Slight adjustments in the column temperature were made to keep the retention time within the desired time window, when necessary. Helium, otherwise diverted, was allowed to flow into the ion source from 0.1 to 1.3 min after sample injection. The multiplier and electron voltages were only applied during the data collection period from 0.3 min until the termination of the GLC run. When required, portions of the column packing or the entire column was replaced to maintain optimum chromatographic conditions. The septum was replaced each day.

Positive chemical ionization GLC–MS was obtained with methane as the GLC carrier gas, at a flow rate of 20 cm³/min, directly into the source to create a 1-torr source pressure. Otherwise, the chromatographic conditions were identical to that of the electron impact-GLC–MS.

Direct chemical ionization mass spectra and measurements were taken on a modified quadrupole mass spectrometer[13] equipped with a data acquisition system[14]. The respective emission and electron energy were 1000 μA and 300 V. Resolution, sensitivity, and mass calibration were made according to the recommended procedures. Water was employed as the reagent gas, admitted from behind the sample and from a separate line into the chemical ionization source. The selected ion monitoring data were recorded on the MH^+ at a nominal source pressure of 1 torr and a source temperature of 250°. For the direct chemical ionization experiments ~1 μl of solution was deposited on a quartz probe.

RESULTS AND DISCUSSION

While the extraction procedure remains essentially unchanged (3), organizational efficiencies permitted each of four technicians to extract daily 11 samples plus the control. The sample data collection procedure was modified to increase the daily capacity to approximately twice the number of samples extracted. An isothermal column, a solids sample injector, and a retention time of the analyte of 0.6 min allowed sample injections at the rate of 12–15/hr. There was also a noticeable decrease in the background from the elimination of the solvent. Otherwise diverted by a dump valve, the helium carrier gas flowed into the source only during data acquisition to reduce column bleed. Instrument maintenance was also reduced by operating the ion source and multiplier only while collecting data.

Because the manual peak height measurement routine provided with the instrument was time consuming, a program was written to scan each data file, determine the baselines, the net peak heights for each acquired ion, and calculate the peak height ratios and concentrations. As elabo-

rated in the experimental section, multiple measurements of the control sample allows for the single-point calibration to increase the accuracy of the measurements. It is also essential to keep the ion source at a controlled temperature to achieve the most precise measurements. Changes in the control ratio value may result from contaminant deposits on the source and quadrupole rods. In the case of the low-concentration urine extracts, the repeller was frequently shorted out because of the extraneous materials present in the extract. When this occurred, a sudden loss in sensitivity and a drastic change in the value of the control ratio was noted. While not capable of the same limit of detection, the extraction procedure for the higher concentration urine is preferred.

The specificity of the measurements of captopril was independently validated using positive chemical ionization GLC–selected ion monitoring by measuring the MH^+ of the reference (II*b*) and analyte (I*b*) derivatives. A comparison with the electron-impact data of two subjects demonstrates good correlation between the two data sets (Table II) reconfirming the specificity of the electron-impact method and also qualifying the positive chemical ionization GLC–selected ion monitoring procedure as an alternate method.

A limited set of data compares the electron-impact GLC–selected ion monitoring data with results obtained by direct chemical ionization. Nanogram quantities of a sample deposited on the direct insertion probe produce readily measureable intensities (Fig. 1) that can be used in the quantitative measurement of captopril related compounds (Table III).

The limit of detection and sensitivity of the method using the isotopomer as the internal reference was established (18) (Table IV). Three sets of calibration extracts were each measured three times to provide a total of nine measurements per calibration point. The weighted regression was chosen because the ratio of the standard deviations (s) to respective mean varies over the concentration range. From 0 to 60 ng/ml, the coefficient of variation (CV) is 13%. The 3s value of the lowest calibration point puts the limit of detection at 13 ng/ml (99% confidence limit). The actual distribution of 108 zero-hour samples has two-thirds of the values at ≤6 ng/ml and 95% of the values at ≤14.5 ng/ml (Fig. 2), in good agreement with the value derived from the detection limit of the lowest nonzero calibration 3s value. The limit of detection and the sensitivity could have been enhanced if a low level calibration curve were employed using one-tenth the amount of internal reference. No significant benefit would have been derived for these bioavailability studies, however.

Table VI—Comparative Bioavailability Parameters of 100-mg Direct Compression Tablets and Solution Formulations of Captopril

Parameter	Direct Compression Tablet[a] Captopril	Solution[b] Captopril
C_{max}, μg/ml Mean[c]	0.90	0.82
(SEM)	(0.05)	(0.05)
T_{max}, hr Mean	0.74	0.84
(SEM)	(0.04)	(0.07)
$AUC_{0\rightarrow12}$, hr Mean	1.23	1.16
μg × hr/ml (*SEM*)	(0.05)	(0.04)

[a] Captopril (100 mg) as a direct compression tablet. [b] Captopril (100 mg) as a solution. [c] For 18 subjects.

The relative standard deviation (RSD)[15] of 53 pairs of duplicate extracts of 0.75-hr blood samples is 3.9%, which is in good agreement with the CV ≤5.5% calculated from the 125 to 1500 ng/ml calibration data.

Because of intra- and intersubject variation in the disposition of drugs, a significant number of subjects, usually ≥16, are required to demonstrate bioequivalence in a multiple crossover study. Using simultaneous administration with isotopomeric formulations (9–15), superior bioavailability data may be obtained with fewer subjects. A pilot two-way crossover study was performed to compare the bioavailability of a 100-mg direct compression tablet with a 100-mg solution of I, given orally, along with a coadministered solution of 100 mg of the isotopomer, II.

The mean bioavailability parameters determined for the tablet and oral solution given to four subjects in this study compare favorably (Table V) with data obtained from 18 subjects administered in the usual way (Table VI). No significant difference was found for the mean bioavailability data derived from the coadministration of captopril and isotopomer as solutions (Tables V and VII). Consequently, the relative bioavailability parameters, C_{m1}/C_{m2} and AUC_1/AUC_2[16] are approximately in unity. However, the relative bioavailability parameters, C_{m1}/C_{m2} and AUC_1/AUC_2, for the direct compression tablet and isotopomer solution are significantly different. Examination of the data (Table VIII) reveals the captopril blood levels of subject 1 were approximately three times

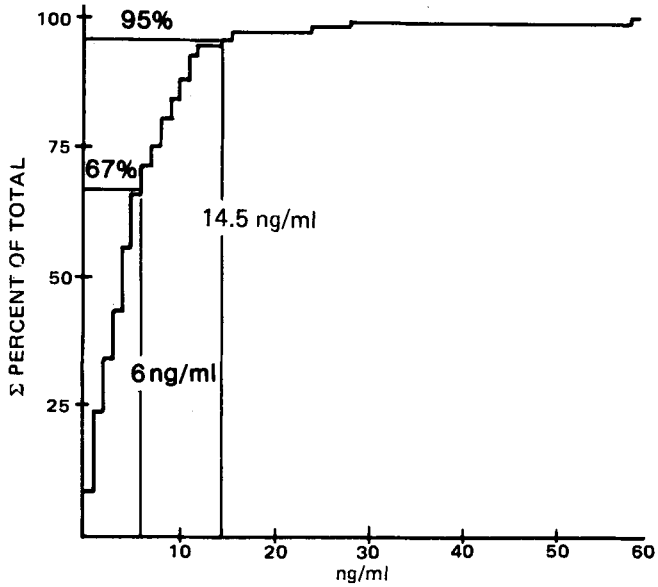

Figure 2—*Distribution of measured values of 108 zero-hour blood samples as a percent of total number of samples: maximum concentrations containing 67 and 95% of values are shown.*

[15] $RSD = (\Delta/M) \times 100$; $\Delta = (Ext_1 - Ext_2)$, $M = (Ext_1 + Ext_2)/2$.

greater than the isotopomer levels, as were the levels of compounds excreted in urine (Table IX). Significantly, this difference would have gone undetected in a conventional study. If the data for this subject are eliminated, the relative bioavailability parameters, while not in unity, are significantly lower. Previous bioavailability studies have also shown that a small difference in bioavailability parameters exists between direct compression tablet and solution formulations (Table VI).

The statistical evaluation of the coadministration bioavailability data was made to determine the power of the method to meet criteria for establishing differences in bioavailability. Excluding the suspect data of subject 1, data from only two of the three remaining subjects would be sufficient to establish differences in bioavailability that might require 14–40 subjects in a conventional study. However, from a practical point of view, it would seem more appropriate to expand such a study as this to ~6 subjects to provide a wider range of disposition, which would still result in a substantial savings in clinical and laboratory expense.

Pharmacokinetics of Procainamide in Rats with Extrahepatic Biliary Obstruction

PETER J. BASSECHES *x and G. JOHN DiGREGORIO

Received August 3, 1981, from the *Department of Pharmacology, Hahnemann Medical College, Philadelphia, PA 19102.* Accepted for publication January 19, 1982. *Present address: Division of Developmental Oncology Research, Department of Oncology, Mayo Clinic, Rochester, MN 55905.

Abstract □ The pharmacokinetics of the widely used antiarrhythmic agent, procainamide, was studied in rats with extrahepatic biliary obstruction produced by ligation of the common bile duct. Various biological fluids, including plasma, saliva, and urine, were analyzed for procainamide and/or its major metabolite, *N*-acetylprocainamide. Ligation of the common bile duct immediately prior to intravenous administration of 50 mg/kg procainamide did not alter plasma, saliva, or urine concentrations of procainamide, indicating that biliary excretion was of minor importance in the elimination of procainamide. However, bile duct ligation allowed to persist for 4 days significantly elevated plasma, saliva, and urine levels of procainamide. While the increase in urinary procainamide paralleled the increase observed in plasma, salivary concentrations did not. Bile duct ligation did not appear to impair nonmicrosomal acetylation of procainamide, although a significantly greater amount of unchanged drug was found in the urine after 24 hr. Pharmacokinetic analysis *via* the two-compartment open model showed that bile duct ligation caused a decrease in overall clearance from ~61.94 to 28.71 ml/kg/min. This reduction probably resulted from the decreased microsomal metabolism of procainamide. The significant reduction in the apparent volume of distribution from 3.76 to 2.72 liter/kg could be the result of reduced binding sites. There was also a significant increase in the elimination half-life of procainamide from 47.39 to 78.64 min in bile duct ligated rats.

Keyphrases □ Pharmacokinetics—procainamide, rats with extrahepatic biliary obstruction □ Procainamide—pharmacokinetics in rats with extrahepatic biliary obstruction □ Biliary obstruction—extrahepatic, pharmacokinetics of procainamide in rats

Biliary stasis in humans can be caused by tumors, drugs, or various pathophysiological alterations. Many patients with biliary stasis are also critically ill with other serious conditions and therefore are under treatment with a number of pharmacological agents. Inhibition of bile flow and/or biliary excretion may have profound consequences on the pharmacokinetics of drugs, not only because bile can be a route of irreversible elimination, but also because cholestasis may affect microsomal drug metabolism. Tavolini and Guarino (1) demonstrated altered disposition of doxorubicin[1], an antineoplastic agent eliminated extensively in the bile. Other investigators (2–5) demonstrated that microsomal metabolism of a number of drugs that are not extensively excreted in bile is significantly decreased, thus prolonging the elimination half-life ($t_{1/2\beta}$). However, the effects of biliary stasis on the pharmacokinetics of drugs with minimal biliary excretion and minimal microsomal metabolism are unclear. The antiarrhythmic agent procainamide (I) is such a drug. It was the purpose of this investigation to study the effects of cholestasis, induced by mechanical obstruction of the common bile duct, on the pharmacokinetics of I. Salivary levels were measured as an index of drug distribution to the peripheral tissue compartment, and urine levels were assayed to obtain an estimate of the renal clearance of procainamide and the relative urinary metabolic profile.

[1] Adriamycin.

EXPERIMENTAL

Urine, saliva, and plasma were obtained from a group of normal Wistar rats (weight 190–260 g) for the quantitation of I. Rats were anesthetized with 50 mg/kg ip pentobarbital[2]. Initially, a tracheotomy was performed to facilitate breathing, and then the animals were prepared for collection of parotid saliva according to a previously described method (6). Stimulation of salivation was accomplished by infusing pilocarpine[3] (0.25 mg/ml) into the right brachial artery at a rate of 0.11 ml/min for 90 min. For the administration of I[4] (50 mg/kg), the femoral vein was cannulated. Urine was collected *via* cannulation of the ureters. Urine and saliva were collected over three 30-min collection periods, and 1.5 ml of whole blood was collected at 30, 60, and 90 min postinjection from a cannula placed in the femoral artery. From a separate group of normal rats, plasma was obtained at 30, 60, and 90 min following administration of 50 or 100 mg/kg of I for the quantitation of the acetylated metabolite, *N*-acetylprocainamide (II).

In anticipation of the fact that saliva was to be collected simultaneously with the other biological fluids, preliminary studies were performed to determine the effects of pilocarpine infusion of plasma procainamide concentration and urinary procainamide excretion. Ten control (no pilocarpine) and 10 test rats were used for plasma collection, and another group of five controls and five test animals were used for urine collection.

Extrahepatic biliary obstruction was produced in another group of

animals by double ligation of the common bile duct following anesthesia with 100 mg/kg of 98% ketamine[5]–2% acepromazine[6] ip. The animals were then sutured and allowed to recover for 4 days. On the fourth day, bile duct ligated animals were prepared for the simultaneous collection of saliva, urine, and plasma after administration of 50 mg/kg iv of I as described above, and the samples were quantitated for I. Plasma samples were also quantitated for II. Animals that did not exhibit jaundice, as evidenced by yellowish skin and bright yellow urine, were not used. Sham operated animals (with laparotomies) were also prepared in a manner identical to actual bile duct ligated animals. A group of six animals were utilized for I determinations immediately after bile duct ligation (Day 0).

To determine the effects of bile duct ligation on the metabolic disposition of I, control rats were injected with 50 mg/kg ip and placed in metabolic cages[7] for 24-hr urine collection. During this period the animals were allowed no food but were given water *ad libitum*. After the 24-hr period of urine collection, a period of 3 days was allowed to elapse to permit the animals to regain a normal metabolic profile. The animals were then anesthetized and the bile ducts were ligated. After 4 days these animals were again administered 50 mg/kg ip of I and placed in metabolic cages for 24-hr urine collection.

Six control and six bile duct ligated animals were prepared for pharmacokinetic studies by performing tracheotomies and cannulating the femoral vein and artery. After administration of 50 mg/kg iv of I, 0.4–0.5 ml of blood was sampled at 5, 15, 30, 45, 60, 90, and 120 min for analysis of the plasma I kinetics. To prevent major perturbation of drug levels, a separate group of six control and six bile duct ligated animals were used to obtain 1- and 5-min levels. The 1-min levels were then included with the values for the other animals for mathematical analysis on the basis of how closely matched the 5-min values were. The two-compartment open pharmacokinetic model was used to describe the kinetics of I, utilizing the biexponential function:

$$C_t = Ae^{-\alpha t} + Be^{-\beta t} \qquad \text{(Eq. 1)}$$

where C_t is the plasma concentration at time t, A and B are the zero-time intercepts of the fast and slow linear components, respectively, and α and β are the distribution and elimination rate constants, respectively. The pharmacokinetic parameters, A, B, α, and β, were calculated by linear regression of the two linear components of the plasma disappearance curve. Distribution half-life ($t_{1/2\alpha}$), elimination half-life ($t_{1/2\beta}$), volume of distribution (V_d), and clearance (Cl) were calculated by conventional techniques (7).

Analysis of I in all fluid samples and II in urine involved organic extraction of samples into 10 ml of methylene chloride and quantitation *via* a gas chromatograph[8] using dipropylprocainamide[4] as an internal standard as previously described (8). For reasons of sensitivity, plasma of II was quantitated *via* an enzyme–immunoassay method[9]. All statistical determinations of significance were done using the Student's t test. In all cases, except the 24-hr urinary disposition studies (Table I), the unpaired t test was used; in the case of the latter, the paired t test was employed.

RESULTS

Preliminary studies on the effect of pilocarpine infusion indicated that infusion of 0.25 mg/ml pilocarpine at a rate of 0.11 ml/min for 90 min had no effect on the plasma I concentration at any time period studied; however, urinary excretion did show significant decreases during the second and third 30-min collection periods (Table II).

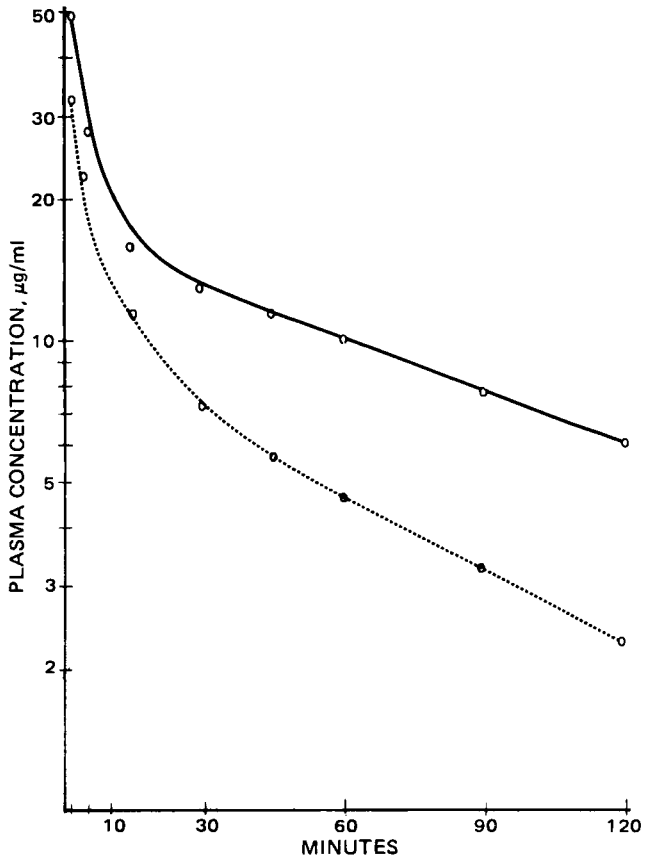

Figure 1—*Plasma disappearance of procainamide.*

The results of GC analysis of plasma, saliva, and urine samples from normal animals receiving a dose of 50 mg/kg iv of I are shown in Table III. The mean I levels in the three biological fluids of sham-operated rats were not significantly different from those of the normal rats at any time period studied. Similarly, in rats whose bile ducts were ligated immediately prior to administration of I (day 0), there were no significant differences in I levels of any of the biological fluids at any time period compared to normal rats. However, when bile duct ligation was allowed to persist for 4 days, significantly higher plasma, saliva, and urine levels were observed at all time periods. Plasma I concentrations increased 100, 125, and 105% at 30, 60, and 90 min, respectively. The increase in urinary excretion paralleled the increase in plasma levels with increases of 94, 125, and 133% over the three respective 30-min collections, indicating that renal excretion is not impaired by bile duct ligation. Salivary I concentrations also increased, but the increases did not parallel those observed in plasma except during the last collection periods. The salivary levels increased ~47, 77, and 125% over the three respective time periods (Table III).

Figure 1 illustrates the disappearance of I from plasma with time for normal animals and animals with 4-day bile duct ligation. The mean pharmacokinetic parameters for both groups are shown in Table IV. Distribution half-life ($t_{1/2\alpha}$) in 4-day bile duct ligated rats is not significantly different compared to normal rats. Elimination half-life ($t_{1/2\beta}$), however, is significantly prolonged ($p < 0.025$). Volume of distribution (V_d) is significantly decreased in 4-day bile duct ligated rats compared to normals ($p < 0.05$). Clearance (Cl) is also decreased by 115% ($p < 0.025$).

To determine whether the observed pharmacokinetic alterations were the result of bile duct ligation-induced metabolic changes, the urinary disposition of I was examined. Table I shows that in the 4-day bile duct ligated rats, the percentage of the drug excreted as II did not change significantly compared to controls. However, the amount of drug excreted unchanged increased significantly ($p < 0.025$). The absence of a change in the production of II during 4-day bile duct ligation was confirmed by measurement of plasma II concentrations in normal and 4-day bile duct ligated rats. In normal rats mean plasma II concentrations at 30, 60, and 90 min were 4.48 ± 0.48, 5.43 ± 0.59, and 7.72 ± 4.77 μg/ml, respectively. In 4-day bile duct ligated rats, mean plasma II concentrations at the same time periods were 4.54 ± 0.36, 7.06 ± 0.72, and 8.96 ± 0.06 μg/ml, respectively.

Table II—Effects of Pilocarpine Infusion on Plasma Procainamide Concentration and Urinary Excretion

	n	30 min		60 min		90 min	
		C[a]	P[b]	C	P	C	P
Plasma procainamide[c]	10	7.49 ± 0.60	8.65 ± 0.73	4.44 ± 0.43	4.53 ± 0.68	3.24 ± 0.28	2.95 ± 0.46
Urinary procainamide[d]	5	0.76 ± 0.17	0.65 ± 0.26	0.50 ± 0.07	0.30 ± 0.10	0.33 ± 0.06	0.20 ± 0.04

[a] C = control (no pilocarpine). [b] P = pilocarpine (0.25 mg/ml) infused at a rate of 0.11 ml/min; the dose was 50 mg/kg iv procainamide. [c] Data expressed as micrograms per milliliter (± *SE*). [d] Data expressed as milligrams (± *SE*).

Table III—Mean Procainamide Concentrations in Various Biological Fluids[a]

Condition	n	Plasma[b]			Saliva[b]			Urine[c]		
		30 min	60 min	90 min	30 min	60 min	90 min	30 min	60 min	90 min
Normal rats	8–10	8.65 ± 0.73	4.53 ± 0.68	2.95 ± 0.46	16.73 ± 1.69	7.75 ± 1.32	2.82 ± 0.35	0.65 ± 0.26	0.30 ± 0.10	0.20 ± 0.04
Sham-operated rats	5	8.58 ± 0.59	5.42 ± 0.69	3.20 ± 0.33	16.62 ± 1.17	8.00 ± 1.15	3.5 ± 0.41	0.61 ± 0.11	0.33 ± 0.08	0.22 ± 0.06
Day 0 bile duct ligation	6	9.40 ± 0.69	5.43 ± 0.96	4.23 ± 0.85	17.48 ± 1.84	7.56 ± 1.46	3.55 ± 0.60	0.51 ± 0.08	0.31 ± 0.03	0.21 ± 0.05
4-Day bile duct ligation	5–8	17.32 ± 2.15	10.20 ± 2.13	6.06 ± 1.06	24.55 ± 2.23	13.71 ± 1.98	5.68 ± 0.92	1.26 ± 0.19	0.70 ± 0.11	0.46 ± 0.10

[a] Dose of procainamide = 50 mg/kg iv; 0.25 mg/ml pilocarpine infused at a rate of 0.11 ml/min. [b] Data expressed as micrograms per milliliter (± *SE*). [c] Data expressed as milligrams (± *SE*).

It was thought that the higher plasma I levels observed in bile duct ligated animals should result in higher plasma II levels, since more I was apparently available to the liver for acetylation. Since no increase was noted, it was theorized that either bile duct ligation was inhibiting acetylation due to liver damage or that the enzyme responsible for conversion of I to II, *N*-acetyltransferase, was being saturated. To test these alternative hypotheses, a 100-mg/kg dose of I was administered to control animals to achieve blood levels comparable to those in bile duct ligated animals receiving 50 mg/kg. Plasma I concentrations in normal rats receiving 100 mg/kg iv at 30, 60, and 90 min were 18.22 ± 2.45, 10.93 ± 1.69, and 6.48 ± 1.25 μg/ml, respectively, while plasma II concentrations in those animals were 5.28 ± 0.47, 6.90 ± 0.66, and 7.53 ± 0.75 μg/ml at the three respective time periods. These data show that while plasma I levels in these animals did approximate those seen in bile duct ligated animals receiving half the dose, plasma II levels did not differ from either control or bile duct ligated animals receiving half the dose, suggesting that a saturation of the acetylation process was occurring even at the 50-mg/kg dose.

DISCUSSION

It has been demonstrated (9) that the transport of I into bile is an active process, since the biliary excretion exhibited a concentrative mechanism that was saturable and could be competitively inhibited by other tertiary and quaternary amines. However, since ligation of the bile duct immediately prior to intravenous administration of I did not significantly elevate plasma, saliva, or urine levels of the drug at any time period studied, it is apparent that biliary excretion of I is a minor component in its overall elimination (Table III). This is in agreement with previous findings (10), which state that renal excretion is the major route of elimination for this drug. Furthermore, simply shutting off the biliary route of excretion cannot be invoked as the primary explanation for pharmacokinetic alterations observed in 4-day bile duct ligation in the case of I. However, the small amount of I that normally appears in bile, which according to a previous report (11) amounts to 3–5% of the administrated dose, would be reabsorbed and contribute to elevated plasma levels.

The most logical hypothesis concerning the underlying mechanism for the altered kinetics would be that the metabolism of I was being inhibited due to liver damage resulting from the reflux of bile acids in a manner similar to that proposed for a number of drugs by various investigators (2–5) (*i.e.*, destruction or decreased synthesis of cytochrome P_{450}).

Table IV—Mean Pharmacokinetic Parameters of Procainamide in Normal and 4-Day Bile Duct Ligated Rats[a]

Parameters	Control	Bile Duct Ligated
$t_{1/2\alpha}$, min ± *SE*	4.87 ± 1.06	2.95 ± 0.90
$t_{1/2\beta}$, min ± *SE*[b]	47.39 ± 3.81	78.64 ± 13.13
V_d, liter/kg ± *SE*[c]	3.72 ± 0.47	2.76 ± 0.21
Cl, ml/kg/min ± *SE*[b]	61.94 ± 13.68	28.71 ± 3.80

[a] Dose of procainamide was 50 mg/kg iv; $n = 6$ rats. [b] $p < 0.025$. [c] $p < 0.05$.

However, the 24-hr urinary II levels as well as plasma II levels indicate that there is no difference in the amount of II produced by 4-day bile duct ligated rats compared to normal rats. Since II, the major metabolite of I, is a product of a nonmicrosomal metabolism (*i.e.*, not dependent on the mixed-function oxidase system), it appears that nonmicrosomal acetylation of I is relatively resistant to inhibition by ligation of the common bile duct. Furthermore, the studies with 100 mg/kg I in normal rats indicate that the acetylation enzyme, *N*-acetyltransferase, is saturable at the 50-mg/kg dose level of I, and thus, the activity of the enzyme in normal and 4-day bile duct ligated animals is apparently the same. These results also indicate that decreased production of II is not the primary mechanism responsible for the elevation of I concentrations in the various biological fluids.

However, inhibition of microsomal metabolism may play a contributing role in the altered kinetics of I, since a small percentage of the drug undergoes some microsomal metabolism. Recently, two other metabolites of I were found (12): desethylprocainamide and *N*-acetyldesethylprocainamide; the former being the primary intermediate in the formation of the latter. Since bile duct ligation has been shown to inhibit microsomal metabolism and the data in this study show significantly greater amounts of unchanged drug excreted (Table I), it is probable that these metabolites are not produced to the normal extent, thereby contributing to higher plasma levels of the parent compound. This may explain the prolonged $t_{1/2\beta}$ calculated in this study.

Since elimination by the biliary route of excretion or decreased acetylation apparently are not the major mechanisms underlying the bile duct ligation-induced alteration in the pharmacokinetics of I, other mechanisms must be operative. Calculation of various pharmacokinetic parameters (Table IV) revealed that there is a significant reduction in V_d of I in 4-day bile duct ligated rats. The reduction in V_d suggests that the drug is not leaving the central compartment as readily as in normal rats, thus contributing to higher than normal plasma concentrations. The fact that there was no significant difference in the calculated $t_{1/2\alpha}$ indicates that the rate of distribution is not affected by 4-day bile duct ligation, only the extent of the distribution is. The idea that bile duct ligation can induce a change in drug distribution has also been advanced in a previous report (2) where it was postulated that increased thiopental sleeping times may be due to this phenomenon. The decreased distribution to the peripheral compartment observed in this study is borne out by the salivary excretion data which showed that while there was an increase in saliva I concentration, it was not of the same magnitude as the increase in plasma except at the 90-min mark. One possible explanation for the decreased V_d may involve elevated bilirubin levels, which result from bile duct ligation (13). High levels of bilirubin have been associated with displacement of drugs from plasma proteins. Since plasma protein binding of I is negligible (10–15%) but tissue protein binding is extensive, it is possible that hyperbilirubinemia caused a significant reduction in tissue binding. Such an idea has been suggested previously (14). A significant decrease in tissue binding of a drug, which is normally bound to tissues extensively, would cause a decrease in the V_d of the drug.

Thus, although biliary excretion of I is of minor importance as a route of elimination, this study demonstrates that extrahepatic biliary obstruction induced by bile duct ligation can still lead to a significant al-

teration in the pharmacokinetics of I through a combination of effects including decreased microsomal metabolism and decreased volume of distribution. Furthermore, this study shows that nonmicrosomal hepatic metabolism, such as acetylation, is relatively resistant to pathological insults such as bile duct ligation.

Bioavailability of Tolazamide from Tablets: Comparison of *In Vitro* and *In Vivo* Results

P. G. WELLING *x, R. B. PATEL *, U. R. PATEL *, W. R. GILLESPIE ¶, W. A. CRAIG ‡§, and K. S. ALBERT ¶

Received September 24, 1981, from the *Schools of *Pharmacy and ‡Medicine, University of Wisconsin, Madison, WI 53706,* the *§Veterans Administration Hospital, Madison, WI 53705,* and *¶The Upjohn Co., Kalamazoo, MI 49001.* Accepted for publication January 26, 1982.

Abstract □ The relative bioavailability of tolazamide was determined, in healthy male volunteers, from four different tablet formulations manufactured by direct compaction or granulation processes and the results were compared with *in vitro* disintegration and dissolution values. Serum tolazamide levels were determined by a high-pressure liquid chromatographic method developed in this laboratory. Serum tolazamide levels from the formulation that gave rise to rapid absorption were described by one-compartment model kinetics with a mean absorption half-time of 1.0 hr and an elimination half-life of 4.6 hr. Peak serum levels occurred at 3.3 hr after drug administration. Marked differences were observed in drug bioavailability from the four tablets, and the mean cumulative relative fraction of dose absorbed was 1.0, 0.42, 0.75, and 0.91 from Formulations A, B, C, and D, respectively. The hypoglycemic effect was closely related to serum tolazamide levels. Disintegration times did not predict *in vivo* tolazamide bioavailability. Dissolution rates provided an approximate rank order correlation with *in vivo* absorption but failed to be predictive among formulations. Currently available *in vitro* tests do not accurately predict tolazamide *in vivo* bioavailability characteristics among different formulations and manufacturing processes but may be useful to ensure lot-to-lot uniformity in bioavailability for a given formulation and specific method of manufacture.

Keyphrases □ Bioavailability—tolazamide from tablets, comparison of *in vitro* and *in vivo* results, humans □ Tolazamide—bioavailability from tablets, comparison of *in vitro* and *in vivo* results, humans □ High-pressure liquid chromatography—determination of tolazamide bioavailability from tablets, comparison of *in vitro* and *in vivo* results, humans

The hypoglycemic effect of oral sulfonylureas is related to the size of the dose and to the bioavailability of administered drug to the systemic circulation (1, 2). Large differences in circulating levels of chlorpropamide (3, 4) and tolbutamide (5) have been reported from different generic brands, and the *in vivo* bioavailability of tolbutamide did not correlate well with *in vitro* dissolution rates (6).

Although the sulfonylurea tolazamide has been used clinically since 1965, there appears to be little or no information on its pharmacokinetic or bioavailability characteristics. Therefore, this study was designed to investigate the pharmacokinetics of tolazamide after administration of oral tablets to healthy volunteers and to compare relative *in vivo* bioavailability of different tablets with their *in vitro* disintegration and dissolution rates.

EXPERIMENTAL

Tolazamide Formulations—The four tolazamide tablet formulations selected for study were:

A: Tolazamide 250-mg tablets, marketed Formulation[1]

B: Tolazamide 250-mg tablets, experimental Formulation 1[2]

C: Tolazamide 250-mg tablets, experimental Formulation 2[3]

D: Tolazamide 250-mg tablets, experimental Formulation 3[4]

Formulation A was the commercial brand of tolazamide. Formulations B, C, and D were experimental tablets containing similar excipients as Formulation A but in different quantities to produce different *in vitro* dissolution characteristics. Tablets A and D were wet granulation formulations; B and C were direct compression formulations.

***In Vitro* Studies**—Disintegration times were determined by the official USP XX method for uncoated tablets (7).

Tablet dissolution rates were determined by a rotating paddle procedure. The apparatus[5] consisted of a 1000-ml flask containing 900 ml of 0.05 *M tris*(hydroxymethyl)aminomethane aqueous buffer (pH 7.6) and a paddle stirring rate of 75 rpm. Drug dissolution was monitored by continuously pumping the dissolution medium through a 0.5-mm pathlength flow cell[6] and measuring UV absorbance at 224 nm.

***In Vivo* Studies**—*Subjects*—Subjects[7] were 20 healthy male volun-

Table I—Disintegration Times and Dissolution Rates of Tolazamide Tablets[a]

Tablet	Mean Disintegration Time[b], min (range)	Percent Dissolved in 30 min[c] (range)
A	3.8 (3.0–4.0)	103.9 (100.5–106.3)
B	2.2 (1.8–2.5)	10.9 (9.3–13.5)
C	2.3 (2.0–2.5)	31.6 (26.4–37.2)
D	26.5 (22.5–30.5)	29.7 (20.8–38.4)

[a] n = 6. [b] By the method of USP XX (Ref. 7). [c] Dissolution rates in pH 7.6 buffer.

teers between 18 and 38 years of age (mean 26) and weighing between 61.4 and 95.5 kg (mean 74.5). Two subjects were classified as heavy frame, 14 as medium, and four as small (8). Sixteen subjects were nonsmokers, and four were moderate smokers.

Before participation in the study, subjects were shown to be healthy by physical examination, including complete blood and urine biochemistry. All values were within the normal range.

Any individual with peptic ulcer, psychosis, who had ever had a myocardial infarction, or who had a history of drug allergy or diabetes was automatically excluded. Subjects were instructed to take no enzyme-inducing agents for 1 month prior to and no drugs other than the required doses of tolazamide during the study.

Subjects were advised to ingest an adequate diet of ~2500 cal/day, high in carbohydrate (minimum 300 g) for 3 days before each dose of tolazamide.

Protocol—The 20 subjects were randomly assigned to four groups of five each, and the four treatments were administered according to a 4 × 4 Latin square design. Each subject received the four treatments at 1-week intervals.

At 10 pm on the day before a tolazamide dose, subjects received a snack of two cupcakes and 240 ml (8 oz) of whole milk. Following an overnight fast, subjects reported to the clinic at 6:45 am. At 7 am 500 mg of tolazamide was administered with 180 ml of water. No food or further water were permitted until 5 hr postdose when a standard meal, consisting of one cheese sandwich, one packet of potato chips, and a small carton of milk, was provided. Food and liquid intake was unrestricted after that time.

Blood samples (10 ml) were taken from a forearm vein into evacuated glass tubes[8] (containing no anticoagulant) immediately before and then at 1, 2, 3, 4, 5, 6, 8, 12, 16, and 24 hr following tolazamide administration. Blood was allowed to clot and serum was separated by centrifugation. Serum was divided into two portions. One portion was assayed for glucose by utilizing the potassium ferricyanide–ferrocyanide oxidation reduction reaction[9] (9). The other portion was assayed for tolazamide by the high-pressure liquid chromatographic (HPLC) method described below. All samples were stored at −20° until assayed. Assays were done within 4 weeks of sampling. Assay of selected serum samples immediately after sampling and during storage showed that both tolazamide and glucose were stable at −20° for 4 weeks.

Side Effects—Subjects were monitored for drug-related side effects following each dose of tolazamide. Subjects were requested to classify each side effect as mild, moderate, or severe. Classification was subjective and no attempt was made to assess any effect quantitatively.

Assay for Tolazamide in Serum—Concentrations of tolazamide in serum were determined by an HPLC procedure developed in this laboratory. To 0.5 ml of serum was added 0.5 ml of internal standard, 5-(*p*-methylphenyl)-5-phenylhydantoin[10] in chloroform[11], 0.5 ml of aqueous sodium acetate buffer (pH 4.5), and 5 ml of methylene chloride[11]. After shaking for 5 min on a horizontal shaker and centrifuging at 3000×*g* for 3 min, the aqueous layer was discarded and the organic layer was transferred to a clean tube and evaporated to dryness under nitrogen at room temperature. The residue was reconstituted in 80 μl of methanol by vortexing, and 20 μl was injected onto the chromatograph.

The HPLC system consisted of a solvent pump[12], a fixed-volume (20 μl) sample injection valve[13], a 10-μm particle size reversed-phase octadecyl column[14] (25 cm × 4.6 mm), and a 254-nm fixed wavelength detector[15]. All chromatograms were recorded at a chart speed of 20 cm/hr.

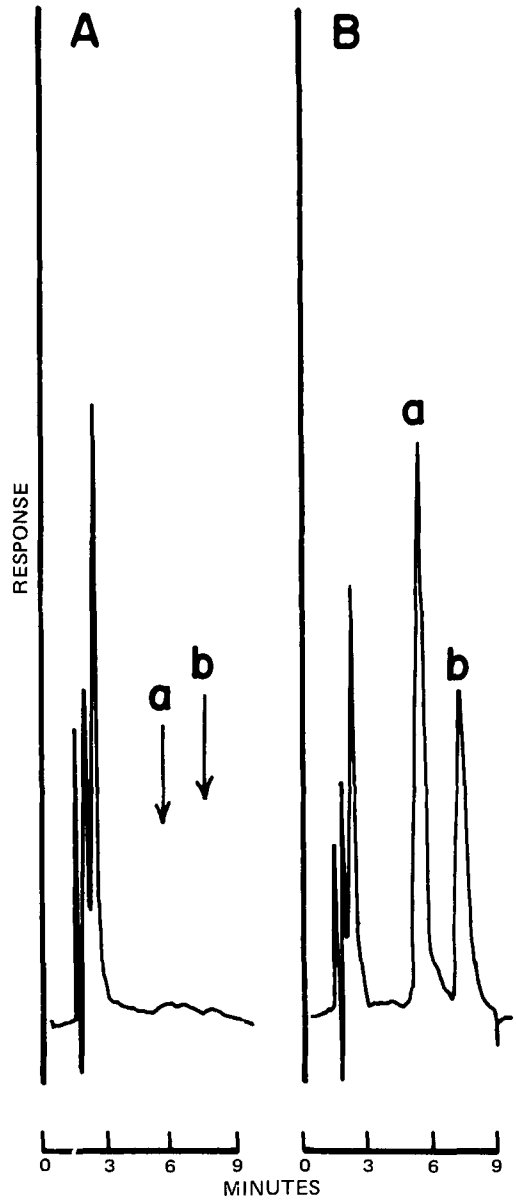

Figure 1—*Chromatograms obtained from HPLC analysis of serum containing (A) no added compounds and (B) 25 μg/ml tolazamide (a) and internal standard (b).*

The mobile phase was 52.3% methanol in pH 5.6 acetate buffer. The flow rate was 2 ml/min at a pump pressure of ~1000 psi. Concentrations of tolazamide were determined by the method of peak height ratios. Tolazamide[16] for assay standardization was reference standard quality.

Analysis of the Data—Individual serum tolazamide profiles from Formulation A were analyzed according to a single-compartment kinetic model with first-order drug appearance and elimination and an absorption lag time (10). Nonlinear regression analysis of the data was done using the program NONLIN (11) on a digital computer[17].

Estimates of the cumulative relative fraction of drug absorbed (*CRFA*) during 16 hr following each tolazamide dose were calculated by means of Eq. 1, which was derived from a previously described method for generating percent absorbed *versus* time plots (12):

$$CRFA = \frac{C_t + k_{el}^A (AUC)_{0-t}}{k_{el}^A (AUC)_{0-\infty}^A} \qquad \text{(Eq. 1)}$$

[a] Concentrations ±1 *SD*, $n = 20$. [b] For explanation see text. [c] Maximum concentration of tolazamide in serum. [d] Time of maximum concentration. [e] Area under the 0–24-hr serum tolazamide concentration curve calculated by trapezoidal rule.

where

$$(AUC)^A_{0-\infty} = (AUC)^A_{0-T} + \frac{C_T}{k^A_{el}},$$

C_t is the concentration of tolazamide in serum at time t, $(AUC)_{0-t}$ is the area under the tolazamide concentration *versus* time curve to time t calculated by trapezoidal rule, and C_T is the tolazamide concentration in serum at the last sampling time T. The values $k_{el}{}^A$, $(AUC)_{0-T}{}^A$, and $(AUC)_{0-\infty}{}^A$ are the first-order rate constants for loss of tolazamide from serum, the area under the tolazamide concentration curve to time T, and the area to infinite time, respectively, following Formulation A. This method permits the cumulative absorption of drug from each treatment to be calculated in individual subjects, relative to that from Formulation A.

Serum tolazamide and glucose levels from the four treatments were examined by analysis of variance for crossover design. When significant treatment effects were obtained, differences between individual products were examined by Tukey's significant difference test (13). In the statistics columns of Tables II and IV, the various values obtained from the different treatments are given in descending order of magnitude. All values under a common bar are statistically indistinguishable ($p > 0.05$); whereas, all values not under a common bar are statistically different ($p \leq 0.05$).

RESULTS

***In Vitro* Studies**—The disintegration times and dissolution rates of the four tablets are shown in Table I. While Formulations A, B, and C disintegrated within 4 min, Formulation D disintegrated more slowly with a mean time of 26.5 min. In the dissolution system used, Formulation A dissolved completely within 30 min. Formulations C and D exhibited similar dissolution characteristics to each other, with both tablets dissolving ~30%. Formulation B dissolved slowly, releasing only 10.9% of the drug during the 30-min period.

t_0[f], hr	0.75 ± 0.49
FD/V[g], μg/ml	43 ± 14
r^{2h}	0.99 ± 0.02

[a] Values ±1 *SD*, $n = 20$. [b] First-order rate constant for absorption of tolazamide in serum. [c] Absorption half-life (ln $2/k_a$). [d] First-order rate constant for loss of tolazamide from serum. [e] Elimination half-life (ln $2/k_{el}$). [f] Lag time between dosing and appearance of drug in serum. [g] Fraction of dose absorbed expressed as a concentration in the body distribution volume. [h] Coefficient of determination from nonlinear regression analysis [$r^2 = (\Sigma obs^2 - \Sigma dev^2)/\Sigma obs^2$].

Assay for Tolazamide in Serum—Typical chromatograms from serum containing both tolazamide and internal standard and from serum containing neither compound are shown in Fig. 1. Retention times for tolazamide and internal standard were 5.5 and 7.5 min, respectively. The procedure was highly specific and reproducible. Chromatographic response was linear for serum tolazamide concentrations between 1 and 100 μg/ml, and assay reproducibility from multiple replicates ($n \simeq 20$) done throughout the analytical procedures was within ±3% *SD* at the highest concentration and within ±12% at the lowest.

Drug-Related Side Effects—Side effects were noted following 41 of the 80 tolazamide doses. In each case the effect was judged by the subject as mild. On no occasion was supplementary medication or glucose considered to be necessary by the attending physician.

Side-effects were noted primarily 1–4 hr postdose and were generally typical manifestations of transient, mild hypoglycemia. In all there were 21 reports of lightheadedness or dizziness, 14 of excess perspiration, 12 of headache, 12 of tremor, 7 of weakness, 2 of dry mouth, 2 of drowsiness, 1 of constipation, and 1 of blurred vision.

The number of subjects reporting side effects was independent of the

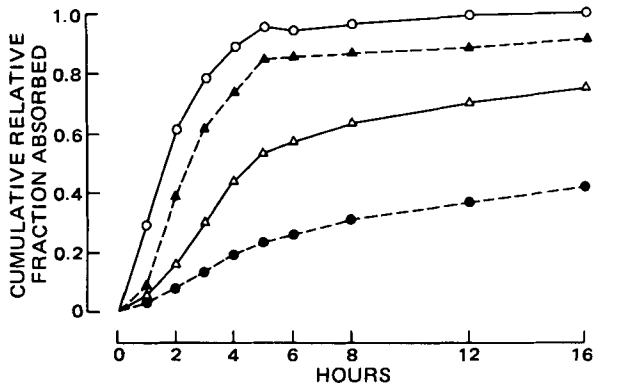

Figure 3—*Mean cumulative relative fractions of tolazamide absorbed as a function of time. Key: (○) Treatment A; (●) Treatment B; (△) Treatment C; (▲) Treatment D.*

Table IV—Parameter Values[a] for Glucose Response Following Four Tolazamide Treatments

Value	Treatment A	Treatment B	Treatment C	Treatment D	Statistic
G_{min}[b], mg/dl	54.6 ± 8.5	70.1 ± 6.2	66.0 ± 5.0	59.2 ± 6.5	B C D A
T_{min}[c], hr	1.7 ± 0.9	2.8 ± 1.0	2.6 ± 1.3	2.3 ± 1.1	B C D A
G_{dec}[d], mg/dl	41.2 ± 12.5	22.1 ± 10.2	29.2 ± 8.1	34.8 ± 6.8	A D C B
AUC_{0-5}, mg hr/dl	136 ± 41	71 ± 42	99 ± 32	116 ± 24	A D C B

[a] Values ±1 *SD*, $n = 20$. [b] Minimum serum glucose level. [c] Time of minimum serum glucose level. [d] Maximum decrease in serum glucose level. [e] Area under serum glucose reduction curve during 5 hr following tolazamide administration calculated by trapezoidal rule.

study phase but was dependent on treatment. Seventeen individuals reported side effects following Treatment A compared to 13 following Treatment D, 7 following Treatment C, and 4 following Treatment B.

Serum Tolazamide Levels—The mean concentrations of tolazamide in serum at each sampling time, maximum values, times of maximum values, and areas under serum tolazamide concentration curves from 0 to 24 hr, are shown in Table II. The mean data are summarized in Fig. 2.

Formulations A and D yielded serum drug profiles that were statistically indistinguishable ($p > 0.05$) at all times except 1 and 2 hr. Both treatments yielded mean peak drug levels >20 μg/ml at 3–4 hr. At 24 hr, drug levels had decreased to ~2.5 μg/ml. Serum tolazamide levels from Formulation C were lower than from A and D, the difference being significant ($p < 0.05$) at most sampling times. Formulation B yielded lower serum drug profiles than all other treatments, and the mean peak drug level of 7.7 μg/ml was not achieved from this tablet until 7 hr after drug administration.

The value of C_{max} increased in the treatment order B < C < D < A, and differences between all treatments were significant. The values of T_{max} and AUC_{0-24} were similar for Formulations A and D but were significantly different among all other pairs of treatments.

Pharmacokinetic Analysis—Analysis of individual data from Treatment A in terms of the pharmacokinetic one-compartment model yielded the values in Table III. From this product serum tolazamide levels are characterized by a mean lag time of 45 min, an absorption half-time of 1 hr, and an elimination half-life of 4.6 hr. The high coefficient of determination attests to the accuracy of the kinetic model employed. Pharmacokinetic analysis of data resulting from the other treatments is not presented, since delayed or prolonged tolazamide absorption prevented accurate determination of drug elimination parameters in some individuals receiving these products.

Estimates of *CRFA* values for each sampling time to 16 hr postdose from all four treatments are summarized in Fig. 3. The values confirm that tolazamide was absorbed at a similar rate and with similar overall efficiency from Formulations A and D. Absorption from the other two tablets was slower and less efficient, with Formulations B and C yielding *CRFA* values 42 and 75%, respectively, of Formulation A.

Serum Glucose Levels—The mean serum glucose levels during the initial 5-hr period following the four treatments are shown in Fig. 4.

The effects by the treatment on glucose levels are related to circulating drug levels. Formulations A and D caused rapid and marked reductions in serum glucose. Minimum values were observed at 1–2 hr. The reduction following Formulation C was less than from A and D and occurred at a slower rate. Formulation B had the least effect on serum glucose, and minimum levels were not achieved until 3 hr postdose.

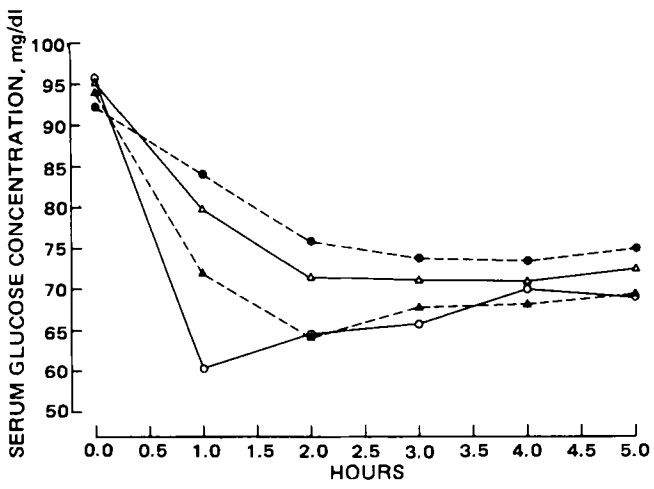

Figure 4—*Mean serum glucose concentrations as a function of time. Key: (○) Treatment A; (●) Treatment B; (△) Treatment C; (▲) Treatment D.*

Comparison of glucose levels at each sampling time indicates differences in glucose response between Treatments A and B and between B and D. Significant differences between Treatments A and C were observed at two sampling times and between Treatments C and D at one sampling time.

Some parameters defining the overall decrease in serum glucose are summarized in Table IV. The differences in minimum glucose levels and the maximum reduction in glucose levels were significant between all treatments. The area under the glucose response curve during the initial 5 hr following tolazamide administration was similar from Treatments A and D and from Treatments D and C but was different among all other treatment pairs. While a similar trend was observed in the 0–24-hr area, differences between treatments did not reach the 95% confidence level.

DISCUSSION

Increasing interest in the use of *in vitro* disintegration and dissolution testing procedures is reflected in the proliferation of such tests in national compendia (7). The use of such tests to determine drug product bioavailability or bioequivalence has been emphasized by the U.S. Food and Drug Administration (14).

The data obtained in this study have shown that different formulations of tolazamide may give rise to marked variations in drug bioavailability and in hypoglycemic response. The ability of *in vitro* tests to predict product-related *in vivo* bioavailability changes is less clear. The official disintegration test (7) yielded similar disintegration times for Formulations A, B, and C but a more prolonged time for D. These results are at variance with the relative *in vivo* bioavailability of the four products. The dissolution test yielded rapid dissolution for Formulation A, slow dissolution for B, and intermediate values for C and D, which were indistinguishable from each other. Although this test provided a reasonable rank-order correlation with *in vivo* bioavailability, there were some important discrepancies.

Formulations C and D yielded almost identical dissolution rates to each other, which were significantly slower than A, yet Formulation D yielded serum tolazamide levels similar to those from A, and significantly higher than those from C. Thus, while the dissolution test suggests that Formulations C and D are bioequivalent to each other and that both are bioinequivalent to A, the *in vivo* results show that Formulations A and D are bioequivalent, while C is not. The two formulations giving rise to superior *in vivo* bioavailability, A and D, were prepared by wet granulation; whereas Tablets B and C were prepared by direct compression. The absolute bioavailability of tolazamide could not be determined from any treatment in this study.

Although serum glucose reduction and resulting drug-related side effects (transient, mild hypoglycemia) were less well defined between treatments than drug levels, a similar product-related trend was observed. This was particularly evident at early sampling times before food was ingested.

These results indicate that bioavailability of tolazamide from oral tablets is dissolution-rate controlled, but *in vitro* methods currently available do not predict *in vivo* drug absorption and hypoglycemic response among formulations and manufacturing processes with acceptable accuracy. For a specific formulation and manufacturing process, *in vitro* tests may be useful to assure lot-to-lot uniformity in bioavailability. However, human trials may be necessary to demonstrate that bioavailability remains reasonably constant within a given range of dissolution rates and/or disintegration times.

Antitumor Agents LV: Effects of Genkwadaphnin and Yuanhuacine on Nucleic Acid Synthesis of P-388 Lymphocytic Leukemia Cells

I. H. HALL ˣ, R. KASAI, R. Y. WU, K. TAGAHARA, and K. H. LEE

Received August 26, 1981, from the *Division of Medicinal Chemistry, School of Pharmacy, University of North Carolina at Chapel Hill, Chapel Hill, NC 27514.* Accepted for publication January 26, 1982.

Abstract □ The diterpene esters, genkwadaphnin and yuanhuacine, have been shown to possess significant antileukemic activity in the P-388 screen. The major metabolic effects of the diterpene esters were on DNA and protein synthesis. The effects on DNA synthesis *in vitro* were evoked at a lower concentration than that required for protein synthesis inhibition. The sites in DNA synthesis which were inhibited were DNA polymerase and purine synthesis. In the latter pathway the enzyme activities inhibited were phosphoribosyl aminotransferase, inosinic acid dehydrogenase, and dihydrofolate reductase. *In vivo* administration of the diterpene esters at 0.8 mg/kg afforded identical types of effects on purine and DNA synthesis and in addition suppressed histone phosphorylation and reduced the number of surviving tumor cells. The *in vivo* effects on purine and DNA synthesis were evident as early as 6 and 24 hr after administration of a single dose of the diterpene esters.

Keyphrases □ Antitumor agents—nucleic acid synthesis by genkwadaphnin and yuanhuacine of P-388 lymphocytic leukemia cells, diterpene esters □ Genkwadaphnin—antitumor agents, nucleic acid synthesis by yuanhuacine of P-388 lymphocytic leukemia cells, diterpene esters □ Yuanhuacine—antitumor agents, nucleic acid synthesis by genkwadaphnin of P-388 lymphocytic leukemia cells, diterpene esters

Genkwadaphnin (I) and yuanhuacine (II) are two *ortho* esters bearing daphnane type diterpenes which possess an isopropylene side chain at C_{13}. Compounds belonging to the daphnane diterpene esters have previously been shown to have antileukemic activity as opposed to tigliane diterpene esters, *e.g.*, phorbol esters, which are known to be carcinogenic promoting agents (1). Compound II (odoracin or gnidilatidin) has previously been isolated from *Daphne genkwa*, *Daphne odorata*, *Gnidia latifolia*, and *Gnidia glaucus* Fres, and like other diterpene esters, such as 12-hydroxydaphnetoxin, gnidimacrin, gnidimacrin-20-palmitate, gnidilatidin-20-palmitate, gnididin, gniditrin, and gnidicin, has been demonstrated to have antileukemic activity in the 20- to 100-μg/kg dose range in rodents (2–6). The isolation and chemical characterization of a new diterpene ester (I) has recently been reported (7) which also has demonstrated antileukemic activity. The effects of daphnane diterpene esters on nucleic acid and protein synthesis in P-388 lymphocytic leukemia is now reported to establish a mode of action in P-388 lymphocytic leukemia cells to explain their *in vivo* antileukemic activity.

Table I—The Antineoplastic Activity of Genkwadaphnin and Yuanhuacine in the P-388 Lymphocytic Leukemia Screen in BDF_1 Male Mice

Compound (n = 6)	Dose, mg/kg/day	Average Survival Days, (T/C)	T/C %[a]
0.05% Polysorbate 80		11.0/11.0	100
Genkwadaphnin	0.4	15.5/11.0	141
	0.8	19.0/11.0	173
Yuanhuacine	0.4	16.0/11.0	145
	0.8	16.6/11.0	151
5-Fluorouracil	12.5	19.6/11.0	178

[a] (Number of days survived by the treated group/number of days survived by the control group) × 100.

solved in a methanol–water mixture (1:1) and then partitioned into n-hexane and ether successively. Column chromatography of the active ethereal extract (55 g) on silica gel[2] (500 g) in chloroform afforded two fractions (fraction A, 540 mg and fraction B, 820 mg), which possessed P-388 antileukemic activity. Subsequent purification of fraction B by preparative TLC led to the isolation of the new antileukemic principle I, as reported previously (7).

Column chromatography of fraction A (540 mg) on modified dextran beads[3] (3 g) in chloroform afforded a fraction (420 mg), which was further purified by preparative TLC[4] eluted with n-hexane–2-propanol (10:1) and then ether–n-hexane (5:1) to yield compound II (132.5 mg). Final purification of II was achieved by high-performance liquid chromatography (HPLC)[5] to give 82.3 mg of pure II: $[\alpha]_D^{25}$ + 62.4 (c = 0.242, $CHCl_3$) [previously reported: $[\alpha]_D^{24}$ + 34.3° (c = 0.184, $CHCl_3$) for odoracin (8), $[\alpha]_D^{23}$ + 28° (c = 0.16, $CHCl_3$) for gnidilatidin (2), and $[\alpha]_D^{32}$ + 61.7° (c = 1.07, $CHCl_3$) for yuanhuacine (9)]; UV_{max} (ethanol) 227 nm (ϵ, 44,300) [previously reported λ_{max} (ethanol) 232 nm (ϵ 36,000) and λ_{max} 232 nm (ϵ 52,706); MS m/z 648.2939 (M^+, Calc. for $C_{37}H_{44}O_{10}$: 648.2935 (9)].

The IR, ^1H-NMR, and ^{13}C-NMR spectra of II were identical to those of odoracin (8). Since the structure of odoracin is also identical to that of gnidilatidin (2) or yuanhuacine (9), yuanhuacine is thereby used as the name of II, since the work dealing with the isolation and structural determination of II was submitted for publication earlier than odoracin or gnidilatidin.

The P-388 lymphocytic leukemia tumor line was maintained in DBA/2 male mice (~20 g) and the antineoplastic activity was established by using the NCI protocol (6). For the *in vitro* studies, P-388 cells were harvested from the peritoneal cavity 10 days after administering 10^6 P-388 ip lymphocytic leukemia cells into BDF_1 male mice (~20 g) on day 0 (10).

In the *in vivo* studies, BDF_1 male mice were inoculated on day 0 with 10^6 P-388 cells ip, and on days 7, 8, and 9 the mice were administered 0.8 mg/kg, the optimum dose for antineoplastic activity, of I or II intraperitoneally. The biochemical studies were performed on cells harvested from the peritoneal cavity on day 10. Alternately, mice were injected with a single dose of drug at 0.8 mg/kg, the optimum dose for antineoplastic activity, on day 7 and sacrificed either 6 or 24 hr later.

The *in vitro* incorporation studies were conducted using 1 μCi of thymidine (6-^3H, 21.8 Ci/mmole), uridine (6-^3H, 22.4 Ci/mmole), or L-leucine (4.5-^3H(N), 56.5 Ci/mmole) with 10^6 P-388 whole cells or homogenized cells in minimum essential growth medium[6], pH 7.2, in a total volume of 1 ml, incubated for 60 min at 37°. Thymidine incorporation into DNA was terminated with perchloric acid containing pyrophosphate, which was filtered on glass fiber paper (GF/F) by vacuum suction. RNA and protein assays were terminated with trichloroacetic acid and collected on nitrocellulose membranes by vacuum suction. The acid-insoluble nucleic acid or protein precipitated on the filter papers was placed in scintillation vials and counted[7]. The control value for *in vitro* DNA synthesis for 10-day P-388 cells was 31,777 dpm/mg of DNA, for RNA 38,615 dpm/mg, and for protein 76,518 dpm/mg (11). *In vivo* thymidine incorporation into DNA was determined by injecting into the animal 1 hr before sacrifice 10 μCi ip of [^3H](methyl)thymidine (21.5 Ci/mmole).

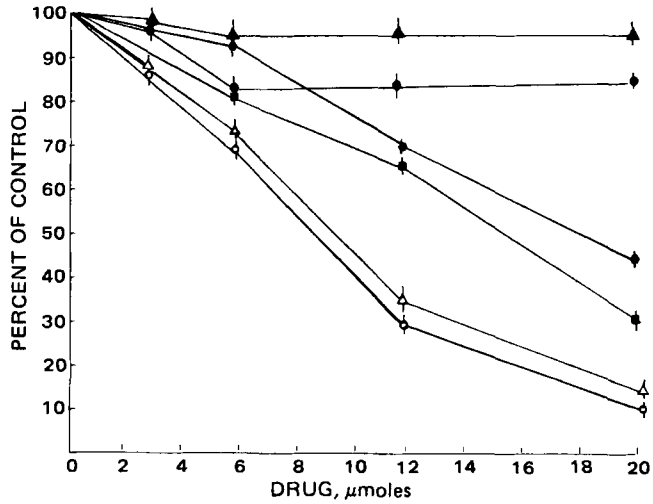

Figure 1—*The* in vitro *effects of genkwadaphnin (I) and yuanhuacine (II) on nucleic acid and protein synthesis of P-388 lymphocytic leukemia cells (60-min incubation)* (n = 5). *Key: [^3H]uridine into RNA, (▲) yuanhuacine, (●) genkwadaphnin; [^3H]leucine into protein, (■) yuanhuacine, (□) genkwadaphnin; [^3H]thymidine into DNA, (△) yuanhuacine, (○) genkwadaphnin; (|) standard deviation.*

The DNA was isolated (12), and the tritium content determined in scintillation fluid[7] and corrected for quenching. The DNA concentration was determined by the diphenylamine reaction using calf thymus DNA as the standard. The results were expressed as disintegrations per minute per milliliter of DNA isolated. Uridine incorporation into RNA was determined in an analogous manner with 10 μCi of 6-[^3H]uridine (22.4 Ci/mmole) and the RNA extracted (13). Leucine incorporation into protein was determined by a previous method (14) with 10 μCi [^3H]4,5(N)-L-leucine (52.0 Ci/mmole). The control values for DNA incorporation were 202,098 dpm/mg DNA, for RNA incorporation 356,926 dpm/mg RNA, and for leucine incorporation 319,300 dpm/mg of protein isolated.

After *in vivo* administration of the drug, on day 10, the number of tumor cells per milliliter and the 0.4% trypan blue uptake were determined with a hemocytometer (15). The *in vitro* UV binding studies were conducted with diterpene esters (5 μg/ml) incubated with DNA (38 μg/ml) in 0.1 M phosphate buffer, pH 7.2 from 0–24 hr and measured over the range of 200–340 nm (15).

The *in vitro* enzymatic studies were conducted with diterpene esters present in a final concentration of 12 μM[8]. The *in vitro* and *in vivo* enzymatic assays have been described previously (10). Briefly, nuclear DNA polymerase activity was determined on isolated P-388 cell nuclei (16) using a previous incubation medium (17), except that [^3H]methyldeoxyribothymidine triphosphate (82.4 Ci/mmole) was used. The insoluble nucleic acids were collected on glass fiber papers (GF/F). The control value was 24,568 dpm/mg of nuclear protein. Messenger, ribosomal, and transfer RNA polymerase enzymes were isolated using different concentrations of ammonium sulfate (18), namely, 0.3 M, 0.04 M, and 0.00 M, respectively, and the individual polymerase activities were measured using 5-[^3H]uridine-5-triphosphate (23.2 Ci/mmole).

Insoluble RNAs were collected on nitrocellulose filters (18, 19). Control values for messenger, ribosomal, and transfer RNA polymerase activities were, respectively, 21,434; 25,408; and 2,082 dpm/mg of nucleic protein. Ribonucleotide reductase activity was measured by a previous method (20) using 5-[^3H]cytidine-5′-diphosphate (21.5 Ci/mmole). The deoxyribonucleotides were separated from ribonucleotides by poly(ethyleneimine)cellulose TLC. The control value for the reductase was 577,720 dpm/mg of protein. Deoxythymidine kinase, deoxythymidylate monophosphate kinase, and deoxythymidylate diphosphate kinase activities were measured by spectrophotometric assay (21) based on the disappearance of nicotinamide dinucleotide at 340 nm. Control values using a postnuclear supernatant fraction (600×g, 10 min) were a change in absorbance of 0.385, 0.386, and 0.378 optical density units/20 min/mg of protein, respectively. Thymidine incorporation into the nucleotides was evaluated by using a previous medium (21). The reaction was extracted with ether and the aqueous layer plated on poly(ethylene)imine cellulose F plates eluted with 0.5 N formic acid–lithium chloride (1:1).

[8] Concentration of drug was selected because the micromolar range would be between ID_{50} values required to inhibit DNA and protein synthesis.

[a] $p \leq 0.001$.

Areas that correlated with R_f values of thymidine monophosphate, diphosphate, and triphosphate standards were scraped and counted[9]. Enzymes of the pyrimidine synthetic pathway were also measured. Carbamyl phosphate synthetase activity was determined by a previous method (22). The colorimetric determination of citrulline was performed according to another method (23), resulting in 3.26 mg of citrulline formed/hr/μg of protein.

Aspartate carbamyl transferase activity was carried out in the presence of aspartate transcarbamylase (22), and the colorimetric determination of the carbamyl aspartate formed was according to a previous method (24), resulting in 0.301 μmole formed/hr/mg of protein. Orotidine monophosphate decarboxylase activity was measured using a (16,300×g, 20 min) supernatant fraction by a previous technique (25) using [^{14}C]-(*carboxyl*)*orotidine monophosphate* (34.9 mCi/mmole). The control value was 41,760 dpm/mg of protein. Thymidylate synthetase activity was determined by a previous method (26), utilizing a postmitochondrial (9000×g, 10 min) supernatant fraction with 5 μCi of 5-[^{3}H]deoxyuridine monophosphate (14 Ci/mmole), affording a control value of 14,500 dpm/hr/mg of protein.

Dihydrofolate reductase activity was determined using a (600×g, 10 min) supernatant fraction by a spectrophotometric method (27) based on the disappearance of reduced nicotinamide adenine dinucleotide resulting in a value of 0.761 optical density U/hr/mg of protein for 10-day P-388 cells. [^{14}C]Formate incorporation into purines was measured by a method used previously (28), using 0.5 μCi of [^{14}C]formic acid (52.0 mCi/mmole). Purine separation was achieved by silica gel TLC eluting with n-butanol–acetic acid–water (4:1:5). Using the standards, guanine and adenine, the appropriate spots were scraped and the radioactivity determined. The control value for purine synthesis was 23,682 dpm/mg of protein. Phosphoribosyl pyrophosphate aminotransferase activity was determined by a previous spectrophotometric method (29) at 340 nm using a (600×g, 10 min) supernatant fraction resulting in a control value of 0.806 optical density U/hr/mg of protein. Inosinic acid dehydrogenase activity was determined by a previous method (30) using 8-[^{14}C]inosine-5′-monophosphate (61 mCi/mmole). The control value was 5745 dpm/mg of protein.

Histone phosphorylation was determined by injecting 10 μCi ip of γ-[^{32}P]adenosine triphosphate (27 Ci/mmole). The nuclei were isolated 1 hr later, and the histone chromatin protein was extracted by a method used previously (31). Nonhistone chromatin phosphorylation by nucleic acid kinase was determined on isolated nuclei (16) utilizing 2 nmoles of γ-[^{32}P]adenosine triphosphate. Chromatin protein was collected on nitrocellulose membrane filters (32). The control value for histone phosphorylation was 2612 dpm/mg of chromatin protein isolated. Nonhistone phosphorylation was 18,616 dpm/mg of protein. Protein was determined by a previous method (33).

Data are expressed in the tables as percent of control with standard

[9] Packard Scintillation Counter in Fisher scintillation fluid and corrected for quenching.

Table IV—The *In Vivo* Effects of Genkwadaphnin and Yuanhuacine on P-388 Lymphocytic Leukemia Cell Metabolism 24 hr After a Single Dose at 0.8 mg/kg

Biochemical Parameter (n = 6)	Control	Percent Control, Day 8

[a] $p \leq 0.001$.

deviation. The number of animals per group is represented by n. The probable (p) significant differences were determined by Student's t test.

RESULTS

Genkwadaphnin (I) and yuanhuacine (II) both demonstrated significant antineoplastic activity against the growth of P-388 lymphocytic leukemia. Compound I at 0.8 mg/kg/day afforded a T/C % value of 173, whereas II afforded a T/C % value of 151 (Table I). The antileukemic activity of the diterpene esters was comparable to the standard, 5-fluorouracil (T/C = 178% at 12.5 mg/kg) in their ability to inhibit P-388 tumor growth.

The *in vitro* studies involving whole cells and homogenized cells showed pellucidly that the major effect of the diterpene esters was on DNA synthesis, with I producing a 77% suppression and II producing a 67% suppression at 12 μM concentrations (Fig. 1). The effects of diterpene esters on DNA synthesis were identical in the studies on whole cells and homogenized cells, indicating that the effects of diterpene esters were not on the membrane transport of the radiolabeled precursor, but rather on cellular synthesis. The ID_{50} for the inhibition of DNA was 5.62 μM for I and 7.11 μM for II. The studies demonstrated that the diterpene esters inhibited *in vitro* protein synthesis at a higher concentration, compared with the concentration required to inhibit DNA synthesis, affording an ID_{50} of ~14.8 μM for I and an ID_{50} of 18.5 μM for II.

Further *in vitro* studies (Table II) showed that the principal pathway in nucleic acid synthesis which was suppressed by the diterpene esters was the purine pathway. Formate incorporation into purines was reduced 49% by I and 24% by II. A number of enzyme sites in purine synthesis appeared to be blocked by the diterpene esters. Phosphoribosyl aminotransferase activity was reduced 32% by I and 26% by II. Inosinic acid dehydrogenase activity was reduced 34% by I and 33% by II. Dihydrofolate reductase activity was suppressed 45% by I and 39% by II *in vitro*. Marginal inhibition of DNA polymerase activity was observed with 29% reduction by I and 16% by II. *In vitro* the diterpene esters had little effect on the enzymatic activities of the pyrimidine pathway, on the thymidylate kinases, or on the RNA polymerases.

In the *in vivo* studies, after dosing for 3 days at 0.8 mg/kg/day ip, I reduced the number of cells per milliliter from 206 to 33 × 10^6, and II reduced this number from 206 to 56 × 10^6 (Table III). The diterpene esters, *in vivo*, suppressed DNA synthesis significantly, with I causing an 86% reduction and II producing an 81% reduction after 3 days of dosing. Inhibition of RNA synthesis was observed *in vivo* with I causing a 77% reduction and II causing a 32% reduction. Likewise, protein synthesis was also reduced *in vivo* with I administration resulting in a 60% reduction and II a 49% reduction. *In vivo* purine synthesis was suppressed 40% by I and 34% by II. As observed in the *in vitro* studies, key enzymes of the purine pathway were blocked by the diterpene esters. Phosphoribosyl aminotransferase activity was reduced 30% by I and 31% by II after 3 days of administration. Inosinic acid dehydrogenase activity was suppressed *in vivo* 42% by I and 49% by II. Dihydrofolate reductase activity was inhibited 65% by I and 49% by II therapy. DNA polymerase activity *in vivo* was suppressed 57% by I and 60% by II administration. Phosphorylation of the chromatin basic histones was reduced by the administration of the diterpene esters, such that I caused 35% suppression and II caused 49% reduction. *In vivo* administration of the diterpene esters had little effect on the pyrimidine synthetic pathway or on the RNA polymerase activities.

Examination of the studies (Table IV) 24 hr after a single dose of the agents showed that DNA synthesis was inhibited significantly, with I resulting in 83% inhibition and II resulting in 84% inhibition. However, RNA synthesis and protein synthesis produced <20% inhibition 24 hr after a single dose of the diterpene esters. Formate incorporation into purines was reduced 31% by I and 25% by II administration. Phosphoribosyl aminotransferase activity was inhibited 52% by I and 54% by II therapy. Similarly, inosinic acid dehydrogenase activity was reduced 42% by I and 47% by II and dihydrofolate reductase activity was inhibited 46% by I and 47% by II after a single dose. DNA polymerase activity was inhibited 25% by I and 30% by II administration.

In vivo administration of a single dose of daphnane diterpene esters (Table V) with sacrifice of the mice 6 hr later demonstrated that DNA synthesis was suppressed 87% by I and 65% by II. Formate incorporation into purines after 6 hr demonstrated that I caused 33% reduction and II caused 27% reduction. Phosphoribosyl aminotransferase activity was reduced 53% by I and 20% by II administration. Inosinic acid dehydrogenase activity was reduced ~50% by a single dose of the diterpene esters. Dihydrofolate reductase activity was reduced 23% by I and reduced 32% by II therapy. DNA polymerase activity was reduced ~30% by the diterpene esters using a single dose.

The *in vitro* UV studies with DNA indicated that there were no hyperchromic effects or shift of absorbance to a higher wavelength. These studies indicate the diterpene esters did not bind to DNA or interfere with template activity for nucleic acid synthesis.

DISCUSSION

The diterpene esters, I and II, had significant effects on cellular metabolism which would explain their antineoplastic activity in the P-388 screen. The major effect is the suppression of DNA synthesis of P-388

lymphocytic leukemia cells. The observed inhibition of key regulatory steps of the purine pathway are of a sufficient magnitude to account for the reductions observed in DNA synthesis. In addition, other sites of inhibition by the diterpenes were DNA polymerase and dihydrofolate reductase activity. The inhibition DNA synthesis occurs within 6 hr, suggesting that it is not directly related to the abilities of the agents to suppress protein synthesis.

The effects on P-388 cellular metabolism induced by the daphnane diterpene esters are in direct contrast to the reported cellular effects of the tigliane diterpenes, croton oil, and 12-*O*-tetradecanoyl-phorbol-13-acetate. These esters are hyperplasia-inducing agents (34) and induce cell proliferation (35, 36) augmenting carcinogenesis. It has been suggested that they act on cellular or intercellular membranes causing irritation and inflammation (37). Both crude extracts and esters have been observed to stimulate DNA and RNA synthesis, which was positively related to their ability to induce tumors (38). Stimulation of protein synthesis also occurs after the increase in RNA synthesis but before stimulation of DNA synthesis (38, 39). Stimulation of phosphorylation of histones by the croton esters (40) has been observed. Increased histone phosphorylation is related to the ability of the croton oil esters to promote tumors and stimulate nucleic acid synthesis. Further studies have indicated that the croton oil esters inhibit the DNA repair enzyme system (41).

Plants of the Euphorbiaceae family are known for their toxic effects on cells (42). However, these plants historically were used in herbal medicine to treat human cancer and warts (42). An antileukemic phorbol ester has been isolated from *Croton tiglium* and an antileukemic ingenol ester has been isolated from *Euphorbia eoula* (43). Two of the more potent diterpene esters are the macrocyclic diterpenoid gnidimacrin and its C-20 palmitate (44). It has been suggested that the C-20 and C-12 ester groups are necessary for antileukemic activity and that these groups enable the agent to pass through the cellular membrane (2, 44), thus facilitating its antineoplastic effect on cell metabolism. Compounds I and II have an ester in the C-12 position but not the C-20 which contains a hydroxy group.

Studies on structural requirements for the antileukemic activity such as the effect of the cyclopentenone ring, 6,7-epoxide group, the ortho esters and the configuration of A/B rings of the daphnane nucleus are currently in progress.

Isolated Perfused Rabbit Lung As a Model for Intravascular and Intrabronchial Administration of Bronchodilator Drugs I: Isoproterenol

R. K. BRAZZELL ‡, R. B. SMITH §, and H. B. KOSTENBAUDER *x

Received November 12, 1981, from the **College of Pharmacy, University of Kentucky, Lexington, KY 40506.* Accepted for publication January 29, 1982. ‡Present address: Hoffmann-La Roche Inc., Department of Pharmacokinetics and Biopharmaceutics, Nutley, NJ 07110, §The Upjohn Co., Kalamazoo, MI 49001.

Abstract □ The absorption, uptake, and metabolism of isoproterenol was studied following intravascular, intrabronchial, and aerosol administration of the drug to the isolated perfused rabbit lung. Capacity-limited metabolism of isoproterenol was observed following the addition of five doses, ranging from 10^{-7} to 10^{-5} moles, directly into the circulation of the lung system. A physiologically based perfusion model was developed to describe the disposition of the drug and metabolite in the isolated lung preparation. This model was also used to analyze data collected following intrabronchial and aerosol administration of isoproterenol.

Keyphrases □ Isoproterenol—intravascular and intrabronchial administration, isolated perfused rabbit lung □ Bronchodilators—isoproterenol, intravascular and intrabronchial administration, isolated perfused rabbit lung □ Pharmacokinetics—isolated perfused rabbit lung as a model for intravascular and intrabronchial administration of isoproterenol

Isoproterenol is often administered directly into the lungs by aerosol inhalation in the treatment of bronchial asthma. Little of the inhaled dose actually reaches the airways (1), but that which does is responsible for the bronchodilating effect. Little is known of the fate of the small fraction which reaches the airways and of the role of the lung in the disposition of the drug. The objective of this study was to evaluate the absorption, uptake, and metabolism of isoproterenol in the isolated perfused rabbit lung following intravascular, intrabronchial, and aerosol administration.

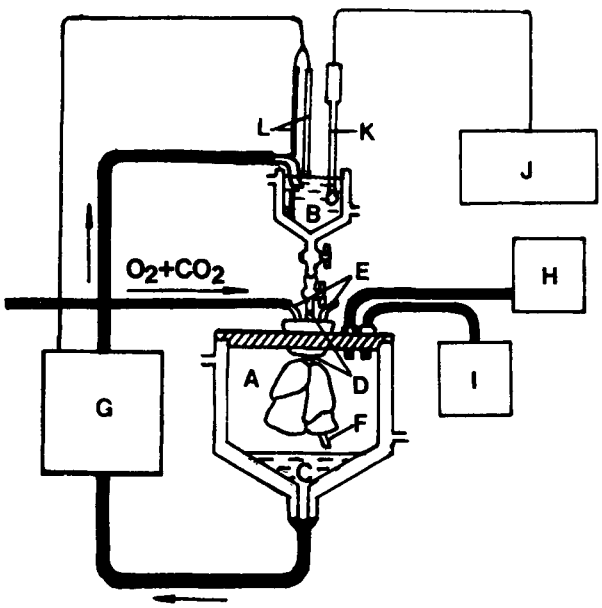

Figure 1—*Diagram of the isolated perfused rabbit lung apparatus. The isolated perfused rabbit lung preparation offers an ideal experimental system for studying the disposition of drugs by the lung, as it allows the lung to be studied independent of the rest of the body. The design of the system facilitates rapid and convenient sample withdrawal and complete recovery of the lung tissue and perfusate. Viability of the isolated perfused rabbit lung preparation has been documented by physiological, hematological, histological, and biochemical methods for periods up to 4 hr (2–5). Similar preparations have been used in the past to study the uptake and metabolism of various pharmacological agents. Little has been done, however, to apply pharmacokinetic concepts to the analysis of the data generated from these studies.

Previous experiments dealing with the disposition of isoproterenol in isolated lung preparations indicate that the drug is not taken up extensively by the lung (6) and that 3-*O*-methylisoproterenol is the only metabolite formed by the lung (7). The drug appears to be well-ab-

sorbed when administered directly into the airways, and a 30% first-pass *O*-methylation during absorption has been reported (7).

EXPERIMENTAL

Isolated Perfused Rabbit Lung—The isolated perfused rabbit lung system has been described previously (2, 3). A schematic drawing of the apparatus is shown in Fig. 1. Male New Zealand rabbits (3–5 kg) were anesthetized with sodium pentobarbital and treated with heparin. The animals were exsanguinated *via* cardiac puncture; the heart, lungs, and trachea were removed; and the trachea, pulmonary artery, and left atrium were cannulated. The lung preparation was suspended in a cylindrical thorax[1] and connected to an upper reservoir such that perfusion medium could flow from the reservoir through the pulmonary vasculature and exit *via* a cannula inserted in the left atrium. The pooling perfusate was pumped back to the reservoir by a perfusion pump[2], providing constant circulation through the lung system. The lungs were ventilated with warm humidified air containing carbon dioxide by operating a small animal respirator[2] to create an alternating negative pressure within the lung chamber. This resulted in expansion and contraction of the lung and inspiration and expiration much like that in the intact animal. The thorax and the reservoir were water-jacketed to regulate the temperature at 37°. Once the system was in operation, it was allowed to equilibrate 15–20 min prior to drug administration. Sampling (1-ml specimens) was from the upper reservoir. For each perfusion, Krebs-Ringer bicarbonate solution (150 ml) containing 4.5% bovine serum albumin and the following in grams per liter was used: NaCl, 6.57; KCl, 0.355; $CaCl_2$, 0.28; KH_2PO_4, 0.16; $MgSO_4$, 0.145; $NaHCO_3$, 2.1; and glucose, 0.18. The pH was adjusted to 7.4 with sodium hydroxide.

Drug Administration—Isoproterenol hydrochloride was administered to the isolated lung system by intravascular, intrabronchial, and aerosol administration. One milliliter aliquots of aqueous isoproterenol hydrochloride solutions containing 10^{-5}, 5×10^{-6}, 10^{-6}, 5×10^{-7}, and 10^{-7} moles/ml were added to the upper reservoir for intravenous administration. For intrabronchial dosing, 250-μl aliquots containing 10^{-5} and 10^{-6} moles of drug were delivered to the airways as a bolus *via* a small bore plastic tubing inserted through the tracheal cannula. For aerosol administration, a 50-mg/ml aqueous solution of isoproterenol hydrochloride was nebulized[3] and delivered to the airways through a plastic tubing attached to the tracheal cannula for a 1-min dosing period. During drug administration, the respirator controls were changed from the normal settings of 30-ml stroke volume and 50% inspiration to 50-ml stroke volume and 70% inspiration. This maximized the flow of aerosolized drug into the lung by causing deep inspirations.

Chromatography—The perfusate concentrations of isoproterenol and 3-*O*-methylisoproterenol[4] were determined by high-pressure liquid chromatography (HPLC). The compounds were separated on a strong cation exchange column[5] and detected with a variable wavelength UV

detector[6]. Due to the column-to-column variability and the tendency of the columns to lose efficiency during use, various mobile phases were utilized during the study. Potassium phosphate buffers (0.003–0.03 M) containing 5–30% methanol (pH 3.0) were used at a flow rate of 2 ml/min. The compounds were detected at either 278 or 220 nm. The higher wavelength was used when large concentrations of isoproterenol were present and isoproterenone hydrochloride[7] was used as an internal standard. A sample chromatogram is shown in Fig. 2. Detection at 220 nm afforded greater sensitivity, but the chromatographic conditions needed to separate isoproterenol and 3-O-methylisoproterenol from interfering extraneous peaks precluded the use of isoproterenone as the internal standard; morphine hydrochloride was used as the standard in this case.

Extraction of Perfusate Samples—All procedures were performed under yellow light to protect isoproterenol against photodecomposition. To each sample was added 1 ml of 0.1 N acetate buffer (pH 4.0) containing internal standard (isoproterenone hydrochloride or morphine hydrochloride) and 3 ml of 5% (v/v) diethylhexylphosphoric acid in freshly distilled diethyl ether. This was vortexed 1 min and centrifuged, and the ethereal layer was decanted into a conical centrifuge tube. To this was added 25–100 μl of 1 N HCl with 1% ascorbic acid, and the mixture was vortexed 1 min and centrifuged. An aliquot of the aqueous phase was injected into the chromatographic system.

Standard curves were prepared for each experiment by spiking 1-ml blank perfusate samples with 100 μl of 1% ascorbic acid and varying concentrations of isoproterenol and 3-O-methylisoproterenol. These standards were extracted and analyzed in the same manner as experimental samples.

Preparation of Lung Homogenate Samples—The lungs were thawed and blotted dry. Extraneous tissue was removed and the lung was weighed. The tissue was cut into small slices, diluted with 40 or 60 ml of normal saline containing 1% ascorbic acid, and homogenized[8]. A 1-ml aliquot of the homogenate was then extracted in the same manner as the perfusate samples previously described. Standard curves were prepared by adding varying amounts of isoproterenol and 3-O-methylisoproterenol to blank homogenate samples and analyzing these along with the unknown samples.

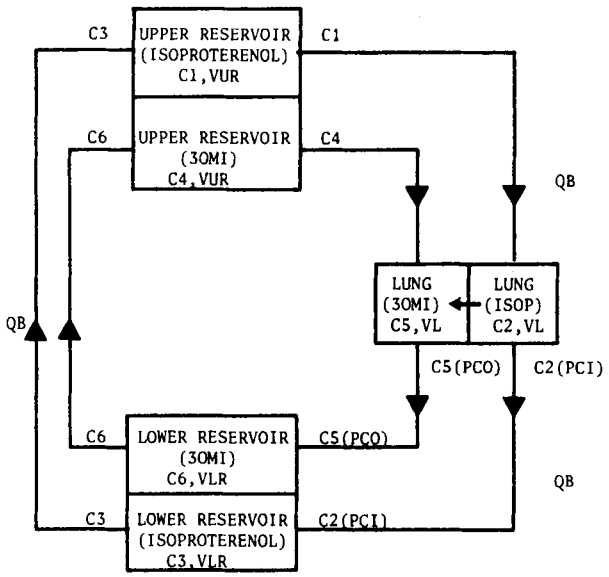

Figure 4—*Perfusion model used to describe the disposition of isoproterenol and 3-O-methylisoproterenol by the isolated perfused rabbit lung.*

RESULTS

Intravascular Administration—Five doses of isoproterenol hydrochloride ranging from 10^{-7} to 10^{-5} moles were administered directly into the circulating perfusion medium, and samples were withdrawn for 180 min and analyzed for isoproterenol and 3-O-methylisoproterenol. In each experiment, isoproterenol concentrations appeared to decline monoexponentially with a corresponding increase in metabolite levels. The apparent half-life for drug elimination from the perfusate decreased with decreasing dose as the fraction of the dose appearing as 3-O-methylisoproterenol increased. This suggested a capacity-limited process for metabolism of isoproterenol. To investigate this possibility, data were analyzed pharmacokinetically using both a compartmental and perfusion model.

Compartmental Analysis—Each set of isoproterenol and 3-O-methylisoproterenol perfusate concentration–time data were fitted to a simple one-compartment model with the metabolism of isoproterenol to 3-O-methylisoproterenol being described by the Michaelis–Menten equation. The rates of change of drug and metabolic concentrations were described by the differential equations:

$$\frac{dC_1}{dt} = -\frac{Vm \times C_1}{Km + C_1} \quad \text{(Eq. 1)}$$

$$\frac{dC_2}{dt} = \frac{(Vm \times C_1)V_1}{(Km + C_1)V_2} \quad \text{(Eq. 2)}$$

where

C_1 = perfusate concentration of isoproterenol (μg/ml);
C_2 = perfusate concentration of 3-O-methylisoproterenol (μg/ml);
Vm = theoretical maximum metabolic rate (μg $ml^{-1}min^{-1}$);
Km = Michaelis constant (μg/ml);
V_1 = apparent volume of distribution of isoproterenol (ml);
V_2 = apparent volume of distribution of 3-O-methylisoproterenol (ml).

The isoproterenol and 3-O-methylisoproterenol perfusate concentration–time data from the intravascular studies were fitted to the differential equations using the NONLIN (8) digital computer program for nonlinear least-squares regression. The entire set of data (*i.e.*, isoproterenol and 3-O-methylisoproterenol from all five experiments) were fitted to this model resulting in unique estimates of Vm and Km describing the metabolism over the entire range of doses, whereas, V_1 and V_2 were allowed to vary for each dose independent of the others. Table I shows the parameter estimates obtained from these fits. Semilogarithmic plots comparing the observed data to that predicted from the composite fit are shown in Fig. 3.

Perfusion Model—A perfusion model was developed to describe the isolated perfused rabbit lung system and to assist in the analysis and interpretation of the observed data.

Figure 4 depicts the isolated perfused lung model as used to describe the concentration–time course for isoproterenol and 3-O-methylisoproterenol following intravascular administration of isoproterenol. This model is based on the following assumptions: (*a*) the concentration of isoproterenol and 3-O-methylisoproterenol entering the lung vasculature is the same as that in the upper reservoir; (*b*) the concentration of the two compounds in the lung tissue is in equilibrium with that in the perfusion medium leaving the lung and entering the lower reservoir; (*c*) the concentration entering the upper reservoir is the same as that leaving the lower reservoir; (*d*) the metabolism of isoproterenol to 3-O-methylisoproterenol occurs in the lung tissue by a capacity-limited process described by the Michaelis–Menten equation.

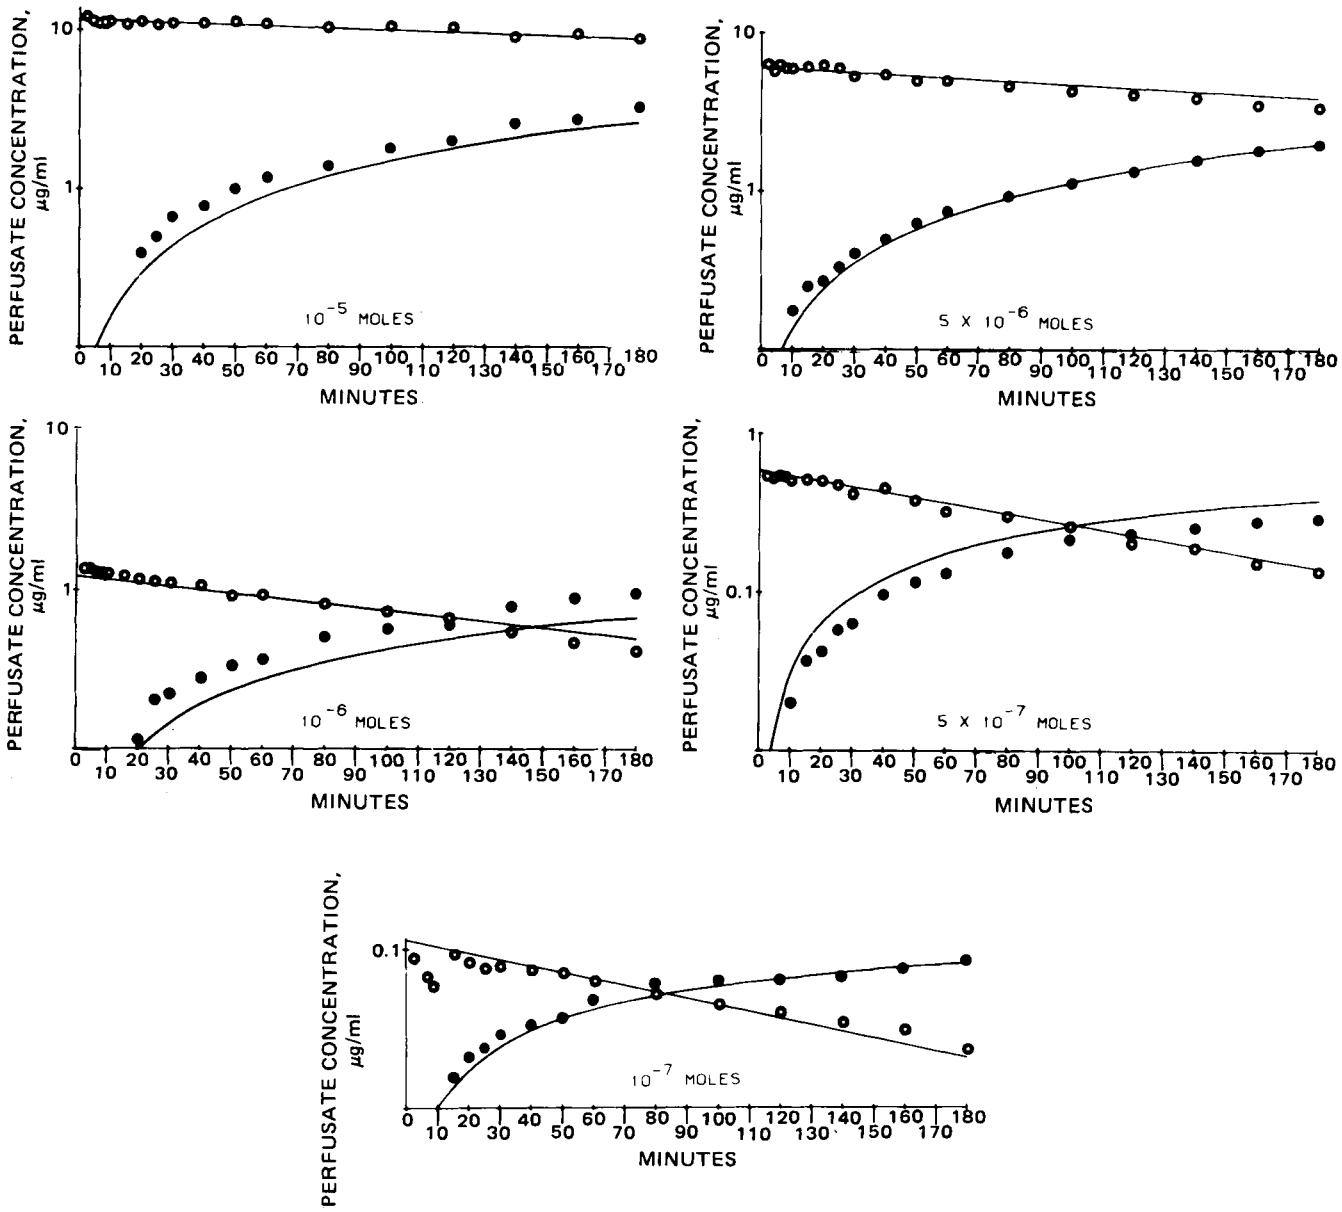

Figure 5—*Semilogarithmic plots of concentration* versus *time for (○) isoproterenol and (●) 3-O-methylisoproterenol comparing observed values with those predicted from perfusion model simulations for five intravascular doses of isoproterenol administered to the isolated perfused rabbit lung.*

The following differential equations describe the rate of change of isoproterenol and 3-*O*-methylisoproterenol concentrations in the lung tissue and in the reservoir compartments following introduction of a bolus of isoproterenol into the upper reservoir:

$$\frac{dC_1}{dt} = \frac{Q_b}{V_{UR}}(C_3 - C_1) \qquad \text{(Eq. 3)}$$

$$\frac{dC_2}{dt} = \frac{Q_b \times C_1}{V_L} - \frac{Q_b \times C_2}{PC_I \times V_L} - \frac{Vm \times C_2}{Km + C_2} \qquad \text{(Eq. 4)}$$

$$\frac{dC_3}{dt} = \frac{Q_b \times C_2}{PC_I \times V_{LR}} - \frac{Q_b \times C_3}{V_{LR}} \qquad \text{(Eq. 5)}$$

$$\frac{dC_4}{dt} = \frac{Q_b(C_6 - C_4)}{V_{UR}} \qquad \text{(Eq. 6)}$$

$$\frac{dC_5}{dt} = \frac{Q_b \times C_4}{V_L} - \frac{Q_b \times C_5}{PC_0 \times V_1} + \frac{Vm \times C_2}{Km + C_2} \qquad \text{(Eq. 7)}$$

$$\frac{dC_6}{dt} = \frac{Q_b \times C_5}{PC_0 \times V_{LR}} - \frac{Q_b \times C_6}{V_{LR}} \qquad \text{(Eq. 8)}$$

where

C_1 = concentration of isoproterenol in the upper reservoir (μmoles/ml);
C_2 = concentration of isoproterenol in the lung tissue (μmoles/ml);
C_3 = concentration of isoproterenol in the lower reservoir (μmoles/ml);
C_4 = concentration of 3-*O*-methylisoproterenol in the upper reservoir (μmoles/ml);
C_5 = concentration of 3-*O*-methylisoproterenol in the lung (μmoles/ml);
C_6 = concentration of 3-*O*-methylisoproterenol in the lower reservoir (μmoles/ml);
V_{UR} = volume of the upper reservoir (ml);
V_L = volume of the lung (ml);
V_{LR} = volume of the lower reservoir (ml);
PC_I = apparent partition coefficient for isoproterenol between the lung tissue and the emergent perfusion medium;
PC_0 = apparent partition coefficient for 3-*O*-methylisoproterenol between the lung tissue and the emergent perfusate;
Vm = maximum rate of metabolism of isoproterenol to 3-*O*-methylisoproterenol in the lung tissue (μmoles $ml^{-1}min^{-1}$);
Km = Michaelis constant (μmoles/ml);
Q_b = rate of flow of perfusion medium (ml/min).

The parameters used to describe this model were derived from actual

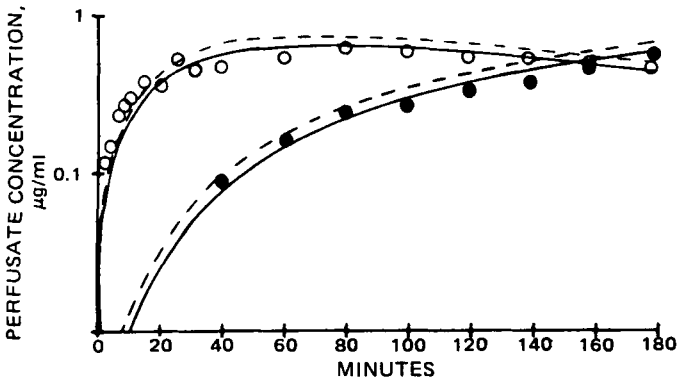

Figure 6—*Semilogarithimic plot of concentration* versus *time for (○) isoproterenol and (●) 3-O-methylisoproterenol following intrabronchial administration of 10^{-6} moles of isoproterenol assuming (- - -) 100% and (—) 90% absorption.*

experimental conditions associated with the isolated lung system. The values for V_{UR}, V_{LR}, PC_I, PC_0, Vm, Km, and Q_b were the same for all simulations. Only the dose and V_L were varied. The volumes of the upper and lower reservoirs were measured as 62 and 88 ml, respectively. The flow rate was constant at 150 ml/min. The partition coefficients for isoproterenol and 3-*O*-methylisoproterenol were determined experimentally from several experiments and an average value for each was used (1.5 for isoproterenol and 3.8 for 3-*O*-methylisoproterenol). Michaelis–Menten constants were estimated from those obtained with the compartmental model fits and were adjusted to represent metabolism occurring from the lung tissue. The following conversions were used to determine these constants from those reported in Table I:

$$Vm^* = \frac{Vm \times V_1}{MW \times V_L} \qquad \text{(Eq. 9)}$$

$$Km^* = \frac{Km \times PC_I}{MW} \qquad \text{(Eq. 10)}$$

where

Vm and Km = Michaelis–Menten constant generated from the composite compartmental fit assuming metabolism from the central compartment (perfusate);
Vm^* and Km^* = Michaelis–Menten constants representing metabolism from the lung tissue;
V_1 = volume of the central compartment of the compartmental model;
V_L = volume of the lung;
MW = molecular weight of isoproterenol;
PC_I = apparent partition coefficient for isoproterenol.

The Vm obtained from this conversion was 0.001 µmoles $ml^{-1}min^{-1}$ while the Km was 0.014 µmoles/ml. The weight of each lung was used as the lung volume.

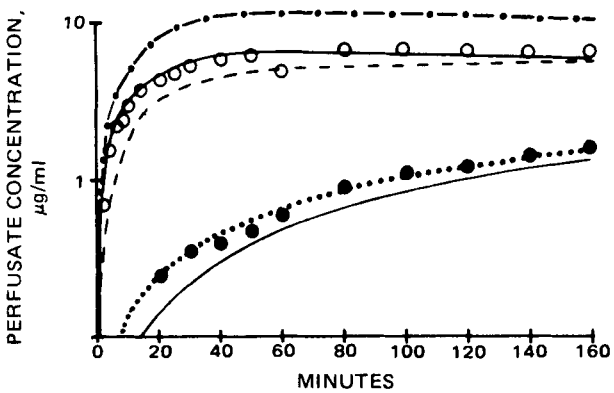

Figure 7—*Semilogarithmic plot of concentration* versus *time for (○) isoproterenol and (●) 3-O-methylisoproterenol following intrabronchial administration of 10^{-5} moles of isoproterenol hydrochloride. Perfusion model predictions for isoproterenol assuming (- · · · · ·) 100% and (—) 60% absorption are shown along with predicted 3-O-methylisoproterenol profiles assuming (- - - -) 40%, (· · · · ·) 2.5%, and (—) no first-pass metabolism.*

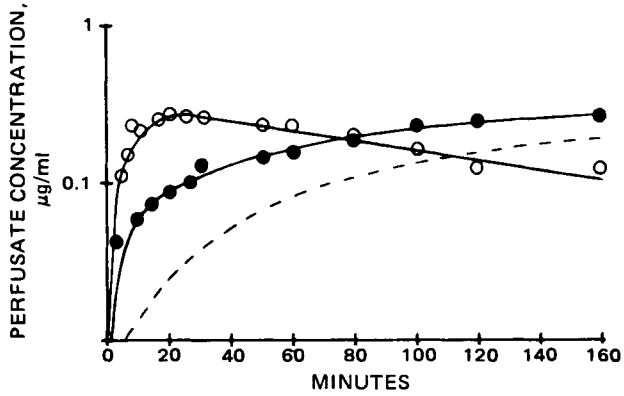

Figure 8—*Semilogarithmic plot of concentration* versus *time for (○) isoproterenol and (●) 3-O-methylisoproterenol following aerosol administration of isoproterenol hydrochloride. Perfusion model predictions for the absorption of 2.75×10^{-7} moles of (—) isoproterenol are shown along with predicted 3-O-methylisoproterenol concentrations with (—) and without (- - - -) 20% first-pass metabolism.*

These equations and parameter estimates were used to produce simulations of the isoproterenol and 3-*O*-methylisoproterenol concentration–time profile in the upper reservoir of the isolated lung system following administration of isoproterenol into the upper reservoir. These simulations were compared to the observed data to determine how the model actually described that which was occurring. These comparisons are shown in Fig. 5. There was good agreement for the isoproterenol data, whereas, slight deviations from the observed metabolite data are observed in some cases.

Intrabronchial Studies—The absorption and subsequent metabolism of isoproterenol was studied following endotracheal instillation of aqueous solutions containing 10^{-5} and 10^{-6} moles of isoproterenol hydrochloride. In both cases the absorption was relatively slow with peak drug levels occurring at 60–80 min. Comparison of isoproterenol and 3-*O*-methylisoproterenol concentrations to those observed following equivalent intravascular doses suggest that less drug and metabolite appeared in the circulation following intrabronchial administration. Determining the fraction of the dose absorbed by the usual method of comparing areas under the curves was not possible, because an accurate estimate of the area under the curve could not be obtained due to nonlinear pharmacokinetics.

The perfusion model was used to assist in the interpretation of the data. The only modification from the previous model was the addition of a first-order pathway for the absorption of isoproterenol from the airways into the lung tissue. In this case the dose was entered into the absorption site rather than the upper reservoir. All other parameters and estimates were identical to those used in the previous flow model.

The simulations produced by this model adequately matched the 10^{-6} mole dose (Fig. 6) but predicted higher isoproterenol concentrations than actually observed for the 10^{-5} mole dose (Fig. 7). The intravascular data suggested that if first-pass metabolism were occurring, it would most likely be due to conversion of isoproterenol to 3-*O*-methylisoproterenol as the drug was being absorbed. This preabsorptive first-pass metabolism was incorporated into the model as the absorption of a fraction of the dose as the metabolite (with the same rate of absorption as isoproterenol). Simulations involving various fractions of the dose being absorbed as intact isoproterenol and as 3-*O*-methylisoproterenol were compared to the observed data to determine if the first-pass model could describe the data.

The results of some of these simulations for the 10^{-5} mole dose are shown in Fig. 6. An absorption rate constant of 0.056 min^{-1} was used in these simulations. Comparing the simulations to the observed data shows that the model with 60% of the dose being absorbed intact and 2.5% as the metabolite best agrees with the data. This suggests that the intrabronchial dose was not totally absorbed but does not indicate an extensive first-pass effect. Similar simulations were produced for the 10^{-6} mole dose. The best agreement with the observed data was achieved with a model assuming that 90% of the dose was absorbed as isoproterenol with no first-pass effect occurring (Fig. 6). An absorption rate constant of 0.025 min^{-1} was used in these simulations.

Aerosol Studies—Isoproterenol hydrochloride was administered to the lung as a nebulized aqueous solution and the resulting concentrations of drug and metabolite were determined. Absorption following aerosol administration was faster than that with intrabronchial administration

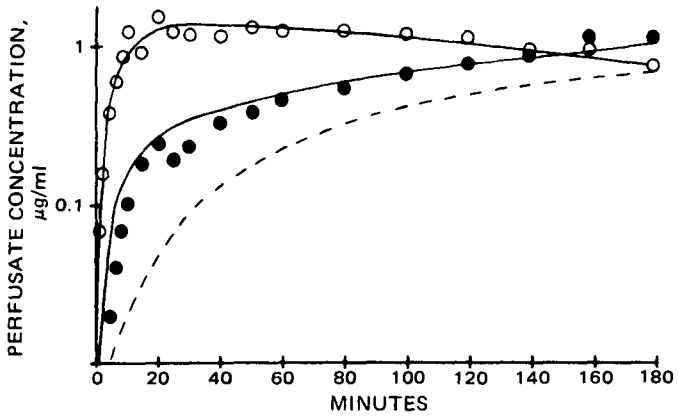

Figure 9—*Semilogarithmic plot of concentration* versus *time for (○) isoproterenol and (●) 3-O-methylisoproterenol following aerosol administration of isoproterenol hydrochloride. Perfusion model predictions for the absorption of 1.3 × 10^{-6} moles of (—) isoproterenol are shown along with predicted 3-O-methylisoproterenol concentrations with (—) and without (- - -) 16% first-pass metabolism.*

(Figs. 8 and 9). The *O*-methyl metabolite also appeared at a faster rate than that following intrabronchial administration. Data were analyzed in the same manner as were the intrabronchial data. The dose delivered to the lung by the nebulizer was not known and was estimated by the simulations. Simulations representing absorption of various fractions of the dose as the metabolite were generated and compared to the observed data. Figure 8 shows observed isoproterenol and 3-*O*-methylisoproterenol concentrations compared to that predicted for the absorption of 2.75 × 10^{-7} moles of aerosolized isoproterenol with and without a simulated 20% first-pass effect represented as absorption of the metabolite. An absorption rate constant of 0.12 min^{-1} was employed for both drug and metabolite. In Fig. 9, the simulated amount of drug absorbed was 1.3 × 10^{-6} moles while that of 3-*O*-methylisoproterenol was 2.5 × 10^{-7} moles (16% of the dose). The absorption rate constant for both was 0.08 min^{-1}. In both cases the incorporation of the first-pass phenomenon into the model provided simulations which matched the observed data much better than that seen when the phenomenon was not included in the model. Although this in itself is not sufficient documentation for concluding that first-pass metabolism was occurring, it does support similar findings by other investigators (7).

Lung Uptake—Lungs were homogenized and analyzed for isoproterenol and 3-*O*-methylisoproterenol. Partition coefficients were calculated for isoproterenol and the metabolite by dividing the lung concentration by the concentration in the final perfusate sample. The mean partition coefficient for isoproterenol was 1.49 ± 0.56 (n = 5), while that for the *O*-methyl metabolite was 3.79 ± 0.66 (n = 7). A plot of the amount of drug in the lung as a function of perfusate concentration for the two (Figs. 10 and 11) shows that uptake was linear over a 100-fold range of concentrations for both drug and metabolite.

DISCUSSION

The results of these studies suggest that pulmonary disposition is of little significance in the overall systemic clearance of isoproterenol when the drug is administered orally or parenterally. When administered *via* the airways, however, isoproterenol may be subject to first-pass metabolism, and the lung may play a significant role in the overall disposition of the drug.

Isoproterenol was metabolized in the lung tissue to 3-*O*-methylisoproterenol. The rate and extent of metabolism was dependent on the amount of drug administered to the lung system, and the kinetics of this process could be described by the Michaelis–Menten equation. The pulmonary clearance of the drug following intravascular administration of the lowest dose (10^{-7} moles) was ~2 ml/min. Lower doses would not be expected to be cleared much faster. Accumulation of the drug by the lung was limited, with concentrations in the lung tissue ~1.5 times those in the perfusion medium. The perfusate concentration profiles following intravascular administration displayed no discernible distribution phase, suggesting rapid equilibration of drug between the perfusate and lung tissue.

Interpretation of the data following intrabronchial and aerosol administration was complicated by the capacity-limited metabolism of isoproterenol. Reports in the literature have suggested a 30% first-pass

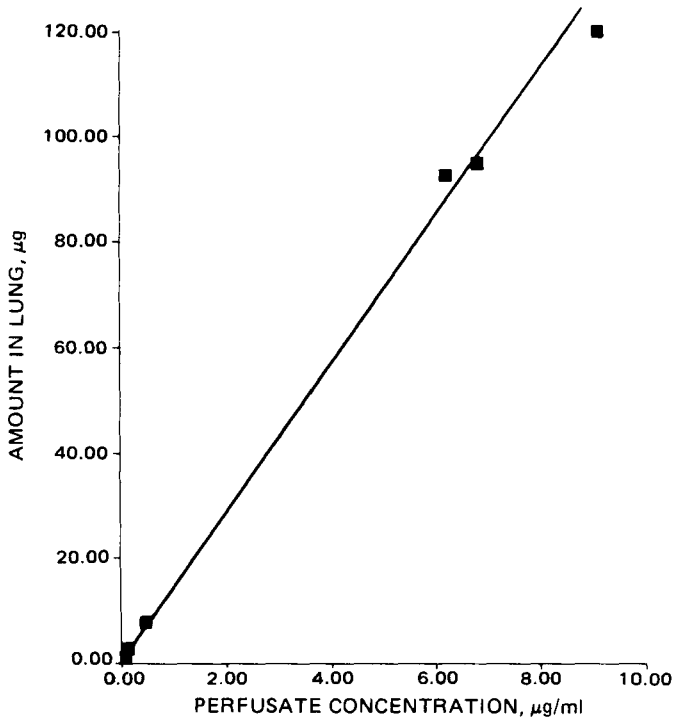

Figure 10—*Uptake of isoproterenol by the lung.*

metabolism of isoproterenol to its *O*-methyl metabolite following administration of the drug *via* the airways (7). Usual methods for evaluating first-pass metabolism (*i.e.*, *AUC* comparisons) were not applicable, as accurate estimates of infinity *AUC* values could not be obtained. As an alternative for interpreting the data, a mathematical model similar to the perfusion model described previously (9) was developed, based upon mass balance and the flow of perfusion medium through the various compartments of the isolated perfused lung system. The model described the drug and metabolite data following intravascular administration of isoproterenol.

Before the perfusion model could be modified to simulate first-pass metabolism, the nature of the first-pass effect had to be established. Two possible mechanisms for first-pass metabolism were discussed previously in a review of presystemic drug elimination (10). Postabsorptive first-pass metabolism occurs when a drug is absorbed into an eliminating organ; the fraction eliminated presystemically is equivalent to the organ extraction ratio (Cl/Q_h) following systemic administration (where Cl is the

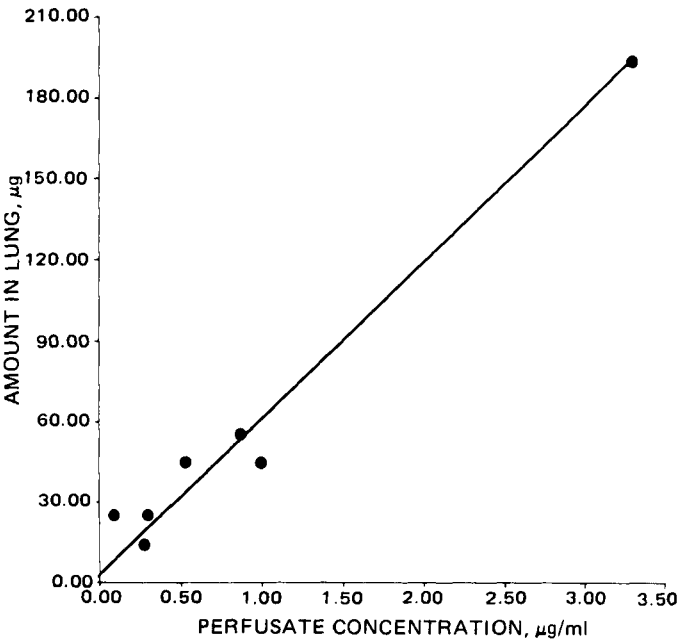

Figure 11—*Uptake of 3-O-methylisoproterenol by the lung.*

organ clearance of the drug following systemic administration, and Q_b is the flow rate through the organ). In this case the fraction of the absorbed dose reaching the circulation intact (F) is given as:

$$F = 1 - Cl/Q_b \qquad \text{(Eq. 11)}$$

Preabsorptive first-pass metabolism involves metabolism of a drug as it is absorbed into the circulation from the site of administration. In this case the fraction eliminated presystemically is not equal to the systemic extraction ratio.

The maximum pulmonary clearance of isoproterenol following systemic administration to the rabbit lung was ~2 ml/min, representing an extraction ratio of ~0.01. If only postabsorptive first-pass metabolism were occurring, this would predict that 99% of an intrabronchial or aerosol dose of isoproterenol should reach the circulation intact. If >1% first-pass metabolism occurs, as has been reported (7), preabsorptive first-pass metabolism must be involved. The preabsorptive metabolism would be observed experimentally as absorption of the metabolite into the circulation along with the parent drug. This was incorporated into the perfusion model as first-order absorption of both drug and metabolite, and various simulations with this model were compared to the experimental results following intrabronchial and aerosol administration of isoproterenol. These comparisons indicate little or no first-pass metabolism of isoproterenol following intrabronchial instillation of an aqueous solution of isoproterenol but suggest the possibility of a substantial first-pass effect when the drug was inhaled as an aerosol. The drug was also more rapidly absorbed following aerosol administration; it may be that this route of administration delivers the drug over a larger surface area in the airways than is achieved with intrabronchial administration. This may result in greater exposure of the drug to the epithelial cells of the bronchi and small airways, leading to more rapid absorption and avoiding local saturation of metabolizing capacity during absorption. This would hinder extrapolation of data following intrabronchial administration to situations involving aerosol inhalation of a drug and suggests that intrabronchial or endotracheal administration may be an inappropriate technique for studying drugs which are intended for aerosol administration.

Isolated Perfused Rabbit Lung as a Model for Intravascular and Intrabronchial Administration of Bronchodilator Drugs II: Isoproterenol Prodrugs

R. K. BRAZZELL * and H. B. KOSTENBAUDER ˣ

Received November 12, 1981, from the *College of Pharmacy, University of Kentucky, Lexington, KY 40506.* Accepted for publication January 29, 1982.

*Present address: Hoffmann-LaRoche Inc., Department of Pharmacokinetics and Biopharmaceutics, Nutley, NJ 07110.

Abstract □ The pulmonary disposition of two diester prodrugs of isoproterenol (di-*p*-toluoylisoproterenol and dipivaloylisoproterenol) was studied in the isolated perfused rabbit lung preparation. High-pressure liquid chromatographic methods were developed to measure diester, monoester, isoproterenol, and 3-*O*-methylisoproterenol from a single 1-ml perfusate sample. The prodrugs were administered directly into the circulating perfusion medium and by endotracheal instillation. Perfusate concentrations of diester, monoester, isoproterenol, and 3-*O*-methylisoproterenol were measured for 180 min. The diesters were rapidly eliminated from the perfusate with a subsequent increase in monoester concentrations. Isoproterenol levels were observed within minutes of prodrug administration, peaked at 60–80 min, and declined slowly thereafter. The prodrugs were rapidly absorbed following endotracheal administration with 30–50% of the diester being metabolized during the first pass through the lung.

Isoproterenol is a β-adrenergic agonist which is often employed in the treatment of bronchial asthma. The drug has limited oral activity because of the extensive first-pass metabolism which occurs during absorption of the drug from the GI tract (1, 2). Aerosol inhalation is the most commonly used route of administration and offers the advantages of a rapid onset of activity and delivery of the drug directly to the airways (3). The duration of action following inhalation is short, however, and frequent dosing is often required to maintain the desired effect. This can result in side effects such as cardiac stimulation, which can hinder effective therapy with the drug. Increasing the duration of action of isoproterenol would offer a significant improvement in the clinical use of the drug for the treatment of asthma.

Prodrugs have been used in the past to improve the delivery of pharmacological agents, and this approach seems feasible with isoproterenol. An inactive derivative of isoproterenol, which itself possesses more favorable physicochemical and pharmacokinetic properties than the

Isoproterenol is a β-adrenergic agonist which is often employed in the treatment of bronchial asthma. The drug has limited oral activity because of the extensive first-pass metabolism which occurs during absorption of the drug from the GI tract (1, 2). Aerosol inhalation is the most commonly used route of administration and offers the advantages of a rapid onset of activity and delivery of the drug directly to the airways (3). The duration of action following inhalation is short, however, and frequent dosing is often required to maintain the desired effect. This can result in side effects such as cardiac stimulation, which can hinder effective therapy with the drug. Increasing the duration of action of isoproterenol would offer a significant improvement in the clinical use of the drug for the treatment of asthma.

Prodrugs have been used in the past to improve the delivery of pharmacological agents, and this approach seems feasible with isoproterenol. An inactive derivative of isoproterenol, which itself possesses more favorable physicochemical and pharmacokinetic properties than the

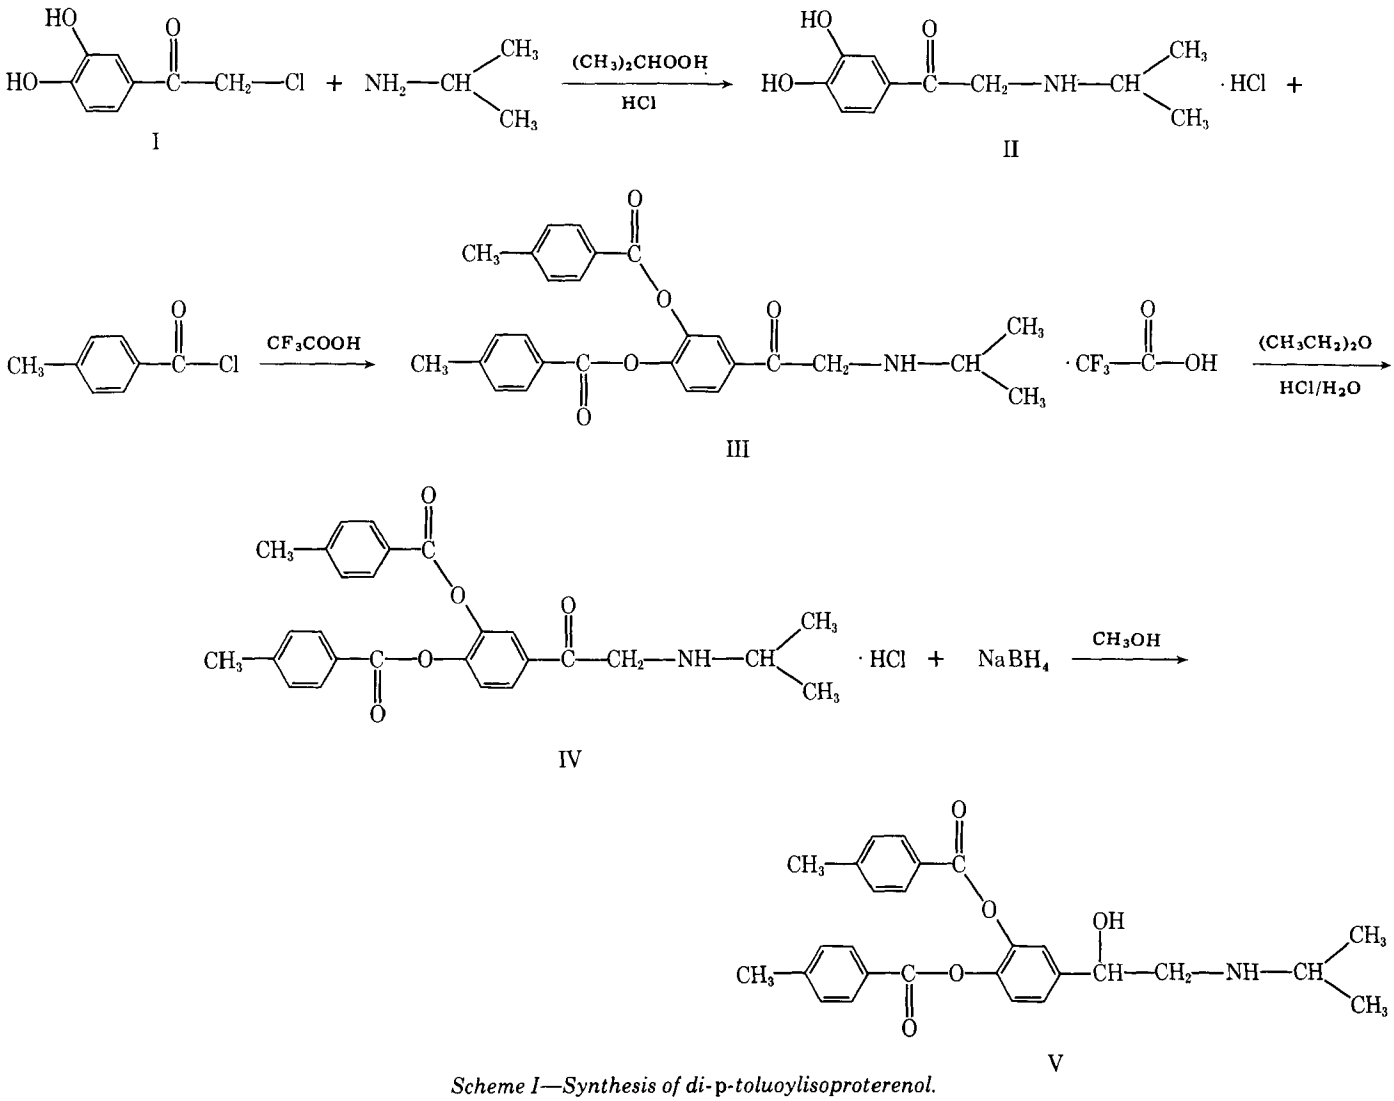

Scheme I—Synthesis of di-p-toluoylisoproterenol.

parent drug, and which would be converted to the active compound in the body, could provide a mechanism for improving the efficacy of the drug while eliminating some of its problems. Esterifying the phenolic hydroxyl groups of isoproterenol is a practical approach as these functionalities are involved in the metabolism and chemical degradation of the drug. Esterases capable of hydrolyzing these esters are distributed throughout the body and have been demonstrated in the lung tissue itself (4–6). The rate of hydrolysis of the ester could be controlled somewhat by the choice of the ester moiety (7–9); a slowly hydrolyzed hydrophobic ester might be taken up extensively by the lung tissue with subsequent slow release of the parent compound, resulting in a prolonged bronchodilating effect.

The present report details the preliminary evaluation of two prodrugs of isoproterenol, di-*p*-toluoylisoproterenol and dipivaloylisoproterenol. The absorption, uptake, and metabolism of these two drugs by the isolated perfused rabbit lung system were evaluated following their administration into the circulation of the system and into the airways of the lung. Disposition of isoproterenol in the isolated perfused rabbit lung has been discussed previously (10). The drug was converted to its *O*-methyl metabolite in the lung by a dose-dependent process. Uptake of the drug by the lung tissue, however, was linear over a 100-fold concentration range. A physiological pharmacokinetic perfusion model was developed to describe the disposition of isoproterenol and 3-*O*-methylisoproterenol by the isolated lung system, and a similar model is used in the evaluation of the data from this investigation.

EXPERIMENTAL

Di-*p*-toluoylisoproterenol—Synthetic procedures were modeled after published methods for preparation of esters of isoproterenol (7) and *N-tert*-butylarterenol (9). The overall reaction scheme is shown in Scheme I.

3,4-Dihydroxy-α-(isopropylamino)acetophenone Hydrochloride—A mixture of 37.5 g (0.2 mole) α-chloro-3′,4′-dihydroxyacetophenone[1] (I), 125 ml of isopropyl alcohol, and 60 ml of isopropylamine was slowly heated to 75° and maintained at that temperature for 5 min. While cooling, the mixture was acidified with hydrochloric acid. The hydrochloride salt was precipitated by the addition of 400 ml of acetone and overnight refrigeration. The filtered product (II) was slurried with 100 ml of acetone, filtered, and dried to yield 21.2 g (43%) of II, mp 239–242°.

3,4-Di-*p*-toluoyl-α-(isopropylamino)acetophenone Hydrochloride—Twenty grams of II was suspended in 60 ml of trifluoroacetic acid, and 35 ml of *p*-toluoyl chloride was added slowly, with stirring, over a period of 20 min. The mixture was heated slowly to 80° and held at that

temperature for 75 min. Most of the solvent was evaporated *in vacuo* and the residue stirred with 400 ml of ether and refrigerated. Filtration yielded 40 g of III. Compound III was partitioned between ether and water and made basic with sodium hydroxide. The ether layer was removed and 40 ml of 20% HCl was added slowly with constant stirring. The crystalline product that precipitated was filtered, dried, and recrystallized from isopropyl acetate–methanol (9:1) to yield 20 g of IV, mp 198–202°.

Di-*p*-toluoylisoproterenol (V)—A cold solution of 0.5 g of sodium borohydride in methanol was added to 5 g of IV in 25 ml of methanol over a 1-hr period in an ice bath. Most of the solvent was evaporated *in vacuo* and the residue was suspended in 20 ml of isopropyl acetate. This mixture was rapidly stirred and 25 ml of 10% sodium bicarbonate (pH 10.5) was slowly added. The organic layer was separated and dried over magnesium sulfate. The solution was partially concentrated *in vacuo* and refrigerated. The precipitated product was filtered and dried to yield 2 g (40%) of di-*p*-toluoyl isoproterenol (V), mp 110–111°.

cipitated product was filtered and dried to yield 2 g (40%) of di-*p*-toluoyl isoproterenol (V), mp 110–111°.

Anal.—Calc. for $C_{27}H_{29}NO_5$: C, 72.48; H, 6.48; N, 3.13; O, 17.89. Found: C, 72.49; H, 6.4; N, 3.12; O, 17.6. NMR (CD_3COCD_3): δ 6.9–8.3 (m, 11, aromatic); δ 4.5–4.9 (s, 1, —CHO*H*); δ 2.5–3.2 (m, 5, —CH_2—N*H*—CH_2—); δ 2.2–2.5 (s, 6, p-methyl); δ 0.9–1.2 [d, 6, —CH—(CH_3)$_2$]. The UV spectrum displayed a maximum of 245 nm with a molar absorptivity of 3.4×10^{-4} liters/mole/cm.

Isolated Perfused Rabbit Lung—Details of the perfusion technique have been described in detail in previous reports (10–12). Krebs-Ringer bicarbonate solution with 4.5% bovine serum albumin was used as the perfusion medium. Di-*p*-toluoylisoproterenol and dipivaloylisoproterenol were administered to the system by intravascular and intrabronchial administration. Doses of 10^{-5} and 5×10^{-5} moles of the two drugs were administered intravascularly as aqueous solutions added to the perfusion medium in the upper reservoir of the lung system. Intrabronchial administration of 5×10^{-6} and 10^{-5} moles of di-*p*-toluoylisoproterenol and 10^{-5} moles of dipivaloylisoproterenol was accomplished by delivering

250-μl aliquots of drug solution into the airways *via* a small polytef tube attached to a 1-ml syringe. Dipivaloylisoproterenol was dissolved in isotonic saline while di-*p*-toluoylisoproterenol was dissolved in saline which had been adjusted to pH 4.0 with hydrochloric acid.

Analysis—The perfusate concentrations of diester (di-*p*-toluoylisoproterenol or dipivaloylisoproterenol[2]), the corresponding monoester, isoproterenol, and 3-*O*-methylisoproterenol[3] were measured by high-pressure liquid chromatography (HPLC). The compounds were separated on a strong cation exchange column[4] and detected with a variable-wavelength UV detector[5]. Differences in physicochemical properties prevented the extraction of the four compounds with one procedure, and a double extraction technique was developed.

The same extraction procedure was used for both prodrugs. Samples were thawed to room temperature and 10 ml of methylene chloride containing codeine phosphate (internal standard) was added; this was vortexed for 1 min and centrifuged. The aqueous layer (750 μl) was transferred to a 15-ml culture tube and 100 μl of 1% ascorbic acid was added. This was stored at −20° and later analyzed for isoproterenol. The organic phase was evaporated under nitrogen, the residue reconstituted with 100 μl of methanol, and an aliquot was injected onto the HPLC system to measure the concentrations of the diester along with the monoester and 3-*O*-methylisoproterenol.

The 750-μl aqueous aliquot was thawed and 1 ml of 0.1 *N* acetate buffer (pH 4.0) containing morphine hydrochloride (internal standard) was added followed by 3 ml of 5% diethylhexyl phosphoric acid in ether. This was vortexed and centrifuged and the ether layer was transferred to a centrifuge tube; 100 μl of 1 *N* HCl containing 1% ascorbic acid was added, the mixture was vortexed and centrifuged, and a 10–50-μl aliquot was injected onto the HPLC system to measure isoproterenol.

Separation of di-*p*-toluoylisoproterenol, the monotoluoyl ester, isoproterenol, 3-*O*-methylisoproterenol, and codeine and morphine (internal standards) was accomplished with a strong cation exchange column and a mobile phase of 0.03 *M* KH_2PO_4 with 25% methanol and a final pH of 3.0. Flow rate was 2.5 ml/min and detection was at 220 nm. Aliquots

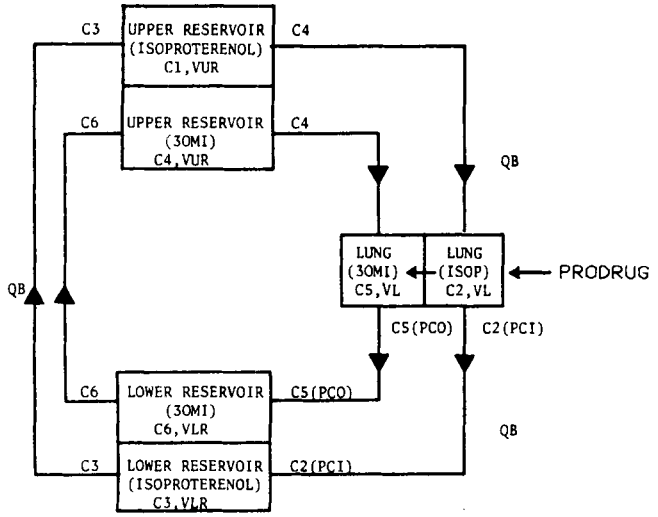

Figure 5—*Flow model used to describe the disposition of isoproterenol and 3-O-methylisoproterenol by the isolated perfused rabbit lung following administration of the diester prodrugs.*

(10–50 μl) from the methylene chloride extractions were injected onto this system to quantitate the diester, monoester, and 3-*O*-methylisoproterenol while aliquots (10–50 μl) from the diethylhexyl phosphoric acid extractions were injected to measure isoproterenol. This procedure provided adequate sensitivity for the monoester, isoproterenol, and 3-*O*-methylisoproterenol but was not capable of measuring diester concentrations <0.1 μg/ml. When diester concentrations below this limit were encountered, the methylene chloride extraction aliquots were also analyzed with an alternate chromatographic system utilizing a mobile phase of 0.04 *M* KH_2PO_4 with 20% acetonitrile and a final pH of 3.0 pumped through the cation exchange column at 3.0 ml/min with 250-nm detection. This provided sensitivity for the diester down to 0.01 μg/ml. Sample chromatograms are shown in Fig. 1.

A similar procedure was used for measuring dipivaloylisoproterenol. A cation exchange column was used; the mobile phase consisted of 0.01 *M* KH_2PO_4 with 10% methanol (pH 3.0) pumped at 2.5 ml/min with 220-nm detection. This system was used for measuring the monoester, isoproterenol, 3-*O*-methylisoproterenol, and concentrations of dipivaloylisoproterenol exceeding 0.5 μg/ml. The alternate system used to measure dipivalylisoproterenol concentrations <0.5 μg/ml also employed the cation exchange column with 0.045 *M* KH_2PO_4 with 20% methanol (pH 3.0) at a flow rate of 2.5 ml/min and 220-nm detection. Sample chromatograms are presented in Fig. 2.

For standard curves, the monoesters of di-*p*-toluoylisoproterenol and dipivaloylisoproterenol were produced by hydrolysis of the diesters in deoxygenated 1 *N* HCl containing 5% ascorbic acid as an antioxidant. Hydrolysis was relatively slow under these conditions and appreciable amounts of monoester could be produced while maintaining measurable amounts of the diester and isoproterenol by heating the solutions for 12–24 hr protected from light and air. These solutions were injected onto one of the previously described HPLC systems, and the concentrations of the diester and isoproterenol were determined by comparing their response to calibration curves prepared for the two compounds. Using the amounts of these two compounds and the diester initially added, the amount of monoester present in the solutions was determined using mass balance calculations.

Aliquots of these solutions were added to fresh blank perfusate samples along with equivalent volumes of 1 *N* NaOH such that the final perfusate sample volume was 1 ml. To each sample, 100 μl of 1 *M* phosphate buffer (pH 7.4) with 1% ascorbic acid was added. These samples were assayed in the manner described for the unknown samples. Standard curves for the diester, isoproterenol, and 3-*O*-methylisoproterenol were also generated. Peak heights were measured manually and the concentration *versus* peak height ratio of each compound to internal standard were fitted to a linear regression line. Correlation coefficients ≥0.98 were obtained using these methods. Standard curves for all compounds were produced on each day that samples were analyzed.

Care was taken in the storage, processing, and analysis of samples to minimize hydrolysis of the esters during this time. Small amounts of monoester and isoproterenol were observed in some diester standard perfusate samples processed in the same manner as the unknown samples, but these amounts never exceeded 5%.

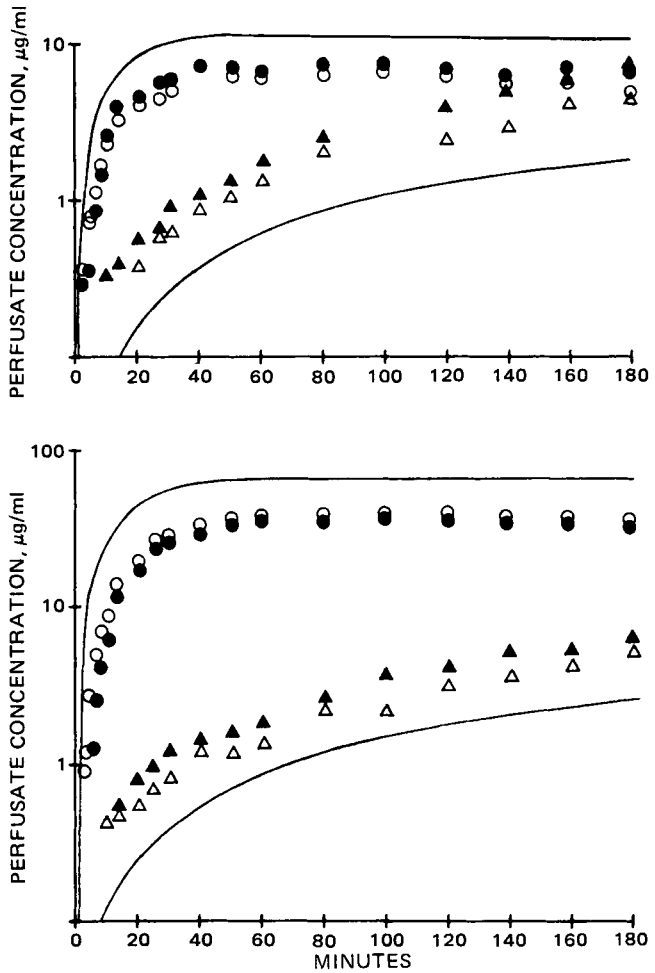

Figure 6—*Comparisons of observed concentrations to those predicted by the flow model for the intravascular administration of 10^{-5} moles of di-p-toluoylisoproterenol and dipivaloylisoproterenol (upper) and 5×10^{-5} moles of di-p-toluoylisoproterenol and dipivaloylisoproterenol (lower). Open symbols represent data from di-p-toluoylisoproterenol experiments, while closed symbols represent data from dipivalylisoproterenol experiments. Key: (○,●) isoproterenol; (△,▲) 3-O-methylisoproterenol.*

RESULTS AND DISCUSSION

Initial Studies—Preliminary studies involved administration of 10^{-5}-mole doses of dipivaloylisoproterenol and di-*p*-toluoylisoproterenol into the circulation of the isolated lung system. In each experiment, samples were withdrawn periodically from the upper reservoir and assayed for the prodrug, isoproterenol, and 3-*O*-methylisoproterenol. Both prodrugs were rapidly cleared from the perfusion medium, and in both cases isoproterenol appeared within 4–6 min. Following administration of each diester, an unidentified chromatographic peak was observed on the early sample chromatograms which eluted between 3-*O*-methylisoproterenol and the diester.

The peak height ratio *versus* time profile of this unknown component was suggestive of a monoester intermediate formed during the hydrolysis of the diester. The chromatographic behavior of this component under various conditions was identical to a similar component observed in partially hydrolyzed aqueous solutions of the corresponding diester. Earlier spectral kinetic studies with dipivaloylisoproterenol in diluted serum solutions had suggested the possibility of an intermediate in the hydrolysis of the diester[6].

These analytical comparisons help substantiate the presence of the monoester in the lung perfusate after administration of the prodrug, and chromatographic procedures were developed to separate and quantitate this compound in the perfusate samples.

Intravascular Administration—Dipivaloylisoproterenol and di-

[6] Unpublished data.

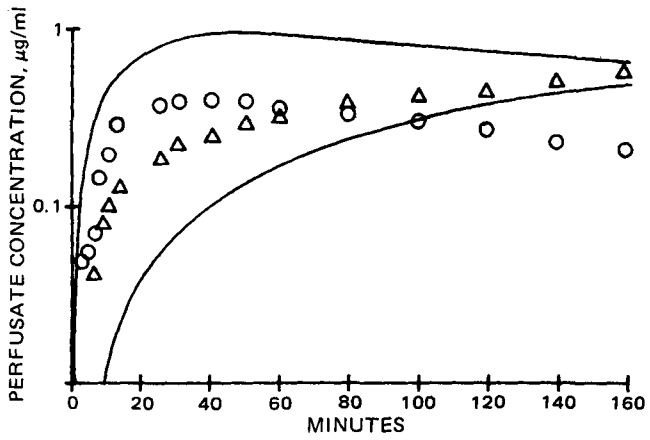

Figure 7—*Comparison of observed concentrations to those predicted by the flow model of the intravascular administration of 10^{-6} moles of di-p-toluoylisoproterenol to the isolated perfused rabbit lung. Key: (○) isoproterenol; (△) 3-O-methylisoproterenol.*

p-toluoylisoproterenol were administered to the circulation of the isolated lung system at 10^{-5}- and 5×10^{-5}-mole doses. Perfusate concentrations of diester, monoester, isoproterenol, and 3-*O*-methylisoproterenol were measured periodically for 180 min. A 10^{-6}-mole dose was also administered, but only isoproterenol and 3-*O*-methylisoproterenol were measured. The perfusate concentration–time profiles generated from these experiments are presented in Figs. 3 and 4.

Both diesters were rapidly cleared from the perfusion medium following their administration directly into the circulation. At the two 10^{-5}-mole doses, the clearance of di-*p*-toluoylisoproterenol was 92 and 106 ml/min, while that for dipivaloylisoproterenol was 59 and 89 ml/min. The diester perfusate concentration–time data were fitted best with a triexponential equation. The two initial rapid phases were barely distinguished from one another, but a slow terminal phase was observed for both diesters at very low concentrations. Detectable concentrations of the monoester intermediates were observed within 2–4 min of drug administration, indicating rapid uptake and hydrolysis of the diesters. Peak monoester concentrations occurred at 6–8 min. Isoproterenol appeared in the circulation within 6 min of prodrug administration but its elimination was very slow, as was the appearance of 3-*O*-methylisoproterenol. The perfusate concentration–time profiles of the four compounds of interest from the intravascular studies were initially fitted with complex compartmental pharmacokinetic models; the concentration–time profiles predicted from the curve fitting are represented by the solid lines in Figs. 3 and 4.

These models were successful in describing the data but provided little useful information about the disposition of these prodrugs. The limited number of experiments performed minimized the amount of pharmacokinetic information obtained, but the use of a physiologically based flow model provides some basic information concerning the disposition of isoproterenol following prodrug administration.

Perfusion Model Analysis—The perfusion model had been developed previously to describe the disposition of isoproterenol and 3-*O*-methylisoproterenol in the isolated perfused rabbit lung and was discussed previously (10). A similar model was used to evaluate the isoproterenol and 3-*O*-methylisoproterenol data resulting from the prodrug administrations (Fig. 5). Appearance of isoproterenol in the circulation of the lung system was modeled as a first-order release of the drug (from the prodrug) into the lung tissue with instantaneous partitioning into the perfusion medium. The parameters utilized to describe the model were, for the most part, identical to those described previously (10). An average lung volume of 11.7 ml and a rate constant for the appearance of isoproterenol of 0.05 min^{-1} were employed. The isoproterenol and 3-*O*-methylisoproterenol perfusate concentration–time profiles predicted by the perfusion model simulations are shown in Fig. 6 (5×10^{-5}- and 10^{-5}-mole doses) and Fig. 7 (10^{-6}-mole dose) along with the observed data.

These comparisons illustrate consistent disagreement between the observed and predicted data; the observed isoproterenol concentrations were lower than the predicted values, whereas the observed 3-*O*-methylisoproterenol concentrations were higher than those predicted by the model. This suggests that the disposition of isoproterenol is altered when the drug is delivered into the tissue *via* a prodrug. This might result from penetration of the more lipophilic prodrug into tissues to which isoproterenol does not penetrate.

Intrabronchial Administration—Solutions of the prodrugs in saline were instilled into the airways of the isolated lung; the upper reservoir was sampled periodically and perfusate concentrations of the diester, monoester, isoproterenol, and 3-*O*-methylisoproterenol were measured. Di-*p*-toluoylisoproterenol was administered at doses of 10^{-5} and 5×10^{-6} moles while dipivaloylisoproterenol was given at 10^{-5}-mole doses. In some studies, samples were initially collected at 15-sec intervals to characterize the absorption of the diester. The perfusate concentration–time profiles from these experiments are presented in Figs. 8 and 9.

Absorption of both prodrugs from the airways was quite rapid, with maximum concentrations of the intact diesters observed at ~2 min. Feathering the diester perfusate concentration–time curves yielded absorption rate constants of 1.4 min^{-1} and 0.9 min^{-1} for dipivaloylisoproterenol and di-*p*-toluoylisoproterenol, respectively, suggesting that absorption is virtually complete within 5 min. The subsequent metabolic profiles were quite similar to those following intravascular administration, except that the diester concentrations following intrabronchial administration were somewhat lower. Isoproterenol and 3-O-methylisoproterenol concentrations, however, were comparable to those following intravascular administration, and mass balance calculations suggest that most of the administered dose was absorbed.

A comparison of the apparent clearances of the diesters following in-

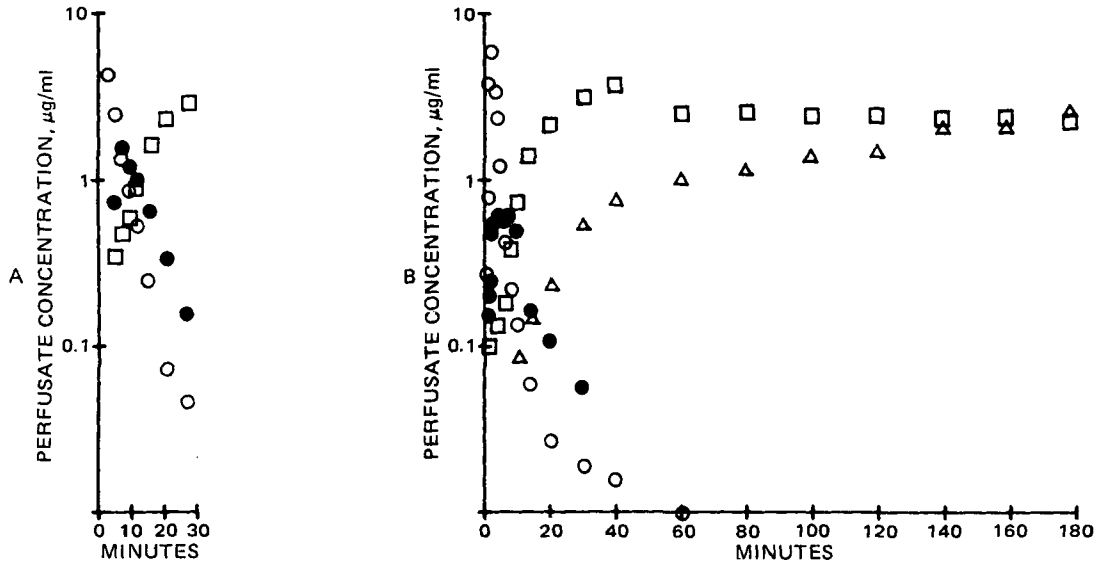

Figure 8—*Perfusate concentrations following the endotracheal instillation of 10^{-5} moles of di-p-toluoylisoproterenol (A) and 5×10^{-6} moles of di-p-toluoylisoproterenol (B). Key: (○) di-p-toluoylisoproterenol; (●) mono-p-toluoylisoproterenol; (□) isoproterenol; (△) 3-O-methylisoprotrenol.*

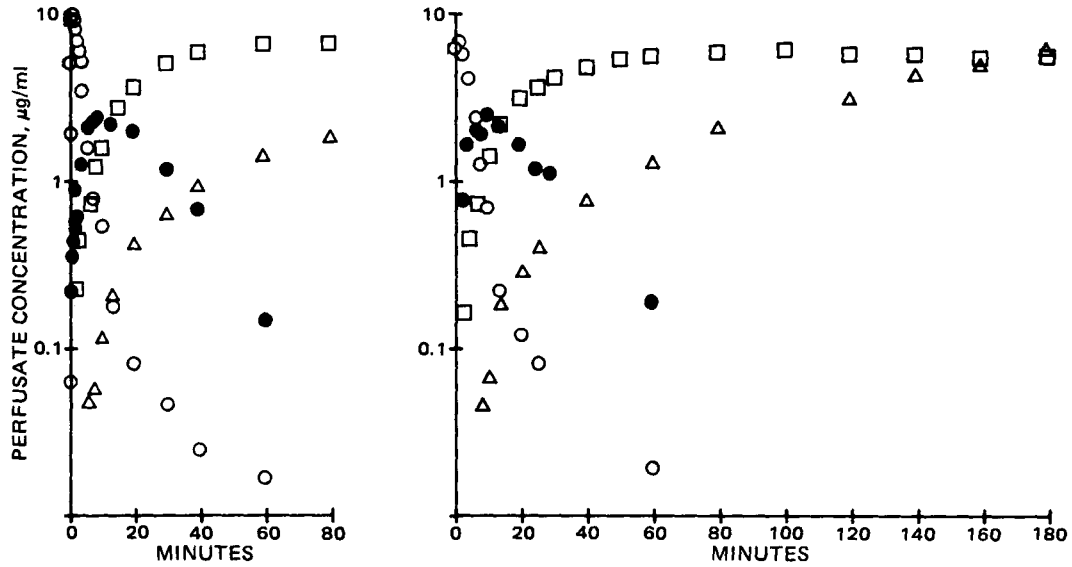

Figure 9—*Perfusate concentrations following the endotracheal instillation of two 10^{-5}-mole doses of dipivaloylisoproterenol. Key: (○) dipivaloylisoproterenol; (●) monopivalylisoproterenol; (□) isoproterenol; (△) 3-O-methylisoproterenol.*

trabronchial administration (172–203 ml/min for di-*p*-toluoylisoproterenol and 96–102 ml/min for dipivaloylisoproterenol) with those following intravascular administration (92–106 ml/min for di-*p*-toluoylisoproterenol and 59–89 ml/min for dipivaloylisoproterenol) suggests that a substantial portion of the intrabronchial dose does not reach the circulation as intact diester. From the data it appears that only ~50% of the di-*p*-toluoylisoproterenol and 75% of the dipivaloylisoproterenol reached the circulation intact after intrabronchial administration. This suggests that first-pass metabolism of the diesters following intrabronchial administration likely involves hydrolysis of the diester to the corresponding monoester (or isoproterenol) during the passage of the diester from the site of absorption to the systemic circulation. This possibility is consistent with the diester perfusate concentration data following intravascular administration to the lung from which an extraction ratio of 0.67 for di-*p*-toluoylisoproterenol and 0.5 for dipivaloylisoproterenol was calculated.

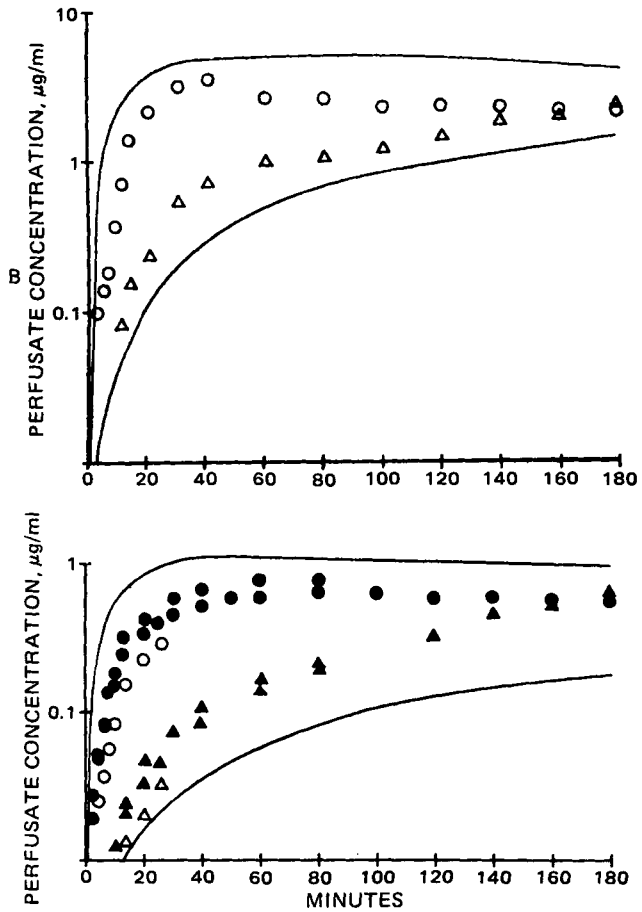

Figure 10—*Comparisons of observed concentrations to those predicted by the flow model for the intrabronchial administration of 10^{-5} moles of di-p-toluoylisoproterenol and dipivaloylisoproterenol (upper) and 5×10^{-6} moles of di-p-toluoylisoproterenol (lower). Key: (○,●) isoproterenol; (△,▲) 3-O-methylisoproterenol.*

The isoproterenol and 3-*O*-methylisoproterenol perfusate concentration data from the intrabronchial experiments were compared with perfusion model predictions in the same manner as the intravascular data. These comparisons are presented in Fig. 10 and exhibit a pattern very similar to that seen with intravascular data. Isoproterenol concentrations were lower than predicted, whereas 3-*O*-methylisoproterenol concentrations were higher, again suggesting that the disposition of isoproterenol by the lung was altered when the drug was administered as a prodrug.

Diester prodrugs of sympathomimetic amines have been suggested to increase the potency and duration of action of these drugs. Bitolterol, the di-*p*-toluate ester of *N*-*tert*-butylarterenol, has been studied rather extensively (13–15). This compound is very similar in structure to di-*p*-toluoylisoproterenol, and the disposition of the two might be expected to be similar. When administered to humans by aerosol inhalation, bitolterol displayed a 5-hr duration of activity compared with 1 hr for the parent compound (15). This has been attributed to uptake of the intact diester by the lung followed by slow release and subsequent hydrolysis to *N*-*tert*-butylarterenol, an active β_2 adrenoceptor agonist (14). Studies with dipivaloylisoproterenol and di-*p*-toluoylisoproterenol were designed to determine if these prodrugs exhibited a similar pattern.

These results suggest that the isoproterenol prodrugs do not accumulate to a great extent in the lung tissue and do not support the assumption that the prolonged activity of similar prodrugs is related to accumulation in the lung. Both dipivalylisoproterenol and di-*p*-toluoylisoproterenol were rapidly taken up by the lung but were quickly hydrolyzed, first to monoesters and then to active drug. The monoesters appeared in the circulation in appreciable concentrations and under normal conditions, *i.e.*, in the whole body, most of this intermediate would be swept away into the general circulation. These results do not explain the prolonged activity displayed by bitolterol and suggest the need for further studies in this area.

NOTES

An Improved High-Pressure Liquid Chromatographic Assay for Secobarbital in Serum

H. L. LEVINE *‡, M. E. COHEN §, P. K. DUFFNER§, K. A. KUSTAS *, and D. D. SHEN *x

Received July 22, 1981, from the **Department of Pharmaceutics, School of Pharmacy*, and the §*Department of Neurology, School of Medicine, State University of New York at Buffalo, Buffalo, NY 14260.* Accepted for Publication January 12, 1982. ‡Present address: Department of Clinical Pharmacy, School of Pharmacy, Duquesne University, Pittsburgh, PA 15219.

Abstract □ A high-pressure liquid chromatographic method for the analysis of secobarbital in serum was developed. Secobarbital was extracted from buffered serum (pH 5.5) with a solvent mix of hexane–ether–*n*-propanol. 5-(4-Methylphenyl)-5-phenylhydantoin was added as an internal standard. Separation of secobarbital and internal standard from serum constituents and other drugs was achieved on a 5-μm C-18 reversed-phase column using an acetonitrile–phosphate buffer (pH 4.4) mobile phase. The eluent was monitored at 195 nm. The sensitivity limit of the assay was ~0.02 μg/ml with 0.5 ml of serum sample. The application of this method to pharmacokinetic studies in pediatric patients was demonstrated.

Keyphrases □ Secobarbital—high-pressure liquid chromatographic assay in human serum, anticonvulsants, pharmacokinetics □ High-pressure liquid chromatography—secobarbital, anticonvulsant, pharmacokinetics, human serum □ Anticonvulsants—secobarbital, high-pressure liquid chromatographic assay in human serum, pharmacokinetics □ Pharmacokinetics—secobarbital, high-pressure liquid chromatographic assay in human serum, anticonvulsant

Secobarbital is used primarily as a hypnotic agent. Like many other barbiturates, when administered in anesthetic doses it is an effective anticonvulsant (1). Rectal secobarbital is prescribed for the emergency home treatment of prolonged seizures in poorly controlled epileptic children (2). In an attempt to study the bioavailability of rectally administered secobarbital in pediatric patients, a sensitive method for quantitating the drug in serum was required.

A number of analytical procedures for determining secobarbital in serum have been described in the literature. These include spectrophotometry (3), gas-liquid chromatography (GLC) (4–8), and high-pressure liquid chromatography (HPLC) (9, 10). However, many of these existing procedures are aimed at detecting high concentrations (>5 μg/ml) of secobarbital for screening purposes related to drug abuse. The more sensitive methods such as GLC with electron capture detection require tedious sample clean up and derivatization procedure prior to analysis. Also, with many of these methods, the problem of interference from other drugs and their metabolites in serum has not been evaluated. This report describes an improved HPLC method that permits the determination of submicrogram quantities of secobarbital in small volumes of serum in the presence of various antiepileptic drugs.

EXPERIMENTAL

Reagents and Chemicals—Secobarbital[1] and 5-(4-methylphenyl)-5-phenylhydantoin[2] (internal standard) were used as supplied. The solvents used for extraction and chromatography were all of HPLC grade[3,4]. All chemicals were of analytical reagent grade.

A stock solution of sodium secobarbital (120 μg/ml) and the internal standard (7 μg/ml) were prepared in water. The phosphate buffer component of the mobile phase was prepared by adding 300 μl of 1.0 *M* KH_2PO_4 and 50 μl of 0.9 *M* H_3PO_4 to 1800 ml of water (pH 4.4). For the extraction procedure, a pH 5.5 acetate buffer consisting of 0.01 *M* sodium acetate–0.01 *M* acetic acid (88.5:11.5, v/v) was prepared.

Apparatus and Operating Conditions—The liquid chromatograph consisted of a constant flow pump[5], a variable volume sampling valve[6], and a variable wavelength detector[7]. A 4.6-mm × 25-cm column packed with 5 μm of microporous silica chemically bonded with octadecylsilane was obtained from a commercial source[8]. The mobile phase consisting of 28% acetonitrile and 72% pH 4.4 phosphate buffer (v/v) was filtered[9]

and degassed before use. The column was heated to 50° and the eluting solvent was pumped through the column at a flow rate of 2.8 ml/min with precolumn pressure of ~2800 psi. The column effluent was monitored at 195 nm.

Extraction—Extraction of serum samples was carried out in 15 glass centrifuge tubes sealed with polytef-lined screw caps. One milliliter of the acetate buffer and 50 μl of internal standard solution were added to 0.5 ml of serum. The mixture was agitated in a vortex mixer for 10 sec, followed by gentle shaking with 5 ml of hexane–ether–n-propanol (49:49:2, v/v/v) for 20 min. The organic and aqueous phases were separated by centrifugation at 1000×g for 5 min. The upper organic layer was transferred to a 1.5-ml polypropylene microcentrifuge tube[10]. The aqueous layer was reextracted with another 5-ml aliquot of the hexane–ether–n-propanol mixture. The second organic phase aliquot was pooled with the first and evaporated to dryness under nitrogen in a water bath at 50°. The residue was reconstituted in 300 μl of mobile phase and 50–100 μl was injected onto the column.

Standard Curves—Standardization samples were prepared by spiking blank serum (0.5 ml) with 50-μl aliquots of various dilutions of secobarbital stock solution to yield a concentration range between 0.022 and 4.4 μg/ml. Standard curves were constructed by plotting peak height ratios (secobarbital–internal standard) against the corresponding secobarbital concentration.

RESULTS AND DISCUSSION

Figure 1 shows typical chromatograms of serum samples from a pediatric patient before and after a single 5-mg/kg rectal dose of secobarbital. The drug and its internal standard were eluted at 8.5 ± 0.5 and 11.5 ± 0.7 min, respectively, under the described chromatographic conditions. Extraction recovery was evaluated by analyzing spiked serum samples. In these experiments, internal standard was added after transfer of organic phases to reduce error due to injection and chromatography. The extraction yield from serum was nearly complete and reasonably consistent (85–95%) over the chosen concentration range (0–4.4 μg/ml).

The detection limit with a 0.5-ml sample was ~0.02 μg/ml. This limit corresponded to a serum concentration that yields a peak height with a signal to noise ratio of at least 4.

Linear calibration curves were observed over the 0–4.4 μg/ml range. Calibration data obtained on six separate days are summarized in Table I. Precision was assessed by estimating the variations on normalized peak height ratios (*i.e.*, peak height ratios of each standard divided by the corresponding secobarbital concentration) (11). The coefficient of variation varied from 2.1 to 7.0%. Within-day reproducibility was also evaluated by replicate analysis of a 1.1-μg/ml serum standard. The coefficient of variation was 4.2% (n = 9). The day-to-day precision data are shown in Table II. The range of coefficient of variation for the eight concentrations was 0.3–9.7%.

Interference from endogenous materials and other drugs posed a major problem during the development of this assay. To attain good sensitivity, the loss of drug during sample preparation must be minimized. Precipitation of serum proteins with acetonitrile followed by direct injection of

Secobarbital	8.5
5-(4-methylphenyl)-5-phenylhydantoin[b]	11.4

[a] Anticonvulsants that are either not detectable or not extracted include valproic acid, clonazepam, diazepam, chlorazepate, and thioridazine. [b] Internal standard.

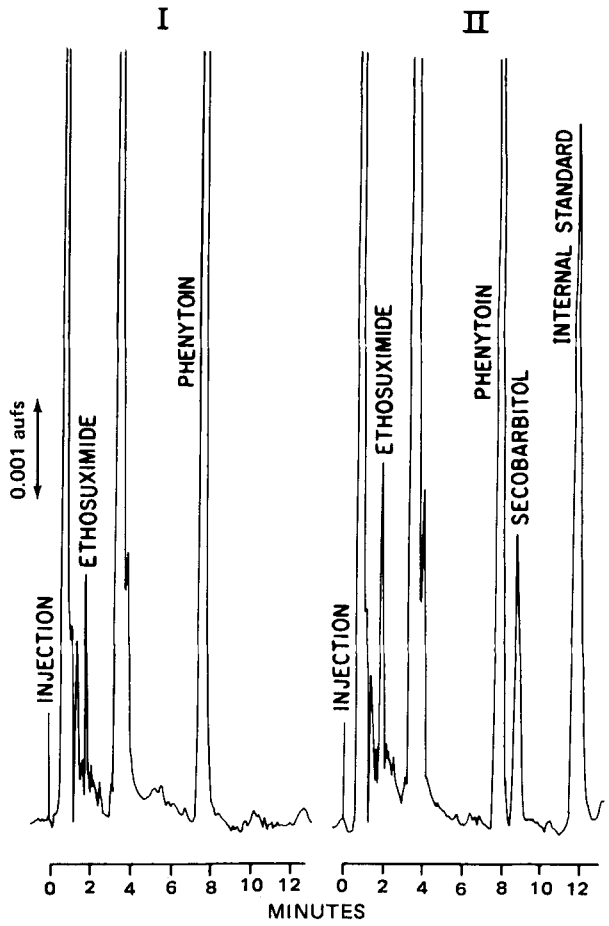

Figure 1—*Chromatogram of 0.5-ml serum extracts from a patient immediately before (I) and 90 min after (II) rectal administration of a 120-mg dose of secobarbital. The extract was reconstituted in 300 μl of eluting solvent; 50 μl was injected. The patient was a 7-year-old boy weighing 23 kg. The serum concentration of secobarbital was 0.447 μg/ml. The patient was also receiving phenytoin, ethosuximide, and clonazepam at the time of study. The observed peaks for ethosuximide and phenytoin represent serum drug concentrations of 20 and 21 μg/ml, respectively. Note the baseline separation between the secobarbital and phenytoin peaks.*

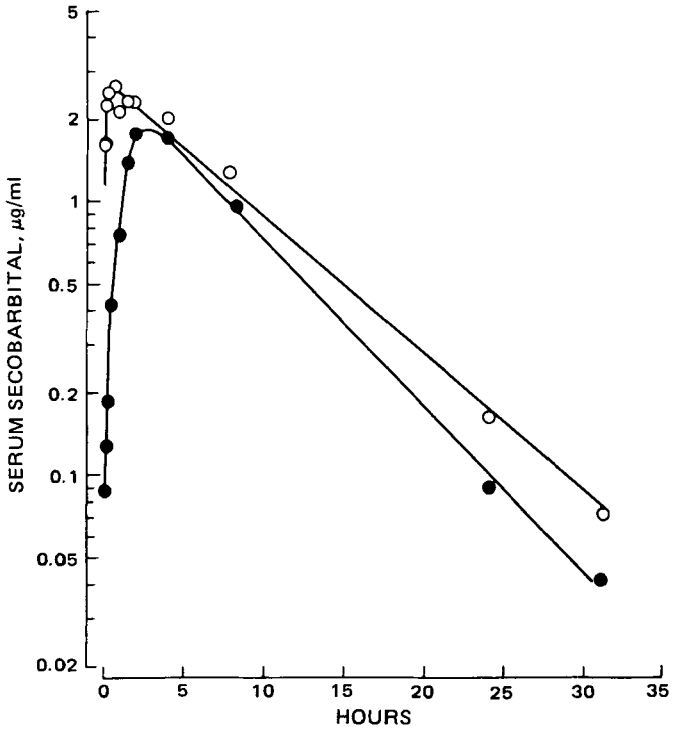

Figure 2—*Serum concentration–time course of secobarbital following separate rectal administration of a solution (○) and a suppository (●) to two 5-year-old female epileptic children with respective body weights of 17 and 19 kg.*

supernatant on the column as suggested previously (9) did produce a high recovery yield, but interference from serum constituents was observed on the chromatograms of blank samples from some patients. The problem was readily overcome by solvent extraction with hexane–ether–*n*-propranol, which provided good recovery with no interference seen in serum blanks. The extraction procedure is relatively simple, and up to 40 samples can be processed in ~1 hr.

Reversed-phase chromatography was chosen because of its versatility in separating compounds over a wide spectrum of polarity. A 10-μm reversed-phase octadecylsilane column[11] was used. Both phenytoin and carbamazepine, which coextracted with secobarbital, were eluted sufficiently close to secobarbital to hamper detection at low concentration limits. Although carbamazepine as a base can be eliminated by acid wash or back extraction, these procedures would not remove phenytoin. Also, multiple extractions reduced the recovery of secobarbital. Separation of secobarbital was achieved from both phenytoin and carbamazepine by an addition of a small quantity of tetrahydrofuran (1–2%) to the mobile phase (12). Unfortunately, this also resulted in an unstable baseline at the highest sensitivity setting (*i.e.*, 0.01 aufs) on a detector. This is probably due to the high absorptivity of tetrahydrofuran at 195 nm.

[11] μBondapak C-18, Waters Associates, Milford, Mass.

Complete resolution of secobarbital from the interfering drugs was achieved when a high-efficiency 5-μm C-18 reversed-phase column was employed. The chromatograms, as shown in Fig. 1, are taken from a patient receiving high doses of phenytoin (serum phenytoin concentration of 21 μg/ml). The phenytoin and secobarbital peaks were clearly separated.

Table III compares the retention times of secobarbital to those anticonvulsants that are detectable in our chromatographic system.

As an illustration of the applicability of our assay procedure to a single-dose pharmacokinetic study, the serum concentration–time course after rectal administration of a 5-mg/kg dose of sodium secobarbital in solution[12] and by suppository[13] in two age and weight matched epileptic children is shown in Fig. 2. The rate of absorption of secobarbital from the fatty base suppository was much slower as compared with that from the solution. Peak serum concentration was not reached until 3–4 hr after administration of the suppository, whereas peak serum concentration was achieved within 30 min with the solution preparation. The serum half-life of secobarbital in these two patients, being 6.0 and 4.9 hr, are shorter than estimates reported for adults (13).

In summary, a rapid procedure for analyzing nanogram quantities of secobarbital in serum is described. Sample preparation is minimal, and there is no interference from many other anticonvulsants.

Differential Pulse Polarography of Some Degradation Products of Tetracycline

T. JOCHSBERGER ˣ, A. J. CUTIE, HOU-YEH WANG, and N. Y. MARY

Received October 6, 1981, from the *Arnold and Marie Schwartz College of Pharmacy and Health Sciences, Long Island University, Brooklyn, NY 11201.* Accepted for publication January 19, 1982.

Abstract □ In an attempt to develop a more rapid, convenient, and precise method for the direct detection and analysis of the degradation products of tetracycline, a study of those products utilizing differential pulse polarography was initiated. The investigation was concentrated on the subject of the kinetics of the epimerization of anhydrotetracycline to 4-epianhydrotetracycline in acetate buffer. The reaction was followed at 25 and 50°. Duplicate experiments were run at each temperature. The apparent rate constants obtained were $4.17 \pm 0.13 \times 10^{-1}$/hr (25°) and $6.97 \pm 1.00 \times 10^{-2}$/hr (50°).

Keyphrases □ Tetracycline—differential pulse polarography, degradation products, kinetics, epimerization □ Kinetics—differential pulse polarography, degradation products of tetracycline, epimerization □ Epimerization—differential pulse polarography of degradation products of tetracycline, kinetics □ Degradation—differential pulse polarography, products of tetracycline, epimerization, kinetics

A unique method is reported for the determination of degradation products of tetracycline. It is well known that tetracycline undergoes spontaneous degradation to an epimer, 4-epitetracycline and dehydration to anhydrotetracycline. In addition, both of the latter compounds undergo further transformation to produce 4-epianhydrotetracycline (1–3). There has been much concern over the kinetics and mechanisms (4–6) of these reactions and methods for determining the various products (7–15). The application of differential pulse polarography to the detection of tetracycline and a number of its derivatives has been described previously (16). This report describes the use of differential pulse polarography for detecting anhydrotetracycline in the presence of epianhydrotetracycline and for following the conversion of the former compound to the latter.

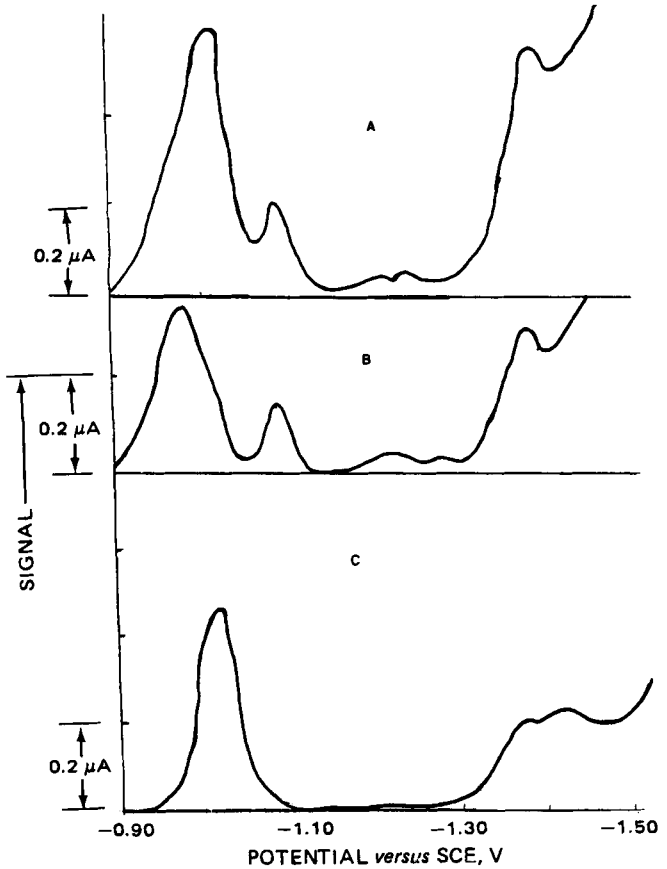

Figure 1—*(A) Differential pulse polarogram of a mixture of anhydrotetracycline and epianhydrotetracycline; (B) differential pulse polarogram of anhydrotetracycline; (C) differential pulse polarogram of epianhydrotetracycline.*

EXPERIMENTAL

Apparatus—The apparatus and technique used in this work have been described previously (17).

Materials—Anhydrotetracycline and 4-epianhydrotetracycline reference grade[1], were used as received. Acetate buffer (pH 4.31) was freshly prepared from reagent grade acetic acid and sodium acetate[2].

Procedure—Known amounts of anhydrotetracycline hydrochloride and/or 4-epianhydrotetracycline hydrochloride were added to a 250-ml volumetric flask. The materials were dissolved and brought to volume with acetate buffer solution. A fixed volume (25 ml) of each solution was withdrawn, deaerated, and assayed polarographically. Polarograms were recorded between −0.9 and −1.5 V.

In the rate studies, four different concentrations of anhydrotetracycline hydrochloride ($5.0–8.0 \times 10^{-5}$ *M*) in acetate buffer solution (pH 4.31) were followed as a function of time at the desired temperature. Polarograms of each sample were run immediately upon preparing the solution. Each solution was transferred into two separate 56.8-ml prescription bottles. The bottles were sealed with plastic covers and immediately placed in a thermostated shaker bath.

At appropriate time intervals, each sample bottle was withdrawn and immersed in ice to reduce the possibility of further reaction. The samples were analyzed by differential pulse polarography as described. Duplicate kinetic experiments were run at 25 and 50°.

RESULTS AND DISCUSSION

Figure 1A is a typical polarogram of a mixture of anhydrotetracycline and epianhydrotetracycline showing separate peaks attributable to the two compounds. The polarograms demonstrate clearly diverse curves at a peak potential of −1.09 V (Figs. 1B and 1C). A linear relationship between current and concentration exists at the peak potential at which these currents were measured. This is the major reduction potential in the polarographic spectrum for the compound.

At appropriate time intervals, solutions of anhydrotetracycline kept at various temperatures and concentrations were analyzed polarographically by the measurement of peak currents of the polarograms at the peak potential of −1.09 V.

The epimerization was observed to follow first-order kinetics as reported previously (18). The rate constants obtained from semilogarithmic plots are 0.0417 ± 0.0013 at 25° and 0.0697 ± 0.0100 at 50°. The values obtained in this study are somewhat lower than those reported (18) for the same reaction in phosphate buffer at pH 1.5. It is suspected that acid catalysis plays a role in the conversion.

Estimation of the activation energy for this reaction based on the two

temperatures studied leads to a low apparent value. It may be speculated that the reaction involves a low-energy bond rotation. However, it is not the intent of this report to provide a detailed mechanistic evaluation of the process. Such studies are to be conducted.

The technique of differential pulse polarography has been applied to the detection of anhydrotetracycline in the presence of epianhydrotetracycline and used to study the rate of conversion of anhydrotetracycline to its epimer. The authors feel this is a unique application of this technique. It is also felt that this work proves that this method, which is somewhat simpler to utilize than most commonly employed analytical procedures, might be useful in studying the reactions of other tetracycline derivatives.

Extended Hansen Approach: Calculating Partial Solubility Parameters of Solid Solutes

P. L. WU *, A. BEERBOWER ‡, and A. MARTIN *x

Received October 13, 1981, from the **Drug Dynamics Institute, College of Pharmacy, University of Texas, Austin, TX 78712*, and the ‡*Energy Center, University of California at San Diego, La Jolla, CA 92093.* Accepted for publication January 21, 1982.

Abstract □ A multiple linear regression method, known as the extended Hansen solubility approach, was used to estimate the partial solubility parameters, δ_d, δ_p, and δ_h for crystalline solutes. The method is useful, since organic compounds may decompose near their melting points, and it is not possible to determine solubility parameters for these solid compounds by the methods used for liquid solvents. The method gives good partial and total solubility parameters for naphthalene; with related compounds, less satisfactory results were obtained. At least three conditions, pertaining to the regression equation and the solvent systems, must be met in order to obtain reasonable solute solubility parameters. In addition to providing partial solubility parameters, the regression equations afford a calculation of solute solubility in both polar and nonpolar solvents.

Keyphrases □ Solubility, partial—extended Hansen approach, parameters of solid solutes, naphthalene, decomposition □ Naphthalene—extended Hansen approach, partial solubility parameters of solid solutes, decomposition □ Decomposition—extended Hansen approach, partial solubility parameters of solid solutes, naphthalene

A multiple regression method using Hansen partial solubility parameters, δ_d, δ_p, and δ_h, was reported (1) for calculating the solubility of naphthalene in pure polar and nonpolar solvents.

THEORETICAL

The method, called the extended Hansen solubility approach, uses a regression equation of three terms involving solvent and solute solubility parameters:

$$-\log X_2 = -\log X_2{}^i + A[C_1(\delta_{1d} - \delta_{2d})^2 + C_2(\delta_{1p} - \delta_{2p})^2 + C_3(\delta_{1h} - \delta_{2h})^2] + C_0 \quad \text{(Eq. 1)}$$

where X_2 and $X_2{}^i$ are the mole fraction solubility and mole fraction ideal solubility, and A is a term from regular solution theory:

$$A = \frac{V_2\phi_1{}^2}{2.303RT} \quad \text{(Eq. 2)}$$

where V_2 is the molar volume of the solute in the supercooled liquid state, ϕ_1 is the volume fraction of solvent, R is the gas constant, and T is the absolute temperature.

The partial solubility parameters for dispersion, δ_d, dipolar interaction forces, δ_p, and hydrogen bonding and other Lewis acid–base interactions, δ_h, are found in Eq. 1 for solvent (subscript 1) and solute (subscript 2). The coefficients C_0, C_1, C_2, and C_3 are provided in the computer output resulting from the least-squares analysis.

The equation obtained for naphthalene in 24 solvents by the extended Hansen solubility approach was (1):

$$\log \alpha_2 = \log \frac{X_2{}^i}{X_2} = 1.0488A(\delta_{1d} - \delta_{2d})^2 - 0.3148A(\delta_{1p} - \delta_{2p})^2 + 0.2252A(\delta_{1h} - \delta_{2h})^2 + 0.0451 \quad \text{(Eq. 3)}$$

This equation provided solubilities of naphthalene in polar and nonpolar solvents at 40° with <30% error (except for *tert*-butanol, 53% error); for ~50% of the cases results were obtained within <5% error. The method allowed the calculation of the solubility of naphthalene in solvents not included in the series under investigation. The extended Hansen solubility approach was tested against the UNIFAC method (2) and the extended Hildebrand solubility approach (3), two alternate methods undergoing recent development.

RESULTS AND DISCUSSION

The partial solubility parameters of Hansen and Beerbower (4) are available for a large number of liquids, but the values for only a few solids (represented as supercooled liquids) are found in the literature. A table was prepared of group contributions for calculating partial solubility

temperatures studied leads to a low apparent value. It may be speculated that the reaction involves a low-energy bond rotation. However, it is not the intent of this report to provide a detailed mechanistic evaluation of the process. Such studies are to be conducted.

[a] V_2 = 123 cm³/mole, X_2^i (40°) = 0.46594. [b] Values recalculated from Reference 1. [c] Changed from values used in Reference 1 to those found in Reference 4. [d] From Reference 7.

parameters for both liquids and solids (4). This method provides only rough estimates of δ_d, δ_p, and δ_h for crystalline solids, and it would be advantageous to have another method to obtain these values.

The approach suggested here involves regressing $(\log \alpha_2)/A$ against δ_{1d}, δ_{1p}, δ_{1h}, δ_{1d}^2, δ_{1p}^2, and δ_{1h}^2 using a number of solvents. The result of this procedure using an SPSS regression program (5) is the expression:

$$(\log \alpha_2)/A = -13.5114\delta_{1d} + 0.6702\delta_{1d}^2 + 0.5570\delta_{1p} - 0.1418\delta_{1p}^2 - 0.2448\delta_{1h} + 0.1326\delta_{1h}^2 + 68.0377 \quad \text{(Eq. 4)}$$

$n = 26$, $s = 1.45$, $R^2 = 0.986$, $F = 276$, $F(6, 20, 0.01) = 3.87$.

The terms for δ_{1d}, δ_{1d}^2, δ_{1p}, δ_{1p}^2, δ_{1h}, and δ_{1h}^2 are paired together with the coefficient of the squared term taken outside the parenthesis in each instance:

$$(\log \alpha_2)/A = 0.6702(\delta_{1d}^2 - 20.1603\delta_{1d}) - 0.1418(\delta_{1p}^2 - 3.9281\delta_{1p}) + 0.1326(\delta_{1h}^2 - 1.8462\delta_{1h}) + 68.0377 \quad \text{(Eq. 5)}$$

The terms in parentheses can be cast into the form of perfect squares if 20.1603 is taken as $2\delta_{2d}$, 3.9281 as $2\delta_{2p}$, and 1.8462 as $2\delta_{2h}$ in Eq. 5. This leads to the result:

$$(\log \alpha_2)/A = 0.6702(\delta_{1d}^2 - 20.1603\delta_{1d} + 101.6094) - 0.1418(\delta_{1p}^2 - 3.9281\delta_{1p} + 3.8575) + 0.1326(\delta_{1h}^2 - 1.8462\delta_{1h} + 0.8521) - (0.6702)(101.6094) + (0.1418)(3.8575) - (0.1326)(0.8521) + 68.0377 \quad \text{(Eq. 6)}$$

Therefore, 101.6094 is δ_{2d}^2 and $(101.6094)^{1/2} = 10.08 = \delta_{2d}$; and likewise for δ_{2p} and δ_{2h}:

$$(\log \alpha_2)/A = 0.6702(\delta_{1d} - 10.08)^2 - 0.1418(\delta_{1p} - 1.964)^2 + 0.1326(\delta_{1h} - 0.923)^2 + 0.3731 \quad \text{(Eq. 7)}$$

It is observed that the partial solubility parameters, $\delta_{2d} = 10.08$, $\delta_{2p} = 1.964$, and $\delta_{2h} = 0.923$, have been obtained by a regression method involving only solvent partial solubility parameters, together with experimental solubility data from which $(\log \alpha_2)/A$ is calculated. The total solubility parameter δ_T for naphthalene by this method is:

$$\delta_T^2 = \delta_{2d}^2 + \delta_{2p}^2 + \delta_{2h}^2 = (10.08)^2 + (1.964)^2 + (0.923)^2 = 106.32$$
$$\delta_T = (106.32)^{1/2} = 10.31 \quad \text{(Eq. 8)}$$

The partial solubility parameters from the literature (4) are $\delta_d = 9.4$, $\delta_p = 1.0$, and $\delta_h = 1.9$[1], leading to a $\delta_T = 9.64$. The total solubility parameter of naphthalene from its maximum solubility in 24 solvents has been estimated to be $\delta_T = 9.6$ (1); the value $\delta_T = 10.31$ was obtained in the present study (Eq. 8). When a different number of solvents or different kinds of solvents are employed in the regression, the δ values may vary, since the coefficients of the equation change with various solvents. The δ_T value obtained by multiple regression was 10.43 when 23 solvents were used.

Nonlinear regression (6) led to the following results:

$$(\log \alpha_2)/A = 0.7429\delta_{1d}^2 - 13.5559\delta_{1d} - 0.1440\delta_{1p}^2 + 0.5781\delta_{1p} + 0.1883\delta_{1h}^2 - 0.5987\delta_{1h} + 63.6363 \quad \text{(Eq. 9)}$$

$$(\log \alpha_2)/A = 0.7429(\delta_{1d} - 9.124)^2 - 0.1440(\delta_{1p} - 2.007)^2 + 0.1883(\delta_{1h} - 1.590)^2 + 1.902 \quad \text{(Eq. 10)}$$

$n = 26$, s(based on X_2) = 0.052, R^2(based on X_2) = 0.927

The total solubility parameter is obtained:

$$\delta_T^2 = \delta_{2d}^2 + \delta_{2p}^2 + \delta_{2h}^2 = (9.12)^2 + (2.01)^2 + (1.59)^2$$
$$\delta_T = (89.74)^{1/2} = 9.47 \quad \text{(Eq. 11)}$$

It is too early to claim validity for the use of multiple regression as a means of establishing total and partial solubility parameters for solid solutes. However, if multiple regression can be shown to yield consistent results in the future, the method may be useful for drugs, biochemicals, and similar organic solutes, the solubility parameters of which cannot be obtained by the methods used for solvents. The regression procedure would also provide a check on the group contribution method of Hansen and Beerbower (4) for obtaining partial solubility parameters.

In preliminary work with similar systems, it appears that certain conditions must apply for the method to be successful: (*a*) The constant term C_0 of Eq. 1 should be <1.0 or 2.0, as observed in Eqs. 7 and 10. (*b*) The regression equation must be one that successfully predicts solubilities of the solute in the solvent systems employed. (*c*) The regression equation must be obtained by using a sufficient number of solvents (20 is good, 40 is much better) with solubility parameters both below and above that of the solute. The larger the number of known solubilities used in the regression analysis, the better the chance of obtaining reasonable solute solubility parameters.

[1] The δ_h for naphthalene is given in Reference 4 as 2.9 but this is in error; the value was intended to be 1.9.

The first right hand term of Eqs. 7 and 10 express London interaction (dispersion forces) between solute and solvent. These omnidirectional forces do not operate only on 67% of the nearest neighbor molecules, as suggested by the coefficient of Eq. 7, nor on 74%, as shown in Eq. 10. Instead, the coefficient of the $(\delta_{1d} - \delta_{2d})^2$ term should be unity. This can be ensured in the regression method by moving this term to the left hand side of the expression for the calculation of coefficients, then returning it to the right side to display the final equation. The δ_{2d} was taken as 9.40 and the equation obtained was:

$$(\log\alpha_2)/A = (\delta_{1d} - 9.40)^2 - 0.1463(\delta_{1p} - 2.059)^2 + 0.1319(\delta_{1h} - 0.778)^2 + 0.8640 \quad \text{(Eq. 12)}$$

This method reduces the variables of regression by one, but it does not seriously reduce the correlation coefficient: R^2 of Eq. 7 is 0.986 and of Eq. 12 is 0.980. Also from Eq. 13, $\delta_T{}^2 = 9.42 + 2.059^2 + 0.7782$; $\delta_T = (93.205)^{1/2} = 9.65$.

Although this report is devoted to the calculation of solubility parameters for crystalline solids, Eqs. 7, 10, and 12 provide the calculation of the solubility of naphthalene in both polar and nonpolar solvents, as was demonstrated in an earlier report (1). The results, $X_{2(calc)}$, are found in Table I together with the percentage error for naphthalene solubility in each of the 26 solvents studied. Most of the solubilities were very satisfactory, ~50% exhibiting errors of <10%. Most values have an error of < ~30%. Isopropanol and acetic acid exhibited errors of >30% when Eqs. 7 and 12 were used. The predicted solubilities for naphthalene in hexane, acetic acid, ethanol, methanol, and water were >30% error using Eq. 10. The reason that solubilities in these five solvents are >30% cannot be stated definitively at this time. Ethanol, methanol, isopropanol, acetic acid, and water are highly hydrogen bonded and exhibit self-association. However, other polar solvents such as propanol, butanol, and cyclohexanol have reasonable values in this work. The error of 37% for hexane is surprising, as this solvent tends to form regular solutions with nonpolar solutes such as naphthalene.

GLC Determination of Phenacemide in Tablets

PAUL CONNOLLY, SUSAN SIRMANS, ALBERT A. BELMONTE *x, and CHARLES M. DARLING

Received March 3, 1981, from the *School of Pharmacy, Auburn University, Auburn, Alabama 36849.* Accepted for publication January 13, 1982. *Present address: St. John's University, College of Pharmacy and Allied Health Professions, Jamaica, NY 11439

Abstract □ A GLC procedure was developed for phenacemide and was shown to be less time consuming than the official assay without sacrificing accuracy. The procedure involves extraction from powdered tablets and addition of pentylenetetrazol as the internal standard. The amount of phenacemide is determined by comparison of the ratio of the area under the curves to that of a standard.

Keyphrases □ Phenacemide—analysis in tablets, GLC determination, pentylenetetrazol □ Pentylenetetrazol—analysis of phenacemide in tablets, GLC determination □ GLC—phenacemide, analysis in tablets, pentylenetetrazol.

Phenacemide, an open chain analog of 5-phenylhydantoin, is used in temporal lobe epilepsy (psychomotor) which is refractory to other agents (1, 2). It is a white, odorless, and tasteless crystalline solid (3). While performing routine analyses in another experiment, a rapid method of analysis for phenacemide was needed. The official assay involves acid hydrolysis, extraction of the acidic products into chloroform, and back titration (4). The procedure is time consuming and requires much handling and transfer. Other methods for phenacemide determination have been developed but offer no distinct advantages (5–7).

This report outlines a rapid GLC method that has proven to be less time consuming. In addition to requiring less handling and transfer, it does not appear to sacrifice accuracy.

EXPERIMENTAL

Materials—Phenacemide powder[1] and phenacemide tablets[1] were utilized in the assay as received. Pentylenetetrazol[2] was used as the internal standard. Methanol[3] and isopropyl alcohol[3], ACS reagent grade, were used as solvents.

Apparatus—A basic gas chromatograph[4] with a flame ionization detector (FID) was used. A 3.17-mm, 1.83-m silicone column[5] was used. The temperature of the column and detector was maintained at 200 ± 20°. The flow rate of the carrier gas (helium) was ~20 ml/min. The detector was connected to an integrating recorder[6] for easy and accurate determination of area under the curve.

Standard Curve—Seven samples of varying ratios of phenacemide to pentylenetetrazol in methanol (Table I) were used to obtain a standard curve. Exact amounts of phenacemide and pentylenetetrazol were weighed directly into 10-ml volumetric flasks. A small volume of methanol was added to dissolve the sample and then made to volume with methanol.

Three microliters of each of the seven solutions was chromatographed and the results recorded. A standard curve was obtained by plotting the

6	0.0200	0.0520
7	0.0377	0.0305

ratio of the area under the curve of phenacemide to pentylenetetrazol *versus* the ratio of the concentration of phenacemide to pentylenetetrazol in moles per liter.

Analysis of Phenacemide—In keeping with the USP method, 20 tablets were crushed in a porcelain mortar and pestle. The powder was dried over anhydrous calcium sulfate[7] in a dessicator. Samples containing ~400 mg of drug were accurately weighed and placed in a 500-ml round bottom flask. Approximately 450 ml of isopropyl alcohol was added and the solution was refluxed for 1 hr, cooled to room temperature, and filtered. Approximately 500 mg of an accurately weighed sample of pentylenetetrazol was added and the solution was brought to volume (1 liter) with isopropyl alcohol. A 3-μl sample was injected onto the chromatograph and the area under the curve recorded. The average of at least three determinations was used in the subsequent calculations.

RESULTS AND DISCUSSION

The equation of the standard curve using regression analysis[8] was found to be:

$$y = 1.30x - 0.0612 \qquad \text{(Eq. 1)}$$

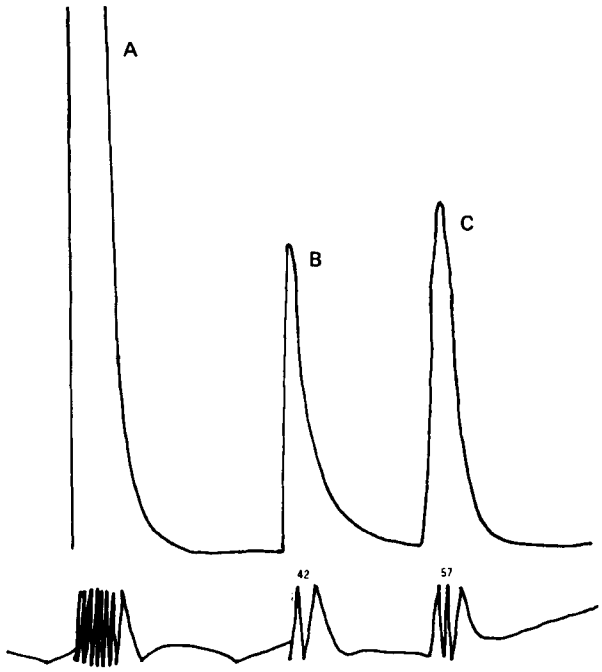

Figure 1—*A sample chromatogram from phenacemide tablets. Key: (A) solvent isopropyl alcohol; (B) phenacemide; (C) pentylenetetrazol.*

Table II—Recovery and Assay Results from USP and GLC Methods

Phenacemide[a], g	Expected Phenacemide Control, g	Phenacemide Found, g	Recovery, %
	GLC Method		
0.5726	0.3843	0.3985	103.8
0.5966	0.4004	0.4120	102.9
0.5946	0.3991	0.4152	104.0
0.5950	0.3993	0.3993	100.1
	USP Method		
0.5944	0.4002	0.3976	99.4
0.5969	0.4006	0.4148	100.6
0.5962	0.4002	0.3992	99.8

[a] Powdered tablet weighed.

where:

$$y = \frac{\text{area under the curve of phenacemide}}{\text{area under the curve of pentylenetetrazol}} = \frac{AUCP}{AUCM} \qquad \text{(Eq. 2)}$$

$$= \frac{\text{concentration of phenacemide}}{\text{concentration of pentylenetetrazol}} = \frac{CONCP}{CONCM} \qquad \text{(Eq. 3)}$$

The standard curve was linear and the amount of phenacemide was determined using Eq. 1. The values are recorded in Table II.

The gas chromatogram resulting from each sample injection exhibited three peaks: the solvent (isopropyl alcohol), phenacemide, and pentylenetetrazol. Tailing was minimal and each peak approached the base line before the appearance of the next peak. A typical chromatogram is shown in Fig. 1.

The standard curve was linear in the range used for this study. The correlation coefficient of concentration *versus* area under the curve was 0.9996. Statistical comparison, using Student's t test for independent samples, showed no statistical difference between recovery of phenacemide using the USP assay and the GLC method. The calculated t-value was 0.7649, while the critical value was $t_{0.95} = 2.571$, with 5 df.

The GLC determination of phenacemide in tablets offers an improvement over the USP method without sacrificing accuracy in the samples assayed. The GLC determination of phenacemide in tablets is a simpler and quicker method which produces results essentially the same as that of the time-consuming official assay.

The Desolvation and Oxidation of Crystals of Dialuric Acid Monohydrate

RONALD J. CLAY, ADELBERT M. KNEVEL, and STEPHEN R. BYRN ˣ

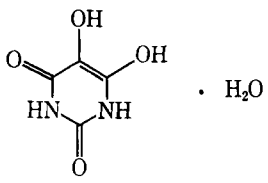
Received June 29, 1981, from the *Department of Medicinal Chemistry and Pharmacognosy, School of Pharmacy and Pharmacal Sciences, Purdue University, West Lafayette, IN 47907.* Accepted for publication January 13, 1982.

Abstract □ Examination of the influence of the solvent of crystallization on the solid-state oxidation of dialuric acid (I) monohydrate to alloxantin (II) is reported. This reaction was investigated at low and high humidities using photomicrography, X-ray crystallography, and IR and mass spectrometry. Crystals of dialuric acid desolvated somewhat anisotropically; this behavior was consistent with crystal packing. The desolvated crystals of dialuric acid monohydrate had approximately the same crystal structure as the monohydrate and were stable in air at room temperature at low humidities. At high humidity, these crystals rehydrated and rapidly oxidized to alloxantin. These studies showed for the first time that desolvation was not a necessary prerequisite to solid-state oxidation and that solid-state oxidation reactions could be accelerated by high humidity.

Keyphrases □ Dialuric acid monohydrate—desolvation and solid-state oxidation of crystals □ Crystallization—desolvation and solid-state oxidation of dialuric acid monohydrate □ Solid-state oxidation—crystals of dialuric acid monohydrate, desolvation □ Desolvation—crystals of dialuric acid monohydrate, solid-state oxidation

Recent studies (1, 2) have correlated desolvation patterns of crystalline hydrates of drugs and related compounds with crystal packing (1, 2). Several crystal solvates, including those of dihydrophenylalanine (2, 3), ergosterol (4), hydrocortisone *tert*-butylacetate (5), dialuric aicd (6), bis(salicylidene)ethylenediimine Co(II) (7), and the picket fence porphyrins, are oxygen sensitive (8). In many of these solvates, desolvation precedes or coincides with reaction with oxygen.

The present report represents an extension of previous research (1, 2) and is aimed at understanding the relationship between desolvation and oxygen reactivity; the oxidation of dialuric acid monohydrate (I) is discussed as well.



I

The results of this study, which show that moisture and factors other than oxygen permeability of the crystal influence solid-state oxidation reactions, may have important implications for the proper design and storage of drugs and dosage forms.

EXPERIMENTAL

Photomicrography of crystals was performed with a microscope[1] equipped with a hot stage[2]. The X-ray powder diffraction patterns were measured on film using CuKα radiation on a powder camera[3], and elemental analyses were obtained[4]. The extent of reaction was determined using polarographic[5] analysis (quantitative) and IR spectroscopy[6] (qualitative). The constant humidity experiments were performed in chambers with the humidity controlled by various saturated salt solutions: LiCl, 15%; NaCl + KNO_3 + $NaNO_3$, 30%; KSCN, 47%; NH_4Cl + KNO_3, 72%; KBr, 84%; and $NH_4H_2PO_4$, 93%. MS were measured on a mass spectrometer[7] in the chemical ionization mode.

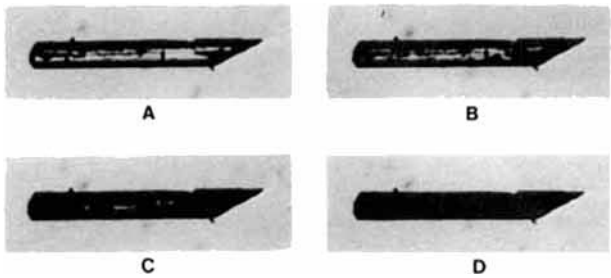


Figure 1—*Behavior of a crystal of dialuric acid monohydrate at 100°: (A) start (B) after 18 min; (C) after 28 min; (D) after 36 min.*

Dialuric acid was prepared according to a previous method (9). Two grams of recrystallized alloxan[5] was dissolved in 100 ml of freshly boiled deoxygenated water. Hydrogen sulfide[6] (5% H_2S, 95% N_2) was then passed through this solution until it became opalescent and free sulfur was liberated. Carbon disulfide (10 ml) then was added and the hydrogen sulfide passed through the solution for an additional 10 min. The carbon disulfide layer was removed and this process repeated for another 10 min. The aqueous solution then was filtered and evaporated to dryness. The product, dialuric acid monohydrate, was obtained by recrystallization from boiled, deoxygenated water. Dialuric acid gave an IR spectrum, elemental analysis, and X-ray diffraction patterns consistent with those in the literature (9).

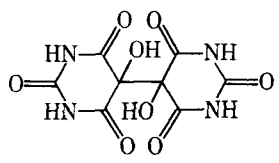
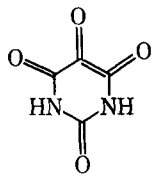
RESULTS

Dialuric acid monohydrate was prepared following literature procedures. It gave a satisfactory elemental analysis and its IR spectrum and X-ray powder pattern were identical to the published data (9). Heating at 76 or 100° led to the formation of the anhydrous form. The X-ray powder pattern of this anhydrous form, as measured on film, was approximately identical to that of the monohydrate. Crystals of dialuric acid monohydrate heated to 100° generally behaved anisotropically, with the reaction proceeding from the ends of the needle-like crystals toward the middle as shown in Fig. 1. The dehydrated solid was polycrystalline since it gave only a powder pattern, had approximately the same crystal structure as dialuric acid monohydrate, and was stable to oxidation. The dehydrated crystals had to be heated at 76° at room humidity for 56–70 days to be completely oxidized.

The structure of the oxidation product was shown to be alloxantin (II) rather than alloxan (III) as had been previously suggested (6). The X-ray powder diffraction pattern of two oxidized samples essentially was identical to that of alloxantin as shown in Table I. In addition, elemental



II



III

analysis of oxidized dialuric acid gave C, 29.77; H, 3.38; and N, 17.40%. The data calculated for alloxantin ($C_8H_6N_4O_8$) are C, 29.82; H, 3.13; and N, 17.39%; while the calculated values for alloxan are C, 30.01; H, 2.52; and N, 17.50%. Infrared and mass spectral measurements on alloxan and alloxantin and oxidized dialuric acid confirmed that dialuric acid is oxidized to alloxantin not alloxan (10).

The dehydrated crystals could be rehydrated at room temperature at humidities ranging from 30 to 84% in a constant humidity chamber. The results of these rehydration studies are shown in Table II. At 93 and 100% relative humidity, a rapid and unexpected oxidation to alloxantin occurs at room temperature. This oxidation complicates the weight gain measurements, which indicate that the equivalent of one molecule of water has been absorbed. In addition, the higher the humidity the faster the reaction, since complete oxidation occurs in <3 hr at 100% relative humidity.

Figure 2 shows the behavior of a clump of crystals of dialuric acid monohydrate at 100% relative humidity. The oxidation reaction begins at several nucleation sites and is nearly complete after 2 hr.

DISCUSSION

Dehydration of Dialuric Acid—The anisotropic behavior of dialuric acid monohydrate crystals during dehydration is probably due to the preferential exit of the water molecules along the tunnel direction (1, 2).

Table II—Structure Changes of Anhydrous Dialuric Acid at Room Temperature and Various Relative Humidities

Relative Humidity, %	Initial Weight Gain Equivalent	Structure Change[a]
2	None	None
15	None	None
30	0.018 g (1·H_2O)	Anhydrous to hydrate
47	0.018 g (1·H_2O)	
72	0.018 g (1·H_2O)	
84	0.018 g (1·H_2O)	
93	0.018 g	Anhydrous to hydrate to alloxantin hydrate (<24 hr)
100	0.018 g	Anhydrous to hydrate to alloxantin hydrate (<3 hr)

[a] As determined by IR and X-ray powder diffraction after 5-days exposure, except where noted.

An examination of the crystal packing of dialuric acid monohydrate (Fig. 3) shows that tunnels of water molecules lie approximately parallel to the needle axis of the crystal. Thus, an individual water molecule exits out these tunnels rather than penetrating the closely packed dialuric acid layers. Similar but more dramatic behavior has been observed for other crystals during desolvation (1, 2).

In addition, the crystal structure of the dehydrated crystals is approximately the same as the hydrate, since the X-ray powder patterns of dialuric acid monohydrate and anhydrous dialuric acid are nearly identical. Thus, dialuric acid is an example of crystal pseudomorphism, a term used to describe similar behavior of the solvates and anhydrous forms of the cephalosporin antibiotics (11).

Oxidation of Desolvated Dialuric Acid Monohydrate—The stability of the desolvated crystals toward oxidation in air was unexpected. Dialuric acid is unstable in solutions exposed to air and has a half-life of ~30 sec at room temperature in aqueous solution. In contrast, the desolvated crystals required 56–70 days at 76° for complete oxidation. Unlike dialuric acid, desolvated crystals of dihydrophenylalanine and bis(salicylidene)ethylenediamine Co(II) (1, 2) react with oxygen at room temperature in a few days. Also, anhydrous dialuric acid has approximately the same crystal structure as dialuric acid monohydrate and, thus, should contain voids previously occupied by water molecules. These voids do not result in facile oxidation. This shows that factors other than the ability of oxygen to penetrate the crystal can influence solid-state oxidation reactions.

Rehydration of Anhydrous Dialuric Acid—Exposure of desolvated crystals of dialuric acid to water vapor results in rehydration at humidities >30%. This is a well-known process for pharmaceuticals with the cephalosporin antibiotics exhibiting unusual ability to desolvate and resolvate (11). As with the cephalosporins, the crystal structures of dialuric acid monohydrate and anhydrous dialuric acid are nearly the same.

Rehydration and Oxidation of Anhydrous Dialuric Acid at High Humidities—If crystals of anhydrous dialuric acid are exposed to room temperature and relative humidities >93%, they rehydrate and oxidize. An increase in the rate of reaction at increased relative humidity is also apparent from the data. The rate of the decarboxylation of solid *p*-aminosalicylic acid and the hydrolysis of solid aspirin also increased with increasing relative humidities (12). The decreased stabilities of these compounds at increased relative humidities were interpreted in terms of the formation of a moisture layer a few molecules thick on the crystals and solution reaction in this moisture layer (12). A similar process may also explain the behavior of dialuric acid. However, because of the rehydration and the rapid oxidation, it is impossible to interpret the weight gain of the crystals at high humidities. For batches of crystals of

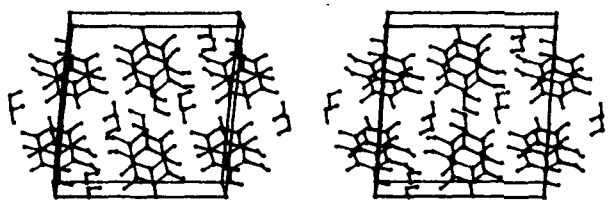


Figure 3—*Crystal packing of dialuric acid. The direction of the crystal axes are: with origin at top left a across b out of the plane of the paper, and c down. (Data from Ref. 6 were used to make this figure.)*

dialuric acid with an (assumed) area of 0.01 m^2/g, a monolayer of water molecules on a 0.100-g sample would weigh 2.14×10^{-7} g. Thus, a water layer 1000 molecules thick would barely be detectable in the absence of the complicating oxidation reaction.

These results indicate that factors other than the apparent permeability of oxygen into the crystal can govern solid-state oxidation reactions. Desolvated crystals of dialuric acid, which are expected to contain voids, are unreactive. Thus, desolvation does not always increase the reactivity of a crystal toward oxygen. Instead, solvated crystals exposed to high humidities react very rapidly, showing that high humidities can accelerate solid oxygen reactions. Also, reactions of the type: solid + gas → solid can be accelerated in high humidities presumably *via* reaction in an invisible moisture layer.

In contrast to other solids, these results indicate that stabilization of pharmaceuticals with solid-state behavior related to dialuric acid would best be accomplished, not by avoiding desolvation as indicated by some published results (1–3, 7, 8), but rather by preventing exposure to high humidities.

A Rapid Quantitative Determination of Acetaminophen in Plasma

SANDRA E. O'CONNELL[x] and FRANK J. ZURZOLA

Received August 26, 1981, from the *Research and Development Center, Bristol-Myers Products Division, Hillside, NJ 07207.* Accepted for publication January 27, 1982.

Abstract □ A simple method is described for the rapid, quantitative analysis of acetaminophen in plasma. The nonconjugated acetaminophen present in the plasma following drug administration is determined after plasma protein precipitation by high-pressure liquid chromatography (HPLC) at a wavelength of 240 nm. Acetaminophen (I) is detectable at levels as low as 0.1 μg/ml. Mean recoveries of 94% with a coefficient of variation of 3% were obtained for plasma standards whose concentrations ranged from 0 to 32 μg/ml. Interassay variability of the slope of the standard curve had a coefficient of variation of 2.7%. Application and verification of this method by comparison with another procedure run simultaneously during several human bioavailability studies are described.

Keyphrases □ Acetaminophen—high-performance liquid chromatographic analysis in human plasma □ High-performance liquid chromatography—analysis, acetaminophen in human plasma and blood □ Analgesics—acetaminophen, high-performance liquid chromatographic analysis in human plasma

The widespread use of acetaminophen (I) as an analgesic and antipyretic has stimulated an interest in the development of a simple and rapid free acetaminophen plasma determination suitable for analyzing multiple samples. The pharmacology of acetaminophen is such that ~80% of a dose is conjugated predominately with glucuronic acid and to a lesser extent with sulfuric acid. These conjugated metabolites lack efficacious biological activity (1). Most of the published methods determine total (*i.e.*, free plus conjugated) acetaminophen in plasma (2–4), while those that determine free acetaminophen by a variety of techniques (5–14), including HPLC (7–14), involve time-consuming and labor intensive organic extractions, solvent evaporations (7–10), deal with toxic levels rather than the lower therapeutic levels (11, 12), or are unsuitable for routine multiple therapeutic level samples because of lack of sensitivity, insufficient sample cleanup (11–14), or long analysis time (14).

The present method involves a single plasma protein precipitation step followed by liquid chromatographic determination of acetaminophen in the clear supernatant. The plasma proteins are denatured and precipitated using 0.3 *N* $Ba(OH)_2$ and 5% $ZnSO_4$ solutions described previously (15). The method is capable of detecting <0.1 μg/ml, and the reproducibility eliminates the need for an internal standard. Furthermore, the ease and rapidity of sample workup make this method ideal for multiple sample analysis.

This method has been used routinely for over a year with good results and has been verified by a comparison with an extraction–HPLC acetaminophen method[1] and a colorimetric procedure (16).

EXPERIMENTAL

Reagents—Standard solutions were prepared in distilled water. The 0.3 *N* $Ba(OH)_2$ and 5% $ZnSO_4$ solutions were obtained commercially[2]. The combination of these two salt solutions has been known for years as an effective plasma protein precipitant.

Instrumentation and Operating Conditions—The analysis was performed using a high-performance liquid chromatograph[3] with a variable wavelength UV detector[4] set at 240 nm, an automated injection system[5] fitted with a 75-μl loop, and a 30 cm × 4-mm i.d. reversed-phase,

high efficiency C_{18} column[6]. The mobile phase was methanol–water (15:85), which was filtered through a 0.45-μm pore filter[7] and degassed before use. The flow rate was 1.0 ml/min. The column was fitted with a precolumn packed with C_{18} Corasil 37–50 μm[8]. This precolumn was repacked once a week during panel use since particulate matter accumulated on the precolumn frit and would cause an increase in column pressure after the weekly load of 300 to 400 injections. The detector was set at a sensitivity of 0.2 aufs.

Plasma Acetaminophen Study in Humans—Patients were fasted overnight and were drug free for 72 hr prior to dosing. Each subject received a 650-mg oral dose of acetaminophen consisting of two 325-mg tablets taken with 100 ml of water. Venous blood specimens were withdrawn by syringe and discharged into centrifuge tubes containing heparin as an anticoagulant. Specimens were taken prior to and at specified times after drug administration through 1 hr. Collected specimens were centrifuged immediately for 15 min at 3500 rpm using a bench-top centrifuge. Plasma was separated and analyzed for free acetaminophen by the proposed method.

Analysis—One milliliter of freshly drawn plasma was added to a 16 × 100-mm screw top culture tube. To each tube was added 1 ml of the saturated 0.3 *N* $Ba(OH)_2$ solution. The tubes were vortexed at sufficient speed to ensure thorough mixing for 2 min on a multiple tube vortex mixer[9]. One milliliter of the 5% $ZnSO_4$ solution was then added to each sample which should have a milky opaque appearance. Each tube was capped and vortexed at high speed for 1 min. The tubes were then centrifuged in a bench-top centrifuge at high speed for 10 min. The resulting clear water-like supernatant was separated from the precipitate and filtered directly into an auto injector vial using a Pasteur pipet plugged

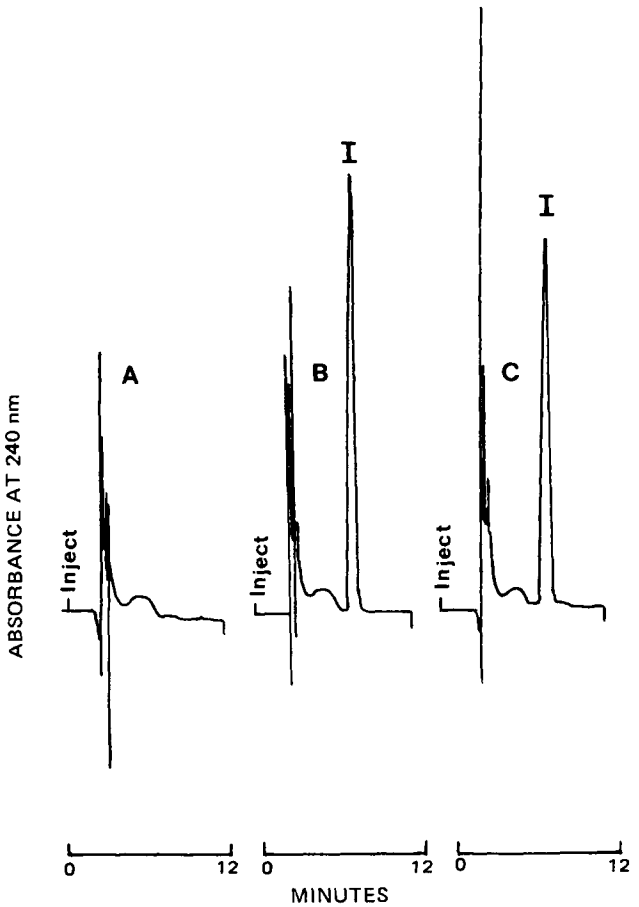

Figure 1—*Chromatograms for a typical subject. Key: (A) taken prior to acetaminophen (I) administration; (B) taken 20 min after oral administration of two 325-mg tablets; (C) taken 40-min postdosing.*

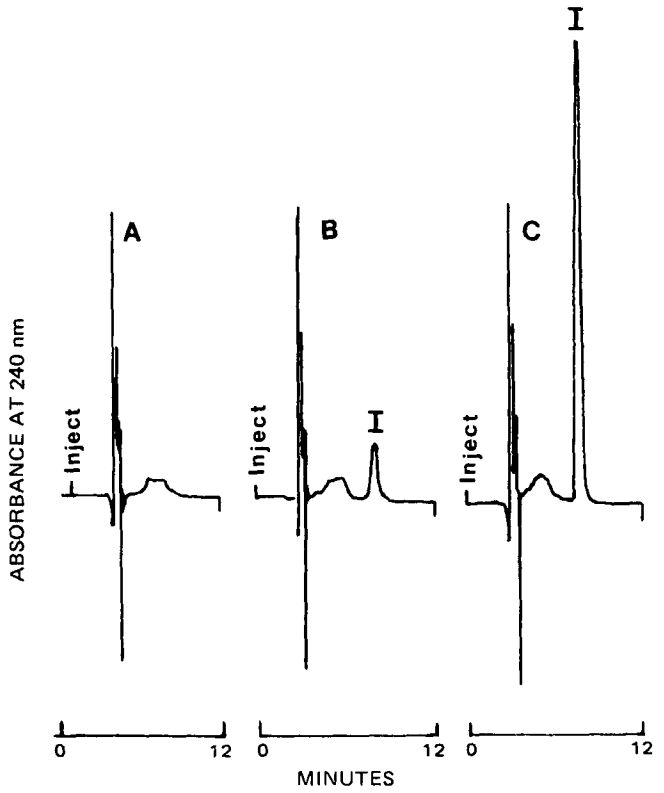

Figure 2—*Chromatograms of 1-ml human plasma sample processed by the described precipitation method. Key: (A) blank; (B) spiked with 1 μg of acetaminophen (I); (C) spiked with 8 μg of I. The mobile phase was 15% (v/v) methanol at a flow rate of 1.0 ml/min, and the chart speed was 15 cm/hr.*

with glass wool. This ensured a minimal volume loss and a particulate-free sample.

Standard Curves—Calculations were carried out using standard curves constructed by analyzing 1-ml samples of the pooled predose plasma spiked with 1–32 μg of acetaminophen and plotting the area counts *versus* the corresponding concentration. The standard curve data were subjected to least-squares linear regression analysis, and the resulting equation was utilized for the calculation of the drug concentration in the unknown samples.

RESULTS AND DISCUSSION

Typical chromatograms of a predose plasma sample (Fig. 1A) and the 20- and 40-min postdose plasma samples (Fig. 1B and C) obtained for a typical subject, demonstrate the specificity of this method by the absence of interfering peaks. With 15% methanol in water as the eluent at a flow rate of 1.0 ml/min, the retention time for acetaminophen was 7 min. Additional peaks are observed eluting close to the solvent front. They are ascribed to the more polar metabolites of acetaminophen. Earlier elution of the acetaminophen is possible by increasing the methanol content of the mobile phase, but an occasional interfering peak was observed eluting close to the peak of interest.

Figure 2 represents the chromatograms of a 1-ml blank plasma sample, a 1-ml plasma sample spiked with 1 μg of acetaminophen, and a 1-ml plasma sample spiked with 8 μg of acetaminophen. The standards and samples are chromatographically clean to the extent that acetaminophen concentrations <1 μg/ml can be detected with this procedure. Since therapeutic acetaminophen levels normally encountered in blood plasma monitoring require detection of ≥1 μg/ml, the sensitivity of this method is more than adequate for use in blood level studies.

Recovery—The recovery of free acetaminophen from plasma relative to its recovery from water as measured by the ratio of the slopes of the

standard curves in plasma and water, respectively, was 0.94 ± 0.03 with a coefficient of variation of 3%. Interassay variability of the slope and y-intercept of the five standard curves generated during the bioavailability study had coefficients of variation of 2.7 and 8%, respectively. A typical calibration regression line is $y = 0.229x + 0.0296$ and is linear over a 1–32-μg/ml concentration range. The good linearity between the peak area and acetaminophen concentration in plasma is indicated by the correlation coefficient of $r > 0.999$.

Accuracy—Table I shows the actual amounts with which 1-ml blank plasma samples were spiked and the amounts found when the plasma was analyzed according to the described method. The experiment was performed in duplicate on each of 5 days. The percent error for each unknown sample was calculated according to (17):

$$\text{percent error} = \frac{\text{amount added} - \text{amount found}}{\text{amount added}} \times 100 \quad \text{(Eq.1)}$$

The average percent error was 2.2%. In no case did it exceed 7.0%.

Reliability—A comparison was made of acetaminophen levels determined by the described method with levels determined simultaneously by a previously validated extraction procedure. Table II shows the acetaminophen levels found with both methods for 16 subjects who had been studied on a three-way crossover with samples taken at 10, 20, 40, and 60 min postdosing. The comparison gave a correlation coefficient of 0.993. In addition, the application of a paired Student's t test and the Wilcoxon-Mann-Whitney rank-sum test to the two sets of data indicated at the 95% confidence level that there was no significant difference between results obtained by the two methods.

Summary—The proposed method is simple and sensitive for the rapid determination of nonconjugated acetaminophen in plasma or blood at levels likely to be encountererd after a usual 650- or 1000-mg total dose. Plasma proteins are denatured by the addition of a saturated $Ba(OH)_2$ solution and then precipitated with 5% $ZnSO_4$ solution. The resulting clear supernatant is analyzed by HPLC. The reproducibility, sensitivity, and selectivity of the method make the use of an internal standard unnecessary.

Since the major biotransformation of acetaminophen in humans is direct conjugation with sulfate and glucuronic acid to form the sulfate and glucuronic metabolites, these polar metabolites do not interfere in the assay as they are eluted along with the solvent. The accuracy and reliability of this method have been proven by comparison of results obtained with an established extraction procedure in over 400 comparative determinations.

Abstract □ The pharmacokinetics of bretylium in dogs and the efficacy of hemoperfusion with a resin column in its removal from the body following intravenous administration of bretylium tosylate were investigated. Five mongrel dogs weighing 18–26 kg were given a bolus dose of 15 mg/kg. Serial blood samples were taken for 24 hr. Hemoperfusion, through a resin column, was then initiated and continued for 4 hr under pentobarbital anesthesia. During hemoperfusion, arterial and venous blood samples were collected several times; venous blood samples were then withdrawn for an additional 8 hr. Urine was collected from each dog in three portions for up to 48–54 hr. Pharmacokinetics of bretylium in dogs could be characterized by a two-compartment open model with a distribution half-life of 7 min and biological half-life of 15.9 ± 1.9 hr. Plasma levels declined rapidly from ~20 μg/ml at 6 min to <2 μg/ml within 1 hr. The ratio of intercompartmental rate constants, k_{12}/k_{21}, was 16.7, and the volume of the central compartment and apparent volume of distribution were 0.245 and 5.22 liter/kg, respectively, indicating a wide distribution of bretylium into the tissues. Plasma dialysis clearance averaged 29.7 ml/min, which is 30% of the total body clearance (98.8 ml/min). These data suggest that resin hemoperfusion may not be useful in the treatment of bretylium intoxication.

Bretylium tosylate is a quaternary ammonium compound used in the treatment of ventricular tachycardia or ventricular fibrillation. It has been demonstrated that bretylium increases the action potential duration along the entire left ventricular conducting system (1).

In humans and rats, bretylium is primarily eliminated unchanged *via* the kidneys. No metabolites have been identified following administration of bretylium in humans (2–5). A half-life of 9.75 ± 4.19 (*SD*) hr in eight patients aged 48.4 ± 10.8 years has been reported (6). The longest

half-lives were found in the oldest patients, which would be consistent with the reduction in the renal function known to occur with aging. More recently, an average half-life of 8.1 hr for normal subjects and 16.1 and 31.5 hr for two patients with creatinine clearance of 21.0 and 1.0 ml/min, respectively, has been reported (3, 4). As renal function declines, dosage alteration may be required to avoid toxicity. A half-life of 13.6 hr has been reported (5) for 10 normal volunteers given 5 mg/kg iv of bretylium.

The purpose of this investigation was to study the efficacy of hemoperfusion with a clinically used resin[1] column in the removal of bretylium from the body following intravenous administration of bretylium tosylate to dogs. This resin[1] is a macroreticular copolymer of styrene and divinyl benzene with a surface area of 750 m^2/g, a porosity of 51%, and an affinity for lipid-soluble materials. This column is used clinically to treat intoxication (7).

EXPERIMENTAL

Five mongrel dogs weighing 23.3 ± 3.1 (*SD*) kg were randomly selected. Each dog received a rapid intravenous bolus dose of 15 mg/kg bretylium tosylate[2]. Blood samples (3 ml each) were taken frequently during the first 2 hr for characterization of distribution phase and then every 2–4 hr for the next 14–18 hr and at 24 hr to characterize the elimination phase.

Twenty-four hours after administration of bretylium, the dogs were hemoperfused for 4 hr using clinically available columns[3] containing 312 ± 15 g (dry weight) of loosely packed resins[1]. Immediately prior to hemoperfusion, the animals were anesthetized with pentobarbital (30 mg/kg iv) and intubated with an endotracheal tube. A femoral artery and vein were cannulated, and 10,000 U of heparin was given. The extracorporeal circuit (~300 ml) was washed with 3 liters of normal saline containing 1000 U/liter of heparin and primed with the same solution. The primer was infused at the beginning of hemoperfusion. Blood was pumped through the circuit at a constant antigravity flow of ~112 ml/min as determined by timed collections of saline before and after each experiment.

During hemoperfusion samples of blood were withdrawn from the arterial (inlet) and venous (outlet) lines at 0.5, 1.0, 2.0, 3.0, and 4.0 hr following the start of hemoperfusion. At the conclusion of hemoperfusion, blood was returned to the dog by gravity. The artery and vein were then closed and blood sampled for an additional 8 hr. Immediately after the collection of blood samples, they were centrifuged and plasma was separated and frozen until assayed. The hematocrit of all blood samples taken during hemoperfusion was measured.

After the hemoperfusion, the column was eluted with methanol to remove all the adsorbed bretylium. The final volume was measured and an aliquot was stored for bretylium assay.

Quantitative urine samples were collected from each dog and divided into three time intervals: prehemoperfusion, during, and posthemoperfusion urine. Aliquots were frozen until assayed for bretylium.

Bretylium Assay—Plasma, urine, and methanol eluate of the hemoperfusion column were assayed for bretylium as described previously (8). The sensitivity of this procedure was not sufficient enough to determine the bretylium levels in the methanol eluate. Therefore, the same eluate was concentrated 10–50 times and assayed again.

Pharmacokinetic Analysis—The prehemoperfusion plasma concentration *versus* time profiles were fitted to a two-compartment open model using the NLIN procedure (9). Pharmacokinetic parameters were obtained for three of the five dogs (numbers 217, 224, and 256). For dogs 289 and 299, the best fit was obtained when the postperfusion plasma concentrations were used. Bretylium plasma dialysis clearance during hemoperfusion (Cl_d) was calculated as previously described (10):

$$Cl_d = Q_p(A - V)/A$$

where Q_p is plasma flow, and A and V are arterial and venous plasma concentrations of bretylium, respectively.

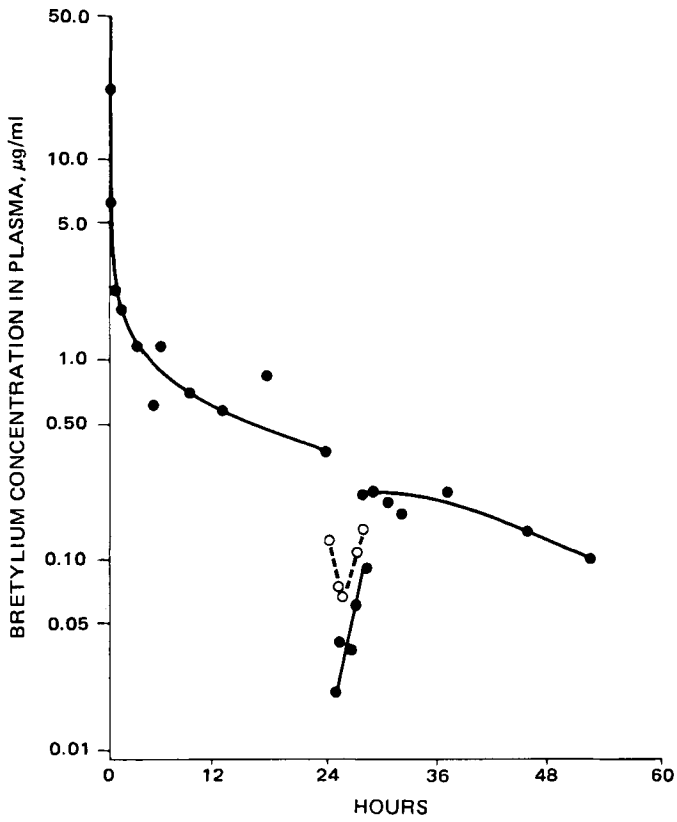

Figure 1—*Semilogarithmic plot of plasma concentrations of bretylium versus time following intravenous administration of bretylium tosylate, 15 mg/kg, in one dog (No. 217). Hemoperfusion was done 24 hr after administration of the drug. Key: (●) venous concentrations; (○) arterial concentrations; the solid line, through the first 24 hr, represents the least-squares computer fit.*

[a] Plasma dialysis clearance during hemoperfusion. [b] Preperfusion total body clearance.

RESULTS AND DISCUSSION

The plasma concentration *versus* time plot, for a typical dog, is shown in Fig. 1. Immediately after the intravenous dose of 15 mg/kg, bretylium is distributed rapidly in the body. The plasma levels decreased from ~20 μg/ml at 6 min to <2 μg/ml within 1 hr. During the elimination phase, the levels declined more slowly with an average half-life of ~16 hr. In three dogs (217, 224, and 256), the preperfusion elimination phases were well defined with a half-life ranging from 13.5–16.2 hr. In dogs 289 and 299, the plasma concentrations could be best fitted to the model by using also the postperfusion data that were in line with the preperfusion levels.

Pharmacokinetic parameters, derived constants, and the means, are listed in Table I. The parameters were in good agreement in all dogs. As seen from Table I, bretylium is widely distributed in the body, with a volume of distribution of 5.22 liter/kg (±1.07) and a very small volume of central compartment of 0.245 ± 0.046 liter/kg. The average distribution half-life was 6.72 min. The intercompartmental rate constants, k_{12} and k_{21}, were 5.09 and 0.304 hr^{-1}, respectively. The extremely large volume of distribution and the very high ratio of k_{12}/k_{21} (16.7) signify strong affinity of bretylium to the tissues in the peripheral compartment. Earlier studies in dogs and rats (11, 12, and unpublished data) have shown an extremely high affinity of bretylium to the myocardium, with heart to plasma concentration ratio >20. The heart was found to be a part of the peripheral compartment in rats (12). The elimination rate constant, k_{10}, averaged 1.0 hr^{-1}, with a total body clearance (TBC) of 0.231 liter/hr/kg or 3.85 ml/min/kg.

The percentage of dose recovered in urine collected during the study period is also shown in Table I. An average of 79% of the dose was recovered unchanged in urine 48–54 hr following intravenous administration, and only an insignificant amount was cleared during hemoperfusion through the column. Available data on glomerular filtration rate in dogs (13) show that it ranges from 3.33–4.75 ml/min/kg. Total body clearance of bretylium in the dogs was 3.85 ml/min/kg and the renal clearance was ~3.0 ml/min/kg. These values indicate that bretylium might not be eliminated by an active mechanism in dogs. In humans and rats, bretylium is excreted extensively by active tubular secretion (4, 12).

A hemoperfusion 24 hr after the bretylium tosylate dose caused an immediate decrease (twofold–tenfold) in the arterial as well as venous plasma levels within 1 hr; this was followed by a gradual increase and reached a normal expected level by the completion of hemoperfusion in all animals (Fig. 1). Pertinent hemoperfusion parameters for each dog are given in Table II. Plasma dialysis clearance (Cl_d) averaged 29.7 ± 12.8 ml/min or 30% of the endogenous (preperfusion) TBC. The actual amount of bretylium removed from each dog *via* hemoperfusion and, consequently, recovery clearance (14) could not be calculated.

The rapid fall in the plasma concentration (central compartment), due to perfusion clearance, causes a shift in the equilibrium between the two compartments resulting in redistribution of bretylium from the peripheral compartment to the central compartment. When the rate of this redistribution exceeds the clearance from the central compartment, ~1 hr following the initiation of hemoperfusion, the plasma concentration rises (Fig. 1).

The efforts to determine the concentration of bretylium in the methanol eluate of the perfusion column did not succeed because the concentration was below the detection limit of 10 ng/ml. Concentrating the eluate, 10- to 50-fold, did not indicate a significant removal of bretylium by the column. Because of low bretylium concentrations and high background, the gas chromatogram did not provide any meaningful data. Even assuming a 10-ng/ml concentration of the eluate, the total amount removed would not be >10 μg total. Theoretically, the rate of removal of drug from plasma depends on the concentration in plasma. Because of the wide distribution in the tissues, *i.e.*, very large k_{12}/k_{21}, the plasma concentrations are very low and the rate of removal is very slow. These data are quite similar to those after digoxin in dogs and confirm that the rate-limiting step may be the clearance from tissues and not from plasma (15).

After the hemoperfusion was stopped, the plasma levels increased further till a new equilibrium was reached. Thereafter, levels declined exponentially as shown in Fig. 1. The plasma levels in the postperfusion equilibrium phase were very close to the levels that could be predicted by extrapolation of the curve fitted to the preperfusion data. This fact indicates that (resin) hemoperfusion may not be capable of substantially increasing the total body clearance of bretylium in subjects with normal renal function. Similar increase in the plasma levels after hemoperfusion has also been demonstrated for digoxin (15) and has been attributed to reequilibration of digoxin between two compartments.

In patients with severely impaired renal function, in whom the plasma concentrations are relatively high and the total body clearance of bretylium is markedly reduced, it is not clear whether resin hemoperfusions will be of any benefit in removing the drug. However, marked differences may exist in the ability of different commercially available hemoperfusion devices to remove a specific drug (16). Therefore, the results of this study should not be taken to indicate that hemoperfusion with other devices will produce identical results.

This study describes the pharmacokinetics of bretylium in dogs and demonstrates that hemoperfusion with a resin column does not remove bretylium equilibrated in the body. These data suggest that resin hemoperfusion may not be useful in the treatment of human bretylium intoxication.

Determination of Sodium Fusidate and Fusidic Acid In Dosage Forms by High-Performance Liquid Chromatography and a Microbiological Method

AHMED H. HIKAL ˣ, ATEF SHIBL, and SAMMY EL-HOOFY

Received November 2, 1981, from the *Department of Pharmaceutics, College of Pharmacy, King Saud University of Riyadh, Riyadh, Saudi Arabia.* Accepted for publication January 21, 1982.

Abstract □ A new High-performance liquid chromatographic (HPLC) method for the assay of sodium fusidate (I) or fusidic acid in dosage forms was developed and compared to a microbiological assay. A linear relationship was obtained between absolute peak area and amount of I (r = 0.99+) in the 50–1000-μg/ml range. In the microbiological assay, *Staphylococcus aureus* (NCTC 6571) was the test organism, using an agar diffusion technique. With five test levels of the standard, potencies were interpolated from standard curve using a log transformation straight-line method with least-squares fitting (r = 0.99+). Both methods were applied to assay I (or fusidic acid) in tablets, a suspension, and an ointment. Excellent agreement was observed between results of the two methods.

Keyphrases □ Fusidate sodium—determination in dosage forms, high-performance liquid chromatography, microbiological method, tablets, suspension, ointment □ Fusidic acid—determination in dosage forms, sodium fusidate, high-performance liquid chromatography, microbiological method, tablets, suspension, ointment □ High-performance liquid chromatography—determination of fusidate sodium and fusidic acid in dosage forms, microbiological method, tablets, suspension, ointment

Fusidic acid is an antibiotic produced by the growth of certain strains of *Fusidium coccineum* (K. Tubaki). Its structure is related to helvolic acid and to cephalosporins. The structure also includes the cyclopentanoperhydrophenanthrene ring system, thus, it belongs to the steroid group of substances. Fusidic acid, or its sodium salt, shows a very high antistaphylococcal activity (1, 2). Available methods for the quantitative determination of fusidic acid are based mainly on microbiological procedures (3, 4). A colorimetric assay has been reported (5) which involved modification of an earlier sulfuric acid color test for steroids and measurement in the visible range of the spectrum (365–595 nm). Microbiological procedures are, by nature, time consuming and call for specialized technique, while the colorimetric assay involves the added steps of producing the color.

The present report describes a simple, sensitive, and specific procedure for the quantitative determination of fusidic acid and its sodium salt using high-performance liquid chromatography (HPLC). This new procedure was compared to a microbiological assay and was applied to the determination of fusidic acid or its sodium salt in tablets, a suspension, and an ointment.

EXPERIMENTAL

Reagents—Sodium fusidate, BP[1], was purified by crystallization from absolute ethanol before use. All other chemicals were USP or analytical reagent grade, and were used as obtained. All solvents were spectroscopic or chromatographic grade; water used in the mobile phase was double-distilled in an all-glass still. Drug products containing sodium fusidate or fusidic acid were purchased from commercial sources.

[1] Leo Pharmaceutical Products, Ballerup, Switzerland, lot no. 22176.

Apparatus—The liquid chromatograph[2] used was equipped with an automatic sample injector[3], a variable wavelength detector[4] set at 254 nm, a dual-pen recorder[5], and a data system[6]. The column was stainless steel 30 cm × 4-mm i.d. packed with microparticulate silica (5 μm) bonded with octadecylsilane[7]. Experiments were conducted at ambient temperature (25°).

Mobile Phase—The mobile phase consisted of a 3:1 mixture of

methanol[8] and 0.01 *M* KH_2PO_4 (pH ~6.6, not adjusted), at a flow rate of 2 ml/min.

Calibration Curve—Using the mobile phase as the solvent, nine different solutions of fusidate sodium were prepared to cover the 50–1000-μg/ml range. Duplicate injections of 10 μl were made, and the peak area was plotted against concentration. The line of best fit was calculated by linear regression, and was used to determine concentrations of the test solutions. The standard solutions were interspersed with solutions obtained from the extraction of dosage forms (see below), and all were run on the same working day.

Extraction Procedure—*Tablets*[9]—Six tablets were individually crushed in glass stoppered flasks, and shaken with 100 ml of methanol for 30 min. The extract was filtered through a membrane filter[10]. A 10-ml aliquot was diluted with 65 ml of methanol and 25 ml of 0.01 *M* KH_2PO_4 for HPLC assay. A 1-ml aliquot was used for microbiological assay as described below.

Suspension[11]—After shaking the bottle thoroughly, six 5-ml aliquots were pipeted using a wide-mouthed pipet, individually placed in 100-ml volumetric flasks, and treated with 0.5 ml of 1 N NaOH solution. Methanol was then added to volume, and the solution was filtered through a membrane filter[10].

Ointment[12]—Six 1-g aliquots were accurately weighed in small beakers and individually extracted as follows: Five milliliters of benzene was added, the mixture was transferred to a separatory funnel, and extracted with three 10-ml portions of 0.01 N NaOH. The combined aqueous extracts were filtered through a membrane filter[13]. A 10-ml aliquot was diluted with the mobile phase to a concentration of ~200 μg/ml for HPLC assay. A 1-ml aliquot was used for microbiological assay as described below.

Microbiological Assay—Aliquots obtained from extraction of tablets or suspension were evaporated at 50° and redissolved in 10 ml of saline. Solutions were transferred to 100-ml volumetric flasks, and saline was added to volume. Aliquots obtained from extraction of ointment were placed in 50-ml volumetric flasks, and saline was added to volume. An agar plate diffusion technique was employed using *Staphylococcus aureus* (NCTC 6571) as the test organism. A 1:10 dilution of an 18-hr culture in antibiotic assay broth[14] was added to melted and cooled (50°) antibiotic assay agar medium[14], mixed thoroughly, and poured into replica plate petri dishes. After the agar had solidified, wells (4-mm i.d.) were punched out, and a drop of a standard or test dilution was applied. Standard dilutions contained 10, 5, 2.5, 1.25, or 0.625 μg/ml of fusidate sodium in saline. Test solutions were diluted similarly. The zone of inhibition diameter was measured after an 18-hr incubation at 37°. Potencies were interpolated from a standard curve using a log transformation straight-line method with least-squares fitting.

RESULTS AND DISCUSSION

Inasmuch as fusidic acid is structurally related to steroid hormones, HPLC conditions that previously (6, 7) have been employed for steroid hormones were tried before the conditions described herein were selected. Under the experimental conditions described, sodium fusidate showed a single peak with a retention time of 7.4 min. A plot of peak area *versus* concentration produced a linear relationship (r for the least-squares line = 0.999, y-intercept = −294851, and slope = 22456); thus, no internal standard was needed. Figure 1 shows a representative chromatogram of the solution obtained from the extraction of tablets. It can be seen that the chromatogram shows an additional peak prior to the fusidate sodium peak. A similar peak appeared in the chromatogram of the solution obtained from the suspension. These additional peaks may be caused by formula additives or decomposition products; however, no definite assignment can be made at present. The absence of any interference with the sodium fusidate peak is an indication of the specificity of this procedure.

Table I gives the results of assaying commercial dosage forms by HPLC and by microbiological procedure. Good agreement is seen between results of the two methods. When six tablets were assayed by both methods, the mean (±*SD*) percent of labeled amount was 93.08 ± 3.49 by HPLC, and 93.28 ± 4.06 by microbiological procedure. The mean (±*SD*) percent of labeled amount obtained in the assay of the suspension was 103 ± 3.06 by HPLC and 101 ± 4.29 by microbiological method. HPLC assay of the ointment gave a mean (±*SD*) percent of labeled amount of 100.20 ± 3.23 compared to 98.05 ± 2.78 obtained by the microbiological method.

Microbiological procedures require considerable expenditure of time and effort and call for specialized skills. The HPLC procedure described is simple, sensitive, specific, and can be applied in routine quality control.

2-Bromo-1-hydroxyquinolizinium Bromide Substituted Anilinium Salts: A New Class of Anti-inflammatory Agents

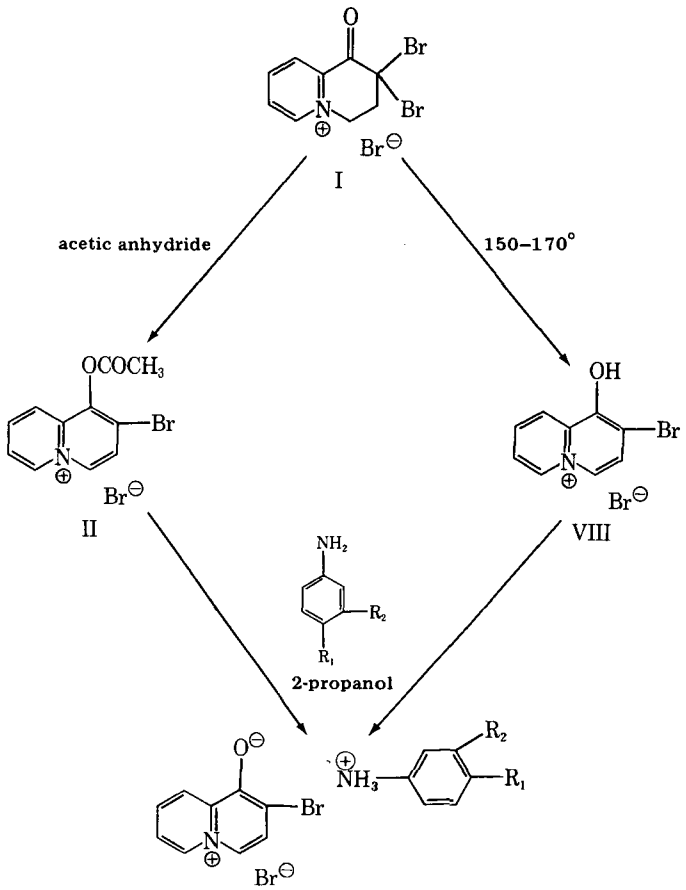
ROBERT J. ALAIMO *x **and MARVIN M. GOLDENBERG** ‡

Received October 6, 1981, from the *Chemical and ‡Biological Research Divisions, Norwich Eaton Pharmaceuticals, Inc., Norwich, NY 13815. Accepted for publication January 28, 1982.

Abstract □ A series of 2-bromo-1-hydroxyquinolizinium bromide substituted anilinium salts have been prepared by reaction of 1-acetoxy-2-bromoquinolizinium bromide with an appropriately substituted aniline. The resulting anilinium derivatives exhibited a moderate to high degree of anti-inflammatory activity in the carrageenin-induced rat paw edema assay. The most active anilinium salt of the series was evaluated for antiarthritic activity in the adjuvant induced arthritis rat model.

Keyphrases □ Anti-inflammatory agents—2-bromo-1-hydroxyquinolizinium bromide substituted anilinium derivatives, antiarthritic activity, rat □ 2-Bromo-1-hydroxyquinolizinium bromide—anti-inflammatory agents, substituted anilinium derivatives, antiarthritic activity, rat □ Derivatives, anilinium—2-bromo-1-hydroxyquinolizinium bromide, anti-inflammatory agents, antiarthritic activity, rat

As part of an investigation of the chemistry of quinolizinium salts, a number of 2-bromo-1-hydroxyquinolizinium bromide substituted anilinium salts were prepared and screened for biological activity. These anilinium compounds exhibited a moderate to high degree of anti-inflammatory activity in the carrageenin-induced rat paw edema assay. No structure–activity relationships, however, were found.



Scheme I

EXPERIMENTAL[1]

Chemistry—2-Bromo-1-hydroxyquinolizinium bromide-*p*-phenetidinium salt (III) was prepared by adding *p*-phenetidine (24 g, 0.18 mole) to a solution of 1-acetoxy-2-bromoquinolizinium bromide (30 g, 0.09 mole) (II) (1–3) in 2-propanol (600 ml). The stirred mixture was boiled under reflux for 4 hr, then chilled and filtered. The yellow crystalline product was washed thoroughly with ether and weighed 37 g (97%).

The remaining compounds in Table I were prepared in a similar manner from II and the appropriately substituted aniline. The reaction of 2-bromo-1-hydroxyquinolizinium bromide (VIII) (3) with the appropriate aniline under similar conditions provided the corresponding substituted anilinium compound III–VII in comparable yields (4). The microanalytical data for compounds III–VII are given in Table II.

Pharmacologic Testing—The compounds were tested for anti-inflammatory activity according to the carrageenin method as described previously (5). Each compound was suspended in distilled water by sonification and administered orally, 300 mg/kg in three male Wistar rats, 1 hr before subplantar injection of 0.05 ml of a 1% solution of carrageenin[2] into the left hind foot. The percentage reduction in edema formation (as compared to a nondrug-tested control) of the rat foot was recorded 4 hr after carrageenin administration.

Examination of VI for antiarthritic activity was determined by use of the adjuvant-induced arthritis model described previously (6). Ten male Wistar rats per treatment group were used in the antiarthritic evaluation. Three principal areas were considered in determining the efficacy of a drug: edema formation, body weight changes, and arthritic scores.

The arthritic lesion scores are based on a modification of previous procedures (6), in which a maximum lesion score of 27 is possible. The results are given in Table III.

RESULTS AND DISCUSSION

The 1-hydroxy-2-(substituted anilino)quinolizinium bromides (III–VII) (Table I) were readily prepared by the reaction of the known 1-acetoxy-2-bromoquinolizinium bromide (II) (1–3) or 2-bromo-1-hydroxyquinolizinium bromide (VIII) (3) with an appropriately substituted aniline in 2-propanol as shown in Scheme I (4). The preparation of the intermediate (II or VIII) proceeded through 2,2-dibromo-1,2,3,4-tetrahydro-1-oxo-quinolizinium bromide (I) either by reaction with acetic anhydride or by heating at 150–170° as shown in Scheme I. The synthesis of I has been described earlier (3).

Since II was more readily available synthetically than VIII, the procedure for the preparation of III–VII involving the use of II was favored. The yields of the final products III–VII were comparable, proceeding through either intermediate. The spectra of compounds III–VII (IR, NMR, UV), as well as the microanalytical data were consistent with the assigned structures. Further confirmation of the structure assignment was obtained when the starting material VIII was regenerated and the corresponding aniline hydrobromide salt isolated during treatment of III–VII with 48% hydrogen bromide.

These quinolizinium anilinium salts (III–VII) were evaluated for anti-inflammatory activity in the carrageenin-induced rat paw edema assay (5). The results are shown in Table I. The reference drug phenylbutazone (IX) is included for purposes of comparison. No apparent un-

[1] Melting points were determined in open capillary tubes using a Mel-Temp melting point apparatus and are uncorrected.

VI	50	0	10	22	13
	200	20	30	33	12
Aspirin	300	36	39	27	14
Phenylbutazone IX	100	78	82	40	8
Adjuvant control 0.5% methylcellulose	—	0	0	22	17

toward gross signs of drug action were observed for compounds III–VII.

The most active member of the series (VI) was examined for antiarthritic activity by use of the adjuvant-induced arthritis model (6). The results of the study were grouped into three principal areas: edema formation, body weight changes, and arthritic scores. All three areas are equally important in determining the anti-inflammatory efficacy of a drug. The results indicate that VI is at least as active as aspirin but less active than phenylbutazone. The results are presented in Table III.

The anti-inflammatory activity of compounds III–VII as revealed by the percent inhibition of edema formation was less than that elicited by several of the 2-(substituted amino)quinolizinium bromides reported previously (7).

Theophylline Bioavailability in the Dog

FRANCIS L. S. TSE *x **and DANIEL W. SZETO** ‡

Received July 16, 1981, from the *College of Pharmacy, Rutgers—The State University, Piscataway, NJ 08854.* Accepted for publication February 4, 1982. Present address: *Drug Metabolism Section, Sandoz Pharmaceuticals, East Hanover, NJ 07936; ‡Department of Basic Research, Berlex Laboratories, Cedar Knolls, NJ 07927.

Abstract □ The bioavailability of theophylline following single oral doses of a theophylline capsule, a theophylline tablet, and an aminophylline tablet in beagle dogs was compared against an intravenous standard. Plasma theophylline levels after oral and intravenous drug administration were described by the one-compartment open model. The onset of theophylline absorption from the oral products was rapid. While the theophylline tablet showed a slower absorption rate than the capsule or the aminophylline tablet, all three products appeared to be completely bioavailable.

Keyphrases □ Theophylline—absorption, bioavailability in the dog, capsule, tablet, aminophylline tablet □ Bioavailability—theophylline absorption in the dog, capsule, tablet, aminophylline tablet □ Absorption—theophylline bioavailability in the dog, capsule, tablet, aminophylline tablet

The absorption of the bronchodilator theophylline from conventional and sustained-release dosage forms has been extensively studied in humans (1–11). In one study using an aqueous solution as a standard (5), the absolute bioavailability of 13 different types of theophylline tablets marketed in the United States was determined. All yielded an absorption of >90%.

Similar comparative bioavailability data in animal models are limited. The absolute bioavailability of theophylline from five commercial dosage forms in rabbits has been examined (12). In that study significant interproduct differences in the percent of dose absorbed were reported. The data showed no evidence of dose-dependent kinetics after single oral doses (65–200 mg) of capsules or tablets.

The present report concerns theophylline bioavailability in the dog following single oral doses of a theophylline capsule, a theophylline tablet, and an aminophylline tablet, using an intravenous aminophylline dose as a reference standard.

EXPERIMENTAL

A 1-year-old male beagle dog (dog 1, 11.4 kg) and a 2-year-old female beagle dog (dog 2, 11.7 kg) each received four single doses of aminophylline or theophylline in separate experiments. The dogs were fasted overnight predose and 4 hr postdose, but had access to water at all times. During the experiment, the dogs were initially placed in a restraining sling to facilitate accurate dosing and blood sample collection.

Intravenous Administration—Each dog received a single 50-mg aminophylline[1] (85% theophylline) dose by rapid injection into a cephalic vein. Blood samples (5 ml) were collected from a cephalic or femoral vein immediately before and at 7, 10, 15, 30, and 45 min and 1, 1.5, 2, 3, 4, 6, 8, 12, and 24 hr after dosing.

Oral Administration—The capsule (A)[2] or tablet (B[3] or C[4]) was administered by placing it on the posterior portion of the dog's tongue so that it was not fractured or chewed before swallowing. The dose was followed by 20 ml of water. Venous blood samples were collected in the same manner as described for the intravenous dosing experiments, but the 7- and 10-min samples were omitted.

Blood samples were placed in heparinized tubes[5]. Plasma was separated by centrifugation and stored at −20° until analyzed.

Experiments were performed 3 weeks apart to avoid changes in pharmacokinetic parameters due to prior drug exposure and to allow complete drug washout from previous doses.

Plasma Assay—Plasma concentrations of theophylline were measured by reversed-phase high-performance liquid chromatography (HPLC) as previously described (13).

Data Interpretation—Plasma theophylline data after intravenous and oral dosing were analyzed in terms of the pharmacokinetic one-compartment open model. The equations and symbols pertaining to this model have been described (14). Intravenous pharmacokinetic parameters were calculated by linear regression of the natural log of the theophylline concentration against time. Oral data were analyzed on a digital computer[6] following standard graphical treatment; individual data sets were fitted to the appropriate equation by iterative least-squares methods using the NONLIN program (15).

RESULTS

Individual plasma levels of theophylline obtained from the four treatments are given in Table I. The results of the pharmacokinetic analysis are described in Table II.

Following intravenous dosing, plasma theophylline levels were highest (~5 μg/ml) at the first sampling time (7–10 min). Drug levels then declined monoexponentially, with plasma half-lives of 6.4 and 3.8 hr in dogs 1 and 2, respectively. The distribution volume, calculated from the y-intercept of the regression line, was 9.6 liter (84% of body weight) for dog 1 and 8.1 liter (70% of body weight) for dog 2. The plasma clearance was 1.5 ml/min/kg for dog 1 and 2.1 ml/min/kg for dog 2.

Following oral administration of each of the three products tested, theophylline was detected in plasma within 30 min. The observed onset was in good agreement with the computer estimated lag time of absorption (Table II). Product B appeared to be absorbed at a slower rate than products A and C, as indicated by its longer absorption half-time and time of peak concentration, although statistical comparison of data was not possible due to the small number of animals used. Normalized peak theophylline levels were similar for products A and B, but the level was lower for product C. The half-life of drug elimination was consistent between products, although variation between dogs was apparent. Plasma clearance values were calculated using the distribution volumes obtained from intravenous dosing.

Comparison of the areas under the plasma theophylline curves from the oral and intravenous doses, corrected for the different dose sizes, suggested complete absorption of theophylline from the three products. Correction for plasma clearance yielded F values of approximately unity in all cases.

DISCUSSION

Aminophylline, the ethylenediamine salt of theophylline, is generally used for the intravenous administration of this drug, primarily because of the low aqueous solubility of the weak acid (theophylline). A study using three volunteers (16) showed that, when given intravenously as aminophylline, theophylline was metabolized more rapidly and extensively than when given as the free acid. A previous study (17) compared the pharmacokinetics of theophylline and aminophylline after oral and intravenous administration in eight healthy male subjects, and reported virtually identical serum concentration–time curves for the two drug entities. While data in the present study also showed no apparent differences between aminophylline and theophylline disposition kinetics, plasma clearance was corrected for in the bioavailability calculations.

t_{max}, hr	—	—	1.7	1.2	2.5	3.5	0.5	1.6

[a] D, dose of theophylline or equivalent; k_a, first-order rate constant for drug absorption; $t_{1/2,abs}$, half-time of absorption = $0.693/k_a$; k_{el}, first-order rate constant for drug elimination; $t_{1/2}$, half-life of elimination = $0.693/k_{el}$; F, fraction of dose absorbed; Vd, apparent distribution volume of theophylline in the body; t_0, lag time between dosing and the appearance of drug in plasma; r, correlation coefficient; Normalized AUC, area under theophylline plasma concentration *versus* time curve = FD/Vk_{el}, normalized to a dose of 42.5 mg theophylline; PCl, plasma clearance = Vk_{el}; C_{max}, maximum concentration of theophylline in plasma after oral dosing = $(FD/V)(k_a/k_{el})^{k_{el}/(k_{el}-k_a)}$; t_{max}, time at which C_{max} occurs = $\ln(k_a/k_{el})/(k_a - k_{el}) + t_0$. [b] Plasma concentration data were weighted by their reciprocals during computer analysis. [c] Not relevant. [d] The 95% confidence interval.

In experiments with rabbits (12), no dose-dependent theophylline pharmacokinetics after single oral doses in the 65–200-mg range were found. In the dogs used in the present study, elimination half-lives and distribution volumes following a 50-mg iv dose were similar to those obtained previously (18) after a 100-mg iv aminophylline dose. Therefore, the 50-mg iv aminophylline dose was adequate as a reference dose for oral bioavailability assessment. It should be noted, however, that dose-dependent characteristics in theophylline distribution and elimination were observed at higher doses (13.8–52.0 mg/kg of aminophylline) in guinea pigs (19) and in children (20, 21).

Although the decline in plasma theophylline levels after intravenous dosing is biphasic (22), the distribution of theophylline into peripheral tissues is so rapid that a one-compartment model has been shown appropriate for the analysis of data obtained in rabbits (12), dogs (18), and humans (23, 24). This was also the case in this study.

Based on the results shown in Table II, the GI absorption of theophylline is efficient in dogs given an oral dose of either theophylline or aminophylline, despite the lower aqueous solubility of the former. This observation supports previous findings in humans (2, 17). All three products studied here were immediate-release formulations. They were similar to each other with respect to the onset of drug absorption, but the absorption rate from the theophylline tablet (B) was slower than that from the theophylline capsule (A) or aminophylline tablet (C). However, all three products showed virtually complete bioavailability.

The efficient absorption of theophylline from these different dosage forms is consistent with available data in humans (5). However, experiments with rabbits showed erratic drug absorption from commercial tablets and capsules of theophylline or aminophylline; the same brand products as used in the present study yielded F values of 0.50 to 1.20 (12). Thus, the beagle dog appears to be a more appropriate animal model for conducting theophylline pharmacokinetic studies.

A New Technique for Determining *In Vitro* Release Rates of Drugs From Creams

Keyphrases □ Dosage forms, topical—new technique for determining *in vitro* release rates of drugs from creams □ Release rate, *in vitro*—new technique for determination, drugs from creams

To the Editor:

Within about the last 10 years, dissolution testing has become recognized as one of the most useful methods for evaluating tablets and capsules. In fact, such testing has all but supplanted the traditional disintegration test. Equipment and procedures for measuring the rate and extent of drug dissolution are now becoming standardized as a result of intensive research and, necessarily, some compromises.

No such standardization appears to be occurring, however, with the equipment or procedures used for testing the release of drugs from topical dosage forms (*i.e.*, creams, ointments, gels, suppositories, *etc.*). Many investigators have done extensive research on the release of drugs from such carriers, but it seems that, almost without exception, each used a unique method for presenting the drug to some receptor phase. The reason for this may be that each was faced with unique problems with regard to the formulations.

We present here a convenient and versatile technique for the *in vitro* testing of the release of drugs from creams or ointments. This technique could be used for a wide variety of vehicles, although it was developed specifically for cream formulations which are oil in water emulsions containing 0.01% estradiol.

The ideal procedure would be one in which the sample is in direct contact with the receptor phase, because barriers used to isolate the sample from that phase have a potential leveling effect on the rate of appearance of drug (in the receptor phase). Thus, the absence of barriers should maximize the probability of measuring differences between creams which differ only slightly in their drug-release characteristics. Therefore, we first tried filling shallow cups with the cream and immersing these in water at 37° in a fashion similar to that reported previously (1). This was attempted with a variety of cups of different dimensions supported upright or inverted in the receptor phase (water). These attempts failed because the cream swelled and eventually sloughed into the water. We noted also that the creams were no longer homogeneous, *i.e.*, the first few millimeters of sample nearest the water were physically different from the bulk of the sample before the end of the test time. In addition, samples were necessarily so large (a few grams) that only a small fraction of the total estradiol was near the surface where it could be expected to be released in a reasonable length of time.

Attempts were made to isolate the cream samples from the receptor phase using semipermeable membranes. Two membranes were tested, dialysis tubing and filter paper, in procedures similar to those reported previously (2). When these barriers were used, drug appeared in the receptor phase more slowly than when they were not. Although the problems associated with sample swelling and subsequent sloughing could be alleviated by using these barriers, this approach was abandoned because of the effects on the rate of appearance of drug in the receptor phase.

With these results in mind, we developed a simple technique which allows direct contact between the cream sample and the receptor phase (water) and which eliminates or minimizes sample sloughing. Cream samples are spread into the interstices of an 80-mesh stainless steel screen. The samples prepared in this way can be submerged in gently stirred water for long periods of time. The equipment and procedure are as follows.

A number of appropriately sized pieces of stainless steel screen were first prepared by cutting 7.5 × 7.5-cm squares and removing ~1 cm from each corner (Fig. 1).

Each screen was covered on both sides along the top edge with a piece of 2.54 cm wide masking tape such that 30 cm^2

A New Technique for Determining *In Vitro* Release Rates of Drugs From Creams

Keyphrases □ Dosage forms, topical—new technique for determining *in vitro* release rates of drugs from creams □ Release rate, *in vitro*—new technique for determination, drugs from creams

To the Editor:

Within about the last 10 years, dissolution testing has become recognized as one of the most useful methods for evaluating tablets and capsules. In fact, such testing has all but supplanted the traditional disintegration test. Equipment and procedures for measuring the rate and extent of drug dissolution are now becoming standardized as a result of intensive research and, necessarily, some compromises.

No such standardization appears to be occurring, however, with the equipment or procedures used for testing the release of drugs from topical dosage forms (*i.e.*, creams, ointments, gels, suppositories, *etc.*). Many investigators have done extensive research on the release of drugs from such carriers, but it seems that, almost without exception, each used a unique method for presenting the drug to some receptor phase. The reason for this may be that each was faced with unique problems with regard to the formulations.

We present here a convenient and versatile technique for the *in vitro* testing of the release of drugs from creams or ointments. This technique could be used for a wide variety of vehicles, although it was developed specifically for cream formulations which are oil in water emulsions containing 0.01% estradiol.

The ideal procedure would be one in which the sample is in direct contact with the receptor phase, because barriers used to isolate the sample from that phase have a potential leveling effect on the rate of appearance of drug (in the receptor phase). Thus, the absence of barriers should maximize the probability of measuring differences between creams which differ only slightly in their drug-release characteristics. Therefore, we first tried filling shallow cups with the cream and immersing these in water at 37° in a fashion similar to that reported previously (1). This was attempted with a variety of cups of different dimensions supported upright or inverted in the receptor phase (water). These attempts failed because the cream swelled and eventually sloughed into the water. We noted also that the creams were no longer homogeneous, *i.e.*, the first few millimeters of sample nearest the water were physically different from the bulk of the sample before the end of the test time. In addition, samples were necessarily so large (a few grams) that only a small fraction of the total estradiol was near the surface where it could be expected to be released in a reasonable length of time.

Attempts were made to isolate the cream samples from the receptor phase using semipermeable membranes. Two membranes were tested, dialysis tubing and filter paper, in procedures similar to those reported previously (2). When these barriers were used, drug appeared in the receptor phase more slowly than when they were not. Although the problems associated with sample swelling and subsequent sloughing could be alleviated by using these barriers, this approach was abandoned because of the effects on the rate of appearance of drug in the receptor phase.

With these results in mind, we developed a simple technique which allows direct contact between the cream sample and the receptor phase (water) and which eliminates or minimizes sample sloughing. Cream samples are spread into the interstices of an 80-mesh stainless steel screen. The samples prepared in this way can be submerged in gently stirred water for long periods of time. The equipment and procedure are as follows.

A number of appropriately sized pieces of stainless steel screen were first prepared by cutting 7.5 × 7.5-cm squares and removing ~1 cm from each corner (Fig. 1).

Each screen was covered on both sides along the top edge with a piece of 2.54 cm wide masking tape such that 30 cm^2

0022-3549/82/1100-1303$01.00/0

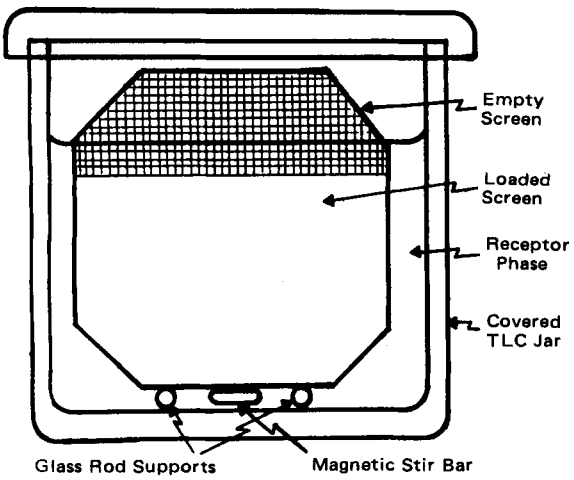

Figure 1—*The apparatus used to evaluate the* in vitro *release of estradiol from creams. The rectangular TLC developing jar normally is partially immersed in a constant temperature bath. A magnetic stirrer located beneath the constant temperature bath rotates the stir bar.*

of screen remained exposed. The taped screen was then weighed. Cream was smeared liberally into the mesh using a spatula, and excess cream was then wiped rapidly from the surface by placing the loaded screen between two disposable paper towels, pressing the towels firmly together, and pulling the screen out. After the screen with its sample was reweighed, the tape was removed and the screen was placed vertically into 120 ml of degassed water held at 37° in an 8 × 8 × 3-cm covered rectangular TLC developing jar. Small glass rods at the bottom of the jar held the screen slightly off the bottom and allowed a micromagnetic stir bar to spin fast enough (~300 rpm) just below the screen to gently mix the medium, yet not dislodge the cream from the screen. At the end of the test period, the screen with cream sample was removed from the water. The drug released into the water was recovered using a small C_{18} extraction column[1] and then analyzed by HPLC on an analytical C_{18} column using an acetonitrile–water mobile phase in a fashion similar to that reported previously (3) for dienestrol.

Figure 2 illustrates the results obtained using this procedure for a number of experimental formulations of a 0.01% estradiol cream. These formulations were alike quantitatively but differed in their processing during manufacture. These results point out a number of features of this method. First, samples can be exposed to the receptor phase for any convenient length of time; thus, a release profile can be constructed. Second, the results are easily interpreted, since they can be expressed in terms of a percentage of the total amount of drug available for release. This is possible because large (thick) samples are not necessary and the surface area of the small (~300 mg), thin sample exposed directly to the water is maximized. (The interstitial spaces comprise ~35% of the total surface area of an 80-mesh screen; thus, when both sides of the screen are taken into account, the exposed surface area of the cream is ~21 cm^2.) Third, the absence of rate-limiting or rate-influencing barriers allows subtle differences in release characteristics to be identified.

in this table represents the amount released from a separate test sample. The values demonstrate the typical reproducibility obtained with this procedure.

This technique could be useful for testing a wide variety of topical formulations where direct contact with the receptor phase is desired. The screen size and configuration could easily be altered to accommodate different types of vehicles, release rates, and concentrations of drugs. This technique may be unsuitable where the drug or vehicle interacts with stainless steel. Such instances are expected to be rare, however, and normally the technique should allow investigators to routinely and uniformly prepare and test small samples with high surface area to weight ratios.

Comparison of Chromatographic and Spectrophotometric Analysis of Indocyanine Green in Plasma Following Administration of Multiple Doses to Humans

Keyphrases □ High-pressure liquid chromatography—comparison with spectrophotometric analysis of indocyanine green in plasma following multiple dose administration, humans □ Spectrophotometry—comparison with high-pressure liquid chromatographic analysis of indocyanine green following multiple dose administration, humans □ Indocyanine green—comparison of spectrophotometric and high-pressure liquid chromatographic analysis following multiple dose administration, humans

To the Editor:

Following the administration of small doses (0.5 mg/kg), indocyanine green (I) is highly extracted from blood by the liver (1). Compound I has been used extensively, therefore, to evaluate hepatic function (2, 3) and to estimate hepatic blood flow in humans and laboratory animals (4, 5). Numerous reports have suggested that I is not metabolized in any species (4, 6, 7). Thus, simple spectrophotometric assays (*i.e.*, typically the determination of the absorbance at ~800 nm of plasma samples diluted with distilled water) have been used extensively to estimate the concentration of I in biological fluids. However, it has been reported recently that spectrophotometric and high-pressure liquid chromatographic (HPLC) assays yield radically different estimates of the concentration of I in plasma following the administration of a large dose (25.6 mg/kg) to the rabbit (8). Estimates of the plasma concentration of I ≥30 min postdose were found to be significantly lower using the HPLC assay (almost an order of magnitude lower at many time points). Thus, the total body clearance of I in the rabbit, calculated on the basis of plasma concentrations determined by HPLC, was much higher than that calculated from the spectrophotometric assay results. These investigators postulated that this discrepancy was due to a previously unidentified metabolite. If humans also metabolize I to a compound that interferes with the classical spectrophotometric methods, the clearance value of I based on these assays will not provide a reliable estimate of hepatic blood flow. Because of the potential implications of this assay discrepancy, we compared the spectrophotometric and HPLC assays for I using plasma samples from humans.

Two healthy male subjects (25 and 35 years of age) each received five intravenous bolus doses (0.5 mg/kg each) of I at ~1-hr intervals. Blood samples (5 ml) were collected into heparinized evacuated blood collection tubes[1] prior to and at 1, 3, 5, 7, 9, 11, and 15 min after the first, third, and fifth doses. Plasma was separated and stored at −20° until analyzed (within 36 hr). Previous studies have demonstrated the stability of I under these conditions (8), and preliminary work in our laboratory confirmed these findings.

After the addition of 1.0 μg of diazepam (internal standard) in 100 μl of methanol, proteins were precipitated with acetonitrile (1 ml plasma–1 ml acetonitrile) and the sample was centrifuged. The supernatant was then analyzed by spectrophotometric and HPLC methods. Samples were analyzed using a double beam spectrophotometer[2] equipped with a red-sensitive photomultiplier. The peak absorbance of I in the supernatant was found to occur at 786 nm, and this wavelength was chosen for analysis of all samples. The HPLC method used was that described recently (8) with the following modifications: Dual wavelength (254 and 650 nm)[3] monitoring was employed utilizing two detectors[4,5] in series. Absorbance at 650 nm was examined, since any degradation or metabolic products of I which contained an unaltered chromophore would be expected to absorb at a high wavelength similar to that of the parent compound. The high wavelength monitoring was achieved with a tungsten lamp in a variable wavelength monochromator[4]. A wavelength shorter than the maximum for absorbance by I was utilized in order to maintain an acceptable signal–noise ratio. Chromatography was performed on a reversed-phase column[6]. Of the various mobile phases studied previously (8), one composed of 0.05 *M* KH_2PO_4-Na_2HPO_4 (pH 6.0)–acetonitrile–methanol (50:47:3) was found to be most satisfactory. The peak height ratio was determined at both wavelengths relative to the diazepam peak height at 254 nm. Calibration curves were obtained in each subject's plasma for each analytical method.

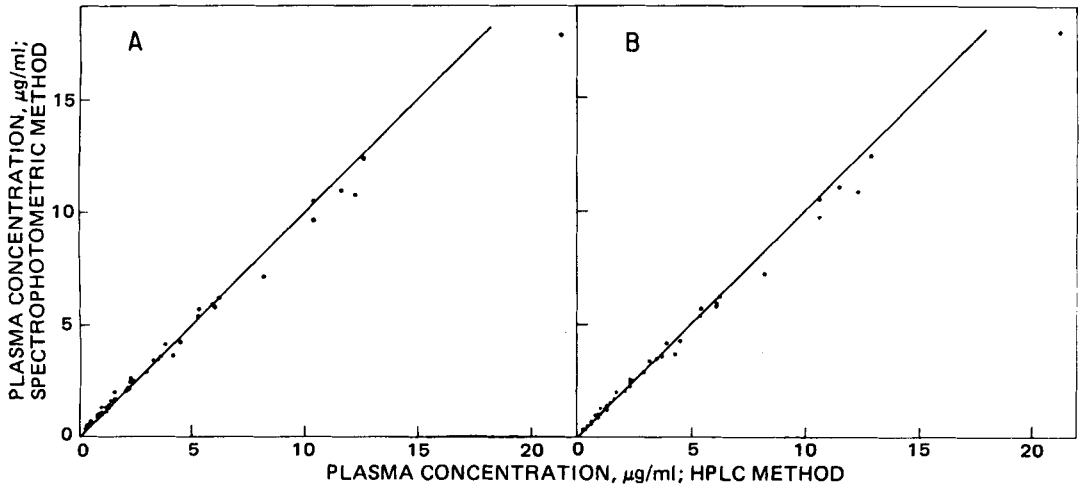

Figure 1—*Comparison of estimates of plasma indocyanine green concentration using spectrophotometric and HPLC procedures. Eluent was monitored at (A) 254 and (B) 650 nm.*

Figure 1A illustrates the relationship between estimates of the plasma concentration of I using the spectrophotometric assay and the HPLC assay (254 nm) which closely approximates the method that yielded the disparate rabbit data (8). As can be seen, a strong correlation exists between the results of the two procedures (r = 0.998; Spearman rank correlation). Similarly, a strong correlation was found between the results of the spectrophotometric method and the HPLC method with monitoring at 650 nm (r = 0.997; Fig. 1B) as well as between the two HPLC results (r = 0.999; data not shown). The close proximity of the data to the line through the origin with a slope of unity (Fig. 1) suggests that all of these assays provide comparable specificity. The single highly aberrant point (Fig. 1) was a sample drawn immediately after the first bolus; hence, the substantial difference between the two methods could not be attributed to accumulated metabolites. Indeed, the HPLC estimate was much higher than the spectrophotometric estimate.

The clearance of I (obtained by least-squares regression of the log plasma concentration *versus* time curve and the relationship: clearance = volume of distribution × elimination rate constant) estimated from concentrations determined by the spectrophotometric as well as HPLC assays at 254 and 650 nm was essentially identical (711 ± 144, 710 ± 145, and 695 ± 142 ml/min, respectively; n = 6; mean ± SD). No detectable concentration of I was present in plasma just prior to the third or fifth dose in either volunteer (lower limit of detection with HPLC method is 0.2 μg/ml). This suggests that accumulation of I does not occur following administration of small doses at 1-hr intervals. No extraneous chromatographic peaks (*i.e.*, peaks other than I and internal standard) appeared at any time points at either wavelength. However, this does not rule out the existence in humans of a metabolite similar to that suggested previously (8), since the metabolite which they proposed eluted in the solvent front, and in the present study this component of the eluent was not investigated. It is also possible that measurable quantities of such a metabolite are only formed when the capacity for biliary excretion is exceeded and, therefore, only seen following large doses or in selected species (*i.e.*, the rabbit) (9). However, the data presented in Fig. 1 suggest that the spectrophotometric assay utilized in this study and the HPLC procedures yield essentially identical estimates of the concentration of I in plasma following typical doses (0.5 mg/kg) in humans.

Substituent Contribution to the Partition Coefficients of Substituted Benzenes in Solvent–Water Mixtures

Keyphrases □ Partition coefficients—substituted benzenes in solvent–water mixtures, substituent contribution □ Solvent–water mixtures—substituent contribution to the partition coefficients of substituted benzenes □ Benzenes—substituted, substituent contribution to the partition coefficient, solvent–water mixtures

To the Editor:

In the course of correlation analysis for biological activities, octanol–water partition coefficients (P) have been used widely to express the lipophilic interactions of organic compounds with biological substrates. The contribution of a given substituent to the partitioning of a molecule is measured by a substituent constant, π, that is derived empirically from partition coefficients (1). Since discrepancies are found between some π values from different parent compounds and these variations depend also on the nature of the solvent–water system being used (2, 3), it is of interest to examine the relationship between π and pertinent physicochemical properties to identify the factors that account for the discrepancies.

By convention (1), the substituent constant π_X for a functional group attached to a reference compound (benzene or a benzene derivative) is defined as:

$$\pi_X = \log P_X - \log P_R \qquad \text{(Eq. 1)}$$

where P_X is the octanol–water partition coefficient of the compound containing substituent(s) X, and P_R is the partition coefficient of the parent or unsubstituted molecule. The extent to which π_X varies with various parent compounds was found to be relatively small for most nonpolar and weakly polar substituents (1), whereas more variation is observed for polar substituents. The values of π_X were analyzed in terms of the net partition free energies of the substituents and the free energies of interactions of the substituents with the parent aromatic structure. Because the values of the assumed free energy terms are not readily available for verifying the results, no specific rules have been constructed to indicate that π_X derived from different reference systems for a given functional group would be either constant or related in some simple way. The following analysis considers the factors affecting π_X.

Since π_X is a derived quantity, the factors that affect π_X must be contained in the expression for log P. In the absence of solute association or dissociation, the partition coefficients of slightly water-soluble organic solutes between an organic solvent and water, in which the solvent has small solubility in water, can be expressed as (4):

$$\log P = -\log S_w - \log \gamma_0^* + \log(\gamma_w^*/\gamma_w) - \log \overline{V}_0^* \qquad \text{(Eq. 2)}$$

where S_w is the water solubility (moles/liter) of the liquid (or supercooled liquid) solute, γ_0^* is the activity coefficient (Raoult's law convention) in the water-saturated solvent phase, γ_w is the activity coefficient in water at saturation, γ_w^* is the activity coefficient in solvent-saturated water, and $\overline{V}_0^*$ is the molar volume (liters/mole) of the water-saturated solvent. The log $\overline{V}_0^*$ term is essentially constant for solutes in dilute solution.

Benzaldehyde	CHO	−0.23	−0.65	−1.21
Nitrobenzene	NO_2	0.14	−0.28	−0.77
Benzonitrile	CN	−0.26	−0.57	−1.36

[a] The Δ values are calculated from the respective γ_w values of the compounds at ~25° and log γ_w = 3.38 for benzene as the standard (Ref. 7). Data for halobenzenes, dichlorobenzenes, 1,2,4-trichlorobenzene, *m*-chloroaniline, and toluidines are taken from the citations given in Ref. 4; anisole and benzonitrile from Ref. 8; and the remainder from the citations in Ref. 6. [b] The π (octanol–water) values are based on log P = 2.13 for benzene (Ref. 1) as the standard and the log P data from the citations in Refs. 1 and 9 for all compounds, except for 1,2,4-trichlorobenzene from Ref. 4. [c] The π (heptane–water) values are calculated from the respective log P values of the compounds using log P = 2.26 for benzene (Ref. 9) as the standard. Data for toluene, xylenes, aniline, *m*-chloroaniline, *m*-toluidine, benzoic acid, and anisole are from the citations in Ref. 9 and the rest from this work.

In octanol–water systems, it has been shown (4, 5) that the primary determinant of the solute partition coefficient is the extent of solute solubility in water (S_w), followed in decreasing order by solute incompatibility with octanol (γ_0^*) and the alteration of solute water solubility by dissolved octanol (γ_w^*/γ_w). The log (γ_w^*/γ_w) term is relatively small for those solutes that have comparable or greater solubility in water than octanol (solvent) in water, and thus can be neglected for many simple aromatic liquids.

Substituting Eq. 2 into Eq. 1 gives:

$$\pi_X \simeq \log[(S_w)_R/(S_w)_X] - \log[(\gamma_0^*)_X/(\gamma_0^*)_R] \qquad \text{(Eq. 3)}$$

or

$$\pi_X \simeq \log[(\gamma_w)_X/(\gamma_w)_R] - \log[(\gamma_0^*)_X/(\gamma_0^*)_R] \qquad \text{(Eq. 4)}$$

where the solubility ratio in Eq. 3 may be replaced by the inverse of the activity coefficient ratio (4, 5). The magnitude of π_X for a functional group in a reference compound thus is equal to the difference between $\log[(\gamma_w)_X/(\gamma_w)_R]$ and $\log[(\gamma_0^*)_X/(\gamma_0^*)_R]$, *i.e.*, between the effects of the substituent on solute compatibility with water and with octanol (solvent).

0022-3549/82/1100-1307$01.00/0

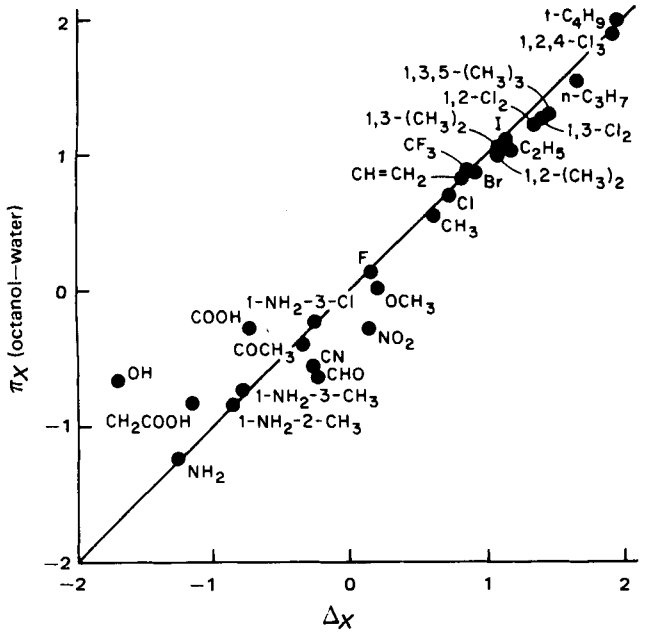

Figure 1—*A comparison of* Δ_X *and* π_X *(octanol–water) values for common substituents with benzene as the reference standard. Key: (—)* π_X *(octanol–water)* = Δ_X.

To illustrate the relative effects of these two terms on the values of π_X for some substituents in the octanol–water system, benzene is chosen as the reference compound. For both benzene and benzene substituted with nonpolar and weakly polar groups (such as X = halogens, alkyl groups, and amino), the logarithmic effects on activity coefficients in octanol (log γ_0^*) are considerably less than in water (log γ_w) (4, 5). For example, the $\log[(\gamma_w)_X/(\gamma_w)_R]$ values with benzene as reference are −1.24, 0.72, 0.91, and 1.66 for X = NH_2, Cl, Br, and n-C_3H_7, respectively, and the corresponding $\log[(\gamma_0^*)_X/(\gamma_0^*)_R]$ values are ~0.00, 0.01, 0.05, and 0.10 calculated following a previously described method (4). Consequently, the magnitude of each π_X should be essentially equal to the value of $\log[(\gamma_w)_X/(\gamma_w)_R]$, which is designated for brevity as Δ_X (6).

A comparison of π_X and Δ_X values is shown in Table I, and a plot of π_X versus Δ_X is shown in Fig. 1. The results indicate that when π_X approximates Δ_X for substituent X and π_Y approximates Δ_Y for substituent Y in monosubstituted benzenes, the values of π_{XX} (or π_{YY}) and π_{XY} also approximate the corresponding values of Δ_{XX} (or Δ_{YY}) and Δ_{XY} for disubstituents X,X and X,Y attached to benzene. Supporting data are demonstrated with xylenes and dichlorobenzenes ($\pi_{XX} \simeq \Delta_{XX}$) and with toluidines and m-chloroaniline ($\pi_{XY} \simeq \Delta_{XY}$). It is recognized, however, that the magnitudes of π_{XX} and π_{XY} (or Δ_{XX} and Δ_{XY}) in disubstitution are not necessarily equal to the sum of π_X and π_Y (or correspondingly of Δ_X and Δ_Y). This is because the increment in solute activity coefficient with addition of a substituent may vary from compound to compound (*i.e.*, from benzene to a substituted benzene) and from solvent to solvent (in this case from water to octanol). Since the additivity rule may not be strictly obeyed when more than one substituent is present, it is better to consider the set of substituents as a whole rather than to treat them as a sum of independent components.

The value of π_X would be expected to deviate significantly from Δ_X when a benzene derivative and benzene show appreciable differences in their respective compatibilities with octanol. If the derivative is more compatible than benzene with octanol, *i.e.*, if $\log[(\gamma_0^*)_X/(\gamma_0^*)_R]$ is negative, then π_X will be greater than Δ_X. The finding that π_X is significantly greater than Δ_X for X = COOH and CH_2COOH is reasonable, because the addition of these highly polar groups to relatively nonpolar benzene should make for better compatibility with the partially polar octanol phase, which also contains 2.3 M of water (10). Although phenol is expected to be more compatible with the octanol than benzene (*i.e.*, $\pi_X > \Delta_X$ when X = OH), the large difference between π_X and Δ_X could partly be due to hydrate formation of phenol in water (11), which introduces inaccuracies into the value of Δ_X (*i.e.*, γ_w for phenol) as calculated from the apparent phenol solubility in water.

With X = NO_2, CN, and CHO, the values of π_X are much smaller than the respective values of Δ_X. It is not clear whether these anomalies are caused by some specific interactions of octanol with nitrobenzene, benzonitrile, and benzaldehyde or by possible solute associations or dissociations in water and/or octanol. In general, although the π_X values for highly polar groups might deviate significantly from the respective Δ_X values in octanol–water systems, the differences are usually well within ±1 for simple aromatic compounds in the absence of association or dissociation. This may be attributed to the partially polar nature of the octanol medium that allows it to accommodate relatively indiscriminately a wide range of benzene derivatives of varying polarities (4, 5).

The foregoing analysis with benzene as reference also applies to systems with other compounds as reference standards. Again, the values of π_X and Δ_X derived with respect to a new reference compound should be comparable with nonpolar and weakly polar functional groups. For instance, when aniline (log P = 0.90) is used as the reference, the values of π_X and Δ_X are 0.98 and 0.98 for X = Cl (*meta*); 0.39 and 0.42 for X = CH_3 (*ortho*); and 0.50 and 0.46 for X = CH_3 (*meta*). With toluene (log P = 2.69) as reference, π_X and Δ_X are 0.43 and 0.48 for X = CH_3 (*ortho*) and 0.51 and 0.49 for X = CH_3 (*meta*). These results agree with the earlier findings that the group contribution to partition coefficient derives mainly from the variation of the solute incompatibility with water, although π_X may vary from one reference standard to another. Again, significant (but not remarkable) differences between π_X and Δ_X would occur if $\log[(\gamma_0^*)_X/(\gamma_0^*)_R]$ should become significant.

While the values of $\log[(\gamma_0^*)_X/(\gamma_0^*)_R]$ are relatively small and comparable for most substituents in the octanol–water system, they can be highly important for certain substituents in other solvent–water systems in which the solvent is sensitive to the polarity difference of the two partitioned solutes. This argument follows a general rule that components of similar polarities and structures usually form more ideal solutions than components of different polarities and structures (*i.e.*, like dissolves like). Consider now the π_X values for the substituents derived from the heptane–water system using again benzene as the parent compound (Table I). A plot of π_X (heptane–water) *versus* Δ_X is given in Fig. 2. The extremely nonpolar structure of

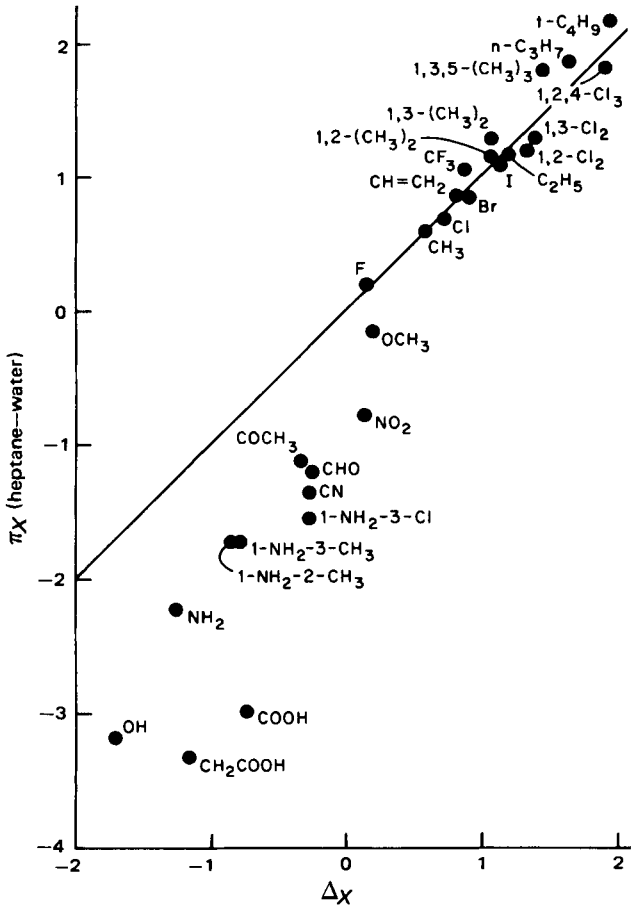

Figure 2—*A comparison of* Δ_X *and* π_X *(heptane–water) values for common substituents with benzene as the reference standard. Key: (—)* π_X *(heptane–water)* = Δ_X.

heptane, as evidenced by small water content of 3.3×10^{-3} *M* at saturation (10), makes it sensitive to the difference in polarity between a substituted and parent (benzene) molecules. With X = NH_2, CHO, NO_2, CN, $COCH_3$, COOH, and CH_2COOH attached to benzene, the observed π_X (heptane–water) values are markedly lower than the corresponding Δ_X values. These results presumably from greatly increased polarities of the substituted benzenes (over that of benzene), which reduce the compatibilities of the substituted benzenes with heptane. Addition of alkyl groups to benzene (making the molecules more hydrocarbon-like) gives somewhat higher π_X (heptane–water) than π_X (octanol–water), as would be expected. Addition of halogen groups shows insignificant differences between the two sets of π_X values. In other words, the values of $\log[(\gamma_0^*)_X/(\gamma_0^*)_R]$ in the heptane phase are reasonably close to zero for relatively nonpolar substituents but are very significant and positive for polar substituents. As a whole, those substituents which cause large differences between π_X (heptane–water) and Δ_X are the same ones that show large differences between π_X (heptane–water) and π_X (octanol–water).

In conclusion, the correspondence between Δ_X and π_X in heptane–water is less obvious than in octanol–water, because heptane shows greater sensitivity than octanol to the polarities of the substituted benzenes.

Effect of Water Deprivation on Chloramphenicol Disposition Kinetics in Humans

Keyphrases □ Kinetics, disposition—effect of water deprivation on chloramphenicol, humans □ Chloramphenicol—effect of water deprivation, disposition kinetics in humans

To the Editor:

The first study of the effect of water deprivation on drug disposition kinetics was recently reported (1). Temporary water deprivation causes significant changes in drug metabolizing enzymes, hormones responsible for water balance in the body, and blood chemistry and physiology (2–4). Despite these significant changes, little has been reported in the literature on the effect of water deprivation resulting from various disease states and environmental factors on drug disposition kinetics.

The present study reports the effect of highly restricted water intake on chloramphenicol absorption and urinary elimination in humans.

The panel of subjects studied consisted of four healthy male volunteers (weight, 60–72 kg; age, 22–24 years). A total of 14 days was allowed for the conditioning of the subjects for the treatment studies. During the first 11 days,

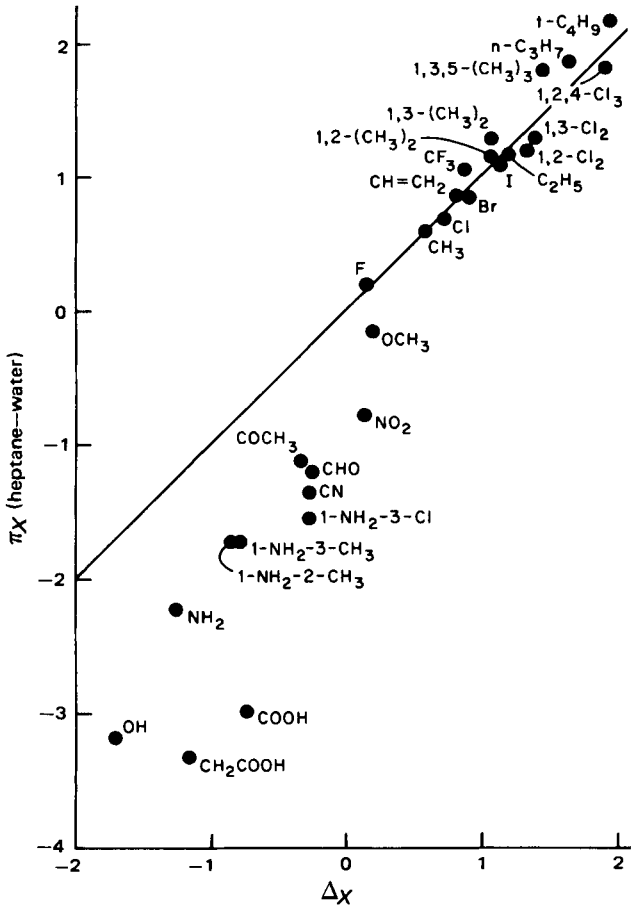

Figure 2—*A comparison of* Δ_X *and* π_X *(heptane–water) values for common substituents with benzene as the reference standard. Key: (—)* π_X *(heptane–water)* = Δ_X.

Effect of Water Deprivation on Chloramphenicol Disposition Kinetics in Humans

Keyphrases □ Kinetics, disposition—effect of water deprivation on chloramphenicol, humans □ Chloramphenicol—effect of water deprivation, disposition kinetics in humans

To the Editor:

The first study of the effect of water deprivation on drug disposition kinetics was recently reported (1). Temporary water deprivation causes significant changes in drug metabolizing enzymes, hormones responsible for water balance in the body, and blood chemistry and physiology (2–4). Despite these significant changes, little has been reported in the literature on the effect of water deprivation resulting from various disease states and environmental factors on drug disposition kinetics.

The present study reports the effect of highly restricted water intake on chloramphenicol absorption and urinary elimination in humans.

The panel of subjects studied consisted of four healthy male volunteers (weight, 60–72 kg; age, 22–24 years). A total of 14 days was allowed for the conditioning of the subjects for the treatment studies. During the first 11 days,

each was allowed 1 liter of water/day, for the next 2 days only 350 ml/day, and 24 hr before the study only 200 ml of water/day. All subjects were fasted overnight. The treatment studies began at 8 am when chloramphenicol was given as 10 ml of suspension[1] (250 mg) with 150 ml of water. Urine samples were collected afterward on a periodic basis during an interval of 24 hr and analyzed for chloramphenicol using a previously described method (5). A 2-week wash-out period was allowed between control and treatment studies. In the control studies, which preceded the treatment studies, food and water were available *ad libitum*. Otherwise, conditions of the control studies were the same as for the treatment studies. The data of Table I show the effect of water deprivation on the absorption rate and the urinary excretion of chloramphenicol. Although there was no significant change in the total absorption of chloramphenicol, the absorption half-life decreased significantly (~66%), while the peak excretion rate increased, and the time at which the peak excretion occurred decreased significantly.

These findings are of great interest, since the overall effect of water deprivation is specified in terms of the rate of absorption change, which results in the substantially higher plasma levels of chloramphenicol in the water deprivation state. The influence of such (water deprivation) alteration in the peak plasma levels of chloramphenicol on the efficacy and toxicity of this antibiotic will profoundly affect its clinical utility. These observations are the first of their kind, and mechanisms for the effects observed remain to be investigated.

BOOKS

REVIEWS

ISI Atlas of Science. By Dr. EUGENE GARFIELD. Institute of Scientific Information, 3501 Market Street, University City Science Center, Philadelphia, PA 19104. 1982. 540 pp. 23 × 29 cm. Price $45.00 to individuals, $90.00 to institutions.

The *ISI Atlas of Science* is a new information and research guide in biochemistry and molecular biology. The *Atlas* is a unique new aid containing concise, convenient lists of papers and current literature in 102 active research areas in the life sciences.

This atlas contains a reference system of core clusters of research areas identified objectively by the use of citation patterns of publishing scientists, graphically displayed in detail by the use of maps.

Research areas described in the *Atlas* are divided into minireviews, core document bibliographies, specialty maps, and key citing document bibliographies. Also included within this atlas is a unique multi-colored fold-out map providing a "global" view of the relationships and interactions of the 102 research areas, ideal for display in labs, classrooms, and libraries.

The *Atlas* was designed to be used as a tool for analytical and utilitarian research needs. This publication should be a valuable tool for specialists in biochemistry and molecular biology for overviews of new fields of research and fields related to present work. Librarians can use the *Atlas* for subject bibliographies. This should also be of interest to historians for bibliographic and analytical information in tracing the structure and growth of scientific fields.

Staff Review

Drug Absorption. Edited by L. F. PRESCOTT and W. S. NIMMO. Adis Press, 404 Sydney Road, Balgowlah, NSW 2093, Australia. 1979. 353 pp. 16 × 24 cm.

This multi-authored book describes the proceedings of an international conference of Drug Absorption which was held in Edinburgh in September 1979.

The editors of the book are recognized authorities in the field of drug absorption, and the many authors who have contributed to the 31 chapters represent a broad, international array of specialists in this area.

Topics covered include anatomical and physiological factors affecting absorption, membrane effects, rectal absorption, presystemic and intestinal metabolism, toxicity, formulations and novel drug delivery systems, transdermal and controlled GI drug absorption, effect of age and disease states on drug bioavailability, methods of assessing drug absorption, *in vitro–in vivo* correlations, and problems in the assessment of drug absorption. The concluding chapter summarizes the viewpoints of regulatory agencies, clinical pharmacology, and of the pharmaceutical industry on drug bioavailability and pharmacokinetic studies.

Most of the chapters contain a discussion section, and all chapters are adequately referenced. A subject index is included.

This is a useful and instructive book that is broad-reaching in scope. The extensive coverage of many factors related to drug absorption, and the clear and articulate way in which the material is presented, makes it a required text for those interested in this broad area of research and clinical practice.

The treatment studies began at 8 am when chloramphenicol was given as 10 ml of suspension[1] (250 mg) with 150 ml of water. Urine samples were collected afterward on a periodic basis during an interval of 24 hr and analyzed for chloramphenicol using a previously described method (5). A 2-week wash-out period was allowed between control and treatment studies. In the control studies, which preceded the treatment studies, food and water were available *ad libitum*. Otherwise, conditions of the control studies were the same as for the treatment studies. The data of Table I show the effect of water deprivation on the absorption rate and the urinary excretion of chloramphenicol. Although there was no significant change in the total absorption of chloramphenicol, the absorption half-life decreased significantly (~66%), while the peak excretion rate increased, and the time at which the peak excretion occurred decreased significantly.

These findings are of great interest, since the overall effect of water deprivation is specified in terms of the rate of absorption change, which results in the substantially higher plasma levels of chloramphenicol in the water deprivation state. The influence of such (water deprivation) alteration in the peak plasma levels of chloramphenicol on the efficacy and toxicity of this antibiotic will profoundly affect its clinical utility. These observations are the first of their kind, and mechanisms for the effects observed remain to be investigated.

BOOKS

REVIEWS

ISI Atlas of Science. By Dr. EUGENE GARFIELD. Institute of Scientific Information, 3501 Market Street, University City Science Center, Philadelphia, PA 19104. 1982. 540 pp. 23 × 29 cm. Price $45.00 to individuals, $90.00 to institutions.

The *ISI Atlas of Science* is a new information and research guide in biochemistry and molecular biology. The *Atlas* is a unique new aid containing concise, convenient lists of papers and current literature in 102 active research areas in the life sciences.

This atlas contains a reference system of core clusters of research areas identified objectively by the use of citation patterns of publishing scientists, graphically displayed in detail by the use of maps.

Research areas described in the *Atlas* are divided into minireviews, core document bibliographies, specialty maps, and key citing document bibliographies. Also included within this atlas is a unique multi-colored fold-out map providing a "global" view of the relationships and interactions of the 102 research areas, ideal for display in labs, classrooms, and libraries.

The *Atlas* was designed to be used as a tool for analytical and utilitarian research needs. This publication should be a valuable tool for specialists in biochemistry and molecular biology for overviews of new fields of research and fields related to present work. Librarians can use the *Atlas* for subject bibliographies. This should also be of interest to historians for bibliographic and analytical information in tracing the structure and growth of scientific fields.

Staff Review

Drug Absorption. Edited by L. F. PRESCOTT and W. S. NIMMO. Adis Press, 404 Sydney Road, Balgowlah, NSW 2093, Australia. 1979. 353 pp. 16 × 24 cm.

This multi-authored book describes the proceedings of an international conference of Drug Absorption which was held in Edinburgh in September 1979.

The editors of the book are recognized authorities in the field of drug absorption, and the many authors who have contributed to the 31 chapters represent a broad, international array of specialists in this area.

Topics covered include anatomical and physiological factors affecting absorption, membrane effects, rectal absorption, presystemic and intestinal metabolism, toxicity, formulations and novel drug delivery systems, transdermal and controlled GI drug absorption, effect of age and disease states on drug bioavailability, methods of assessing drug absorption, *in vitro–in vivo* correlations, and problems in the assessment of drug absorption. The concluding chapter summarizes the viewpoints of regulatory agencies, clinical pharmacology, and of the pharmaceutical industry on drug bioavailability and pharmacokinetic studies.

Most of the chapters contain a discussion section, and all chapters are adequately referenced. A subject index is included.

This is a useful and instructive book that is broad-reaching in scope. The extensive coverage of many factors related to drug absorption, and the clear and articulate way in which the material is presented, makes it a required text for those interested in this broad area of research and clinical practice.

A New Editor Takes the Helm

This past week, we read an article forecasting the demise of scientific journals as we know them today, and predicting that ten, or at most fifteen, years from now computerized information systems will have completely displaced print and paper for the recording and dissemination of technical reports and research findings.

That article was not the first one we read along that line. In fact, it was just the latest of many such articles that have made similar predictions over the past twenty years or more. And, of course, had the initial forecasts of results and timing been accurate, neither this journal nor its many companion research periodicals would be appearing in printed format (so-called "hard copy") today.

So we must view such sweeping prognostications with an appropriate air of skepticism.

On the other hand, we also recall similar forecasts being made less than twenty years ago with regard to conventional office typewriters, both manual and electric. And, lo and behold, this very editorial is being composed today on a computerized word processor complete with video screen, disc storage, and a whole array of modern electronic hardware. Hence, this second experience simply confirms the adage that, with regard to the future, precious little can be said with any certainty.

Nevertheless, regardless of how our information systems may be automated, and regardless of whatever novel devices may be developed for the storage and transmittal of that information, human judgment, human decisions, and human selection will remain just as important and necessary in determining what qualifies as good research deserving of publication twenty years from now as today. Consequently, the talents and expertise of a knowledgeable, trained scientist-editor will be just as important as ever before in the research journal publication process.

All of which brings us to the purpose of this editorial.

The *Journal of Pharmaceutical Sciences* has had the particular good fortune to have the sharp blue pencil, the perceptive watchful eye, and, yes, even the devoted loving care, of a highly dedicated and competent editor ever since this writer relinquished the position in December 1973. Mary Hudson Ferguson, Ph.D., had previously served with distinction as assistant editor, and subsequently as associate editor, from the time she joined the American Pharmaceutical Association staff in January, 1967. Having amply demonstrated that she could handle the editorship, it was with complete confidence that the full editorship was then entrusted to her almost nine years ago.

And over the years, numerous authors and an equally numerous group of reviewers developed well-deserved respect and appreciation for the obvious interest and efforts she devoted to the *Journal* as a whole as well as to each and every manuscript submitted to it for publication consideration. Through her efforts and professional contribution, we believe that a very good journal was made even much better, and that it achieved a new high level of national and international recognition as a first-rate research-oriented publication.

For personal and family reasons, Dr. Ferguson decided about a year ago to take early retirement. It was with great reluctance that the Association and its Board of Trustees acceded to her wishes and accepted her resignation. Her associates on staff, as well as the many professional friends she made over the years in her work on the *Journal*, were saddened to learn of her impending departure. All, however, wish her the best in her decision and hope for her personal happiness.

And now a new chapter has begun in the life of the *Journal of Pharmaceutical Sciences.* Effective November 1, Sharon G. Boots, Ph.D., took over the reins from Dr. Ferguson. In succeeding to the editorship, Dr. Boots continues in the scientific mold that the APhA established for the *Journal's* editors when it was initially founded over seventy years ago. Drawing on her background, it is her intention to maintain and extend the tradition of high scientific quality that has been the *Journal's* hallmark over the years. Moreover, she has the training and experience to enable her to achieve that goal.

We are pleased, therefore, to welcome Dr. Boots as the new editor, and to introduce her to the *Journal's* readership.

And to her we offer the old naval officer's greeting of "Welcome aboard!"

Effects of Surfactants on the Aqueous Stability and Solubility of β-Lactam Antibiotics

AKIRA TSUJI *x, ETSUKO MIYAMOTO ‡, MUNEAKI MATSUDA *, KEIKO NISHIMURA *, and TSUKINAKA YAMANA §

Received June 8, 1981, from the *Faculty of Pharmaceutical Sciences and §Hospital Pharmacy, Kanazawa University, Takara-machi, Kanazawa 920, Japan, and the ‡School of Pharmacy, Hokuriku University, Kanagawa-machi, Kanazawa 920-11, Japan. Accepted for publication February 4, 1982.

Abstract □ Studies were undertaken to elucidate the interaction between β-lactam antibiotics and surfactant micelles and to examine the effects of surfactants on their aqueous stability and solubility. The apparent binding constant of the micelle–antibiotic complex was determined as a function of the solution pH at 37° and $\mu = 0.15$ by the dynamic dialysis method and hydrolysis study. In the interaction with nonionic and anionic micelles of polyoxyethylene-23-lauryl ether (I) and sodium lauryl sulfate (II), large differences were noted in the binding constants between the undissociated and ionized species of penicillins. However, the cationic surfactants, cetyltrimethylammonium bromide (III), showed no significant difference in the binding constants for both species. Acid degradation of penicillins was protected in micellar solutions of I and III but was facilitated in micelles of II. The surfactants exerted no influence on the neutral degradation of the antibiotics used. The solubilization of penicillin V acid by micelles of I was studied at pH 2.0 and 35°. The solubility increased threefold in the presence of 10 m*M* I.

Keyphrases □ Antibiotics, β-lactam—effects of surfactants on the aqueous stability and solubility, interactions with surfactant micelles □ Surfactant micelles—effects on the aqueous stability and solubility of β-lactam antibiotics □ Binding constant—interaction between β-lactam antibiotics and surfactant micelles, aqueous stability and solubility

The interaction of surface-active agents with drugs is of theoretical and practical importance, since such surfactants represent one of the most important groups of adjuvants in pharmaceutical preparations. Surfactants incorporated in the drug dosage form are able to influence the drug stability and dissolution as a result of drug–surfactant micellar interactions.

So far there have been only a few reports on the interaction (1–3) between β-lactam antibiotics and surfactant micelles. Recently, a catalytic effect of cationic surfactants on the degradation of cephalexin at neutral pH by entrapment of the antibiotic micelles was described. No effects on the cephalexin stability, however, were observed in anionic micelles (2).

The aims of the present study were to elucidate the entrapment of penicillin and cephalosporin antibiotics into the micelle of various types of surfactants as a function of the solution pH, and to investigate the effects of the antibiotic–micelle interaction on the stability and solubility of these antibiotics under a gastric pH environment. A preliminary report has already been published (3).

EXPERIMENTAL

Materials—*Antibiotics*—The following β-lactam antibiotics were used as supplied: propicillin potassium[1] (993 μg/mg), penicillin V potassium[2] (1490 U/mg), and cefazolin sodium[3] (966 μg/mg). Free acid of penicillin V was obtained from a commercial source[4].

Surfactants—Polyoxyethylene-23-lauryl ether (I), sodium lauryl sulfate (II), and cetyltrimethylammonium bromide (III) were obtained from commercial sources and used without further purification except II. Compound II was recrystallized according to the literature (4).

Chemicals—All other chemicals employed were of reagent grade and used without further purification except imidazole. Imidazole was recrystallized from benzene followed by a thorough washing with ether.

Analytical Procedures—Propicillin and penicillin V were determined by the spectrophotometric method developed previously (5). No influence of surfactants in this assay was observed. The concentration of the antibiotic in the samples was calculated from a calibration curve prepared daily. Cefazolin was analyzed in the stability experiment by reversed-phase high-performance liquid chromatography (HPLC). The liquid chromatograph[5] was equipped with a UV detector[6] set at 254 nm. The stationary phase was octadecylsilane chemically bonded on totally porous silica gel, prepacked into a 125-mm stainless steel column[7] (4.6-mm i.d.). The mobile phase was 10% (v/v) acetonitrile–0.01 *M* ammonium acetate. The instrument was operated at ambient temperature and at a flow rate

of 1.0 ml/min, and then samples were injected through a 100-μl injector[8]. The peak heights were used for quantification.

Procedure—*Dynamic Dialysis*—The method employed was essentially the same as that described previously (6). The apparatus used in this study is illustrated in Fig. 1. The system consisted of a jacketed beaker (500 ml) set in a thermostated water bath. Three hundred milliliters of buffer solution (ionic strength 0.15) was placed in the beaker. A cellulose tube[9] was knotted at one end to form a bag (length 10 cm) and attached with a rubber band to the glass tubing with a stirring shaft. Eight milliliters of antibiotic buffer solution with or without surfactants was placed into the bag. The bag attached with a stopper was fitted on the beaker. Both the inner and outer solutions were stirred. All experiments were carried out at 37 ± 0.1° and at various pHs with phosphate, acetate, and citrate buffer systems maintained at an ionic strength of 0.15. At appropriate time intervals, aliquots (10 ml) of the outer solution were withdrawn and 10 ml of drug-free buffer solution preheated at 37° was added. The samples were analyzed by the spectrophotometric method or HPLC described in the previous section. The concentration of the outer solution samples was corrected as follows:

$$(C_{II})_n = (C_{II})_n^{obs} + (V_s/V_{II}) \sum_{i=1}^{n} (C_{II})_{i-1} \qquad \text{(Eq. 1)}$$

where $(C_{II})_n$ and $(C_{II})_n^{obs}$ represent the true and observed concentrations of the nth sample from the outer solution, respectively, and V_s and V_{II} represent the sampling volume and volume of the outer solution, respectively.

Degradation Kinetics—Unless otherwise stated, kinetic studies were carried out at 37 ± 0.1° and an ionic strength of 0.15. Each antibiotic was dissolved in hydrochloric acid–potassium chloride aqueous solution with or without surfactant to give a final antibiotic concentration of 6×10^{-4} *M*. A saturated solution of the antibiotic was sometimes used because of limited solubility. At appropriate time intervals, aliquots were withdrawn, cooled, and analyzed. The pseudo first-order rate constants, k_{deg}, were calculated by least-squares analysis of the slopes of plots between the logarithm of the antibiotic concentration and time.

Solubility Measurement—An excess of penicillin V (acid form) was added to the hydrochloric acid–potassium chloride solution (pH 2.0 and ionic strength 0.5) in a glass-stoppered flask. The flask was placed in a thermostated water bath at 35 ± 0.1° and shaken mechanically until the antibiotic concentration in the solution showed an equilibrium value. A sample was taken through a 0.45-μm membrane filter[10] and, if necessary, assayed after appropriate dilution with distilled water. The pH of the sample solution was measured[11] before use and at the end of the experiment; no significant change was observed.

Determination of Critical Micelle Concentration—The determination of the critical micelle concentration (CMC) was accomplished by determining the concentration at which the break in the log concentration *versus* surface tension plot occurs. The surface tension of surfactant solutions of ionic strength of 0.15 containing various concentrations of I, II, or III and the antibiotic at the concentration used for dialysis and degradation studies was determined at 37° by a Du Nöuy tensiometer[12].

RESULTS

Kinetics of Dynamic Dialysis—For quantification of the interaction between a drug molecule and surfactant micelles, various methods are available such as equilibrium dialysis (7), dynamic dialysis (8), micellar solubilization (9), the potentiometric titration method (10), molecular sieve (11), and micellar catalysis kinetics in the drug degradation (9). Among these, the dynamic dialysis method provides quick information for the existence of the interaction with macromolecules by utilization of marked difference of the permeation rate through a dialysis membrane.

According to Fick's first law of diffusion, the rate of drug dialysis can be expressed by:

$$\frac{d(C_I)_T}{dt} = -k_{dia}[(C_I)_T - (C_{II})_T] \qquad \text{(Eq. 2)}$$

where $(C_I)_T$ and $(C_{II})_T$ represent the total concentration of the drug in the inner and outer solutions of the dialysis bag, respectively. Since the present experiments were carried out under the sink condition, $(C_I)_T - (C_{II})_T$ was assumed to be equal to $(C_I)_T$. The apparent first-order dialysis rate constant, k_{dia}, therefore, was calculated from:

$$\ln(C_I)_T/C_0 = -k_{dia}t \qquad \text{(Eq. 3)}$$

where C_0 represents the initial concentration of the drug solution in the dialysis bag. The value for $(C_I)_T$ was calculated from the mass balance equation as follows:

$$(C_I)_T = \frac{C_0V_I - (C_{II})_TV_{II}}{V_I} \qquad \text{(Eq. 4)}$$

where V_I and V_{II} represent the volume of the inner and outer solutions, respectively. Figure 2 shows typical semilogarithmic plots of the molar fraction of propicillin remaining in various surfactant solutions in the bag *versus* time, and it indicates that the dialysis rates follow first-order kinetics in conformity with Eq. 3. Plots of the k_{dia} for propicillin *versus* the concentration of surfactants are given in Fig. 3 and show a marked decrease of k_{dia} with increase in the surfactant concentration and a tendency to reach constant rate constants. The results apparently indicate the occurrence of entrapment of propicillin in the micelles, which are difficult to be dialyzed.

If the drug is incorporated into the micelle, there then will be an equilibrium between the drug in solution and that in the micelle. The apparent binding constant, K_{app}, can be expressed as:

$$K_{app} = \frac{(C_I)_m}{(C_I)_f(C_D - CMC)} \qquad \text{(Eq. 5)}$$

[12] Du Nöuy tensiometer, Shimadzu, Co., Kyoto, Japan.

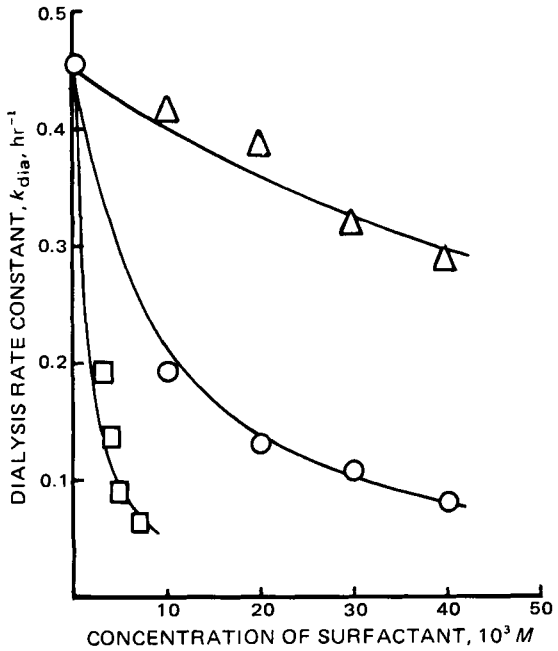

Figure 3—*Plots of the pseudo first-order rate constant,* k_{dia}, versus *total surfactant concentration for the dialysis of propicillin at 37° and* μ = *0.15. Key: (○) I (pH 3.50); (△) II (pH 4.40); (□) III (pH 6.50). The points are experimental values. The solid curves were generated from Eq. 6 using the parameters in Table II.*

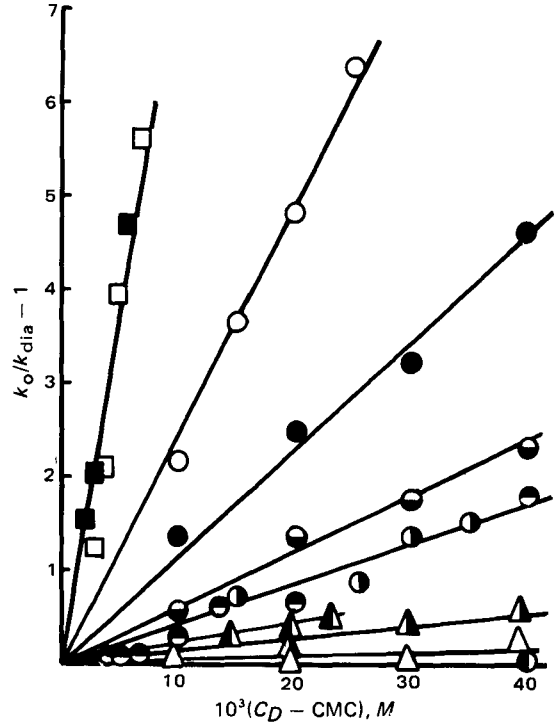

Figure 4—*Plots according to Eq. 7 for the dialysis of cefazolin (◐) and propicillin (other symbols) in the presence of I (cirles), II (triangles), and III (squares) at various pHs, 37°, and* μ = *0.15. Key: (□) pH 6.50; (■) pH 4.00; (○) pH 3.00; (●) pH 3.50; (◒) pH 4.00; (◑) pH 5.00; (◓) pH 6.50; (△) pH 6.50; (▲) pH 4.00; (▲) pH 4.40; (◐) pH 3.40 and pH 6.50.*

where $(C_1)_f$ and $(C_1)_m$ represent the concentration of the drug free and bound with the surfactant micelle, respectively, and C_D is the total concentration of surfactant. When it is assumed that only free drug can permeate through the dialysis membrane, Eq. 6 is obtained from Eqs. 3 and 5:

$$k_{dia} = k_0 \frac{1}{1 + K_{app}(C_D - CMC)} \quad \text{(Eq. 6)}$$

where k_0 represents the first-order dialysis rate constant of the drug in the absence of surfactant. Rearrangement of Eq. 6 gives:

$$\frac{k_0}{k_{dia}} - 1 = K_{app}(C_D - CMC) \quad \text{(Eq. 7)}$$

Equation 7 predicts that plots of $(k_0/k_{dia} - 1)$ *versus* $(C_D - CMC)$ passing through the origin are linear. The values of CMC used for the calculation are 0.092 m*M*, 0.46 m*M*, and 0.32 m*M* for I, II, and III, respectively, which were determined in this laboratory in the presence of the antibiotic at 37° and μ = 0.15. As illustrated in Fig. 4, the results obtained for propicillin with various surfactants revealed a linear relationship in accordance with Eq. 7. The apparent binding constant, K_{app}, was calculated from the slopes and the values are listed in Table I. During the periods of the dialysis experiments, there was negligible degradation of propicillin.

pH-Dependency of the Apparent Binding Constant in Micelle–Antibiotic Interactions—Penicillins have a pKa value of 2.7–2.9 (12) and exist in aqueous solutions in undissociated and ionized forms. The respective forms may yield different binding behavior in surfactant micellar solutions. Figure 5 shows the pH-dependency of K_{app} for propicillin in solutions of I, II, and III as determined by the dynamic dialysis method. Some of the data were those determined in a stability kinetic study, which will be described. In the solutions of I and II, the values of K_{app} for propicillin decreased markedly as the pH increased approaching a constant value. It is supposed that a considerable difference exists in the micellar interactions between undissociated species of propicillin and its ionized form. The relationship between the hydrogen ion activity of the bulk solution and the apparent binding constant can be represented by (see Appendix):

$$K_{app} = K_{HA}\frac{a_H}{a_H + Ka} + K_A\frac{Ka}{a_H + Ka} \quad \text{(Eq. 8)}$$

where K_{HA} and K_A are the binding constants for the undissociated form of propicillin and its ionized form, respectively. Incorporation at pKa 2.76 of propicillin gave parameters of K_{HA} = 489.0 ± 27.0 M^{-1} and K_A = 40.4 ± 2.7 M^{-1} for I as the best fit to the data using a NONLIN computer program (13). The curves in Fig. 5 were generated for I and II from Eq. 8 by the use of these parameters as listed in Table II.

In the interaction of propicillin and the micelles of III, the apparent binding constant was virtually independent of the bulk solution pH. This indicates no significant difference in the magnitude of K_{HA} and K_A, and analysis of the data gave $K_{HA} = K_A$ = 810.1 M^{-1} as the mean of experimental data at all pH values.

A similar experiment was also carried out for the interaction between cefazolin [p*K*a = 2.54 (14)] and the micelle of I. The values of K_{app} were extremely low, being ~3 M^{-1} in the wide pH range of 3–7, indicating negligible entrapment of the undissociated and ionized cefazolin into the micelles of I (Fig. 4).

Effect of Surfactants on the Stability of the Antibiotics—The acid-catalyzed degradation of β-lactam antibiotics was examined in the surfactant solutions of I, II, and III at 37 ± 0.1° and an ionic strength of 0.15. The degradation followed first-order kinetics with regard to the antibiotic concentration in all surfactant solutions. Typical results for propicillin obtained by linear semilogarithmic plots of the residual molar fraction of antibiotic *versus* time are shown in Fig. 6.

As illustrated in Fig. 7, the pseudo first-order rate constant for the degradation of propicillin at acidic pH was increased significantly by the

Table I—Apparent Binding Constant, K_{app}, between Propicillin and Various Surfactants [a]

I		II		III	
pH	K_{app}, M^{-1}	pH	K_{app}, M^{-1}	pH	K_{app}, M^{-1}
1.10	459.3[b]	1.61	175.0[b]	1.10	856.0[b]
1.92	404.9[b]	2.60	119.0[b]	4.00	793.8
3.00	247.2	3.00	91.3[b]	6.50	780.4
3.50	115.1	3.50	28.5[b]		
4.00	59.5	4.00	20.7		
5.00	42.5	5.00	13.2		
6.50	42.0	6.50	4.0		

[a] The values were calculated from the experimental data according to Eq. 7 by the least-squares treatment at 37° and μ = 0.15. [b] These values were determined in the stability study.

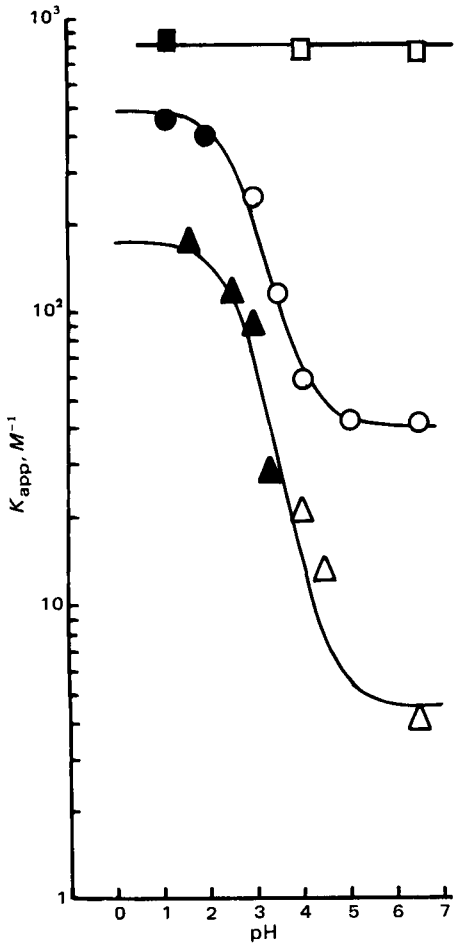

Figure 5—*Plots of the apparent binding constant,* K_{app}, *of propicillin* versus *the bulk solution pH at 37° and* $\mu = 0.15$. *Key:* (○,●) *I;* (△,▲) *II;* (□,■) *III; (open symbols, dynamic dialysis; closed symbols, stability).*

addition of anionic surfactant (II); whereas, it decreased on increasing the concentration of both nonionic and cationic surfactants (I and III). For other penicillins, similar results have been reported (3). In all cases, the rate constants first increased or decreased rapidly and then approached a constant value above the CMC of the surfactants, suggesting the formation of penicillin–micelle complexes.

According to the literature (9), the apparent first-order degradation rate constant thus, is expressed by:

$$k_{deg} = \frac{k_0 + k_m(C_D - \text{CMC})}{1 + K_{app}(C_D - \text{CMC})} \qquad \text{(Eq. 9)}$$

Rearrangement of Eq. 9 gives:

$$\frac{1}{k_0 - k_{deg}} = \frac{1}{k_0 - k_m} + \left(\frac{1}{k_0 - k_m}\right)\left(\frac{1}{C_D - \text{CMC}}\right)\frac{1}{K_{app}} \qquad \text{(Eq. 10)}$$

Equation 10 predicts that plots of $1/(k_0 - k_{deg})$ *versus* $1/(C_D - \text{CMC})$ should give a straight line from which it should be possible to obtain k_m and K_{app} values.

Plots of Eq. 10 for the degradation of propicillin in the presence of I and III are shown in Figs. 8 and 9, respectively. The values of K_{app} for the various reaction systems are given in Table I.

Table II—Binding Constants for Undissociated and Ionized Propicillin with Various Surfactants [a]

Surfactant	K_{HA}, M^{-1}	K_A, M^{-1}
I	489.0 ± 27.0	40.4 ± 2.7
II	171.8 ± 29.9	4.5 ± 1.3
III	810.1 ± 40.3[b]	810.3 ± 40.3[b]

[a] The binding constants were calculated by nonlinear regression program, NONLIN, at 37° and $\mu = 0.15$. [b] This value is the mean ± *SD* of the experimental data.

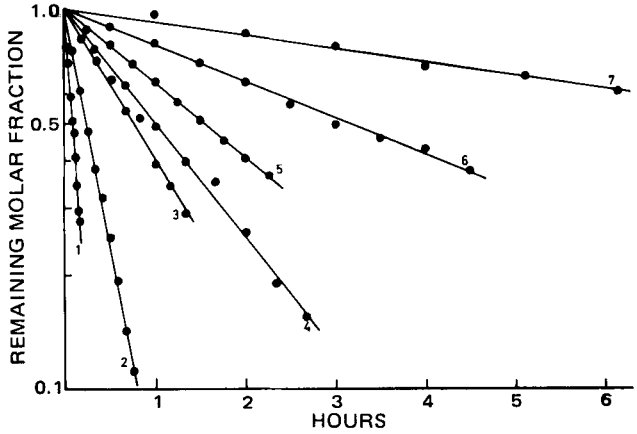

Figure 6—*First-order plots for the degradation of propicillin in the presence of surfactants at various pHs, 37°, and* $\mu = 0.15$. *Key: 1 (3 × 10⁻³ M II, pH 1.61); 2 (control, pH 1.10); 3 (4.5 × 10⁻³ M II, pH 2.50); 4 (1 × 10⁻² M I, pH 1.10); 5 (8.9 × 10⁻² M III, pH 1.10); 6 (3.1 × 10⁻² M III, pH 1.10); 7 (1 × 10⁻² M I, pH 1.92).*

Within an experimental period of <1 day, there was no influence of the surfactants on the neutral degradation of the antibiotic used in this study.

Effect of Surfactants on the Antibiotic Solubility—The saturable solubility of penicillin V, C_s, at pH 2.0 and 35° increased with concentration of I as shown in Table III. The data indicated that the aqueous solubility of penicillin V increased threefold in the presence of 10 m*M* I at pH 2.0 and 35°, showing that penicillins are solubilized by surfactant micelles.

DISCUSSION

Solutions of penicillin G are highly unstable at a gastric pH, the half-lives being 1 min at pH 1 and 7 min at pH 2 (15, 16). Such chemical inactivation of penicillin G in the gastric fluid has been reported to be responsible for the poor bioavailability of this antibiotic. The acid degradation rates of penicillin derivatives are known to depend on their 6-sidechain nature due to the rearrangement initiated by the attack of the sidechain amidocarbonyl on the β-lactam to produce the corresponding penicillenic acid and penillic acid (16).

Considerable efforts have been made to stabilize acid-labile penicillins. Previous authors (17) succeeded in stabilizing potassium salts of penicillin G and penicillin V in simulated gastric juice by coating with cholesteryl acetate, yielding 1.6- and twofold higher urine levels, respectively, after oral administration of these pharmaceutical preparations to humans.

The previous (3) and present studies revealed a marked stability of penicillins in acid solutions with both cationic and nonionic micelles. Four kinds of derivatives, penicillin G, penicillin V, phenethicillin, and propicillin, can be stabilized to maximal extents of 6-, 10-, 8-, and 10-fold by the micelles of III and of 4-, 6-, 7-, and 13-fold by the micelles of I, respectively (3). These stabilization effects are attributed to incorporation of the penicillin molecules into both types of micelles. As is apparent from these results (3), the apparent binding constant between the penicillins and micelles increased with increasing lipophilic character of the penicillins, as expressed in terms of their octanol–water partition coefficients, *P* (12). This suggests that hydrophobic binding is involved in the interaction between the cationic or nonionic micelle and undissociated species of the penicillins. These strong interactions resulted in protection of the β-lactam ring sterically and/or electrostatically from intramolecular and nucleophilic attack of the sidechain amidocarbonyl oxygen. However, it is probable that due to the localized hydrogen ion activity surrounding the negatively charged micelle, the anionic micellar state by II leads to an increase in the rate of degradation. The maximal acceleration of the β-lactam cleavage of propicillin by micelles of II was predicted to be 60-fold at pH 1.6 and 37°.

In contrast to penicillins, the acid degradation of cefazolin, a relatively acid-unstable cephalosporin (14), was not influenced by the presence of any type of surfactant, like cephalothin described previously (3). This was due to the fact that cefazolin was not sufficiently bound to the micelles, the apparent binding constant being confirmed as almost negligible by the dynamic dialysis method (Fig. 4). The very weak interaction of

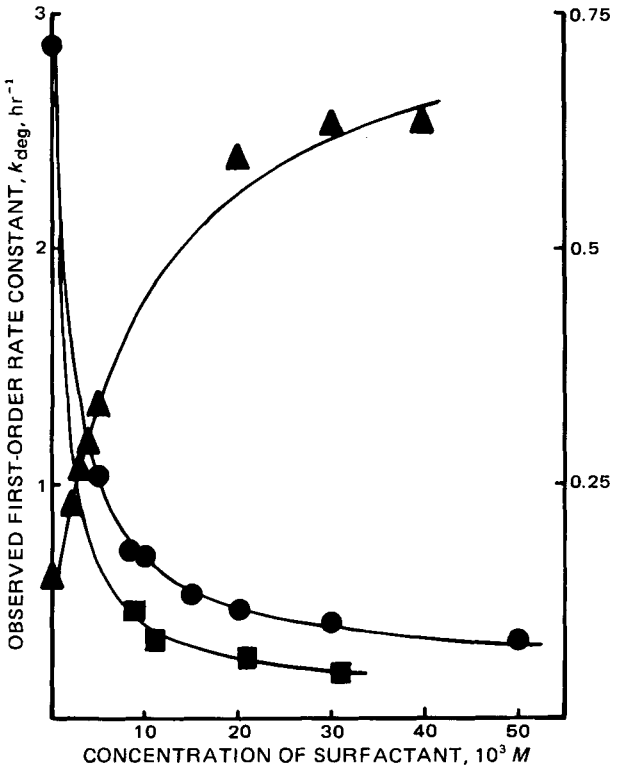

Figure 7—*Plots of the pseudo first-order rate constant* versus *total concentration of surfactant for the degradation of propicillin at 37° and μ = 0.15. Key: (●) I (pH 1.10, left scale); (▲) II (pH 3.00, right scale); (■) III (pH 1.10, left scale). The points are experimental values. The solid curves were generated from Eq. 9.*

the cefazolin molecule with surfactant micelles undoubtedly is due to the low lipid solubility of the antibiotic itself.

The partitioning behavior of β-lactam antibiotics was investigated (12), both in *n*-octanol–water and isobutyl alcohol–water systems, as a function of the aqueous phase solution pH and showed that both the undissociated and ionized species could be partitioned into the oil phase, although the

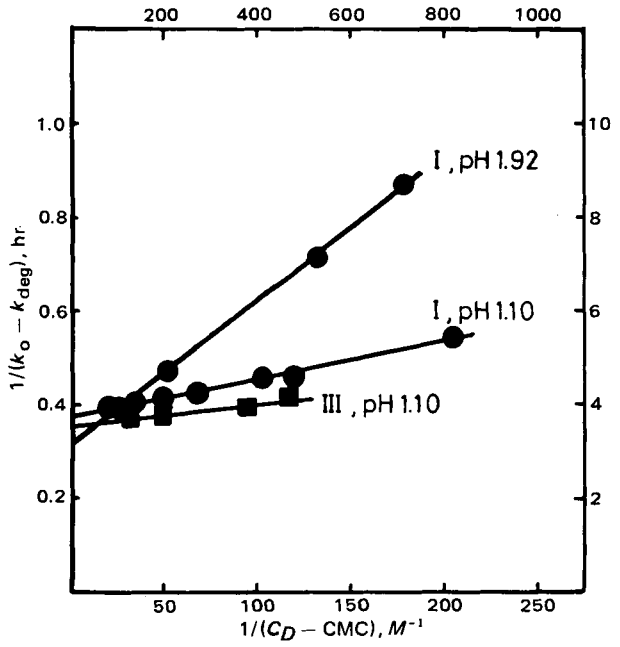

Figure 8—*Double reciprocal plots according to Eq. 10 for the degradation of propicillin in the presence of I and III at 37° and μ = 0.15. Key: upper and right scales for pH 1.10; lower and left scales for pH 1.92.*

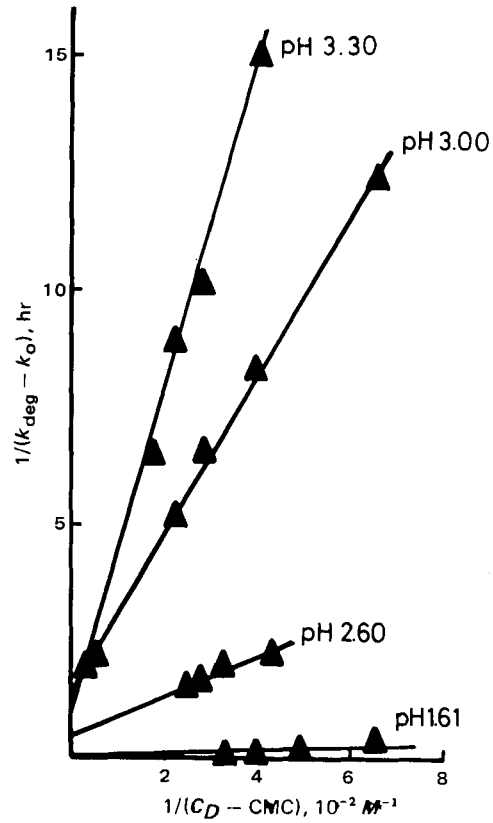

Figure 9—*Double reciprocal plots according to Eq. 10 for the degradation of propicillin in the presence of II at 37° and μ = 0.15.*

former was far more lipophilic than the latter. As shown in Fig. 5, the pH dependency of the K_{app} values in the propicillin interaction with I was parallel to that of the apparent partition coefficients in oil–water systems. The interactions of propicillin with the micelles of II and III showed a marked contrast in the dependencies of their respective K_{app} values on the pH of the bulk aqueous solution. In the case of the micelle of II, K_{app} clearly decreased as the pH increased, while in the micelle of III, K_{app} exhibited independency in the wide pH range betwen 1 and 6. These results can be explained on the basis of the participation of electrostatic forces between the ionized species of the antibiotic and the ionized surfactant micelles in addition to the hydrophobic contribution.

Electrical repulsive forces may play a significant role between ionized propicillin and the anionized surfactant micelle to produce the deduced K_A value, as seen from the K_{HA}/K_A ratio being ~100. Unlike the anionic case, the attraction due to the electrostatic forces between the ionized form of propicillin and cationic surfactant micelle may lead to an effective cancellation of charge within the molecule, resulting in $K_{HA} = K_A$. However, the magnitude of K_A is dependent on the differences both of the hydrogen ion activity and the acid dissociation behavior between aqueous and micellar phases (see Appendix).

Based on the present study, it should be emphasized that the acid-labile penicillins were significantly stabilized and solubilized by incorporating the unionized species into nonionic surfactant micelles, and the penicillin molecules entrapped in the micelle could then be easily released at neutral pH values by reducing the force in the interaction between the

Table III—Solubility of Propicillin in the Presence of I [a]

Concentration of I, 10^3 M	Solubility of Propicillin, 10^3 M
0.0	0.72
3.0	1.21
5.0	1.55
7.0	1.89
10.0	2.40
20.0	4.09

[a] Values at 37°, pH 2.00, and μ = 0.5.

ionized species and micelles. Cephalosporins, which have a much lower lipophilicity than penicillins (12), are not incorporated into nonionic surfactant micelles, so that there is no significant influence on the chemical stability and solubility in aqueous solution.

APPENDIX

Alteration of the acid dissociation equilibrium of the drug in surfactant micelles would be in terms of local alteration in hydrogen ion concentration in the micelles. It is to be expected that the hydrogen ion activity ($a_{H,m}$) will be greater near the surface of the anionic micelles and lower near the surface of the cationic micelles than that (a_H) in the bulk aqueous phase.

Assuming that both species of undissociated and ionized drugs which exist in the aqueous phase are incorporated into the micellar phase, the various equilibria can be described as:

$$Ka = \frac{(A)_{aq} a_H}{(HA)_{aq}} \quad \text{(Eq. A1)}$$

$$Ka,m = \frac{(A)_m a_{H,m}}{(HA)_m} \quad \text{(Eq. A2)}$$

$$K_{HA} = \frac{(HA)_m}{(HA)_{aq}\,(C_D - \mathrm{CMC})} \quad \text{(Eq. A3)}$$

$$K_A = \frac{(A)_m}{(A)_{aq}\,(C_D - \mathrm{CMC})} \quad \text{(Eq. A4)}$$

where HA and A refer to the undissociated and ionized species, respectively, and the subscripts aq and m refer to the aqueous and micellar phases, respectively. The other parameters are the same as described in the text. It is clear that the $K_{HA}/K_A = (Ka/Ka,m)$ from Eqs. A1–A4. The apparent binding constant, K_{app}, between drugs and micelles is given by:

$$K_{app} = \frac{(HA)_m + (A)_m}{[(HA)_{aq} + (A)_{aq}]\,(C_D - \mathrm{CMC})} \quad \text{(Eq. A5)}$$

Rearrangement of Eq. A5 gives:

$$K_{app} = \frac{(HA)_m}{(HA)_{aq}\,(C_D - \mathrm{CMC})}\left[\frac{1}{1 + (A)_{aq}/(HA)_{aq}}\right] + \frac{(A)_m}{(A)_{aq}\,(C_D - \mathrm{CMC})}\left[\frac{1}{1 + (HA)_{aq}/(A)_{aq}}\right] \quad \text{(Eq. A6)}$$

By use of the equilibrium constants defined above, Eq. 8 can be arrived at from Eq. A6. Therefore, the binding constants, K_{HA} and K_A, for incorporation of the undissociated and ionized forms of drugs into the micelles can be calculated, without knowledge of $a_{H,m}$ and $K_{a,m}$, from the dependence of the bulk aqueous solution pH upon the K_{app} values.

The present results were presented in part at the APhA Academy of Pharmaceutical Sciences, 29th National Meeting, San Antonio, Texas, November, 1980.

The authors acknowledge the gifts of β-lactam antibiotics from Takeda Chemical Industries, Banyu Pharmaceutical Co., and Fujisawa Pharmaceutical Co. The computer analysis was performed on the digital computer, FACOM M-160 at the Data Processing Center, Kanazawa University.

Synthesis and Antimicrobial Activities of Certain Cannabichromene and Cannabigerol Related Compounds

HALA N. ElSOHLY ˣ, CARLTON E. TURNER, ALICE M. CLARK, and MAHMOUD A. ElSOHLY

Received October 15, 1981, from the *Research Institute of Pharmaceutical Sciences, The University of Mississippi, School of Pharmacy, University, MS 38677.* Accepted for publication January 27, 1982.

Abstract □ Cannabichromene homologs, analogs, and isomers as well as the C_1-homolog and isomer of cannabigerol were prepared and tested for their antimicrobial and antifungal properties. Spectral data of all compounds synthesized are presented.

Keyphrases □ Cannabichromene—analogs, synthesis and antimicrobial activities of related compounds, cannabigerol □ Antimicrobial activities —cannabichromene and cannabigerol, analogs, synthesis and related compounds □ Analogs—cannabichromene and cannabigerol, synthesis and antimicrobial activities of related compounds

Different cannabinoids have been isolated from *Cannabis sativa* L. (1). Most of the biological studies carried out concentrate on the major psychoactive constituent Δ^9-tetrahydrocannabinol and its isomers (2–4). However, little attention has been given to the biological activity of cannabichromene (I) because of its relatively low concentration in the plant material.

Recently, a procedure was developed for the synthesis of I in high yield (60%) (5), which made the material available for pharmacological testing.

The biological activities of cannabichromene has been reported (6–9), as well as its homologs and isomers (10, 11). This paper describes the synthesis and antimicrobial activities of cannabichromene homologs, analogs, and isomers and that of cannabigerol-C_1, isocannabigerol-C_1, and tetrahydrocannabigerol-C_1.

EXPERIMENTAL

Melting points[1] were determined in open glass capillary tubes and are uncorrected. Proton nuclear magnetic resonance (^{1}H-NMR) spectra[2] were recorded in deuterochloroform or in deuteromethanol using tetramethysilane as the internal standard. IR spectra[3] were recorded in liquid film, chloroform, or in potassium bromide pellets. Mass spectra[4] were recorded at an electron energy of 70 eV. UV spectra[5] were recorded in methanol. ^{13}C-NMR spectra[6] were recorded in deuterochloroform or deuteromethanol.

Biological Activities–Antibacterial and Antifungal Activities—All compounds were tested for activity against Gram-positive, Gram-negative, and acid-fast bacteria and selected fungi. A qualitative screen was performed on all compounds, while quantitative assays were done on active compounds only. Routine qualitative screens were carried out using the agar well diffusion assay as previously described (12). Minimum inhibitory concentrations were determined using the twofold (broth) serial dilution method (12) with a concentration of 100 μg/ml in the first tube. Streptomycin sulfate was used as a positive control for antibacterial activity, while amphotericin B was used as an antifungal positive control.

2-Methyl-2-(4′-methylpent-3′-enyl)-5-hydroxy-7-methylchromene (II)—Orcinol (3.45 g, 0.028 mole) was dissolved in 55 ml of toluene with heating and stirring. Equimolar quantities of *tert*-butylamine were added to the resulting solution followed by dropwise addition of citral. The reaction mixture was refluxed for 9 hr. The mixture was then cooled to room temperature, transferred to a round-bottom flask, and the solvent evaporated. GC analysis of the reaction mixture showed 48.3% conversion to II. About one half of the crude reaction product (5 g) was applied over a dry packed silica gel 60 column (100 g) using 15 ml of cyclohexane–chloroform (1:1), and elution was continued with the same solvent. Fractions of 25 ml were collected and combined based on TLC similarities. Fractions containing II (1.96 g) were rechromatographed as before to yield II of >95% purity as light brown oil. UV λ_{max} (methanol) nm (log ϵ): 229 (4.38) and 280 (3.92); IR (liquid film) major bands at 3400, 2970, 2820, 1620, 1575, and 1420 cm^{-1}; ^{1}H-NMR ($CDCl_3$) signals at δ 6.68 (1H, d, J = 10 Hz), δ 6.27 (1H, s), δ 6.13 (1H, s), δ 5.45 (1H, d, J = 10 Hz), δ 5.12 (1H, br, t, J = 6 Hz), δ 2.17 (3H, s), δ 1.67 (3H, s), δ 1.58 (3H, s), and δ 1.38 (3H, s); ^{13}C-NMR ($CDCl_3$) signals at δ 154.1 (s), δ 151.3 (s), δ 139.6 (s), δ 131.5 (s), δ 127.1 (d), δ 124.4 (d), δ 117.9 (d), δ 109.9 (d), δ 108.8 (d), δ 107.2 (s), δ 74.4 (s), δ 41.1 (t), δ 26.2 (q), δ 25.5 (q), δ 22.7 (t), δ 21.4 (q), and δ 17.5 (q); MS M$^+$ at m/z: 258 (10%), for $C_{17}H_{22}O_2$, 175 (100%) 243 (3%), 215 (7%), 183 (3%).

2-Methyl-2-(4′-methylpent-3′-enyl)-5-methyl-7-hydroxychromene (III)—Compound III was formed as a side product from the synthesis of II when pyridine was used both as a base and a solvent. Equi-

molar quantities of pyridine and citral were added to 1.73 g of (0.014 mole) orcinol. The mixture was refluxed with stirring for 7 hr, cooled, and evaporated to yield a brownish residue (3.97 g). On TLC[7], the residue showed two major spots using chloroform–cyclohexane (4:1) and benzene–hexane (4:1) as solvent systems. The crude reaction mixture was purified on a silica gel 60 column followed by preparative chromatography[8] using benzene–hexane (4:1) as the solvent system. The compound with the high R_f value (0.30, 15%) was II, while that with the low R_f value (0.16, 24%) was identified as III. Compound III was isolated as an amber colored oil. UV λ_{max} (methanol) nm (log ϵ): 224 (4.17), 285 (3.70), and 305 (3.57); IR (liquid film) major bands at 3380, 2970, 2915, 1610, and 1460 cm^{-1}; ^{1}H-NMR ($CDCl_3$) signals at δ 6.47 (1H, d, J = 9 Hz), δ 6.18 (2H, s), δ 5.43 (1H, d, J = 9 Hz), δ 5.12 (2H, br, t, J = 7 Hz), δ 2.18 (3H, s), δ 1.67 (3H, s), δ 1.58 (3H, s), and δ 1.37 (3H, s); ^{13}C-NMR ($CDCl_3$) signals at δ 156.1 (s), δ 154.7 (s), δ 135.1 (s), δ 131.4 (s), δ 126.5 (d), δ 124.4 (d), δ 119.6 (d), δ 113.2 (s), δ 109.6 (d), δ 101.7 (d), δ 78.1 (s), δ 41.1 (t), δ 26.2 (q), δ 25.5 (q), δ 22.7 (t), δ 18.3 (q), and δ 17.5 (q); MS M^+ at m/z 258 (6%) for $C_{17}H_{22}O_2$, 175 (100%).

2-Methyl-2-(4′-methylpent-3′-enyl)-5-hydroxy-7-methylchroman (IV) and 2-Methyl-2-(4′-methylpentyl)-5-hydroxy-7-methylchroman (V)—Compounds IV and V were prepared by catalytic hydrogenation of Compound II. A mixture of IV and V was formed when the reaction was allowed to go for 20 min under hydrogen atmosphere. However, Compound V was the only product obtained when hydrogenation was allowed to occur for a longer period of time or under pressure (0.702 kg/cm^2). Compound II (0.15 g, 5.8×10^{-4} mole) was dissolved in 8 ml of ethanol and 20 mg of 5% pallidium on carbon (Pd/C) was added. The reaction mixture was stirred for 20 min under a hydrogen atmosphere. TLC examination of the reaction product on silver nitrate-treated silica gel plates using chloroform–benzene (8:2) as the solvent system showed two major spots with R_f 0.22 and 0.35. The two compounds were separated on an HPLC using a reversed-phase column[9] with methanol–water (8:2) as the solvent system. Twenty-two milligrams (14.6%) of IV and 99 mg (66%) of V were obtained. Compound IV was isolated as a light yellow oil. UV λ_{max} (methanol) nm (log ϵ): 283 (2.92), 273 (2.92), 232 (3.82), 217 (3.95). IR ν_{max} ($CHCl_3$) cm^{-1}: 2968, 2924, 2858, 1620, 1580, 1450, 1375, 1349, 1320, 1260, 1155, 1132, 1100, 1055, 995, 875; ^{1}H-NMR ($CDCl_3$) δ 6.27 (1H, s, aromatic H), δ 6.17 (1H, s, aromatic H), δ 5.15 (1H, t, olefinic proton), δ 2.61 (2H, t, benzylic proton), δ 2.18 (3H, s, aromatic methyl), δ 1.67 (3H, s, methyl on double bond), δ 1.60 (3H, s, methyl on double bond), δ 1.28 (3H, s, methyl on oxygenated carbon); MS M^+ at m/z 260 (25.5%) for $C_{17}H_{24}O_2$, 177 (36%), 175 (55%), 136 (100%). The tetrahydro-derivative was separated as a light yellow oil; UV λ_{max} (methanol) nm (log ϵ): 282 (2.93), 275 (2.93), 233 (3.88), 217 (4.09); IR ν_{max} ($CHCl_3$) cm^{-1}: 2950, 1622, 1580, 1450, 1378, 1350, 1320, 1260, 1150, 1130, 1100, 1070, 995, 875; ^{1}H-NMR ($CDCl_3$): δ 6.16 (1H, s, aromatic H), δ 6.03 (1H, s, aromatic H), δ 2.56 (2H, t, benzylic protons), δ 2.16 (3H, s, aromatic methyl), δ 1.25 (3H, s, methyl on oxygenated carbon), δ 0.92 (3H, d, J = 6 Hz), and δ 0.80 (3H, d, J = 6 Hz); MS M^+ 262 (36.5%) for $C_{17}H_{22}O_2$, 177 (57%), and 136 (100%).

2-Methyl-2-(4′-methylpent-3′-enyl)-5-hydroxychromene (VI) and 2-Methyl-2-(4′-methylpent-3′-enyl)-7-hydroxy-chromene (VII)—Compounds VI and VII were prepared by reaction of 1.53 g of resorcinol (0.014 mole), and equimolar amounts of *tert*-butylamine and citral in 27.5 ml of toluene following the same conditions described under preparation of II. The reaction of the nonsubstituted resorcinol under these conditions result in the formation of both VI and VII. The crude reaction mixture was purified by repeated chromatography on a silica gel 60 column and preparative liquid chromatography[10] with benzene as the solvent to obtain Compounds VI and VII in 10% yield. Compound VI was isolated as a yellowish-brown oil. UV λ_{max} (methanol) nm (log ϵ): 225 (4.35) and 278 (3.90); IR (liquid film) major bands at 3395, 2970, 2920, 1610, 1580, and 1460 cm^{-1}; ^{1}H-NMR ($CDCl_3$) signals at δ 6.38 (1 H, d, J = 10 Hz), δ 5.52 (1H, d, J = 10 Hz), δ 5.13 (1H, br, t, J = 6 Hz), δ 1.67 (3H, s), δ 1.60 (3H, s) and 1.40 (3H, s); ^{13}C-NMR ($CDCl_3$) signals at δ 154.2 (s), δ 151.5 (s), δ 131.5 (s), δ 129.0 (d), δ 128.1 (d), δ 124.4 (d), δ 117.0 (d), δ 109.7 (s), δ 109.1 (d), δ 107.9 (d), δ 78.4 (s), δ 41.4 (t), δ 26.2 (q), δ 25.5 (q), δ 22.7 (q), δ 17.5 (q); MS m/z (%), M^+ 244 (2%), 161 (100%), 115 (2%). Compound VII was separated as a brownish oil; UV λ_{max} (methanol) nm (log ϵ): 220 (4.39), 283 (3.86), 305 (3.83), and 310 (sh, 3.79); IR (liquid film) major bands at 3400, 2970, 2920, 1650, and 1500 cm^{-1}; ^{1}H-NMR ($CDCl_3$) signals at δ 6.68 (1H, d, J = 9 Hz), δ 6.25 (2H, br, s), δ 6.07 (1H, br, s), δ 5.30 (1H, d, J = 9 Hz), δ 5.03 (2H, br, t, J = 6 Hz), δ 1.63 (3H, s), δ 1.53 (3H, s), and δ 1.18 (3H, s); ^{13}C-NMR ($CDCl_3$) signals at δ 156.8 (s), δ 154.5 (s), δ 131.6 (s), δ 127.3 (d), δ 126.7 (d), δ 124.4 (d), δ 122.5 (d), δ 114.7 (s), δ 107.8 (d), δ 103.8 (d), δ 78.9 (s), δ 41.5 (t), δ 26.6 (q), δ 25.6 (q), δ 22.8 (t), and 17.6 (q); MS M^+ at m/z 244 (6%), 161 (100%), and 115 (7%).

2-Methyl-2-(4′-methylpent-3′-enyl)-5-hydroxy-7-pentadec-8″enylchromene (VIII)—Compound VIII was prepared by reaction of 5-pentadec-8′-enyl resorcinol with citral in the presence of *tert*-butylamine (equimolar amounts) in toluene solution following the same procedure as described under synthesis of I. Pentadecenyl resorcinol was isolated from *Ginkgo* fruits. Compound VIII was isolated as a brownish colored oil (60% yield). UV λ_{max} (methanol) nm (log ϵ): 228 (4.39) and 279 (3.97); IR (liquid film) major bands at 3400, 2920, 2855, 1620, 1575, 1430 cm^{-1}; ^{1}H-NMR ($CDCl_3$) signals at δ 6.62 (1 H, d, J = 10 Hz), δ 6.22 (1H, s), δ 6.10 (1H, s), δ 5.42 (1H, d, J = 10 Hz), δ 1.65 (3H, s), δ 1.57 (3H, s), δ 1.39 (3H, s), δ 1.32 (18H, br, s); ^{13}C-NMR ($CDCl_3$) signals at δ 154.3 (s), δ 151.5 (s), δ 144.8 (s), δ 131.4 (s), δ 130.1 (d), δ 127.2 (d), δ 124.6 (d), δ 117.1 (d), δ 109.2 (d), δ 108.0 (d), δ 107.3 (s), δ 78.3 (s), δ 41.3 (t), δ 36.1 (t), δ 31.9 (t), δ 31.0 (t), δ 29.9 (t, 2C), 29.4 (t, 2C), 29.0 (t), δ 27.4 (t, 3C), δ 26.3 (q), δ 25.6 (q), δ 22.9 (t), δ 22.7 (t), δ 17.6 (q), δ 14.1 (q); MS M^+ at m/z 452 (0.16%), for $C_{31}H_{48}O_2$, 369 (100%), 187 (16%), 174 (11%).

2-Methyl-2-(4′-methylpent-3′-enyl)-5,7-dihydroxychromene—Phloroglucinol (2.52 g, 0.02 mole) was dissolved in 25 ml of acetonitrile–toluene (1:1). *tert*-Butylamine (0.022 mole) was added to the resulting solution, followed by the dropwise addition of 0.022 mole citral, and the reaction mixture was refluxed for 1 hr. The material was applied on a silica gel 60 column packed in 20% ethyl acetate–cyclohexane; 220 mg of the cyclol (IX) were obtained. Yield: 4.4%.

The cyclol was obtained as fine needles (cyclohexane–acetone), mp 150–150.5°. UV λ_{max} (methanol) nm (log ϵ): 280 (2.11), 240 (3.06), 222 (3.61); IR ν_{max}^{KBr} cm^{-1}: 3360, 2970, 2920, 1615, 1596, 1490, 1462, 1378, 1365, 1340, 1312, 1270, 1255, 1240, 1215, 1160, 1150, 1135, 1122, 1081, 1065, 1032, 995, 945, 900, 878, 825, 750; ^{1}H-NMR ($CDCL_3$) signals at: δ 5.93 (2H, s, aromatic), δ 2.76 (1H, m, C_3—H), δ 1.46, δ 1.35, and δ 1.01 (3H, each, s); ^{13}C-NMR: δ 157.82 (s), δ 157.32 (s), δ 155.94 (s), δ 109.42 (s), δ 98.50 (d), δ 96.94 (d), δ 84.33 (s), δ 47.04 (d), δ 37.5 (t), δ 35.54 (t), δ 29.76 (q), δ 29.04 (d or q), δ 28.00 (d), δ 23.7 (q), δ 22.3 (q or d); MS M^+ 260 (8%), 245 (3%), 217 (6%), 189 (7%), 177 (100%).

2-Geranyl-5-methyl Resorcinol (X) and 4-Geranyl-5-methyl Resorcinol (XI)—Compound X was prepared by condensation of geraniol (3.47 ml) and orcinol (2.844 g, 20 mmoles) in methylene chloride (100 ml) in the presence of *p*-toluenesulfonic acid (20 mg) at 20° for 30 min. The reaction mixture, after workup, was repeatedly chromatographed on silica gel to yield X (794 mg, 15%) and XI (100 mg, 2%). Compound X was obtained as a crystalline material, mp 50–51° (hexane). UV λ_{max} (methanol) nm (log ϵ): 275 (2.93), 209 (4.55); IR ν_{max}^{KBr} (cm^{-1}): 3420, 3380, 3268, 3120, 2960, 2908, 2850, 1630, 1580, 1510, 1450, 1375, 1322, 1268, 1220, 1198, 1145, 1080, 1042, 985, 825; ^{1}H-NMR ($CDCL_3$) δ 6.2 (2H, s), δ 5.36–5.08 (2H, m, olefinic), δ 3.4 (2H, d, J = 8 Hz), δ 2.18 (3H, s), δ 1.81 (3H, s), δ 1.70 (3H, s) and δ 1.60 (3H, s); ^{13}C-NMR: signals at δ 155.0 (s), δ 138.9 (s), δ 137.6 (s), δ 132.0 (s), δ 124.0 (d), δ 122.0 (d), δ 111.0 (d), δ 109.4 (d), δ 39.8 (t), δ 26.6 (t), δ 25.6 (q), δ 22.3 (t), δ 21.0 (t), δ 17.7 (q), δ 16.2 (q); MS M^+ 260 (2.68%) for $C_{17}H_{24}O_2$, 191 (8%), 175 (23%), 163 (22%), 149 (20%), 137 (100%).

Compound XI yielded fine needles, mp 50–51° (hexane). UV λ_{max} (methanol) nm (log ϵ): 283 (3.19), 207 (4.32); IR ν_{max}^{KBr} cm^{-1}: 3200, 2982, 2960, 2830, 1610, 1510, 1470, 1450, 1375, 1335, 1310, 1220, 1140, 1050, 980, 900, 835; ^{1}H-NMR ($CDCl_3$) signals at δ 6.23 (2H, s), δ 5.6–5.13 (2H, m, olefinic), δ 3.3 (2H, d, J = 8 Hz), δ 2.2 (3H, s), δ 2.03 (4H, br, s), δ 1.76 (3H, s), δ 1.66 (3H, s), δ 1.60 (3H, s); ^{13}C-NMR ($CDCl_3$) δ 155.4 (s), δ 154.3 (s), δ 138.8 (s), δ 137.2 (s), δ 131.8 (s), δ 124.2 (d), δ 122.5 (d), δ 118.6 (d), δ 110.1 (d), δ 101.4 (d), δ 39.8 (t), δ 26.7 (t), δ 25.7 (q), δ 25.1 (t), δ 19.9 (q), δ 17.7(q), δ 16.2 (q); MS M^+ 260 (2.92%) for $C_{17}H_{24}O_2$, 191 (13.5%), 175 (26.64%), 163 (17.44%), 149 (22.52%), and 137 (100%).

2-Tetrahydrogeranyl-5-methyl Resorcinol (XII)—Compound X was dissolved in 8 ml of ethanol, 20 mg of 5% Pd/C was added, and the reaction mixture was allowed to proceed under a hydrogen atmosphere for 4 hr. TLC examination of the reaction product showed complete conversion of the starting material. Filtration followed by crystallization from hexane yielded a crystalline material, mp 84–85°. UV λ_{max} (methanol) nm (log ϵ): 280.5 (3.05), 271 (3.09), 232 (sh, 3.00), 209 (4.60); IR λ_{max}^{KBr} cm^{-1}: 3420, 3300, 2960, 2928, 2870, 2850, 1630, 1580, 1518, 1468, 1380, 1365, 1328, 1270, 1200, 1160, 1112, 1025, and 830; ^{1}H-NMR (CD_3OD) signals at δ 6.13 (2H, s), δ 2.56 (2H, t), δ 1.53–1.23 (m, 9H), δ 0.9 (6H, s), δ 0.82 (3H, s); ^{13}C-NMR (CD_3OD): signals at δ 156.9 (s), δ 136.8 (s), δ 114.9 (s), δ 108.7 (d), δ 40.5 (t), δ 38.3 (t), δ 37.4 (t), δ 34.11 (d), δ 29.0 (t), δ 25.7

RESULTS AND DISCUSSION

Cannabichromene (I) derivatives were prepared according to a previously published method for the synthesis of cannabichromene (5). That method involves the reflux of equimolar quantities of the properly substituted resorcinol, citral and *tert*-butylamine in toluene for 9 hr. In this way, 48% of II was obtained. However, when pyridine was used as the solvent and base, Compound III was obtained in a 24% yield. Compounds IV and V were obtained through catalytic hydrogenation of II using 5% Pd/C. When the reaction was allowed to proceed for 20 min, a mixture of IV and V was obtained in a yield of 15 and 66%, respectively. When the reaction was carried out for a longer period of time or under pressure V was obtained quantitatively. ^{1}H-NMR of IV shows that the double bond was located in the side chain as shown by the presence of only one olefinic signal at δ 5.15 (1H, t). This is in contrast to the ^{1}H-NMR spectrum of II, which showed two additional signals at δ 6.68 and 5.45 (1H each, d, J = 10 Hz) characteristic of the double bond at Δ^3 of the chromene system. Compounds VI and VII were obtained in a 10% yield after repeated chromatography, while VIII was obtained in ~60% yield. All compounds were purified by column chromatography over silica gel or through preparative liquid chromatography and were characterized by spectral methods including IR, UV, MS, ^{1}H-NMR and ^{13}C-NMR.

Attempts at preparing cannabichromene derivatives having the R group either as COOH, $COOCH_3$, HN—O(=C)—CH_3, NH—SO_2—CH_3 under the same conditions for preparing cannabichromene failed. We can conclude that the R group on the resorcinol moiety has a significant effect on the reactivity of the molecule with citral to give the chromene structure. When the R group was an electron-withdrawing group (—O(=C)—OH, —O(=C)—OCH_3) the reaction did not proceed. When R was an OH group the reaction proceeded rapidly to many products of which <5% was the desired product. Attempts to increase the yield were unsuccessful. When R was a long chain alkyl group, the yield of the desired product was fairly high (~60%). Even when R was CH_3 a 48% yield was obtained. However, when R was H the yield dropped back to ~10% with almost an equal amount of iso-compound being formed, and thus, the selectivity of the reaction was lost.

XVI

In addition to cannabichromene-type compounds, the antibacterial activity of other cannabinoids were investigated. Δ^9-Tetrahydrocannabinol (XIV), Δ^8-tetrahydrocannabinol (XV), cannabidiol (XVI), cannabinol (XVIII), cannabigerol (XIII), and cannabicyclol (XVII) were tested. Only XIII showed significant activity. Thus, the C_1-homolog of cannabigerol and its isomer were synthesized to test their activity against the various organisms with the idea that the C_1-homolog might be more active than the C_5-homolog as is the case with cannabichromene homologs.

Compounds X and XI were prepared according to a method described previously (13) for the preparation of cannabigerol. Although the yield was reported to be 52%, only a 10% isolated yield was obtained.

Organisms utilized in the screens included Gram-positive, Gram-negative, and acid-fast bacteria as well as different types of fungi (Table I).

Compounds I–XII were subjected to the antibacterial antifungal activity screens (Tables II–V). Qualitative screening using the agar well diffusion assay showed that these compounds possess strong antibacterial and mild antifungal properties. These compounds exhibited large zones of inhibition when compared to positive standards at the same concentrations. The minimum inhibitory concentrations for these compounds were determined using selected bacteria and fungi as recorded in Tables IV and V. The organisms selected for the minimum inhibitory concentration determinations were based on the largest zone of inhibition resulting in the qualitative screen (Tables II and III).

[a] Expressed in micrograms per milliliter. [b] Not tested.

It can be concluded from Tables III and IV that the antimicrobial activity of the normal series, in cannabichromene and cannabigerol homologs and isomers, is more pronounced than in case of the iso-series. Cannabichromene type compounds having a methyl or a pentyl group in the side chain show the highest antimicrobial activity. An intermediate type of activity is seen when R is a hydrogen. However, lengthening the side chain up to C_{15} leads to a tremendous decrease in activity. Total saturation of the two double bonds in the cannabichromene and cannabigerol type compounds having a methyl side chain in most of the cases leads to an increase in the antifungal and antibacterial activities as in the case of Compounds XII and V, respectively (Tables IV and V).

This is the first reported synthesis and spectral data of most of the compounds prepared in this investigation. In addition, the antimicrobial activities of these compounds show encouraging results. The activities of the compounds prepared in this report were compared qualitatively with those of some known cannabinoids, namely, cannabigerol, cannabidiol, cannabicyclol, Δ^8- and Δ^9-tetrahydrocannabinols and were found to be far superior in most instances (Tables II and III).

Preparation of Hydrophilic Albumin Microspheres Using Polymeric Dispersing Agents

WILLIAM E. LONGO, HIROO IWATA, THOM A. LINDHEIMER, and EUGENE P. GOLDBERG[x]

Received August 19, 1981, from the *Department of Materials Science and Engineering, University of Florida, MAE 217, Gainesville, FL 32611.* Accepted for publication October 13, 1981.

Abstract □ A new method for preparing glutaraldehyde cross-linked human serum albumin microspheres has been developed. Important aspects of this method include addition of glutaraldehyde in the organic phase and use of concentrated solutions of hydrophobic polymers (polymethylmethacrylate) or hydrophilic polymers (polyoxyethylene–polyoxypropylene block copolymer) as dispersion media. Uniform, round, solid, 3–150-μm hydrophilic microspheres were readily prepared by this process. The average size of microspheres was a function of dispersion time and energy input. Surface properties were altered by chemical modification using either 2-aminoethanol or aminoacetic acid to quench residual aldehyde groups. Optical and scanning electron microscopy and electronic particle size characterization indicate that the process is versatile in producing solid microspheres in a wide size range. Albumin microspheres of this type are readily dispersed in aqueous media for injection, without the need for surfactants.

Keyphrases □ Microspheres—hydrophilic albumin, preparation using polymeric dispersing agents □ Polymeric dispersing agents—preparation of hydrophilic albumin microspheres □ Glutaraldehyde—cross-linked human serum albumin microspheres, preparation using polymeric dispersing agents

Insoluble drug carriers for prolonged and controlled delivery of therapeutic agents in biological systems recently have generated growing interest (1–3). Many different carrier systems have been studied, including synthetic liposomes, erythrocyte ghosts, permeable polymeric microcapsules, and solid microspheres (4–7). Each of these drug carriers has its own advantages and problems, and there are adequate reviews of the literature (8).

The use of albumin microspheres as drug carriers has been studied to an increasing extent (9, 10). Soluble human serum albumin in blood plasma is a natural circulatory drug carrier (11). Equilibrium binding to various drugs depends primarily on hydrophobic and electrostatic interactions (12). This type of drug binding eliminates the need for covalent attachment between drug and carrier and may facilitate drug release. Human serum albumin is also degraded *in vivo*. The stability of albumin microspheres is, therefore, a function of the degree of albumin cross-linking, porosity, and accessibility of microspheres to enzymatic and phagocytic processes in the body (13).

Current methods of albumin microsphere preparation involve either thermal denaturation at elevated temperatures (110–165°) or chemical cross-linking in vegetable oil or isooctane emulsions (14, 15). Because small amounts of surfactants are needed to disperse such microspheres in water, they appear to be somewhat hydrophobic because of the method of formation. Widder *et al.* (16) hypothesize that hydrophobicity is due to the polar regions of the albumin aligning at the oil–water interface to form a hydrophobic crust or mantle at room temperature. Since their process involves thermal denaturation for microsphere stabilization, a further increase in surface hydrophobicity may occur due to additional albumin conformational changes and surface binding of oil at elevated temperatures. Surface hydrophilicity is important, because a hy-

It can be concluded from Tables III and IV that the antimicrobial activity of the normal series, in cannabichromene and cannabigerol homologs and isomers, is more pronounced than in case of the iso-series. Cannabichromene type compounds having a methyl or a pentyl group in the side chain show the highest antimicrobial activity. An intermediate type of activity is seen when R is a hydrogen. However, lengthening the side chain up to C_{15} leads to a tremendous decrease in activity. Total saturation of the two double bonds in the cannabichromene and cannabigerol type compounds having a methyl side chain in most of the cases leads to an increase in the antifungal and antibacterial activities as in the case of Compounds XII and V, respectively (Tables IV and V).

This is the first reported synthesis and spectral data of most of the compounds prepared in this investigation. In addition, the antimicrobial activities of these compounds show encouraging results. The activities of the compounds prepared in this report were compared qualitatively with those of some known cannabinoids, namely, cannabigerol, cannabidiol, cannabicyclol, Δ^8- and Δ^9-tetrahydrocannabinols and were found to be far superior in most instances (Tables II and III).

Preparation of Hydrophilic Albumin Microspheres Using Polymeric Dispersing Agents

WILLIAM E. LONGO, HIROO IWATA, THOM A. LINDHEIMER, and EUGENE P. GOLDBERG[x]

Received August 19, 1981, from the *Department of Materials Science and Engineering, University of Florida, MAE 217, Gainesville, FL 32611.* Accepted for publication October 13, 1981.

Abstract □ A new method for preparing glutaraldehyde cross-linked human serum albumin microspheres has been developed. Important aspects of this method include addition of glutaraldehyde in the organic phase and use of concentrated solutions of hydrophobic polymers (polymethylmethacrylate) or hydrophilic polymers (polyoxyethylene–polyoxypropylene block copolymer) as dispersion media. Uniform, round, solid, 3–150-μm hydrophilic microspheres were readily prepared by this process. The average size of microspheres was a function of dispersion time and energy input. Surface properties were altered by chemical modification using either 2-aminoethanol or aminoacetic acid to quench residual aldehyde groups. Optical and scanning electron microscopy and electronic particle size characterization indicate that the process is versatile in producing solid microspheres in a wide size range. Albumin microspheres of this type are readily dispersed in aqueous media for injection, without the need for surfactants.

Insoluble drug carriers for prolonged and controlled delivery of therapeutic agents in biological systems recently have generated growing interest (1–3). Many different carrier systems have been studied, including synthetic liposomes, erythrocyte ghosts, permeable polymeric microcapsules, and solid microspheres (4–7). Each of these drug carriers has its own advantages and problems, and there are adequate reviews of the literature (8).

The use of albumin microspheres as drug carriers has been studied to an increasing extent (9, 10). Soluble human serum albumin in blood plasma is a natural circulatory drug carrier (11). Equilibrium binding to various drugs depends primarily on hydrophobic and electrostatic interactions (12). This type of drug binding eliminates the need for covalent attachment between drug and carrier and may facilitate drug release. Human serum albumin is also degraded *in vivo*. The stability of albumin microspheres is, therefore, a function of the degree of albumin cross-linking, porosity, and accessibility of microspheres to enzymatic and phagocytic processes in the body (13).

Current methods of albumin microsphere preparation involve either thermal denaturation at elevated temperatures (110–165°) or chemical cross-linking in vegetable oil or isooctane emulsions (14, 15). Because small amounts of surfactants are needed to disperse such microspheres in water, they appear to be somewhat hydrophobic because of the method of formation. Widder *et al.* (16) hypothesize that hydrophobicity is due to the polar regions of the albumin aligning at the oil–water interface to form a hydrophobic crust or mantle at room temperature. Since their process involves thermal denaturation for microsphere stabilization, a further increase in surface hydrophobicity may occur due to additional albumin conformational changes and surface binding of oil at elevated temperatures. Surface hydrophilicity is important, because a hy-

drophilic albumin surface may enhance surface physical and chemical behavior *in vivo*, and the surfactants presently used to disperse human serum albumin microspheres may influence tissue interactions, drug release, and activity.

The use of insoluble drug carriers for localized or intratumor injection chemotherapy was reported previously (17–19). Therefore, methods have been explored for preparing hydrophilic albumin microspheres which readily form stable dispersions for injection without surfactants and which may be easily surface-modified to introduce functional groups (*e.g.*, —CHO) or ligands (*e.g.*, antibodies) for binding to tumor tissue (17, 19).

The present report is concerned with the preparation of human serum albumin microspheres by a new procedure which yields hydrophilic, solid spheres. Glutaraldehyde cross-linking of the albumin phase also produces free aldehyde groups on the surface of the microspheres. Because of aldehyde–protein amino group coupling, these aldehyde handles may enhance tissue immobilization. The aldehyde functionality also facilitates surface chemical coupling of 2-aminoethanol or aminoacetic acid for increased hydrophilicity. Attachment of drugs, immunoglobulins, lectins, enzymes, and anionic or cationic ligands is also feasible.

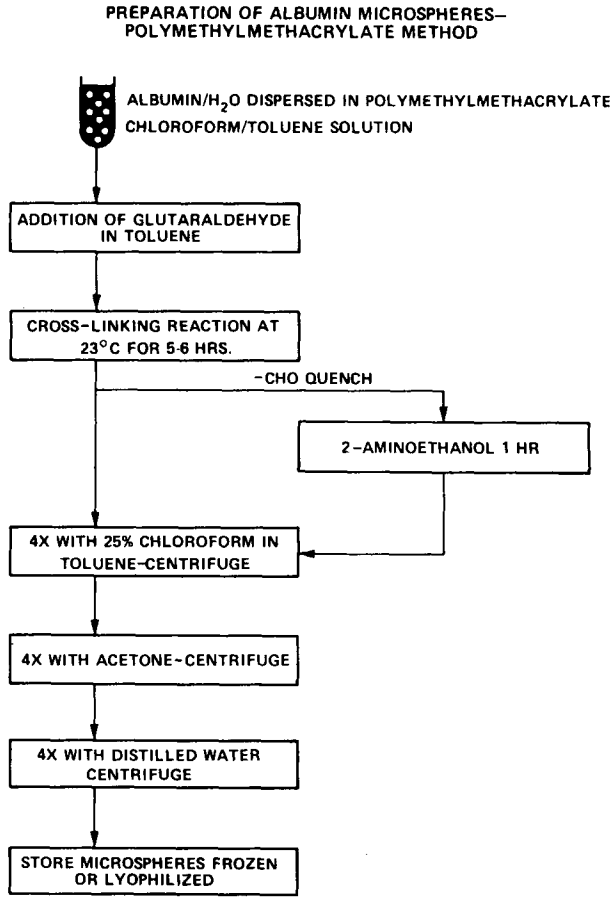
EXPERIMENTAL

Preparation of Microspheres—*Polymethylmethacrylate–Chloroform/Toluene Dispersion*—Human serum albumin[1] (150 mg) was dissolved in 0.5 ml of distilled water (pH 7.0) at 23° and added dropwise to a 25–30% solution of polymethylmethacrylate[2] (intrinsic viscosity 1.4) in a mixture of 1.5 ml of chloroform[3] and 1.5 ml of toluene[3] in a 16- × 125-mm screw-cap test tube. The mixture was dispersed with a vortex mixer[4] for various time periods (1–10 min) until the desired microsphere size was achieved. Microsphere particle size was determined by optical microscopy[5] using aliquots removed at various times.

Glutaraldehyde in toluene was used for cross-linking. Aqueous glutaraldehyde (25% biological grade)[2], 1.0 ml, and 1.0 ml of toluene were combined in a 13- × 100-mm test tube. The two phases were dispersed by sonication[6] with a microtip power head attachment (20 sec at 50 W). The resulting toluene solution of glutaraldehyde (0.14 mole was determined with 3-methyl-2-benzothiazolinone hydrazone)[1] (20) was allowed to phase separate, pipeted off, and added to the albumin dispersion. After addition of the glutaraldehyde-saturated toluene, the dispersion was mixed with a rotary mixer[7] at room temperature until albumin cross-linking was complete (5–6 hr). One milliliter of either 2-aminoethanol[8] or aminoacetic acid[1] then was added to cap any free aldehyde groups. After a 1-hr reaction time, the suspension was centrifuged (2000 ×*g*, 2 min) and the supernatant discarded. Microspheres were then washed four times each with 25% chloroform in toluene, acetone, and distilled water. Between each washing, microspheres were centrifuged (2000×*g*, 2 min), the supernatant discarded, and the pellet resuspended. The washed microspheres were either stored frozen or lyophilized. Yields were 75–85% (Scheme I).

Polyoxyethylene–Polyoxypropylene Copolymer–Chloroform Dispersion—Human serum albumin (150 mg) was dissolved in 0.5 ml of distilled water (pH 7.0) at 23° and added dropwise to a 25–30% solution of polyoxyethylene–polyoxypropylene copolymer[9] in 4.0 ml of chloroform in a 16- × 125-mm screw-cap test tube. The mixture was emulsified with a vortex mixer for various time periods (1–10 min) until the desired size of microsphere was achieved.

Glutaraldehyde in chloroform for cross-linking was prepared from 25% aqueous glutaraldehyde and chloroform by sonication as previously described. Gluturaldehyde, 0.40 mole in 1.0 ml of chloroform, was added and the dispersion was mixed with a rotary mixer at room temperature until albumin cross-linking was complete (5–6 hr). Then, 1.0 ml of either 2-aminoethanol or aminoacetic acid was added to cap any free aldehyde groups. After a 1-hr reaction time, 10 ml of acetone was added, the suspension briefly shaken, then centrifuged (2000×*g*, 2 min) and the supernatant discarded. Microspheres were then washed 10 times each with acetone and distilled water. Between each washing, microspheres were centrifuged (2000×*g*, 2 min), the supernatant decanted, and the pellet resuspended. As before, washed microspheres were either stored frozen or lyophilized. Typical yields were 75–85% (Scheme II).



Scheme I—Albumin microsphere preparation using polymethylmethacrylate solution for dispersion.

Microscopic Characterization of Microspheres—Size and morphology were characterized by scanning electron microscopy (SEM)[10] at 20 kV. SEM samples were prepared by applying a 200 Å coating of gold–palladium on samples using a sputter coater[11] in an argon atmosphere with a digital thickness monitor. Internal structures were determined by transmission electron microscopy[12]. Microspheres mounted in epoxy were sliced with an ultramicrotome[13]. Microsphere compositions and porosity were verified with 0.5 ml of dye added to 10-mg spheres in 2 ml of distilled water[14] using optical microscopy. Protein stained microspheres were also mounted in epoxy, sliced with the ultramicrotome, and examined by optical microscopy.

Effect of Polymer Dispersant Concentration—Human serum albumin microspheres were prepared by the two methods, and the concentrations of polymer solutions (polymethylmethacrylate and polyoxyethylene–polyoxypropylene) were varied from 0 to 25% in 2% intervals. After cross-linking with glutaraldehyde, the dispersions were evaluated for microsphere stability against coagulation.

Measurement of Microsphere Size Distribution as a Function of Dispersion Time—Human serum albumin microspheres were prepared

using both described procedures. Dispersion times of 1, 3, 5, and 8 min were used at constant energy input (speed setting 8 on vortex mixer). The washed microspheres were suspended in 10 ml of distilled water. Aliquots were withdrawn from a well-shaken sample and placed on an SEM sample holder. One hundred random microspheres for each dispersion time were counted and measured. Aliquots (10 μl) were also added to 150 ml of continuously stirred 0.14 *M* potassium chloride solution. A 1.0-ml sample was withdrawn over a 4-sec time span by an electronic particle size counter[15] equipped with a 100-μm sampling aperture. The counter was calibrated with 9.76 μm of polystyrene microspheres. This enabled accurate size measurements from 2 to 40 μm. The total number of microspheres counted ranged from 7000 to 23,000/sample.

Microsphere Size Distribution as a Function of Energy Input—Human serum albumin microspheres were prepared using the polymethylmethacrylate procedure. Dispersion time was held constant (10 min), and energy input was varied by adjusting the speed setting on the vortex mixer, using speeds of 2, 4, 6, and 8. The washed microspheres were suspended in 10 ml of distilled water and size distributions were measured by the SEM technique.

Measurement of Reactive Aldehyde Groups—Human serum albumin microspheres (10 μm average diameter) were prepared by the polymethylmethacrylate method. The cross-linked microspheres were divided into two samples. One was quenched with 0.5 ml of 2-aminoethanol while the other sample was left unquenched. [^{3}H]Leucine[16], specific activity 134.2 Ci/mmoles/ml, was diluted with a carrier (L-leucine)[17] to a final activity of 5 μCi/50 mmoles/ml. One milliliter of isotope solution was added to each of three samples of 7.4 mg/ml unquenched and three samples of 7.99 mg/ml quenched microspheres in 13- × 100-mm test tubes. The samples were incubated for 40 min in a tabletop sonicator[18], then washed four times with distilled water (pH 7.0) by centrifugation (1000×*g*, 2 min). Microsphere pellets were resuspended in 2 ml of a scintillation cocktail[16] and slightly shaken until microspheres were completely dissolved. From each of these solutions, 1.0-, 0.5-, and 0.25-ml aliquots were removed and added to scintillation counter containers. The

final volumes were adjusted to 15 ml with additional cocktail. Activity was determined using a scintillation counter[19] and values plotted against prepared standards.

RESULTS

Figure 1 shows the uniform, smooth spherical geometry of albumin microspheres typically prepared by the procedure (SEM photomicrograph at 2200×). The human serum albumin microspheres in Fig. 1 averaged 10 μm in diameter and were made using polymethylmethacrylate as the polymer dispersant.

The SEM photomicrograph in Fig. 2 clearly shows the solid internal structure of the human serum albumin microspheres. Figure 2 is consistent with the transmission electron microscopic results (not shown) of sectioned microspheres obtained from both dispersant systems. Microtomed sections of the protein stained microspheres showed the blue dye color throughout the albumin spheres. This complete dye penetration is indicative of the porous internal structure of the albumin spheres.

Washed, lyophilized, or air-dried microspheres were readily resuspended in a variety of aqueous media such as distilled water, physiological saline, phosphate buffer, and acetate buffer. The microspheres were easily wetted and dispersed without the need for surfactants.

Figures 3 and 4 show the size distributions of the microspheres as a function of dispersion time using the vortex apparatus. Polymethylmethacrylate was used as a dispersant for the microspheres in Fig. 3 and polyoxyethylene–polyoxypropylene for those in Fig. 4. These data were obtained using an electronic size counter. Average diameters from these data were in close agreement with data obtained from SEM measurements. These results are presented in Table I. SEM size distribution as

[a] Assumed one bound leucine equals one reactive aldehyde group.

tablished that there were ~1.0×10^{10} microspheres/ml in a 10-μm diameter preparation. This is equivalent to 2.42×10^{6} reactive aldehyde groups/sphere based on one leucine molecule covalently bound per reactive aldehyde group. From the data of Ikada *et al.* (21) 1.1 μg of a human serum albumin monolayer would cover a 1.0-cm^2 area, and if perfect molecular packing for albumin molecules were assumed, 3.02×10^{7} molecules would fill the surface area of a 10-μm microsphere. On this basis, the 2.42×10^{6} reactive aldehyde groups measured/10-μm sphere, therefore, would be equivalent to ~8 reactive aldehyde groups/100 human serum albumin molecules at the surface, which is clearly a maximum value, since a significant fraction of —CHO groups must also be present within the spheres.

DISCUSSION AND CONCLUSIONS

Good dispersion and stabilization of aqueous human serum albumin was obtained in concentrated polymer solutions. No additional surfactants were required. Insoluble human serum albumin microspheres were produced with glutaraldehyde cross-linking in a wide particle size range as shown in the SEM photomicrographs. Optical photomicrographs (Figs. 6*a* and *b*) show the polymer coating surrounding the human serum albumin microsphere dispersion in the aqueous wash phase. This polymer coating or microcapsule apparently affords dispersion stability and prevents coagulation before and during glutaraldehyde cross-linking.

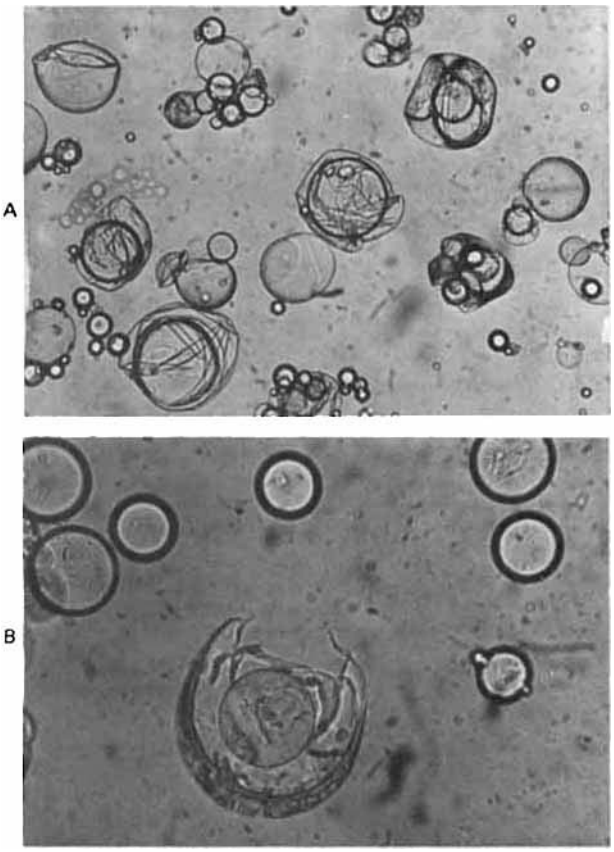

Figure 6—*(a) Optical micrograph of stabilized albumin microspheres showing the surrounding polymer coating. Microspheres in aqueous wash phase; average particle size 40 μm; polyoxyethylene–polyoxypropylene dispersant. (b) Polymer coated microspheres, as in (a), showing ruptured polymer coating during aqueous wash.*

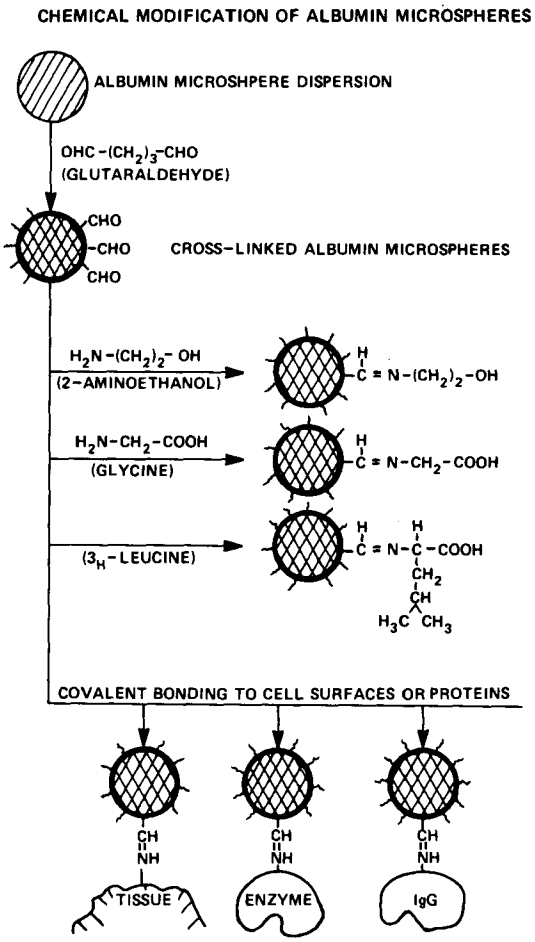
The concentration of the polymer dispersant solutions was important; concentrations <25% (w/w) were not sufficient to prevent coagulation when small microspheres (≤10 μm) were desired, and concentrations >30% retarded complete removal of the polymer. Polymer molecular weight was also important. Low molecular weight polymethylmethacrylate (intrinsic viscosity 0.4) was unsatisfactory at concentrations of 25–30% (w/w), since coagulation occurred.

The size of the microspheres was directly related to power input and dispersion time (Figs. 3–5 and Tables I and II). Thus, by adjusting power input and time, particle size was readily controlled.

Two unique distinguishing features of this method for albumin microsphere preparation as compared with methods reported to date (9, 10, 14–16) are the addition of the glutaraldehyde cross-linking agent in an organic medium to the aqueous albumin dispersion and use of concentrated high polymer solutions as the organic phase for preparing dispersions. Human serum albumin microspheres prepared by thermal denaturation in oil or by glutaraldehyde cross-linking with aqueous aldehyde (sometimes incorporated at low temperature into the aqueous albumin phase) are hydrophobic to the extent that surfactants must be used to prepare microsphere dispersions in water (10, 22). This is probably a result of preferential hydrophobic organization of the albumin surface at a hydrophobic oil interface coupled with thermal denaturation or homogeneous cross-linking with glutaraldehyde.

Use of concentrated polymer solutions as the organic dispersing phase



Scheme III—Schematic representation of albumin microsphere surface chemistry.

affords excellent dispersion and control, wide particle size latitude, and smooth, uniform spheres without the need for surfactants. More importantly, because glutaraldehyde is presented to the aqueous albumin microsphere dispersion from the organic phase, there must be a strong preference for aldehyde-amino group reactions and cross-linking at or near the albumin surface. This probably produces a case-hardening effect with a higher cross-link density near the surface of the microspheres accompanied also by a much higher concentration of mono-reacted dialdehyde at the surface (Scheme III). The result of monofunctional glutaraldehyde capping of lysine amino groups at the albumin microsphere surface would be to increase surface anionicity and hydrophilicity, especially if a portion of the free aldehyde functions oxidize to carboxyl groups.

The availability of a relatively high surface concentration of aldehyde functionality also facilitates a variety of chemical modifications including: aminoalcohol capping to enhance hydrophilicity; enzyme, antibody, or other protein ligand binding; covalent attachment of amino-functional drugs. As suggested in Scheme III, such changes in surface functionality may be used to enhance tissue immobilization by covalent or physical binding, for specific tissue targeting using biospecific affinity ligands (*e.g.*, tumor-specific antibodies), or for improved diagnostic or immune assay reagents and procedures.

Kinetics and Mechanism of the Equilibrium Reaction of Triazolam in Aqueous Solution

MASAHARU KONISHI ˣ, KENTARO HIRAI ‡, and YOSHIO MORI *

Received October 6, 1981, from the **Division of Analytical Chemistry* and the ‡*Division of Organic Chemistry, Shionogi Research Laboratories, Shionogi & Co., Ltd., Fukushima-ku, Osaka 553, Japan.* Accepted for publication January 11, 1982.

Abstract □ The equilibrium kinetics of triazolam in aqueous solution was investigated in the pH range of 1–11 at body temperature. The quantitative study indicated that it forms equilibrium mixtures consisting of ring-opened and closed forms with the composition being dependent on pH. The equilibrium constants of the two species in the pH range studied were determined by GLC method. The apparent first-order rate constants were estimated from the decreasing or increasing absorbance of the mixture in solutions. The forward-reaction rate constant (k_f) showed a bell-shaped k_f–pH profile with a rate maximum at pH 4.59, which indicates not only that the carbinolamine intermediate forms during the equilibrium reaction, but that the rate-determining step of the reaction differs for the acidic and basic sides of the rate maximum. The reverse-reaction rate constant decreased with increasing pH and could not be estimated in the pH region >5.65. Theoretical curves for both forward and reverse reactions satisfactorily fit the observed data. The pKa values of triazolam and its opened-form amine were estimated to be 1.52 and 6.50, respectively.

Keyphrases □ Triazolam—kinetics, mechanism of equilibrium in aqueous solution □ Kinetics—triazolam, mechanism of equilibrium in aqueous solutions □ Equilibrium reaction—triazolam, kinetics, mechanism in aqueous solutions

1,4-Benzodiazepines, first synthesized in the early 1960s, are important minor tranquilizers. These tranquilizers are being extensively used as sedative, hypnotic, muscle relaxant, and anticonvulsant drugs. Their stability and reactivity in aqueous solutions have been under study extensively in the last 5 years. Reaction mechanisms for the hydrolysis of 1,4-benzodiazepines have been reported for chlordiazepoxide (1, 2), oxazepam (3), diazepam (4), nitrazepam (4, 5), desmethyldiazepam (6), and clonazepam (6). Furthermore, equilibrium reactions of these compounds have been reported for pyrazolodiazepinone (7), diazepam (8), nitrazepam (9), triazolobenzodiazepines (10), flunitrazepam (11), and desmethyldiazepam (12). It is now well known that hydrolysis of an azomethine bond

0022-3549/82/1200-1328$01.00/0

affords excellent dispersion and control, wide particle size latitude, and smooth, uniform spheres without the need for surfactants. More importantly, because glutaraldehyde is presented to the aqueous albumin microsphere dispersion from the organic phase, there must be a strong preference for aldehyde-amino group reactions and cross-linking at or near the albumin surface. This probably produces a case-hardening effect with a higher cross-link density near the surface of the microspheres accompanied also by a much higher concentration of mono-reacted dialdehyde at the surface (Scheme III). The result of monofunctional glutaraldehyde capping of lysine amino groups at the albumin microsphere surface would be to increase surface anionicity and hydrophilicity, especially if a portion of the free aldehyde functions oxidize to carboxyl groups.

The availability of a relatively high surface concentration of aldehyde functionality also facilitates a variety of chemical modifications including: aminoalcohol capping to enhance hydrophilicity; enzyme, antibody, or other protein ligand binding; covalent attachment of amino-functional drugs. As suggested in Scheme III, such changes in surface functionality may be used to enhance tissue immobilization by covalent or physical binding, for specific tissue targeting using biospecific affinity ligands (*e.g.*, tumor-specific antibodies), or for improved diagnostic or immune assay reagents and procedures.

1,4-Benzodiazepines, first synthesized in the early 1960s, are important minor tranquilizers. These tranquilizers are being extensively used as sedative, hypnotic, muscle relaxant, and anticonvulsant drugs. Their stability and reactivity in aqueous solutions have been under study extensively in the last 5 years. Reaction mechanisms for the hydrolysis of 1,4-benzodiazepines have been reported for chlordiazepoxide (1, 2), oxazepam (3), diazepam (4), nitrazepam (4, 5), desmethyldiazepam (6), and clonazepam (6). Furthermore, equilibrium reactions of these compounds have been reported for pyrazolodiazepinone (7), diazepam (8), nitrazepam (9), triazolobenzodiazepines (10), flunitrazepam (11), and desmethyldiazepam (12). It is now well known that hydrolysis of an azomethine bond

0022-3549/82/1200-1328$01.00/0

in acidic solution gives the corresponding aminobenzophenone, which reversibly cyclizes into the original form in alkaline medium. Namely, 1,4-benzodiazepines exist as pH-dependent equilibrium mixtures of ring-opened and closed forms. However, no extensive, detailed study on the mechanism of the equilibrium reaction has been reported.

This study describes the mechanism of the equilibrium reaction between triazolam and its opened form in an aqueous solution.

EXPERIMENTAL

Materials—2′,5-Dichloro-2-(3-aminomethyl-5-methyl-4H-*s*-triazol-4-yl) benzophenone (I), 8-chloro-1-methyl-6-(*o*-chlorophenyl)-4H-*s*-triazolo[4,3-*a*] 1,4-benzodiazepine (triazolam, II), 4-amino-7-chloro-5-(2-chlorophenyl)-1-methyl-4H-*s*-triazolo[4,3-*a*] quinoline (III), and 3-amino-6-chloro-4-(2-chlorophenyl)-1-*n*-propylquinolin-2-one (IV) were synthesized. Dotetracontane was purchased from a commercial source[1]. All other reagents and solvents were of reagent grade and were used without further purification. Deionized water was further distilled before use in the aqueous solutions.

Equipment—UV spectra were recorded using a spectrophotometer[2] equipped with a thermostatically controlled cell holder. The pH was measured with a pH meter[3] at the temperature of the study.

TLC was done with a precoated 0.25-mm silica gel TLC plate[4] using a developing solvent system of chloroform–acetone–ethanol (3:1:1).

The gas chromatograph[5] was equipped with a 10-mCi ^{63}Ni-electron-capture detector (ECD) or a flame ionization detector (FID). The column was coiled glass (0.5 m × 3-mm i.d.), packed with 3% OV-17 on 100–120 mesh Gas Chrom Q[6]. The carrier gas was ultrapure nitrogen flowing at a rate of 60 ml/min. Temperature settings during operation were 320° for the injection port and detector and 290° for the column. Peak heights of the compounds were determined using an integrator[7]. Under these GC conditions, the retention times for the compounds under study were 2.25 min for II, 3.35 min for III, 0.9 min for IV, and 6.15 min for dotetracontane.

Kinetic Studies—All rate studies were performed in aqueous buffer solutions at 37.0 ± 0.1°. The buffer systems used were: pH 1.1–5.6, acetate; pH 6–8, phosphate; pH 9–10, borate; and pH 11–12, phosphate. The ionic strength of each was adjusted to 0.5 with potassium chloride.

The compound to be studied was dissolved in ethanol and diluted (1:20) with preincubated buffer solution kept at 37° to make a 10^{-4} *M* solution. Next, an appropriate volume of the solution was pipeted into the UV cell, and the reaction was followed spectrophotometrically by reading the decrease or increase in absorbance at 264 nm.

Reactions starting from I were studied in the pH range of 1.92–11.44. The sum of the first-order rate constants for the forward and reverse reactions (k_f and k_r) was determined from linear plots of ln $(A_t - A_\infty)$ *versus* time by the least-squares method (Eq. 1), where A_t, A_∞, and A_0 are the absorbance at time t, infinity, and time 0, respectively:

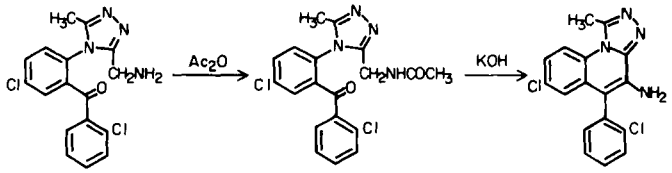
$$\ln(A_t - A_\infty) = \ln(A_0 - A_\infty) - (k_f + k_r)t \qquad \text{(Eq. 1)}$$

Reactions initiating from II were studied in the pH region of 1.13–1.40. The sum of the first-order rate constants for the forward and reverse reactions was obtained from the linear plots of ln $(A_\infty - A_t)$ against time by the least-squares method (Eq. 2), where A_∞, A_t, and A_0 are the absorbance at infinity, time t, and time 0, respectively:

$$\ln(A_\infty - A_t) = \ln(A_\infty - A_0) - (k_f + k_r)t \qquad \text{(Eq. 2)}$$

Product Identification—For the identification studies, 2×10^{-3} *M* solutions of I were prepared using 0.5 *N* NaOH solution, the pH 6.5 buffer solution, and a 0.01 *N* HCl solution. These solutions were left standing at room temperature for 15 hr, then a 5-ml sample was taken from each solution and was subjected to extraction with dichloroethane for TLC analysis. The chromatograms were visualized under UV light and iodine vapour to identify the products. Dichloroethane solutions of reference standards were spotted directly on the TLC plates.

Determination of I and II in Aqueous Solutions—*ECD-GC Method*—In this method, caution was paid to determine the compounds without disturbing the equilibrium. The triazoloaminoquinoline derivative (III) was derived by acetylation followed by cyclization to obtain a suitable compound for GC as shown in Scheme I.



I III

Scheme I

The pH 11 phosphate buffer (containing 0.2 *M* Na_2HPO_4) was added to 1 ml of reaction solution (initially containing 2×10^{-4} *M* of I) to make a 10-ml solution at pH 10, with the temperature kept at 0° with ice (quenched solution). This quenching procedure was necessary to prevent disturbance of the equilibrium mixture during assay. Triethylamine (0.2 ml), 2 *N* KOH (1 ml) quenched reaction solution (1 ml), and acetic anhydride (0.1) were added with ice cooling to a 12-ml centrifuge tube containing 3 ml of dichloroethane. After this mixture was shaken for 15 min on a mechanical shaker (for acetylation of I), 1 ml of the dichloroethane solution was transferred to another 12-ml centrifuge tube by Eppendorf pipet and evaporated to dryness. To dissolve the residue, 0.2 ml of ethanol was added followed by 2 ml of 2 *N* KOH and the solution was heated for 3 hr at 91 ± 1° (cyclization to III). After it had cooled, the reaction solution was extracted with 5 ml of benzene containing 1 μg of IV as an internal standard for 5 min, then 2 μl of the benzene layer was subjected to ECD-GC. Calculation was done by the internal standard method using the peak height ratios. Recoveries of I for the acetylation and the cyclization were 80 and 83.9%, respectively, and the overall recovery was 60.0% (n = 36, CV = 3.30%). Recovery of II was 86.7% (n = 27, CV = 4.64%) in this procedure.

FID-GC Method—In the equilibrium solutions, if the weight ratios of II to I were >5, separation of the peaks of Compounds II and III on ECD-GC was difficult because of low resolution. This problem was overcome by using the FID-GC, in which no peak broadening of Compound II was observed. The quantities of I and II were determined by separate procedures.

For Compound I, 5.7 ml of the pH 11 phosphate buffer and 0.3 ml of 1 *N* KOH were added to 4 ml of reaction solution (initial concentration of I: 4×10^{-4} *M*) to make a 10-ml solution of pH 10, keeping the temperature at 0° with ice (quenched Solution I). Quenched Solution I (2.5 ml) and acetic anhydride (0.1 ml) were added with ice cooling to a 12-ml centrifuge tube containing 3 ml of dichloroethane, 0.2 ml of triethylamine, and 1 ml of 2 *N* KOH. The mixture was shaken for 15 min, then the dichloroethane layer was transferred to another 12-ml centrifuge tube and evaporated to dryness. Next, 0.2 ml of ethanol was added to dissolve the residue and 2 ml of 2 *N* KOH was added to this solution, which was then heated for 3 hr at 91 ± 1°. After cooling, the reaction solution was subjected to extraction for 5 min with a mixture of 4 ml of benzene and 1 ml of *n*-hexane containing 3.5 μg of dotetracontane as an internal standard, then the resulting organic layer was transferred to a 30-ml round-bottom flask and evaporated to dryness. The residue was dissolved in 0.1 ml of solvent (acetone–*n*-hexane, 1:2) and 4 μl of the solution was subjected to FID-GC. Recovery of I was 64.3% (n = 18, CV = 2.94%).

For Compound II, the pH 11 phosphate buffer was added to 1 ml of reaction solution (the same solution as that for Compound I) to make a 10-ml solution of pH 10 with ice cooling (quenched Solution II). Quenched Solution II and acetic anhydride (1 ml) were added with ice cooling to a 12-ml centrifuge tube containing 3 ml of dichloroethane, 0.2 ml of triethylamine, and 1 ml of 2 *N* KOH. The mixture was shaken for 15 min, then the dichloroethane layer was removed by pipeting and evaporated to dryness. The residue was dissolved in 0.2 ml of ethanol and 2 ml of 2 *N* KOH, and the solution was subjected to extraction with a mixture of 4 ml of benzene and 1 ml of *n*-hexane containing 35 μg of dotetracontane for 5 min. The organic layer was transferred to a 30-ml round-bottom flask and evaporated to dryness. The residue was dissolved in 0.5 ml of solvent (acetone–*n*-hexane, 1:2) and 2 μl of this solution was subjected to FID-GC. Recovery of Compound II was 81.1% (n = 10, CV = 2.34%).

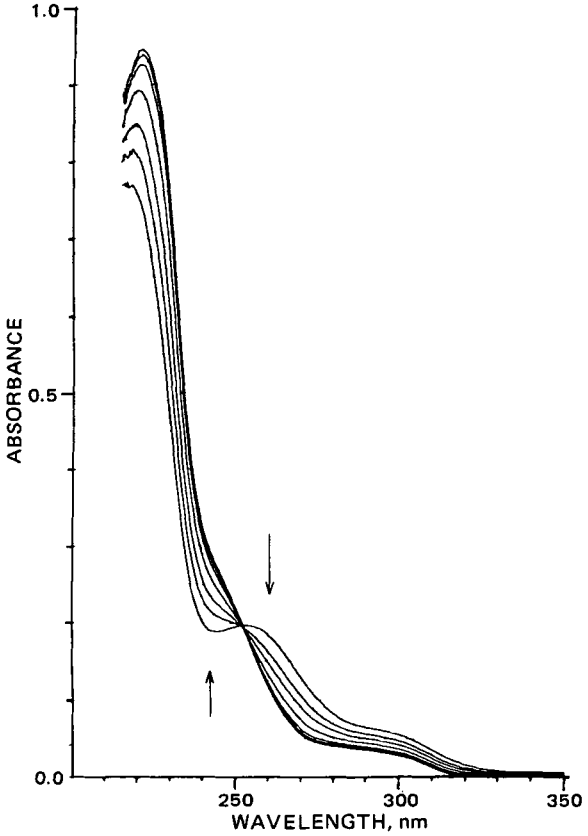

Figure 1—*Typical spectral changes due to the ring-closure reaction of Compound I (× 10^{-4} M) into triazolam in 0.1 M acetate buffer, pH 5.65 (μm = 0.5) at 37°. Spectra were measured at 5, 13, 20, 35, 60, 85, and 150 (∞) min after initiation of the reaction.*

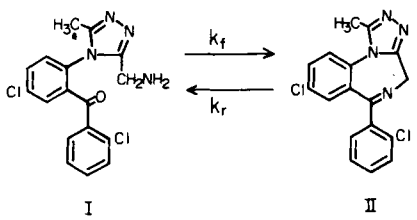
RESULTS AND DISCUSSION

Spectral Change and the Nature of the Reaction—After the pH 6.5 buffer solution and the 0.5-*N* NaOH solution of I had been left standing for several hours, both showed only one spot with an R_f value (0.68) identical to that of II on TLC (R_f for I was 0.18 in this system). The chromatogram for the standing solution of I in 0.01 *N* HCl gave two spots, identical to I and II, of compounds present in approximately equivalent amounts.

The UV spectral change of I in the pH 5.65 buffer at 37° is shown in Fig. 1. Immediately after I had dissolved, the absorption spectrum showed an absorption maximum (λ_{max}) at 257 nm, which decreased concurrently with time. At infinity, the shape of the redundant spectrum was identical to that of II in the same medium. An isosbestic point at 253 nm was observed during the reaction. On the other hand, the spectral change of II in 0.1 *N* HCl showed a reverse change in which the absorption at λ_{max} increased with time when the isosbestic point was kept at 253 nm; the final spectrum could be superimposed on that of I in the same solution. Furthermore, the spectrum of II obtained by mixing the equilibrium pH 5.65 solution of II and 1 *N* HCl rapidly changed into a spectrum similar to that of II in 0.1 *N* HCl solution.

These observations indicate that I and II in these aqueous solutions undergo reversible reactions involving cyclization and hydrolytic azomethine bond cleavage, respectively, to produce equilibrium mixtures of Compounds I and II (Scheme II), as in the case of estazolam (10).



I II

Scheme II

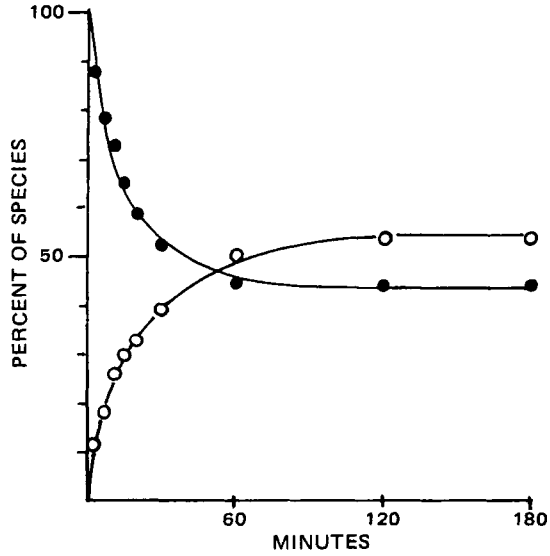


Figure 2—*Time courses for Compound I (●) and triazolam (○) in a 0.2 M acetate buffer, pH 2.30 (μm = 0.5) at 37° initially containing 2 × 10^{-4} M of Compound I.*

Cyclization of I to II and Quantitative Aspects—The equilibrium mixture of I and II was analyzed quantitatively by GC procedure. The result obtained for the 0.2 *M* acetate buffer solution of pH 2.3 (initial concentration of I: 2 × 10^{-4} *M*) is shown in Fig. 2. The data plotted as the percent of I and of II with time showed a continuous decrease and increase, respectively. During the time course of the equilibrium reaction, the total recoveries of I plus II were >98% based on the initial concentration of I. Moreover, the rate of decrease for I was equivalent to the rate of increase for II. These results also support the fact that both I and II exist as equilibrium mixtures in solution.

Effect of pH on the Equilibrium Constant—The apparent equilibrium constant, *K*, is defined by Eq. 3, where $[I]_\infty$ and $[II]_\infty$ are the molar concentrations of I and II at equilibrium, and k_f and k_r are first-order rate constants of the forward and reverse reaction, respectively:

$$K = \frac{[II]_\infty}{[I]_\infty} = \frac{k_f}{k_r} \qquad \text{(Eq. 3)}$$

The value for *K* was determined at various pH values over the range of pH 1.13–11.44 at 37° by determining the components of the reaction solutions after they had attained equilibrium state. The results are shown in Table I. The *K* values increased with increasing pH and became >400 at pH >5.02.

When equilibrium is attained at any pH, the fractions of I (F_I) and II (F_{II}) in the reaction solutions are defined by Eqs. 4 and 5. The plots of the fractions of the individual species against pH are shown in Fig. 3. F_I

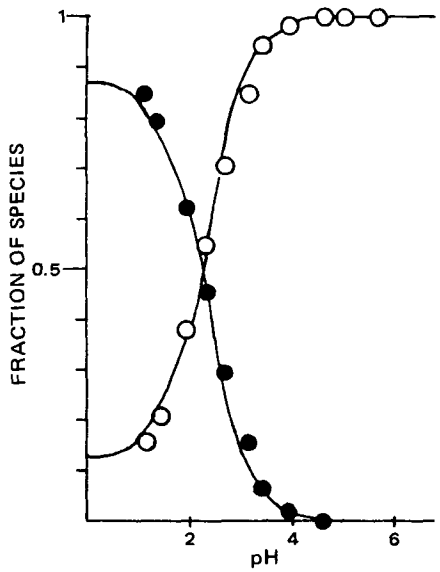

Figure 3—*Plot of the composition of the equilibrium mixture consisting of Compound I (●) and triazolam (○) versus pH at 37°. Solid lines are values calculated using Eqs. 4, 5, and 23.*

decreases with increasing pH from 0.85 at pH 1.13 to <0.002 at pH >5.02 at which the equilibrium mixture contains >99.8% of ring-closed Compound II.

$$F_I = \frac{[I]_\infty}{[I]_\infty + [II]_\infty} = \frac{1}{1+K} \quad \text{(Eq. 4)}$$

$$F_{II} = 1 - F_I = \frac{K}{1+K} \quad \text{(Eq. 5)}$$

Rate Constant Determination and Rate–pH Profiles—Semilogarithmic plots of $(A_t - A_\infty)$ against time for the equilibrium reaction in various pH solutions are shown in Fig. 4. In the pH region studied, all the plots displayed strict first-order kinetics for >5 half-lives. The apparent first-order rate constants (k_{app}) are expressed as Eq. 6. Each rate constant for the forward and reverse reactions can be derived from Eqs. 3 and 6.

$$k_{app} = k_f + k_r \quad \text{(Eq. 6)}$$

In Fig. 5, the first-order rate constants for the formation and the hydrolysis of II at 37°, which were extrapolated to zero buffer concentration, are plotted against pH.

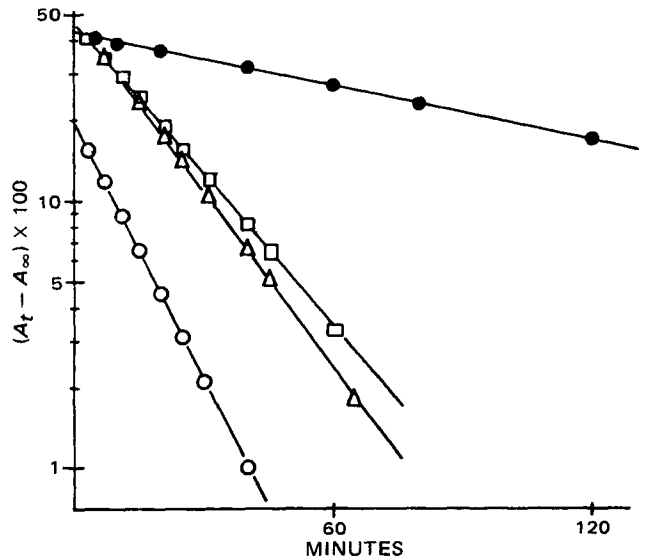

Figure 4—*Typical apparent first-order plots for the equilibrium reaction between Compound I and triazolam at 37°, μm = 0.5. Key: (○) pH 1.92; (△) pH 5.02; (□) pH 3.39; (●) pH 7.74.*

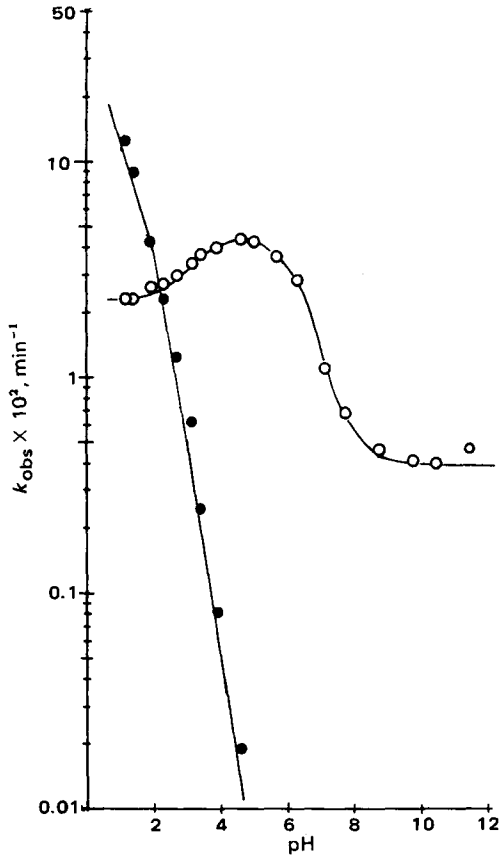

Figure 5—*Log k–pH profile for the equilibrium reaction consisting of forward (○) and reverse reactions (●) at 37°, μm = 0.5. Solid lines were based on calculations using Eq. 18 or Eq. 22. All rates are extrapolated to zero buffer concentration.*

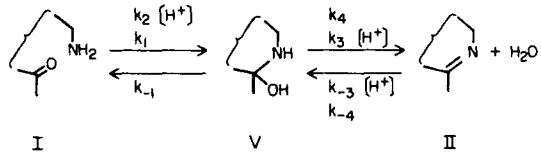
For the formation rate, a maximum occurs near pH 4.5. On the alkaline side of the pH–rate maximum (pH 4.5–9), the rate increases with increasing acidity, suggesting that an acid-catalyzed reaction is predominant. In the solution at pH >9, the rate becomes constant. On the acidic side of the pH–rate maximum, the rate decreases with increasing acid concentration and becomes independent of pH at pH <1.40, indicating the existence of a specific acid-catalyzed reaction as well as an uncatalyzed one of the free form of I.

The hydrolysis of II shows an acid-catalyzed reaction over the pH range used in this study and its rate could not be determined ≥pH 5.65 because the equilibrium constants were too large to be determined.

General Reaction Mechanism—Reactions of carbonyl compounds with amines have been reviewed previously (13–15). Moreover, a noteworthy series of papers have reported on studies of the formation of semicarbazones (16, 17), Schiff base (18, 19), and oxime (16) in aqueous solutions. These studies have pointed out that the formation and hydrolysis of these compounds proceed by a two-step mechanism involving a tetrahedral carbinolamine intermediate. The evidence for the two-step mechanism is based on the results that the Schiff base formation undergoes a transition in the rate-determining step from the dehydration of the carbinolamine intermediate at neutral pH to the amine attack under acidic conditions. Formation of II exhibits a pH–rate maximum similar to that in the formation of oxime (16) and *N*-*p*-chlorobenzylideneaniline (18). Therefore, the formation and the hydrolysis of II are considered to proceed by the two-step reaction mechanism, as shown:



Scheme III

In the forward reaction, the acid-catalyzed dehydration of the carbinolamine intermediate (V) at nearly neutral pH determines the rate

which may account for a leveling off, but not a decrease in the rate with increasing pH. At low pH values, the rate of dehydration becomes very fast, and at the same time, the rate of the amine attack is retarded because of the conversion of the free amine form of I into its conjugate acid. Consequently, a change in the rate-determining step occurs and the attack of the amine becomes rate-determining, accounting for the observed decrease in the rate on the acid side of the pH–rate maximum.

In the reverse reaction, the hydrolysis rates are measurable only on the acidic side of the pH–k_f maximum. The rate-determining step of this reaction in this pH region is the cleavage of the C—N bond from V to I. Since the carbinolamine intermediate is formed by a water molecule attack at the conjugate acid of II, the hydrolysis rate is directly proportional to the concentration of the conjugate acid as an active acidic species of II.

In Scheme III, k_1 and k_{-1} represent uncatalyzed reaction rate constants; k_2, k_3, and k_{-3} represent acid-catalyzed rate constants; and k_4 and k_{-4} represent water-catalyzed rate constants. When a steady-state approximation is applied to the carbinolamine intermediate, the rate equations for the forward and the reverse reaction can be written as Eqs. 7 and 8, respectively; where a_{H^+} is hydrogen ion activity; K_I and K_{II} are dissociation constants for the conjugate acid of I and II:

$$k_{f(obs)} = \frac{K_I(k_1 + k_2a_{H^+})\,(k_3a_{H^+} + k_4)}{(K_I + a_{H^+})\,(k_{-1} + k_3a_{H^+} + k_4)} \qquad \text{(Eq. 7)}$$

$$k_{r(obs)} = \frac{k_{-1}a_{H^+}\,(k_{-3}a_{H^+} + k_{-4})}{(K_{II} + a_{H^+})\,(k_{-1} + k_3a_{H^+} + k_4)} \qquad \text{(Eq. 8)}$$

Formation Mechanism—On the alkaline side of the rate maximum (Fig. 5), the rate-determining step should be the dehydration from the carbinolamine intermediate. This implies $k_{-1} \gg (k_3a_{H^+} + k_4)$; therefore, Eq. 7 can be reduced to Eq. 9:

$$k_{f(obs)} = \frac{K_I(k_1 + k_2a_{H^+})\,(k_3a_{H^+} + k_4)}{k_{-1}(K_I + a_{H^+})} \qquad \text{(Eq. 9)}$$

If k_1 is assumed to be much larger than $k_2a_{H^+}$, Eq. 10 will be obtained:

$$k_{f(obs)} = \frac{k_1K_I(k_3a_{H^+} + k_4)}{k_{-1}(K_I + a_{H^+})} \qquad \text{(Eq. 10)}$$

In Eq. 10, two pH regions, $k_3a_{H^+} \gg k_4$ and $K_I \gg a_{H^+}$ are considered. In the former, Eq. 11 can be derived:

$$k_{f(obs)} = \frac{k_1k_3K_Ia_{H^+}}{k_{-1}(K_I + a_{H^+})} \qquad \text{(Eq. 11)}$$

When both sides of Eq. 11 are divided by a_{H^+} and the equation is converted into its reciprocal form, Eq. 12 is obtained:

$$a_{H^+}/k_{f(obs)} = \frac{k_{-1}}{k_1k_3K_I}a_{H^+} + \frac{k_{-1}}{k_1k_3} \qquad \text{(Eq. 12)}$$

Consequently, k_{-1}/k_1k_3 and K_I can be obtained from the plot of $a_{H^+}/k_{f(obs)}$ against a_{H^+}. The linear relationship between $a_{H^+}/k_{f(obs)}$ and a_{H^+} is shown in Fig. 6. From the extraordinate intercept and the slope of the linear plot, k_1k_3/k_{-1} and K_I were 1.39×10^5/min and 3.13×10^{-7} ($pK_I = 6.50$), respectively. Furthermore, since a_{H^+} was much larger than K_I at the pH which gave the rate maximum, Eq. 11 could be reduced to:

$$k_{f(max)} = \frac{k_1}{k_{-1}}k_3K_I \qquad \text{(Eq. 13)}$$

Putting the parameter obtained from Fig. 6 into Eq. 13, $k_{f(max)}$ was estimated to be 4.35×10^{-2}/min, which agreed with the observed data.

In the case of $K_I \gg a_{H^+}$, Eq. 10 can be reduced to Eq. 14.

$$k_{f(obs)} = \frac{k_1}{k_{-1}}k_3a_{H^+} + \frac{k_1}{k_{-1}}k_4 \qquad \text{(Eq. 14)}$$

Further, if k_4 is $>k_3a_{H^+}$, the following equation can be derived:

$$k_{f(obs)} = \frac{k_1}{k_{-1}}k_4 \qquad \text{(Eq. 15)}$$

Equation 15 indicates that the formation rate becomes constant in a high pH region when $K_I \gg a_{H^+}$ and $k_4 \gg k_3a_{H^+}$. From the observed data, k_1k_4/k_{-1} was calculated to be 0.4×10^{-2}/min. The value k_4/k_3 obtained by dividing k_1k_4/k_{-1} by k_1k_3/k_{-1} was 2.88×10^{-8}. This inductively proves that Eq. 15 can be used to explain the constant value of k_f at the pH region >9, because $k_4 \gg k_3a_{H^+}$ is valid in these pH solutions.

The assumption that the rate-determining step of the reaction of the acidic side of the rate maximum changes to attack of the free amine is equivalent to the statement: $(k_3a_{H^+} + k_4) \gg k_{-1}$. Therefore, Eq. 7 is reduced to:

$$k_{f(obs)} = \frac{K_I(k_1 + k_2a_{H^+})}{K_I + a_{H^+}} \qquad \text{(Eq. 16)}$$

In the pH region under discussion, $a_{H^+} \gg K_I$, and Eq. 17 is obtained:

$$k_{f(obs)} = \frac{K_I(k_1 + k_2a_{H^+})}{a_{H^+}} = k_2K_I + k_1K_I\frac{1}{a_{H^+}} \qquad \text{(Eq. 17)}$$

Consequently, k_1K_I and k_2K_I can be obtained from the slope and the ordinate intercept of a straight line when the observed formation rate constants are plotted against $1/a_{H^+}$. By dividing each value by K_I, the parameters k_1 and k_2 were estimated to be 7.38 × 10/min and 7.32×10^4/min M, respectively (Fig. 7). The parameters obtained are summarized in Table II.

A theoretical equation for the formation rate was obtained by putting these parameters into an equation which was derived by dividing both

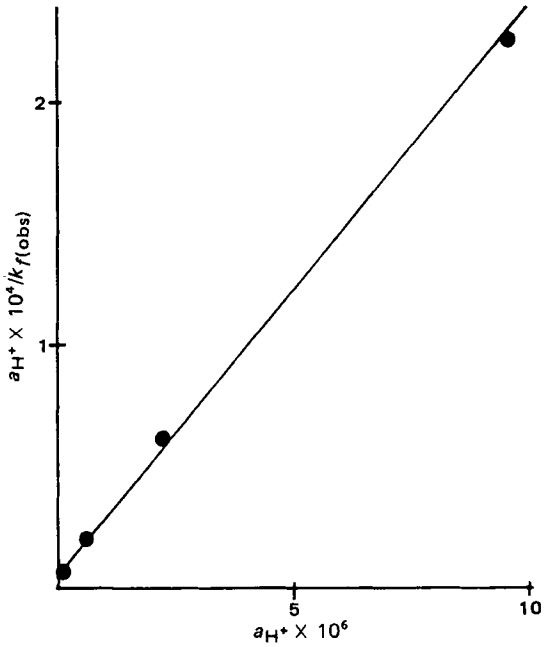


Figure 6—*Derivation of the constant* k_{-1}/k_1k_3 *and* K_I *by plotting rate data according to Eq. 12.*

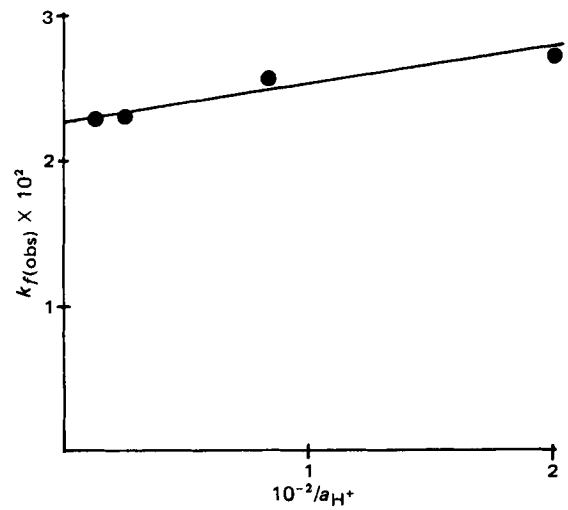

Figure 7—*Derivation of the rate constants* k_1 *and* k_2 *by plotting rate data according to Eq. 17.*

Table II—Kinetic Constants for the Equilibrium Reaction of Triazolam in Aqueous Buffer Solutions [a]

Parameter	Estimated Value	Parameter	Estimated Value
k_1, min^{-1}	7.38×10	k_3/k_{-1}, M^{-1}	1.88×10^3
k_2, $min^{-1}\ M^{-1}$	7.32×10^4	k_4/k_{-1}	5.42×10^{-5}
K_I, M	3.13×10^{-7}	$k_{-1}k_{-3}k_3$, min^{-1}	1.58×10^{-1}
k_1k_3/k_{-1}, $min^{-1}M^{-1}$	1.39×10^5	k_{-3}, $min^{-1}\ M^{-1}$	2.98×10^2
k_1k_4/k_{-1}, min^{-1}	4.0×10^{-3}	k_{-4}, min^{-1}	8.58×10^{-6}
k_4/k_3, M	2.88×10^{-8}	K_{II}, M	3.02×10^{-2}

[a] $\mu = 0.5$, at 37°.

denominator and numerator of Eq. 7 by k_{-1} (Eq. 18). The theoretical curve for the formation rate is shown as a solid line in Fig. 5. It satisfactorily fits the observed data over the pH range studied:

$$k_{f(obs)} = \frac{K_I(k_1 + k_2a_{H^+})\,(k_3a_{H^+}/k_{-1} + k_4/k_{-1})}{(K_I + a_{H^+})\,(1 + k_4/k_{-1} + k_3a_{H^+}/k_{-1})}$$
$$= 3.13 \times 10^{-7}\,(7.38 \times 10 + 7.32 \times 10^4 a_{H^+})\,\frac{(1.88 \times 10^3 a_{H^+} + 5.41 \times 10^{-5})}{(3.13 \times 10^{-7} + a_{H^+})\,(1 + 1.88 \times 10^3 a_{H^+})} \quad \text{(Eq. 18)}$$

Hydrolysis Mechanism—In the pH range studied, the term $(k_3a_{H^+} + k_4) \gg k_{-1}$, and Eq. 8 can be reduced to Eq. 19:

$$k_{r(obs)} = \frac{k_{-1}a_{H^+}\,(k_{-3}a_{H^+} + k_{-4})}{(K_{II} + a_{H^+})\,(k_3a_{H^+} + k_4)} \quad \text{(Eq. 19)}$$

In these pH solutions, the terms, $(k_3a_{H^+} + k_4)$ and $(k_{-3}a_{H^+} + k_{-4})$ are reduced to $k_3a_{H^+}$ and $k_{-3}a_{H^+}$, respectively, because the ratio k_4/k_3 or k_{-4}/k_{-3} is 2.88×10^{-8}, where the equilibrium constant of the second step in Scheme II can be represented by k_3/k_{-3} or k_4/k_{-4}. Therefore, Eq. 19 can be reduced to Eq. 20:

$$k_{r(obs)} = \frac{k_{-1}k_{-3}a_{H^+}}{k_3(K_{II} + a_{H^+})} \quad \text{(Eq. 20)}$$

Then Eq. 20 may be converted into the reciprocal form, Eq. 21:

$$\frac{1}{k_{r(obs)}} = \frac{k_3}{k_{-1}k_{-3}} + \frac{k_3K_{II}}{k_{-1}k_{-3}}\frac{1}{a_{H^+}} \quad \text{(Eq. 21)}$$

As shown in Fig. 8, plots of $1/k_{r(obs)}$ against $1/a_{H^+}$ gave a straight line with an intercept equal to $k_3/k_{-1}k_{-3} = 6.32$ min and a slope of $k_3K_{II}/k_{-1}k_{-3} = 0.191$ min M. Accordingly, K_{II} was estimated to be 3.02×10^{-2} ($pK_{II} = 1.52$). Furthermore, k_{-3} was calculated to be 2.98×10^2/min M from the $k_3/k_{-1}k_{-3}$ and k_3/k_{-1} values, which had already been known.

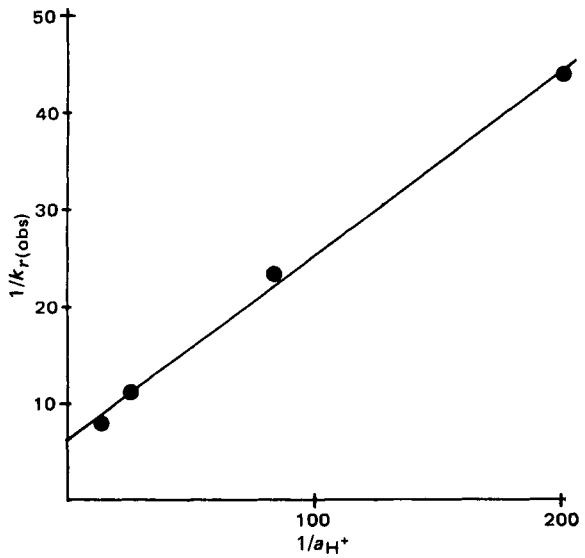

Figure 8—*Derivation of the constants* $k_3/k_{-1}k_{-3}$ *and* K_{II} *by plotting rate data according to Eq. 21.*

Also, $k_{-4} = 8.58 \times 10^{-6}$/min was obtained from the ratio of k_{-4}/k_{-3} and k_{-3}.

On the basic side of the formation rate maximum, no measurable hydrolysis rate constant has been obtained because the equilibrium exclusively favors the ring-closed form. Therefore, no information could be gained concerning the alkali hydrolysis.

A theoretical equation for the hydrolysis rate can be expressed as Eq. 22 by putting the parameters into the equation obtained after dividing both the denominator and the numerator of Eq. 8 by k_{-1}:

$$k_{r(obs)} = \frac{a_{H^+}(k_{-3}a_{H^+} + k_{-4})}{(K_{II} + a_{H^+})(1 + k_3a_{H^+}/k_{-1} + k_4/k_{-1})}$$
$$= \frac{a_{H^+}\,(2.98 \times 10^2/a_{H^+} + 8.58 \times 10^{-6})}{(3.02 \times 10^{-2} + a_{H^+})\,(1 + 1.88 \times 10^3\,a_{H^+})} \quad \text{(Eq. 22)}$$

The theoretical curve of Eq. 22 is shown in Fig. 5 as a solid line. The curve satisfactorily fits the observed reverse-reaction rate constants.

Equilibrium Constant—From the definition of the equilibrium, the Constant K is expressed by Eq. 23:

$$K = \frac{k_{f(obs)}}{k_{r(obs)}}$$
$$= \frac{K_I(K_{II} + a_{H^+})\,(k_1 + k_2a_{H^+})\,(k_3a_{H^+} + k_4)}{k_{-1}a_{H^+}\,(K_I + a_{H^+})\,(k_{-3}a_{H^+} + k_{-4})}$$
$$= \frac{K_I(K_{II} + a_{H^+})\,(k_1 + k_2a_{H^+})\,(k_3a_{H^+}/k_{-1} + k_4/k_{-1})}{a_{H^+}(K_I + a_{H^+})\,(k_{-3}a_{H^+} + k_{-4})}$$
$$= 3.13 \times 10^{-7}\,(3.02 \times 10^{-2} + a_{H^+})\,(7.38 \times 10 + 7.32 \times 10^4 a_{H^+})\,\frac{(1.88 \times 10^3 a_{H^+} + 5.42 \times 10^{-5})}{a_{H^+}\,(3.13 \times 10^{-7} + a_{H^+})\,(2.98 \times 10^2\,a_{H^+} + 8.58 \times 10^{-6})} \quad \text{(Eq. 23)}$$

The theoretical F_I and F_{II} curves obtained from Eqs. 4, 5, and 23 are given in Fig. 3 as solid lines. The theoretical curves showed good agreement with the observed data, in which K and F_I were calculated to be 0.15 and 0.87 at pH 0, respectively.

Evaluation of the Reaction Rate—For an aromatic Schiff base, the maximum formation rate of *N*-*p*-chlorobenzylideneaniline was calculated to be 3.72×10^{-3}/min, if the equimolar reaction of *p*-chlorobenzaldehyde with aniline would occur in an aqueous solution of pH 4.0 at 25° (18). The maximum reaction rate from I to II was 10 times larger than that of the above intermolecular reaction. Generally, an intramolecular reaction would occur much more rapidly than an intermolecular one because of the more feasible approach between the active sites (20). However, this result indicates that the difference between the formation rates of *N*-*p*-chlorobenzylideneaniline and of Compound II would not be as large as expected if the rate measurements were performed under the same reaction conditions. To compare the formation rates of II for intra- and intermolecular reactions, the reactions of substituted triazolobenzophenone with aminoacetic acid needed to be investigated.

The rates of hydrolysis of several 1,4-benzodiazepines into the corresponding amines have been obtained in 0.1 *N* HCl solution at 37°. The values were 2.5×10^{-3}/min for diazepam (8), 4.25×10^{-1}/min for estazolam (10), 1.5×10^{-2}/min for fludiazepam (11), and 1.30×10^{-1}/min for flurazepam (11). The hydrolysis rate for triazolam in this study, as well as the pKa value, were similar to that for flurazepam. Moreover, the water catalyzed rate constant of hydrolysis for II ($k_{-4} = 8.58 \times 10^{-6}$/min) was similar to those for demoxepam (2) and oxazepam (3).

General Discussion—The pKa for the conjugate acid of Compounds I and II was estimated to be 6.50 and 1.52, respectively. No information has been reported about the pKa's for these compounds because the reaction in aqueous solution is too fast for measurement of the dissociation constant spectrometrically. However, the pKa for 2-aminoacetamido-5-chlorobenzophenone has been reported to be 6.3 (12), which is nearly the same as that for I. These constants indicate that the basicities of the ring-opened compounds are somewhat stronger than that of hydroxylamine, pKa 6.0. On the other hand, the pKa for the conjugate acid of 1,4-benzodiazepines has been widely studied. As already known, the 1,4-benzodiazepines which possess a 2′-halogen substituent in the 5-phenyl group exhibit a pKa value lower than that for corresponding nonsubstituent compounds (21, 22). Namely, the pKa's for fludiazepam, flunitrazepam, and lorazepam were reported to be 2.29, 1.71, and 1.3, respectively, which were significantly lower than those of the corresponding compounds without halogen in the 2′-position, diazepam (pKa = 3.3), nitrazepam (pKa = 3.2), and oxazepam (pKa = 1.7). The pKa

value for 8-chloro-6-phenyl-4H-*s*-triazolo[4,3-*a*][1,4] benzodiazepine (estazolam) was reported to be 2.84 from the UV absorption spectral change (23). Considering the structural difference mentioned, the estimated pKa value for triazolam, 1.52, is reasonable.

The bioavailability or the pharmacological effect of a drug would greatly depend on the formation rate in the cyclization reaction from the opened form to the closed form because only the cyclized 1,4-benzodiazepines possess pharmacological CNS activity (24), which are discussed in reports on diazepam (8) and desmethyldiazepam (12). The half-time of the forward reaction of I at pH 7.4, which was calculated to be 80.6 min (Fig. 5), indicates that much time is required to convert I into the closed form II, only if the *in vivo* reaction proceeds chemically.

Extended Hildebrand Solubility Approach: Testosterone and Testosterone Propionate in Binary Solvents

A. MARTIN *x, P. L. WU *, A. ADJEI §, M. MEHDIZADEH ‡, K. C. JAMES ‡, and CARL METZLER *¶

Received October 9, 1981, from the **Drug Dynamics Institute, College of Pharmacy, University of Texas, Austin, TX 78712* and the ‡*Welsh School of Pharmacy, University of Wales, Institute of Science and Technology, Cardiff, CF1 3NU, United Kingdom.* Accepted for publication January 28, 1982.

§Present address: Abbott Laboratories, North Chicago, IL. ¶On leave from The Upjohn Co., Kalamazoo, MI.

Abstract □ Solubilities of testosterone and testosterone propionate in binary solvents composed of the inert solvent, cyclohexane, combined with the active solvents, chloroform, octanol, ethyl oleate, and isopropyl myristate, were investigated with the extended Hildebrand solubility approach. Using multiple linear regression, it was possible to obtain fits of the experimental curves for testosterone and testosterone propionate in the various binary solvents and to express these in the form of regression equations. Certain parameters, mainly K and $\log \alpha_2$, were employed to define the regions of self-association, nonspecific solvation, specific solvation, and strong solvation or complexation.

Keyphrases □ Testosterone—extended Hildebrand solubility approach, solubility in binary solvents □ Solubility—extended Hildebrand solubility approach, testosterone and testosterone propionate in binary solvents □ Binary solvents—solubility of testosterone and testosterone propionate, extended Hildebrand solubility approach

Solute–solvent complexes of testosterone and testosterone propionate in binary solvents composed of cyclohexane with ethyl oleate, isopropyl myristate, and octanol have been reported previously (1). These solvents are pharmaceutically important; the first two are useful as solvents for steroid injectable preparations.

The calculated complexation constants (1) between the steroids and solvents were based on a previous method (2). The solute-mixed solvent systems are analyzed here with the extended Hildebrand solubility approach (3), an extension of the Hildebrand regular solution theory (4) which was introduced to allow the calculation of solubility of nonpolar and semipolar drugs in mixed solvents having a wide range of solubility parameters.

THEORETICAL

Solubility on the mole fraction scale, X_2, may be represented by the expression:

$$-\log X_2 = -\log X_2^i + \log \alpha_2 \qquad \text{(Eq. 1)}$$

where X_2^i is the ideal solubility of the crystalline solid, and α_2 is the solute activity coefficient in mole fraction terms. Scatchard (5) and Hildebrand and Scott (4) formulated the solubility equation for regular solutions in the form:

$$\log \frac{a_2^s}{X_2} = \log \alpha_2 = \frac{V_2 \phi_1^2}{2.303RT}(a_{11} + a_{22} - 2a_{12}) \qquad \text{(Eq. 2)}$$

where

$$\phi_1 = \frac{V_1(1 - X_2)}{V_1(1 - X_2) + V_2 X_2} \qquad \text{(Eq. 3)}$$

The activity of the crystalline solid (a_2^s), taken as a supercooled liquid, is equal to X_2^i as defined in Eq. 1. Variable V_2 is the molar volume of the

0022-3549/82/1200-1334$01.00/0

value for 8-chloro-6-phenyl-4H-*s*-triazolo[4,3-*a*][1,4] benzodiazepine (estazolam) was reported to be 2.84 from the UV absorption spectral change (23). Considering the structural difference mentioned, the estimated pKa value for triazolam, 1.52, is reasonable.

The bioavailability or the pharmacological effect of a drug would greatly depend on the formation rate in the cyclization reaction from the opened form to the closed form because only the cyclized 1,4-benzodiazepines possess pharmacological CNS activity (24), which are discussed in reports on diazepam (8) and desmethyldiazepam (12). The half-time of the forward reaction of I at pH 7.4, which was calculated to be 80.6 min (Fig. 5), indicates that much time is required to convert I into the closed form II, only if the *in vivo* reaction proceeds chemically.

§Present address: Abbott Laboratories, North Chicago, IL. ¶On leave from The Upjohn Co., Kalamazoo, MI.

Abstract □ Solubilities of testosterone and testosterone propionate in binary solvents composed of the inert solvent, cyclohexane, combined with the active solvents, chloroform, octanol, ethyl oleate, and isopropyl myristate, were investigated with the extended Hildebrand solubility approach. Using multiple linear regression, it was possible to obtain fits of the experimental curves for testosterone and testosterone propionate in the various binary solvents and to express these in the form of regression equations. Certain parameters, mainly K and $\log \alpha_2$, were employed to define the regions of self-association, nonspecific solvation, specific solvation, and strong solvation or complexation.

Keyphrases □ Testosterone—extended Hildebrand solubility approach, solubility in binary solvents □ Solubility—extended Hildebrand solubility approach, testosterone and testosterone propionate in binary solvents □ Binary solvents—solubility of testosterone and testosterone propionate, extended Hildebrand solubility approach

Solute–solvent complexes of testosterone and testosterone propionate in binary solvents composed of cyclohexane with ethyl oleate, isopropyl myristate, and octanol have been reported previously (1). These solvents are pharmaceutically important; the first two are useful as solvents for steroid injectable preparations.

The calculated complexation constants (1) between the steroids and solvents were based on a previous method (2). The solute-mixed solvent systems are analyzed here with the extended Hildebrand solubility approach (3), an extension of the Hildebrand regular solution theory (4) which was introduced to allow the calculation of solubility of nonpolar and semipolar drugs in mixed solvents having a wide range of solubility parameters.

THEORETICAL

Solubility on the mole fraction scale, X_2, may be represented by the expression:

$$-\log X_2 = -\log X_2^i + \log \alpha_2 \qquad \text{(Eq. 1)}$$

where X_2^i is the ideal solubility of the crystalline solid, and α_2 is the solute activity coefficient in mole fraction terms. Scatchard (5) and Hildebrand and Scott (4) formulated the solubility equation for regular solutions in the form:

$$\log \frac{a_2^s}{X_2} = \log \alpha_2 = \frac{V_2 \phi_1^2}{2.303RT}(a_{11} + a_{22} - 2a_{12}) \qquad \text{(Eq. 2)}$$

where

$$\phi_1 = \frac{V_1(1 - X_2)}{V_1(1 - X_2) + V_2 X_2} \qquad \text{(Eq. 3)}$$

The activity of the crystalline solid (a_2^s), taken as a supercooled liquid, is equal to X_2^i as defined in Eq. 1. Variable V_2 is the molar volume of the

0022-3549/82/1200-1334$01.00/0

hypothetical supercooled liquid solute (subscript 2), ϕ_1 is the volume fraction of the solvent (subscript 1), R is the molar gas constant, and T is the absolute temperature of the experiment.

The terms a_{11} and a_{22} are the cohesive energy densities of solvent and solute, and a_{12}, referred to in other reports (3, 6) and elsewhere in this report as W, is expressed in regular solution theory as a geometric mean of the solvent and solute cohesive energy densities:

$$a_{12} = W = (a_{11}a_{22})^{1/2} \quad \text{(Eq. 4)}$$

The square roots of the cohesive energy densities of solute and solvent, called solubility parameters and given the symbol δ, are obtained for the solvent from the energy or heat of vaporization per cubic centimeter:

$$\delta_i = (a_{ii})^{1/2} = \left(\frac{\Delta E^v}{V_i}\right)^{1/2} \cong \left(\frac{\Delta H^v - RT}{V_i}\right)^{1/2} \quad \text{(Eq. 5)}$$

When the solubility parameters and the geometric mean are introduced into Eq. 2, the expression becomes:

$$\log \alpha_2 = A(\delta_1^2 + \delta_2^2 - 2\delta_1\delta_2) = A(\delta_1 - \delta_2)^2 \quad \text{(Eq. 6)}$$

where

$$A = \frac{V_2\phi_1^2}{2.303RT} \quad \text{(Eq. 7)}$$

By substituting Eq. 6 into Eq. 1, one obtains:

$$-\log X_2 = -\log X_2^i + A(\delta_1 - \delta_2)^2 \quad \text{(Eq. 8)}$$

which is the Hildebrand–Scatchard solubility equation (4) for a crystalline solid compound of solubility parameter δ_2 dissolved in a solvent of solubility parameter δ_1. Equation 8 may be referred to as the regular solution equation; the term regular solution will be defined. The ideal solubility term is ordinarily expressed in terms of the heat of fusion of the crystalline solute at its melting point:

$$-\log X_2^i \cong \frac{\Delta H_m^f}{2.303RT}\frac{T_m - T}{T_m} \quad \text{(Eq. 9)}$$

although this is an approximation that disregards the molar heat capacity difference ΔC_p of the liquid and solid forms of the solute. An approximation involving the entropy of fusion, ΔS_m^f, was introduced (7) as:

$$-\log X_2^i \cong \frac{\Delta S_m^f}{R}\log\frac{T_m}{T} \quad \text{(Eq. 10)}$$

to partially correct for the failure to include ΔC_p in Eq. 9, and this form of log ideal solubility is employed in the current report. Equations 9 and 10 are approximations, and currently it has not been determined which is more appropriate for use in solubility analysis.

The Hildebrand–Scatchard equation (Eq. 8) may be used to estimate solubility only for relatively nonpolar drugs in nonpolar solvents which adhere to regular solution requirements. The molar volumes of the solute and solvent should be approximately the same, and the solution should not expand or contract when the components are mixed. Dipole–dipole and hydrogen bonding interactions are absent from regular solutions, with only physical forces being present. In such a system the mixing of solvent and solute results in a random arrangement of the molecules. The entropy in a regular solution is the same as that in an ideal solution, and therefore, the entropy of mixing is zero. Only the enthalpy of mixing has a finite value and it is always positive.

In most solutions encountered in pharmacy, interactions and selective ordering of molecules occur; these systems are referred to as irregular solutions. In pharmaceutical solutions, the geometric mean rule (Eq. 4) is too restrictive, and Eq. 6 or 8 ordinarily provides a poor fit to experimental data in irregular solutions. Instead, $\delta_1\delta_2$ is replaced in Eq. 6 by $W = a_{12}$, which is allowed to take on values as required to yield correct mole fraction solubilities:

$$-\log X_2 = -\log X_2^i + A(\delta_1^2 + \delta_2^2 - 2W) \quad \text{(Eq. 11)}$$

It is not possible at this time to determine W by recourse to fundamental physical chemical properties of solute and solvent. It has been found, however, for drugs in binary solvent mixtures (3, 6, 8) that W may be regressed in a power series on the solvent solubility parameter:

$$W_{calc} = C_0 + C_1\delta_1 + C_2\delta_1^2 + C_3\delta_1^3 + \ldots \quad \text{(Eq. 12)}$$

A reasonable estimate, W_{calc}, is obtained by this procedure, and when W_{calc} is substituted in Eq. 11 for W, mole fraction solubilities in polar binary solvents are obtained ordinarily within ≤20% of the experimental results. Log α_2/A may also be regressed directly on powers of δ_1, bypassing W and obviating the need for δ_2. The estimated solubility, X_2, with this method is identical to that obtained with W_{calc} except for rounding-off errors. The entire procedure, referred to as the extended Hildebrand solubility approach (3), may be conducted by using a polynomial regression program and carrying out the calculations on a computer. It is useful to include a statistical routine which provides R^2, Fisher's F ratio, and a scatter plot of the residuals. Terms of the polynomial (*i.e.*, powers of δ_1) are added sequentially and the values of R^2 and F, together with the appearance of the residual scatter plot, indicate when the proper degree of the polynomial has been reached. A well-known polynomial program using multiple regression analysis, SPSS (9), is convenient for this purpose.

Parameters for Solute–Solvent Interaction—The activity coefficient of the solute, α_2, may be partitioned into a term, α_V, for physical or van der Waals (dispersion and weak dipolar) forces and a second term, α_R, representing residual and presumably stronger solute–solvent interactions (Lewis acid-base type forces). In logarithmic form:

$$\log \alpha_2 = \log \alpha_V + \log \alpha_R \quad \text{(Eq. 13)}$$

According to this definition of log α_2, Eq. 11 may be written:

$$(\log \alpha_2)/A = (\delta_1 - \delta_2)^2 + 2(\delta_1\delta_2 - W) \quad \text{(Eq. 14)}$$

where

$$(\log \alpha_V)/A = (\delta_1 - \delta_2)^2 \quad \text{(Eq. 15)}$$

and

$$(\log \alpha_R)/A = 2(\delta_1\delta_2 - W) \quad \text{(Eq. 16)}$$

Hildebrand *et al.* (10) introduced a parameter, l_{12}, to account for deviations from the geometric mean. In terms of W, l_{12} may be written:

$$W = (1 - l_{12})\delta_1\delta_2 \quad \text{(Eq. 17)}$$

Therefore, the second right-hand term of Eq. 14, representing the residual activity coefficient, is:

$$(\log \alpha_R)/A = 2l_{12}\delta_1\delta_2 \quad \text{(Eq. 18)}$$

and the modified equation for solubility of a drug in binary polar solvents becomes:

$$-\log X_2 = -\log X_2^i + A(\delta_1 - \delta_2)^2 + 2A(l_{12})(\delta_1\delta_2) \quad \text{(Eq. 19)}$$

The variable W may be related to the geometric mean, $\delta_1\delta_2$, by the introduction of a proportionality constant, K (11), such that:

$$W = K(\delta_1\delta_2) \quad \text{(Eq. 20)}$$

From Eqs. 17 and 20:

$$(1 - l_{12}) = W/(\delta_1\delta_2) = K \quad \text{(Eq. 21)}$$

or

$$l_{12} = 1 - K \quad \text{(Eq. 22)}$$

The extended Hildebrand solubility expression (Eq. 11) may now be written:

$$-\log X_2 = -\log X_2^i + A(\delta_1 - \delta_2)^2 + 2A(1 - K)\delta_1\delta_2 \quad \text{(Eq. 23)}$$

By employing Eq. 20 to replace W of Eq. 11, another form of the extended Hildebrand equation is obtained:

$$-\log X_2 = -\log X_2^i + A(\delta_1^2 + \delta_2^2 - 2K\delta_1\delta_2) \quad \text{(Eq. 24)}$$

or, with Eq. 17:

$$-\log X_2 = -\log X_2^i + A[\delta_1^2 + \delta_2^2 - 2(1 - l_{12})\,\delta_1\delta_2] \quad \text{(Eq. 25)}$$

It was found (12) that a plot of l_{12} against a branching ratio, r, provided a good linear correlation for testosterone in a number of branched hydrocarbon solvents.

Variable K was employed (11) to describe the dissolving power of solvents for polyacrylonitrile, and it was concluded that the solvent action of organic solvents on the polymer solute was determined "by a very delicate balance between the various intermolecular forces involved." Solvent power could not be explained alone in terms of dipolar interaction and hydrogen bonding; it depended rather on whether dipolar and hydrogen bonding energies for the solvent–polymer contacts were a few percentage points less than, equal to, or greater than the sum of the sol-

vent–solvent and polymer–polymer interaction energies. The same conclusions can be reached for steroids in the various solvents in the present study and are elaborated.

The various extended solubility equations (Eqs. 11, 24, and 25) are equivalent, and the deviation of polar (or nonpolar) systems from regular solution behavior may be expressed in terms of $(\log \alpha_2)/A$, $(\log \alpha_R)/A$, W, l_{12}, or K. Any one of the parameters may be regressed on a polynomial in δ_1 to obtain values of solubility, X_2. These quantities may also be regressed against the volume fraction or percent of one of the solvents in the mixture or against the mean molar volume of the binary solvent mixture (3). Volume percents and mean molar volumes of chloroform in mixtures of cyclohexane and chloroform are given in Table I. The $X_{2(\text{calc})}$ values may be converted to molal solubility units and, if densities of the solutions are available, to molar or gram per milliliter concentration.

Solubility Parameters for Crystalline Solids—It is not possible to obtain solubility parameters of crystalline drugs by vaporization using Eq. 5, because many organic compounds decompose above their melting points. Instead, it has been shown (13) that the solubility parameter of solid drugs can be estimated from the point of maximum solubility in a binary solvent such as ethyl acetate and ethyl alcohol. The solubility parameter of the solute must lie between the δ values of the two solvents for this technique to be successful. In a regular solution, when:

$$\log X_2 = \log X_2^i \qquad \text{(Eq. 26)}$$

the system represents an ideal solution, and the maximum solubility is obtained, excluding specific solvation effects. When a pure solvent or solvent mixture is found that yields a peak in the solubility profile for a regular solution, δ_1 is assumed to equal δ_2, and the final term of Eq. 8 becomes zero, then Eq. 26 holds.

In an irregular solution, these relations do not hold exactly as in a regular solution. Equation 24 may be written as:

$$\frac{1}{A}(\log X_2^i - \log X_2) = \frac{\log \alpha_2}{A} = \delta_1^2 + \delta_2^2 - 2K\delta_1\delta_2 \qquad \text{(Eq. 27)}$$

The partial derivative of $(\log \alpha_2)/A$ then is taken with respect to δ_1 and the result set equal to zero to obtain the value of δ_2 at the peak in the solubility profile:

$$\left[\frac{\partial(\log \alpha_2/A)}{\partial(\delta_1)}\right]_{\delta_2} = 2\delta_1 - 2K\delta_2 = 0 \qquad \text{(Eq. 28)}$$

$$\delta_1 = K\delta_2 \qquad \text{(Eq. 29}a\text{)}$$

or, from Eq. 5 and the corresponding equation for the solute:

$$a_{11} = K^2 a_{22} \qquad \text{(Eq. 29}b\text{)}$$

Thus, $\delta_1 \neq \delta_2$ at the maximum in the solubility curve, but rather is equal to $K\delta_1$ (11). In irregular solutions, K is slightly greater than unity (~1.01) when solvation occurs between the solute and solvent; K is slightly less than unity (~0.98) when the species of the solution self-associate; and $K = 1.00$ when the solution is regular. As pointed out (11), a very small change in K can bring about large changes in solvent action; this phenomenon is considered in another report (8). Since K is nearly unity, even for highly solvated solutions, δ_2 is almost equal to δ_1 at the point of peak solubility in the system. This gives the researcher a good method for estimating solubility parameters of crystalline drugs. A differentiation method was introduced to obtain this value more precisely (12). Methods for calculating the solubility parameters of solid drugs, involving a regression of $(\log \alpha_2)/A$ on δ_1 in a second degree power series, have been introduced (14, 15). Satisfactory values of δ_2^2 and K are obtained[1] by use of the coefficients of the polynomial in moderately polar systems, but the technique is inadequate for highly irregular solutions. Another approach was introduced (16) to calculate δ_2 of solid compounds. Solubility parameters for solutes may also be obtained by a group contribution method (17).

EXPERIMENTAL

The solubility analyses of testosterone and testosterone propionate in solvent mixtures (*i.e.*, cyclohexane–chloroform, cyclohexane–octanol, cyclohexane–isopropyl myristate, and cyclohexane–ethyl oleate) were reported earlier (1), and the reported values were used in this study.

[1] The K value reported in Ref. 15 is constant over the range of solvent solubility parameters used. It differs from K introduced in the extended Hildebrand solubility approach which has a different value for each solvent used. The term in Ref. 15 should properly be differentiated from K by use of another symbol, such as κ, kappa.

[a] Parameters: $\Delta H_m{}^f$ = 6190 cal/mole; T_m = 427.2°K, δ_2 = 10.9 $(\text{cal/cm}^3)^{1/2}$; V_2 = 254.5 cm^3/mole; $X_2{}^i$ = 0.07264; $-\log X_2{}^i$ = 1.1388. [b] Equation 33. [c] Equation 32.

RESULTS

Testosterone in Cyclohexane–Chloroform—The solubilities of testosterone at 25° in mixtures of cyclohexane and chloroform are found in Table I. The $\Delta H_m{}^f$ value for testosterone is 6190 cal/mole and T_m is 427.2°K. The $-\log X_2{}^i$ value is 1.1388 ($X_2{}^i$ = 0.07264), and δ_2 is 10.90 $(\text{cal/cm}^3)^{1/2}$. The solubility parameter for cyclohexane is 8.19 and for

chloroform is 9.14. The molar volume of testosterone is 254.5 cm^3/mole (12). The log activity coefficients are calculated using the expression:

$$\log \alpha_2 = \log X_2{}^i - \log X_2 \qquad \text{(Eq. 30)}$$

The values of W for the various mixtures are obtained directly from the solubility data, using a rearranged form of Eq. 11:

$$W = \tfrac{1}{2}\left[\delta_1{}^2 + \delta_2{}^2 - \frac{\log (X_2{}^i/X_2)}{A}\right]$$

$$= \tfrac{1}{2}\left[\delta_1{}^2 + \delta_2{}^2 - (\log \alpha_2)/A\right] \qquad \text{(Eq. 31)}$$

Also included in Table I are the calculated values of $(\log \alpha_2)/A$ and W obtained by regressing $(\log \alpha_2)/A$ and W on δ_1 in a third degree polynomial:

$$W = -3298.82 + 1084.56\delta_1 - 116.904\delta_1{}^2 + 4.26742\delta_1{}^3 \qquad \text{(Eq. 32)}$$

$$n = 15, R^2 = 0.999, F = 6702, F(3, 11, 0.01)^2 = 6.22$$

and:

$$\frac{\log \alpha_2}{A} = 6716.38 - 2169.12\delta_1 + 234.809\delta_1{}^2 - 8.53485\delta_1{}^3 \qquad \text{(Eq. 33)}$$

$$n = 15, R^2 = 0.998, F = 2352, F(3, 11, 0.01) = 6.22$$

The observed mole fraction solubilities, and the calculated values (obtained with Eqs. 30 and 33), together with percent differences between calculated and observed solubilities, are given in Table I. Variables K, l_{12}, and $(\log \alpha_R)/A$ were also regressed on δ_1 and the equations are:

$$K = -41.1320 + 13.7685\delta_1 - 1.50351\delta_1{}^2 + 0.0549512\delta_1{}^3 \qquad \text{(Eq. 34)}$$

$$n = 15, R^2 = 0.997, F = 1476, F(3, 11, 0.01) = 6.22$$

$$l_{12} = 42.1320 - 13.7685\delta_1 + 1.50351\delta_1{}^2 - 0.0549512\delta_1{}^3 \qquad \text{(Eq. 35)}$$

$$n = 15, R^2 = 0.997, F = 1476, F(3, 11, 0.01) = 6.22$$

and:

$$\frac{\log \alpha_R}{A} = 918.478\delta_1 - 300.154\delta_1{}^2 + 32.7765\delta_1{}^3 - 1.19794\delta_1{}^4 \qquad \text{(Eq. 36)}$$

$$n = 15, R^2 = 0.997, F = 1476, F(4, 10, 0.01) = 5.99$$

Since $K = 1 - l_{12}$ from Eq. 21 and $(\log \alpha_R)/A = 2l_{12}\delta_1\delta_2$ from Eq. 18, any one of the regression equations for K, l_{12}, and $(\log \alpha_R)/A$ can be obtained from the others. For example, replacing K in Eq. 34 by $(1 - l_{12})$ yields Eq. 35 for l_{12}. It is seen that the only differences are in the constant terms, −41.1320 in Eq. 34 and +42.1320 in Eq. 35, and the change in sign of each coefficient. Equation 36 for $(\log \alpha_R)/A$ is observed to take on an interesting form: no constant term exists and the polynomial is carried to the fourth rather than the third power.

Once the calculated value for one of these parameters is obtained from the regression equation, it may be substituted in the appropriate expression given earlier to obtain $X_{2(calc)}$. For example, $l_{12(calc)}$ for testosterone solubility in 50% chloroform–50% cyclohexane (v/v) ($\delta_1 = 8.67$) is obtained with Eq. 35:

$$l_{12(calc)} = 42.1320 - 13.7685(8.67) + 1.5035(8.67)^2$$

$$-0.0549512(8.67)^3 = -0.0362$$

Then, from the second right hand term of Eq. 25:

$$\frac{\log \alpha_2}{A} = \delta_1{}^2 + \delta_2{}^2 - 2(1 - l_{12})\delta_1\delta_2 = (8.67)^2 + (10.9)^2$$

$$- 2(1 + 0.0362)\,(8.67)\,(10.9) = -1.8691$$

[2] $F(3, 11, 0.01)$ is the tabulated F value with p degrees of freedom in the numerator and n-p-1 degrees of freedom in the denominator, where $p = 3$ is the number of independent variables and $n = 15$ is the total number of samples. The value 0.01 signifies that the F ratio is compared with the tabular value obtained at the 99% level of confidence.

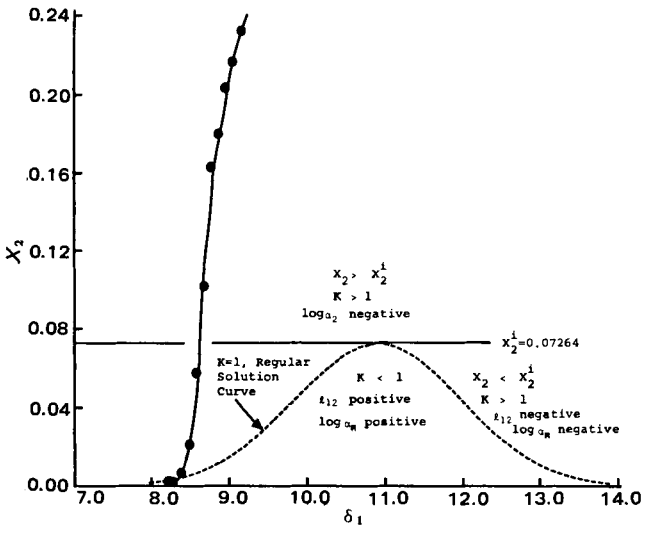

Figure 1—*Mole fraction solubility of testosterone ($\delta_2 = 10.9$) at 25° in cyclohexane and chloroform. Key: (●) experimental points; (—) solubility calculated by extended Hildebrand solubility approach; (- - - -) solubility curve calculated using regular solution theory.*

where the solubility parameter of testosterone is 10.9 $(cal/cm^3)^{1/2}$. Log $X_2{}^i$ is equal to −1.1388 for testosterone at 25°, and A from Table I is 0.1096 at 50% by volume chloroform. Continuing with Eq. 25, one obtains:

$$-\log X_2 = 1.1388 + (0.1096)(-1.8691) = 0.9340$$

$$X_{2(obs)} = 0.102$$

$$X_{2(calc)} = 0.116\ (-13.7\%\ \text{error})$$

Variables K, l_{12}, and $\log \alpha_R$ are three different means of expressing deviation from regular solution behavior. Log α_R (Column 12, Table I) is a measure of the residual activity coefficient due to dipolar interactions between solvent and solute, inductive effects, and hydrogen bonding. Variables K and l_{12} are also used to represent solution irregularities. When log α_R is negative, l_{12} (Column 11) becomes negative and K (Column 10) becomes greater than unity, indicating that X_2 is greater than the mole fraction solubility in a regular solution. As observed in Table I, this effect occurs at 20% chloroform in cyclohexane. Above this concentration of chloroform, it may be assumed that the predominant factor promoting the solubility of testosterone is solvation of the drug by chloroform, most probably in this case through hydrogen bonding. At 50% chloroform in cyclohexane, the interaction between testosterone and chloroform has increased sufficiently to elevate the drug solubility above the ideal mole fraction solubility, $X_2{}^i = 0.0726$. At this point the total logarithmic activity coefficient, log α_2, as well as log α_R, is negative, indicating the beginning of strong solvation. It is suggested that the term complexation is appropriate for interactions between solute and solvent when $X_2 \gg X_2{}^i$, observed in Table I for testosterone in pure chloroform.

The various parameters, and the manner in which they may be used to express self-association ($K < 1$), nonspecific solvent effects or regular solution ($K \cong 1$), weak solubilization ($K > 1$ and $X_2 < X_2{}^i$), and complexation or strong solubilization ($K > 1$ and $X_2 > X_2{}^i$), are depicted in Fig. 1 for testosterone in a mixture of chloroform and cyclohexane. As the real or irregular solubility line crosses the regular solution line at the lower left side of Fig. 1, K changes from <1.0 to >1.0. Then, as the irregular solution line crosses the ideal solubility line, K remains >1.0, X_2 becomes greater than $X_2{}^i$, and log α_2 becomes negative. At 100% chloroform, log $\alpha_2 = -0.506$, which means that the ratio of X_2 to $X_2{}^i$ is ~3:1. The curve for testosterone propionate in chloroform–cyclohexane (not shown) is similar to Fig. 1 for testosterone, demonstrating complexation between the steroid ester and chloroform >30% by volume chloroform in the chloroform–cyclohexane mixture.

Testosterone Propionate in Mixed Solvents—The solubilities of the steroidal ester, testosterone propionate, at 25° in octanol–cyclohexane, ethyl oleate–cyclohexane, and isopropyl myristate–cyclohexane are plotted in Figs. 2–4 as a function of the solubility parameter of the mixed solvent. The logarithmic ideal solubility of testosterone propionate, log $X_2{}^i$, is −0.81356 at 25°; $X_2{}^i = 0.15362$. The solubility parameter, δ_2, and

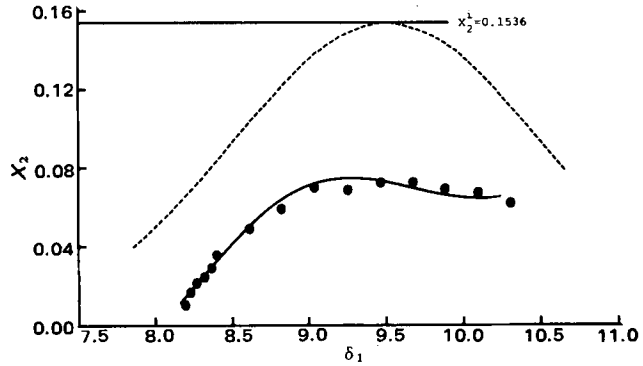

Figure 2—*Mole fraction solubility of testosterone propionate (δ_2 = 9.5) at 25° in cyclohexane and octanol. Key: (●) experimental points; (—) solubility calculated by extended Hildebrand solubility approach; (- - -) solubility curve calculated using regular solution theory.*

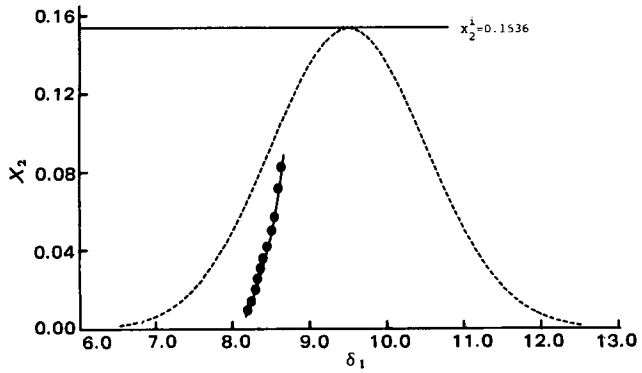

Figure 3—*Mole fraction solubility of testosterone propionate (δ_2 = 9.5) at 25° in cyclohexane and ethyl oleate. Key: (●) experimental points; (—) solubility calculated by extended Hildebrand solubility approach; (- - -) solubility curve calculated using regular solution theory.*

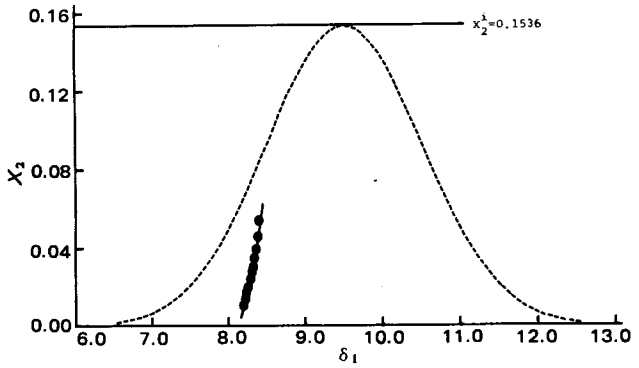

Figure 4—*Mole fraction solubility of testosterone propionate (δ_2 = 9.5) at 25° in cyclohexane and isopropyl myristate. Key: (●) experimental solubility; (—) solubility calculated by extended Hildebrand solubility approach; (- - -) solubility curve calculated using regular solution theory.*

the molar volume, V_2, of testosterone propionate are, respectively, 9.5 $(cal/cm^3)^{1/2}$ and 294.0 cm^3/mole. The solubility parameter is 8.19 for cyclohexane, 10.30 for octanol, 8.63 for ethyl oleate, and 8.85 for isopropyl myristate.

Use of the extended Hildebrand solubility approach to calculate solubilities yields good results for these systems as observed by the fit of the calculated line to the points in Figs. 2–4.

As seen by comparing the regular solution curve (calculated using Eq. 8) with the extended Hildebrand solubility line (calculated using Eq. 11, 24, or 25), the observed solubilities are smaller than those predicted for a regular solution over most of the range of δ_1 values of the mixed solvents, as contrasted to the chloroform–cyclohexane mixture. At no composition of mixed solvent do the solubilities exceed the ideal solubility, as observed earlier in chloroform–cyclohexane (Fig. 1). The regression equations used to calculate solubilities in these systems are:

Octanol–Cyclohexane Mixtures (Fig. 2):

$$\frac{\log \alpha_2}{A} = 1142.47 - 356.237\delta_1 + 37.0357\delta_1^2 - 1.28137\delta_1^3 \quad \text{(Eq. 37)}$$

$$n = 15, R^2 = 0.965, F = 101, F(3, 11, 0.01) = 6.22$$

Ethyl Oleate–Cyclohexane Mixtures (Fig. 3):

$$\frac{\log \alpha_2}{A} = 27888.99 - 9867.80\delta_1 + 1164.77\delta_1^2 - 45.8617\delta_1^3 \quad \text{(Eq. 38)}$$

$$n = 11, R^2 = 0.999, F = 2589, F(3, 7, 0.01) = 8.45$$

Isopropyl Myristate–Cyclohexane Mixtures (Fig. 4):

$$\frac{\log \alpha_2}{A} = 157348.62 - 56738.3\delta_1 + 6821.48\delta_1^2 - 273.439\delta_1^3 \quad \text{(Eq. 39)}$$

$$n = 11, R^2 = 0.999, F = 3970, F(3, 7, 0.01) = 8.45$$

Nonlinear Regression—The solubility of testosterone in octanol–cyclohexane and in ethyl oleate–cyclohexane are plotted in Figs. 5 and 6. The extended Hildebrand solubility approach with polynomial regression, used with success for the other systems, failed to provide a satisfactory fit of the data, as shown by the dotted lines in Figs. 5 and 6.

The polynomial regression method contains potential numerical difficulties which show themselves only in certain applications. The source of these difficulties may be seen by recognizing that to date the extended

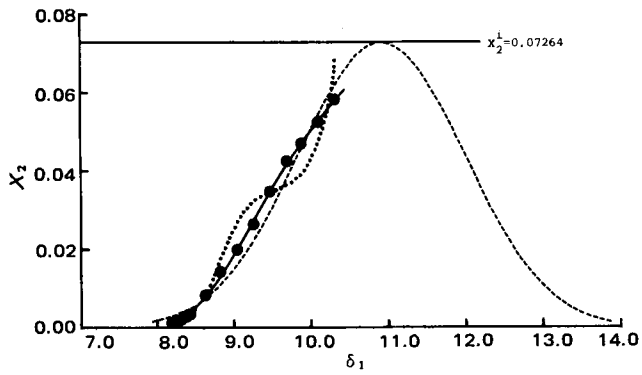

Figure 5—*Mole fraction solubility of testosterone (δ_2 = 10.9) at 25° in cyclohexane and octanol. Hildebrand solubility approach has fitted observed values of X_2 to a model that defines X_2 as a function of δ and other variables and constants. That is, the relations expressed by Eq. 11 may be written as:

$$\log (X_2^i/X_2) - \frac{V_2}{2.303RT}\left[\frac{V_1(1-X_2)}{V_1(1-X_2)+V_2X_2}\right]^2 f(\delta) = 0 \quad \text{(Eq. 40)}$$

where $f(\delta)$ is a polynomial in δ. Thus, Eq. 40 defines the dependent variable X_2 as an implicit function of the independent variables δ and V_1. The terms X_2^i, R, T, and V_2 are known constants, and the parameters to be estimated are the coefficients of $f(\delta)$.

The polynomial regression method contains a circular element in that it uses the observed values of X_2 in W or $(\log \alpha_2)/A$ to estimate the coefficients of $f(\delta)$, and then uses these values of $f(\delta)$ to obtain calculated values of X_2. This circular process can be thought of as the first step in an iteration; the conditions necessary for this process to converge are not known. In many applications the iteration gives acceptable results; in some cases, as shown in Figs. 5 and 6, the results are poor.

Another potential source of difficulty is that the values of W or $(\log \alpha_2)/A$ are fit by least squares to the polynomials of δ. Thus, the coefficients are estimated by minimizing the squared deviations between observed and predicted (model) values of functions of X_2 [W or $(\log \alpha_2)/A$]. When X_2 then is calculated, this is equivalent to weighted least squares, with the weights being complicated functions of the constants in W or in $(\log \alpha_2)/A$.

To use Eq. 40 as a model for predicting X_2 as a function of δ and V_1, it must be determined that there is a unique value of X_2 that satisfies the equality. Writing the expression in Eq. 40 as $F(X_2)$, it can be verified that $\lim F(X_2)_{X_2 \to 0} = \infty$ and $F(X_2)_{X_2 \to 0} = \log X_2^i < 0$. Thus, $F(X_2)$ has a root between 0 and 1. It can also be shown that if $f(\delta) > 0$ then $F^1(X_2) < 0$ for $0 \le X_2 \le 1$. Thus, $F(X_2)$ is monotonic decreasing on [0,1] and has one, and only one, root.

Equation 40 can be used in any nonlinear regression program that accepts the model defined as an implicit function. In this application good inital estimates are important; they can be obtained as the coefficients of the polynomial in δ used in the polynomial regression method.

The regression equations for testosterone in octanol–cyclohexane and in ethyl oleate–cyclohexane were obtained by fitting Eq. 40 with the nonlinear regression program NONLIN (18). The results are:

Testosterone in Octanol–Cyclohexane (Fig. 5):

$$\frac{\log \alpha_2}{A} = 895.34 - 264.088\delta_1 + 26.1217\delta_1^2 - 0.865608\delta_1^3 \quad \text{(Eq. 41)}$$

and

Testosterone in Ethyl Oleate–Cyclohexane (Fig. 6):

$$\frac{\log \alpha_2}{A} = 50518.74 - 17713.3\delta_1 + 2071.82\delta_1^2 - 80.8331\delta_1^3 \quad \text{(Eq. 42)}$$

To solve Eq. 40 for X_2, the rootfinder subroutine ZBRENT (19) was called from DFUNC of NONLIN. Figures 5 and 6 show that fitting observed values of X_2 directly to values of X_2 predicted by Eqs. 41 and 42, respectively, greatly improves the fit. NONLIN was also used to fit the data shown in Figs. 1–4. In these applications the improvement in fit was so small as to be of little importance.

CONCLUSIONS

In another report (1), the interaction of testosterone and testosterone propionate was shown in mixed solvents of cyclohexane combined with ethyl oleate, isopropyl myristate, and octanol. The interaction was analyzed using association constants (2) with limited success. The present study shows that the interaction of testosterone and testosterone propionate with mixed solvents may be represented accurately by use of the extended Hildebrand solubility approach, a method that employs a polynomial on δ_1 rather than association constants.

The solubility is plotted in Figs. 1–6 in reference to the regular solution curve and the ideal solubility, X_2^i of the drug. This method of plotting the results delineates systems in which self-association or solvation predominates, and it differentiates these from regular and ideal solutions. It is suggested that although the drug and active (solvating) solvent (cyclohexane is considered to be the inactive solvent of the binary solvent mixture) interact to a lesser or greater extent, strong interaction or specific solvation, such as that resulting from hydrogen bonding effects, occurs when the solubility rises well above the ideal solubility line, X_2^i. Some self-association of solute or solvent may exist above X_2^i, leading to reduced solubility, but the overriding effect is strong solvation (complexation between solute and solvent).

A combination of X_2^i and K may be used to define various classes of interaction between solute and solvent. As observed in Fig. 1, when a solubility point falls on or near the regular solution line, it is defined as a regular solution (4). Referring to Eq. 24, when $K \cong 1$, the geometric mean obtains, and the solution may be considered to be a regular system. However, it is conceivable that W equals $\delta_1\delta_2$ (*i.e.*, $K \cong 1$) in polar systems by cancellation of solvating and self-associating effects, rather than because of the criteria layed down (4) for regular solution behavior.

When $K < 1$, the solubility points in a graph such as Fig. 2 fall below the regular solution line. The solute, solvent, or both are ordinarily considered to be self-associated when $K < 1$, resulting in decreased solubility.

When $K > 1$ and $X_2 > X_2^i$, association of a specific nature (*i.e.*, hydrogen bonding, dipolar interaction, or charge transfer complexation) is considered to exist between solute and solvent.

Finally, when $K > 1$ but $X_2 < X_2^i$, an intermediate situation exists. Some self-association may be present, but association results in solubilities above those found on the regular solution line. Various classes of solvation, self-association, and regular solution behavior have been defined (4), but the case where $X_2 < X_2^i$ and $K > 1$ was not addressed. This is neither a regular, self-associated, or strongly solvated solution, but rather an intermediate or weakly solvated system. The system treated in the present study are interesting because most of them are of the self-associated–weakly solvated class (*i.e.*, except for the chloroform systems, $X_2 < X_2^i$ and, depending on the composition of the solvent, K is greater or less than unity).

The solvents consisting of chloroform in cyclohexane exhibit weak to strong solvating effects on testosterone, depending on the concentration of chloroform in the solvent mixture (Fig. 1).

When the ester, testosterone propionate, is dissolved in the binary solvent, octanol in cyclohexane, a self-associating system results. As observed in Fig. 2, $K < 1$ across the range of solvent composition. This system exhibits a peak in the solubility because the solubility parameter of testosterone propionate, 9.5, lies between the solubility parameters of cyclohexane, $\delta = 8.2$, and octanol, $\delta = 10.3$. The methyl xanthines in dioxane–water mixtures have been reported (3, 6, 8) to show this kind of solubility profile. The calculated curve (solid line) of Fig. 2 should exhibit a parabolic shape somewhat like the dashed regular solution curve above it and should attain a maximum X_2 value at $\delta_1 = \sim 9.5$. The scatter of the experimental points caused the regression line (solid line) to take on an irregular shape and to rise slightly rather than fall on the right hand side of the figure. Testosterone propionate in ethyl oleate–cyclohexane (Fig. 3) yields solutions that appear to be self-associating rather than weakly solvating (*i.e.*, $K < 1$). Testosterone propionate in isopropyl myristate–cyclohexane (Fig. 4) follows a pattern similar to the drug in ethyl oleate–cyclohexane. The solubilities fall under the bell-shaped regular solution curve and may be classified as predominately self-associating ($K < 1$).

As observed in Fig. 5, testosterone in octanol–cyclohexane appears to follow regular solution behavior rather closely over the composition from 0 to 100% octanol. However solutions of a polar solvent, octanol, and a multifunctional solute, testosterone, do not meet the requirements of a regular solution (*e.g.*, molecules of approximately the same size, no change in entropy on mixing, no specific interaction of either species). The fact that such solutions follow the regular solution line are probably due to cancellation of self-association and solvation effects in these polar systems rather than an absence of specific interactions. Such solutions should not be called regular, although $K \cong 1$.

Testosterone in ethyl oleate–cyclohexane (Fig. 6) forms solutions that are characterized for the most part as weakly solvating (*i.e.*, $K > 1$ and $X_2 < X_2^i$).

The solubility parameters for testosterone and testosterone propionate have not been determined unequivocally. Testosterone is assigned a tentative value of 10.8 and testosterone propionate, 9.5. The latter value has more validity than the former at this time. If the solubility parameter of testosterone later is found to be essentially that of testosterone propionate, as some results appear to indicate, the position of the regular solution line will need to be moved relative to the solubility data points, and the above interpretations will change. For example, if it is found that δ for testosterone is 9.5 rather than 10.8, both testosterone and testosterone propionate will be observed to form weakly self-associated rather than weakly solvated solutions in ethyl oleate–cyclohexane.

However, the findings of chloroform as strongly solvating and the other solvents—octanol, ethyl oleate, and isopropyl myristate—as weakly solvating or self-associating is evident in these results, regardless of the exact solubility parameters of testosterone and testosterone propionate.

In earlier work (3, 4, 6, 8) the extended Hilidebrand solubility approach employed a polynomial regression routine for calculating quantities such as W and $(\log \alpha_2)/A$, and this statistical method has proved successful in most instances. It is demonstrated in the current study that direct polynomial regression sometimes may produce an unsatisfactory fit of solubility data. A nonlinear regression program, NONLIN (17), has been shown to improve the fit when ordinary polynomial regression fails.

Antitumor Agents LVI: The Protein Synthesis Inhibition by Genkwadaphnin and Yuanhuacine of P-388 Lymphocytic Leukemia Cells

Y. F. LIOU, I. H. HALL ˣ, and K. H. LEE

Received August 26, 1981, from the *Division of Medicinal Chemistry, School of Pharmacy, University of North Carolina at Chapel Hill, Chapel Hill, NC 27514.* Accepted for publication January 26, 1982.

Abstract □ Two natural products isolated from the plant *Daphne genkwa* have been shown to possess antileukemic activity in mice. Genkwadaphnin and yuanhuacine were observed to inhibit DNA and protein synthesis in P-388 leukemic cells. A detailed study of the effects of these two diterpene esters on protein synthesis of leukemic cells was undertaken. The major effects of genkwadaphnin and yuanhuacine on protein synthesis were blockage of the elongation process and interference with the peptidyl transferase reaction. The latter reaction was suppressed at concentrations of the diterpene esters which were commensurate with concentrations that inhibited whole cell *in vitro* protein synthesis in P-388 cells.

Keyphrases □ Antitumor agents—inhibition of DNA and protein synthesis by genkwadaphnin and yuanhuacine in P-388 lymphocytic leukemia cells, daphnane deterpene esters □ Genkwadaphnin—antitumor agents, inhibition of DNA and protein synthesis in P-388 lymphocytic leukemia cells, daphnane diterpene esters □ Yuanhuacine—antitumor agents, inhibition of DNA and protein synthesis in P-388 lymphocytic leukemia cells, daphnane diterpene esters

These T/C% values were comparable to 5-fluorouracil at 12.5 mg/kg/day in the P-388 screen. Therefore, it was concluded that daphnane diterpene esters may have potential as antineoplastic therapeutic agents and that their modes of action on cellular metabolism were of interest, particularly since these agents resemble, structurally, phorbol esters which are tumor pro-

0022-3549/82/1200-1340$01.00/0

moting agents that stimulate nucleic acid and protein synthesis.

Previous studies demonstrated that I and II inhibited DNA synthesis after 60 min of incubation, with ID_{50} values of 5.62 and 7.11 μM in P-388 lymphocytic leukemia cells (2). A higher concentration of daphnane diterpene esters was required to observe protein synthesis inhibition of P-388 cells ($ID_{50} \cong$ 14.8 and 18.5 μM) (2). Similar observations in P-388 cells were made when the agents were administered *in vivo*, in that DNA synthesis was inhibited initially, followed by inhibition of protein synthesis at a later time or at a higher dose (2). Since a cursory review of the literature indicates that effects of daphnane diterpene esters on cellular metabolism have not been studied, the purpose of the present investigation is to establish the mechanism of action of I and II as protein synthesis inhibitors.

EXPERIMENTAL

The studies on the effects of daphnane diterpene esters on protein synthesis were conducted on P-388 lymphocytic leukemia cells harvested on day 10 (3) and maintained according to the NIH Protocol (3). P-388 lymphocytic leukemia lysates from DBA/2 male mice (~25 g) were prepared by a previous method (4). The following were isolated from P-388 lysates by literature techniques: ribosomes[1] (5), pH 5 enzyme (4), and uncharged transfer ribonucleic acid (tRNA) (6). The P-388 lymphocytic leukemia cell initiation factors for protein synthesis were prepared as described previously (7). Standard protein synthesis inhibitors were used as a comparison in the assay at concentrations which were known to cause maximum inhibition. Whole cell *in vitro* incorporation of [^{3}H]leucine (56.6 Ci/mmole) into protein was determined with drug concentrations from 0–50 μM in 1 ml of minimum essential medium[2] for 90 min at 37°. Acid insoluble protein was collected on nitrocellulose filters[3] by vacuum suction (8). [^{3}H]Methionyl-transfer ribonucleic acid (met-tRNA) was prepared from P-388 cell tRNA according to a previous method (9). The effects of the diterpene esters on endogenous protein synthesis of P-388 lysates were performed in a reaction mixture (9) (0.5 ml) containing 10 mM tris(hydroxymethyl)aminomethane, pH 7.6, 76 mM KCl, 1 mM adenosine triphosphate, 0.2 mM guanosine triphosphate, 15 mM creatine phosphate, 2 mM $MgCl_2$, 1 mM dithiothreitol, 0.1 mM of each of the 19 essential amino acids, 0.9 mg/ml of creatine phosphokinase, and 20 μCi of [^{3}H]leucine (56.6 Ci/mmole). The reaction mixture was incubated at 30°. After 90 sec of incubation, test drugs or the standards, pyrocatechol violet or emetine, were added with a final concentration of 1, 10, and 100 μM. At specific minute intervals, 50-μl aliquots were removed from the reaction tubes and spotted on filter papers[4] which were treated for 10 min in boiling 5% trichloroacetic acid, followed by 10 min in cold 5% trichloroacetic acid and washed with cold 5% trichloroacetic acid, ether–ethanol (1:1), and ether. The filter papers were dried and counted in scintillation fluid.

The effects of daphnane diterpene esters, pyrocatechol violet, cycloheximide, and emetine on the ribosome profile (8) of P-388 cell lysates were assayed using the reaction medium described above (500 μl). The control tubes, as well as tubes containing standards or drugs affording a 100 μM final concentration, were incubated for 4 min at 37°. The reactions were terminated in ice and gradient buffer (1 ml of tris(hydroxymethyl)aminomethane, pH 7.6, 10 mM KCl, and 1.5 mM $MgCl_2 \cdot 6H_2O$) was added. The mixtures were layered over 36 ml of 10–25% linear sucrose gradient (8), prepared in gradient buffer, and centrifuged for 165 min at 25,000 rpm in a swinging bucket rotor[5] at 4°. The absorbance profiles at 260 nm were determined using a flow cell (light path 0.2 cm) attached to a spectrophotometer[6]. The incorporation of [^{3}H]leucine into polypeptide chains was measured for each fraction.

The reaction medium for the polyuridine-directed polyphenylalanine synthesis (10) contained 50 mM tris(hydroxymethyl)aminomethane, pH 7.6, 12.5 mM magnesium acetate, 80 mM KCl, 5 mM creatine phosphate, 0.05 mg/ml of creatine phosphokinase, 0.36 mg/ml of polyuridine[7] (A_{280}/A_{260} = 0.34), 0.5 μCi of [^{14}C]phenylalanine (536 mCi/mmole), 75 μg of uncharged P-388 cell tRNA, 70 μg of P-388 pH 5 enzyme preparation, and 0.9 A_{260} of P-388 cell ribosomes. Test compounds were present in 5, 10, and 50 μmole concentrations. The tubes were incubated for 20 min at 30° after which a 35-μl aliquot was spotted on filter paper[2] and processed as indicated previously.

The reaction medium (200 μl) used to measure the formation of the 80 S initiation complex and the methionyl puromycin reaction (11) contained 15 mM tris(hydroxymethyl)aminomethane, pH 7.6, 80 mM KCl, 1 mM adenosine triphosphate, 0.5 mM guanosine triphosphate, 20 mM creatine phosphate, 0.2 mg/ml creatine phosphokinase, 3 mM magnesium acetate, 0.1 mM (ethylenedinitrilo)tetraacetic acid, 1 mM dithiothreitol, 0.1 mM of each of the 19 essential amino acids, 3 mg of P-388 cell lysates, 100 μg/ml chlortetracycline[8], 3 × 10^5 cpm of [^{3}H]-met-tRNA, and 20 μg/ml of polyadenosine–uridine–guanosine and 0–50 μM of diterpene esters.

The incubation was carried out at 23°, and after 2 min aliquots were withdrawn to analyze for 80 S complex formation. Puromycin (10 μg/ml) was then added to the reaction medium. The incubation was continued for another 6 min and aliquots were withdrawn to analyze for reaction of the 80 S complex with puromycin. All aliquots (50 μl) were diluted to 250 μl with buffer (20 mM tris(hydroxymethyl)aminomethane, pH 7.6, 80 mM KCl, 3 mM magnesium acetate, 1 mM dithiothreitol, and 0.1 mM (ethylenedinitrilo)tetraacetic acid), layered on 11.8 ml of a 15–30% linear sucrose gradient and centrifuged for 3 hr × 36,000 rpm in a swinging bucket rotor[9]. Fractions (0.4 ml) were collected and protein was precipitated with 10% trichloroacetic acid on filter papers and counted[10].

The reaction mixtures (75 μl) for the ternary complex formation (12) contained 21.4 mM tris(hydroxymethyl)aminomethane, pH 8.0, 80 mM KCl, 0.26 mM guanosine triphosphate, 2.14 mM dithiothreitol, 10 μg of bovine serum albumin, 5 pmoles of P-388 cell [^{3}H]met-tRNA (1 × 10^4 cpm), 100 A_{260}/ml of crude P-388 cell initiation factors, and 25 or 100 μM of drug or standard. The incubation was conducted for 5 min at 37° and terminated by the addition of 3 ml of cold buffer (21.4 mM tris(hydroxymethyl)aminomethane, pH 8.0, 80 mM KCl, 2.14 mM dithiothreitol). The samples were filtered through 0.45-μm nitrocellulose filters, washed twice in buffer, and counted.

The reaction mixture (75 μl) for the 80 S initiation complex (12) formation contained, in addition to the components necessary for the ternary complex formation reaction, 1.9 mM magnesium acetate, 5 A_{260}/ml of polyadenosine-uridine-guanosine[5] and 100 A_{260}/ml of 80 S P-388 cell ribosomes. Incubation was 10 min at 37° which was then cooled to 4°, the samples were diluted with cold buffer (21.4 mM tris(hydroxymethyl)-aminomethane, pH 8.0, 80 mM KCl, 5 mM magnesium acetate, and 2.14 mM dithiothreitol), and filtered as indicated for the ternary complex formation experiment.

RESULTS AND DISCUSSION

Both I and II significantly suppressed *in vitro* whole cell P-388 lymphocytic leukemia protein synthesis (Fig. 1). Compound I afforded an $ID_{50} \simeq 6.7$ μM and compound II an $ID_{50} \simeq 8.9$ μM after 90 min of incubation. The studies on the effects of various concentrations of the diterpene esters on endogenous protein synthesis of P-388 lysates (Fig. 2) demonstrated that at low concentration (1 μM) there was a lag of 2–4 min before the inhibition of protein synthesis was observed. At higher concentrations of drug (10–100 μM), cessation of protein synthesis occurred immediately, suggesting that the diterpene esters mimicked the action of an elongation inhibitor such as emetine, more so than an initiation inhibitor such as pyrocatechol violet.

A comparison of the effects of I and II with known inhibitors of protein synthesis on the ribosome profile and [^{3}H]leucine incorporation into polypeptides can be seen in Fig. 3. During the incubation of the P-388 lymphocytic leukemia cell lysates, [^{3}H]leucine was incorporated into the nascent peptide bound to the polysomes (Fig. 3a). However, when I or II was incubated with the P-388 lysates for 4 min at 100 μM, the radioactive peptides were released from the ribosomes. Clearly, all of the agents suppress polypeptide synthesis observed as reduced leucine incorpora-

tion. The standard, pyrocatechol violet (Fig. 3b), allows completion or release of the nascent polypeptide chain and the accumulation of the 80 S ribosomal peak, whereas emetine (Fig. 3c), I (Fig. 3d), and II (Fig. 3e), do not allow accumulation of the 80 S ribosomal peak which is reduced from the control. These data suggest that the daphnane diterpene esters

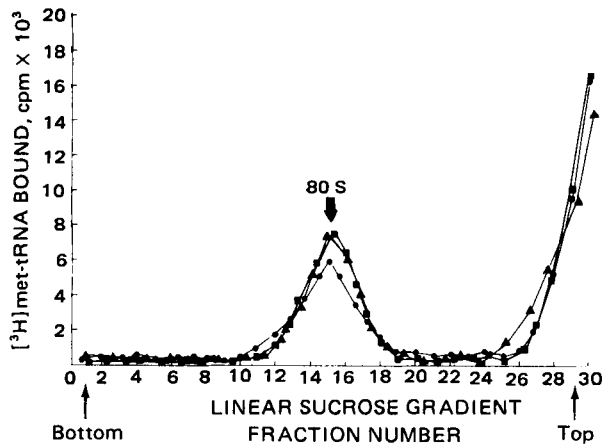

Figure 5a—*Control treated with chlortetracycline. The formation of the 80 S initiation complex of P-388 lymphocytic leukemia lysate (n = 5). Key: (●) control; (▲) genkwadaphnin; (■) yuanhuacine.*

80 S initiation complex[12] studies were performed (Table I) on P-388 lysates, which showed that at 25 and 100 μM concentrations, the diterpene esters had essentially no effect on the initiation steps of polypeptide chain synthesis. Figure 4 illustrates the effects of the diterpene esters on polyuridine directed polyphenylalanine synthesis of purified ribosomes isolated from 10-day P-388 cells. Polyuridine directed polyphenylalanine synthesis does not require the normal initiation and termination reactions of protein synthesis, and thus, agents that block this reaction are considered exclusively elongation inhibitors. At 50 μM, I suppressed polyuridine directed polyphenylalanine synthesis 92%, while II suppressed it 88%. The degree of inhibition of polyuridine synthesis by the diterpene esters was of sufficient magnitude to account for the degree of inhibition alone observed by these esters on whole cell protein synthesis.

In an effort to further evaluate the effects of diterpene esters on the elongation step of peptide synthesis, the formation of the 80 S initiation complex[12] and peptide bond formation were examined by treating the P-388 cell lysates with the elongation inhibitor chlortetracycline which specifically inhibits the binding of aminoacyl-tRNA to the ribosome A site but does not inhibit the peptidyl transferase reaction of elongation. Thus, when [³H]met-tRNA was added to the system, most of the radioactivity was found associated with the 80 S initiation complex. Addition of polyadenosine-uridine-guanosine to the chlortetracycline-treated lysate allows the formation of the 80 S initiation complex (Fig. 5a) which then reacts with puromycin. The puromycin induces the release of

[12] 80 S Adenosine–uridine–guanosine–eIF–guanosine triphosphate–[³H]met-tRNA.

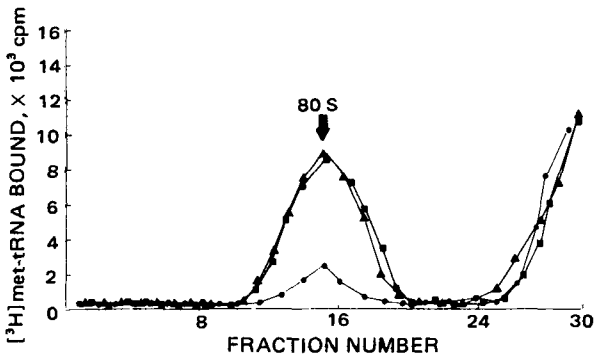

Figure 5b—*Addition of puromycin. Effect of genkwadaphnin and yuanhuacine on the methionyl puromycin reaction of P-388 lymphocytic leukemia lysate (n = 5). Key: (●) control plus puromycin; (▲) genkwadaphnin; (■) yuanhuacine plus puromycin.*

[³H]methionine from the 80 S complex (Fig. 5b). The diterpene esters did not interfere with the formation of a stable 80 S initiation complex but rather inhibited the puromycin release of labeled methionine from the polysome.

These data indicate that I and II similarly block peptide bond formation during elongation peptide chain synthesis. The concentration of drug to block peptide transferase activity was consistent with concentrations required to inhibit whole cell protein synthesis *in vitro*.

The daphnane diterpene esters did not have any significant effects on the individual steps leading to the formation of a stable 80 S initiation complex. The daphnane diterpene esters significantly inhibited both the polyuridine-directed polyphenylalanine synthesis and the formation of the first peptide bond between puromycin and the met-tRNA bound to the 80 S initiation complex. These data strongly indicate that the diterpene esters are potent inhibitors of the peptidyl transferase reaction of the elongation process of protein synthesis of P-388 lymphocytic leukemia cells.

Bayesian Individualization of Pharmacokinetics: Simple Implementation and Comparison with Non-Bayesian Methods

LEWIS B. SHEINER ˣ and STUART L. BEAL

Received October 18, 1981 from the *Department of Laboratory Medicine and Division of Clinical Pharmacology, Department of Medicine, University of California, San Francisco, CA 94143.* Accepted for publication February 1, 1982.

Abstract □ One may attempt to individualize drug dosage by estimating an individual's pharmacokinetic parameters. Information useful for this purpose consists of certain population pharmacokinetic parameters (notably those describing the typical relationship between dosage and drug concentrations) and also measured drug concentrations from the individual of concern. Both types of information should be used. A (Bayesian) method that does so has been described in the pharmacokinetic literature. In this report an implementation of the Bayesian method that is readily adapted to a microcomputer is presented. Using simulated data it is compared with two other methods proposed by others, for estimating individual theophylline clearances. Both previously suggested methods are shown to be less precise than the Bayesian method: their typical error magnitudes are 20–70% larger.

Keyphrases □ Bayesian method—individualization of pharmacokinetics, simple implementation and comparison with non-Bayesian methods, theophylline □ Pharmacokinetics—Bayesian individualization, simple implementation and comparison with non-Bayesian methods, theophylline □ Theophylline—Bayesian individualization of pharmacokinetics, simple implementation and comparison with non-Bayesian methods

A great deal of attention has been given to the problem of estimating the pharmacokinetic parameters of individual patients in order to optimize dosage choices. Initially, most attention has been directed at obtaining estimates of individual parameters from the population information relating kinetics to certain patient features (sex, age, renal function, *etc*). More recently, considerable attention has been directed at the estimation of parameters using measured drug levels (1–4).

One particular method, the Bayesian method (3), is intuitively appealing. It involves a continuously changing view of the patient. Before any drug levels are measured,

Keyphrases □ Bayesian method—individualization of pharmacokinetics, simple implementation and comparison with non-Bayesian methods, theophylline □ Pharmacokinetics—Bayesian individualization, simple implementation and comparison with non-Bayesian methods, theophylline □ Theophylline—Bayesian individualization of pharmacokinetics, simple implementation and comparison with non-Bayesian methods

A great deal of attention has been given to the problem of estimating the pharmacokinetic parameters of individual patients in order to optimize dosage choices. Initially, most attention has been directed at obtaining estimates of individual parameters from the population information relating kinetics to certain patient features (sex, age, renal function, *etc*). More recently, considerable attention has been directed at the estimation of parameters using measured drug levels (1–4).

One particular method, the Bayesian method (3), is intuitively appealing. It involves a continuously changing view of the patient. Before any drug levels are measured,

0022-3549/82/1200-1344$01.00/0

the patient is regarded as a typical member of the population of all similar patients with respect to pharmacokinetic parameter values. Once considerable drug level information has become available, the patient is regarded as a unique individual whose pharmacokinetic parameters are distinct from other patients. The point of view is continuously shifted from the first one to the second one as drug level information accumulates.

In this report, a method for implementing the Bayesian approach is outlined that involves only a simple modification of any standard nonlinear least-squares fitting procedure (see *Appendix*). Then, using simulated data, the Bayesian method is compared with two other methods for estimating individual theophylline clearances.

THEORETICAL

Implementation—The basic model used here for the observations of an individual is:

$$y_i = f(P,X_i) + \epsilon_i \qquad \text{(Eq. 1)}$$

where y_i is the ith drug level, $P = (p_1,p_2,\ldots p_s)$ is the vector of the s pharmacokinetic parameters of the model for the individual, X_i is the vector of independent variables (such as time, dose) associated with y_i, and ϵ_i is statistical error that includes measurement error and random intraindividual kinetic variability over time.

The errors, ϵ_i, are assumed to be independent, with zero mean and common variance, σ^2, assumed known. The vector of individual parameters, P, is regarded as arising randomly from a population of such vectors (one for each individual of the population). For each $1 \leq k \leq s$, the population mean and variance of the p_k are the known quantities, θ_k and ω_k^2, respectively. They are obtained presumably from a population study of the drug in question. The assumption allowing for the simplicity of the implementation to be described is that the p_k are pairwise uncorrelated in the population. For convenience, θ will denote the vector $(\theta_1,\theta_2,\ldots\theta_s)$ and Ω will denote the vector $(\omega_1^2,\omega_2^2,\ldots\omega_s^2)$.

When faced with y_i, $i = 1, n$ observations of drug levels, the usual approach is to estimate P using ordinary least squares (OLS). The ordinary least-squares estimate of P, $\hat{P}_{OLS}$, is that value of P minimizing the ordinary least-squares objective function:

$$O_{\text{OLS}}(P) = \sum_{i=1}^{n} (y_i - \hat{y}_i)^2 \qquad \text{(Eq. 2)}$$

where

$$\hat{y}_i = f(P,X_i) \qquad \text{(Eq. 3)}$$

We shall call the $\hat{y}_i$ prediction functions.

The ordinary least-squares estimate minimizes the squared errors between the observations and the prediction functions. Call these squared errors of the first kind.

If the only observations available for estimating P were those of y_i, $\hat{P}_{\text{OLS}}$ would be a natural estimate. However, there are other available observations—the elements of θ, obtained from the population study of the drug. Define $\eta = \theta - P$ to be the vector of differences between the population mean parameters (θ) and each individual's parameters (P). Then, for each k:

$$\theta_k = p_k + \eta_k \qquad \text{(Eq. 4)}$$

Just as Eq. 1 says that the drug level observations (y_i) are equal to prediction functions $f(P,X_i)$, themselves functions of the unknown individual parameters (P) plus a random error (ϵ_i) with known variance (σ^2), so Eq. 4 says that the population observations (θ_k) are equal to prediction functions (p_k) trivial functions of P, plus a random error (η_k) with known variance (ω_k^2). Therefore, the estimate of P should attempt to minimize the squared errors between these population observations and their prediction functions, as well as those of the first kind.

When faced with observations having different error variances, it is customary to estimate parameters using weighted least-squares (WLS). The weighted least squares estimate of P,$\hat{P}_{\text{WLS}}$, is that value of P minimizing

$$O_{\text{WLS}}(P) = \sum_{i=1}^{n} \frac{(y_i - \hat{y}_i)^2}{\sigma^2} + \sum_{k=1}^{s} \frac{(\theta_k - p_k)^2}{\omega_k^2} \qquad \text{(Eq. 5)}$$

Statistical theory states that with different error variances, weighted least-squares estimates are more efficient (and possibly less biased) than ordinary least-squares estimates.

The same estimator ($\hat{P}_{\text{WLS}}$) can be as justified as a Bayesian estimator when a somewhat different line of argument is pursued (3). The authors prefer, therefore, to call the set of parameter values that minimize the expression (5) the Bayesian estimates. The weighted least-squares justification, however, leads directly to a simple practical implementation of the method. The implementation requires only a slight modification of any standard nonlinear weighted least-squares fitting algorithm. The details are presented in the *Appendix* to this paper. The essence of the method is straightforward: the list of data (y_i, $i = 1, n$) is lengthened to include the additional values of $\theta_1,\ldots\theta_s$. The weights for y_i, $i = 1, n$ are set to $1/\sigma^2$, and those for the additional s observations are set to $1/\omega_k^2$, $k = 1, s$. Finally, the user-supplied subroutine that computes and returns $\hat{y}_i$ (required by all nonlinear least-squares programs) is modified to return the current estimate of p_k when called upon to predict the kth additional observation.

A slight modification of the basic approach (see *Appendix*) deals with the special case of uncertain dosage. It may sometimes happen that there is uncertainty about the prior dose history (perhaps because the patient was an outpatient) but that an initial drug level is available so that the dose history for all subsequent levels is known (perhaps because the patient became an inpatient). It may then be preferable to initialize to the first level as suggested in a previous approach (1), to be discussed further in *Examples*. To accommodate this case in the Bayesian approach, a revised model is written that treats the true unknown initial level as another unknown parameter (p_{s+1}) and predicts observations as a function of time and dosage only after that level (see *Examples*). Logically, however, the (measured) initial level may deviate from its true value (p_{s+1}) as much as any other measured level deviates from its predicted value. To allow this, the variance of the error between the observed initial level and p_{s+1} is given by $\omega_{s+1}^2 = \sigma^2$.

Examples—Two examples of common clinical pharmacokinetic situations, the estimation problem for each of which has been approached by other workers, are presented in detail here. The Bayesian method is compared with those other methods using simulated data.

The following are some aspects common to both. The drug used for illustration in both cases is theophylline. The basic pharmacokinetic model for its disposition is the one-compartment model. This model, when used only for intravenous doses has two parameters, volume of distribution (Vd) and clearance (Cl). An initial level, if present in the model, constitutes a third parameter. A reparameterization is used; the new parameters are $p_1 = \log Vd$, $p_2 = \log Cl$, and p_3 = initial level. Logs of Vd and Cl are used because choosing a symmetrical population distribution for them (*e.g.*, the normal) imparts a skewed distribution to Vd and Cl, which accords well with actual experience.

The data used to test the various approaches were simulated. For each example, one hundred pairs of individual clearance (Cl) and volume of distribution (Vd) values were chosen at random. The parameters, p_1 and p_2 for each case, were chosen randomly from normal distributions with means of θ_1 = log (0.5 liters/kg), θ_2 = log (0.052 liters/kg/hr), respectively, (5, 6). The standard deviation of the distribution of the log of a random quantity is approximately equal to the coefficient of variation of the quantity itself. The standard deviations (coefficients of variation of Vd and Cl) used in simulating p_1 and p_2 values were ω_1 = 32% for p_1 and ω_2 = 44% for p_2 (6). Every choice of p_1 and p_2 gave rise to a choice of Vd and Cl by exponentiation. The simulated Vd and Cl values were substituted into pharmacokinetic equations to obtain simulated true drug levels. Random normally distributed errors (ϵ) were then added to these true levels to arrive at simulated observed levels. The ϵ were chosen to have mean zero and standard deviations equal to 1 mg/liter (corresponding to a coefficient of variation of 10% at a typical concentration of 10 mg/liter). The random numbers needed for the simulations were obtained using standard methods (7, 8).

Two estimation methods are applied in each example: the Bayesian method and one of the alternative methods proposed by others and described below. In both examples only clearance is estimated. Each method is used to estimate the clearance of each of the 100 simulated patients, using whatever population parameters the method may entail and the simulated drug level(s). The Bayesian method proceeds by a numerically minimizing expression (5). On the other hand, the alternative methods estimate clearance from the available data using simple direct formulas. The estimate of clearance by any method is denoted $\hat{Cl}$.

The Bayesian method depends on population parameters (standard deviations, ω_1 and ω_2) not used by the other methods. The Bayesian method naturally behaves best when it is provided with the standard

Table I—Performance of Clearance Estimation Methods

Method	$\frac{\omega_{Cl}}{\sigma}$[a]	$\frac{\omega_{Vd}}{\sigma}$[a]	Mean Clearance Error (±*SEM*) as Percent of Mean Clearance: Error, Example 1	Error, Example 2	Absolute Error, Example 1	Absolute Error, Example 2
Alternative	—	—	−5.77(5.8)	−2.82(3.3)	37.1(4.5)	26.4(2.1)
Bayesian	1	1	−1.02(3.0)	−1.08(3.1)	22.2(2.0)[b]	21.7(2.2)[b]
	3/2	1	−4.94(3.4)	−3.77(3.0)	25.6(2.3)[b]	23.1(2.1)[b]
	2/3	1	5.02(3.2)	2.52(3.4)	23.7(2.2)[b]	23.5(2.4)
	1	3/2	0.44(3.0)	−0.26(3.1)	22.5(2.1)[b]	21.4(2.2)[b]
	1	2/3	−0.76(3.0)	−1.56(3.1)	22.5(1.9)[b]	21.7(2.2)[b]

[a] Ratio of standard deviation of clearance (or Vd) to σ used in the Bayesian method. All ratios are divided by the correct ratio so that a value of unity signifies that the correct ratio itself was used. [b] Mean absolute error of Bayesian method less than that of alternative ($p < 0.05$).

deviations actually used to simulate the data. To test its robustness, the Bayesian method was applied five times: once with the true (simulation) standard deviations, once with the ratio of ω_1 to σ assumed to be 3/2 times its true value, once with the ratio assumed to be 2/3 times its true value, and once each for the same changes in the assumed ratio of ω_2 to σ.

To assess the absolute and relative performance of the estimation methods the differences may be examined between estimates of clearances and their true (simulation) values. For each estimation method, the mean error, defined as the mean of the differences between the true clearances and the estimated values, measures the bias of the method. The mean absolute error, defined as the mean of the absolute values of the errors, can be used to measure precision. The relative precision of two methods can be assessed using a paired t-test on the paired absolute errors (*i.e.*, on the value of the absolute error of the first method minus that of the second method). If the mean difference is significantly greater than (less than) zero, the first method is less (more) precise than the second method. It remains only to explain how $f(P,X_i)$ is computed for the Bayesian method, and for the alternative methods, how $\hat{Cl}$ is computed. These definitions follow.

Example 1—A method has been proposed (2) to estimate the maintenance dose required to achieve a target plasma concentration of drug. This method uses the observation of a single drug level after a test dose of drug. Since the maintenance dose must be proportional to individual clearance, the proposal amounts to a method to estimate individual clearance from a single drug level measurement. The appropriate pharmacokinetic model for the single true drug level is:

$$f(P,X) = W = \frac{d}{t_1 Cl}[1 - \exp(-kt_1)]\exp(-k(t_2 - t_1)) \quad \text{(Eq. 6)}$$

where the subscript i has been suppressed, d is the size of the test dose [according to the previous suggestion (2), taken to be 5 mg/kg], t_1 is the duration of the test infusion (0.5 hrs), t_2 is the sampling time for the drug level (6 hr), and k is the ratio of Cl to Vd. The simulated observed level, y, is equal to W plus a randomly chosen value for ϵ.

Using the relationship suggested previously (2), and adjusting its constants so that it estimates clearance, rather than maintenance dose, this method becomes:

$$Cl = 0.266\exp(-0.311\,y) \quad \text{(Eq. 7)}$$

Example 2—A method has been proposed (1) for estimating individual theophylline clearance using one drug level measured shortly after a maintenance infusion has begun (and perhaps shortly after a loading infusion has terminated) and another level measured some hours later. Two drug levels are used, but the first one is regarded as an initial level so that prior dosage may be regarded as unknown. Since both levels are assumed to be measured, errors in both of them must be simulated. Accordingly, the appropriate pharmacokinetic model for the first true drug level is:

$$f(P,X_1) = W_1 = \frac{d}{Vd}\exp(-kt_1) + \frac{R}{Cl}[1 - \exp(-kt_1)] \quad \text{(Eq. 8)}$$

where, for convenience, the initial loading dose, d (5.6 mg/kg), is assumed to be given by an infusion rapid enough so that its contribution to the level measured at time t_1 (2 hr later) may be predicted by a bolus-dose model; R is the maintenance infusion rate, set equal to 0.52 mg/kg/hr so as to result in a typical steady-state concentration of 10 mg/liter; and k is Cl/Vd.

The second true level is modeled as:

$$f(P,X_2) = W_2 = W_1\exp(-kt_2) + \frac{R}{Cl}[1 - \exp(-kt_2)] \quad \text{(Eq. 9)}$$

where t_2 is the time at which y_2 is sampled, measured as the time since t_1. This time is varied randomly from patient to patient according to a normal distribution with a mean of 5 hr, and a standard deviation of 2 hr (but values <3 hr were discarded). These sampling times are in accordance with previous suggestions (1) for sampling times. (Note that for the Bayesian method, the third parameter to be estimated is simply W_1, the true first level.) The simulated observed levels, y_1 and y_2, are obtained from W_1 and W_2 by adding randomly chosen errors ϵ_1 and ϵ_2, respectively.

Clearance is predicted (1) from:

$$\hat{Cl} = \frac{2R}{(y_1 + y_2)} + \frac{2\exp(\theta_1)(y_1 - y_2)}{t_2(y_1 + y_2)} \quad \text{(Eq. 10)}$$

Note that a single population parameter, θ_1, is used here.

RESULTS

Both examples can be discussed together, since the results are quite similar.

Table I presents the performance of the Bayesian and alternative estimation methods for both examples. In Table I, the mean (estimation) error and absolute error for clearance, and their standard errors, are expressed as percentages of the (approximate) population mean clearance, 0.052 liter/hr/kg. The performance of the Bayesian method is shown for all five cases tested: the case in which the method was supplied with the correct ratios of the ω's to σ and the four cases in which incorrect ratios were used. None of the Bayesian performances nor those of the alternative methods exhibited substantial bias (*i.e.*, mean errors were relatively small and in all cases were within two standard errors of zero).

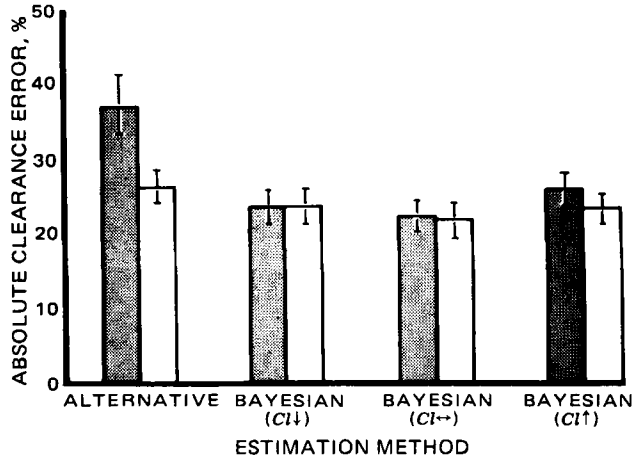

Figure 1—*The mean percent absolute error (true clearance minus predicted clearance expressed as a percent of the population mean clearance) for predictions by the alternative methods and the Bayesian method are shown. Dark bars refer to example 1. Clear bars refer to example 2. Lines at tops of bars show the 95% confidence intervals for the mean percent absolute errors. Three performances for the Bayesian method are shown; the center one (Cl ↔) corresponds to adjusting clearance in correct proportion to differences between observed and predicted levels. The performance marked Cl↓ (Cl↑) refers to clearance predictions made when adjusting clearance less (more) than appropriate. The absolute error of the Bayesian method is significantly smaller ($p < 0.05$) than that of the alternative method for all but the clear bar, Cl↓ case.*

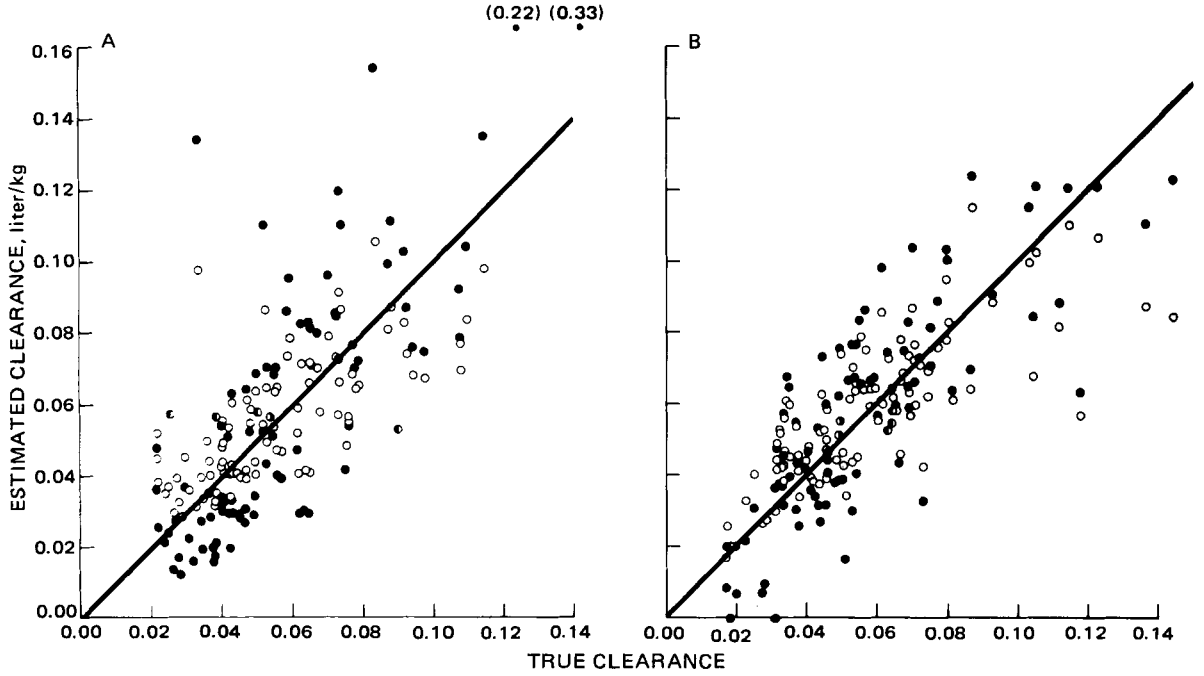

Figure 2—*Plots of predicted clearance* versus *true (simulated) clearance for predictions by the Bayesian (○) and alternative (●) methods. The diagonal line on each graph is the line of identity. A shows results for example 1; B shows results for example 2.*

The results for precision (absolute error) are different. The precision of the Bayesian method estimates typically exceeded that of the alternative method estimates. This was true whether or not the Bayesian method standard deviation ratios were correct or not, although some degradation of performance with incorrect ratios was seen. In the first example, the absolute errors of the alternative method were typically 50–70% larger than those of the Bayesian method, while in the second they were 10–25% larger.

Figure 1 illustrates the precision results of Table I. For the Bayesian method, the cases in which the ratio of ω_1 to σ was incorrect are not shown, as the performances in those cases were little different from those in which the correct ratios were used (Table I).

Figure 2 shows the predictions of the Bayesian and alternative methods for all 100 simulated points for both examples.

DISCUSSION

Various methods for revising estimates of individual pharmacokinetic parameters based on measured drug levels have been put forward. Most previously suggested methods for doing so can be criticized for not attempting to integrate already available information regarding population pharmacokinetic behavior with the information from the observed drug concentrations. A previous study (3) has pointed out that such behavior is not optimal, and has presented a general (Bayesian) framework that allows use of all available information at all times.

In this paper the Bayesian method is seen as an example of weighted least-squares estimation. This leads directly to a simple implementation of the method involving only minor modifications to any standard nonlinear weighted least-squares computer program (see *Appendix*).

In this paper the Bayesian approach has been applied to simulated data, representing two dosage adjustment examples for which other investigators have proposed alternative approaches. In both cases, the Bayesian method is superior to the alternative. Moreover, the former is relatively insensitive to major inaccuracies in some of the parameters it uses. This finding supports the suggestion (see *Appendix*) to use approximate values for those parameters when their true values are in doubt.

Regarding the simulations, one further point merits comment. The similarity of the magnitude of the errors for the Bayesian method in the first and second examples may, at first, seem surprising, since the first example uses only one measured level, while the second uses two. However, it should be recalled that the first level in the second example essentially substitutes for knowledge of initial dosage so that all the drug level information, *per se*, is actually confined to the second level.

Regarding the generality of the Bayesian approach, the basic method can be extended to arbitrary dosage and blood sampling patterns (9), numbers of samples, and pharmacokinetic models (10). In contrast, most other estimation methods, including the alternative ones evaluated herein, apply only to specific models or dosage patterns.

Regarding the theoretical advantages of the Bayesian approach, the most important one is its use of population information at all times. By using population information even when individual observations are available, the Bayesian method must perform better than methods that do not. Figure 2 illustrates this point. The clearance estimates from the Bayesian method seen there tend to err in the direction of the population mean (for true clearances less than the mean, Bayesian estimates tend to be high, and *vice versa*), while those of the alternative methods do not demonstrate this tendency. Rather, they can be quite erratic and have large associated errors. See the off-scale points in Fig. 2A. Even when absolute error is modest, the non-Bayesian estimates can be quite misleading. See the several instances in Fig. 2B where clearance is estimated by a previous method (1) to be at or near zero. The first example is an instance in which random error causes the observed levels to differ greatly from the corresponding true levels. The second occurs when the error, no matter what its magnitude, represents a large fraction of the true difference, which itself may be quite small. The non-Bayesian methods trust the observations implicitly, and will often magnify small differences from expectation in these so as to produce large estimation errors. In contrast, the Bayesian method discounts observations, the more so the more they are in conflict with (prior) parameter expectations. In some cases this conservatism will mean that a parameter truly different from expectation will be incorrectly regarded as closer to expected than it really is—at least until further drug levels are obtained. The incorrect discounting of truly unusual responses is more than compensated by the correct tendency to discount falsely unusual ones. Indeed, the Bayesian method is likely to perform well in precisely those circumstances in which other methods do not perform well: when observed drug levels actually provide little information about the parameters of interest.

APPENDIX

Implementation of the Bayesian method involves the use of suitable computer programs. The availability of a computer program that can perform parameter estimation using nonlinear weighted least squares is assumed[1]. Although large programs running on large machines are often

[1] A users manual and listings of computer programs that implement the above approach on a microcomputer are available. The authors should be contacted for information on obtaining these items.

used for this purpose [*e.g.*, NONLIN (11)], short programs that run on a microcomputer are also available (12).

Nonlinear weighted least-squares programs usually require at least the following: (*a*) data, consisting of a series of observations, $Z = (Z_1,Z_2,\ldots Z_N)$ and corresponding weights, $W = (W_1,W_2,\ldots W_N)$; (*b*) a subroutine that for each Z_i accepts as arguments a list of independent variable values (X_i) and a list of current parameter estimates (P), and produces as output, a prediction ($\hat{Z}_i$) of Z_i, as a function $[f(P,X_i)]$ of its arguments. Some programs are less sophisticated than others and restrict one to scalar X_i, usually denoting time, t_i. The following procedure for specifying (*a*) and (*b*) for a nonlinear weighted least-squares program is designed to function even with that restriction. These programs will also require other arguments, such as the maximum number of iterations allowed, the convergence criterion, *etc.* Specification of these is no different for the current application than it is for the usual ones.

It is assumed that there are N observations of drug levels, and s pharmacokinetic parameters to be estimated ($s + 1$ estimates are needed when an initial level is used). Further, it is assumed for now that the vector of mean population parameters, θ, is known as is ω_1 through ω_s and σ^2.

Any nonlinear weighted least-squares program can be used to find the P minimizing expression (5), by fulfilling requirements (*a*) and (*b*), as follows:

(*a*) The data: There are a total of $N + s$ observations. For $i = 1,\ldots,N$, let $Z_i = y_i$ and $W_i = 1/\sigma^2$. For $i = N + 1,\ldots,N + s$, let $Z_i = \theta_k$ and $W_i = 1/\omega_k^2$, where $k = i - n$.

(*b*) The subroutine: Let one component of X_i, X_{li}, say, be defined by $x_{li} = t_i$ if $i \leq n$ and $X_{li} = -(i - N)$ if $i > N$. Then the subroutine should return $\hat{Z}_i = f(P,X_i)$ if $X_{li} \geq 0$, but it should return $\hat{Z}_i = p_k$ where $k = -X_{li}$, if $X_{li} < 0$.

When the initial level idea is to be used, one does not regard the initial level as one of the N others. Rather, one modifies the data by adding observation number $N + s + 1$, corresponding to the new parameter, number $s + 1$. Then for $i = N + s + 1$, $Z_i = y_0$, $W_i = 1/\sigma^2$ and $X_{li} = -(s + 1)$, where y_0 is the measured value of the initial level. The subroutine need not be modified from its specification above.

The sole remaining problem is that of obtaining values for the population parameters, σ^2, θ, and ω_1 through ω_s. Methods for analyzing patient data in order to estimate population parameters have previously been presented [*e.g.*, (13)]. Many investigators have studied normal volunteers or selected patient populations and have published equations that predict average pharmacokinetic parameters as a function of body weight, renal function, and other factors. Recently, a compilation of such parameters for selected drugs has been assembled (14).

Available information, however, is often of varying quality and completeness. In particular, estimates of ω_1 through ω_s and σ^2 are least available, and, when available, least reliable. When this is the case, it is proposed not that the Bayesian method be abandoned, but that certain rules of thumb be used. For many pharmacokinetic parameters, a coefficient of variation, CV_1, of interindividual variability that is on the order of 25–50% is not uncommon, with volume of distribution often at the lower value and clearance at the upper (12). This variability is present after correcting for age, sex, renal function, and other observable patient features. A reasonable coefficient of variation, CV_2, of y, given P, is often 5–15%, since the ϵ error includes not only assay error but model misspecification error and error due to intraindividual kinetic variability. To compute an estimate of ω_k^2 and σ^2, the only further information needed are the values of θ_k and a typical value for y, a value in the therapeutic range; let the latter be denoted $\tilde{y}$. Then, for example, for $CV_2 = 10\%$, $\sigma^2 = (0.1\tilde{y})^2$, and for $CV_1 = 50\%$, $\omega_k^2 = (0.5\theta_k)^2$.

It is the author's experience that the Bayesian estimates are not too sensitive to the choices involved in this rule of thumb, while the ordinary least-squares estimates can be rather poor in comparison when sample size, N, is small. Of course when $N < s$, the ordinary least-squares estimates do not exist, whereas the Bayesian estimates do.

Effects of Microsomal Enzyme Induction on Toxicity of *p*-*N*,*N*-Bis(2-chloroethyl)aminophenyl Alkyl Ethers in Mice and Survival Times in L-1210 Leukemic Mice

C. T. BAUGUESS[x], SHIAO PING CHANG, and J. E. WYNN*

Received September 16, 1981, from the *Department of Basic Pharmaceutical Sciences, College of Pharmacy, University of South Carolina, Columbia, SC 29208.* Accepted for publication February 1, 1982. *Present address: Department of Pharmaceutical Sciences, College of Pharmacy, Medical University of South Carolina, Charleston, SC 29425.

Abstract □ Four alkyl ethers of *p*-*N*,*N*-bis(2-chloroethyl)aminophenol were selected to study the effects of microsomal enzyme induction by phenobarbital on the toxicity changes as reflected by LD_{50} and alteration of survival times in L-1210 leukemic mice. In the phenobarbital pretreated mice the LD_{50} for the ethyl ether of *p*-*N*,*N*-bis(2-chloroethyl)-aminophenol was decreased from 1641 to 1213 μm/kg. This result suggests that *O*-dealkylation is the major metabolic pathway. The LD_{50} for the propyl ether of *p*-*N*,*N*-bis(2-chloroethyl)aminophenol was increased by the pretreatment from 605 to 678 μm/kg. The LD_{50} for the butyl ether was increased from 714 to 910 μm/kg. An additional metabolic pathway, (ω-1)-hydroxylation, is suggested for the propyl and butyl ethers. The hexyl ether appeared to be unaffected by the pretreatment; thus, *O*-dealkylation was ruled out as a major pathway. In the survival studies, the pretreatment reduced the antitumor effectiveness of the ethyl and the butyl ethers. The survival times were increased for some dose levels for the propyl ether. No significant trend in survival times was observed for the hexyl ether in the pretreated mice.

Keyphrases □ Microsomal enzyme induction—effects on toxicity in mice, survival times in L-1210 leukemic mice of *p*-*N*,*N*-bis(2-chloroethyl)aminophenyl alkyl ethers, phenobarbital □ *p*-*N*,*N*-Bis(2-chloroethyl)aminophenyl alkyl ethers—effects of microsomal enzyme induction on toxicity in mice, survival in L-1210 leukemic mice, phenobarbital

Variations in the alkyl chain lengths of esters and ethers of *p*-*N*,*N*-bis(2-chloroethyl)aminophenol have been shown to alter the toxicity and survival times of L-1210 leukemic mice over that of *p*-*N*,*N*-bis(2-chloroethyl)aminophenol (1–3). It was proposed that the fatty acid esters would undergo ester hydrolysis and release the *p*-*N*,*N*-bis(2-chloroethyl)aminophenol and its other degradation products. Previous reports suggest that the short chain alkyl aryl ethers may be metabolized by an α-hydroxylation pathway resulting in *O*-dealkylation, while the longer chains may be subjected to another pathway. It is likely that the metabolism of this series of alkyl aryl ethers would be similar to the *p*-nitrophenyl alkyl ethers reported previously (4). The hexyl ether of *p*-nitrophenol was not *O*-dealkylated as were the lower members in that series. Although the metabolism of the hexyl ether of *p*-*N*,*N*-bis(2-chloroethyl)aminophenol has not been studied, toxicity studies and survival studies in L-1210 leukemic mice have suggested the absence of the α-hydroxylation pathway. A dual metabolic pathway, α- and (ω-1)-hydroxylation, is possible for the *n*-propyl and *n*-butyl ethers of *p*-*N*,*N*-bis(2-chloroethyl)aminophenol. These pathways on *p*-nitrophenyl-*n*-butyl ether have been demonstrated (5) with the identification of 3-hydroxy-*n*-butyl ether of *p*-nitrophenol as a major metabolite.

The purpose of this research was to study the effects of microsomal enzyme induction in mice on the toxicity and survival times of L-1210 leukemic mice treated with the ethyl, *n*-propyl, *n*-butyl, and *n*-hexyl ethers of *p*-*N*,*N*-bis(2-chloroethyl)aminophenol. An increase in toxicity would be expected to accompany an increase in *O*-dealkylation in induced mice and provide further evidence for the presence of the (ω-1)-hydroxylation pathway for the higher members in the alkyl ether series.

EXPERIMENTAL

Test Animals—DBA/2[1], BDF_1[1], and HA/ICR mouse strains[2] and L-1210 leukemic mice (tumor source)[3] were used.

Instruments—The necessary equipment included an electronic cell counter[4], a channelizer[4], a dilutor[4], an *xy* recorder[4], a hemocytometer[5], and a microscope[6].

Materials—Counting diluent[4], red cell-lysing reagent[7], crystal violet[8], Giemsa stain[7], isotonic diluting solution[9], trypan blue[10], and Wrights' strain[8] were used. The alkyl ethers of *p*-*N*,*N*-bis(2-chloroethyl)aminophenol (the ethyl-propyl-, butyl-, and hexyl ethers) and *p*-*N*,*N*-bis(2-chloroethyl)aminophenol were prepared and have been reported previously (3). All other chemicals and reagents were obtained from commercial sources.

Microsomal Enzyme Induction—A modification of a previous method was employed in the enzyme induction phases of the study (6). Thirty-five HA/ICR mice (6-weeks-old) were given sodium phenobarbital (75 mg/kg) by intraperitoneal injection daily for 7 days. The onset and duration of sleeping time for each mouse was recorded. Sleeping time is the time interval between the loss and recovery of the righting reflex (6). Changes in the duration of sleeping time were used as an indicator of the degree of enzyme induction. After the 7th day of treatment the mice were randomly divided into seven groups, five mice to each. On day 9 sodium phenobarbital (75 mg/kg) was administered to the first group to observe any changes in the onset and duration of sleeping time after the discontinuation of the pretreatment for one day. The same dose of sodium phenobarbital was administered to the remaining groups 2, 3, 4, 5, 6, and 7 days, respectively, after the discontinuation of the daily pretreatment.

Toxicity Evaluation—HA/ICR mice were divided into groups of six for the test and control groups. The test groups were given sodium phenobarbital (75 mg/kg ip) daily for 7 days prior to intraperitoneal injections of *p*-*N*,*N*-bis(2-chloroethyl)aminophenol or its alkyl ethers. Each injection consisted of a known concentration of each drug dissolved in 0.1 ml of propylene glycol. The mice were observed and weighed daily for 28 days. The number of mortalities at each dose level was evaluated by a previous method to determine the LD_{50} number for each drug in the test and control groups (7).

Tumor Transplant Procedure—DBA/2 mice bearing L-1210 leukemia for 7 days were used as a source for tumor cells. The L-1210 cells were collected according to a previously described procedure (1). Inoculations containing 10^5 L-1210 cells were administered intraperitoneally to groups of BDF_1 mice to be used in the survival studies.

Survival Studies—One group of healthy BDF_1 mice was pretreated with sodium phenobarbital (75 mg/kg) daily for 5 days. The alkyl ethers of *p*-*N*,*N*-bis(2-chloroethyl)aminophenol were administered intraperitoneally in propylene glycol to two groups of leukemic mice, one group referred to as the control, which did not receive the phenobarbital pretreatment, and the group described above. Dosages of 25, 50, 75, 100, 150, and 200 mg/kg of the alkyl ethers were given on days 2 and 5 after inoculation to subgroups of six mice for the control group and the pretreated group. An additional group of six BDF_1 mice inoculated with L-1210 cells was employed as the untreated control and received only the injection vehicle, propylene glycol.

RESULTS AND DISCUSSION

The onset and duration of sleeping times for mice pretreated with phenobarbital are reported in Table I and Fig. 1. The onset time for sleeping did not show any relationship with the degree of enzyme induction. The sleeping times gradually decreased during the periods of daily injections of phenobarbital, but gradually returned to normal after termination of the treatment. The increased function of the microsomal enzyme system persisted into the following week. Hypertrophy of the mice livers was observed in all studies 3 or 4 days after the pretreatment was initiated and disappeared after the daily injections were stopped. This observation is consistent with a previous report (8).

In the toxicity studies on the nitrogen mustards, a 7-day pretreatment period was considered adequate for the induction period. Table II shows the results of the toxicity studies performed on the five compounds in phenobarbital pretreated mice and untreated mice. The LD_{50} for compound I, *p*-*N*,*N*-bis(2-chloroethyl)aminophenol, was 164 μm/kg (38 mg/kg) in untreated HA/ICR mice. In the phenobarbital pretreated mice, a reduction in toxicity was suggested by the increase in the LD_{50} to 253 μm/kg (59 mg/kg). This increase in LD_{50} was probably due to an increase in the rate of conjugation of compound I, which should have resulted in a faster excretion rate (9).

A tenfold decrease in toxicity was observed for compound II, the ethyl ether of *p*-*N*,*N*-bis(2-chloroethyl)aminophenol, over that of the parent compound (I) in untreated mice. The LD_{50} was 1641 μm/kg which decreased to 1213 μm/kg when the mice were pretreated with phenobarbital. It is presumed that compound II is *O*-dealkylated to the more toxic mustard, compound I, which would lead to one of the ultimate metabolites through hydrolysis of the chloroethyl groups. Some of the toxicity expected from the *O*-dealkylation pathway *via* hydroxylation on the α-carbon on the alkyl group would be mollified by an increase in the rate of conjugation of compound I, its metabolites, other metabolites which have hydroxyl groups, and the various rate processes of the α- and (ω-1)-hydroxylation pathways.

The toxicity of compound III was greater than compound II but less than compound I. The LD_{50} of compound III was 605 μm/kg (160 mg/kg) in untreated mice and increased to 678 μm/kg in the pretreated mice. Compound III, the propyl ether, could undergo metabolism by the α-hydroxylation and the (ω-1)-hydroxylation pathways. If the α-hydroxylation were the major pathway, the toxicity for the propyl ether would be expected to increase in the pretreated mice due to the increased formation of the parent compound, *p*-*N*,*N*-bis(2-chloroethyl)aminophenol. The (ω-1)-hydroxylation of compound III would lead to the 2-hydroxy propyl ether of *p*-*N*,*N*-bis(2-chloroethyl)aminophenol which should be less lipid soluble and possibly less toxic.

Similar results were obtained for compound IV. The LD_{50} was 714 μm/kg (207 mg/kg) in untreated mice and increased to 910 μm/kg in the pretreated mice.

Both hydroxylation pathways would be expected for the butyl ether, but α-hydroxylation would have to play a minor role to explain the lowered toxicity in the pretreated mice. If the butyl ether mustard is metabolized by the (ω-1)-hydroxylation pathway, it would appear as the 3-hydroxybutyl ether mustard or corresponding metabolites. This pathway was verified for *p*-nitrophenyl butyl ether (5). The increase in the LD_{50} for compound IV suggests that phenobarbital pretreatment enhances the rate for the alternate pathway over that of α-hydroxylation.

The effect of pretreatment on the toxicity of compound V was negligible. The LD_{50} was 1069 μm/kg (340 mg/kg) in the untreated mice and changed only slightly to 1104 μm/kg in the pretreated mice. This result was anticipated since the aryl alkyl ether mustards would be expected to follow the same metabolic pathways as reported for the alkyl ethers of *p*-nitrophenol (4). In that report *O*-dealkylation was negligible for the hexyl ether of *p*-nitrophenol. The insignificance of the α-hydroxylation pathway in mice is supported by the results of the toxicity studies.

The expected metabolite of compound I, *p*-*N*,*N*-bis(2-hydroxyethyl)aminophenol, has been isolated from rat blood as a major metabolite of compound II and to a lesser extent for compounds III and IV. Unidentified metabolites which did not conform to the α-hydroxylation pathway were observed for compounds III and IV[11].

The results of a study of the influence of microsomal enzyme induction on the survival times of leukemic mice treated with alkyl ethers of *p*-*N*,*N*-bis(2-chloroethyl)aminophenol are presented in Table III and illustrated in Fig. 2. The ethyl ether, compound II, would be expected to undergo α-hydroxylation and hydrolysis would yield acetaldehyde and the more toxic form of the mustard, compound I, and its metabolites. The ethyl mustard produced a maximum survival of 126% T/C at a dose of 383 μm/kg in the control group (leukemic mice treated with the mustard

[a] Six BDF_1 mice were used for each dose level for each group. [b] Statistical differences at $p < 0.05$ for Control *versus* Pretreatment. [c] The T/C % represents the rates of the sum of days (T) each treated animal survives to the sum of the number of days each control animal (C) survives times 100.

only), but was reduced to 106% T/C in the corresponding group pretreated with phenobarbital. The survival times for all dose levels of compound II were lower in the phenobarbital pretreated groups over the control groups, with the exception of two dose levels. A dose level of 479 μm/kg produced a survival of 120% T/C in both groups. It was generally expected that an increase in the rate of *O*-dealkylation of compound II in the pretreated mice would increase host toxicity and overcome some of the benefits of drug treatment.

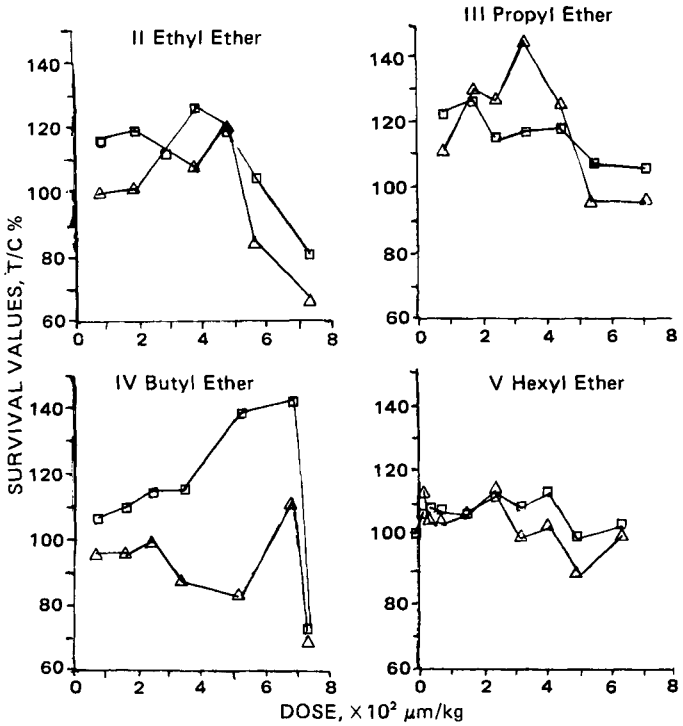

Figure 2—*Survival values of L-1210 leukemic mice treated with* p-N,N-*bis(2-chloroethyl)aminphenyl alkyl ethers, (II) ethyl ether, (III) propyl ether, (IV) butyl ether, and (V) hexyl ether. Key: (□) Control; (△) Pretreated.*

The propyl ether, compound III, was more effective in increasing survival values at the four dose levels ranging from 181 through 455 μm/kg in the pretreated groups. The highest survival value was 145% T/C in the pretreated group, which was significantly different from the control value of 117% T/C. If the metabolism of compound III were accelerated by the α-hydroxylation pathway in the pretreated group, a decrease in the survival value would have been expected, as observed with compound II, due to increased host toxicity. α-Hydroxylation has been demonstrated in propyl ethers (4), but an alternate pathway would be suspected to satisfactorily explain these results. One other major metabolite, which would result from an (ω-1)-hydroxylation, has been suggested (5). An active metabolite other than the parent compound may be the 2-hydroxy propyl ether of *p*-*N*,*N*-bis(2-chloroethyl)aminophenol. Although the differences are not significant, in the lowest dose, 91 μm/kg, and the two highest doses, 546 and 727 μm/kg, the survival values of the pretreated groups fell below the untreated groups.

All dose levels of compound IV exhibited lower survival values in the pretreated groups when compared with the control groups. A dose level of 519 μm/kg produced a significant difference between survival values of pretreated *versus* control groups, although the best value, 143% T/C, occurred at 692 μm/kg in the control group. A decrease in the rate of *O*-dealkylation of *p*-nitrophenyl alkyl ethers as the length of the carbon chain increased has been found (4). The (ω-1)-hydroxylation pathway is favored as a possible explanation consistent with the results from both the toxicity and the survival data. If the 3-hydroxybutyl ether of *p*-*N*,*N*-bis(2-chloroethyl)aminophenol is produced more rapidly than the parent compound, that would provide a possible explanation for the toxicity differences between control and pretreated group, and it would have less antitumor activity than compound IV.

The results from previous studies on the *O*-dealkylation of *p*-nitrophenyl alkyl ethers and survival studies on the *p*-*N*,*N*-bis(2-chloroethyl)alkyl ethers are consistent with the lack of significant differences between the control groups and pretreated groups for the hexyl ether. Since α-hydroxylation of hexyl aryl ethers is unlikely, minimal effects

[a] R^2 (coefficient of determination) indicates the proportion of variation in life span explained by dose only or by both dose and treatment. [b] The form of multiple regression equation: $Y = a + b(\text{dose}) + c(\text{treatment})$ Y = life span, a = intercept of y axis, b = regression coefficient for dose, c = regression coefficient for treatment (dummy variable). [c] $B(b)$ indicates the number of standard derivation units of change in life span that could be predicted when dose changes by one standard unit. $B(c)$ indicates the number of standard derivation units of change in life span that could be predicted when treatment changes by one standard unit. [d] $F(b)$ presents the F value of dose. $F(c)$ presents the F value of treatment. Except $F(b)$ of hexyl ether, all other F values are greater than the critical values at the 0.05 level of significance. [e] NS = no significance.

on toxicity or survival times in leukemic mice would be expected to result from phenobarbital pretreatment (3, 4). It is not known if the hexyl ether of *p*-*N*,*N*-bis(2-chloroethyl)aminophenol undergoes (ω-1)-hydroxylation, but if it were to occur, these results suggest a metabolite similar in toxicity and antitumor activity to compound V.

A regression analysis was performed on survival data from the control and pretreated groups (Table IV). The analysis, taken over the entire range of doses, failed to show significant trends for any of the compounds tested. Negative trends in the ascending points for data sets from compounds II and IV indicate a decrease in the antitumor effectiveness for the pretreated mice. Crossover trends at the lowest and two highest doses for compound III precluded significance. The medium level doses were not tested. No trend could be established for compound V.

Antipyrine and Acetaminophen Kinetics in the Rat: Comparison of Data Based on Blood Samples from the Cut Tail and a Cannulated Femoral Artery

WENCHE M. JOHANNESSEN *[x], INGVALD M. TYSSEBOTN [‡], and JARLE AARBAKKE *

Received September 3, 1981, from the **Department of Pharmacology, Institute of Medical Biology, University of Tromsø, N-9001 Tromsø, Norway* and the [‡]*Institute of Physiology, University of Bergen, Årstadveien 19, N-5000 Bergen, Norway.* Accepted for publication February 1, 1982.

Abstract □ Antipyrine and acetaminophen kinetics were determined from concentration data obtained by simultaneous blood sampling from the cut end of the tail and a cannulated femoral artery in the rat. Significant differences in concentrations and kinetics for both drugs were found by comparison of the two sampling sites. The hypothesis that the differences were due to a low tail blood flow was tested. The tail blood flow was measured with a microsphere technique, and tail antipyrine concentrations were calculated from the relationship between arterial antipyrine concentration, tail flow, and time for comparison with the observed antipyrine concentrations. Mean blood flow of the rat tail was 0.02 ml/min/ml tail tissue at 22°, which was 8.8 and 0.9% of the liver and kidney flow, respectively. Tail flow increased more than twofold by elevation of the tail temperature to 37°. The calculated tail antipyrine concentration *versus* time curve showed a very close correspondence to the observed antipyrine tail concentration *versus* time curves. The results show that tail flow is a major determinant of antipyrine tail concentration in the rat. Kinetic data based on blood samples from the cut end of the tail, therefore, should be interpreted with caution.

Keyphrases □ Antipyrine—pharmacokinetics in the rat, comparison of data based on blood samples from the cut tail and a cannulated femoral artery □ Acetaminophen—pharmacokinetics in the rat, comparison of data based on blood samples from the cut tail and a cannulated femoral artery □ Pharmacokinetics—acetaminophen and antipyrine in the rat, comparison of data based on blood samples from the cut tail and a cannulated femoral artery □ Microsphere technique—pharmacokinetics in the rat, comparison of data based on blood samples from the cut tail and a cannulated femoral artery

The development in recent years of a multitude of sensitive drug assays in microsamples of blood and a variety of techniques for repeated blood sampling have made it possible to perform pharmacokinetic studies in individual animals as small as mice, rats, and guinea pigs. Whereas published methods for drug assays are routinely validated

on toxicity or survival times in leukemic mice would be expected to result from phenobarbital pretreatment (3, 4). It is not known if the hexyl ether of *p*-*N*,*N*-bis(2-chloroethyl)aminophenol undergoes (ω-1)-hydroxylation, but if it were to occur, these results suggest a metabolite similar in toxicity and antitumor activity to compound V.

A regression analysis was performed on survival data from the control and pretreated groups (Table IV). The analysis, taken over the entire range of doses, failed to show significant trends for any of the compounds tested. Negative trends in the ascending points for data sets from compounds II and IV indicate a decrease in the antitumor effectiveness for the pretreated mice. Crossover trends at the lowest and two highest doses for compound III precluded significance. The medium level doses were not tested. No trend could be established for compound V.

Antipyrine and Acetaminophen Kinetics in the Rat: Comparison of Data Based on Blood Samples from the Cut Tail and a Cannulated Femoral Artery

WENCHE M. JOHANNESSEN *[x], INGVALD M. TYSSEBOTN [‡], and JARLE AARBAKKE *

Received September 3, 1981, from the **Department of Pharmacology, Institute of Medical Biology, University of Tromsø, N-9001 Tromsø, Norway* and the [‡]*Institute of Physiology, University of Bergen, Årstadveien 19, N-5000 Bergen, Norway.* Accepted for publication February 1, 1982.

Abstract □ Antipyrine and acetaminophen kinetics were determined from concentration data obtained by simultaneous blood sampling from the cut end of the tail and a cannulated femoral artery in the rat. Significant differences in concentrations and kinetics for both drugs were found by comparison of the two sampling sites. The hypothesis that the differences were due to a low tail blood flow was tested. The tail blood flow was measured with a microsphere technique, and tail antipyrine concentrations were calculated from the relationship between arterial antipyrine concentration, tail flow, and time for comparison with the observed antipyrine concentrations. Mean blood flow of the rat tail was 0.02 ml/min/ml tail tissue at 22°, which was 8.8 and 0.9% of the liver and kidney flow, respectively. Tail flow increased more than twofold by elevation of the tail temperature to 37°. The calculated tail antipyrine concentration *versus* time curve showed a very close correspondence to the observed antipyrine tail concentration *versus* time curves. The results show that tail flow is a major determinant of antipyrine tail concentration in the rat. Kinetic data based on blood samples from the cut end of the tail, therefore, should be interpreted with caution.

Keyphrases □ Antipyrine—pharmacokinetics in the rat, comparison of data based on blood samples from the cut tail and a cannulated femoral artery □ Acetaminophen—pharmacokinetics in the rat, comparison of data based on blood samples from the cut tail and a cannulated femoral artery □ Pharmacokinetics—acetaminophen and antipyrine in the rat, comparison of data based on blood samples from the cut tail and a cannulated femoral artery □ Microsphere technique—pharmacokinetics in the rat, comparison of data based on blood samples from the cut tail and a cannulated femoral artery

The development in recent years of a multitude of sensitive drug assays in microsamples of blood and a variety of techniques for repeated blood sampling have made it possible to perform pharmacokinetic studies in individual animals as small as mice, rats, and guinea pigs. Whereas published methods for drug assays are routinely validated

0022-3549/82/1200-1352$01.00/0

with respect to their sensitivity, specificity, and precision, methods for blood sampling in small animals mostly have been evaluated as to their feasibility in practical laboratory work (1, 2). The widespread use of small animals in pharmacokinetic studies of old and new drugs, however, has created a need for precise information also of the reproducibility and validity of the methods used for blood sampling. Recently, the reproducibility and validity of pharmacokinetic data obtained with a surgical procedure for cannulation of an artery and vein in the rat was investigated (3).

The present study was undertaken to investigate a frequently employed nonsurgical method: sampling of blood from the cut end of the rat tail. Assuming a low flow to the rat tail (4), both theoretical considerations (5–8) and previous experience (9) raised doubts about the validity of tail concentration data. Significant differences in antipyrine and acetaminophen concentrations in blood sampled simultaneously from the cut end of the tail and a cannulated femoral artery are presented. A low blood flow of the rat tail is demonstrated, to which the differences in tail and arterial antipyrine concentrations are attributable.

EXPERIMENTAL

Animals and Operation—Male Wistar rats[1] (150–400 g) were used. All surgery was performed in fluanisone/fentanyl[2] anesthesia (6.6/0.13 mg/kg sc) in the evening, and the experiments were carried out the next day. Arteries and veins were cannulated with polyethylene tubing[3] previously filled with 0.2 ml of heparinized (100 IU/ml) 0.9% NaCl, with the indwelling part of the tubing having been stretched to reduce its diameter and lubricated with silicone oil to facilitate insertion. For pharmacokinetic experiments a femoral artery and a femoral vein were cannulated; for blood flow measurements, the right carotid and a femoral artery were cannulated. The tubing was secured and transferred dorsally through a subcutaneous tunnel and made accessible through a skin perforation. The rats were placed in restraining cages[4] and allowed free access to food and water. Sampling of blood from the tail was performed after removal of its distal part (0.5 cm) with a sharp scalpel by a previous method (10), but without prewarming of the rat and occlusion of the lateral tail veins. The tail was allowed to bleed freely, usually a few seconds after blood sampling, and no hemostat was applied. Repeated bleeding was obtained by removal of the blood clot from the end of the tail and the samples collected in heparinized capillary tubes.

Pharmacokinetic Experiments—Experiments were carried out in unanesthetized rats. The test drugs, dissolved in 0.6–0.9 ml of physiological saline, were infused *via* the catheter in the femoral vein. The infusion period (30 sec) was immediately followed by flushing of the catheter with 0.3 ml of saline. An equal dose of [^{14}C]antipyrine[5] and [^{3}H]acetaminophen[6] was given (15 mg/kg, 1–2 μCi/animal). Blood samples (0.1 ml) were drawn from the cannula in the femoral artery and the cut end of the tail. After dosing with antipyrine, blood samples were drawn at 2, 4, 8, 10, 15, 20, 35, 50, 75, 100, 135, 160, and 200 min. After dosing with acetaminophen, blood samples were drawn at 2, 4, 6, 8, 12, 20, 30, 40, 50, and 60 min.

The dead space of the catheter was discarded before each sampling and replaced by saline afterwards. Concentrations of [^{14}C]antipyrine and [^{3}H]acetaminophen in whole blood were analyzed essentially by the methods described previously (11, 12). These assays have been shown to measure specifically only unchanged antipyrine or acetaminophen, with 95 and 90% recovery of the drugs from blood, respectively (11, 12).

Concentrations of antipyrine and acetaminophen were plotted *versus* time on semilogarithmic graphs. Arterial and tail blood concentrations exhibited biexponential and monoexponential decay curves, respectively. The arterial blood concentrations were analyzed according to a two-compartment open model with first-order elimination kinetics. The best fitting line was drawn by means of a formula of linear regression of the natural logarithm of concentration *versus* time based on the method of least squares.

Total clearance was calculated by:

$$\text{dose}/(A/\alpha + B/\beta) \qquad \text{(Eq. 1)}$$

where A and B are γ-intercepts of the extrapolated lines of the α- and β-phases, respectively. The central volume of distribution (V_c) was obtained by dividing the dose by $(A + B)$, and V_β was calculated by dividing total clearance by β.

Data obtained from tail blood were analyzed as follows: The area under the observed concentration curves were calculated by the trapezoidal rule and the total area under the curve by the equation:

$$AUC_{0-\infty} = AUC_{0-t} + \frac{C_t}{\beta} \qquad \text{(Eq. 2)}$$

assuming that C_t represents a point on the concentration curve where a linear terminal line can be drawn (pseudodistribution equilibrium). Total clearance was calculated by dose/$AUC_{0-\infty}$ and V_β by dividing total clearance by β.

Determination of Tail Flow—Blood flow through the rat tail was measured by means of the radioactive microsphere technique for determinations of regional blood flow (13).

Calculation of the Blood Flow—The blood flow through each piece of the tail was calculated by (14):

$$Q = \frac{F_r\, i_{x/g}}{i_\gamma} \qquad \text{(Eq. 3)}$$

where Q is the rate of the blood flow (ml/min/g of tissue); F_r is the rate of the reference sample (0.49 ml/min); i_x is the radioactivity of the piece of the tail; and i_γ is the radioactivity of the reference blood sample (gram).

Each piece of the tail (2 cm) was calculated as percent of the total tail length. In the calculations a mean value of the blood flow in the tail was used: The blood flow of each piece of the tail was summarized and divided by the number of tail pieces, and the mean value of all the rat tails was calculated. The value was transformed from milliliter per minute per gram of tail tissue to milliliter per minute per milliliter of tail tissue after correction for the density of the tail tissue.

Comparison of Calculated and Measured Tail Concentrations of Antipyrine—Concentrations of antipyrine in the tail blood were calculated by means of a formula (15) based on Fick's principle. When a freely diffusible biologically inert tracer substance is carried to a tissue by the blood, the concentration in the tissue (C_i) at time T, is determined by the arterial concentration (C_a), the tissue–blood partition coefficient (λ_i), and blood flow per unit mass of tissue volume (F_i/V_i):

$$C_i\,(T) = \lambda_i k_i\, e^{-k_i T} \int_0^T C_a e^{kt} dt \qquad \text{(Eq. 4)}$$

where $k_i = m_i F_i/\lambda_i V_i$ and m_i is the diffusion coefficient for the substance. Equation 4 was used to calculate the concentration of antipyrine in the rat tail. The following values were used for the calculation: It is assumed that the diffusion of antipyrine does not limit tissue uptake and accordingly the coefficient of diffusion (m_i) is 1 (15). The partition coefficient of antipyrine between tissue and blood (λ_i) is 1, as taken from investigations of antipyrine distribution between brain–blood (16) and kidney–blood (17). Accordingly, it is assumed that the antipyrine concentration of tail tissue is equal to the concentration of tail blood.

Experimental Design—Blood flow to the tail was measured in each unanesthetized rat placed in restraining cages at ambient temperatures of 22 and 37°. The tail was placed in a water bath of 37°, and after 30 min ~300,000 microspheres labeled with cesium 141 were infused. The tail was then transferred to a water bath of 22°, and after 30 min an approximately equal amount of microspheres labeled with strontium 85 were infused. In this way the rats served as their own controls. Room temperature was kept constant at 22°.

Experiments—The microspheres[7] (15 ± 1 μm, density 1.3) were dissolved in sucrose/epichlorohydrin polymer[8] and sterile 0.9% saline to

a concentration of ~6 × 10^5 microspheres/ml. Prior to microsphere infusion, a pump connected with the femoral artery catheter was started, sampling arterial blood at a constant rate of 0.49 ml/min for 2 min. This reference blood sample was used to calculate the blood flow to different organs according to a previous report (14). The solution of microspheres (0.5 ml) was infused *via* the cannula in the carotid artery within 15 sec, including flushing of the catheter with 0.3 ml of saline. After the last microsphere injection, rats were sacrificed by an intravenous injection of saturated potassium chloride. The tails were divided into pieces of ~2 cm, weighed, and placed in separate counting vials. The radioactivity was counted in a gamma liquid scintilation counter. The activity of the reference blood samples and both of the kidneys were also counted.

Statistical analysis—The results are given as means ±*SEM* and evaluated by paired Student's *t* test. Values for $p < 0.05$ were considered significant.

RESULTS

Pharmacokinetic Experiments—The time course of arterial and tail blood concentrations of both antipyrine and acetaminophen were widely different, and differences were also seen between the two drugs (Figs. 1 and 2). Individual tail concentration curves for both drugs were greatly variable, as indicated by the high standard error of the mean in the early phases of the experiment. After intravenous infusion of antipyrine, arterial concentrations showed the expected biexponential decline. Tail concentrations, however, increased until 40–60 min after the end of infusion. Acetaminophen concentrations showed a biexponential decline both in arterial and tail blood. Within the first 6 min after antipyrine infusion, the mean ratio of arterial to tail concentration decreased from 3 to 1.5. Mean arterial values were significantly different from mean tail values 0–15 min and >75 min after infusion ($p < 0.05$). Crossing of the curves took place 40–60 min after infusion. After 180 min the ratio of arterial to tail concentration was further decreased to 0.67. Corresponding values for acetaminophen concentrations for the first 6 min were 1.5, and after 60 min 0.5. Crossing of the acetaminophen curves was seen 12–20 min after infusion. All mean arterial concentrations of acetaminophen measured were significantly different from corresponding tail concentrations ($p < 0.05$).

Comparison of data based on arterial and tail concentrations of antipyrine showed statistically significant differences ($p < 0.05$) in the following pharmacokinetic variables (Table I). The biological half-life ($t_{1/2}\,\beta$) calculated from tail concentrations was higher by 47.5% compared with calculations based on arterial data, and the apparent elimination rate constant β was lower by 24%. Total clearance for antipyrine based on tail data was lower by 29.5% compared with arterial data. Significant changes were also found for the calculated variables of acetaminophen (Table I). The value for $t_{1/2}\,\beta$ based on tail blood data was higher by 46% compared with arterial blood data and was reduced by 46% for tail blood

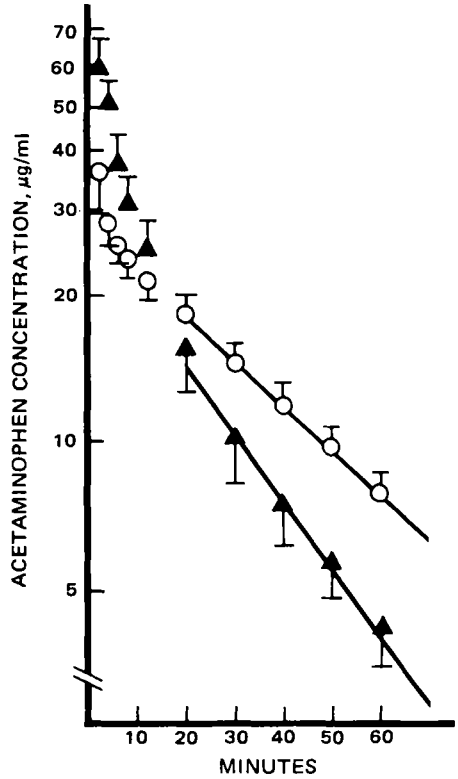

Figure 2—*Concentrations of acetaminophen after administration of 15 mg/kg iv in blood sampled simultaneously from the cut end of the tail (○) and from a cannulated inguinal artery (▲). Values are mean ± SEM (n = 5).*

data. In addition, the intercept of the extrapolated β phase, B, was lower by 11% for the tail blood data compared with arterial blood data. Also, the apparent volume of distribution, V_β, was significantly smaller with tail blood concentrations (35%).

Determination of Tail Blood Flow—The mean tail blood flow for five rats is shown as a function of the length of the tail in Fig. 3. The flow at an environmental temperature of 37° was significantly larger than the flow at 22° ($p < 0.05$).

Comparison of Calculated and Measured Tail Concentrations of Antipyrine—The mean blood flow of the tail of individual rats was calculated after correction for the density of the tail tissue (1.1 g/ml)[9]. The mean tail flow of five rats was then calculated. Tail blood flow at 37° was 5.0 ± 2.2 × 10^{-2} ml/min/ml tail tissue and at 22° 2.05 ± 0.93 × 10^{-2} ml/min/ml tail tissue. Figure 4 shows mean values of antipyrine arterial concentrations ($n = 3$) and calculated tail antipyrine concentrations at 37 and 22°. The time course of the calculated antipyrine tail concentration (Fig. 4) was grossly similar to actually measured concentrations presented in Fig. 1. Like measured tail concentrations, calculated tail concentrations were less than half the arterial concentration values at the earliest time points. Crossing of the lines likewise was seen 40–60 min after infusion.

DISCUSSION

The present study demonstrates that calculations based on drug concentration data from tail blood may give rise to pharmacokinetic values significantly different from values calculated from arterial blood samples. If it is assumed that rat arterial concentrations represent true kinetics, the use of rat tail concentrations may introduce significant errors in the pharmacokinetic calculations.

Although the pharmacokinetic data of antipyrine calculated from arterial concentrations are in accordance with values reported from other laboratories using different techniques (18, 19), it would be very difficult to prove that arterial blood data represent true kinetics in the rat. Serial sampling of arterial blood from individual rats will always require some kind of cannulation procedure. The stress imposed by the surgical pro-

[9] Obtained by dividing tail weights ($n = 3$) by the volume of water displaced.

Table I—Antipyrine and Acetaminophen Kinetics Based on Arterial and Tail Data [a]

	Site of Blood Sampling	Cl_T, ml min^{-1} kg^{-1}	β, 10^{-3} min^{-1}	$t_{1/2}\beta$, min	$\sqrt{\beta}$, liter kg^{-1}
Antipyrine	Artery	6.4 ± 0.4	5.4 ± 0.4	131 ± 11	1.18 ± 0.06
	Tail	4.5 ± 0.6[b]	4.1 ± 0.6[b]	194 ± 37[b]	1.15 ± 0.13
Acetaminophen	Artery	12.5 ± 1.0	33.0 ± 2.5	21.6 ± 1.8	0.39 ± 0.04
	Tail	13.1 ± 2.0	21.2 ± 1.4[b]	33.4 ± 2.6[b]	0.60 ± 0.09[b]

[a] The pharmacokinetic variables were calculated from arterial and tail concentration data in blood samples drawn simultaneously (see *Experimental*). Values are means ± *SEM* (n = 6, antipyrine; n = 5, acetaminophen). [b] Significantly different from arterial data ($p < 0.05$).

cedure (20) may influence significantly drug kinetics (21–23). The fact that antipyrine and acetaminophen kinetics were not reproducible in untreated animals over a short period of time (3) probably reflects that at least some aspects of normal physiology with relevance to pharmacokinetics are difficult to maintain even for short periods in cannulated rats.

There is only sparse information in the literature with respect to rat tail flow. Therefore, the rat tail flow was investigated by means of the radioactive microsphere technique for determination of regional blood flow (13). The following requirements must be fulfilled for the method to provide an exact measure of regional blood flow: First, there should be homogeneous mixing of microspheres with the arterial blood. According to previous reports (24, 25) this need will be met if the left ventricle is used as the site of injection. Verification of uniform mixing in the left ventricle can be obtained by measuring the left and right kidney blood flow (milliliters per minute per gram). Second, the microspheres must not recirculate. Spheres of 15 μm are shown to be trapped precapillary in the first circulation with only 1–2% ending in the lung capillaries of the rat, hence, they satisfy this requirement (26). Third, blood flow must not be affected by microspheres. Repeated microsphere injections in the same rats using different labels should not give significant changes in cardiac output fractions. Using 15-μm spheres, unchanged distribution was found (27) after the second microsphere injection in rats. In the present investigation, spheres of this size were used, and the present dose of 15-μm spheres have been shown not to interfere with this hemodynamic variable in the rat (14, 28). Fourth, the number of microspheres injected should give at least 400 in each tissue sample to avoid random error (24).

A previous study (4) reported flow values with a less sensitive technique at 17 and 33° that were two- and eightfold higher than the present values measured at 22 and 37°, respectively. However, the data presented here demonstrate that the tail blood flow is very low and represents only a minor fraction of the cardiac output. By comparison, rat tail flow in this study was only 8.8 and 0.4% of the rat liver and kidney flow values reported in a study using the same microsphere technique (28). This explains why tail concentrations lag behind arterial concentrations when the latter change rapidly. If tail flow is increased, for instance by elevation of tail temperature, the lag time will be reduced as shown in Fig. 4.

The close correspondence of the observed and calculated antipyrine tail concentrations strongly suggests that the assumption made for the theoretical relationship between tail concentrations, arterial concentrations, and time were correct; *i.e.*, the coefficient of diffusion (m_i) and the partition coefficient of antipyrine between tissue and blood (λ_i) are 1 (15–17), and accordingly, the organ blood flow becomes the rate-limiting factor. The different ratios observed between arterial and tail concentrations for antipyrine and acetaminophen (Figs. 1 and 2) could reflect that distribution properties of acetaminophen influence tail concentrations of the drug to a greater extent than the corresponding properties of antipyrine.

The effect of temperature changes on tail flow shows that drug kinetics based on tail concentration data may significantly reflect changes in the environment in addition to changes caused by drug distribution and elimination processes. Furthermore, intersubject differences in sensitivity of the tail to environmental factors may explain the great variation in the shape of antipyrine and acetaminophen tail concentration curves shortly after drug injection.

The variation of tail kinetics between individual rats contrasts sharply with the lack of variation observed within individual animals when antipyrine kinetics were retested after intervals of several weeks using blood samples taken >60 min after antipyrine infusion (9, 11, 29).

These observations suggest that by strict standardization of the experimental conditions, tail flow can be reproducible from one experiment

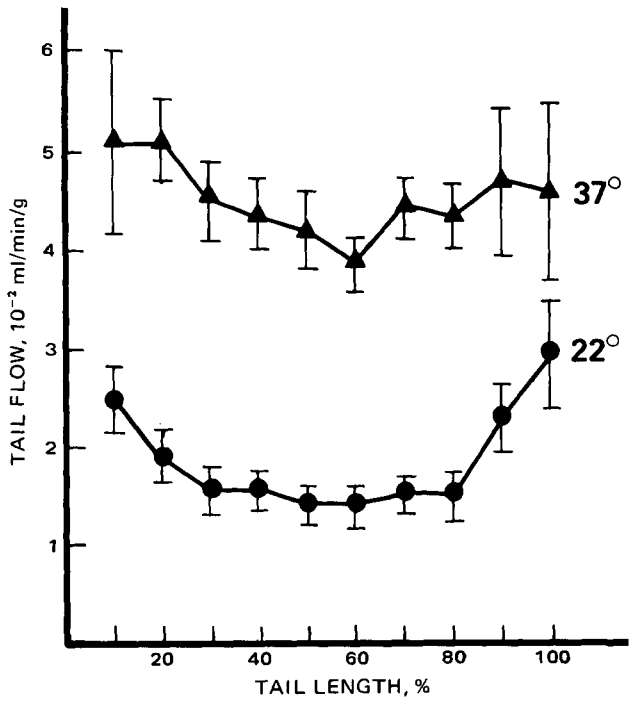

Figure 3—*Blood flow through the rat tail measured by means of microsphere technique at environmental temperatures of 22 (●) and 37° (▲). Values are mean ± SEM (n = 5). From left to right is from the tip to root of the tail.*

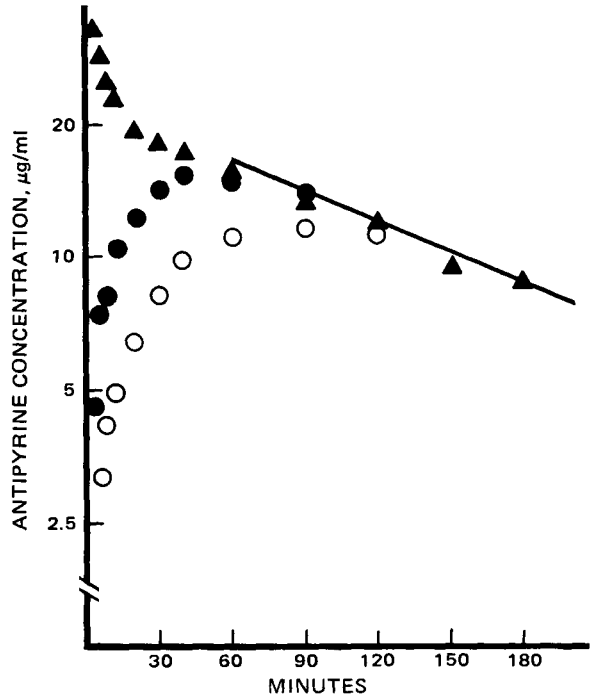

Figure 4—*Concentrations of antipyrine after administration of 15 mg/kg iv in blood sampled from a cannulated inguinal artery (▲) and calculated concentrations of antipyrine in tail tissue at 22° (○) and at 37° (●) (n = 3).*

to another in untreated rats. Problems arise, however, when the method is used to detect changes in pharmacokinetics by some experimental factors. Although the tail method detected changes in antipyrine kinetics by short-term, low-dose treatment of phenobarbital (11) and long-term treatment with ethanol (9), interpretation of data is obscured by possible influences of the treatment on tail blood flow and tail antipyrine distribution. Further investigations of such effects on drug kinetics, therefore, should include *in vitro* studies (9) or kinetic studies with the use of arterial blood samples.

Evaluation of Chemical Analysis for the Determination of Solasodine in *Solanum Laciniatum*

P. G. CRABBE ‡ and C. FRYER *x

Received September 29, 1981, from the *Department of Chemical Engineering, Monash University, Clayton, Victoria, Australia, 3168.* Accepted for publication February 5, 1982. *Present address: Fluor Australia Pty. Ltd., Melbourne, 3001, Australia. ‡Present address: Department of Chemical and Materials Engineering, University of Auckland, New Zealand.

Abstract □ A detailed study of a method for solasodine analysis has been carried out and the suitability of chemical analysis for solasodine determination in plant material evaluated. A number of problems with the analytical isolation of solasodine and its subsequent colorimetric determination have been highlighted: oven drying of plant material >100° leads to solasodine loss; cell disruption of the dry plant material is required if complete and rapid extraction of solasodine is to take place; hydrolysis of plant extract residues in >1 *N* acid leads to solasodine loss; the colorimetric procedure is more temperamental than past methods have indicated, especially with regard to the specificity of the reaction and the instability of the complex.

Keyphrases □ Solasodine—steroidal alkaloid from *Solanum laciniatum*, colorimetric determination by evaluation of chemical analysis □ Steroids—colorimetric determination of the alkaloid, solasodine, in *Solanum laciniatum* □ Colorimetry—determination of solasodine in *Solanum laciniatum*

Since problems arose 6 or 7 years ago with the supply, cost, and steroid content of *Dioscorea*, the source of diosgenin for steroid drug production, there has been renewed interest in alternative raw materials, including solasodine from plants of the genus *Solanum*. This steroidal alkaloid occurs in *S. aviculare* and *S. laciniatum* as the glycosides, solasonine and solamargine.

As part of a study into the production of solasodine from *Solanum* plant material, chemical analysis was considered for the determination of solasodine and its related species. Several important observations were made in the course of this investigation concerning both the isolation of solasodine from the plant (sample preparation, extraction, and hydrolysis) and the subsequent determination of solasodine using colorimetry. Chemical analysis was found not to be suitable for this study, and subsequently, a procedure using high-pressure liquid chromatography was developed (1). However, chemical analysis is suitable for certain purposes and has the advantage of not requiring expensive equipment. Matters concerning the isolation of solasodine from the plant material are important in solasodine analysis in general (including instrumental analysis) and in commercial solasodine production.

Previous methods for chemical analysis of solasodine

to another in untreated rats. Problems arise, however, when the method is used to detect changes in pharmacokinetics by some experimental factors. Although the tail method detected changes in antipyrine kinetics by short-term, low-dose treatment of phenobarbital (11) and long-term treatment with ethanol (9), interpretation of data is obscured by possible influences of the treatment on tail blood flow and tail antipyrine distribution. Further investigations of such effects on drug kinetics, therefore, should include *in vitro* studies (9) or kinetic studies with the use of arterial blood samples.

Evaluation of Chemical Analysis for the Determination of Solasodine in *Solanum Laciniatum*

P. G. CRABBE ‡ and C. FRYER *x

Received September 29, 1981, from the *Department of Chemical Engineering, Monash University, Clayton, Victoria, Australia, 3168.* Accepted for publication February 5, 1982. *Present address: Fluor Australia Pty. Ltd., Melbourne, 3001, Australia. ‡Present address: Department of Chemical and Materials Engineering, University of Auckland, New Zealand.

Abstract □ A detailed study of a method for solasodine analysis has been carried out and the suitability of chemical analysis for solasodine determination in plant material evaluated. A number of problems with the analytical isolation of solasodine and its subsequent colorimetric determination have been highlighted: oven drying of plant material >100° leads to solasodine loss; cell disruption of the dry plant material is required if complete and rapid extraction of solasodine is to take place; hydrolysis of plant extract residues in >1 *N* acid leads to solasodine loss; the colorimetric procedure is more temperamental than past methods have indicated, especially with regard to the specificity of the reaction and the instability of the complex.

Keyphrases □ Solasodine—steroidal alkaloid from *Solanum laciniatum*, colorimetric determination by evaluation of chemical analysis □ Steroids—colorimetric determination of the alkaloid, solasodine, in *Solanum laciniatum* □ Colorimetry—determination of solasodine in *Solanum laciniatum*

Since problems arose 6 or 7 years ago with the supply, cost, and steroid content of *Dioscorea*, the source of diosgenin for steroid drug production, there has been renewed interest in alternative raw materials, including solasodine from plants of the genus *Solanum*. This steroidal alkaloid occurs in *S. aviculare* and *S. laciniatum* as the glycosides, solasonine and solamargine.

As part of a study into the production of solasodine from *Solanum* plant material, chemical analysis was considered for the determination of solasodine and its related species. Several important observations were made in the course of this investigation concerning both the isolation of solasodine from the plant (sample preparation, extraction, and hydrolysis) and the subsequent determination of solasodine using colorimetry. Chemical analysis was found not to be suitable for this study, and subsequently, a procedure using high-pressure liquid chromatography was developed (1). However, chemical analysis is suitable for certain purposes and has the advantage of not requiring expensive equipment. Matters concerning the isolation of solasodine from the plant material are important in solasodine analysis in general (including instrumental analysis) and in commercial solasodine production.

Previous methods for chemical analysis of solasodine

0022-3549/82/1200-1356$01.00/0

have been reviewed. In particular, a colorimetric procedure (2) has been studied; analytical scale sample preparation, extraction of solasodine glycosides, hydrolysis, and determination of solasodine by methyl orange complexing also have been evaluated.

BACKGROUND

In *Solanum* species, steroid alkaloids constitute only 0–5% of the dried plant, making it necessary to determine these components in the presence of a large amount of inert material. In most procedures for determination of solasodine in *Solanum*, solasodine is separated from the plant matrix by selective extraction, then purified before analysis.

Solasodine must be isolated in a relatively pure form before its determination. There is only one reported method in which plant material is analyzed directly for solasodine without extraction or purification steps (3). In all other reported methods, a fairly standard procedure is followed involving sample preparation, extraction of glycosides, and hydrolysis to the aglycon. Because drying stabilizes the solasodine content of the plant material, most procedures start with dry material, although fruits have often been analyzed fresh. Refrigeration has also been used and gives comparable solasodine contents to oven drying of samples at temperatures <100° (4). Oven drying of samples >100° may lead to loss of solasodine (4).

It is normal to crush the dried plant material before extraction. There are reports which suggest that as the average particle size is decreased, the amount of solasodine extracted increases (5, 6). Also, defatting the dry powdered plant material with light petroleum prior to extraction has been shown to reduce significantly the error in the analysis (7).

Solvents used for extraction include dilute aqueous acids, alcohols, and acidified alcohols. Dilute aqueous acid is more specific than alcohols and extracts fewer inert materials. However, if solasodine is present in the plant in partial glycoside or aglycon form because of poor drying and storage, it may not be extracted by dilute aqueous acid, and an alcohol solvent will be more suitable. It has been shown (8) that due to this breakdown of glycosides, previous procedures (9–11) all gave incomplete extraction, and this modified method (8), avoiding acid extraction, gave 30–50% greater solasodine contents for the same material.

Normally solasodine is analyzed as the aglycon, since hydrolysis is a useful purification step, especially if aqueous extraction is used. Increased acid concentration gives increased hydrolysis rates but losses of solasodine have been reported when plant extracts are hydrolyzed with strong acid (4, 7). Many methods combine the extraction and hydrolysis step into a single, direct hydrolysis. Completeness of extraction is ensured due to the more rigorous extraction conditions, and because the less soluble aglycon is produced, mother liquor losses during precipitation, filtration, and washing will be lower. However, such a procedure will extract more inerts, and because the hydrolysis is carried out in the presence of the plant extract, losses of solasodine may occur.

Isolation of solasodine as discussed so far aims only at determining the total steroid base content. To make the isolation procedure more specific, a chromatographic separation (paper, thin-layer, or ion-exchange chromatography) can be introduced at some stage before the final determination is made. If glycoalkaloids are to be distinguished, then separation should follow hydrolysis. In some cases *in situ* colorimetric analytical procedures have been developed using densiometry (12–19). Such methods are rapid but require continual calibration and are subject to large errors.

Three major methods have been used for determination of the amount of solasodine recovered: gravimetric, titrimetric, and colorimetric. Colorimetric determination is the method most widely used. Although there are many dyes that may be used (20, 21), bromthymol blue and methyl orange have been the usual dyes employed.

None of the reported procedures for solasodine determination has been systematically investigated to check for errors arising at each stage in the procedure. Some overall tests have been applied using repeated analysis of plant material to determine reproducibility. This approach identifies random but not systematic errors. A few investigators have used addition of pure solasodine to determine the percentage recovery of solasodine, but this technique will not identify losses during sample preparation and extraction.

In the present investigation, the Birner method (2) for solasodine analysis was subjected to systematic evaluation. The basic procedure of this method was followed, but in a scaled-up form so that larger initial plant samples could be used (1.0 instead of 0.1 g). Three considerations of the Birner method were made: to ensure that the procedure was at optimum conditions, to verify that the solasodine determined was the total solasodine content of the plant material, and to estimate the reproducibility of the method. To achieve these objectives it was necessary to study each step of the method separately and to work backwards through the method starting at the colorimetric assay.

EXPERIMENTAL

The reagents specified previously (2) were used. Standard solutions of solasodine (20 and 100 μg/ml in 20% acetic acid), solasonine (100 and 500 μg/ml in water), and solasodiene (100 μg/ml in ethanol) were prepared from purified compounds. In all cases *S. laciniatum*[1] plant material was used.

Analytical Procedure—Leaf material was oven dried at 70–80° to constant weight, then ground to <75-μm sieve size. This material was divided into six 1.000-g portions, and each portion was analyzed. For the analysis, each portion was refluxed with ethanol (70 ml) for 40 min and then filtered. The filtrate and residue washings were made up to 100 ml with ethanol. An aliquot (20 ml) was evaporated to dryness and 1 *N* HCl (7.5 ml) was added. The mixture was heated on a steam bath (temperature 95–98°) for 5 hr to effect hydrolysis. The solution was cooled and neutralized with 1 *N* NaOH. Glacial acetic acid (5 ml) was added and the solution filtered and made up to 25 ml with water. Aliquots of this hydrolysate (2 ml) were then taken and the solasodine content determined colorimetrically. For the standard solution, an aliquot of hydrolysate plus sodium acetate–acetic acid buffer (5 ml, pH 4.7) and aqueous methyl orange (1.0 ml) were added to chloroform (5 ml) in a separating funnel (100 ml) and the resulting mixture shaken for 4 min. The chloroform layer was separated and dried over anhydrous sodium sulfate and the absorbance read in a spectrophotometer at 425 nm. The same procedure was carried out for the reference solution as for the standard solution, but without added methyl orange.

Instability of the Complex—The solasodine–methyl orange complex formed from 1.0 and 2.0 ml of the 100-μg/ml standard solasodine solution was kept in a capped cuvet and either exposed to room light or left in the spectrophotometer. The absorbance at 425 nm was measured in the spectrophotometer after various time periods.

Hydrolysis of Plant Extract—A standard ethanol extract solution was prepared by refluxing dry leaf material (10 g) in ethanol (1000 ml) for 45 min. Portions of this solution (20 ml) were refluxed with aqueous acid (7.5 ml) for the given period; the solution was cooled and neutralized with equal normality base (7.5 ml) and the solasodine content was determined.

Hydrolysis of Standard Solasonine Solution—For 2 *N* HCl hydrolysis, solasonine (3.2 ml of 500-μg/ml solution) was refluxed on a steam bath with 3.48 *N* HCl (4.3 ml) for the specified period. For 1 *N* HCl hydrolysis, solasonine (3.2 ml of 500-μg/ml solution) with 1.74 *N* HCl (4.3 ml) was used.

Hydrolysis of Plant Extract and Standard Solasodiene—Standard plant extract solution (20 ml) plus solasodiene (5 ml of 100 μg/ml) were evaporated to dryness and 2 *N* HCl added (7.5 ml). The solution was refluxed for the given period then cooled and neutralized with 2 *N* NaOH. The absorbance of the conjugated double bonds of solasodiene at 240 nm was found to be linear and was used to determine the solasodiene content of the final chloroform extract. Reference solution was pure chloroform. For the zero hydrolysis time case, the residue was shaken with the acid for 2 min at room temperature before being neutralized.

Effect of Extraction Time on Solasodine Yield from Crushed Leaf Material—A uniform sample of dry leaf material in the sieve range of 0.5 to 1.0 mm was prepared. Samples (1 g) were refluxed with 70 ml of ethanol for set periods.

Effect of Solid/Solvent Ratio on Extracted Solasodine—The leaf material was oven dried at 70–80° and ground to pass a 1-mm sieve. Samples of 0.25, 0.5, 1.0, and 2.0 g were taken and repeatedly extracted. For each extraction the sample was refluxed in 70 ml of 95% ethanol for 40 min, after which the solution was allowed to cool and settle and the extract solution decanted. The residue leaf material was washed with 95% ethanol and the washings decanted to make the extract solution up to 100 ml. An additional 70 ml of 95% ethanol was then added immediately

[1] The plant material was obtained from plants grown from seeds collected from plants identified as *S. laciniatum* Ait. by Dr. D. E. Symons (Waite Agricultural Research Institute, South Australia, Voucher No. ADW 47361). Seed samples JMS 75/176 are held by Dr. Fryer.

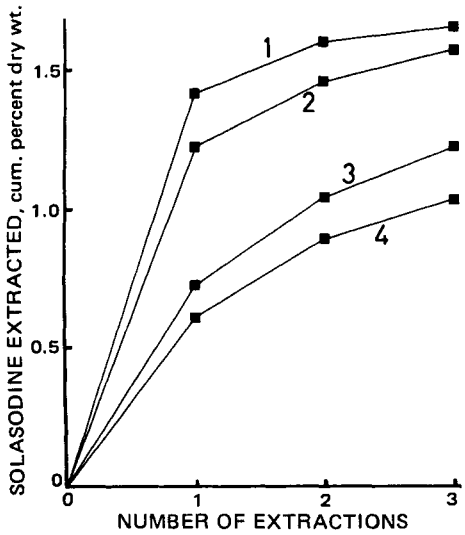

Figure 1—*Combined effect of added base and size reduction on solasodine extracted from dry leaf material. Key: (1) ethanol, ground < 0.25 mm; (2) ethanol, 2% triethylamine, ground < 0.25 mm; (3) ethanol, 2% triethylamine, crushed < 2.812 mm; (4) ethanol, crushed < 2.812 mm.*

to the damp leaf material in the flask and the extraction repeated. Between extractions 4 and 5 of the 1.0-g and 2.0-g samples, the residue leaf material was allowed to stand for 1 week while the analysis of the previous extractions was obtained. During this time the residue dried out completely.

Effect of Particle Size on Extracted Solasodine—A sample of leaf material dried at 70–80° was taken and broken into pieces by crushing. Material in the screen size range of 2.812–1.204 mm was retained, with as much of the leaf stalk material as possible being removed. A portion of this material was put aside and the remainder divided into four quantities. These were either crushed or ground in a mortar and pestle to pass 1.004-, 0.599-, 0.250-, and 0.075-mm screen sizes. This gave five samples of different average particle size, as indicated in Fig. 1. The averge sizes reported are volume average diameters based on sieve analysis, the particle volume estimation allowing for the platelet shape of the leaf particles as described previously (22). Portions of each sample were repeatedly extracted and analyzed as described in the *Analytical Procedure* section. The results were corrected to allow for the contribution of fines (<75 μm) in the samples.

Microscopic observation of the samples, numbered 1–5 as in Fig. 1, revealed: sample 1, large pieces of leaf with no fines; samples 2 and 3, large pieces of leaf plus material of various sizes including cell-size particles; sample 4, mostly fine particles of cell size but also small leaf particles consisting of several cells together (<50 cells); and sample 5, completely ruptured cell material.

The cell structure could be seen clearly on the flat surface regions of the leaf material. Ruptured cells only occurred along the thin edges of the leaf material and not on the flat surface regions. By counting cells along a linear dimension (*e.g.*, 1-mm length), it was found that the average cell size was 40 ± 5 μm for the dried leaf material.

Effect of Added Acid–Base on Extracted Solasodine—The leaf material used was the same as that in the section, Effect of Solid/Solvent Ratio on Extracted Solasodine. Three 1-g portions of this material were taken for repeated extraction and analysis as described in the previous two sections. One portion was repeatedly extracted with 70 ml of ethanol and 1.4 ml of glacial acetic acid (2% v/v acetic acid in ethanol); the second with 70 ml of ethanol and 3.5 ml of glacial acetic acid (5% v/v acetic acid in ethanol); and the third with 70 ml of ethanol and 5 ml of concentrated ammonia solution (2% v/v ammonia/ethanol). Each extraction was carried out under reflux for 40 min.

Combined Effect of Particle Size and Added Base on Extracted Solasodine—Leaf material dried at 70–80° was divided into two portions. One portion was crushed to pass a 2.812-mm sieve size, the other ground to pass a 0.25-mm sieve size. Portions (1 g) of each of these size fractions were repeatedly extracted and analyzed using both 70 ml of ethanol and 1.37 ml of triethylamine. Each extraction was carried out for 40 min under reflux. When the solvent was removed from the portion of the extract solution taken for hydrolysis, care was taken to remove all the triethylamine (bp < 90°) so that it would not interfere in the subsequent colorimetric analysis.

Effect of Extraction Time on Solasodine Yield from Ground Leaf Material—A uniform sample of dry leaf material was ground to pass a 90-μm sieve size. Samples (0.8 g) were refluxed with 60 ml of methanol for set periods. For the zero-extraction time case, the sample was shaken with the methanol for 30 sec at room temperature before filtering.

Effect of Oven Drying Temperature on Solasodine Yield—Leaf material from the same plant and of a similar size and age was divided into six samples of 100–150 g each and dried at various temperatures in an air-circulated oven. Once dry, each leaf sample was ground to pass a 90-μm sieve before extraction. Extraction was a 40-min reflux of 1.0 g/70 ml of ethanol.

RESULTS AND DISCUSSION

Colorimetric Analysis—Results of the colorimetric analysis procedure outlined above showed that the absorbance of the solasodine–methyl orange complex obeys Beer's law over the range of 2–50 μg/ml.

The original method (2) involves no reference for the absorbance readings. Normal plant colored matter, soluble in chloroform, is carried through the procedure and gives absorbance in the <450-nm region. It was found that the use of a reference solution, similar to the standard solution but without the methyl orange, eliminated this effect. The mass transfer of the solasodine–methyl orange complex from the aqueous to the chloroform layer is slow and was found to take up to 5 min.

The methyl orange–solasodine complex was found to be relatively unstable and several precautions must be taken. Contact with rubber, metal, or plastics gave breakdown of the complex and led to erroneous results. Because of this, the complex should be contained in clean, smooth glassware rinsed with an acetone solution of 0.5% *m*-cresol before use (4).

The complex was found to be stable in the dark for up to 3 days after formation but was unstable when exposed to room light or to light of wavelength 425 nm in the spectrophotometer. Losses ranging from 20 to 50% were observed within 20 min of exposure to these conditions, with initial rates of loss from 1 to 5%/min. To obtain reproducible results, it is essential that the time between formation of the complex and measurement of its absorbance be the same in all analysis and calibration tests.

Methyl orange was found to form complexes with amines other than solasodine, including most simple organic amines and even ammonia. Such compounds may be formed during degradation of plant material in storage. These complexes had similar absorption characteristics to the solasodine–methyl orange complex.

Hydrolysis—Only the effects of acid concentration and time on the hydrolysis were considered. Temperatures and solvent were left unchanged from the original method. It was found that, using 0.5 and 1 *N* HCl, hydrolysis was not complete until after 5-hr digestion on a steam bath. Using 1 *N* HCl and a hydrolysis time of 2 hr as in the original procedure (2), the hydrolysis is only 55–60% complete (Fig. 2). At higher acid

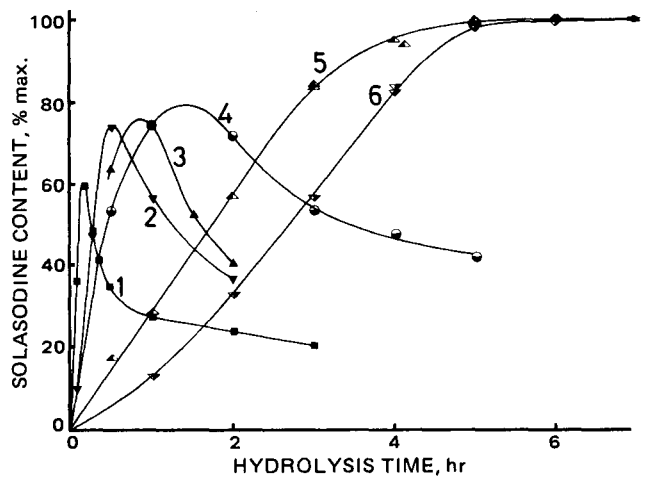

Figure 2—*Effect of acid concentration on the hydrolysis of plant extracts (solasodine contents are expressed as a percentage of the maximum solasodine content, i.e., that found after stable hydrolysis: 0.5 or 1.0 N HCl for 5 hr at 100°). Key: (1) 2.0 N HCl; (2) 1.5 N HCl; (3) 1.5 N H_2SO_4; (4) 1.25 N HCl; (5) 1.0 N HCl; (6) 0.5 N HCl.*

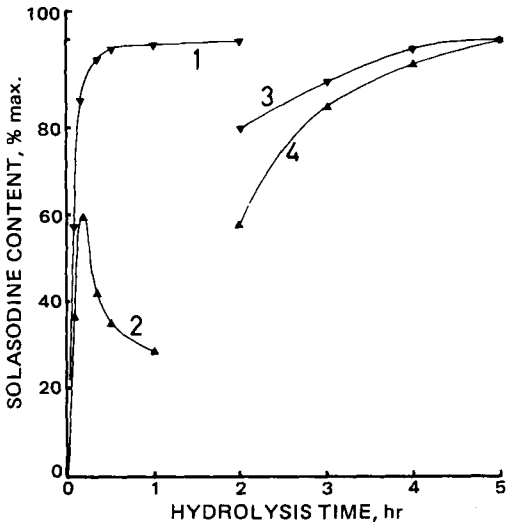

Figure 3—*Hydrolysis of pure solasodine with aqueous hydrochloric acid at 100°, compared with the similar hydrolysis of leaf extracts. Key: (1) 2 N HCl, pure solasonine; (2) 2 N HCl, plant extract; (3) 1 N HCl, pure solasonine; (4) 1 N HCl, plant extract.*

concentrations, the apparent solasodine contents did not stabilize and dropped away after reaching a maximum value. Unstable hydrolysis, as shown in Fig. 2, has only been found by two workers. Unstable hydrolysis with 2 *N* HCl but stable hydrolysis with 0.5 *N* HCl was found (4), while another report (7) indicated that apparently unstable hydrolysis with each of 4, 2, and 1 *N* HCl was found. For the 1 *N* HCl hydrolysis case in the latter study (7), the decrease of solasodine content after the maximum is reached is based on only one experimental point, and represents a <5% change in the apparent solasodine content.

To investigate further the losses of solasodine during hydrolysis, two separate trials were made. In the first experiment, hydrolysis of pure glycoalkaloid (solasonine) was carried out using 1 and 2 *N* HCl levels. The results are given in Fig. 3 and show stable hydrolysis, producing the required amount of solasodine in both cases. The comparable curves for the hydrolysis of the plant extract are reproduced from Fig. 2 for comparison. In the second experiment, 2 *N* HCl hydrolysis of the leaf extract, to which a known amount of pure solasodine was added, gave a reduction of solasodiene with hydrolysis time as shown in Fig. 4. The solasodiene added amounted to 20 μg/ml. The initial increase of solasodiene concentration to this value may be due to the leaching of the solasodiene into aqueous solution from the plant extract residue—a thin, tarry residue on the walls of the flask. The need for such leaching explains why, as

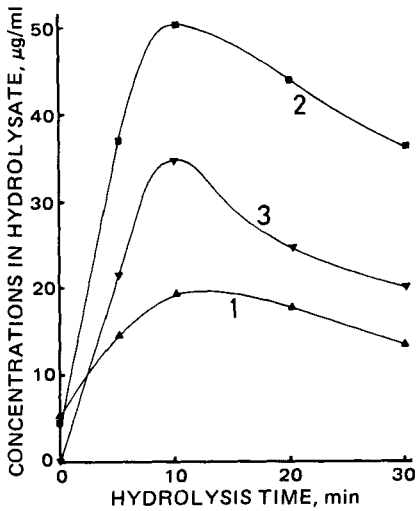

Figure 4—*Hydrolysis with 2 N HCl at 100° of a leaf extract containing added pure solasodiene compared with the similar hydrolysis of leaf extract. Key: (1) solasodiene from extract with added solasodiene; (2) total steroidal base from extract with added solasodiene; (3) solasodine from leaf extract (from Fig. 3).*

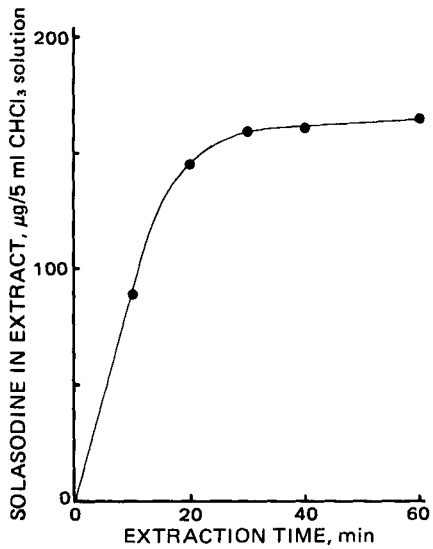

Figure 5—*Effect of extraction time on extraction of solasodine with ethanol from crushed leaf material.*

shown in Fig. 3, hydrolysis of pure solasonine occurred faster than the corresponding hydrolysis of the plant extract: The pure solasonine was being hydrolyzed in solution and no leaching was necessary. The change in total steroidal base is also shown in Fig. 4. This was determined by the normal colorimetric assay procedure and represents the total solasodine plus solasodiene content. The 2 *N* HCl hydrolysis curve from Fig. 2 is also reproduced in Fig. 4 for comparison. The sum of the lower curves approximates the upper (solasodine + solasodiene) curve.

From these two experiments, it appears that it is the formation and the subsequent further reaction of solasodiene which is causing the overall loss of solasodine (determined as total steroidal base). The further reaction of solasodiene is linked to other compounds in the plant extract and is important only >1 *N* acid. Sulfuric acid reportedly produces less solasodiene than hydrochloric acid for a given acid strength (23) but, as shown in Fig. 2, at the 1.5 *N* level, the use of sulfuric acid still does not give stable hydrolysis.

Extraction—Figure 5 shows the effect of time on extraction for uniform dry leaf material of a sieve size range of 0.5–1.0 mm. A 40-min extraction time appears adequate for this material as the curve tends to approach an upper limit after this period. For the extraction of 1 g of plant material with 70 ml of ethanol, the solubility limit of solasodine (in either glycoside or aglycon form) in ethanol is not exceeded. Because of this and the leveling-off of the curve in Fig. 5, it was initially assumed that complete extraction had taken place. However, when the residue of the plant material from the first extraction was re-extracted with ethanol as before, more solasodine was extracted, amounting to as much as 30–40% of that of the first extraction. Further extractions of this same residue yielded more solasodine; complete extraction was not taking place in a single 40-min ethanolic extraction.

To characterize further this problem of incomplete extraction, a series of extractions of the same material but with different solid/solvent ratios was carried out. The results are shown in Fig. 6. The greater the solid/solvent ratio, the less solasodine per weight of sample extracted. Even so, not all the solasodine is extracted after repeated extractions. For example, even after six repeated extractions of the 2.0-g sample, the solasodine extracted in the seventh extraction represents 4% of the total solasodine extracted. There is a discontinuity in the curves for 1.0- and 2.0-g samples between extractions 4 and 5. This corresponded to the extracted residue being allowed to stand for several days before the fifth extraction. As a result, more solasodine was extracted in the fifth extraction, but this has not altered the shape of the curve between the sixth and seventh extractions from the shape prior to the fourth extraction.

Figure 7 shows the results of Fig. 6 plotted as cumulative solasodine extracted against sample size; the total solasodine extracted per weight of sample decreases with an increase in sample size, but the total solasodine extracted increases with sample size. Thus, as the solid/solvent ratio is increased, more solasodine is extracted (per volume of solvent), but the extraction process is less efficient (per weight of solid). These trends are more important <1 g/70 ml than above this ratio.

The effect of decreasing the particle size on solasodine extraction was investigated. The results are shown in Fig. 8. Lower particle size gives

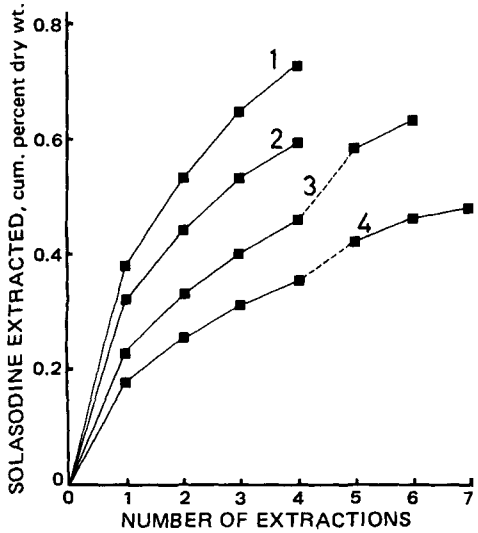

Figure 6—*Effect of altering the proportion of dry leaf material to extractant on solasodine extracted. Key: (1) 0.25 g/70 ml; (2) 0.5 g/70 ml; (3) 1.0 g/70 ml; (4) 2.0 g/70 ml.*

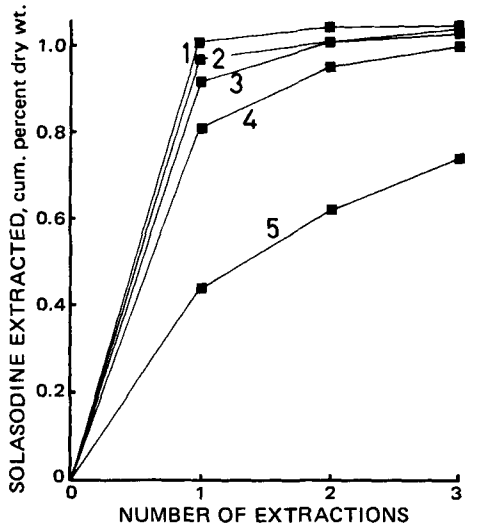

Figure 8—*Effect of average particle size,* D, *on solasodine extracted from dry leaf material. Key: (1)* D < *0.075 mm; (2)* D = *0.16 mm; (3)* D = *0.42 mm; (4)* D = *0.60 mm; (5)* D = *1.93 mm.*

increased extraction, and for the sample of the finest material, 97% of the total solasodine was obtained after a single 40-min extraction. The cell size of the dry leaf material used in this experiment was calculated at 40 ± 5 μm by viewing the material through a microscope. This means that for the material ground to pass the 75-μm sieve size, the majority of the cells are ruptured, while for the largest material [particle size (D) = 1.93 mm] only a small proportion of the cells, those along the edges of the leaf pieces, are ruptured.

It is suggested from these observations that ruptured cells have readily extractable solasodine, while the solasodine within intact cells can only be removed by much slower diffusional transport through cell walls. This would explain the shape of Fig. 5. The curve represents not a single exponential type diffusional process but the combination of two diffusional processes, one much more rapid than the other. The apparent leveling-off seen in Fig. 5, therefore, is misleading and represents the much slower diffusional process becoming dominant in the latter stages of the extraction. This also explains why in Fig. 6 the sudden jump between extractions 4 and 5 of the 1.0- and 2.0-g samples occurred. The greater time permitted to elapse before the next extraction has allowed diffusional processes to distribute the remaining solasodine uniformly throughout the plant material, enabling greater removal during the next extraction.

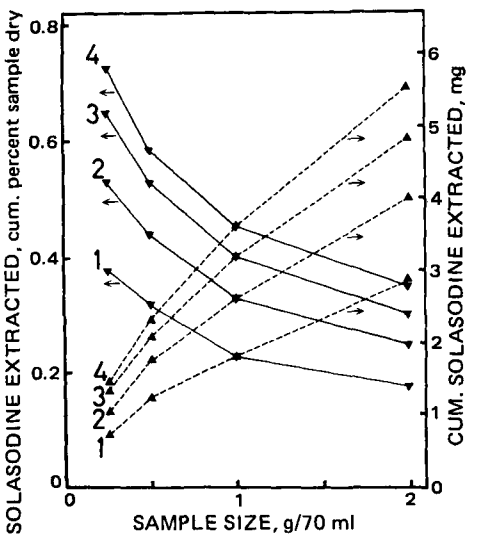

Figure 7—*Effect of altering the proportion of dry leaf material to extractant on cumulative solasodine extracted from successive extractions. Key: (1) first extraction; (2) second extraction; (3) third extraction; (4) fourth extraction; (—) sample size; (- - -) total solasodine extracted.*

If Fig. 7 is reconsidered, from the curves of cumulative solasodine extracted per weight of sample *versus* sample size, it may be seen that the effect of sample size occurs predominantly during the first extraction. During subsequent extractions the effect decreases until in the fourth extraction an approximately equal amount of solasodine per unit weight is extracted for each sample size. The shape of the curves can be attributed to an indirect effect caused by the processes being diffusion-controlled. The diffusional driving force is proportional to the difference in solasodine concentration between the plant material and the bulk solvent. At higher solid/solvent ratios, the bulk solvent concentration will increase to a higher level. Consequently, the diffusion driving force will decrease, causing less solasodine to be extracted over a given time in such cases. The effect can be expected to be greater for the first extraction, where the large proportion of the solasodine is rapidly extracted into the bulk solution from the ruptured cells. The effect becomes less important in subsequent extractions where less solasodine is extracted, and the initial rapid extraction from the ruptured cells no longer occurs.

The effect of adding acid or base to the ethanol to aid the diffusional processes was also investigated. Soaking of plant material in either acid (8, 11, 24) or base (25) prior to extraction has been shown to give higher yields of the alkaloids. The ability to improve extraction is based on the assumption that the solasodine is present in the plant as an ion pair, possibly attached to an anionic site fixed to the plant cell matrix. If this is the case, added acid will form a more mobile solasodine salt, while added base will produce the free base form of solasodine, both unattached to the plant wall. The results for added acetic acid at 2 and 5% (v/v) levels are shown in Fig. 9 for the same material as used in Fig. 6. The curve for extraction of a 1-g sample with pure ethanol is reproduced from Fig. 6 for comparison. The effect is small and possibly not significant. Added base gives a much greater effect but only for coarsely crushed material (Fig. 1). When diffusion strongly limits the extraction process (coarsely crushed material) added base helps by making the solasodine molecule more mobile, but when this diffusional limitation is eliminated (finely ground material) the added base acts only to decrease the solubility of the solasodine.

Mechanical rupture of leaf cells is not the only method of eliminating the cell wall diffusional barriers but is best suited to analytical extraction. The effect of cell disruption by freezing or by cooking under either pressure or vacuum on the diffusion of solasodine from *S. laciniatum* was studied (26); if disruption of the plant cells preceded extraction, then extraction rates, not yields, were found to be higher. The action of endogenous enzymes produces similar results to dry grinding (22). Figure 10 shows the effect of time on the extraction with methanol of dry leaf material ground to pass a 90-μm sieve; very rapid extraction of the solasodine is shown, and within 10 min all the solasodine is extracted. Even a 30-sec wash with methanol at room temperature (the zero point in Fig. 10) extracts ~80% of the total solasodine.

Sample Preparation—It is normal for a plant sample to be dried and crushed to a uniform size fraction before analysis. This stabilizes the solasodine content in the plant material and, if only a fraction of the total sample is to be analyzed, enables a representative portion to be taken.

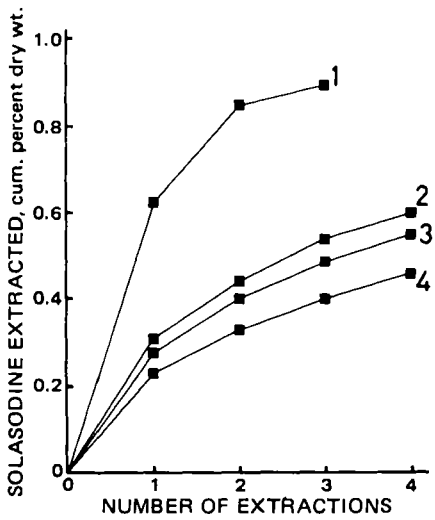

Figure 9—*Effect of added acid or base on solasodine extracted from dry leaf material. Key: (1) ethanol, 2% ammonia; (2) ethanol, 5% acetic acid; (3) ethanol, 2% acetic acid; (4) ethanol.*

The plant sample needs to be very finely ground to ensure complete extraction as already discussed. A number of workers have reported variable solasodine contents for the same material dried under different conditions (27–29). However, preliminary studies of postharvest drying (22) show no such effects and indicate that previous findings have been affected by the problem of incomplete extraction discussed above. Oven drying at 80° is recommended for analytical sample preparation. Below 75° drying rates are slow and >100° losses of solasodine occur (4). Figure 11 presents the results for the same leaf material dried at oven temperatures of 40–120°; severe reduction in extractable solasodine occurs for drying temperatures >100°. In a separate experiment, this loss of solasodine was shown to occur near the end of the drying process. The loss of extractable solasodine is accompanied by a corresponding loss of the green-colored material normally extracted by alcohol. It appears that for leaf material dried >100°, decomposition and transformation of other leaf components take place simultaneously with the drying process, and the decomposition products may restrict later extraction of the solasodine.

Reproducibility—During this study of a previously described method (2) several modifications have been made to provide a method with no systematic errors. To establish an estimate of the reproducibility of the modified method, repeated analysis of the same finely ground plant material was carried out. This enabled calculation of the sample standard deviation of the overall method (s), of the combined hydrolysis–colorimetric assay steps (s_{hc}) and of the colorimetric assay step alone (s_c) (22). The values of the sample standard deviation (expressed as a percentage of the overall mean) and their associated degrees of freedom are included

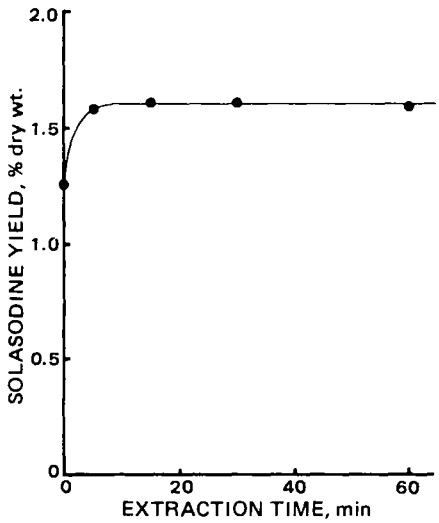

Figure 10—*Effect of extraction time on extraction of solasodine with methanol from ground leaf material.*

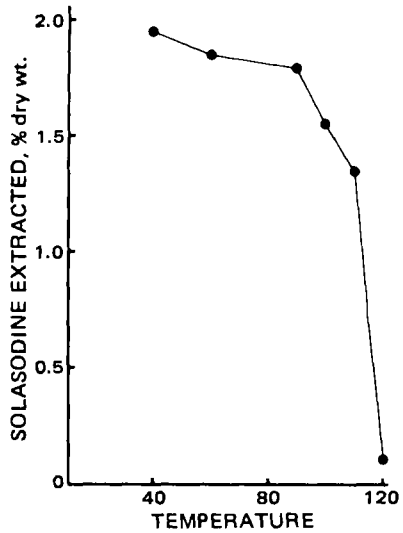

Figure 11—*Effect of drying temperature on solasodine extracted from oven-dried leaf material.*

Table I—Experimentally Determined Standard Deviations for Chemical Analysis

Procedure	Standard Deviation, %[a]	Degrees of Freedom
Colorimetric assay	$s_c = 5.6$	6
Hydrolysis and assay	$s_{ch} = 6.4$	6
Overall analysis	$s = 6.1$	10

[a] As percent of overall mean.

in Table I. From these sample standard deviations, the confidence intervals for the corresponding population standard deviations (σ, σ_{hc}, and σ_c) may be calculated. Based on the χ^2 distribution, the 90% confidence intervals for the standard deviations, expressed as percentages of the overall mean, are:

$$3.9\% < \sigma_c < 10.8\%$$
$$4.4\% < \sigma_{hc} < 12.2\%$$
$$4.5\% < \sigma < 9.7\%$$

These intervals are so large that it is difficult to draw any conclusion from the estimates of σ_c, σ_{hc}, and σ, except that the major proportion of the overall error occurs in the colorimetric assay and that the overall error in the analysis method is 4.5–9.7%. This means that the limiting feature of the method is the final colorimetric determination of solasodine, due probably to the instability of the complex.

CONCLUSIONS

For samples of *S. laciniatum*, where solasodine is the only steroidal alkaloid present, total solasodine glycosides, solasodine aglycon, and solasodiene each can be determined. The aglycons may be extracted into a nonpolar solvent such as chloroform or benzene and the separate contents of total glycosides and total aglycons determined; measurement of solasodiene content in the aglycon fraction can be made at 235 nm in a UV spectrophotometer. If chromatographic separation is incorporated [for examples see previously described procedures (30–33)] then the glycosides may be further separated before the final analysis. Theoretically any analysis related to solasodine production can be performed, but once chromatography is incorporated, the extra errors involved make the results at best semiquantitative.

Study of this particular colorimetric assay technique shows in more detail the problems associated with such a technique. Difficulties have been found in each aspect of the method, difficulties largely overlooked in previously reported methods, and difficulties which in some cases apply to commercial solasodine isolation. The colorimetric procedure is much more temperamental than past methods have indicated, especially with regard to the specificity of the reaction and the instability of the complex. It was implied (2) that the reaction with methyl orange was specific to nitrogen-containing alkaloids; whereas it appears that all amines, in-

cluding ammonia itself, will give similar complex formation. The instability of the complex was also not mentioned.

Although solasodiene can be analyzed along with solasodine to give a total solasodine content, severe hydrolysis conditions (>1 *N* HCl) have been found to give overall solasodine loss. This is apparently caused by reactions, of unknown mechanism, associated with solasodiene formation and in the presence of the plant extract. Using conditions where stable hydrolysis occurs, much longer hydrolysis times than normally specified in reported methods were found to be necessary to complete the hydrolysis (*e.g.*, 5 hr at 100° for 1 *N* HCl in aqueous solution). Even for glycosides in solution, inspection of Fig. 3 shows that at least 4 hr at 100° for 1 *N* HCl is necessary.

For complete extraction of the solasodine to take place within one extraction, it is necessary to remove the cell wall diffusional barriers. For analytical purposes dry grinding of the plant material to pass a 75- to 90-μm sieve is suitable and allows very rapid extraction of the solasodine by alcohol. To stabilize the solasodine content of the plant material, oven drying at 75–90° is recommended. Oven drying >100° leads to loss of extractable solasodine. However, a preliminary fixation at temperatures >100° to arrest biological processes within the plant material does not affect the extraction process.

The final colorimetric assay is the cause of most of the error inherent in the method. Assuming a χ^2 distribution, the confidence interval for the true standard deviation is large, unless a large number of repeated analyses are made for its estimation. In most reported methods, where evaluation of the method is based on the results of repeated analyses, the number of repetitions is small, and consequently, in such cases the confidence interval for the true standard deviation will be large. Thus, the true error inherent in a method may differ greatly from that reported.

The problems of chemical analysis raise doubts about the soundness of previous studies of solasodine production. Results may be subject to large systematic and random errors because of poor analytical procedures. In particular, the problem of incomplete extraction will introduce large systematic errors.

pKa Determination of Benzhydrylpiperazine Antihistamines in Aqueous and Aqueous Methanol Solutions

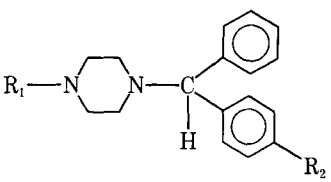
DAVID W. NEWTON *x, **WALLACE J. MURRAY** ‡, and **MICHAEL W. LOVELL** §

Received December 14, 1981, from the *Department of Pharmaceutics, College of Pharmacy, ‡Department of Biomedicinal Chemistry, University of Nebraska Medical Center, Omaha, NE 68105 and the §Department of Pharmaceutics, College of Pharmacy, J. Hillis Miller Health Center, University of Florida, Gainesville, FL 32610. Accepted for publication February 3, 1982.

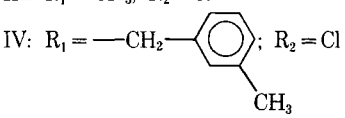
Abstract □ The pKa_1 and pKa_2 values of three benzhydrylpiperazine antihistamines, cyclizine (I), chlorcyclizine (II), and hydroxyzine (III), were determined at 24.5 ± 0.5° by potentiometric titration in aqueous solution to be 2.16 ± 0.02 and 8.05 ± 0.03, 2.12 ± 0.04 and 7.65 ± 0.04, and 1.96 ± 0.05 and 7.40 ± 0.03, respectively. The pKa_2 values were also determined by titration in seven aqueous methanol solutions in the range of 11.5–52.9% (w/w) methanol. The apparent dissociation constants of I–III in the aqueous methanol solutions, p_sKa_2, were plotted according to two linear regression equations from which the values in water, $p_\omega Ka_2$, were extrapolated. The plotted variables were p_sKa_2 *versus* methanol concentration (% w/w) and p_sKa_2 + log (water concentration, *M*) *versus* $1000/\epsilon$, where ϵ is the dielectric constant of the aqueous methanol solution. The maximum difference between pKa_2 and $p_\omega Ka_2$ was observed in the case of II where $p_\omega Ka_2$ was 5.23% higher. Statistical analysis of the linear regression data obtained from the plots showed that slightly better accuracy ($p < 0.13$) and correlation ($p < 0.16$) were obtained, but the precision was essentially equal with both methods. The observed ratio of K_{a1}/K_{a2} in I–III, 2.75×10^5–7.76×10^5, was attributed to solvent- and space-mediated field effects and electrostatic induction between nitrogen atoms in the piperazine ring.

Keyphrases □ Benzhydrylpiperazines—antihistamines, pKa determination in aqueous and aqueous methanol solutions □ Dissociation—pKa determination of benzhydrylpiperazine antihistamines in aqueous and aqueous methanol solutions □ Antihistamines—benzhydrylpiperazines, pKa determination in aqueous and aqueous methanol solutions

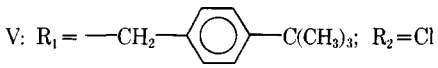
Five benzhydrylpiperazine antihistamines are currently marketed in the U.S.: cyclizine (I), chlorcyclizine (II), hydroxyzine (III), meclizine (IV), and buclizine (V).



I: $R_1 = CH_3$; $R_2 = H$
II: $R_1 = (CH_2)_2O(CH_2)_2OH$; $R_2 = Cl$
III: $R_1 = CH_3$; $R_2 = Cl$



IV: $R_1 =$ —CH_2— (p-CH_3 phenyl); $R_2 = Cl$



V: $R_1 =$ —CH_2— (p-$C(CH_3)_3$ phenyl); $R_2 = Cl$

Although some pKa[1] data for I (1, 2), II (1–3), III (4–7), and IV (6, 8) have been reported (Table I), much of it is based on titrations in 30–50% aqueous alcohols and chloroform–aqueous buffer partition experiments. More recent values of pKa_1 determined potentiometrically for III and IV (6) and spectrophotometrically for III (7) appear to have been conducted more precisely in aqueous solution.

The benzhydrylpiperazine antihistamines are popularly used as prescription and nonprescription dosage forms for their antiemetic, antipruritic, and sedative effects. It was the purpose of this investigation to determine the pKa_1 and pKa_2 values of these drugs for application to various pharmaceutical situations and to evaluate the accuracy of two methods for extrapolating an aqueous pKa estimate from apparent pKa values obtained in aqueous methanol solutions.

BACKGROUND

The low aqueous solubility of nonprotonated amine bases or nondissociated organic acids appears to be the consensus nemesis to determining pKa values of these substances by potentiometric titration. Even the lower limit of 5×10^{-4} *M* for potentiometry (9) is often not achievable. The use of mixed solvent systems, *e.g.*, an alcohol–water and dioxane–water, has been the method most commonly used to surmount this solubility problem. There is little or no disadvantage to this practice if the purpose merely is to compare the relative acidities or basicities of a series of chemical analogs. If, however, the objective is to make judgments pertaining to the aqueous environments of *in vivo* phenomena, the discrepancy between pKa values determined in aqueous and those in aqueous organic solvent solutions could be consequential.

Estimates of aqueous pKa values for inadequately soluble substances have usually been obtained by plots of the apparent pKa values in aqueous organic solvents *versus* solvent concentration (*e.g.*, % w/w) (10, 11):

$$p_sKa' = [\text{solvent}] + p_\omega Ka \qquad \text{(Eq. 1)}$$

where p_sKa' is the apparent dissociation constant in the aqueous organic solvent system, [solvent] is the organic concentration (% w/w), and $p_\omega Ka$ is the value of p_sKa' extrapolated to 0% (w/w) organic solvent or 100% (w/w) water. This method was used extensively in pharmaceutical studies during the 1950s and early 1960s (1–3, 12–15). The errors inherent in pKa estimates with this method have been addressed elsewhere (16–18). In 1959, two authors independently proposed a relationship that they rationalized should provide a more accurate estimate of aqueous pKa values

Table I—Acid Dissociation Constant (pKa) Values Reported for Some Benzhydrylpiperazine Antihistamine Drugs

Drug	pKa_1	pKa_2
Cyclizine (I)	2.54[a]	7.92[a], 8.16[b]
Chlorcyclizine (II)	2.44[a], 2.43[c]	7.78[a], 8.15[b], 7.81[c]
Hydroxyzine (III)	2.13[d], 1.83[e], 2.0[f]	7.9[g]
Meclizine (IV)	3.1[h], 2.05[i]	6.2[h]

[a] In 50% methanol (Ref. 1). [b] In 30–50% alcohol (Ref. 2). [c] In 20–80% alcohol (Ref. 3). [d] *Via* partitioning between 0.5 *M* H_3PO_4 and chloroform (Ref. 4). [e] In aqueous solution at an ionic strength <0.001 (Ref. 6). [f] Spectrophotometrically in aqueous solution (Ref. 7). [g] In unspecified aqueous methanol solutions (Ref. 5). [h] *Via* partitioning between 0.5 *M* H_3PO_4 and chloroform (Ref. 8). [i] In aqueous solution at an ionic strength of 0.005 (Ref. 6).

[1] The symbol pKa is used throughout in reference to the acid dissociation constant. Formally, K_a is the acid dissociation constant for proton loss by neutral and cationic acids or protonated bases, and $pKa = \log(1/K_a)$.

0022-3549/82/1200-1363$01.00/0

obtained by extrapolation of p_sKa' values in aqueous organic solvent mixtures (19, 20):

$$p_sKa' + \log [H_2O] = \frac{1}{\epsilon}(e^2/2.303\,akT) - \log B_H \qquad \text{(Eq. 2)}$$

where p_sKa' is the apparent pKa value in aqueous organic solvent mixtures uncorrected for electrode response, $[H_2O]$ is the water concentration (M), ϵ is the dielectric constant, e is the ionic charge, a is the mean cation–anion ionic diameter, k is the Boltzmann constant, T is the absolute temperature, and B_H is a constant based on the assumption that $[H_3O^+] \gg [\text{solvent } H^+]$. The values of p_sKa' are corrected by subtracting a constant, δ, which takes into account the variability of glass electrode response in aqueous methanol solutions. This gives the actual pKa value in the mixed solvent system, p_sKa (21, 22):

$$p_sKa = p_sKa' - \delta \qquad \text{(Eq. 3)}$$

Thereafter, a plot of $p_sKa + \log [H_2O]$ *versus* $1/\epsilon$ that is essentially linear may be extrapolated to obtain the ordinate intercept value for $p_\omega Ka$, the estimated aqueous pKa when $\log [H_2O]$ is 1.74 and $1/\epsilon$ is 0.01273 [2]. The linearity of the plots may decrease appreciably when $1/\epsilon > 0.02$ (*e.g.*, ≥70% w/w methanol). This corresponds to the value of $\epsilon \simeq 50$, below which ionic dissociation begins to diminish with a concomitant increase in ion-pair association and perturbation of the equilibrium between the neutral and ionic species (18, 21).

The original solubility method for determining pKa values (23) has been applied to determining pKa values of acidic, basic, and amphoteric substances with low aqueous solubility (9, 24–26). This method has the advantage of providing thermodynamic pKa estimates when the ionic strength of the samples is low (*e.g.*, <0.0005). Its disadvantages include the failure to achieve equilibrium conditions and separate emulsified or suspended neutral species from the saturated salt solutions in equilibrium with them. Potential errors in solubility estimates resulting from supersaturation of ionic and/or neutral species and the instability of some compounds also jeopardize the accuracy of this method. Another method involving a single pKa titration in an aqueous organic solvent mixture has been proposed, but it was judged by its author to be generally inapplicable to the estimation of $p_\omega Ka$ values (27).

It is reasonable to expect that the widespread use of organic solvent–water mixtures for pKa titrations of substances with intrinsic water solubilities of <0.0005 M will continue. This is because of historical precedents and the expedient manipulative techniques that can be accomplished using aqueous organic solutions.

EXPERIMENTAL

Materials—Cyclizine hydrochloride (I)[3], chlorcyclizine hydrochloride (II)[4], hydroxyzine dihydrochloride (III)[5], meclizine dihydrochloride (IV)[6], and buclizine dihydrochloride (V)[7] were used as received. Methanol, hydrochloric acid, and potassium hydroxide solutions were ACS analytical reagent grade, and freshly boiled water with a resistivity ≥10^7 ohm cm were used in the solvent systems and titrants.

Procedures—Titrations were conducted in a 25- or 50-ml multinecked glass flask fitted with a thermometer calibrated in 0.1° units. Agitation was provided by a polytef-coated magnetic stirring bar, and pH values were measured with a digital pH meter[8] equipped with a combination glass electrode[9]. The ambient temperature of the systems varied from 24.0 to 25.0° with an average value of 24.5°. Titrant increments were added from a pipet[10] in 0.25-ml portions.

The $p_sKa'_2$ values of 0.002 M I–III were determined in seven aqueous methanol solutions in the range of 11.5–52.9% (w/w) with a titrant of 0.020 N KOH prepared in aqueous methanol that contained to within 0.1% (w/w) the same methanol concentration as the solutions of I–III. Values of pKa'_2, the apparent constant in aqueous solution, were determined in aqueous 0.001 M I and III titrated with aqueous 0.010 N KOH and in aqueous 0.0005 M II titrated with aqueous 0.005 N KOH. The pKa'_1 values of I and II were obtained from titrations of 0.015 M aqueous solutions with aqueous 0.030 N HCl. The pKa'_1 of III was determined by titrating aqueous 0.015 M III with aqueous 0.030 N KOH.

Activity Corrections—Values of p_sK_a' obtained from titrations of I–III in aqueous methanol solutions were corrected to p_sKa values with Eq. 2 using δ values reported elsewhere (22). The pKa'_2 values of I–III were corrected for activity effects of the K_2 equilibria in Scheme I[11] (16, 18, 28–30):

$$HB^+ + OH^- \overset{K_2}{\rightleftharpoons} B + H_2O$$

Scheme I

$$pKa_2 = pKa'_2 - \frac{0.51\sqrt{I}}{1 + 1.6\sqrt{I}} \qquad \text{(Eq. 4)}$$

where I is the ionic strength of the solution, and the entire negative term estimates the logarithm of the activity coefficient, $-\log \gamma_i$. A similar activity correction was used for the K_1 equilibria shown in Schemes II and III[11] (28):

$$H_2B^{+2} + OH^- \overset{K_1}{\rightleftharpoons} HB^+ + H_2O$$

Scheme II

$$HB^+ + H_3O^+ \overset{K_1}{\rightleftharpoons} H_2B^{+2} + H_2O$$

Scheme III

$$pKa_1 = pKa'_1 = \frac{1.5345\sqrt{I}}{1 + 1.6\sqrt{I}} \qquad \text{(Eq. 5)}$$

RESULTS AND DISCUSSION

The values of pKa_1 for I–III were determined to be 2.16 ± 0.02, 2.12 ± 0.04, and 1.96 ± 0.05, respectively. The corresponding values of pKa_2 are 8.05 ± 0.03, 7.65 ± 0.04, and 7.40 ± 0.03[12].

The plots of the data for p_sKa_2 *versus* methanol (% w/w) are shown in Fig. 1 and that for $p_sKa_2 + \log [H_2O]$ *versus* $1000/\epsilon$ in Fig. 2 for I–III. Least-squares regression lines were plotted for all I–III data sets to permit comparison of the accuracy and precision of $p_\omega Ka_2$ extrapolations derived from each set of ordinate and abscissa coordinates. The ϵ values in Fig. 2 were calculated for each aqueous methanol solution from a linear regression equation derived from data for 10–60% (w/w) methanol (31):

$$\epsilon = -0.4523C + 78.9307 \qquad \text{(Eq. 6)}$$

where C is the methanol concentration (% w/w)[13]. The linear regression data for the plots in Figs. 1 and 2 are summarized in Tables II and III, respectively.

A comparison of R values for I–III (Tables II and III) shows that, based on the Student's t test (32), there was a better linear correlation of the p_sKa_2 titration data plotted according to Eq. 2 ($p < 0.16$). There was, however, essentially no difference ($p < 0.001$) in the precision of the plots of Eqs. 1 and 2 based on a comparison of $S_{y,x}$ values (Tables II and III). The accuracy of $p_\omega Ka_2$ values for I–III, *i.e.*, the differences from pKa_2 (Tables II and III), was also better by Eq. 2 than Eq. 1 plots ($p < 0.13$). The slightly improved linear correlation of the Eq. 2 plot may explain, in part, why it has been advocated instead of Eq. 1 (16, 18). Furthermore, the unreported linear regression data for plots of $p_sKa_2 + \log [H_2O]$ *versus* methanol (% w/w) were virtually identical with those reported in Table III. This would be expected from the nearly linear relationship expressed by Eq. 6 (31).

Doubts about the accuracy of $p_\omega Ka$ values extrapolated from aqueous organic solvent mixtures containing >20% solvent have been expressed elsewhere (16–20); curves shaped like hockey sticks have resulted from Eq. 1 plots. One contributing cause of this could be plotting erroneous high values of p_sKa' uncorrected for δ (Eq. 3). The value of δ ranged from 0.02–0.12 in these titrations, increasing with methanol concentration. Failure to have corrected p_sKa' to p_sKa values would have caused progressive decreases in the slopes of Eq. 1 plots. The resulting horizontal inclinations, *i.e.*, the hockey stick appearance, at high methanol concentrations would have produced greater inaccuracy in the extrapolated

[2] The values of $\log [H_2O]$ and $1/\epsilon$ correspond to $[H_2O] = 55.3\ M$ and $\epsilon = 78.54$, respectively, for water at 25°.

[12] Values of pKa_1, pKa_2, and p_sKa_2 represent the means ± standard deviations of seven values in each set of ten titrations.
[13] The correlation coefficient, R, is 0.9997.

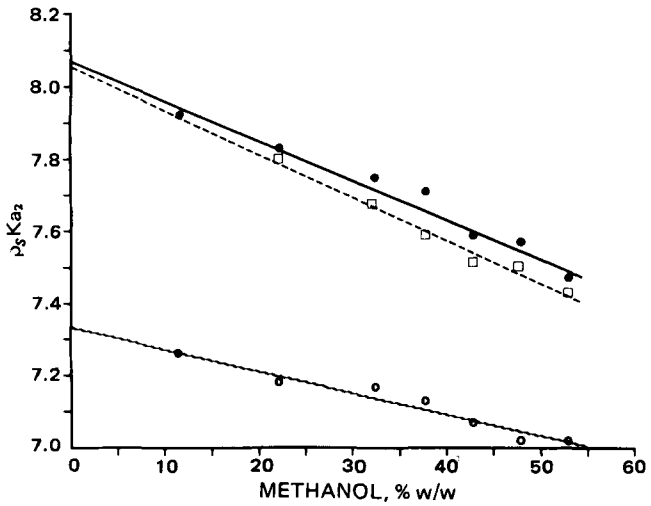

Figure 1—*Plot of p_sKa versus methanol (% w/w) for cyclizine (I), chlorcyclizine (II), and hydroxyzine (III). Key: (●) I; (□) II; (○) III.*

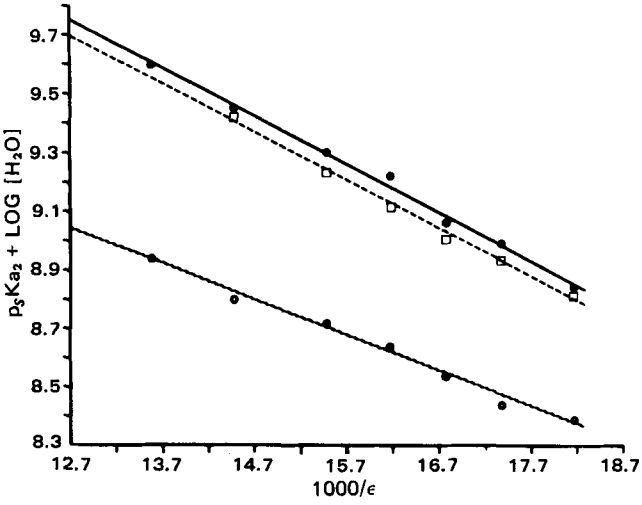

Figure 2—*Plot of p_sKa + log [H_2O] versus 1000/ε for cyclizine (I), chlorcyclizine (II), and hydroxyzine (III). Key: (●) I; (□) II; (○) III.*

$p_\omega Ka_2$ values. Therefore, the I–III p_sKa_2 data were calculated for 37.7% (w/w) ≤ methanol ≤52.9% (w/w) and 16.2 ≤ 1000/ε ≤ 18.2 (Table IV). Statistical analysis showed no difference in the accuracy and precision of I–III $p_\omega Ka_2$ values ($p < 0.001$) and the linear correlation of Eq. 1 and Eq. 2 plots ($p < 0.001$) between the data in Tables II and IV or Tables III and IV. These findings pertain only to I–III under the conditions stated, and they do not warrant general advocation of extrapolating $p_\omega Ka$ values from p_sKa data obtained in >35% (w/w) methanol.

A literature search yielded one similar study of some phenothiazine derivatives (33). Those plots were based on fewer data (mostly three points) obtained in a higher methanol concentration range (mostly ≥40%) and lacked the statistical data necessary for comparing pKa with $p_\omega Ka$ values derived from Eqs. 1 and 2. The plots apparently consisted of empirically connecting the sets of coordinates rather than calculating least-squares regression lines (33).

The magnitude of error in calculating the percent of monoprotonated I–III that would result from using $p_\omega Ka_2$ values to estimate otherwise unreported pKa_2 values for I–III was determined for pH 7.4. The error ranged from 0.72% for I (Table III) to 17.70% for II (Table II) (34):

$$\text{Percent } HB^+ = 100/[1 + 10^{(pH - pKa_2)}] \quad \text{(Eq. 7)}$$

$$\text{Percent } HB^+_\omega = 100/[1 + 10^{(pH - p_\omega Ka_2)}] \quad \text{(Eq. 8)}$$

$$\text{Error, \%} = |\text{Eq. 7} - \text{Eq. 8}| \quad \text{(Eq. 9)}$$

where HB^+ is the monoprotonated conjugate acid of I–III. From Eqs. 7 and 8, as the absolute values of the quantities pH − pKa_2 and pH − $p_\omega Ka_2$ increase, the value of Eq. 9 decreases.

A specific reason for the differences between $p_\omega Ka_2$ and pKa_2 values of I–III obtained by either Eq. 1 or Eq. 2 is not readily apparent. The fact that the titrants and I–III solutions were prepared in the same aqueous methanol concentrations, *i.e.*, within 0.1% (w/w), precluded stoichiometric errors in precision resulting from the nonadditivity of volumes and negative heats of solution. The variability in solvation phenomena

and electrolytic equilibria of I–III in aqueous methanol solutions may partially account for the discrepancies between the pKa_2 and $p_\omega Ka_2$ values (16–19, 21, 22, 33). For example, different solvation mechanisms are possible with III than with I or II because the hydroxyethoxyethanol substituent, R_1 on III, is both a hydrogen bond acceptor and donor. Furthermore, the R_2 chloro substituent on II would increase its partition coefficient over that of I (35, 36). In fact, 0.002 *M* II was inadequately soluble in 11.5% (w/w) methanol while titrating its p_sKa_2, which is attributed to the enhanced hydrophobicity conferred by the chloro group, R_2 (35, 36). The p_sKa_1 values of 0.0005 *M* IV and V were obtainable only in solvents containing ≥47.8% (w/w) methanol. As noted earlier, titration data derived from the latter solutions would be poorly applicable to $p_\omega Ka_1$ estimates (18, 21).

Finally, it remains to be determined why the ratios of K_{a1}/K_{a2} for I–III show a variation of 2.75×10^5 to 7.76×10^5. The comparable ratio of K_{a1}/K_{a2} for piperazine (VI) was reported to be 1.38×10^4 (37)[14]. There are four main types of electrochemical effects that can account for these K_{a1}/K_{a2} ratios: (*a*) mesomerism or resonance in aromatic compounds, (*b*) inductive effects of substituents in aliphatic and aromatic compounds, (*c*) field effects such as intramolecular hydrogen bonding, and (*d*) molecular symmetry or statistical effects (38–42).

Because the piperazine ring is nonaromatic, mesomerism does not explain the observed K_{a1}/K_{a2} ratios. Secondly, the inductive effects of the R_1 and benzhydryl substituents on the piperazine group in I–III account for a maximum difference between K_{a1} and K_{a2} of ~62 as seen from the quotient of $(K_{a1}/K_{a2})_I/(K_{a1}/K_{a2})_{VI}$. It has been shown that electron-withdrawing (*-I*) groups have a marginal influence on K_a values of acids when the *-I* and ionogenic groups are separated by more than two $-CH_2$ residues (38, 40). These inductive effects account primarily for the differences between either K_{a1} or K_{a2} values of I–III. Thirdly, the statistical symmetry factor in VI and its analogs accounts for only a fourfold difference in K_{a1} and K_{a2} values (38–40, 42).

Solvent- and space-mediated field effects and inductive forces between nitrogen atoms of the piperazine ring appear to be the most plausible explanation for the large K_{a1}/K_{a2} ratios in I–III, VI, and similar compounds. Electrostatic attraction between the protonated and neutral nitrogen atoms of the piperazine ring has been alluded to (43), and it has been studied by conformational analysis using molecular orbital methods. (44). However, field effects mediated through solvent molecules may also contribute to these large observed ratios.

CONCLUSIONS

Aqueous pKa_1 and pKa_2 values for I and II, and pKa_2 for III, apparently heretofore unpublished, were determined. These pKa_2 values of I–III were also obtained in aqueous solutions of 11.5–52.9% (w/w) methanol. There was no substantial difference in the precision of $p_\omega K_2$ extrapolated from linear regression plots of p_sK_2 data according to Eqs. 1 and 2. However, Eq. 2 did yield slightly better correlation of the plotted coordinates. The overall accuracy of $p_\omega Ka_2$ compared to pKa_2 values for I–III also was better according to Eq. 2 plots ($p < 0.13$). The maximum difference observed between any pKa_2 and $p_\omega Ka_2$ value occurred in the case II using Eq. 1 by which $p_\omega Ka_2$ was 5.23% higher.

The large ratios of K_{a1}/K_{a2} for I–III and piperazine are attributed to field effects and intramolecular electrostatic attraction or induction in the piperazine ring.

Vaginal Absorption of a Potent Luteinizing Hormone-Releasing Hormone Analog (Leuprolide) in Rats I: Absorption by Various Routes and Absorption Enhancement

HIROAKI OKADA ˣ, IWAO YAMAZAKI, YASUAKI OGAWA, SHINICHIRO HIRAI, TAKATSUKA YASHIKI, and HIROYUKI MIMA

Received December 29, 1981 from the *Central Research Division, Takeda Chemical Industries, Ltd., 2-17-85 Juso, Yodogawa, Osaka 532, Japan.* *Accepted for publication February 4, 1982.*

Abstract □ The absorption of a potent luteinizing hormone-releasing hormone analog (leuprolide) through different routes was evaluated by determining the ovulation-inducing activity in diestrous rats. Vaginal administration showed the greatest potency among nonparenteral routes and was followed successively by rectal, nasal, and oral administration. Mixed micellar solution with monoolein–bile acids improved the intestinal absorption of leuprolide, and nasal absorption was enhanced by adding sodium glycocholate, surfactin, or polyoxyethylene 9 lauryl ether, but these bioavailabilities were still insufficient. The vaginal absorption was enhanced by organic acids: citric, succinic, tartaric, and glycocholic; the absolute bioavailability increased to ~20%. The vaginal absorption from jellies, as practical dosage forms, yielded sufficient activity of leuprolide, but absorption was slightly reduced with highly polar polymers or with higher concentrations of polymers. It was concluded that vaginal administration of leuprolide can be a rational dosage method for a long-term antitumor therapy.

Keyphrases □ Leuprolide—vaginal absorption, potent luteinizing hormone-releasing hormone analog in rats, ovulation-inducing activity □ Absorption, vaginal—potent luteinizing hormone-releasing hormone analog (leuprolide) in rats, ovulation-inducing activity □ Hormones—potent luteinizing hormone-releasing hormone analog (leuprolide) in rats, vaginal absorption

Leuprolide (I), a luteinizing hormone-releasing hormone (II) analog synthesized previously (1), has a high gonadotropin-releasing activity (2) and ovulation-inducing potency (50–80 times greater than II) (3). Recently, this analog

(Pyro)Glu-His-Trp-Ser-Tyr-D-Leu-Leu-Arg-Pro-NH-CH_2CH_3

I

(Pyro)Glu-His-Trp-Ser-Tyr-Gly-Leu-Arg-Pro-Gly-NH_2

II

at relatively large doses, was found to effect regression of hormone-dependent mammary tumors (4–6). In addition, it appears to have birth control potential, without toxic side-effects, in both sexes (7–11).

Peptides are generally absorbed poorly, subject to decomposition in the GI tract, and have short biological half lives after parenteral administration. To establish a convenient and reliable method for nonparenteral self-administration of II and the analogs for long-term therapy, numerous studies have been carried out on the pharmacological effects after oral (12–14), sublingual (15), nasal (15–23), rectal (24), and vaginal (12, 14, 24) administration.

In the present study, the absorption of leuprolide through nonparenteral administration routes for an antitumor therapy was assessed by determining its ovulation-inducing activity in rats. The absorption enhancement was attempted in oral, nasal, and vaginal routes, and a study was also conducted on an experimental dosage form designed for vaginal administration.

EXPERIMENTAL

Animals—Mature female Sprague-Dawley rats[1] aged 120–150 days and weighing 250–330 g were used. Animals exhibiting two or more consecutive 4-day estrous cycles on daily morning examination of vaginal smears were used in the diestrous stage.

Materials—Leuprolide acetate[2] was used after dehydration at 50° under vacuum for 5 hr. Sodium glycocholate[3], sodium taurocholate[3], and polyoxyethylene 9 lauryl ether[4] of commercial grade were used without further purification. The other chemicals were of reagent grade quality.

Ovulation-Inducing Activity by Different Routes—The absorption of leuprolide through various administration routes was estimated by ovulation-inducing activity as described previously (25). A 0.9% NaCl solution of the analog containing 0.1% bovine serum albumin[5], 20 U/ml of aprotinin[6], and 0.1 *N* HCl was used for intravenous, subcutaneous, nasal, and oral administrations. For rectal administration, the analog was dispersed in an oleaginous base[7] molded in a cylindrical shape (Φ5 × 8 mm). For vaginal administration, the analog was dissolved in 0.9% NaCl solution containing 0.1% bovine serum albumin and 20 U/ml of aprotinin or dispersed in an oleaginous base[7]. After the suppository was placed by a glass inserter, the orifice was closed with a surgical adhesive agent. Although the rectal and vaginal administration using an oleaginous base were carried out at a dose per rat, their dose and ED_{50} are shown by dose per kilogram using mean body weight.

Enhancement of Oral, Nasal, and Vaginal Absorption—For the oral administration, a mixed micellar solution with monoolein[4], sodium taurocholate, and sodium glycocholate was prepared according to a previous method (26). One percent sodium glycocholate, surfactin[8], or polyoxyethylene 9 lauryl ether was added to the analog solution for the nasal administration. For the vaginal administration, the following adjuvants were dissolved or dispersed as fine particles at a concentration of 10% (as a free acid), except lactic acid (2%), in the oleaginous base: citric acid, succinic acid, tartaric acid, lactic acid, ascorbic acid, gluconic acid, taurine, glycine, boric acid, dipotassium edetate, sodium citrate, sodium glycocholate, and sodium oleate.

The concentration effect of citric acid and succinic acid was also examined at a range of 2–20% in the oleaginous base.

Leakage of Evan's Blue from the Vaginal Membrane—Under pentobarbital anesthesia, a dose of 1 ml/kg of 1% Evan's blue solution

0022-3549/82/1200-1367$01.00/0

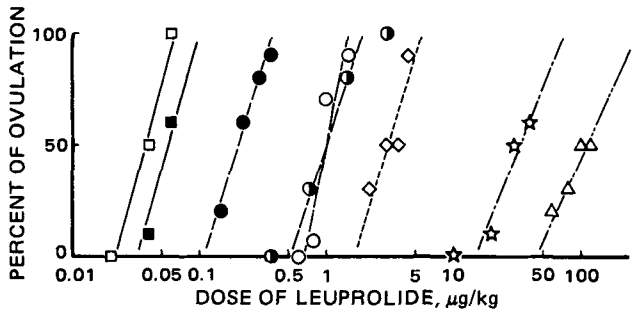

Figure 1—*Ovulation-inducing activity of leuprolide after intravenous, subcutaneous, oral, rectal, nasal, and vaginal administration to diestrous rats. Key: (□) intravenous; (■) subcutaneous; (○) vaginal in 0.9% NaCl; (◑) vaginal in oleaginous base; (●) vaginal with 10% citric acid; (◇) rectal; (☆) nasal; (△) oral.*

was injected intravenously 2 hr after the vaginal administration of the suppository containing 10% organic acids (citric, succinic, tartaric, and aspartic acids), sodium glycocholate, sodium citrate, calcium citrate, or dipotassium edetate. The rats were sacrificed by decapitation 30 min later and their vaginas were isolated and examined for the intensity of stain in the mucous membranes.

Vaginal Absorption from Jelly and Tablet—Methylcellulose[9] (2–7%), a mixture of xanthan gum[2] and locustbean gum[2] (2–3%), carrageenan[2] (5%), starch (7 and 10%), agar (10%), tragacanth gum[2] (4%), sodium carboxymethylcellulose[10] (5%), sodium polyacrylate[5] (5%), glycerogelatin[11], succinated gelatin[12] (61%), and polyethylene glycol 4000[13] (70%) were used as a jelly base. The concentration was adjusted to provide almost the same viscosity for each jelly. The jelly was prepared by dissolving the hydrophilic polymer in 5% citric acid solution (pH 3.5) containing various amounts of leuprolide. Each jelly was administered into the upper vagina by a glass inserter at a dose of 100 mg/rat.

Three kinds of tablets were prepared by a conventional method. The granules with the analog, citric acid, lactose, corn starch, and hydroxypropylcellulose[14] were formed by a wet method and blended with corn starch and magnesium stearate for compression into a cylindrically shaped tablet. The concentration of citric acid was 10% for tablet A, 5% for tablet B, and 10% as a sodium salt for tablet C. The pH value of the solution of tablet C dissolved in 3 ml of distilled water was 4.22.

The leakage of Evan's blue from the vaginal membrane was determined to compare the local reaction by methylcellulose jelly with 5% citric acid (pH 3.5), oleaginous suppository with 10% citric acid, and tablet A. Evan's blue was injected intravenously 30 min after vaginal administration of the suppositories.

RESULTS

Ovulation-Inducing Activity by Different Routes—The ovulation-inducing activities of leuprolide after intravenous, subcutaneous, vaginal, nasal, and oral administration to diestrous rats are shown in Fig. 1. The ED_{50}'s of the activity calculated by Finney's probit analysis (28) were 38 ng/kg by intravenous, 58 ng/kg by subcutaneous, 112 μg/kg by oral, 33.4 μg/kg by nasal, 3.12 μg/kg by rectal, and 1.0 μg/kg by vaginal administration. The activity of the analog by the oral route was 2950 times less than that by intravenous injection. Vaginal administration exhibited the greatest potency of all nonparenteral routes examined; the absolute bioavailability estimated by comparison with the potency of the intravenous injection was 3.8% in both the 0.9% NaCl solution and oleaginous suppository.

Enhancement of Oral, Nasal, and Vaginal Absorption—The ovulation-inducing activity of leuprolide after oral administration in the mixed micellar solution with monoolein and bile acids is shown in Table I. The absorption was enhanced 1.6 times more than that of the 0.9% NaCl solution, but the ED_{50} was still 1870 times larger than that after intravenous injection.

Three surfactants employed as absorption promoters markedly increased the potency of the analog applied nasally by the same degree: the absolute bioavailabilities were 1.8–3.0% (Table II).

For the vaginal administration, the polybasic carboxylic acids (citric, succinic, and tartaric acids) and glycocholic acid increased almost 5 times the ovulation-inducing activity of the analog (Table III). Acidic amino acids (glutamic and aspartic acids), the carboxylic acids having hydroxyl groups (ascorbic and lactic acids), and dipotassium edetate exhibited weak promoting effects, whereas taurine, boric acid, oleic acid, caproic acid, sodium oleate, and polyoxyethylene 9 lauryl ether scarcely enhanced the activity of the analog and glycine reduced it. The promoting effect of the carboxylic acids was reduced by using sodium citrate and sodium glycocholate salts. The concentration effects of citric acid and succinic acid on the vaginal absorption of the analog are shown in Fig. 2. These acids increased the activity of the peptide in concentrations ≤10%, and the activity approached a maximum level of >10%.

Leakage of Evan's Blue on Vaginal Membrane—Staining of the vaginal mucous membrane by Evan's blue injected intravenously after vaginal administration of a suppository containing an additive was examined. The organic acids (citric, succinic, and tartaric acids) and dipotassium edetate, both of which enhanced the vaginal absorption of leuprolide, induced deep staining of vaginal membrane, whereas little staining was observed with sodium glycocholate, sodium citrate, and calcium citrate.

Vaginal Absorption from Jelly and Tablet—The ovulation-inducing activities of leuprolide after vaginal administration of various hydrophilic jellies are shown in Table IV. The activity was affected by the jelly material and its concentration. Polymers having a highly polar functional group (sodium carboxymethylcellulose, sodium polyacrylate, and gelatin) tended to reduce the activity of the analog, whereas polysaccharides with less polar functions (methylcellulose, xanthan gum, locustbean gum, carrageenan, and starch) showed higher activity. In both polymer types, the activity was reduced as the polymer concentration increased.

Tablets containing the analog with 5% citric acid and 10% sodium citrate exhibited one third of the activity of tablet A with 10% citric acid, which induced the highest ovulation effect (Table V).

Staining of the vaginal membrane by Evan's blue injected after vaginal administration of the jelly, oleaginous suppository, and tablet, which were expected to show similar pharmacological effects, was compared. The oleaginous suppository and tablet induced deep blue staining, but the jelly induced only faint or no staining.

DISCUSSION

Determination of the ovulation-inducing activity of leuprolide after administration by different routes revealed that the absorption was good by vaginal administration, which was followed successively by rectal, nasal, and oral administration. The absorption of the analog from 0.9% NaCl solution and oleaginous suppository applied vaginally was almost identical. Their absolute bioavailabilities estimated by the pharmacological effect were 3.8%.

The vaginal absorption of a drug depends on its release from the suppository and on its ability to pass through the vaginal membrane. For the penetration of a drug, a physical model has been proposed (29) comprising an aqueous diffusion layer in series with a membrane consisting of aqueous pores and lipoidal pathways. The considerable absorbability of the analog, a hydrophilic compound, may indicate that its main absorption is thorough a pore-like route, such as intercellular channels, rather than through partition to the membrane cell.

Attempts were made to enhance absorption through the oral, nasal, and vaginal routes. Mixed micelles with lipid–bile salts are known to enhance the intestinal absorption of poorly absorbable polar drugs such as insulin (26), aminoglycosides (30), and heparin (31). The mixed micellar solution with bile salts and monoolein also improved the absorption of leuprolide, but its absolute bioavailability was 0.05%.

The bioavailability following nasal administration was 0.11% from the aqueous solution and was increased to 2–3% when sodium glycocholate, surfactin, or polyoxyethylene 9 lauryl ether was added. The absorption-enhancing effect with the promoters is in agreement with the effect observed previously with insulin (32).

The vaginal absorption of leuprolide was markedly facilitated by the polybasic carboxylic acids, and slightly increased with the hydroxy carboxylic acids and acidic amino acids. All of the carboxylic acids that

[9] METOLOSE (90SH4000, 90SH8000, 90SH15000, and 90SH30000), Shinetsu Chemicals Co., Tokyo, Japan. Four types of methylcellulose were used. In SH type, 4–12% of the methoxy groups was substituted by the hydroxypropoxy groups to raise the thermal gelation temperature. The former numbers represent the thermal gelation temperature and the latter the molecular weight.

showed an absorption promoting effect possess a chelating ability. The absolute bioavailability of the analog after vaginal administration increased to ~20% on the average by adding these polybasic carboxylic acids. The absorption was poorly enhanced with surfactants such as sodium glycocholate, sodium oleate, and polyoxyethylene 9 lauryl ether, which are known to enhance greatly the rectal and nasal absorption of hydrophilic drugs, and was reduced with glycine. The difference between the enhancement effects of surfactants on vaginal and rectal absorption may be attributed to structural differences of the membranes, *i.e.*, the vaginal epithelium, consisting of stratified squamous cells, may resist cleavage or desquamation of epithelial cells by the surfactants. Glycine seems to possess a stabilizing activity on the epithelium that results in the reduced vaginal absorption of salicylate[15].

An intimate relation was observed between the absorption-enhancing effect of leuprolide and the leakage from the vaginal membrane of Evan's blue injected intravenously after treatment with the promoters. Distinct staining of the vaginal epithelial membrane was elicited after vaginal administration of carboxylic acids with chelating ability, but not of calcium citrate. This indicates that the blood–vaginal epithelium barrier has been loosened by the organic acids and that the chelating ability may contribute to the absorption enhancement by expanding the channel bore through reversible electrical uncoupling with calcium ions as demonstrated in gap junctions (33), or by cleaving the intercellular tight junction through uptake of the calcium ions of binding proteins. Sodium citrate, which did not promote absorption, had no effect on the leakage of Evan's blue. The decrease of membrane permeability of the acid and/or of interaction between membrane and acid by dissociation, as a consequence of pH elevation, may reduce the effects.

[15] To be published.

Citric acid and succinic acid showed a similar concentration *versus* effect relation, *i.e.*, the activity increased with concentration to attain a maximum activity >10%. The exudation of body fluid out of the vaginal mucous membrane because of the hypertonicity of the acids may be one of the factors causing saturation of the promoting effect.

Table V—Ovulation-Inducing Activity of Leuprolide after Vaginal Administration in Tablet to Diestrous Rats [a]

Tablet [b]	Dose of Leuprolide, ng/rat									ED_{50}, ng/rat
	10	15	25	50	60	75	100	150	200	
A	0/10	1/10	8/15	5/10	7/10	10/10	8/10	—	—	34.6 (25.1–46.7) [c]
B	—	—	—	—	—	0/5	6/10	—	—	—
C	—	—	—	1/5	—	4/10	4/10	5/10	8/10	114.3 (57.4–256.6)

[a] Number of rats with induced ovulation per number of rats examined. [b] Each tablet consists of leuprolide, citric acid, lactose, corn starch, hydroxypropylcellulose, and magnesium stearate. Citric acid was dispersed as fine powders at the concentration of 10% for tablet A, 5% for tablet B, and 10% as a sodium salt for tablet C. [c] Fiducial limits (95%).

The absorbability of leuprolide from jellies or tablets containing citric acid was examined to determine a practical dosage form. Jellies with a highly polar polymer such as carboxymethylcellulose and polyacrylate reduced the absorption of the analog, whereas those with a less polar polysaccharide elicited sufficient absorption. Since the absorption was reduced by all polymers at a high concentration, the interaction of the analog with the jelly materials appeared to cause the suppression. The tablet containing 10% citric acid allowed considerable absorption of the analog and gave a smaller ED_{50} than the oleaginous suppository.

The local reaction of these suppositories, examined by the leakage of Evan's blue from the vaginal mucosa after a 1-hr treatment, revealed that the tablet and oleaginous suppository exhibited deep staining, while the jelly exhibited only faint staining, or none. This difference may be explained by the fact that citric acid, dispersed as fine particles in the tablet and the oleaginous suppository, is dissolved in exuded body fluids at close to the saturated concentration, resulting in an irritation to the vaginal mucosa. Discernible changes of the mucous membrane, such as destruction or exfoliation of vaginal tract surface cells of rats, were rarely observed by scanning electromicroscopy after 10 consecutive days of administration of jelly containing 5% citric acid[15]. These results indicate that the vaginal jelly will be the most suitable practical dosage form because of the activity with lower concentrations of citric acid, less local reaction, and easy handling due to a high water solubility.

Vaginal administration of leuprolide resulted in a high ovulation-inducing activity, which was enhanced by addition of the carboxylic acids: citric, succinic, tartaric, and glycocholic. It is suggested that vaginal administration of leuprolide in humans can be a rational dosage method especially from the standpoint of self-administration for long-term antitumor therapy.

ACKNOWLEDGMENTS

The authors are grateful to Mr. H. Nakagawa for assistance with the experiments, to Dr. M. Fujino for the supply of leuprolide, to Dr. N. Kitamori for preparation of the tablets, to Dr. T. Shimamoto for valuable discussion, and to Dr. J. R. Miller for comments on the manuscript.

Effect of Moisture and Crushing Strength on Tablet Friability and *In Vitro* Dissolution

Z. T. CHOWHAN[x], I. C. YANG, A. A. AMARO, and LI-HUA CHI

Received November 9, 1981, from the *Syntex Research, Division of Syntex (U.S.A.) Inc., Palo Alto, CA 94304.* Accepted for publication February 5, 1982.

Abstract □ The friability and dissolution of a formulation of compressed tablets were studied by varying the granulation moisture and tablet crushing strength. A general quadratic response surface model was used to analyze the data. The response surface contour plots of tablet friability consisted of a series of ellipsoidal curves. The optimum friability corresponding to a granulation moisture content and a tablet crushing strength was a simple minimum. The *in vitro* dissolution contour plots showed a stationary ridge system. Along the ridge, a large number of combinations of tablet crushing strength and granulation moisture represented 100% drug dissolution. The contour overlays of friability and dissolution contour plots showed a region where both the friability and dissolution requirement could be met. The analysis of the data by means of multiple linear regression was helpful in understanding the role of granulation moisture and tablet crushing strength on tablet friability and *in vitro* dissolution.

Keyphrases □ Dissolution—*in vitro*, effect of moisture and crushing strength, tablet friability □ Crushing strength—effect on tablet friability and *in vitro* dissolution □ Friability—tablets, effect of moisture and crushing strength

Previous studies (1–3) from these laboratories discussed the interrelationships between moisture, crushing strength, and *in vitro* drug dissolution in compressed tablets. Another physical parameter of importance to the tablet formulators, especially in coating and packaging operations, is friability of compressed tablets. The friabilator[1] (4) provides falling as well as frictional abrasion to the tablet sample and is used to measure the resistance to abrasion or attrition of tablets. The loss of weight is measured after a fixed number of revolutions of a drum rotating at a controlled rate. In the development of tablet dosage forms, formulation factors are generally checked to reduce comparative loss in friability testing. Two types of friabilator[1,2] apparatuses were compared (5) using 10 tablet formulations differing in method of granulation or choice of binder. In all instances the percentage of weight loss was higher with friabilator A[1], the differences ranging from 6.2 to 39.7%, depending upon the formulation. After 25 years of use, it was concluded (6) that the weight loss of not more than 0.8% by friabilator A was valid for the control of most pharmaceutical tablets.

Although friability is generally considered important in the development of tablet formulations, factors affecting friability have not been fully explored. The present report describes a study of the interdependence of tablet friability and *in vitro* drug dissolution on granulation moisture content and tablet crushing strength. The data were analyzed using a general quadratic response surface model and the analysis suggested that rational specifications on the in-process variables such as the granulation moisture and initial tablet hardness could ensure proper control of the tablet friability and *in vitro* dissolution.

EXPERIMENTAL

Materials—The drug, ticlopidine hydrochloride[3], 5-(*o*-chlorobenzyl)-4,5,6,7-tetrahydrothieno-[3,2-*c*]pyridine hydrochloride was at least 99.0% pure. The excipients used were microcrystalline cellulose[4] NF, povidone[5] USP, citric acid[6] USP, stearic acid powder[7] NF, corn starch[8] NF, and lactose[9] USP.

Granulation—The formulation used in this study contained 64.1% drug, 22.4% microcrystalline cellulose, 10% starch, 1% citric acid, 2% povidone, and 0.5% stearic acid. The drug and microcrystalline cellulose were mixed together in a small planetary mixer for 10 min. Povidone and citric acid were dissolved in water and the powder mixture was granulated with the binder solution. The wet granulation was mixed for 10 min and passed through a 1.4-mm aperture and dried in a forced-air oven at 60°

The authors are grateful to Mr. H. Nakagawa for assistance with the experiments, to Dr. M. Fujino for the supply of leuprolide, to Dr. N. Kitamori for preparation of the tablets, to Dr. T. Shimamoto for valuable discussion, and to Dr. J. R. Miller for comments on the manuscript.

Effect of Moisture and Crushing Strength on Tablet Friability and *In Vitro* Dissolution

Z. T. CHOWHAN[x], I. C. YANG, A. A. AMARO, and LI-HUA CHI

Received November 9, 1981, from the *Syntex Research, Division of Syntex (U.S.A.) Inc., Palo Alto, CA 94304.* Accepted for publication February 5, 1982.

Abstract □ The friability and dissolution of a formulation of compressed tablets were studied by varying the granulation moisture and tablet crushing strength. A general quadratic response surface model was used to analyze the data. The response surface contour plots of tablet friability consisted of a series of ellipsoidal curves. The optimum friability corresponding to a granulation moisture content and a tablet crushing strength was a simple minimum. The *in vitro* dissolution contour plots showed a stationary ridge system. Along the ridge, a large number of combinations of tablet crushing strength and granulation moisture represented 100% drug dissolution. The contour overlays of friability and dissolution contour plots showed a region where both the friability and dissolution requirement could be met. The analysis of the data by means of multiple linear regression was helpful in understanding the role of granulation moisture and tablet crushing strength on tablet friability and *in vitro* dissolution.

Keyphrases □ Dissolution—*in vitro*, effect of moisture and crushing strength, tablet friability □ Crushing strength—effect on tablet friability and *in vitro* dissolution □ Friability—tablets, effect of moisture and crushing strength

Previous studies (1–3) from these laboratories discussed the interrelationships between moisture, crushing strength, and *in vitro* drug dissolution in compressed tablets. Another physical parameter of importance to the tablet formulators, especially in coating and packaging operations, is friability of compressed tablets. The friabilator[1] (4) provides falling as well as frictional abrasion to the tablet sample and is used to measure the resistance to abrasion or attrition of tablets. The loss of weight is measured after a fixed number of revolutions of a drum rotating at a controlled rate. In the development of tablet dosage forms, formulation factors are generally checked to reduce comparative loss in friability testing. Two types of friabilator[1,2] apparatuses were compared (5) using 10 tablet formulations differing in method of granulation or choice of binder. In all instances the percentage of weight loss was higher with friabilator A[1], the differences ranging from 6.2 to 39.7%, depending upon the formulation. After 25 years of use, it was concluded (6) that the weight loss of not more than 0.8% by friabilator A was valid for the control of most pharmaceutical tablets.

Although friability is generally considered important in the development of tablet formulations, factors affecting friability have not been fully explored. The present report describes a study of the interdependence of tablet friability and *in vitro* drug dissolution on granulation moisture content and tablet crushing strength. The data were analyzed using a general quadratic response surface model and the analysis suggested that rational specifications on the in-process variables such as the granulation moisture and initial tablet hardness could ensure proper control of the tablet friability and *in vitro* dissolution.

until the desired moisture levels were obtained. The dried granulations were screened through a 1.2-mm aperture. Starch and stearic acid were then blended with the granulations for 5 min. The granulations were stored in tightly closed jars. The moisture content of the final granulations were determined prior to compression.

Compression—Tablets were compressed with a rotary tablet machine[10] to a targeted crushing strength. The punches and dies were 10.32 mm in diameter, and the punches were standard concave in shape.

Moisture Determination—The granulation moisture was determined with a moisture balance[11] by exposure to a 125 W IR lamp for 15 min at the 90 V setting. The percent weight loss on drying was read directly from the instrument.

Tablet Crushing Strength—The initial tablet crushing strength was determined[12] immediately after compression. For each determination 10 tablets were tested and the mean calculated.

Friability Determination—At least 20 tablets were brushed with a soft camel hair brush to remove all adhering particles and placed in a friabilator[1]. After accurate weighing, the tablets were placed in the drum. The drum was rotated for 4 min or 100 revolutions. At the end of 4 min, the tablets were removed, brushed to remove adhering particles, and accurately weighed. The loss of weight was calculated. The test was run in duplicate and the mean percent friability was calculated.

***In Vitro* Dissolution**—The USP Method II was used. For each sampling point six tablets were tested. The apparatus consisted of USP paddles driven by a multiple-spindle drive with a variable speed control[13], 1-liter round-bottom plastic flasks[14], and a water bath. The dissolution medium was 700 ml of deaerated water equilibrated at 37° and stirred at 50 rpm. The dissolved drug was analyzed by recording the absorbance at 236 nm using an automated monitoring system consisting of a peristaltic pump[15], 1-mm spectrophotometer flow cells, and automatic sample changer/spectrophotometer[16]. The absorbances were plotted on a recorder every minute until complete dissolution was achieved.

The dissolution apparatus was calibrated using USP dissolution calibrator tablets (prednisone 50 mg). The mean dissolution and the standard deviations were within the required range.

RESULTS AND DISCUSSION

The effects of granulation moisture and tablet crushing strength on tablet friability are given in Fig. 1. The results suggest that the tablet friability depends on moisture content and tablet crushing strength (controllable variables). It is possible to reduce tablet friability at higher crushing strengths and at optimum moisture contents.

Figure 2 gives the results of drug dissolution at the 10-min time point *versus* tablet crushing strength at different moisture contents. At lower moisture contents (1.6 and 2.0%), the drug dissolution is strongly dependent on tablet crushing strength. The higher the tablet crushing strength, the lower the percent drug dissolved and *vice versa*. However, at higher moisture contents (3.0, 3.6, and 4.3%), the dissolution of the drug shows very little dependency on crushing strength of the tablets.

A general multiple linear regression analysis of the results was performed using a program package[17], RSREG, on a computer[18]. The RSREG procedure fits the parameters of a complete quadratic response surface and then determines critical values to optimize the response with respect to the factors in the model. A general quadratic response surface

model is written:

$$Y = b_0 + b_1X_1 + b_2X_2 + b_3X_1^2 + b_4X_1X_2 + b_5X_2^2 + \text{Error} \quad \text{(Eq. 1)}$$

where Y is the response surface such as tablet friability or drug dissolution, X_1 and X_2 are controllable variables such as granulation moisture and tablet crushing strength, and the coefficients b_0, b_1, ... b_5 are the least-square regression coefficients.

The results of the regression analysis are given in Table I. The regression coefficients were substituted in Eq. 1, and by fixing the moisture content, the calculated plots of tablet friability *versus* tablet crushing strength were obtained (Fig. 3). Similarly, by fixing the tablet crushing strength, calculated plots of tablet friability *versus* moisture content were obtained (Fig. 4). These plots suggest that the moisture content in the range of ~1.5–3.0% and tablet crushing strength in the range of ~14–17 Strong Cobb units (SCU) give the least possible tablet friability. Similar conclusions could be drawn from the data given in Fig. 1.

The response surface contour plots of friability and dissolution are given in Figs. 5 and 6. The response surface contour plots illustrate the geometric relationships between the controllable variables and their responses. The predicted values of responses for a grid of the controllable variable data points can be generated. The friability contour plot consists of a series of ellipsoidal curves. The solution for optimum response indicated that the predicted value of friability at optimum was 0.17%, corresponding to a moisture content of 2.3% and a tablet crushing strength of 16.8 SCU.

In tableting, tablet crushing strengths are generally limited to between 8 and 20 SCU because of compression, friability, and dissolution limitations. From Fig. 5 one can obtain a range of crushing strengths (14.2–19.4 SCU) and a range of moisture content (1.5–3%), which gives friability in the minimum possible range of 0.17–0.21%. At a fixed tablet crushing strength of 16 SCU, friability decreases as the moisture content increases until it reaches its optimum value. Further increase in moisture content results in an increase in friability. Similarly, at a fixed moisture content of 2%, friability decreases as the crushing strength is increased until an optimum value is reached, after which time material is generally incompressible due to the tablet density approaching the calculated true density of the formulation.

The response surface contour plots of dissolution given in Fig. 6 show a stationary ridge system. The stationary ridge system has parallel straight line contours running in a direction determined by the relative effect of X_1 and X_2, which are controllable variables. The response surface contour plots using Eq. 1 can take a number of different forms depending on the coefficients b_0, b_1, ... b_5.

Within the practical limitations of tableting, there are a large number of combinations of tablet crushing strength and granulation moisture content all along the ridge which is expected to give 100% drug dissolution. At constant crushing strength, an increase or decrease in the granulation moisture content moving away from the ridge in either direction results in lower dissolution. Similarly, at constant granulation moisture content, an increase or decrease in crushing strength moving away from the ridge results in lower drug dissolution.

In this investigation, not only *in vitro* dissolution but also tablet friability were considered important and both were measured experimentally. If it was desired that the specifications for dissolution in 10 min were >46% and to maintain friability <0.3%, Figs. 5 and 6 could be superimposed. The contour overlays are shown in Fig. 7. The shaded area shows the region where both the friability and dissolution requirements are met. From the deeply shaded rectangle, specifications on granulation moisture and tablet crushing strength could be set. If these specifications were unsatisfactory from a bioavailability or production viewpoint, other factors affecting friability and dissolution such as formulation and processing factors would have to be explored. It also may be possible to reduce tablet friability by considering the punch shape factor.

In conclusion, this study shows that a general multiple linear regression analysis is helpful in understanding the role of the granulation moisture and tablet crushing strength on tablet friability and *in vitro* dissolution. By superimposing the contour plots of tablet friability and drug dissolution, it is possible to set in process specifications for the granulation moisture content and tablet crushing strength.

Relationship of Dissolution Rate to Viscosity of Polymeric Solutions

NARONG SARISUTA * and EUGENE L. PARROTT ×

Received December 28, 1981, from the *Division of Pharmaceutics, College of Pharmacy, University of Iowa, Iowa City, IA 52242.* Accepted for publication February 5, 1982.

* Present address: Mahidol University, Bangkok, Thailand.

Abstract □ The influence of viscosity on the dissolution rate of benzoic acid in aqueous solutions of methylcellulose, hydroxypropyl cellulose, and guar gum was investigated. The viscosities were measured by capillary and rotational viscometers and were calculated from experimental diffusion coefficients by means of the Stokes-Einstein equation. The relationship of the dissolution rate to viscosity may be represented by a single curve. An equation is presented relating the dissolution rate of benzoic acid to solubility, diffusion coefficient, and viscosity for these nonionic viscosity-enhancing agents. To demonstrate that additional factors affect the dissolution rate, similar data were determined using solutions of xanthan gum, which is anionic. The electrical effect modified mass transport so the quantitative relationship of dissolution rate and viscosity was not the same as in the nonionic carbohydrate solution.

Keyphrases □ Dissolution, rate—relationship to viscosity of polymeric solutions, benzoic acid □ Viscosity—relationship of dissolution rate of polymeric solutions, benzoic acid □ Benzoic acid—relationship of dissolution rate to viscosity of polymeric solutions

Although viscosity-enhancing polymers are present in many pharmaceuticals, little research has been reported on the influence of viscosity on the dissolution rate. Diffusion-controlled dissolution would be expected to decrease in rate with an increase in viscosity (1–4). Numerous empirical equations, which show the dissolution rate to be a function of the viscosity raised to a power ranging from −0.25 to −0.8, have been proposed (5–7).

[a] Capillary method.

The influence of viscosity of polymeric solutions on the dissolution rate of soluble inorganic salts was studied (8). No one equation relating rate and bulk viscosity fitted the data. By utilizing an effective viscosity, a plot of the data was approximated by a single curve, which was represented by an empirical equation.

There appears to be no general expression relating the dissolution rate to viscosity. Assuming that, with various solutes and polymeric solutions of markedly different ionic and chemical nature, factors other than viscosity act and affect the dissolution rate at a given viscosity, three nonionic carbohydrate polymers were studied with the thought that the interactions would be essentially constant and that the relation of dissolution rate to viscosity could be better expressed.

EXPERIMENTAL

Dissolution Rate Determinations—The procedure for tablet production and the dissolution apparatus were similar to those previously described (9). Spherical 1.273 ± 0.005-cm tablets of pure benzoic acid were compressed at 2270 kg of force by a hydraulic press[1]. All determinations were made in triplicate at 25 ± 0.1° and at a stirring speed of 324 rpm. The 2 liters of dissolution medium was changed at appropriate intervals so that the concentration of dissolved benzoic acid was not permitted to exceed 3% of its solubility. With each change of dissolution medium, the sphere was weighed and its diameter was measured with a micrometer. Solutions were prepared by a conventional method and allowed to stand 24 hr before use as the dissolution media. Dissolution rates were determined in various concentrations of aqueous methylcellulose[2], hydroxypropyl cellulose[3], xanthan gum[4], and guar gum[5] solutions.

Other Parameters—The solubilities of benzoic acid in various concentrations of polymeric solutions as given in Table I were determined as reported earlier (9). The densities of the solutions were measured using a pycnometer. Viscosities were measured by using a capillary[6] and a rotational[7] viscometer. The diffusion coefficients were determined by use of a diffusion cell previously described (10). The value in Table I is an average of three determinations for each concentration.

RESULTS AND DISCUSSION

Bulk Viscosity—For the concentrations observed, the addition of methylcellulose, hydroxypropyl cellulose, guar gum, and xanthan gum in solution increases the viscosity by at least 15-fold as shown in Fig. 1. The addition of these polymer molecules in solution decreases to less than one-half the dissolution rate of benzoic acid as shown in Fig. 2. The solubility of benzoic acid in water is not significantly affected by the presence of any of these polymers as shown in Table I.

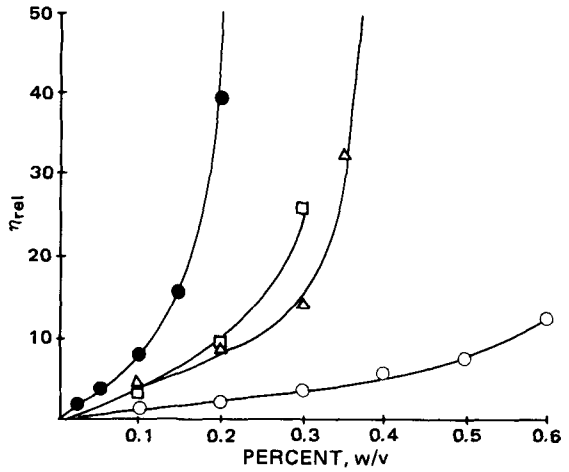

Figure 1—*Relative viscosity (η_{rel}) as a function of concentration in water at 25°. Key: (○) methylcellulose; (△) hydroxypropyl cellulose; (□) guar gum; and (●) xanthan gum.*

With no significant change in solubility, the only experimental variable affecting the dissolution rate appeared to be viscosity. Thus, one would anticipate that at a given viscosity of the dissolution medium, the dissolution rate of benzoic acid would be the same regardless of the noninteracting dissolution medium.

Figure 3 shows the relation of the dissolution rate and relative viscosity as determined by a capillary viscometer. It does not appear that one equation will relate the dissolution rate and bulk viscosity. Since the viscosity measured by the capillary method is a single shear rate viscosity, it probably does not represent the actual viscosity in the dissolution environment.

The viscosity-enhancing polymers studied form pseudoplastic solutions, which possess viscosities that vary with shear rate. The viscosities of the polymeric solutions were measured at rotational speeds from 0.3 to 60 rpm. Similar to the example of the methylcellulose solutions shown in Fig. 4, all of the polymeric solutions exhibited pseudoplastic flow at low rotational speed (<10 rpm), but at speeds >10 rpm, the viscosity did not decrease as the shear rate was increased. The constant viscosity at high shear has been called the upper Newtonian viscosity for dilute so-

lutions (11). At high shear rates, dissolved polymer chains are wholly disentangled and aligned in the direction of flow. As there is no remaining structure to be broken by further increases in shear rate, the viscosity reaches a constant value. In the viscometer at 60 rpm, the shear rate is ~200 sec^{-1} (12). The viscosity determined at speeds >10 rpm should represent the bulk viscosity in the dissolution apparatus (in which the 324 rpm provided a shear rate >200 sec^{-1}) better than the capillary viscosity.

The influence of viscosity measured at 1.5 rpm on the dissolution rate of benzoic acid at 25° in aqueous methylcellulose, hydroxypropyl cellulose, guar gum, and xanthan gum solutions is shown in Fig. 5. For the nonionic polymers (methylcellulose, hydroxypropyl cellulose, and guar gum) the dissolution rate is decreased rapidly to almost the same extent. At rotational speeds >10 rpm, the experimental values of dissolution rate and viscosity of solutions of methylcellulose, hydroxypropyl cellulose, and guar gum essentially fall on a single curve (Fig. 6) indicating that for a dissolution medium of similar ionic and chemical nature, there is a correlation between dissolution rate and viscosity.

Microviscosity—The dilemma with polymeric solutions is to express an observed viscosity, which is a true reflection of the impedance to molecular transport in solution. Since in solutions of macromolecules the bulk viscosity as measured by a viscometer does not necessarily represent the viscosity through which the solute molecules travel, a viscosity measured without the mechanical influence of a viscometer was considered. In the Stokes-Einstein equation, there is an inverse relationship between the viscosity and the diffusion coefficient. Thus, an attempt was made to relate the diffusivity of benzoic acid in the polymeric solution to viscosity by use of the Stokes-Einstein equation, as the concentration of benzoic acid was dilute and the radius (2.95 Å) of the benzoic acid molecule is smaller than that of the solvent molecule (13). The viscosity

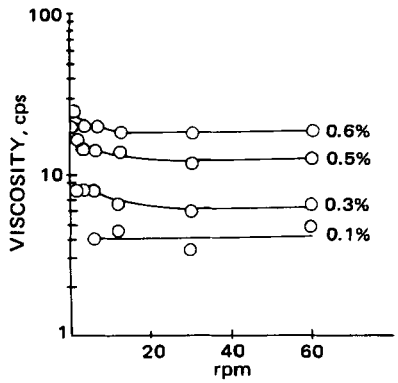

Figure 4—*Influence of rotations per minute on viscosities of aqueous solutions of various concentrations of methylcellulose.*

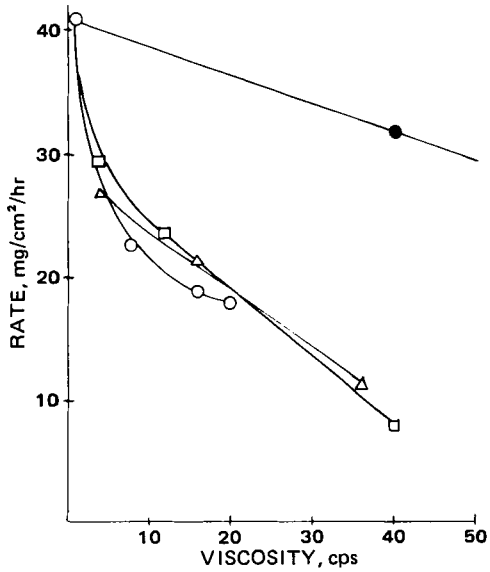

Figure 5—*Influence of viscosity at 1.5 rpm on the dissolution rate of benzoic acid in aqueous polymeric solutions. Key: (○) methylcellulose; (△) hydroxypropyl cellulose; (□) guar gum; and (●) xanthan gum.*

(η_D) of the microenvironment was calculated using the experimental diffusion coefficients (D_{expt}) in various concentrations of polymeric solutions by:

$$\eta_D = \frac{kT}{6\P rD_{expt}} \qquad \text{(Eq. 1)}$$

where k is the Boltzmann constant, T is the absolute temperature, and r is the radius of the benzoic acid molecule. For example, with benzoic acid dissolving in 0.1% methylcellulose solution at 25°, the D_{expt} is 1.036 × 10^{-5} cm^2/sec, and:

$$\eta_D = \frac{(1.38066 \times 10^{-16})(298)}{6\P\,(1.036 \times 10^{-5})(1.95 \times 10^{-8})}$$
$$= 0.0071 \text{ poise}$$

According to a previous report (14), the D_{expt} in polymeric solutions may be corrected for the obstructive effect of the polymer chains by the relation:

$$D_{true} = \frac{D_{expt}}{(1 - 1.5\,\phi)} \qquad \text{(Eq. 2)}$$

[a] Calculated by Eq. 1. [b] Calculated by Eq. 5. [c] Calculated by Eq. 7.

where ϕ is the volume fraction of the polymer. The volume fraction can be calculated from the concentration of the solution using the partial specific volume obtained by density measurements. The partial specific volume of each type of polymeric solution was evaluated by a plot of density against concentration according to the relationship:

$$\rho = \rho_{H_2O} + (1 - V\rho_{H_2O})C \qquad \text{(Eq. 3)}$$

where ρ and ρ_{H_2O} are the densities of the solution and the solvent, respectively, C is the concentration, and V is the partial specific volume. The volume fraction of the polymer was calculated from the partial specific volume and used in Eq. 2 to calculate D_{true}. In none of the systems studied did the difference between the D_{true} and D_{expt} exceed 0.3%.

The viscosity calculated by Eq. 1 and the dissolution rate are given in Table II. As seen in Fig. 7, as the viscosity of the dissolution media is increased, the dissolution rates are slowed to approximately the same extent. A single curve could be constructed to fit the experimental values.

Relation of Dissolution Rate and Viscosity—When the dissolution of a one-component, nondisintegrating sphere occurring in a nonreactive medium at sink conditions is diffusion controlled, the dissolution rate (R) may be expressed as (9):

$$R = \frac{DC_s}{h} \qquad \text{(Eq. 4)}$$

where D is the diffusion coefficient of the solute molecule, h is the effective film thickness, and C_s is the solubility. The experimental conditions used in determining the dissolution rate suggest that the diffusion layer model is operative (10). As shown in Fig. 8 there is a linear relationship between D_{expt} and $1/\eta_D$. It has been shown that at a fixed bulk viscosity the dissolution rate is not a linear function of D_{expt} (10). Similarly, as shown in Fig. 8, the relationship between dissolution rate of benzoic acid and D_{expt} in polymeric solutions is nonlinear. As the relationships of dissolution rate to viscosity and diffusion coefficient are curvilinear, a viscosity function $f(\eta)$ was introduced into Eq. 4:

$$R = \frac{DC_s}{h} f(\eta) \qquad \text{(Eq. 5)}$$

Experimentally all terms were evaluated so that the viscosity function could be calculated, assuming that h remained constant. For example, the viscosity function for 0.1% methylcellulose solution at 25° is:

$$f(\eta) = \frac{32.42 \times 32.2 \times 10^{-4}}{1.036 \times 10^{-5} \times 3600 \times 3.25} = 0.864$$

The values of the viscosity function for various polymeric solutions are given in Table II.

The relationship of the viscosity function to the η_D is shown in Fig. 9, and the equation for this relationship in these nonionic polymeric solu-

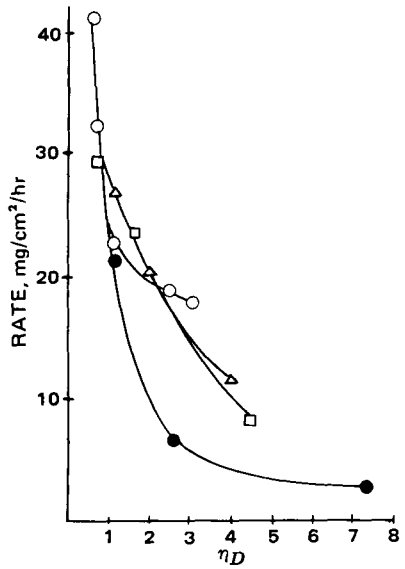

Figure 7—*Influence of η_D on dissolution rate of benzoic acid in aqueous polymeric solutions. Key: (○) methylcellulose; (△) hydroxypropyl cellulose; (□) guar gum; and (●) xanthan gum.*

tions is:

$$f(\eta) = 0.295 + 89.9\eta_D - 1360\eta_D^2 \qquad \text{(Eq. 6)}$$

Determination of η_D of a solution permits the calculation of the viscosity function, which is then used in Eq. 7 to calculate the dissolution rate. For example, in a 0.1% methylcellulose solution at 25° the η_D is 0.0071 poise, and the viscosity function is:

$$f(0.0071) = 0.295 + (89.9 \times 0.0071) - (1360 \times 0.0071^2)$$
$$= 0.865$$

Thus, the dissolution rate of benzoic acid in solutions of carbohydrate polymers of similar chemical and nonionic nature may be expressed as:

$$R = \frac{DC_s}{h}(0.295 + 89.9\eta_D - 1360\eta_D^2) \qquad \text{(Eq. 7)}$$

where D and C_s are the diffusion coefficient and solubility in the dissolution medium, respectively, possessing a microviscosity of η_D poises. The dissolution rate calculated by use of Eq. 7 and the experimental dissolution rates are compared in Table II.

Influence of Ionization of Polymer—Xanthan gum, which is chemically similar to the viscosity-enhancing polymers studied and is anionic, was selected to demonstrate the influence of electrical interactions on dissolution. In Figs. 1–3 the relations of concentration, relative viscosity, and dissolution rates are shown for xanthan gum. The influence of xanthan gum is more marked than the nonionic polymers. In Figs. 3 and 5 the rate–viscosity curve in solutions of the xanthan gum does not appear to have the same relationship as in solutions of the nonionic polymers.

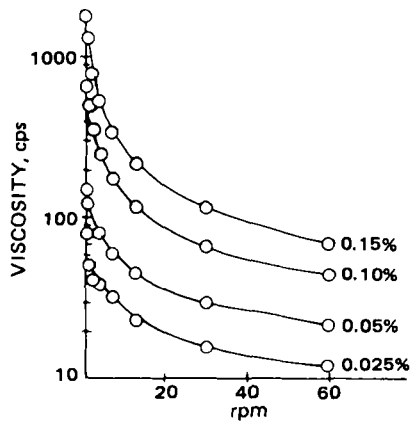

Figure 11—*Influence of rotations per minute on viscosity of solutions of various concentrations of xanthan gum.*

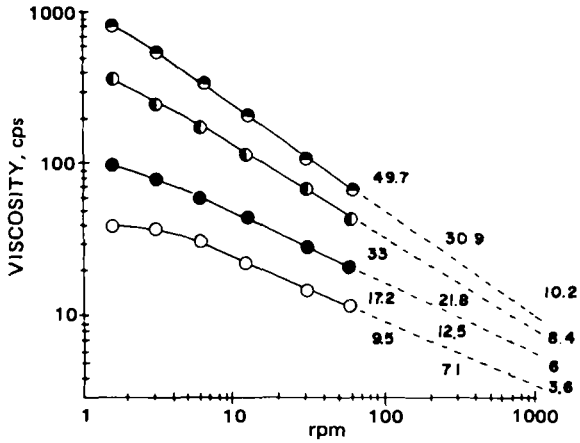

Figure 12—*Log–log relationship of viscosity and rotations per minute for solutions of xanthan gum. The viscosities at 100, 200, and 1000 rpm are given in the figure. Key: (○) 0.025%; (●) 0.05%; (◐) 0.1%; and (⊖) 0.15%.*

As the shear rate is increased by faster speeds of the rotational viscometer, the rate–viscosity curve in solutions of xanthan gum moves downward approaching the curve in solutions of the nonionic polymers, as shown in Fig. 10. Thus, the solutions of xanthan gum are pseudoplastic, but a shear rate greater than that provided by the rotational viscometer is required to reach the upper Newtonian viscosity, as shown in Fig. 11. The viscosity measured at 60 rpm does not represent the bulk viscosity of the solution of xanthan gum in the dissolution apparatus. To estimate the viscosity of the solution of xanthan gum at greater shear rates, the logarithm of viscosity was plotted against the logarithm (rpm) for the various concentrations of xanthan gum. The linear portions of the curves were extrapolated to estimate the viscosities at 100, 200, and 1000 rpm, as shown in Fig. 12.

In Fig. 13 the dissolution rates of benzoic acid are plotted as a function of the extrapolated viscosities at 100, 200, and 1000 rpm. The relationship of dissolution rate to viscosity in solutions of xanthan gum is not the same as that for the solutions of the nonionic polymeric solutions studied. Although the chemical nature is similar for all the polymers, the xanthan gum is anionic. Thus, the transport of benzoic acid in solutions of xanthan gum is complicated by the electrical charge on the xanthan gum chain.

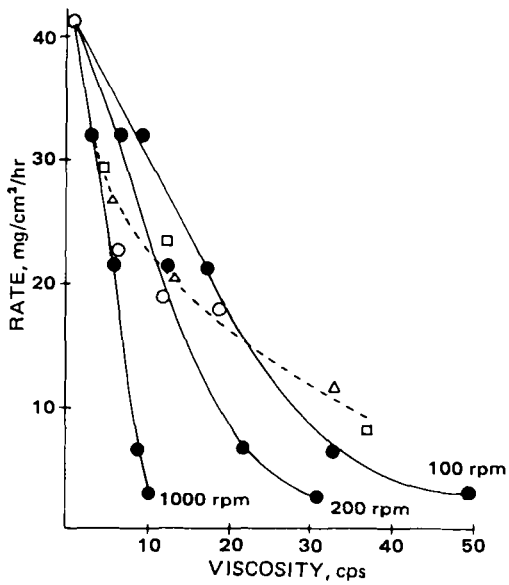

Figure 13—*Influence of viscosity at 100, 200, and 1000 rpm on dissolution rate of benzoic acid in aqueous solutions of xanthan gum. Broken curve is a composite for solutions of nonionic polymers. Key: (○) methylcellulose; (△) hydroxypropyl cellulose; (□) guar gum; and (●) xanthan gum.*

It was reported (15) that for ferricyanide ions diffusing in solutions of xanthan gum, the diffusion coefficient was decreased as much as 20-fold and was decreased as the shear rate was increased. It is thought that the shear causes the xanthan gum molecule to extend, exposing charge sites, and then the interaction between the solute and the charge sites changes diffusivity.

In addition, the viscosity measured by the viscometer may not represent the actual resistance to solute molecule transport. The values of the η_D of solutions of xanthan gum were calculated by Eq. 1. The relation of dissolution rate to viscosity of solutions of xanthan gum shown in Fig. 7 is not the same as the relation of dissolution rate to viscosity of solutions of the nonionic polymers. The difference may be caused by the interaction between the benzoic acid molecule and the anionic segments of the xanthan gum.

It appears that for viscosity-enhancing polymers of similar chemical and nonionic nature, a relationship may be expressed between the viscosity of the dissolution medium and the dissolution rate of a solid. However, if the chemical or ionic nature of the polymers is different, additional factors that influence dissolution rate are introduced and must be considered.

Synthesis and Catalytic Activity of Poly-L-Histidyl-L-Aspartyl-L-Seryl-Glycine

A. N. SARWAL, E. O. ADIGUN, R. A. STEPHANI, and A. KAPOOR ×

Received July 21, 1981, from the *College of Pharmacy and Allied Health Professions, St. John's University, Jamaica, NY 11439.* Accepted for publication February 1, 1982.

Abstract □ Poly(His-Asp-Ser-Gly) was synthesized from the fully protected tetrapeptide active ester hydrochloride, which was prepared by stepwise coupling, using pentachlorophenyl ester and mixed anhydride methods. Complete deprotection of the protected tetrapeptide polymer was achieved by using 90% trifluoroacetic acid. The free polymer was dialyzed for 24 hr using a membrane (which retains molecules with molecular weights >5000). The catalytic activity was determined by studying the hydrolysis of *p*-nitrophenyl acetate in 0.2 *M* phosphate buffer (pH 7.4) at 37°. The catalytic coefficient of the dialyzed polymer was found to be 138 liters/mole/min.

The use of poly(amino acids) as esterase models for structural and mechanistic problems of proteolytic enzymes has been very useful (1, 2). The poly(amino acids) that have been used for this purpose include homopolymers, copolymers, and sequential polypeptides. Sequential polypeptides provide one of the best means to study the factors affecting the folding of various enzymes, since they permit the placement of specific side chains at specific locations on a polypeptide backbone. Thus, suitable folding brings important side chain functionalities required for the activity into closer proximity, even though these amino acids lie at different distances in the enzyme sequences.

Considerable attention has been focused recently on the role played by L-histidine and L-serine in the active site of chymotrypsin and other proteolytic enzymes toward the hydrolysis of various esters such as *p*-nitrophenyl acetate (3, 4). Synthesis and catalytic activity of a number of peptides incorporating histidine and serine have been recently reported (5–7) as esterase models. The synthesis of the pentapeptide; L-Ser-γ-aminobutyryl-L-His-γ-aminobutyryl-L-Asp which had a catalytic coefficient of 147 liters/mole/min has been reported (5). The synthesis of a relatively more potent esterase model, L-His-Gly-L-Asp-L-Ser-L-Phe which had a catalytic coefficient of 179 liters/mole/min has also been reported (6). The comparison of the catalytic activity of various peptide esterase models led to the conclusion that peptides that incorporated L-aspartic acid in addition to L-histidine and L-serine showed considerable increase in catalytic activity (7). For example, L-His-L-Ala-L-Asp-Gly-L-Ser showed a catalytic activity of 210 liters/mole/min. The corresponding pentapeptide, L-His-L-Ala-L-Glu-Gly-L-Ser, where aspartic acid was replaced by glutamic acid, had a catalytic activity of 87

liters/mole/min. Generally, the incorporation of aspartic acid instead of glutamic acid in the peptide sequence led to a threefold increase in catalytic activity. The increased catalytic activity of peptide esterase models containing aspartic acid may be justified on the basis that in the case of chymotrypsin, aspartic acid occupies position 194, which is adjacent to postulated active serine at position 195. The same is true of trypsin, in which case aspartic acid is at position 184, adjacent to active serine at position 185.

While the catalytic activity of a number of peptide esterase models incorporating L-histidyl, L-serine, and L-aspartyl showed an appreciable increase in activity compared with previously reported peptide esterase models, the catalytic activity of these esterase models was considerably lower than that of chymotrypsin. It was, therefore, considered worthwhile to carry out the synthesis of a sequential polypeptide incorporating L-histidyl, L-aspartyl, L-serine, and glycine.

EXPERIMENTAL

All melting points are uncorrected and were taken on a capillary melting point apparatus[1]. Results of microanalyses[2] were within ±0.4% of theoretical and are shown in Table I. Unless otherwise stated, IR spectra were determined in potassium bromide pellets on an IR spectrophotometer[3]. UV spectra were determined on UV spectrophotometer[4]. Optical rotations were measured with a precision polarimeter[5]. Before incorporation all intermediates were purified to homogeneity on TLC in the following solvent systems: (a) butanol–glacial acetic acid–water (4:1:1); (b) butanol–glacial acetic acid–water–pyridine (15:3:12:10); (c) hexane–ethyl acetate–glacial acetic acid (20:10:1; and (d) heptane–*tert*-butyl alcohol–glacial acetic acid (3:2:1). Ninhydrin was used to detect free amino group-containing peptide intermediates. Fluorescent plates were used so that ninhydrin-negative peptides could be visualized. Dialyses were carried out in an ultrafiltration apparatus[6].

All solvents were analytical grade and were distilled before use. Tetrahydrofuran was refluxed with sodium hydroxide and distilled over sodium strips. All intermediates were dried over sodium hydroxide and phosphorus pentoxide in a vacuum dessicator. Triethylamine was purified by storing over *N*-carbobenzoxyglycine pentachlorophenyl ester to remove primary and secondary amines to avoid termination of polymerization reactions (8).

N-Carbobenzoxy-(*O* - *tert* - butyl)-Ser-Gly-pentachlorophenyl Ester (I)—*N*-Carbobenzoxy-*O*-*tert*-butyl-Ser (9) (10 g, 34 mmoles) was dissolved in tetrahydrofuran (50 ml). *N*-Methylmorpholine (3.4 ml, 34 mmoles) was added and the solution was cooled to 20°. Isobutyl chlorocarbonate (4.7 ml, 37 mmoles) was added to this solution in two portions with constant stirring. After stirring for 30 min, glycine pentachlorophenyl ester hydrochloride (8) (11.03 g, 34 mmoles) was added in small portions as a suspension in tetrahydrofuran. *N*-Methylmorpholine (3.4 ml, 34 mmoles) diluted with tetrahydrofuran (20 ml) was added dropwise over a period of 1 hr. The reaction mixture was stirred in an icebath and gradually allowed to reach room temperature overnight. The precipitated material was removed by filtration and the filtrate was evaporated under vacuum.

The residual oil was dissolved in ethyl acetate (50 ml) and washed twice with 5% citric acid solution (50 ml), once with water (50 ml), twice with 2 *N* $KHCO_3$ solution (50 ml), and twice with water (50 ml). The combined aqueous washes were washed with a portion of fresh ethyl acetate. The ethyl acetate solutions were combined, dried with anhydrous magnesium sulfate, filtered, and the solvent was evaporated under vacuum. The residual oil was crystalized from hexane by cooling at dry ice temperature. The resulting solid was filtered, air dried, and recrystallized from aqueous ethanol by seeding with solid from the hexane product. The product was dried over phosphorus pentoxide and sodium hydroxide pellets (13.1 g), 64% yield.

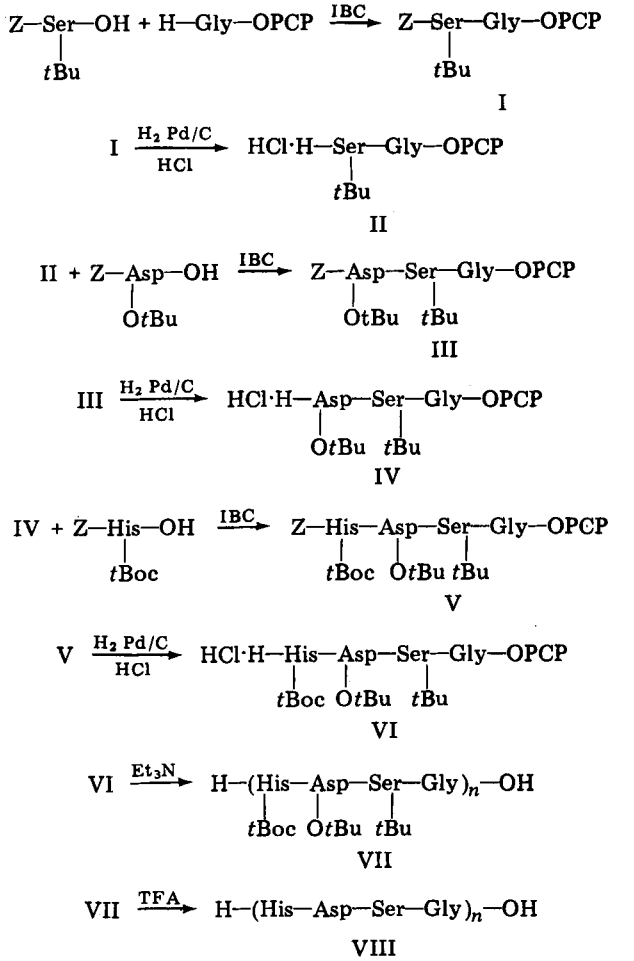
(*O-tert*-Butyl)-Ser-Gly-pentachlorophenyl Ester Hydrochloride (II)—Palladium–charcoal catalyst (10%, 0.5 g) suspended in glacial acetic acid (1 ml) and anhydrous methanol (20 ml) was hydrogenated at atmospheric pressure. Dry methanol containing 0.140 g of hydrogen chloride gas per milliliter (0.45 ml, 1.7 mmoles) was added to the hydrogenated catalyst, and the hydrogenation was continued until no further uptake of hydrogen occurred. A suspension of active ester (I, 1.0 g, 1.67 mmoles) in methanol was added to the reaction mixture and the hydrogenation was carried out until no further uptake of hydrogen occurred (10 min). The reaction mixture was filtered to remove the catalyst and the filtrate was concentrated under reduced pressure to a volume of 2 ml. Anhydrous ether was added and the hydrochloride was crystallized, (0.78 g), 93% yield.

***N*-Carbobenzoxy-(*O*-*tert*-butyl)-Asp-(*O*-*tert*-butyl)-Ser-Gly-pentachlorophenyl Ester (III)**—*N*-Carbobenzoxy(*O*-*tert*-butyl) aspartic acid (10) (3.23 g, 0.01 mole) and *N*-methylmorpholine (1.0 ml, 0.01 mole) in tetrahydrofuran (50 ml) was coupled to pentachlorophenyl ester hydrochloride (II, 5.03 g, 0.01 mole). The residue obtained after evaporation of the ethyl acetate was crystallized from ethyl acetate–ether–petroleum ether to give *N*-protected tripeptide active ester (III) (2.14 g), yield 67%.

(*O*-*tert*-Butyl)-Asp-(*O*-*tert*-butyl)-Ser-Gly-pentachlorophenyl Ester Hydrochloride (IV)—Active ester (II, 1.0 g, 1.3 mmoles) was hydrogenated to give hydrochloride (IV, 0.69 g), yield 78%.

***N*-Carbobenzoxy(imbutyloxycarbonyl)-His-(*O*-*tert*-butyl)-Asp-(*O*-*tert*-butyl)-Ser-Gly-pentachlorophenyl Ester (V)**—*N*-carbobenzoxy(imbutyloxycarbonyl)-histidine (11) (2.6 g, 6.7 mmoles) in tetrahydrofuran (50 ml) was coupled to tripeptide ester hydrochloride (IV, 4.5 g, 6.8 mmoles). The product obtained after evaporation of the ethyl acetate, was crystallized from ethyl acetate–ether–petroleum ether to give compound V (4.35 g), yield 71%.

(Imbutyloxycarbonyl) -His- (*O*-*tert*-butyl) -Asp- (*O*-*tert*-butyl)-Ser-Gly-pentachlorophenyl Ester Hydrochloride (VI)—A suspension of active ester (V, 1.0 g, 0.99 mmole) was hydrogenated to produce the tetrapeptide hydrochloride (VI, 0.53 g), yield 64%.



Scheme I—tBu, tert-butyloxy; OPCP, Pentachlorophenoxy; tBoc, tert-butyloxycarbonyl; IBC, Isobutylchloroformate; TFA, Trifluoroacetic Acid.

Poly(imbutyloxycarbonyl) -His- (*O* -*tert* -butyl)-Asp-(*O* -*tert*-butyl)-Ser-Gly (VII)—Fine powder of tetrapeptide active ester hydrochloride (VI, 2.5 g, 2.8 mmoles) was slowly added to dimethylformamide at room temperature with continuous shaking. To this suspension was added purified triethylamine (0.78 ml, 5.6 mmoles) and shaking was continued at room temperature for 48 hr. After trituration with anhydrous ether (20 ml), the reaction mixture was centrifuged, and the ether layer was decanted. This step was repeated three more times, and the residue was dried under a stream of nitrogen. Further drying of the residue was carried out in a vacuum desiccator over phosphorus pentoxide to yield 1.1 g, the protected polymer (VII, 1.1 g).

Poly(His-Asp-Ser-Gly) (VIII)—A solution of protected polymer (VII, 0.9 g) in 90% trifluoroacetic acid (4 ml) was kept at room temperature for 1 hr and the product was precipitated with ether to yield 0.5 g of unprotected polymer (VIII).

Dialysis of Unprotected Sequential Polymer—Crude unprotected polymer (VIII, 450 mg) was dissolved in water (10 ml) and dialyzed for 14 hr in a continuous filtration apparatus[6]. The concentrates were lyophilized over a period of 24 hr to give 180 mg of a white fluffy solid.

Optical Purity of Poly(His-Asp-Ser-Gly)—A solution of the free dialyzed polymer (VIII, 39.4 mg) in 6 *N* HCl (0.5 ml) and glacial acetic acid (0.5 ml) was refluxed for 24 hr in an atmosphere of nitrogen. The clear hydrolysate was evaporated to dryness under reduced pressure. The residue was dissolved in 5 *N* HCl so that the final volume was 2 ml (50 m*M*). A control sample using histidine (15.5 mg), aspartic acid (13.3 mg), serine (10.5 mg), and glycine (7.5 mg) was treated similarly with 6 *N* HCl and glacial acetic acid, then evaporated and dissolved in 5 *N* HCl as above (50 m*M*). Observed rotations of both were measured at 25°; control was +0.830° and polymer-derived material was +0.831°.

Determination of Catalytic Activity—For the measurement of catalytic activity of a sequential polypeptide (VIII) a modified method (3) was used. The rate of hydrolysis of *p*-nitrophenylacetate was calculated from the rate of appearance of the *p*-nitrophenoxide ion as measured by the increase in optical density at 400 μm. The catalytic coefficient k_2 is defined as $k_1 - k_w/C$, where k_1 is the observed first-order rate constant of hydrolysis measured in the presence of catalyst, k_w is the constant in absence of catalyst (both expressed in min^{-1}), and C is the molar concentration of the catalyst.

RESULTS AND DISCUSSION

While a number of approaches have been utilized for the synthesis of sequential polypeptides, there have been problems encountered with racemization, intramolecular cyclization, and the low degree of polymerization.

In order to limit some of these problems a suitable synthetic method for simple sequential polypeptides was reported (12). In this approach, *C*-terminal activation was provided by the pentachlorophenyl ester, and the peptide chain was extended from the *C*-terminal residue by mixed anhydride activation of the incoming *N*-protected amino acid. A desired sequence of *N*-protected, *C*-activated molecules was prepared by deprotection of the *N*-protected group, followed by coupling with the next amino acid in the sequence. Coupling was achieved by using mixed anhydride followed by a repetition of this procedure. Satisfactory polymerization was achieved upon removal of the final *N*-protection. One of the main advantages of this approach is the avoidance of the use of alkaline conditions which can lead to racemization and other undesirable side reactions (13). In addition, as the peptide chain is extended from the *C*-terminal residue of the amino acids, the degree of racemization is further limited, since the possibility of racemization of the penultimate residue is nonexistent (14).

This successful approach for the synthesis of simple sequential polypeptides was employed for the synthesis of poly(His-Asp-Ser-Gly). Selection of glycine as the *C*-terminal amino acid component was based upon the observation that it occurs around the active site of the proteolytic enzymes. Also, the incorporation of glycine at the *C*-terminal will minimize the degree of racemization during the polyacylation step.

Scheme I outlines the synthesis of the fully protected tetrapeptide. *N*-Carbobenzoxy(*O*-*tert*-butyl)-Ser was coupled with glycine pentachlorophenyl ester hydrochloride *via* the mixed anhydride method using isobutyl chlorocarbonate and *N*-methylmorpholine as base, to yield dipeptide active ester (I).

This product, as well as subsequent ones, were characterized by the presence of both amide I and II bonds and pentachlorophenyl ester bands in the IR spectrum as indicated in Table I.

Table II—pH Dependence of the Catalytic Coefficient for the Hydrolysis of *p*-Nitrophenylacetate by the Sequential Polypeptide (VIII) [a]

pH	k (liter mole^{-1}min^{-1})
6.4	47
6.9	81
7.4	138
7.9	64
8.4	39

[a] In 0.2 *M* phosphate buffer containing 3.5% dioxane (v/v) at 37°.

Dipeptide (I), was successfully deprotected by catalytic hydrogenolysis to give the dipeptide active ester hydrochloride (II). Using the same procedures, *N*-carbobenzoxy(*O*-*tert*-butyl)-aspartic acid was coupled with dipeptide active ester hydrochloride (II) to give protected tripeptide active ester (III). This tripeptide was deprotected to produce *O*-*tert*-butyl-Asp-(*O*-*tert*-butyl)-Ser-Gly pentachlorophenyl ester hydrochloride (IV). *N*-Carbobenzoxy(imbutyloxycarbonyl)-His was coupled with tripeptide active ester hydrochloride (IV) to give the protected tetrapeptide active ester, *N*-carbobenzoxy (imbutyloxycarbonyl)-His-(*O*-*tert*-butyl)-Asp-(*O*-*tert*-butyl)-Ser-Gly pentachlorophenyl ester (V). This was followed by hydrogenolytic deprotection to give (imbutyloxycarbonyl)-His-(*O*-*tert*-butyl)-Asp-(*O*-*tert*-butyl)-Ser-Gly-pentachlorophenyl ester hydrochloride (VI).

Synthesis of Free Sequential Polymer Poly(His-Asp-Ser-Gly)—Tetrapeptide active ester hydrochloride (VI) was allowed to polymerize in presence of dimethylformamide and triethylamine to yield crude protected polymer (VIII), which was converted to deprotected polymer without further purification as characterization.

A suitable method to remove the *t*-butyl protecting groups was that of a previous study using trifluoroacetic acid (15). Using conditions previously reported (8) produced the unprotected polymer (VIII). The completion of reaction was established by the absence of *t*-butyl group absorption in the IR spectrum as well as titration of free carboxyl groups. After dialysis employing a membrane[6] which retains compounds with molecular weight >5000, a polymeric product containing >15 or 16 repeating units was obtained.

Optical Purity of Sequential Polymer—The optical purity of poly-(His-Asp-Ser-Gly) was calculated by determining the optical activity of the total hydrolysate and comparing it with that of a control. It was found that no significant racemization occurred during the polyacylation reactions. Since all intermediates at each stage were extensively purified prior to use in the synthesis of the tetrapeptide, the optical purity of sequential polymer was relatively high, as expected.

Determination of Catalytic Activity—The catalytic hydrolyses of *p*-nitrophenylacetate by various copolymers have been previously studied (1, 2). Hydrolytic activity of the copolymers was found to depend on pH, temperature, and concentration of the substrate. Stereoselectivity is also a striking characteristic of true enzyme action. A previous study (5) reported the stereoselectivity of synthetic peptide esterase models as a catalyst, suggesting that some of the polyfunctional effects associated with the enzyme active site might indeed be operative in these peptide models. A further study (3) showed that in all cases, first-order kinetics are followed over most of the reaction.

Table II describes the catalytic coefficient for the hydrolysis of *p*-nitrophenylacetate by the sequential polypeptide (VIII) at different pH values at 37°. Highest activity was obtained at pH 7.4. Thus, catalytic activity of the sequential polymer (VIII) was done at pH 7.4, and the results are shown on Table III. While it has a higher catalytic coefficient than histidine, imidazole, or mixture of component amino acids, this sequential polymer failed to give a high catalytic coefficient. This occurred even though the polymer-incorporated amino acids were known to be present in the active sites of various proteolytic enzymes. The low activity may be due to lack of sufficient interactions between the imidazole group of histidine, the hydroxyl group of serine, and the carboxyl group of aspartic acid.

Table III—Catalytic Coefficients (k) for the Hydrolysis of *p*-Nitrophenylacetate by the Sequential Polymer (VIII) and Other Catalysts [a]

Catalyst	Catalytic Coefficient (k) liter moles^{-1}min^{-1}
L-His·HCl	7
Imidazole	48
Sequential Polymer (VIII)	138
L-His+Asp+L-Ser+Gly	18
α-Chymotrypsin	10^4

[a] In 0.2 *M* phosphate buffer, pH 7.4, containing 3.5% dioxane (v/v) at 37°.

The synthesis and catalytic activity of the sequential polypeptide incorporating histidine, aspartic acid, and serine was achieved. The active ester method of polymerization gave excellent yields and moderately high molecular weight polymer with little or no racemization as evidenced by the high degree of optical purity. The successful synthesis of sequential polypeptide H-(His-Asp-Ser-Gly)-OH suggests that this method can be utilized for synthesis of polypeptides containing other functional groups. This sequential polypeptide, containing residues known to be involved in the catalytic activity of chymotrypsin, failed to show significant catalytic activity.

Determination of the absolute value of activity per catalytic center is difficult because the number of active sites depends on the shape of the molecule. Also, this work does not provide any information on the stereospecific hydrolysis of the substrate.

Colorimetric Determination of Acetylcysteine, Penicillamine, and Mercaptopropionylglycine in Pharmaceutical Dosage Forms

M. A. RAGGI ˣ, V. CAVRINI, and A. M. DI PIETRA

Received October 13, 1981, from the *Institute of Pharmaceutical Chemistry, University of Bologna, 40126 Bologna, Italy.* Accepted for publication February 5, 1982.

Abstract □ *A colorimetric determination of acetylcysteine, penicillamine, and mercaptopropionylglycine is described. The method is based on the oxidation of mercapto-compounds with iron(III) in the presence of 1,10-phenanthroline. The iron(II) formed was quantitatively and rapidly converted to the stable tris(1,10-phenanthroline)iron(II) complex measured spectrophotometrically at 515 nm. The results obtained from various commercial formulations indicate that the method proposed allows a simple, sensitive determination of these mercapto-drugs with good accuracy (99.5–101% recovery) and remarkable precision (RSD ±0.6–1.6%).*

Keyphrases □ Acetylcysteine—colorimetric determination in pharmaceutical dosage forms, penicillamine, mercaptopropionylglycine □ Penicillamine—colorimetric determination in pharmaceutical dosage forms, acetylcysteine, mercaptopropionylglycine □ Mercaptopropionylglycine—colorimetric determination in pharmaceutical dosage forms, acetylcysteine, penicillamine □ Colorimetry—analysis of penicillamine, acetylcysteine, and mercaptopropionylglycine in pharmaceutical dosage forms

A number of thiol (SH)-containing drugs are commercially available and are utilized in various therapeutic applications. Among the most widely used are acetylcysteine, a topical pulmonary mucolytic agent; penicillamine, a therapeutic agent for the treatment of Wilson's disease and heavy metal poisoning; and mercaptopropionylglycine, a drug used in hepatic disorders.

Numerous analytical methods have been developed for the quantitative assay of the thiol group (1–3). The USP method (4) for acetylcysteine determination, based on the potentiometric titration of the thiol group with mercuric nitrate using a calomel–gold electrode system, was considered affected by some possible ambiguities due to the divalency of mercury (5). Other procedures reported for determining this drug in pharmaceutical dosage forms include spectrophotometric (6) and colorimetric techniques (5, 7).

Numerous extensive studies on the chelating properties of penicillamine *versus* a variety of metals have been reported (8–19), but analytical procedures for its quantitative determination have been developed more for biological (20–24) than for pharmaceutical systems (25). The official USP method (26) involves the use of the highly toxic mercuric acetate, and recently a study (25) investigated alternative procedures such as nonaqueous amine titration, nonaqueous acid titration, and hydroxylamine colorimetric assay.

A few studies on the chelating ability of mercaptopropionylglycine have appeared (27, 28), but no analytical procedures for its determination in pharmaceutical formulations are available to the authors' knowledge.

It is highly desirable to provide a single colorimetric procedure suitable for all these mercapto-compounds, for which a direct spectrophotometric method is unwarranted due to interference from excipients.

In this report a simple and sensitive colorimetric procedure, based on the formation of the tris(1,10-phenanthroline)iron(II) complex, is described for determining acetylcysteine, penicillamine, and mercaptopropionylglycine in various commercial formulations.

EXPERIMENTAL

Instruments—A digital single-beam spectrophotometer[1], a double-beam spectrophotometer[2], a pH meter[3], and a microanalytical balance[4] were used.

Materials—Pharmaceutical grade acetylcysteine[5], penicillamine[5], and mercaptopropionylglycine[5] were used as working standards. All reagents were analytically pure and were used without further purification. Commercially coated tablets, injectable solutions, syrup of mercaptopropionylglycine, and injectable solutions of acetylcysteine and capsules of penicillamine were analyzed as dosage forms.

Reagents—The 0.25% aqueous solution of 1,10-phenanthroline was prepared by dissolving 0.25 g of the compound in distilled water and diluting to 100 ml after gentle heating. This solution was stored for ≤3 days, in a tight light-resistant container. For the iron(III) 4×10^{-3} *M* solution, 1.92 g of ferric ammonium sulfate dodecahydrate dissolved in distilled water was treated with 10 ml of concentrated hydrochloric acid and diluted with water to a 1000-ml volume. This solution was also protected

Table I—Parameters and Correlation Coefficients of Calibration Plots [a] for Mercapto-Compounds

Mercapto-Compound	*A*	*B*	*r*
Acetylcysteine	10791	−0.001	0.9998
Penicillamine	11100	0.01	0.9999
Mercaptopropionylglycine	11267	−0.001	0.9999

[a] Calibration plots are expressed as regression lines of the form $y = Ax + B$; with y = absorbance, x is the molar concentration of mercapto-compounds, B is the y-intercept, A is the slope of the line; r is the correlation coefficient of the line.

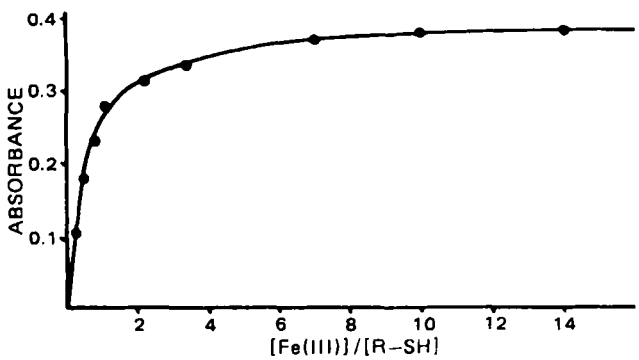

Figure 1—*Absorbance* versus *molar ratio of iron(III) to mercapto-compound (R—SH) for a 0.3 × 10⁻⁴ M acetylcysteine solution, pH 3.4.*

Table II—Assay Results of Commercial Pharmaceutical Dosage Forms

Drug	Dosage Form	Declared, mg	Found[a], mg	Recovery, %	*RSD*, %
Penicillamine	Capsules	150	151.0	100.7	0.72
Mercapto-propionylglycine	Ampuls	100	101.0	101.0	1.60
	Syrup	100	99.5	99.5	0.60
	Coated Tablets	250	252.0	100.8	1.50
Acetylcysteine	Ampuls	100	100.1	100.1	0.63

[a] Average of five determinations.

from sunlight. A pH 4 buffer was prepared by mixing 75 ml of 0.1 *M* CH_3COOH with 25 ml of 0.1 *M* CH_3COONa. Whenever necessary, 0.2 *M* CH_3COONa was also used to adjust the pH.

Standard Solutions—For acetylcysteine, 0.163 g of the drug was dissolved in water up to a 500-ml volume; dilution to a 1:5 ratio gave the desired concentration. For penicillamine, 0.149 g of the drug was dissolved in water up to a 500-ml volume, and the solution was diluted five times to give the desired concentration. For mercaptopropionylglycine, 0.167 g of the drug was dissolved in water up to a 500-ml volume; dilution to a 1:5 ratio gave the desired concentration.

Calibration Curves—For calibration of acetylcysteine, penicillamine, and mercaptopropionylglycine serial volumes of 1–5 ml (in 1-ml steps) of standard solution were transferred to 25-ml volumetric flasks. Six milliliters of iron(III) solution, 2.5 ml of phenanthroline, 3.5 ml of sodium acetate (0.2 *M*), and 4.5 ml of buffer and water to volume were added in succession. After 20 min (after 1 hr for penicillamine) the absorbance at 515 nm was measured against a blank, prepared simultaneously without thiol solution.

To evaluate a possible disodium edetate interference, 1–10% of this compound was added to a 3×10^{-5} *M* thiol solution, and absorbance was measured under the described conditions.

Determination of Acetylcysteine—For the determination of acetylcysteine in injectable solution, a volume equivalent to 100 mg of acetylcysteine was diluted to 200 ml with distilled water and 10 ml of this solution was further diluted five times. The procedure for the calibration curve was followed using 2 ml of the final solution.

Determination of Penicillamine—For the determination of penicillamine in capsules, the contents of 10 capsules were mixed, and an amount equivalent to 150 mg of the drug was accurately weighed and dissolved in water to a 500-ml volume. After stirring, the solution was filtered. To 10 ml of the filtrate were added 10 ml of 0.2 *M* CH_3COONa, 15 ml of pH 4 buffer, and water to a volume of 50 ml. Using 3 ml of this solution, the procedure for the calibration curve was followed.

Determination of Mercaptopropionylglycine—For the determination of mercaptopropionylglycine in syrup, 16 mg of powder was dissolved in water up to a 250-ml volume. Using 3 ml of this solution, the procedure for the calibration curve was followed. For the determination of mercaptopropionylglycine in injectable solutions the content of one ampule (2 ml), equivalent to 100 mg of the drug, was diluted with water to 200 ml; 10 ml of this solution was further diluted five times. Using 2 ml of this solution, the procedure for the calibration curve was followed. For the determination of mercaptopropionylglycine in commercial coated tablets, 10 coated tablets were powdered and mixed. A portion of this powder (117 mg) was transferred to a 500-ml volumetric flask, and water was added with stirring for 10 min before filling to volume. Using 3 ml of this solution, suitably filtered, the procedure for the calibration curve was followed.

RESULTS AND DISCUSSION

The proposed method is based on the ability of mercapto-compounds to reduce iron(III) to iron(II) (reaction 1), which is rapidly converted to the highly stable and colored tris(1,10-phenanthroline)iron(II) complex (reaction 2) with λ_{max} = 515 nm and ϵ = 11,100 (29, 30).

$$2\,Fe^{3+} + 2\,R{-}SH \rightarrow 2\,Fe^{2+} + R{-}S{-}S{-}R + 2\,H^+ \quad (1)$$

$$Fe^{2+} + 3\,(C_{12}H_8N_2) \rightarrow [Fe(C_{12}H_8N_2)_3]^{2+} \quad (2)$$

Scheme I

The conditions under which the reaction of each mercapto-compound with iron(III) in the presence of 1,10-phenanthroline fulfills the necessary analytical requirements were investigated. The amount of phenanthroline added must be at least in a 3:1 ratio with respect to the iron(II), according to reaction 2. The time necessary for the completion of the reaction depends on temperature, pH, and on the amount of iron(III) added. At room temperature, which was chosen to meet the practical requirements of analytical speed, the influence of pH and iron(III) concentration was investigated. It was observed that under the described experimental conditions, the optimum pH range for the reaction was 2.5–4.5. This is markedly different from the 7–8 pH range selected previously for the colorimetric determination of cysteine (31) and thioethylamine (32) by means of nitrilotriacetateferrate(III).

The influence of iron(III) concentration on the color development is illustrated in Fig. 1, where the absorbance *versus* molar ratio of iron III to mercapto-compound is reported. By increasing the iron III concentration, the reaction can be forced to completion, as indicated by the constant value of absorbance for iron(III) concentration in up to tenfold excess of mercapto-compound.

All absorbance readings (515 nm) were taken for acetylcysteine and mercaptopropionylglycine after 20 min *versus* the blank, which contained all the reagents except thiol; for penicillamine, color development was found to be complete in longer times (1 hr). In all cases the absorbance was constant for at least 2 hr. Under these experimental conditions, good reproducibility was obtained (*RSD* = 0.34%).

A calibration curve of absorbance *versus* concentration was constructed for each mercapto-compound in the range of 4.5–80 μM. The parameters and correlation coefficients of calibration plots, expressed as regression lines of the form of $y = Ax + B$, are listed in Table I. As can be seen from the equations obtained, the lines pass very close to the origin and the slopes remain relatively constant for all three drugs investigated.

Regression analysis of all of the data by least squares gave the line $y = 11015x + 0.01$ (correlation coefficient of 0.998), which reproduces satisfactorily the experimental absorbance values obtained for various concentrations of all three mercapto-compounds. These results indicate that acetylcysteine, penicillamine, and mercaptopropionylglycine, according to reaction 1, similarly reduce iron(III) to iron(II), which successively forms the phenanthroline complex. The calibration curve obtained for mercapto-compounds was also compared with the calibration plot for iron(II) solutions treated by phenanthroline under the described experimental conditions. The comparison showed that reaction 1 was quantitative, since the absorbance values for the mercapto-compounds and those for iron(II) solutions at the same molar concentration were essentially identical.

The proposed colorimetric method was applied to analysis of commercially available pharmaceutical dosage forms of acetylcysteine, penicillamine, and mercaptopropionylglycine. The results obtained (Table II) indicate that the proposed method is suitable for analyzing various types of formulations. No interference due to air oxidant effect or due to excipients such as magnesium stearate, titanium dioxide, lactose, *etc.* has been observed. The possible interference by disodium edetate salt present in some preparations containing penicillamine and acetylcysteine was investigated. It was found that under the described experimental conditions, concentrations of disodium edetate as high as 10% of the thiol compound did not interfere with the analysis, at variance with some volumetric procedures reported previously (25).

In summary, the proposed method allows a simple, sensitive determination of the thiol-group containing drugs investigated, with good accuracy (99.5–101% recovery) and remarkable precision (*RSD* ± 0.6–1.6%). The fact that this method requires more time in the case of penicillamine than some methods previously proposed (20, 25), is compensated by the high stability of the colored complex and by the lack of disodium edetate interference.

Arterial and Venous Blood Sampling in Pharmacokinetic Studies: Griseofulvin

MEI-LING CHEN, GILBERT LAM, MYUNG G. LEE, and WIN L. CHIOU ˣ

Received August 3, 1981, from the *Department of Pharmacy, College of Pharmacy, University of Illinois at the Medical Center, Chicago, IL 60612.* Accepted for publication February 4, 1982.

Abstract □ The pharmacokinetics of griseofulvin were evaluated simultaneously using both arterial and venous plasma in three dogs and one rabbit after a rapid bolus intravenous dosing. Initial arterial–venous ratios 20 sec after injection were the highest and ranged from 15- to 752-fold for dogs; the ratio was 3240-fold for the rabbit. Both curves decayed paralleling each other at the terminal phase with the venous levels higher than arterial levels by 14–43 and 8.4% for the dogs and the rabbit, respectively. The use of the instantaneous input principle was found to overestimate the total area under the plasma level–time curve by as much as 166%. An exponential term with a negative coefficient was used to account for the short and steep rising phase of plasma levels after injection. Detailed analyses showed significant differences in various calculated pharmacokinetic parameters based on arterial or venous data. The present study exemplifies the need for careful assessment and interpretation of classical pharmacokinetic parameters. It appeared that short intravenous infusion rather than the instantaneous or rapid bolus intravenous injection should be preferred for routine pharmacokinetic studies.

Keyphrases □ Griseofulvin—pharmacokinetics, arterial and venous blood sampling □ Pharmacokinetics—arterial and venous blood sampling, griseofulvin □ Blood sampling—arterial and venous pharmacokinetics of griseofulvin

Preliminary results showing marked and persistent arterial–venous (A–V) plasma concentration differences of six drugs (propranolol, lidocaine, procainamide, furosemide, theophylline, and griseofulvin), following intravenous administration to dogs or rabbits, were recently reported from this laboratory (1). The pharmacokinetic consequences of data analysis by using arterial or venous data on propranolol also has been described (2).

The present report describes in detail arterial and venous plasma level profiles of griseofulvin in three dogs and one rabbit and discusses the resulting effects on pharmacokinetic analysis.

EXPERIMENTAL

Bolus Injection Studies—Griseofulvin[1] (40 mg/ml) in polyethylene glycol 400[2] (1, 3) was injected as a bolus over 20 sec to the cephalic vein in three male mongrel dogs and to the ear vein in one male New Zealand white rabbit. Dogs 1 and 2 were conscious while dog 3 and rabbit 1 were anesthetized with nitrous oxide during the study. The doses administered to each animal are summarized in Table I. The midpoint of the injection was timed zero. Femoral arterial and venous blood samples were withdrawn simultaneously from permanent cannulas in the dogs and a specially designed T-loop in the rabbit. The preparation of the cannulas and the surgical procedure were described elsewhere (2). Heparinized normal saline (10 U/ml) was used for flushing of the cannula during the study. The sampling times, also midpoints of collection, were usually at 0.33, 0.66, 1, 1.33, 1.66, 2, 3, 6, 9, 15, 30, 60, 80, 100, 120, 140, 160, and 180 min

Table I—Comparison of Arterial–Venous Plasma Difference of Griseofulvin after Intravenous Bolus Administration to Dogs and Rabbit

	Dog 1	Dog 2	Dog 3	Rabbit
Body weight, kg	21.3	19.2	20	3.7
Dose, mg	60	60	60	14
A–V ratio at 0.33 min	176	15	752	3240
Time of intersection, min	4	2	15	45
Percent difference during terminal phase	30.0	43.0	14.7	8.4
Terminal half-life, min	64.8	37.5	73.7	277

in the dog studies, while the collection schedule extended to 300 min in the rabbit. The blood samples were centrifuged immediately to avoid the potential storage effect in the plasma concentration determination (4, 5), and 0.1 ml of plasma was collected in duplicate and frozen until assayed by a fluorometric HPLC method developed earlier in this laboratory (6).

Pharmacokinetic Analysis—The total areas under the plasma level–time curve from time zero to infinity (*AUC*) were estimated by the following three methods:

Method I—The linear trapezoidal rule was used from time zero to the last sampling point followed by the extrapolation method (*i.e.*, the last point concentration divided by the terminal rate constant).

Method II—The logarithmic trapezoidal rule (7) was used from the first to the last sampling point followed by the extrapolation method. The linear trapezoidal rule was used between time zero to the first sampling point. The method was previously employed in a propranolol study (2).

The plasma concentration at time zero in Methods I and II was assumed to be zero (8).

Method III—A NONLIN (9) computer program was employed for the determination of conventional (8) polyexponential equations ($\Sigma A_i e^{-\lambda_i t}$) based on the postpeak plasma data. For the prepeak plasma data, a linear least-squares feathering method was used to obtain another exponential rate constant, m, using a programmable calculator[3].

Since the plasma concentration at time zero was assumed to be zero, the coefficient of this exponential term, M, was set to equal the sum of the positive exponential coefficients, *i.e.*, ΣA_i. The following integration equation was used:

$$AUC = \Sigma\frac{A_i}{\lambda_i} - \frac{M}{m} \quad \text{(Eq. 1)}$$

Standard methods were used to determine the total body clearance, Cl; initial volume of distribution, V_1; apparent volume of distribution at the pseudodistribution equilibrium (10), V; steady-state volume of distribution (2, 11), V_{ss}; mean residence time (12), MRT; and the fraction of dose remaining in the body after bolus injection (2, 13):

$$Cl = \text{dose}/AUC \quad \text{(Eq. 2)}$$

$$V_1 = \text{dose}/C_p{}^0 \quad \text{(Eq. 3)}$$

$$V = \text{dose}/(AUC \times \lambda_n) \quad \text{(Eq. 4)}$$

$$V_{ss} = (\text{dose} \times \int_0^\infty AUC_{t\to\infty}dt)/AUC^2 \quad \text{(Eq. 5)}$$

$$MRT = AUMC/AUC \quad \text{(Eq.6)}$$

$$\text{Fraction remaining in the body} = AUC_{t\to\infty}/AUC \quad \text{(Eq. 7)}$$

where $C_p{}^0$ is the extrapolated plasma concentration at time zero based on the conventional method (8); λ_n is the rate constant of the terminal phase; $AUMC$ is the area under the first moment of the plasma curve, and $AUC_{t\to\infty}$ is the total plasma area from time t to infinity. The AUC values for the calculation of these pharmacokinetic parameters were obtained from Method II.

RESULTS AND DISCUSSION

The arterial and venous plasma concentration profiles of griseofulvin are shown in Figs. 1 and 2. The arterial levels shortly after injection were all much higher than the venous levels indicating an extensive and rapid uptake of griseofulvin by the sampling tissues during a single passage in the leg (1, 2, 11, 13). The maximum A–V ratio for each study occurred at 0.33 min; this ranged from 15 for dog 2 to 3240 for the rabbit (Table I). These ratios decreased to unity at ~2 min for dog 2 and 45 min for the rabbit (Table I) when the net uptake by the sampling tissue was zero (*i.e.*, when the sampling tissue concentration was the maximum). Thereafter, the venous levels were higher than the arterial levels due to the release of griseofulvin from the leg tissues to the venous blood (1, 2, 11, 13). During the apparently parallel arterial and venous terminal phases (Figs. 1 and 2), the venous plasma levels were higher than arterial levels by ~30, 43, 14.7, and 8.4% for dogs 1, 2, 3, and the rabbit, respectively. The terminal half-life in the three dogs studied ranged from 37.5 to 73.7 min, and that for the rabbit was estimated to be 277 min (Table I). A longer sampling time in the rabbit study might be preferred in view of its long terminal half-life.

Various factors affecting the A–V difference during the terminal phase were discussed previously from a theoretical point of view (14). The smaller A–V difference observed in the rabbit study as compared with the dog studies was consistent with the hypothesis (14) that the longer the half-life the smaller the A–V difference in the terminal phase. This is because the rate of release of drug from the sampling tissue to the venous blood would be slower if the half-life were longer (assuming other factors were the same). It should be noted that the terminal arterial or venous plasma half-lives should be theoretically identical (14) as shown in five other drugs in animals (1, 2) and insulin in humans (15).

Unlike the conventional concept of instantaneous input to the central or plasma compartment (1, 2, 14, 16), the venous griseofulvin concentrations after bolus dosing were found to increase from the first 0.33 min and to peak at 1 min in the three dogs and at 2 min in the rabbit (Figs. 1 and 2). For dogs 1 and 2, the arterial plasma levels both peaked at 0.66 min (Fig. 1). These data resembled a rapid absorption plasma level profile

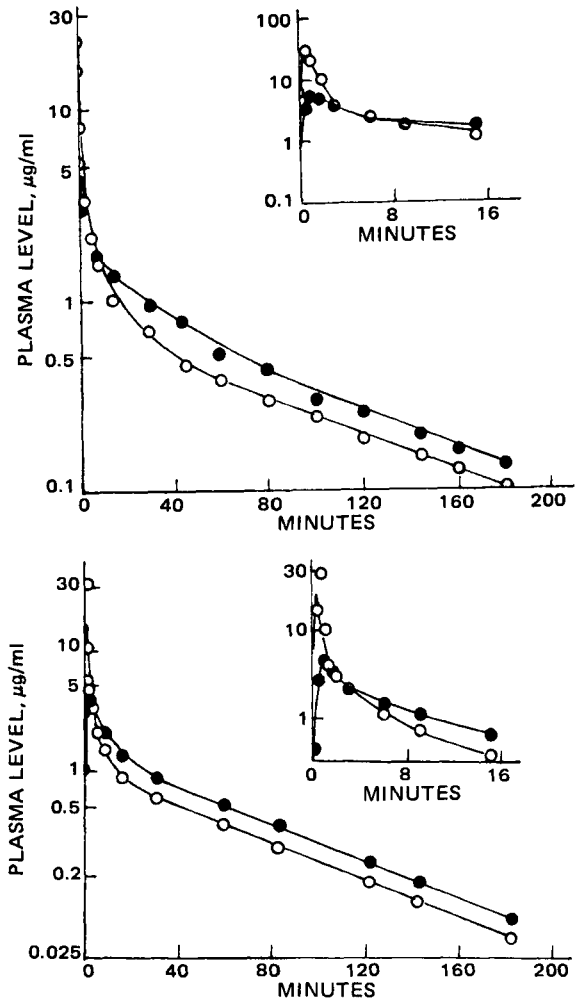

Figure 1—*The arterial (○) and venous (●) plasma level profiles after bolus injection of 60 mg of griseofulvin to dog 1 (upper curve) and dog 2 (lower curve). Solid lines are computer-generated, best-fitted curves. Inserts show the plasma level profiles in the first 16 min.*

[3] Hewlett-Packard, Corvallis, Oreg.

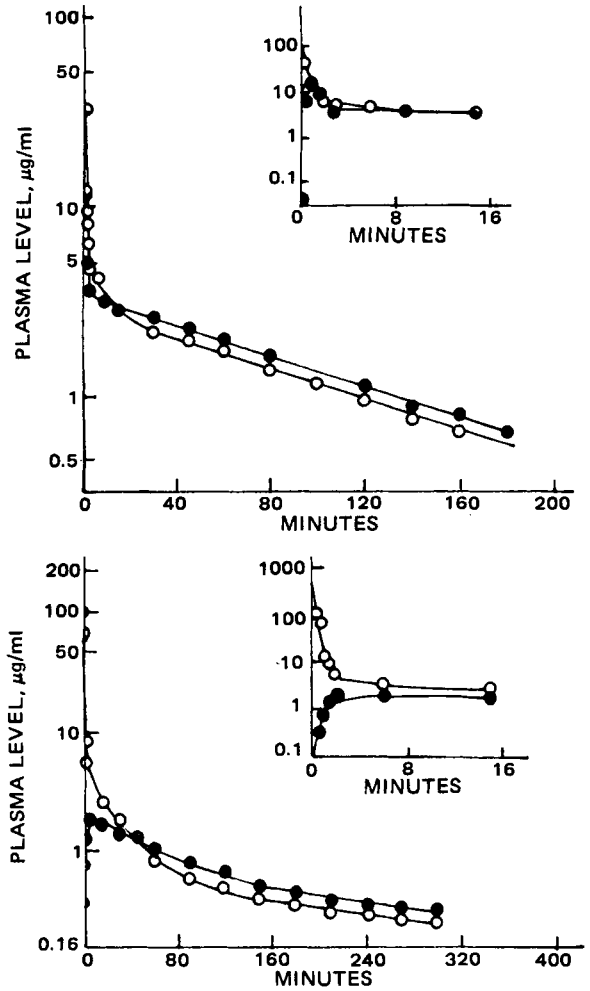

Figure 2—*The arterial (○) and venous (●) plasma level profiles after bolus injection of 60 mg of griseofulvin to dog 3 (upper curve) and 14 mg to the rabbit (lower curve).*

(2, 16). To account for this rising phase, a negative exponential term (Me^{-mt}) was used in curve fittings. The goodness of fit is judged by the closeness between the actual and computer-generated values as shown in Figs. 1 and 2, together with similar *AUC* measurements by the three methods (Table II). Furthermore, the r^2 value for all the fittings was >0.998. In the dog 3 and rabbit studies, the arterial plasma levels were found to peak at 0.33 min, which was the first blood sample; hence, their negative exponential term could not be ascertained.

The importance of recognizing that the plasma level should theoretically be zero at time zero following a bolus injection (8) is best illustrated in dogs 1 and 2. The total arterial plasma areas under the negative exponential curve could be calculated to account for 35 and 166% of the *AUC* for dogs 1 and 2, respectively (100 M/*m*/*AUC* where *AUC* was estimated based on Method II). Failure to consider this factor would result in a large overestimation of the arterial *AUC* in these two dogs if the conventional concept of the instantaneous mixing or polyexponential decay was applied. This effect apparently was minimal for dog 3 as the arterial *AUC* calculated by the conventional method was close to those calculated by the other two methods, assuming zero concentration at time zero (Table II). The effect on the venous *AUC* calculation in most of the studies was also relatively insignificant (Table II). This was in contrast with the furosemide studies in the dogs where the true venous *AUC* values could be overestimated by up to 20% if factors of initial transport lag time (8) and uptake of sampling tissues were not considered (16). The above analysis, together with findings from previous studies (1, 2, 8, 16) indicate the complexity and difficulty in accurately describing the unit-impulse disposition function of drugs (8, 17) in the body. It should be emphasized that an accurate determination of the *AUC* from the instantaneous dosing is important, since the value obtained is often used to calculate other pharmacokinetic parameters. In this regard, it appears that a short-term, intravenous infusion rather than a bolus or instantaneous injection might be preferred. Furthermore, the *AUC* from the infusion study can be more simply estimated by the linear-logarithmic trapezoidal rule-extrapolation method (7) as employed in Method II of the present study.

Theoretically, the arterial *AUC* should equal the venous *AUC* if a drug is not metabolized in the sampling tissues (2, 9, 14, 18). This was confirmed in the dog studies (Table II). In the rabbit study, however, the arterial *AUC* was higher than the venous *AUC* by ~16%. Similar results were found in other drug studies. The reason for such inequality remains to be explored.

Except for the rabbit, the *Cl* and *V* values estimated from arterial and venous plasma data in the three dogs were, as expected, essentially the same (Table III). However, the physiological significance of these values may be different (2, 19, 20). The calculated values for V_1 were found to

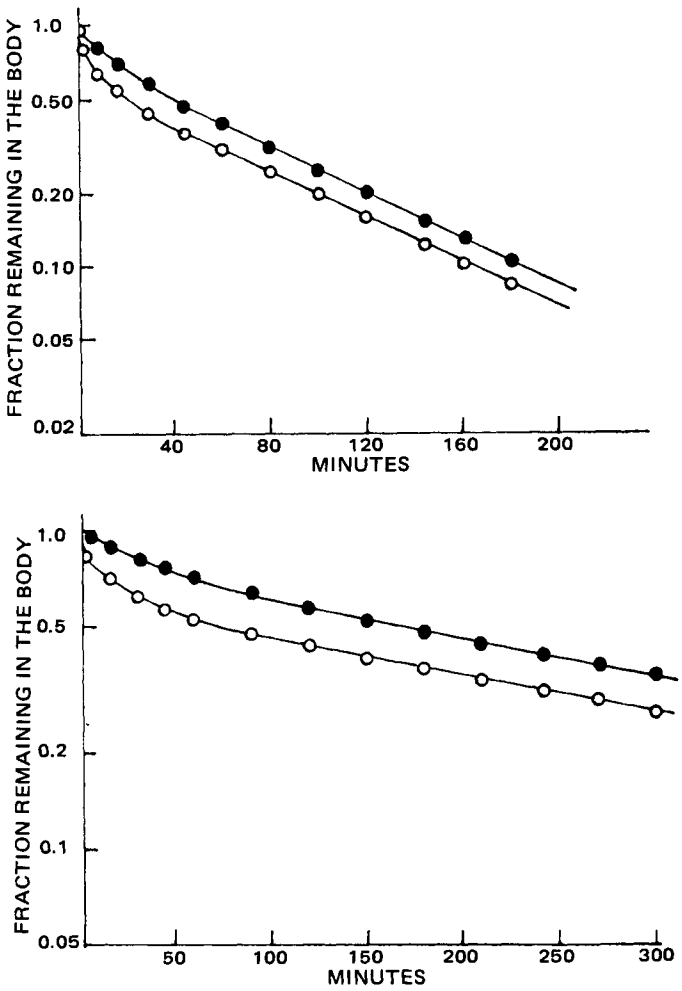

Figure 3—*Calculated fractions of griseofulvin dose remaining in the body after bolus injection of 60 mg of griseofulvin to dog 1 (upper curve) and 14 mg to the rabbit (lower curve). Key: arterial (○) and venous (●) plasma levels.*

vary considerably in the same animal, depending solely on the source of plasma data used (Table III). The venous V_1 values were 6.1, 55.2, 1.5, and 133 times greater than the arterial V_1 values for dogs 1, 2, 3, and the rabbit, respectively. The marked differences primarily were attributed to the initial uptake of griseofulvin by the sampling tissues. Thus, the A–V difference is another factor affecting the calculated V_1 (2, 21). Its implication in the dosing regimen calculation or pharmacodynamic evaluation may have to be considered.

The results of *AUMC* and *MRT* calculations are summarized in Table III. For *AUMC*, those values calculated from the venous data were 33.7, 43.8, 15.8, and 12.1% higher than the arterial data for dogs 1, 2, 3, and the rabbit, respectively. For *MRT*, the corresponding venous data were 27.3, 29.7, 10.8, and 30.8% higher. The effect of the source of blood sampling on the calculated fraction of dose remaining in the body as a function of time in dog 1 and the rabbit is depicted in Fig. 3; the difference was pronounced. For example, at 1 hr the fractions remaining were 53 and 73%, respectively, based on the arterial and venous data for the rabbit. A more marked effect was found for propranolol in dogs and rabbits (2).

Significant and persistent A–V differences were also observed for griseofulvin following intravenous infusion to one unanesthetized dog (1). The A–V plasma levels were found to differ by 20% during the terminal phase. This preliminary study also showed that a similar trend of A–V difference existed when the whole blood was analyzed. The above analyses and discussion suggest that it may be important to investigate the possible A–V difference and its consequences (1, 2, 11, 14, 18, 19) in pharmacokinetic or pharmacodynamic studies of drugs in general.

Stereospecific Metabolic Reduction of Ketones

DANIEL B. PRELUSKY, RONALD T. COUTTS ˣ, and FRANCO M. PASUTTO

Received September 21, 1981, from the *Faculty of Pharmacy and Pharmaceutical Sciences, University of Alberta, Edmonton, Alberta T6G 2N8 Canada.* Accepted for publication February 19, 1982.

Abstract □ The stereospecificity of the metabolic reduction of arylalkylketones was investigated. The ketones, propiophenone (I), phenylacetone (III), and 1-phenyl-1,2-propanedione (V) were reduced *in vitro* and *in vivo* in rats and rabbits to the corresponding alcohols, 1-phenyl-1-propanol (II), 1-phenyl-2-propanol (IV), and 1-phenyl-1,2-propanediol (VIII), respectively. For the analysis, a capillary GLC method employing chiral derivatizing reagents for the resolution of these optically active alcohols was utilized. This study revealed that the metabolic reduction of each ketone produced the corresponding alcohol as a mixture of its enantiomers. With one exception, the mixtures obtained from all *in vivo* and *in vitro* reactions were shown to contain at least 70% of one isomer [*S*(−)-II, *S*(+)-IV, and *erythro*-VIII, respectively], with *in vitro* reduction showing the highest degree of stereospecificity (90–98%). The *in vivo* reduction of I by the rat was exceptional in that both optical isomers of II were recovered in equal proportions.

Keyphrases □ Ketones—stereospecific metabolic reduction, arylalkylketones, rats and rabbits □ Stereospecificity—metabolic reduction of arylalkylketones, rats and rabbits □ Metabolism—reduction of arylalkylketones, stereospecificity, rats and rabbits

Various studies on the biotransformation of xenobiotic ketones have established that ketone reduction is an important metabolic pathway in mammalian tissue (1–12). It has also been shown that when ketones are reduced metabolically, a significant product stereoselectively can be demonstrated to occur upon creation of the chiral alcohol (11–16). To determine the degree of stereoselectivity, a reliable method is required for the resolution of the stereoisomers. In many metabolic studies, the amount of product available for stereochemical analysis is often very small, making isolation and, hence, resolution procedures difficult.

As a continuation of earlier studies (2, 10), the metabolic reduction of three arylalkylketones and the efficient separation of the recovered stereoisomeric alcohols are described. Separation was accomplished by reacting the metabolites with optically active derivatizing reagents and resolving the resulting diastereoisomers by GLC. *In vivo* and *in vitro* metabolic reduction was studied in two species (the rat and the rabbit), and a comparison of the extent to which stereoselectivity occurs is provided.

EXPERIMENTAL

Compounds—Propiophenone (I), phenylacetone (III), and 1-phenyl-1,2-propanedione (V) were obtained commercially[1] and used as received. *RS*-1-Phenyl-1-propanol (II) and *RS*-1-phenyl-2-propanol (IV) were prepared by the asymmetric reduction of the corresponding arylalkylketone with the chiral sodium L-prolinate borane complex prepared according to a previously described procedure (17). Reduction of I gave a 72:28 ratio of the enantiomers of II [*S*(−)/*R*(+), respectively] as determined by polarimetric analysis[2]. Reduction of III gave a 60:40 ratio of the enantiomers of IV [*S*(+)/*R*(−), respectively]. The *erythro* and *threo* diastereoisomers of 1-phenyl-1,2-propanediol (VIII) were synthesized as previously reported (2).

Reagents—Trifluoroacetic anhydride (IX)[3] and *S*(+)-α-methylbenzyl isocyanate (X)[4] were used without further purification. The third derivatizing reagent *R*(−)menthyl chloroformate (XI) was prepared according to a previously described method (18). All solvents were reagent grade, redistilled prior to use.

Metabolic Studies and Extractions—The *in vivo* study involved the oral administration of each substrate (I, III, or V) to male Wistar rats (250 g) and male New Zealand white rabbits (2 kg). The animals were kept in metabolic cages, and urine was collected over 48 hr and stored at 4° until examined. Bulked urine samples from each group of treated animals were divided into three equal portions. One portion was adjusted to pH 7.5 with solid sodium bicarbonate and extracted three times with equal volumes of a diethyl ether–methylene chloride mixture (3:2). A second portion was buffered to pH 7.0 with phosphate buffer and hydrolyzed for 36 hr at 37° after the addition of β-glucuronidase[5] (15,000 U/ml). The sample then was extracted as described above after adjusting the pH to 7.5 with sodium bicarbonate. The third portion was acidified to < pH 1 with concentrated hydrochloric acid and autoclaved at 125° and 15 psi for 45 min. After hydrolysis was complete, the pH was readjusted to 7.5 with 10% NaOH and the resulting solution was extracted as described above for portion 1.

For the *in vitro* studies, each substrate (I, III, or V) was incubated at 37° with 12,000×*g* liver homogenate supernatant (rat or rabbit) to which was added either a nicotinamide adenine dinucleotide phosphate (NADPH) or a nicotinamide adenine dinucleotide (NADH)-generating system (glucose-6-phosphate[6], magnesium chloride, and NADP[7] or NAD[8]). Extraction of metabolic products was carried out as with portion 1 of the *in vivo* study.

All extracts were concentrated and yielded yellowish oils, small aliquots of which were used for analysis by derivatization.

Derivatization—The *R*(−)menthyloxycarbonyl derivatives were prepared as follows: 100 μl of a standard XI solution (50 μmole/ml of toluene) was added to a small portion of the concentrated extract (20 μl) dissolved in 100 μl of pyridine. The mixture was allowed to react at room temperature for 30 min. After washing with water (1 ml), the organic phase was removed, dried over sodium sulfate, and concentrated under nitrogen to 5 μl, of which 0.2 μl was used for GLC.

N-(1-Phenylethyl)urethanes were prepared by adding 50 μl of a X solution (30 μmole/ml of toluene) to a portion (20 μl) of the concentrated extract dissolved in 100 μl of toluene. The mixture was tightly sealed[9] under a nitrogen atmosphere and kept at 120° for 2 hr. The reaction mixture was concentrated to 5 μl under a nitrogen stream, and a suitable portion was used for GLC.

Trifluoroacetyl derivatives of the metabolically produced alcohols were prepared by dissolving a small portion (20 μl) of the concentrated extract in 30 μl of ethyl acetate, to which 70 μl of IX was added. The reaction was allowed to proceed for 30 min at room temperature. The reaction mixture was evaporated under nitrogen and the residue obtained redissolved in 10 μl of cyclohexane, of which a 0.2-μl aliquot was injected.

The derivatized alcohol metabolites were identified by comparing their GLC retention times and mass spectra with those of authentic samples containing one optical enantiomer (or diastereoisomer) in known excess. Analyses were performed with a gas chromatograph[10] equipped with a flame ionization detector. The GLC conditions were: capillary column[11]

(52 m) with temperature programming from 150 to 250° (4°/min). The injection port and detector temperatures were 250 and 300°, respectively. The flow rate of the carrier gas, helium, was 3 ml/min (17 psi). Mass spectrometer[12] conditions were separator and ionization source temperatures, 180° and ionization energy, 70 eV. The GLC column and operating conditions were as described above.

RESULTS

In vivo and *in vitro* metabolism of I by the rat and and rabbit produced various metabolites (2, 11) including the racemate alcohol, *RS*-II. Similarly, racemic *RS*-IV was metabolically produced, together with other metabolites from III (1, 2, 10, 11). In this study the relative amounts of the enantiomeric alcohols were determined by reaction with the chiral derivatizing reagents, X or XI, and resolving the resulting diastereoisomeric derivatives by GLC.

Initially it was necessary to determine the GLC elution sequence of the mixture of diastereoisomers formed by the reaction of the racemate alcohols (II and IV) with the chiral reagents (X and XI). To accomplish this, authentic samples of II and IV were synthesized by a procedure which was known to produce mixtures of alcohols enriched in one of the enantiomers (17). Compound II was prepared by the asymmetric reduction of I with a sodium L-prolinate borane complex to yield a mixture of the enantiomers in which the *S*(−)-isomer predominated (see *Experimental*). A comparison of the magnitude of the optical rotation of the mixture with that of a pure sample of *S*(−)-1-phenyl-1-propanol permitted the calculation of the amounts of *S*(−)-II and *R*(+)-II in the synthetic product (Table I). Compound IV was prepared from III in a similar manner. The mixture of stereoisomers was strongly dextrorotatory, indicative of *S*(+)-IV being in enantiomeric excess. The calculated ratio of *S*(+)-IV/*R*(−)-IV is illustrated in Table I.

The mixture of stereoisomers (II and IV) were then reacted with the chiral reagents (X and XI) and the products analyzed by GLC (Fig. 1). The inability to detect any unreacted alcohols ensured complete derivatization. Peak areas were integrated and the ratio of isomers calculated. The values obtained were in close agreement with those obtained from polarimetric data (Table I), thus permitting peak identification.

The efficiency of peak resolution varied. A greater separation between *R*- and *S*-1-phenyl-2-propanol (IV) was obtained after derivatization with X then with XI (Fig. 1), which resulted in a more precise determination of optical purity (Table I). With *R*- and *S*-1-phenyl-1-propanol (II), better separation was obtained following derivatization with XI than with X. However, isomer ratios calculated from both chromatograms were virtually identical and in good agreement with those obtained polarimetrically (Table I).

Having demonstrated that the enantiomers of the racemate alcohols (II and IV) could be efficiently separated and quantitated as the corresponding diastereoisomers, it was possible to determine the extent to which stereoselectivity occurred during the metabolic reduction of arylalkylketones (I and III) and to assign absolute configuration to the metabolites.

When I was reduced *in vitro* (12,000×*g* liver homogenate) in rats or rabbits, 93–97% of the product alcohol (II) occurred as the *S*(−)-isomer, the remainder being the *R*(+) form (Table II). Species differences were minimal and nicotinamide adenine dinucleotide phosphate or nicotinamide adenine dinucleotide-generating systems were equally efficient. A structurally related alcohol, 1-phenyl-1-ethanol, produced by the reduction of acetophenone by an aromatic ketone reductase isolated from rabbit kidney, was similarly found to be predominantly (76%) in the *S*(−)

	In vivo	—	N/P		81/19	87/13
		—	Enzyme		80/20	88/12
		—	Acid		72/28	79/21

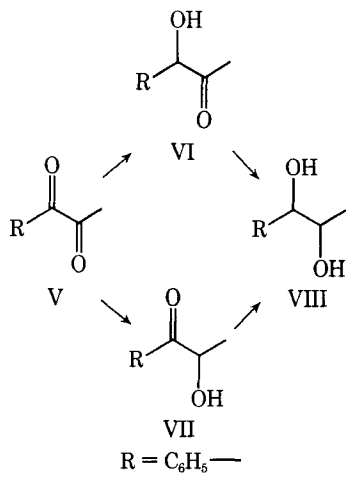
[a] Generating system; glucose-6-phosphate, magnesium chloride, and $NADP^+$ or NAD^+. [b] Hydrolytic pretreatment of biological sample: N/P, no pretreatment; enzyme, β-glucuronidase (15,000 U/ml, incubated 36 hr at 37°); acid, pH < 1 (autoclaved 40 min at 125° and 15 psi). [c] Ratio of enantiomers (as diastereoisomeric derivatives); 1-phenyl-1-propanol [S(−)/R(+)-II] as R(−)menthyl chloroformate derivative, 1-phenyl-2-propanol [S(+)/R(−)-IV] as S(+)-α-methylbenzyl isocyanate derivative.

form (12). *In vitro* reduction of phenylacetone (III) in rats and rabbits paralleled what was observed with the substrate I. The alcohol, IV, was recovered mainly as the S(+)-enantiomer (90–94%), regardless of the species and cofactor (Table II).

In vivo reduction of I by rabbits gave results comparable to those observed in *in vitro* studies. Approximately 90% of the alcohol recovered from urine was determined to be S(−)-1-phenyl-1-propanol [S(−)-II]. An earlier study has shown that after administration of propiophenone to rabbits, II was recovered entirely as the S(−)-glucuronide conjugate (11). In contrast to what occurred in rabbits *in vivo*, reduction of I in rats resulted in the recovery of a markedly higher proportion of the R-alcohol [R(+)-II]. In this instance, stereoselective reduction was less evident (Table II). Both enzymatic and acidic hydrolysis of the urine collected in the *in vivo* studies resulted in an increase in the relative amounts of R(+)-II isolated.

In vivo reduction of III to its corresponding alcohol (IV) resulted in the preferential formation of the S(+)-IV isomer, regardless of species (Table II). The ratio of enantiomers [S(+)/R(−)] formed by rat and rabbit were 81:19 and 87:13, respectively, corresponding to approximately twice the amount of R(−)-IV observed *in vitro*. In contrast, an earlier study (11) reported that when III was reduced in the rabbit, no trace of R(−)-1-phenyl-2-propanol was found. The S(+)-IV/R(−)-IV ratio was again influenced by the method used to hydrolyze urine (Table II).

In vivo and *in vitro* metabolism of V was also investigated in rats and rabbits. Reduction yielded three metabolites of major interest for this study: 1-hydroxy-1-phenyl-2-propanone (VI), 2-hydroxy-1-phenyl-1-propanone (VII), and 1-phenyl-1,2-propanediol (VIII), which was obtained as a mixture of its diastereoisomers (*erythro*- and *threo*-VIII) (Scheme I). Neither of the intermediate ketol metabolites (VI or VII) could be completely derivatized with either chiral reagent (X or XI) and, therefore, the optical purities of these metabolites could not be established. Similarly, the four-component mixture of optical isomers of the diol, VIII (1*S*2*R*- and 1*R*2*S*-*erythro*, 1*S*2*S*- and 1*R*2*R*-*threo*) could not be separated using the chiral reagents, but it was possible to separate the diastereoisomers as their trifluoroacetyl derivatives.



Scheme I

As observed with ketones I and III, *in vitro* reduction of V resulted in the formation of one predominant isomer of the diol metabolite (VIII) (Table III). Between 94 and 98% of VIII was recovered as the *erythro*-diastereoisomer. Only marginal variation in the measured *erythro–threo* ratio of VIII was observed, regardless of the source of the liver preparation or the nature of the cofactor utilized.

In vivo reduction of V similarly produced *erythro*-VIII as the major diastereoisomer, regardless of species. Ratios of the isomers isolated (*erythro–threo*-VIII) were 75:25 and 86:14, recovered from rats and rabbits, respectively. Hydrolysis of urine with either β-glucuronidase or acid caused no change in the ratio (Table III).

DISCUSSION

Conventional methods for determining the optical purity of metabolites have generally relied on isolating sufficient quantities of product for polarimetric analysis (11, 19–22). This presents a problem when the amount of product available is too small for accurate measurement of optical rotation. The use of chiral reagents and subsequent analysis of diastereoisomeric products by GLC (23–27) offers a sensitive alternative for the quantification of stereoisomeric metabolites. This analytical procedure provided the data summarized in Table II, which reveal that the metabolic reduction of I and III demonstrates a high degree of product stereoselectivity. The metabolites, II and IV, respectively, were recovered predominately as S-isomers in all studies with one exception: *In vivo* reduction of I by rats provided anomalous data.

In quantitative terms, the *in vitro* reduction of arylalkylketones has been reported to be significantly dependent on both the species and cofactor (2–4, 6–8, 10, 12), but the present study indicates that enantioselective preference is virtually unaffected by these variables.

The ratios of isomers isolated from the *in vivo* studies did vary, however, depending on the nature of the hydrolytic treatment of the urine samples prior to extraction and derivatization of the alcohol metabolites. A noticeable increase in the amount of R(+)-II recovered, relative to that of S(−)-II, was observed in both species after enzymatic hydrolysis (Table II). Since it has already been demonstrated that both enantiomers of II undergo glucuronide conjugation in rabbits (11), this observation suggests

[b] Hydrolytic pretreatment of biological sample: N/P, no pretreatment; enzyme, β-glucuronidase (15,000 U/ml, incubated 36 hr at 37°); acid, pH < 1 (autoclaved 40 min at 125° and 15 psi). [c] Ratio of diastereoisomers, *erythro–threo*-1-phenyl-1,2-propanediol (VIII) as the trifluoroacetylated derivative.

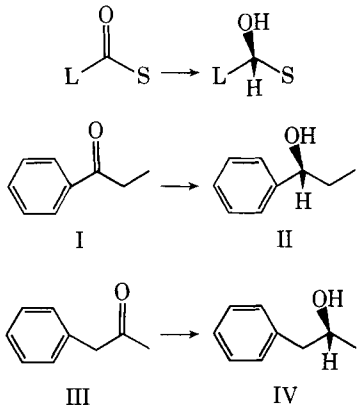
that a greater proportion of the $R(+)$-isomer is conjugated relative to the $S(-)$ form. Only minor changes were detected in the $S(+)/R(-)$ ratio of 1-phenyl-2-propanol (IV) after hydrolysis with β-glucuronidase, when compared with the ratio observed with no pretreatment of the urine samples.

The much higher levels of both $R(+)$-II and $R(-)$-IV measured after acidic hydrolysis possibly could be due to a more efficient cleavage of the conjugate with acid treatment than with β-glucuronidase. However, a more plausible explanation is that racemization of isomers occurred during the harsh treatment created by conditions of low pH and elevated temperature (19). This would account for the difficulty in obtaining reproducible results after acidic hydrolysis.

The absence of any noticeable change in the ratio of diastereoisomers of VIII suggest that both the *erythro* and *threo* isomers are conjugated to the same extent. However, it is perhaps more likely that because of the high polarity of the diols, neither compound (*erythro*-VIII nor *threo*-VIII) undergoes conjugation before being excreted in the urine.

A strong correlation between *in vivo* and *in vitro* results in the rabbit has been demonstrated in the present study with both substrates (Table II). A similar correlation was observed between *in vivo* and *in vitro* reduction of III in the rat, but not when I was the substrate (Table II). In the latter instance, enantioselectivity was clearly demonstrated in *in vitro* studies, but *in vivo* reduction of I appeared to be nonstereoselective. This anomalous situation may be the result of further preferential metabolism of $S(-)$-1-phenyl-1-propanol *in vivo* in the rat. Related studies support this suggestion. It has been established (28) that when 1-phenyl-1-ethanol was administered to rats as the $R(+)$-isomer, it underwent extensive conjugation and was excreted largely as the glucuronide, whereas the $S(-)$-isomer was further oxidized to $S(-)$-mandelic acid. If the metabolite, II, behaved similarly *in vivo* in the rat, it would account for the lower percentage recovery of $S(-)$-II compared with that obtained with the *in vitro* study. In addition, the increased recovery of $R(+)$-II after enzymatic treatment of the urine sample could be rationalized by liberation of the $R(+)$-isomer from the glucuronide conjugate.

The enantioselectivity of the reduction of the arylalkylketones (I and III) can be rationalized, based on a formula established previously (29) and confirmed by others (22, 30–33). This formula essentially states that if the ketone is positioned so the large substituent is placed to the left, reduction mainly occurs such that the resultant hydroxyl group rises above the plane of the molecule. Compounds I and III, therefore, could be predicted to be preferentially reduced to alcohols with the *S*-configuration (Scheme II: L, large substituent; S, small substituent). By applying Prelog's rule, it is possible to predict the stereochemistry of the diol (VIII), assuming that reduction proceeded *via* the ketoalcohol intermediates (VI and VII) and that the pattern of preferred stereoselectivity remains constant. Consequently, VIII should occur predominantly as the 1*R*2*S*-diastereoisomer. Although it was not possible to resolve the 1*R*2*S*- and 1*S*2*R*-*erythro* isomers, this prediction was accurate in as much as VIII recovered from the reduction of the diketone *in vitro* by both rat and rabbit was mainly (94–98%) the *erythro* form, the remainder being *threo*-VIII (Table III). Compound VIII recovered from *in vivo* studies



Scheme II

was also predominantly the *erythro* diastereoisomer, although a greater amount of the *threo*-compound was present compared to what was obtained from *in vitro* studies (Table III). However, caution should be exercised when attempting to explain this apparent decrease in stereoselectivity, since additional factors such as further metabolism and differences in distribution and elimination may contribute to the overall variation in recovery of diastereoisomers. In this instance there is the additional possibility that racemization resulting from interconversion of the ketol intermediates (VI ⇄ VII) could have also occurred (2, 23).

Drug Stability in Liposomal Suspensions: Hydrolysis of Indomethacin, Cyclocytidine, and *p*-Nitrophenyl Acetate

JOSEPH B. D'SILVA * **and ROBERT E. NOTARI** ˣ

Received September 30, 1981, from *Lloyd M. Parks Hall, College of Pharmacy, The Ohio State University, Columbus, OH 43210.* Accepted for publication February 16, 1982. *Present address: Pharmaceutical Research and Development, Central Research, Pfizer, Inc., Groton, CT 06340.

Abstract □ First-order rate constants (k_L) for hydrolysis of *p*-nitrophenyl acetate, cationic cyclocytidine, and anionic indomethacin in the presence of buffered liposomal suspensions of positive, negative, and neutral charge were compared to those determined in the corresponding buffers (k_B) using the ratio, $R_k = k_L/k_B$. Association between the reactants and the liposomes was evaluated by comparing assays for concentration in the filtrates (C_F) with the total concentration in the liposomal suspension (C_T) using $R_C = C_F/C_T$. Liposomes did not influence cyclocytidine hydrolysis rates and no association was observed ($R_k \simeq R_C \simeq 1$). In contrast, indomethacin showed ~80% reduction in hydrolysis rate and ~80% liposome association value ($R_k \simeq 0.2 \simeq R_C$). In neutral and negatively charged liposomal suspensions, *p*-nitrophenyl acetate displayed ~30% decrease in k_B ($R_k \simeq 0.7$) together with ~90% liposomal association ($R_C \simeq 0.1$). However, hydrolysis was greatly accelerated in positively charged liposomal suspensions. Loss was described by a biexponential equation where α is the fast and β is the slow pre-exponential coefficient and $\alpha/\beta/k_B$ = 39:6:1. The observed relationships between hydrolysis rates and reactant-liposome associations are reconciled in terms of the hydrophilicity of the reactants and the potential influence of the liposomes on the expected transition states for the hydrolysis reactions.

Keyphrases □ Indomethacin—hydrolysis, stability in liposomal suspensions, cyclocytidine, *p*-nitrophenyl acetate □ Stability—liposomal suspensions, hydrolysis of indomethacin, cyclocytidine, *p*-nitrophenyl acetate □ Hydrolysis—indomethacin, cyclocytidine, *p*-nitrophenyl acetate, stability in liposomal suspensions □ Liposomes, suspensions—drug stability, hydrolysis of indomethacin, cyclocytidine, *p*-nitrophenyl acetate

Interest in liposomes as potential drug delivery systems has prompted these investigations into the influence of liposomes on drug stability. This report compares the hydrolysis of a cation, an anion, and a neutral reactant in aqueous buffered solutions to that in buffered liposomal suspensions of positive, negative, and neutral charge.

BACKGROUND

The potential for changes in hydrolysis rates in micellar systems (1) and the implications to drug stabilization (2) are well documented and have been applied to aspirin (3–5) and indomethacin (6). Little has been reported on drug stability in liposomal suspensions although they are somewhat analogous to micellar systems. The rate of procaine hydrolysis was reduced in neutral liposomal suspensions relative to that in aqueous buffers, whereas 2-diethylaminoethyl-*p*-nitrobenzoate hydrolysis was accelerated at pH < 7.8 and retarded at pH > 7.8 (7). The degradation rate of *p*-nitrophenol acetate was accelerated by increasing liposomal lecithin concentration (8). These studies measured the total amount of drug in the suspension.

EXPERIMENTAL

Preparation of Liposomes—Cholesterol[1,2] (~7.4 mg) was placed in a 50-ml round bottom-stoppered flask together with either ~21 mg of dicetyl phosphate[1] (for negatively charged liposomes) or ~10.4 mg of stearylamine[1] (for positively charged liposomes). α-Tocopherol[1] (1 ml of 1.5×10^{-3} *M*) in chloroform (9, 10) was added, followed by 7 ml of chloroform and 1 ml of 1% lecithin in methanol–chloroform, 1:9[1]. The resulting solution was concentrated under vacuum for 3 min under a rotary evaporator at 42° (±2°). Evaporation was then continued at ambient temperature with the final traces of chloroform being removed by flushing with nitrogen.

Sixteen milliliters of buffer was added, and the mixture was agitated on a vortex mixer until the material from the sides of the flask formed a suspension of large liposomes. The flask was placed in a cup-horn sonicator[3] and cooled for 2 min using circulating water kept at 2°. The mixture was sonicated for 4 min at 60% power (maximum power = 20 kHz) using one-half second pulses per second. During the sonication the cooling water was kept circulating around the flask. Throughout the procedure the head space of the flask was periodically flushed with nitrogen to minimize oxidation. The size and shape of the liposomes were monitored using a microscope with an eye-piece micrometer together with particle size analysis (see *Kinetics of Hydrolysis*).

Analytical Methods—Stability-indicating spectrophotometric assays for indomethacin[4], *p*-nitrophenyl acetate, and cyclocytidine in buffered aqueous solutions, in total liposomal suspensions and in their filtrates are described below. The chromophoric hydrolysis products of cyclocytidine[1] (cytarabine[1]) and *p*-nitrophenol acetate[5] (*p*-nitrophenol[6]) were also measured. The products of indomethacin hydrolysis were nonchromophoric at 330 nm, which is near the 323-nm indomethacin absorption maximum.

To quench the hydrolysis of either indomethacin or *p*-nitrophenyl acetate in the total liposomal suspension, 1 ml of suspension was added to 4 ml of cold 0.5 *M* formic acid in water–methanol (2:8). The mixture was shaken and stored in a refrigerator. Prior to analysis it was warmed to room temperature and centrifuged at 3200 rpm for 30 min to remove liposomal material. Four milliliters of the supernatant solution was mixed with 4 ml of methanol and the resulting solution was centrifuged for 10 min. The UV absorbance of the resulting clear solution was determined at the appropriate wavelengths in a spectrophotometer[7], against a blank prepared in a similar manner omitting the reactant. The procedure for cyclocytidine was identical but employed 0.2 *M* HCl in water–methanol (1:9) to stabilize cytarabine, and the first centrifugation was 40 min.

Molar absorptivities (ϵ) were determined from the slopes of Beer's law plots using solutions in the buffers. The apparent molar absorptivities (ϵ') representing the procedure for assaying liposomal suspensions in the same buffers were similarly determined. Comparison of the values of ϵ' with those of ϵ indicated that the recovery was 93–100% as shown in Table I.

Since degradation products did not absorb at 330 nm, total indomethacin concentration, C_i, in the liposomal suspension was calculated from:

$$C_i = D\,(A_{330})/(\epsilon'_{330}) \qquad \text{(Eq. 1)}$$

where the dilution factor D is 10, ϵ'_{330} is the apparent molar absorptivity at 330 nm, and A_{330} is the absorbance of the final dilution at 330 nm.

Since the UV spectra of cyclocytidine and *p*-nitrophenyl acetate overlapped with those of their respective degradation products, the total absorbance of a mixture in the final dilution at a given wavelength, A_λ, is defined as:

$$A_\lambda = [\epsilon'_1(C_1) + \epsilon'_2(C_2)]/D \qquad \text{(Eq. 2)}$$

where $D = 10$, C_1 and C_2 are the total concentrations of reactants and products, respectively, in the liposomal suspensions, and ϵ'_1 and ϵ'_2 are their apparent molar absorptivities at wavelength λ. The total absorbance determined at each of two wavelengths, A_x and A_y, then results in two simultaneous equations which may be solved to yield:

$$C_1 = D[\Delta_{1x}(A_x) - \Delta_{1y}(A_y)] \quad \text{(Eq. 3)}$$

$$C_2 = D[\Delta_{2x}(A_x) - \Delta_{2y}(A_y)] \quad \text{(Eq. 4)}$$

where $\Delta_{1x} = \epsilon'_{2y}/(\epsilon'_{1x}\epsilon'_{2y} - \epsilon'_{1y}\epsilon'_{2x})$, $\Delta_{1y} = \epsilon'_{2x}/(\epsilon'_{1x}\epsilon'_{2y} - \epsilon'_{1y}\epsilon'_{2x})$, $\Delta_{2x} = \epsilon'_{1y}/(\epsilon'_{2x}\epsilon'_{1y} - \epsilon'_{1x}\epsilon'_{2y})$, $\Delta_{2y} = \epsilon'_{1x}/(\epsilon'_{2x}\epsilon'_{1y} - \epsilon'_{1x}\epsilon'_{2y})$, ϵ'_{1x} and ϵ'_{1y} are the apparent molar absorptivities of the reactants, and ϵ'_{2x} and ϵ'_{2y} are those of the products, at wavelengths x and y, respectively (Table I).

For the analysis of filtrates, 2-ml aliquots of reactions in the presence of liposomal suspensions were gently filtered using disposable cartridges[8] and a syringe. In the case of indomethacin and *p*-nitrophenyl acetate, 0.5 ml of the filtrate was mixed with 2 ml of cold 0.5 *M* formic acid in water–methanol (2:8). The procedure for cyclocytidine was identical, except that 0.2 *M* HCl in water–methanol (1:9) was employed instead of 0.5 *M* formic acid. Absorbances were measured in microcuvetes and the concentrations were determined using the ϵ values in Table I in Eqs. 1, 3, and 4 with $D = 5$. Total particle counts[9] which were 4×10^6/ml in the liposomal suspensions were reduced to background (<2000/ml) in the filtrate by this procedure.

Kinetics of Hydrolysis in Buffers and in Buffered Liposomal Suspensions—Rates of hydrolysis of cyclocytidine, indomethacin, and *p*-nitrophenyl acetate were studied at 40° in the aqueous buffers described in Table II. Aliquots were removed as a function of time and analyzed for concentrations.

Liposomal suspensions (Table II) were prepared as described and heated at 40° for 12 hr with constant agitation[10]. An aliquot of a stock solution of the reactant was then added to 12 ml of the liposomal suspension, which was maintained at 40° with continued agitation. At appropriate intervals aliquots of the mixture were removed, the reaction head-space flushed with nitrogen, and the samples were analyzed for total concentration in the liposomal suspension and also in the filtrate. Before, and after the reaction, 6-μl aliquots of the liposomal suspension were diluted with 10 ml of the same buffer in which they were prepared. One milliliter of this dilution was further diluted with 10 ml of buffer, and the particle size of the liposomes in this suspension was determined[9].

Hydrolysis rates in filtrates in the absence of liposomes were shown to be the same as those in their corresponding buffered solutions by using the following procedure. Sixteen milliliters of positively charged liposomal suspension was prepared using carbonate buffer and heated at 40° for 12 hr with constant agitation[10]. The suspension was centrifuged at 2600 rpm for 50 min, and the bulk of the liposomes that concentrated at the top of the mixture were removed[11]. Five milliliters of the remaining suspension was filtered through several disposable filter cartridges[8]. The filtrate was used to study the hydrolysis of indomethacin as described previously for aqueous buffers at 40°. This procedure was also employed to study the hydrolysis of *p*-nitrophenyl acetate in the filtrate obtained from positively charged liposomes prepared with phosphate buffer. No difference was observed between the rate constants in buffer and in the corresponding filtrate. These two reactions were chosen because they had shown the greatest change in rate constants in the presence of liposomes.

To estimate the maximum volume occupied by the liposomes in a suspension, 10 ml of a negatively charged suspension prepared in carbonate buffer was heated at 40° for 12 hr with constant agitation. The suspension was then heated for an additional 24 hr with no agitation. The liposomes that concentrated at the top were removed, and the volume of the remaining mixture was determined to be 9.2 ml.

RESULTS

Apparent First-Order Hydrolysis—Except for the loss of *p*-nitrophenyl acetate in the presence of positive liposomes (to be discussed), all kinetic data were adequately described by the first-order equation,

$$\ln C_t = \ln C_0 - k_{obs}t \quad \text{(Eq. 5)}$$

where t is time, C_0 and C_t are the reactant concentrations initially and at time t, and k_{obs} is the observed first-order rate constant.

Cyclocytidine—The sum of the cyclocytidine and cytarabine concentrations as a function of time equaled the initial concentration of cyclocytidine. If the ratio of the rate constant in the presence of liposome

[8] Millex-GS 0.22 μm Filter unit, Millipore Corp., Bedford, Mass.
[9] Elzone Model 80 XY, Particle Data Inc., Elmhurst, Ill.
[10] Submersion Rotator, Scientific Industries, Inc., Queens Village, N.Y.
[11] In these concentrated buffers, liposomes ascended on centrifugation. The direction was reversed if buffers were diluted tenfold before centrifuging.

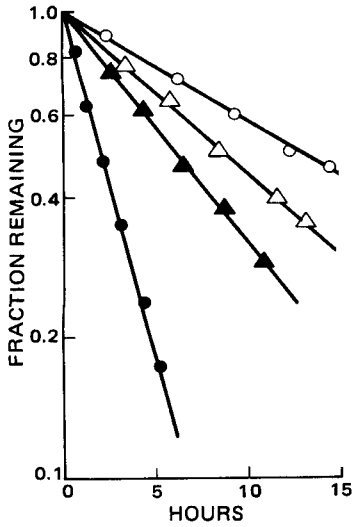

Figure 1—*First-order plot for fraction of indomethacin remaining in carbonate buffer, pH 9.37, (●) and in the presence of liposomes of negative (▲), neutral (△), or positive (○) charge at 40°.*

(k_L) to that in buffered solution (k_B) is defined as:

$$R_k = k_L/k_B \qquad \text{(Eq. 6)}$$

it is apparent that $R_k \simeq 1$ (Table II).

The filtrate concentration (C_F) can be compared with the corresponding concentration in the total liposomal suspension (C_T) using the ratio, R_C where:

$$R_C = [C_F/C_T]_{t_{0.5}} \qquad \text{(Eq. 7)}$$

Although the differences between C_F and C_T are small, the filtrate concentrations were consistently higher than the liposomal concentrations giving R_C values >1 (Table II). This may be due to a small decrease in volume by removal of the liposomes.

Indomethacin—The reduced rates of indomethacin hydrolysis in various liposomal suspensions as compared with that in liposome-free buffer are shown in Fig. 1. This reduction is reflected in the R_k values which are 0.156, 0.318, and 0.226 in positively charged, negatively charged, and neutral liposomal suspensions, respectively.

In negatively charged liposomes R_C = 0.28, and the first-order rate constant obtained from the filtrate data was k_F = 0.106 hr^{-1} (Fig. 2) which agrees with its corresponding k_L value. In filtrates from the neutral and positively charged liposomal suspensions, the low concentrations of indomethacin (relative to assay sensitivity) prevented the accurate estimation of first-order rate constants, k_F. However, average values for R_C could be estimated from the ratios of measured C_F to calculated C_T values. Since each ratio is comprised of a small numerator (C_F) and a large denominator (C_T), the variability in R_C is minimized (Fig. 3, Table II).

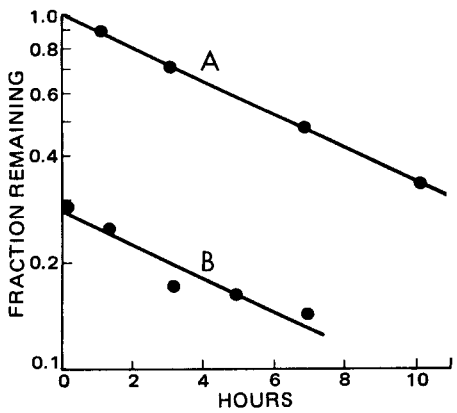

Figure 2—*Comparison of first-order plots for total indomethacin in a negatively charged liposomal suspension (A) to the fraction in the filtrates (B) at 40° in carbonate buffer, pH 9.37.*

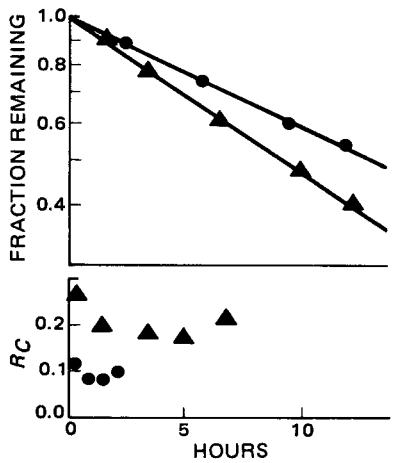

Figure 3—*Calculated R_C values for indomethacin as a function of time and their corresponding first-order plots in neutral (▲) and positively charged (●) liposomal suspensions at 40° in carbonate buffer, pH 9.37.*

p-Nitrophenyl Acetate—The sum of *p*-nitrophenyl acetate and *p*-nitrophenol concentrations as a function of time equaled the initial concentration of *p*-nitrophenyl acetate. The rate of loss of *p*-nitrophenyl acetate in phosphate buffer was decreased in neutral and negatively charged liposomal suspensions. This reduction is reflected in the R_k values of 0.740 and 0.688, respectively. The values of R_C are 0.144 and 0.086 for neutral and negatively charged liposomal suspensions respectively, and the first-order rate constants in the filtrates (k_F) are close to their respective k_L values (Table II).

Semilogarithmic plots of the concentration of *p*-nitrophenyl acetate in positively charged liposomal suspensions as a function of time showed a rapid initial decrease followed by a much slower loss. The biphasic curves were analyzed by the following equation:

$$F = Ae^{-\alpha t} + Be^{-\beta t} \qquad \text{(Eq. 8)}$$

where $F = C_t/C_0$, and $\alpha > \beta$ (Fig. 4). Nonlinear regression analyses provided average values of A = 0.406, B = 0.595, α = 0.233 min^{-1}, and β = 0.0341 min^{-1}. Experimental C_F values and calculated C_T values determined during the beta phase were used to calculate an average R_C value, of 0.508.

DISCUSSION

Cyclocytidine, indomethacin, or *p*-nitrophenyl acetate, in liposomal suspensions can hydrolyze in the bulk aqueous solution or in the liposomal phase. The association of reactant with the liposomal phase might occur in several ways. Those interactions that bring the compounds into the proximity of an organic environment can cause a change in the hydrolysis rate in accordance with the expected solvent effects (Fig. 5).

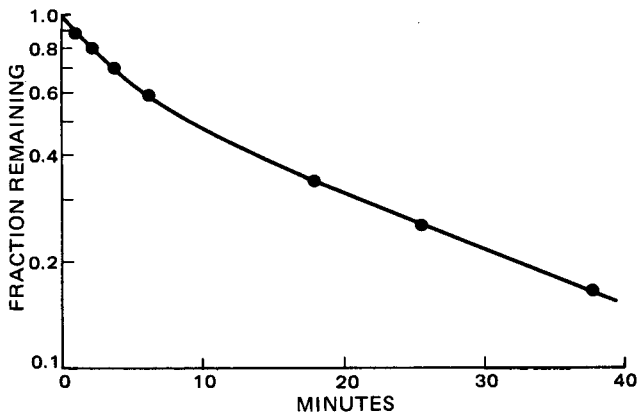

Figure 4—*Semilogarithmic plot for fraction of* p*-nitrophenyl acetate remaining as a function of time in positively charged liposomal suspension at 40° in phosphate buffer pH 7.51. Curve is drawn from nonlinear regression analysis based on Eq. 8.*

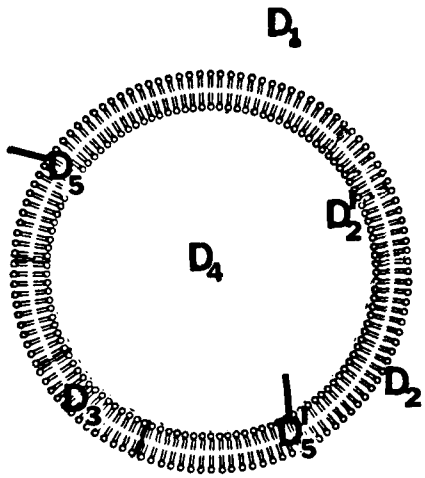

Figure 5—*Possible locations of a compound,* D, *in a liposomal suspension;* D_1 *is in the external aqueous phase;* D_2 *and* D'_2 *are associated with the outer and inner walls;* D_3 *is associated with the hydrocarbon portion of the lipid bilayers;* D_4 *is dissolved in the aqueous portions of the liposome; and* D_5 *and* D'_5 *are solubilized in the hydrocarbon portion of the lipid bilayer with portions protruding into the aqueous environments.*

Media with low ion-solvating power will inhibit the creation or concentration of charges while accelerating charge destruction (11). A change in rate would, therefore, depend on the reaction mechanism and the species involved.

The hydrolysis of cyclocytidine was not affected by the presence of liposomes as evidenced by the similarity between the values of the first-order hydrolysis rate constants determined in aqueous buffer (k_B), in liposomal suspensions (k_L), and using the data representing the filtered samples obtained from the reactions in suspensions (k_F, Table II). Assay of the filtrates accounted for the total drug in the liposomal suspensions. Cyclocytidine, a highly polar, water soluble, positively charged compound, probably resists association due to its hydrophilicity. This, in itself, would not preclude surface participation in the reaction rate. Positive and negative liposomal surfaces could affect reaction intermediates and/or transition states, in that positively charged liposomes would be expected to stabilize negatively charged species and *vice-versa*. Since hydroxyl anion attack on the cyclocytidine cation produces a neutral transition state, no sensitivity to surface charge would be anticipated.

In contrast, indomethacin in the presence of positively charged, negatively charged, and neutral liposomes, and *p*-nitrophenyl acetate in negatively charged and neutral liposomal suspensions all provide hydrolysis rate constants (k_L) that are slower than those in aqueous buffer (k_B). Since this loss can be described by the first-order equation:

$$\frac{-d(DT)}{dt} = k_L(DT) \qquad \text{(Eq. 9)}$$

where (DT) is the total amount of drug in the liposomal suspension at time t, and k_L is the apparent first-order rate constant for loss of drug, the simplest kinetic scheme (Scheme I) that can represent this data is:

$$DF \underset{}{\overset{\text{Fast}}{\rightleftharpoons}} DL$$
$$\downarrow k_B \qquad\qquad \downarrow k_\Delta$$

Scheme I

where (DF) is the drug in the bulk aqueous phase, (DL) is the drug associated with the liposomes and, k_B and k_Δ are the rate constants for the loss of drug from the bulk aqueous and liposomal phases, respectively. It is obvious that:

$$k_L(DT) = k_B(DF) + k_\Delta(DL) \qquad \text{(Eq. 10)}$$

and, therefore, the rate constant k_L can be described:

$$k_L = k_B f_B + k_\Delta k_L \qquad \text{(Eq. 11)}$$

where $f_B = (DF)/(DT)$, and $f_L = (DL)/(DT)$. A similar expression has been applied to the hydrolysis of a number of compounds in the presence of micelles (1). Since the volume occupied by the liposomes in these suspensions was found to be <10%, the ratio $R_C = [C_F]/[C_T]$ is approximately equal to $f_B = (DF)/(DT)$. Setting $f_L = (1 - f_B)$ and substituting R_C for f_B in Eq. 11 results in:

$$k_L = k_B(R_C) + k_\Delta(1 - R_C) \qquad \text{(Eq. 12)}$$

The rate constants for the hydrolysis of indomethacin in positively charged, negatively charged, and neutral liposomes (k_L) are 15.6, 31.8, and 22.6% of k_B. Indomethacin is associated with the liposomes to the extent of 90, 72, and 80% in positively charged, negatively charged, and neutral liposomes, respectively (R_C values, Table II). The extent of this association could be a function of electrostatic attraction. The negatively charged indomethacin molecules would be attracted to the positively charged liposomes to the greatest extent followed by the neutral liposomes, while the carboxylate anion would be repelled by the negatively charged liposomes. At the reaction pH, indomethacin is made up of a hydrophilic carboxylate anion and the remaining hydrophobic moiety. Thus, if indomethacin associates with the liposomes, it could be positioned at the interface of the aqueous bulk and the hydrocarbon portion of the lipid bilayer as shown in Fig. 5.

A similar effect has been reported for the hydrolysis of the sodium salt of mono-*p*-nitrophenyl dodecanedioate in micellar aggregates (12). By analogy to that study, the carboxylate anion of indomethacin could be in an aqueous environment, while the hydrophobic part containing the amide linkage could be stabilized in the hydrocarbon environment of the liposomes. In addition, the hydrolysis of indomethacin involves the attack of a hydroxide ion on the negatively charged molecule, thus causing the collection of similar charges in the transition state. This process would be inhibited by the bilipid layer.

The first-order rate constants for hydrolysis of *p*-nitrophenyl acetate in the presence of negatively charged and neutral liposomes are 68.8% and 74.0%, respectively, of that in the aqueous buffer. *p*-Nitrophenyl acetate is ~90% associated (Table II). Unlike indomethacin, *p*-nitrophenyl acetate does not have a formal charge. If *p*-nitrophenyl acetate associates with the liposomes, it would not selectively shield the ester linkage away from the aqueous environment. It has been shown in micellar phases, that compounds having a slight polar nature (such as nitrobenzene) are solubilized at the surface of a micelle rather than in the hydrocarbon interior (13, 14). Consequently, *p*-nitrophenyl acetate could be largely exposed to the aqueous environments both within the liposomes and at the bulk aqueous interface. This could account for the fact that ~90% association resulted in only an ~30% reduction in rate constant. Since hydroxide attack on *p*-nitrophenyl acetate would provide a negative transition state, electrostatic depression in hydrolysis rate would apply.

The decrease of *p*-nitrophenyl acetate concentration in the presence of positively charged liposomes is described by a biexponential equation in which the exponential coefficients, α and β, are 38.6 and 5.65 times faster, respectively, than k_B. This acceleration and biexponential hydrolysis rate might be attributed to elecrostatic stabilization of the negatively charged transition state by the positive charges on the surface of the liposomes in accordance with the following kinetic scheme (Scheme II):

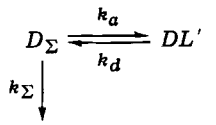
$$DF \underset{}{\overset{\text{Fast}}{\rightleftharpoons}} DS \underset{k_d}{\overset{k_a}{\rightleftharpoons}} (DL')$$
$$\downarrow k_B \qquad \downarrow k_{cat} \qquad\qquad \downarrow k_\Delta$$

Scheme II

Table III—Percent Comparisons for Hydrolysis in Liposomal Suspension Relative to the Buffer ($100\ k_L/k_B$), Hydrolysis of Associated Reactant Relative to Free ($100\ k_\Delta/k_B$), Percentage of Reaction in the Associated Fraction ($100\ k_\Delta f_L/k_L$), and the Percent Associated ($100\ DL/DT$)

Reactant	Liposomal Charge	% = (100) Numerator/Denominator k_L/k_B	k_Δ/k_B	$k_\Delta f_L/k_L$	DL/DT
Cyclocytidine	(+ − 0)	95 ± 4	0	0	0
Indomethacin	(+)	16	6	36	90
	(−)	32	5	12	72
	(0)	23	3	12	80
p-Nitrophenyl acetate	(−)	69	66	88	91
	(0)	74	70	81	86

Surface catalysis has been suggested for the enhanced rate of hydrolysis of *p*-nitrophenyl hexanoate in solutions containing cationic micelles (15). Here, (*DF*) is in rapid pseudo equilibrium with (*DS*), the ester associated with the exterior surface (Fig. 4), (*DL'*) represents liposome–ester association by the remaining mechanisms, k_{cat} is the rate constant for hydrolysis of *p*-nitrophenyl acetate catalyzed by the positively charged liposomal surface, and k_a and k_d are the rate constants for the association and dissociation of (*DS*) with (*DL'*). Since the ratio $\alpha/\beta/k_B$ is 39:6:1 and R_C (beta phase) is ~0.5, it follows that $k_{cat} \gg k_B > k_\Delta$ and the simplest representation would be to set $(D_\Sigma) = (DF + DS)$ and $k_\Sigma = (k_B + k_{cat})$ allowing (Scheme III):



Scheme III

where k_Δ is considered insignificant relative to k_Σ. This is analogous to those cases discussed under Scheme I wherein liposome-associated reactant was stabilized relative to that in liposome-free buffer. Biexponential equations and the calculations for their individual rate constants in models described by Scheme III have been published (16). The fraction remaining, $F = (DT)/(DT)_0$, is given by:

$$F = \left(\frac{\alpha - k_a - k_d}{\alpha - \beta}\right) e^{-\alpha t} + \left(\frac{k_a + k_d - \beta}{\alpha - \beta}\right) e^{-\beta t} \qquad \text{(Eq. 13)}$$

which describes data of the shape shown in Fig. 4. Under these conditions, $k_\Sigma = A\alpha + B\beta = 6.9\ hr^{-1}$, $k_d = \alpha\beta/k_\Sigma = 4.2\ hr^{-1}$, and $k_a = \alpha + \beta - k_\Sigma - k_d = 5.0\ hr^{-}$. The phase ratio, $(DL')/(D_\Sigma)$ may be calculated from $k_a/(k_d - \beta) = 2.3$ (17) which can be used to estimate $R_C = C_F/C_T \simeq 0.3$. Although Scheme III is an oversimplification, the estimated rate constants are reasonable, the shape of Fig. 4 is consistent with Eq. 8, and the calculated R_C approaches that observed (R_C = 0.5, Table II).

Comparisons—While the net influence of liposomes on reaction rates is reflected by the k_L/k_B ratio (R_k, Eq. 6), an overall assessment requires concomitant examination of several aspects. The reactivity in the associated phase (*DL*) relative to that in the bulk aqueous phase (*DF*) is given by k_Δ/k_B, but the percentage contribution of each phase to the reaction (k_L) is 100 $k_\Delta f_L/k_L$ and 100 $k_B f_B/k_L$ rather than the percent of liposomal association (100 *DL/DT*) or the rate constants themselves. It is the competition between $k_\Delta f_L$ and $k_B f_B$ that controls the degree to which the overall process occurs in each phase. Collectively, the four parameters listed in Table III provide an aggregate interpretation of the total kinetic behavior, whereas any one of the components taken alone would be inadequate.

Although differences in pH preclude absolute comparisons of the three reactants, some outstanding contrasts can be noted (Table III). Liposomal association of cyclocytidine was not detected, and its hydrolysis rate constants in all four suspensions are approximately equal to that in the buffer. Both reactant distribution and hydrolysis appear limited to the aqueous bulk. In contrast, *p*-nitrophenyl acetate (in the presence of negative and neutral liposomes) shows 81–88% of the reaction occurring in the *DL* phase. This is the consequence of the percentage values being $k_L/k_B \approx k_\Delta/k_B \approx 70\%$ with 90% association. Rate constants for hydrolysis in the liposomal phases (k_Δ values in hr^{-1} calculated from Eq. 12) are 0.252 in neutral and 0.238 negatively charged liposomal suspensions. Thus, $k_B \approx 1.4k_\Delta$, but only 10% remains in the *DF* phase. Hydrolysis occurs primarily in the *DL* phase at a slightly reduced rate. This is consistent with the hypothesis that the associated ester remains largely accessible to the aqueous environment in the liposome.

Indomethacin is also highly associated (72–90%), but the values of k_Δ were ~0.02, 0.018, and ~0.01 hr^{-1} in positively charged, negatively charged, and neutral liposomes, respectively. In this case the percent of $k_L/k_B \approx 24\%$ since $k_\Delta/k_B \approx 5\%$. The high degree of association subjects most of the reactant to a greatly reduced rate constant. Only 12–36% of the process occurs in the *DL* phase. This provides a significant depression in the overall hydrolysis rate constant, but the reaction occurs primarily in the aqueous bulk. This reduced reactivity in the *DL* phase implies protection of the reactive center by liposomal association.

Thus, Table III provides examples of three different situations. In one case, cyclocytidine is limited to the aqueous buffer and no liposomal influence is observed. The remaining two cases are predominantly associated in roughly equivalent percentages but with differing consequences. Indomethacin reactivity is greatly reduced with only a minor contribution to the reaction occurring in the associated phase. *p*-Nitrophenyl acetate reactivity is slightly reduced occurring primarily in the associated phase where the rate constant is 70% of the constant for the aqueous bulk. The exception in this study is *p*-nitrophenyl acetate in positively charged liposomal suspensions which serve as catalysts to the ester hydrolysis as discussed in the previous section.

Dissolution-Controlled Transport from Dispersed Matrixes

S. K. CHANDRASEKARAN [‡§x] **and D. R. PAUL** [*]

Received June 8, 1981, from [*]*Alza Research, Palo Alto, CA 94304* and the [‡]*University of Texas, Austin, TX.* Accepted for publication February 19, 1982. [§]Present address: ABCOR, Inc., Wilmington, MA 01887.

Abstract □ A simplified mathematical model for dissolution-controlled transport from dispersed matrixes is presented. Analytical solutions have been obtained previously when solute diffusion totally controls the transport process. However, when solute dissolution offers the limiting resistance to mass transport, the solution reduces to a form where the mass released varies directly with time. Experimental release rates of a drug from a dispersed polymeric matrix into water were measured for a range of drug particle sizes in order to test the applicability of the proposed model; the agreement between theory and experimental is good.

Keyphrases □ Dissolution—transport from dispersed matrixes □ Matrixes—dispersed, dissolution-controlled transport □ Models, dissolution—dissolution-controlled transport from dispersed matrixes

The theory of diffusional release of a solute or therapeutic agent from a polymer matrix where the initial loading of solute is greater than the solubility limit was initially proposed by Higuchi (1). Several assumptions were made in this model: (*a*) the suspended solute is present as particles of diameter much smaller than the thickness of the matrix; (*b*) the receptor medium is immiscible with the matrix and serves as a perfect sink for the released solute; and (*c*) a pseudo steady-state condition exists during the transport process. More recently the pseudo steady-state assumption in Higuchi's model was reexamined (2) and it was concluded that an exact analysis offered some advantages under conditions of low solute loadings but became virtually identical with Higuchi's analysis for large solute loadings.

The Higuchi model has been applied extensively in the literature with favorable results (2–6). However, there have been several cases in which the drug release-rate kinetics from drug-dispersed matrixes are not adequately described by this model. The *in vitro* release rate of steroids from silicone elastomeric matrixes was studied (7), and it was found that their results were inconsistent with the Higuchi model. Based on the effect of concentration and particle size on the duration of drug release, a dissolution rather than diffusion-controlled mechanism was suggested. It was determined (8) that the release rate of salicylic acid from ointment bases did not follow the Higuchi model, and the discrepancy was related to an inadequate dissolution rate of the suspended particles. The release of benzocaine from ointment bases was determined (9) and it was found that the release rate was not proportional to the square root of drug concentration.

Several theories have been put forth for dissolution-controlled transport mechanisms. The area of drug release rate processes in biopharmaceutics was reviewed (10), in which dissolution mechanisms are considered as a heterogeneous reaction with mass transfer occurring through the movement of solute molecules from solid surfaces. The thermodynamics of drug release from polymeric matrixes was studied (11) and the process was depicted to involve three energy-activated steps: (*a*) dissociation of drug molecules from a crystal lattice, (*b*) solubilization of drug molecules in the polymer matrix, and (*c*) diffusion of drug molecules in the matrix. More recently a good mathematical model for drug release from suspensions was developed (12, 13), which is relatively complex and requires numerical techniques to obtain general solutions. In that study the dissolution rate of a drug in a vehicle and diffusion through the vehicle was related to drug distribution and cummulative drug uptake by a receptor phase. When dissolution is essentially nonexistent, it was found that the suspension behaved as a solution with respect to drug release, whereas when dissolution is slower than diffusion, the rate of dissolution markedly influenced the rate of drug release.

The purpose of the present study was to develop a simplified model for dissolution-controlled transport from dispersed matrixes. Analytical solutions to the complicated phenomenon of combined dissolution and diffusion mechanisms have been derived, and the results are related to experimental measurements.

THEORETICAL

A combined dissolution and diffusion-controlled transport system is shown in Fig. 1. As an approximation, the controlled release system is depicted in one dimension as a semi-infinite medium. The kinetics of dissolution is assumed to be given by an expression which is proportional

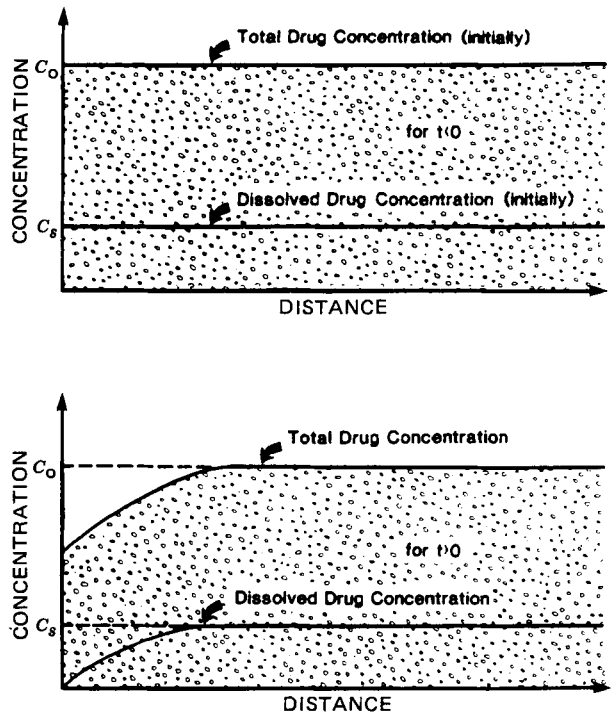

Figure 1—*Drug concentration profiles within the matrix.*

0022-3549/82/1200-1399$01.00/0

to the difference between the solubility of the solute in the matrix and the actual concentration of the solute in the matrix at the point in space. Under these conditions, the equation incorporation of both dissolution and diffusion in the mass transport process can be given to a first approximation by (12, 14):

$$\frac{\partial C}{\partial t} = D\frac{\partial^2 C}{\partial x^2} + K(C_s - C) \quad \text{(Eq. 1)}$$

where D is the solute diffusivity in the matrix, C is the concentration, C_s is the solute solubility, and K is the solute dissolution rate constant. The appropriate boundary conditions for dissolved solute with respect to time and distance are:

(*a*) $C = 0$ at $x = 0$ for all t;

(*b*) $C = C_s$ at $t = 0$ for all x.

Defining $\overline{C}$:

$$\overline{C} = C_s - C \quad \text{(Eq. 2)}$$

Equation 1 can be transformed to read:

$$\frac{\partial \overline{C}}{\partial t} = D\frac{\partial^2 \overline{C}}{\partial x^2} - K\overline{C} \quad \text{(Eq. 3)}$$

with boundary conditions:

(*a*) $\overline{C} = C_s$ at $x = 0$ for all t;

(*b*) $\overline{C} = 0$ at $t = 0$ for all x.

The analytical solution of Eq. 3 is given by (14):

$$\frac{\overline{C}}{C_s} = \tfrac{1}{2}\exp(-x\sqrt{K/D})\,\mathrm{erfc}\left(\frac{x}{2\sqrt{Dt}} - \sqrt{Kt}\right) + \tfrac{1}{2}\exp(x\sqrt{K/D})\,\mathrm{erfc}\left(\frac{x}{2\sqrt{Dt}} + \sqrt{Kt}\right) \quad \text{(Eq. 4)}$$

and

$$M_t = C_s\sqrt{D/K}\left[(Kt + \tfrac{1}{2})\,\mathrm{erf}\sqrt{Kt} + \sqrt{\frac{Kt}{\pi}}\exp - Kt\right] \quad \text{(Eq. 5)}$$

where M_t is the mass released per unit area at time t.

The total mass of solute per unit area is given by:

$$M_\infty = \frac{C_0 l}{2} \quad \text{(Eq. 6)}$$

where C_0 is the total solute loading and l is the thickness of the finite slab. The model assumptions will not be met when l is very small.

The fractional amount of solute released at any time t is now given by:

$$\frac{M_t}{M_\infty} = 2\frac{C_s}{C_0}\sqrt{\frac{D}{Kl^2}}\left[(Kt + \tfrac{1}{2})\,\mathrm{erf}\sqrt{Kt} + \sqrt{\frac{Kt}{\pi}}\exp - Kt\right] \quad \text{(Eq. 7)}$$

The ratio M_t/M_∞ can take values >1 for long enough time periods, since M_t is unbounded because of the semi-infinite medium assumption. The solution is only applicable when there is undissolved solute at every point. Thus, Eq. 7 is only valid for:

$$C_s Kt \le C_0 \quad \text{(Eq. 8)}$$

Under conditions when Kt assumes large values and solute dissolution is offering the limiting control to the transport process, Eq. 7 reduces to (12, 14):

$$\frac{M_t}{M_\infty} = 2\frac{C_s}{C_0}\sqrt{\frac{DK}{l^2}}\left(\frac{1}{2K} + t\right) \quad \text{(Eq. 9)}$$

In this case, the mass, M_t, varies linearly with time. However, under conditions when Kt assumes small values and solute diffusion is controlling mass transport totally, Eq. 7 reduces to:

$$\frac{M_t}{M_\infty} = 4\frac{C_s}{C_0}\left(\frac{Dt}{\pi l^2}\right)^{1/2} \quad \text{(Eq. 10)}$$

which is roughly similar to the solution originally obtained by Higuchi (1).

The release rate of solute for small times is given by:

$$\frac{dM_t/M_\infty}{dt} = 2\frac{C_s}{C_0}\sqrt{\frac{DK}{l^2}}\left(\mathrm{erf}\sqrt{Kt} + \frac{1}{\sqrt{\pi Kt}}\exp - Kt\right) \quad \text{(Eq. 11)}$$

Similarly, under conditions when Kt assumes large values and solute dissolution is offering the limiting control to the overall transport process, Eq. 11 reduces to:

$$\frac{dM_t/M_\infty}{dt} = 2\frac{C_s}{C_0}\sqrt{\frac{DK}{l^2}} \quad \text{(Eq. 12)}$$

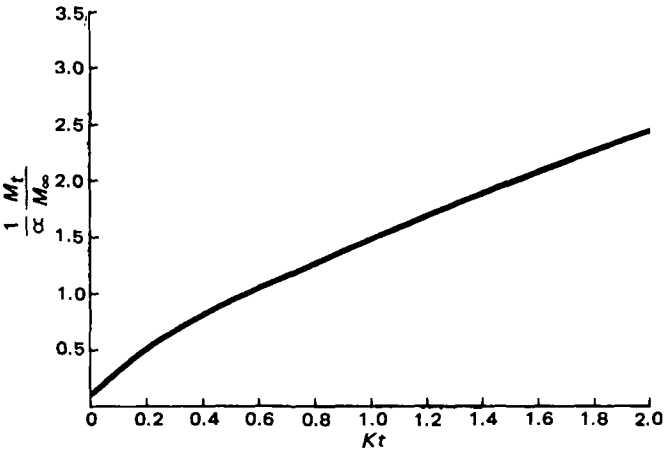

Figure 2—*Variation of* M_t/M_∞ *with* Kt ($\alpha = 2C_s/C_0\sqrt{D/Kl^2}$).

However, when Kt assumes small values and solute diffusion is controlling mass transport, Eq. 11 reduces to:

$$\frac{dM_t/M_\infty}{dt} = 2\frac{C_s}{C_0}\left(\frac{D}{\pi l^2 t}\right)^{1/2} \quad \text{(Eq. 13)}$$

The implications of Eqs. 7 and 11 can be seen in Figs. 2 and 3, where the cummulative mass released and the release rate are plotted as a function of Kt. The release rate is strongly dependent upon Kt in the region where $Kt < 0.3$, after which the release rate becomes almost independent of Kt.

EXPERIMENTAL

Preparation of Monolithic Systems—Solute-dispersed monolithic matrixes were prepared by a solvent casting procedure (15). Polyisobutylene and mineral oil were dissolved in heptane at room temperature and to this solution was added a drug of varied particle size so as to obtain a total solids content in the solution of ~25% by weight. At this concentration, the solution had a suitable viscosity to facilitate casting on a polyester substrate using a gardner knife set-up (15). The cast films were allowed to set at room temperature and subsequently oven dried at 50° to remove the residual traces of heptane. The residual solvent levels were always <100 ppm.

The thickness of the dried films were measured using a thickness gauge and were found to be relatively uniform (50 ± 5 μm). The drug content in the films was determined by dissolving the dried films in heptane followed by extraction into dilute sulfuric acid and subsequent analysis using liquid chromatography. The average particle size of the drug was obtained by specific surface area analysis using a gas absorption (Brunayer, Emmett, and Teller) technique (16).

Release Rate Determinations—The drug release rates as a function of time were determined using a special thermostated holder and bath assembly. The monolithic systems were attached to a suitable sample holder and suspended from a vertically reciprocating shaker such that each system was continuously immersed in a test tube containing 15 ml

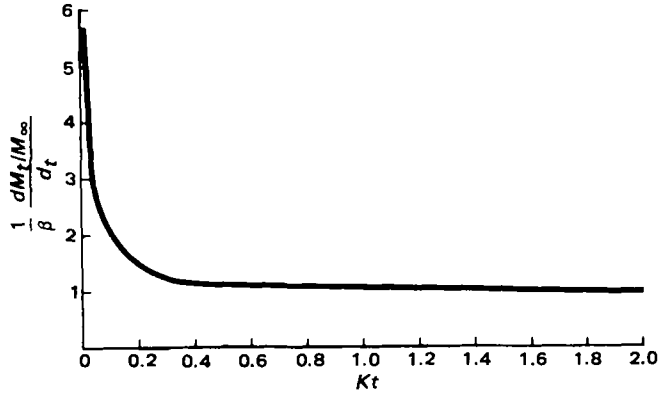

Figure 3—*Variation of* $dM_t/M_\infty/dt$ *with* Kt ($\beta = 2C_s/C_0\sqrt{DK/l^2}$).

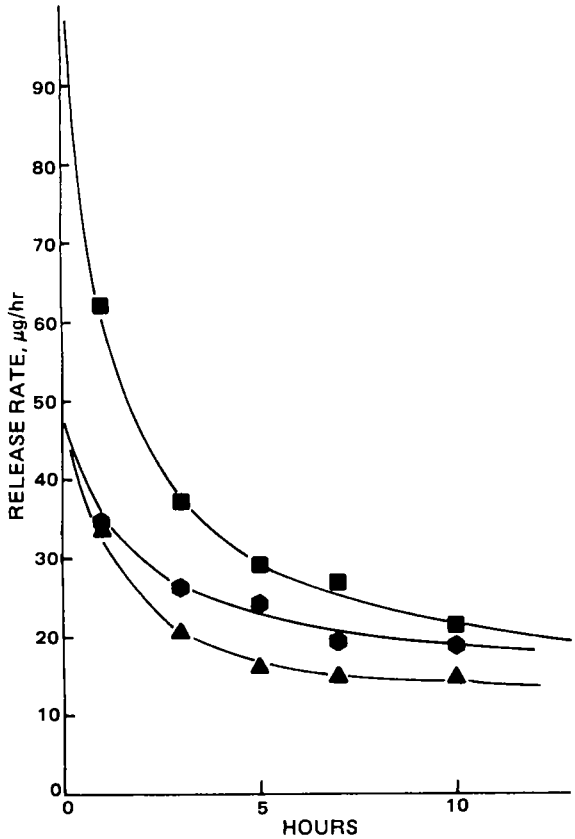

Figure 4—*Drug release rate* versus *time profiles. Key: (■) 2.5 μm; (●) 7.8 μm; (▲) 9.9 μm.*

of water equilibrated at 32.0 ± 0.3°. Agitation was at a frequency of 0.5 cycle/sec with an amplitude of 20–25 mm. At each time interval the systems were transferred to fresh tubes containing 15 ml of water preequilibrated to 32.0 ± 0.3°. Drug concentrations in the solutions were determined using liquid chromatography.

RESULTS

The *in vitro* drug release rate *versus* time profiles for the various monolithic systems are shown in Fig. 4. Three different average particle sizes were used: 2.5, 7.8, and 9.9 μm. The release-rate profile is dependent on particle size, increasing with decreasing particle size; however, the relative flatness of the pseudo steady-state portion of the curve improves markedly with increasing particle size. These results were analyzed using the typical Higuchi model, and assuming that drug diffusion is the controlling mechanism. The apparent drug diffusivity was computed utilizing (1):

$$\frac{1}{A}\frac{dM_t}{dt} = \left(\frac{DC_sC_0}{2}\right)^{1/2} t^{1/2} \qquad \text{(Eq. 14)}$$

where C_0 is the initial drug loading in the matrix.

The normalized flux, DC_s, as a function of drug particle size, is shown in Fig. 5. At the same drug loading, the value of DC_s decreases with increasing particle size, suggesting the presence of a secondary mechanism affecting drug diffusion. As infinite sink conditions were maintained during the release-rate measurements and boundary layer affects were held to a minimum by adequate stirring, drug particle dissolution was considered to be the secondary mechanism.

The apparent drug dissolution rate constant was computed following the procedure outlined in *Theoretical*, together with the normalization of drug diffusivity to zero particle size, *i.e.*, totally dissolved state. These results are presented in Fig. 6, where the dissolution rate constant is plotted as a function of drug particle size. It is apparent that the dissolution rate constant decreases with increasing particle size with a limiting value of $\sim 35 \times 10^{-7}$ sec^{-1} for an infinitely small particle size. Also shown in Fig. 6 is the limiting Sherwood Number (SH = kd/D) relationship normalized to 10 μm (17). The separation between the two lines is probably indicative of the deviation from infinite sink conditions maintained within the matrix.

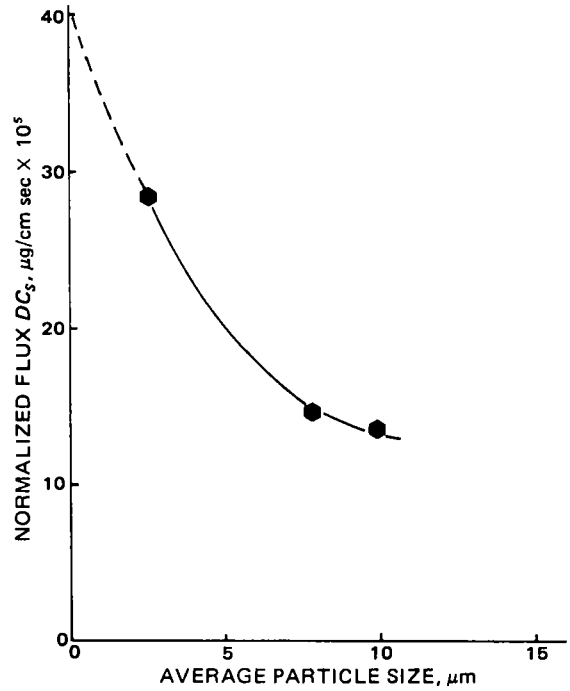

Figure 5—*Effect of particle size on normalized flux.*

CONCLUSIONS

A simplified model for dissolution-controlled transport from dispersed matrixes has been presented. Analytical solutions to the combined phenomenon of dissolution and diffusion mechanisms have been derived. At the limit when diffusion totally controls the mass transport, the solution reduces to a form with the mass released having a square-root dependency with time. However, when solute dissolution offers the

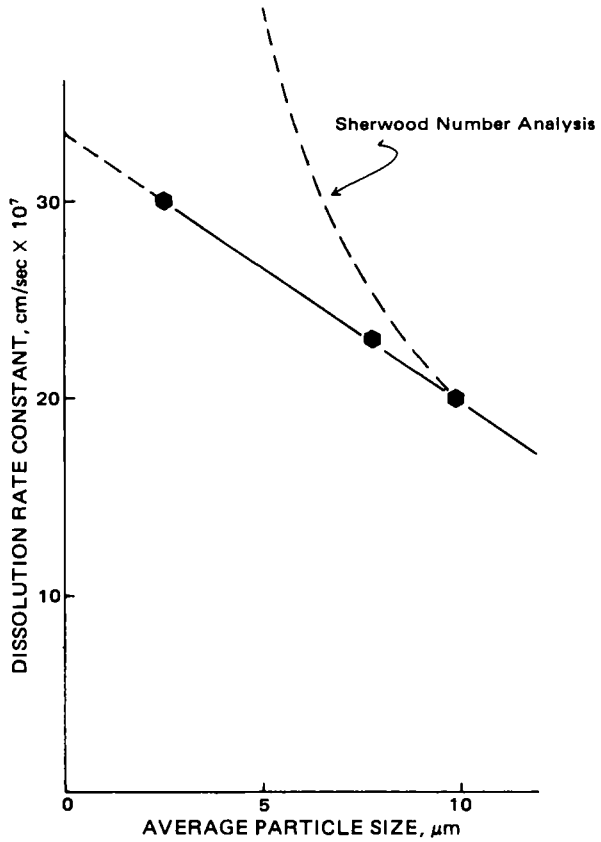

Figure 6—*Effect of particle size on dissolution rate constant.*

limiting resistance to mass transport, the solution reduces to form where the mass released varies directly with time. Under these conditions, the release rate of a dispersed solute would become time independent.

The simplified model can be viewed as an extension of the familiar Higuchi model (1) for drug release from ointments and suspensions. In the region of small time, the conclusions presented here are in agreement with previous studies (12, 13). However, the application of this model is considerably simplified compared to the system presented previously (12, 13), which is more complex and results in equations that do not predict a simple relationship between the various parameters.

Experimental release-rate measurements have been conducted with monolithic systems where the particle size of the dispersed solute has been varied. The results can be adequately analyzed using the proposed mathematical model and indicate that the mass transport resistance offered by particle dissolution increases with increasing particle size. However, the release rate approaches a pseudo steady-state and becomes time independent with this increasing resistance offered to the mass transport process by particle dissolution. This information can be utilized in the design and development of controlled-release formulations.

Determination of Enviroxime in a Variety of Biological Matrixes by Liquid Chromatography with Electrochemical Detection

RONALD J. BOPP ˣ **and DAVID J. MINER**

Received November 12, 1981, from the *Analytical Development Department, Lilly Research Laboratories, Eli Lilly and Co., Indianapolis, IN 46285.* Accepted for publication February 16, 1982.

Abstract □ A simple and specific method has been developed for determination of enviroxime in biological samples. Enviroxime, a substituted benzimidazole, its coisomer zinviroxime, and the internal standard hexestrol were extracted from the samples with benzene. The benzene layer was evaporated and the residue was reconstituted and injected onto a liquid chromatograph. Reversed-phase chromatography on an octylsilane column with a 65% methanol–35% 0.14 *M* sodium acetate mobile phase separated the components. The compounds were detected electrochemically using a glassy carbon electrode held at +0.85 V. The assay could detect as little as 4 ng of enviroxime/ml of plasma, 15 ng/ml of nasal wash, and 20 ng/ml of urine or tissue homogenate. For plasma assays, the procedure was >97% accurate and had a relative standard deviation of <4%. This method has proven to be applicable and reliable for the determination of enviroxime in many types of biological samples. Several problems encountered during the routine use of electrochemical detection were explored and minimized.

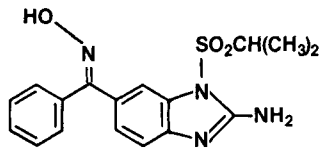
Enviroxime, anti-6-[(hydroxyimino)phenyl]methyl-1-(1-methylethyl)sulfonyl-1*H*-benzimidazole-2-amine (I), has been shown to be a highly specific inhibitor of the multiplication of rhinovirus in tissue cultures (1, 2):



I

Compound I has undergone extensive metabolic and toxicological studies in dogs and rats (3, 4) and is currently being evaluated as a treatment for the common cold (5).

In early work with I in dogs and mice, blood levels were determined using a plaque reduction assay. Plaque assays are nonspecific, since they are capable only of determining antiviral activity. To determine levels of I in the presence of the less active syn–oxime isomer, zinviroxime (II), it was necessary to develop a chemical assay. Initial experiments aimed at developing a GC assay for I and II indicated that such an approach was undesirable. Derivatization of the oxime group was required to make I and II volatile enough. However, such a derivatization eliminated the hydrogen bonding capability of this group and, thus, made the separation of I and II quite difficult. Recently, a method was reported which used high-performance liquid chromatography (HPLC) with UV detection for the determination

0022-3549/82/1200-1402$01.00/0

limiting resistance to mass transport, the solution reduces to form where the mass released varies directly with time. Under these conditions, the release rate of a dispersed solute would become time independent.

The simplified model can be viewed as an extension of the familiar Higuchi model (1) for drug release from ointments and suspensions. In the region of small time, the conclusions presented here are in agreement with previous studies (12, 13). However, the application of this model is considerably simplified compared to the system presented previously (12, 13), which is more complex and results in equations that do not predict a simple relationship between the various parameters.

Experimental release-rate measurements have been conducted with monolithic systems where the particle size of the dispersed solute has been varied. The results can be adequately analyzed using the proposed mathematical model and indicate that the mass transport resistance offered by particle dissolution increases with increasing particle size. However, the release rate approaches a pseudo steady-state and becomes time independent with this increasing resistance offered to the mass transport process by particle dissolution. This information can be utilized in the design and development of controlled-release formulations.

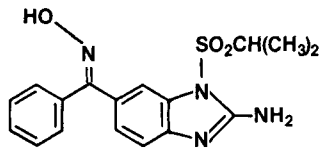
Enviroxime, anti-6-[(hydroxyimino)phenyl]methyl-1-(1-methylethyl)sulfonyl-1*H*-benzimidazole-2-amine (I), has been shown to be a highly specific inhibitor of the multiplication of rhinovirus in tissue cultures (1, 2):



I

Compound I has undergone extensive metabolic and toxicological studies in dogs and rats (3, 4) and is currently being evaluated as a treatment for the common cold (5).

In early work with I in dogs and mice, blood levels were determined using a plaque reduction assay. Plaque assays are nonspecific, since they are capable only of determining antiviral activity. To determine levels of I in the presence of the less active syn–oxime isomer, zinviroxime (II), it was necessary to develop a chemical assay. Initial experiments aimed at developing a GC assay for I and II indicated that such an approach was undesirable. Derivatization of the oxime group was required to make I and II volatile enough. However, such a derivatization eliminated the hydrogen bonding capability of this group and, thus, made the separation of I and II quite difficult. Recently, a method was reported which used high-performance liquid chromatography (HPLC) with UV detection for the determination

0022-3549/82/1200-1402$01.00/0

of several benzimidazoles in body fluids (6). However, UV detection did not have the necessary sensitivity or specificity for the determination of I at nanogram levels in biological media.

This paper describes a sensitive and selective determination of I and II in biological fluids and tissues which is based upon HPLC with electrochemical detection. This method has proven to be extremely versatile and reliable during several years of use.

EXPERIMENTAL

Reagents—Enviroxime, *anti*-6-[(hydroxyimino)phenyl]methyl-1-(1-methylethyl)sulfonyl-1*H*-benzimidazole-2-amine (I), zinviroxime, *syn*-6-[(hydroxyimino)phenyl]methyl -1- (1-methylethyl)sulfonyl-1*H*-benzimidazole-2-amine (II), and hexestrol (III), were used as received[1]. All organic solvents were distilled in glass[2]. Distilled deionized water was used for preparation of the mobile phases. Blank plasma was separated from fresh heparinized blood of animals or human volunteers. The plasma samples were stored at 4° and used within 1 month. All other reagents were analytical grade. A stock solution of I and II was prepared fresh daily. One milligram of each isomer was weighed into a 10-ml volumetric flask and diluted to volume with methanol. These solutions were then diluted 1:100 with methanol–water (50:50) to give final concentrations of 1 μg/ml.

Equipment—The HPLC system consisted of a solvent delivery pump[3], an autoinjector[3], a guard column[3] packed with pellicular packing[4], a 250 × 4.6-mm column packed with 6-μm octylsilane reversed-phase material[5], a column temperature controller[6], and an electrochemical detector[6]. Detector response was recorded on a strip chart recorder and monitored by a central chromatographic data acquisition computer system. The detector potential was maintained at +0.85 V *versus* an Ag–AgCl–3 *M* NaCl reference electrode. The mobile phase consisted of methanol and 0.14 *M* sodium acetate (65:35) with 3 mg of disodium edetate added per liter. This mixture was filtered through a 0.2-μm pore nylon membrane filter[7] and deaerated by sonicating under vacuum. The flow rate was set at 0.9 ml/min, and the column temperature was maintained at 28°.

Some determinations required the addition of column-switching equipment. For this purpose a pneumatically actuated switching valve[8], which had a high-performance 3-cm reversed-phase precolumn[8] instead of a sample loop, was interposed between the automatic injector and the guard/analytical column. A second HPLC pump[9] was connected to this valve. Connections were made so that with the valve in one position the precolumn was in line with the main HPLC system, and in the other position it was connected to the auxiliary pump and to waste. The position of this valve was controlled by a digital timer[10] and a conventional electric solenoid. The timing was set so that the precolumn was in line for 40 sec, and then was out of line for the remainder of a chromatogram. During the latter time the auxiliary pump was turned on so that the mobile phase backflushed the precolumn at 2 ml/min.

Sample Preparation—A 1.0-ml or smaller sample of each plasma, urine, nasal washing, bile, or tissue homogenate was transferred into an individual tube. If necessary the pH was adjusted to ~7.5 by addition of dibasic potassium phosphate. Eleven and a half milliliters of benzene was added and the tubes were capped and rotated at 60 rpm for 40 min. After briefly centrifuging, as much as possible of the benzene was transferred to a second tube. The benzene layer was washed with 0.5 ml of 1 *M* potassium phosphate, pH 11.5. Ten milliliters of benzene was removed to a third tube, 0.1 ml of a 500-ng hexestrol/ml of chloroform solution was added, and the benzene was evaporated at 37° under nitrogen. The residue was reconstituted over a 15-min period with 200 μl of mobile phase. A 110-μl sample was injected onto the HPLC using injection vials equipped with microsample inserts[11]. For relatively interference free samples (plasma and nasal washings), the internal standard was added at the beginning and the pH 11.5 wash step was omitted. Conjugates of I and II were determined indirectly by overnight incubation of the samples at pH 4.0 and 37° with 10 μl of a glucuronidase–sulfatase preparation[12].

Table I—Recoveries of Drugs after Benzene Extraction

	% Recovery as Compared with Nonextracted Standards			
	Water[a]		Plasma[b]	
Compound	200 ng/ml	20 ng/ml	200 ng/ml	20 ng/ml
I	92	91	89	84
II	93	90	89	87
III	97	94	80	70

[a] $N = 5$. [b] $N = 10$.

The concentration of the drugs in the samples was calculated by comparison with calibration curves which were prepared by adding known amounts of drug to the appropriate blank media. Standards were extracted and chromatographed together with the samples. Typical calibration curves for plasma consisted of 5 points over the 20–100 ng/ml range. A linear least-squares analysis of the concentration *versus* peak height ratio (compound–internal standard) data was used to calculate the amount of I and II in the unknowns.

Electrochemistry—Cyclic voltammetry was performed using a conventional cell and electronics[13] with a glassy carbon working electrode. Chromatographically assisted hydrodynamic voltammetry was done as previously described (7).

RESULTS AND DISCUSSION

Choice of Assay Parameters—A variety of solvents were evaluated for their ability to efficiently extract I from water and plasma. Butyl chloride and hexane provided clean plasma extracts but did not extract the drug well. Ether and methylene chloride extracted I nearly quantitatively, but they also extracted a large number of endogenous components which interfered with subsequent chromatographic determination of I and II. Benzene and chloroform extracts of plasma were relatively clean, and the recovery of I and II was good. Benzene was chosen as the solvent for extractions since it is less dense than water, which eased solvent transfer, and because it extracted less of a late-eluting interference than did chloroform. It was found that toluene might be substituted for benzene, but lower recoveries are obtained and evaporation of solvent extracts requires twice as much time.

Extractions of I, II, and III from water into benzene were carried out over a wide pH range. Little or no effect of pH was noted in the 3–11.5 range. Extraction efficiency of all three compounds decreased significantly at >pH 11.5, as did the efficiency of extraction of I and II at <pH 2.0. A pH of 7.5 was used for convenience and to minimize coextraction of acidic or basic endogenous species from biological samples. The recovery of I, II, and III from both water and plasma at pH 7.5 is given in Table I. No difference in extraction efficiency was observed for I and II at 20 ng/ml *versus* 200 ng/ml. In contrast, the extraction efficiency of the internal standard (III) from plasma was lower at the lower concentration. To minimize the contribution of III to assay variability, ≥50 ng was used in this assay. Not surprisingly, the recovery of I and II from plasma was slightly lower than from water.

The good recovery obtained with a single extraction of I and II from biological matrixes allowed the addition of a backwash step to the procedure for urine and tissue extracts. Washing with pH 11.5 buffer presumably removed phenolic compounds which are coextracted at pH 7.5 and which generally are electrochemically active at the oxidation potential used. This removal of interferences more than compensates for any loss of drug during the backwash. Since the extraction efficiency for the internal standard (III) was less than for I and II, when the backwash was included, III was added after the backwash step.

The electrochemistry of I and II was explored initially by cyclic voltammetry. The cyclic voltammogram for I in mobile phase (Fig. 1) showed a nonreversible oxidation with a maximum occurring at ~ +0.8 V. The voltammogram for II was very similar to that for I. When reexamined in 67% 2-propanol–33% 0.3 *M* $HClO_4$, where wave definition is generally

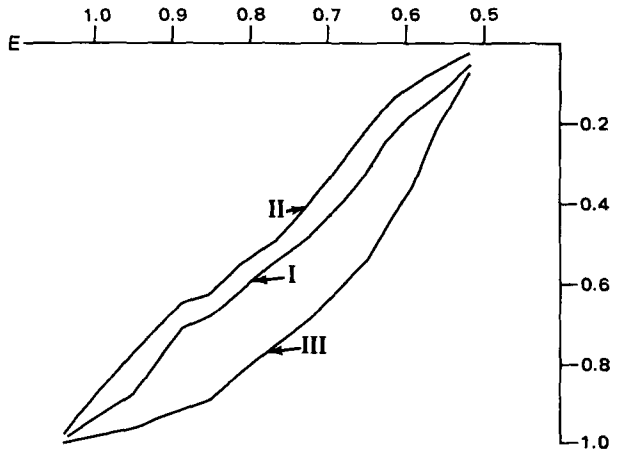

Figure 2—*Hydrodynamic voltammograms under assay conditions. Auxiliary electrode was across the channel from the working electrode. Key: (ϕ) ratio of peak height at a given potential to peak height obtained at greatest potential.*

better, both I and II showed several oxidation waves. The initial oxidation is thought to involve loss of two electrons from the extended conjugated system consisting of the oxime, benzimidazole, and the 2-amine group. The analog of I lacking the 2-amine group was not oxidizable, and the initial oxidation of the analog with a ketone instead of the oxime was 280 mV higher.

The voltammetry of I, II, and III under actual chromatographic conditions is depicted in Fig. 2. These curves were obtained with the auxiliary electrode positioned across the thin layer channel from the working electrode. This configuration minimizes uncompensated resistance between the two electrodes as well as potential gradients across the working electrode and thus allows accurate potential control under conditions of high background current. For all other work described in this paper, the auxiliary electrode was located downstream in the reference compartment. With such a configuration the hydrodynamic voltammograms began to drop off around +1.0 V. It can be seen from Fig. 2 that the voltammetric properties of III are reasonably similar to those of I and II, which is a desirable property for an internal standard. The potential used in this assay (+0.85 V) was chosen as a compromise between the desire for increased response to I and II, and the desire for low noise and a minimum of interferences from the biological matrixes.

The influence of chromatographic flow rate on the peak height of I is shown in Fig. 3. Peak heights normally increase as the flow rate is increased, due to decreased bandspreading. This is more than offset here by the decreasing efficiency of electrochemical conversion of I at higher flow rates. The flow rate chosen for use in this assay (0.9 ml/min) is a compromise between the demands of sensitivity and the need for reasonable retention times.

Assay Characteristics—The method described here was successfully applied to many different types of biological samples. Typical chromatograms from the assay of plasma, urine, and nasal turbinates are shown in Fig. 4. Compounds I and II (t_R ~ 8 and 9 min, respectively) were well resolved from each other and from major coextracted interferences. The small peak observed in the blank plasma chromatogram has a retention time close to but not identical to that of II. The chromatogram depicted represents a worse case situation, this peak not always being observed. Chromatograms of different blank tissue homogenates or urine looked different from each other and from blank plasma, so that A may not be compared against C or D. Although III elutes relatively late (t_R ~ 18 min), an alternative internal standard was not sought, because the region between 10 and 18 min occasionally contained interfering peaks.

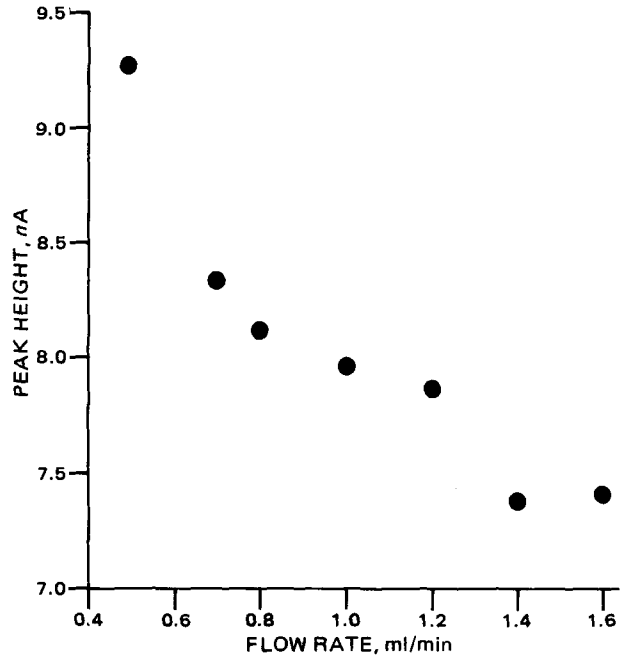

Figure 3—*Effect of flow rate on response to enviroxime. Chromatographic conditions as in text.*

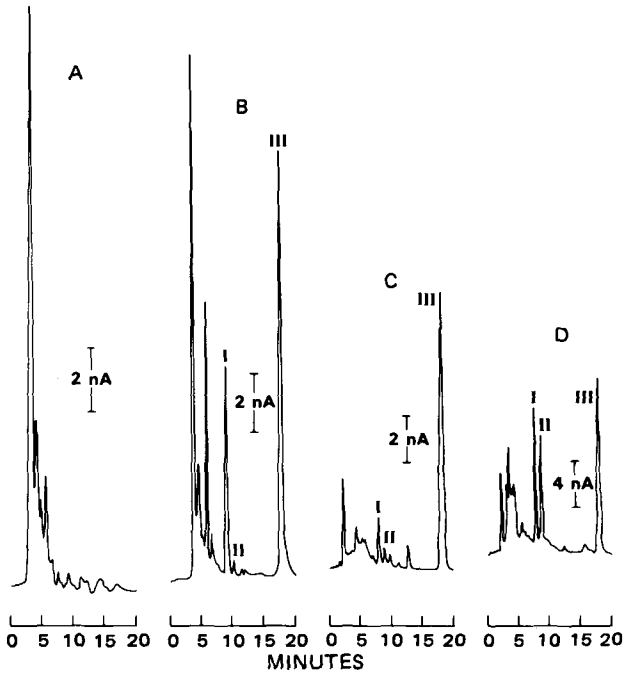

Figure 4—*Chromatograms of extracts of biological samples. Key: (A) predose dog plasma (without III added); (B) 80-min postdose plasma from dog administered 8 mg of I/kg orally, represents 43 ng of I/ml and 9 ng of II/ml; (C) homogenate of nasal tissue from dog administered 80 mg of II/kg for 90 days, represents 144 ng of I/g and 72 ng of II/g; (D) 0–2 hr urine of patient administered 25 mg of I orally, represents 1.6 μg of conjugated I/ml and 1.7 μg of conjugated II/ml.*

[a] $N = 8$.

The assay was found to be linear over the 5–800 ng range of I and II per milliliter of sample. The nonlinearity observed at >800 ng/ml was probably due to uncompensated resistance in the detector cell, a situation that occurs when large amounts of analyte are injected and/or when mobile phases of low conductivity are used. Alternative cell configurations could alleviate this problem (8). Instead, smaller volumes (<1 ml) of sample were used. This simple change kept all samples within a single sensitivity range (20nA/V), minimized electrode coating, and preserved samples.

The precision and accuracy of the determination of I in human plasma are summarized in Table II. Plasma samples spiked with 25, 50, and 100 ng of I and II per milliliter were prepared and eight aliquots were assayed on each of 3 days. The results in Table II show the precision and accuracy of the determination of I to be excellent, with both within-day and between-day variability contributing approximately equally to the overall precision. The determination of II was about one half as precise, with the largest variation observed being 7.4% *RSD* for the 25-ng/ml samples. Roughly 75% of the total *RSD* for II was attributable to between-day variability. Calibration curves were normally prepared with equal amounts of I and II, as in this characterization. However, when curves were prepared for each isomer individually, no significant interconversion of I and II was noted during the assay.

The precision of the determination of conjugated I and II in urine, which involves enzymatic cleavage of the conjugates, was estimated by assaying four aliquots of each of six urine samples on each of 3 days. The mean concentrations of total I and II ranged from 200 to 3600 ng/ml. The overall precision, as measured by the average of the *RSD*s of the individual samples was 9% for I and 11% for II. The proportion of the variability accounted for by between-day variation ranged from 68–96% for I and 50–90% for II. The reason for this day-to-day variation could not be determined, but the overall precision is quite reasonable.

The maximum sensitivity attainable with this method was not limited by detector noise. Trace levels of interferences defined detection limits in all of the many media studied. As little as 4 ng of I per milliliter of plasma, 15 ng/ml of nasal wash or 20 ng/ml of urine or tissue homogenate could be determined. Detection limits for II were always slightly higher than for I due to the lower response of the electrochemical detector to II (Fig. 2).

Improved Reliability of Electrochemical Detection—During the initial development of this assay, the background current at the glassy carbon working electrode oscillated erratically and on the whole increased continually. Some of the oscillations appeared to be very late-eluting peaks, but their locations could not be correlated with the timing of injections. Because disodium edetate is frequently used to stabilize easily oxidized species, such as penicillamine and catecholamines, it was added to the mobile phase used for I and II. Subsequently, the background current became quite stable. The mechanism of this phenomenon is as yet unknown. As a result of long experience with this method, several additional problems were encountered which could be traced to the electrochemical detector.

When samples containing high concentrations of I and II were assayed, it was noted that the peak height of III, which should remain essentially constant, decreased during the chromatography of a single set of samples. Further investigation revealed that the sensitivity of detection of I and II decreased also. Sensitivity could be regained only by repolishing the electrode, indicating that coating or fouling was involved. Phenols are known to polymerize at electrode surfaces (9), and indeed the problem was traced to the use of higher concentrations of internal standard, III, with these samples. In a separate experiment, it was found that when 1 μg of I and III was repeatedly injected, the peak height of I decreased by 14% per injection. When I alone was injected, its peak height decreased by only 0.4% per 1 μg of injection. Thus, the coating is predominantly due to the biphenolic internal standard. With a much lower amount of I, II, and III (40 ng each), the observed decrease in peak height of I and II was 0.1% per injection. To minimize this coating, the amount of III injected onto the column was subsequently kept at or below this level.

Impurities present in the mobile phase can also contribute to electrode coating. Using reagent grade methanol[14], 50% of the sensitivity of a freshly repolished electrode was lost after several days. A grade of methanol described as having been distilled in glass[15] was better but still caused decreased sensitivity when compared with the methanol actually used. This assay is probably particularly sensitive to coating effects because of the high potential required for oxidation of I and II, and because even at +0.85 V, peak heights of I and II are still increasing with increasing potential (Fig. 2). Nonetheless, caution in the preparation of mobile phases for use with electrochemical detection is indicated.

When overnight automated runs were made, the peak heights of I, II, and III in spiked samples were observed to decrease by 5–15% during the late evening and then return to normal the following day. Since this behavior paralleled the cycle of ambient temperature, it was assumed to be due to changes in chromatographic retention time. Thermostating the column eliminated changes in retention and decreased but did not eliminate changes in peak height. The majority of this remaining variability in I and half that of II was compensated for by corresponding changes in III. A thorough description of subsequent investigations of the origins and minimization of temperature-induced variability in electrochemical detection is the subject of a separate report (10).

Late-eluting peaks are strongly retained components from one injection, which elute during subsequent chromatograms. When samples are injected by hand, the time between injections varies and the source and effect of late-eluting peaks are not always obvious. However, when an autosampler is used, the time between injections is reproducible and the position of late-eluting peaks becomes constant, thus making them easier to identify. Determination of I and II in several of the biological media assayed resulted in problems with late-eluting peaks. Dog and rabbit liver homogenates and rabbit lung homogenates were particularly troublesome.

In some simpler cases it is possible, with the proper timing, to cause a late-eluting peak to elute with the solvent front or at some other noncritical time in a subsequent chromatogram. In more complex cases, one may simply delay the next injection until the late-eluting peaks are off the column, but this approach prolongs chromatographic time unduly. A slug or gradient of organic eluent can speed up their elution, but extra time is then required for re-equilibration of the column and the detector.

An alternative approach to removing late-eluting peaks is to use column switching (11). For the determination of I a 3-cm reversed-phase precolumn was positioned between the injector and the analytical column. The precolumn was in line for 40 sec after injection, which is the time required for I, II, and III to traverse the precolumn and enter the main column. The precolumn was then switched out of line for the remaining assay time. While out of line, the mobile phase was pumped through it at 2.0 ml/min to wash strongly retained components to waste. This technique produced cleaner chromatograms, which improved quantitation, and increased sample throughput as compared with the other approaches discussed above. Interestingly, when column switching was used with other relatively clean matrixes, *e.g.*, dog plasma and nasal washings, fewer trace level substances interfering with I and II were seen. The resulting improvement in detection limits was unexpected, since the interference peaks that were eliminated had been so small that they could not be distinguished as being late-eluting peaks.

Assay Applications—The method described above has been used to determine I and II in numerous biological samples arising from toxicology, pharmacology, metabolism, formulation, dose ranging, and clinical studies. One of the many types of results generated is depicted in Fig. 5. In this typical concentration–time profile for I in dog plasma, I was de-

[14] Reagent Grade ACS., MCB Manufacturing Chemists, Cincinnati, Ohio.
[15] HPLC Grade, Tedia Company, Fairfield, Ohio.

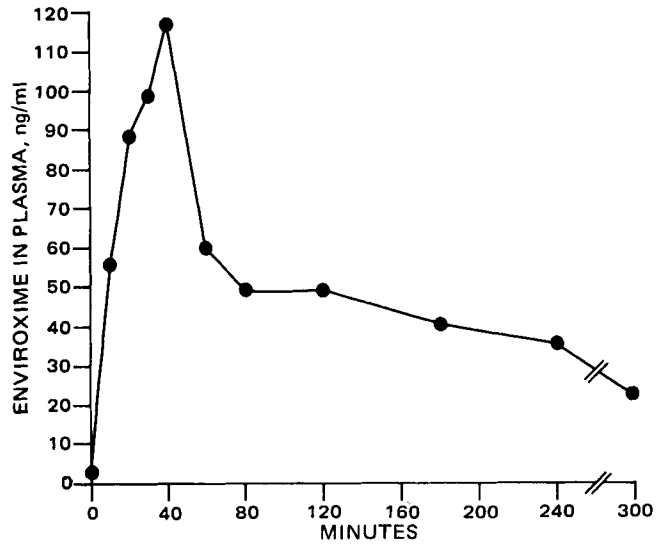

Figure 5—*Enviroxime concentration in dog plasma (ng/ml) after oral administration of an 8-mg/kg dose.*

terminable as early as 10 min after oral dosing to as long as 5–8 hr post-dose. A second example illustrates the value of a chemical assay, as compared with the original plaque reduction assay. The amount of II found in the plasma of dogs following oral dosing with I was usually very small, between 5 and 10% of I. However, when II was administered orally to dogs, I was still the major peak found in plasma. Thus, either by metabolism or by acid-catalyzed isomerization in the GI tract, the two isomers tend to form an equilibrium mixture in the plasma, in which I predominates.

The proven versatility of the methodology here points out the power of the coupling of liquid chromatography with electrochemical detection for determining oxidizable drugs in biological matrixes.

NOTES

Antihypertensive Agents: Pyridazino(4,5-b)indole Derivatives

A. MONGE VEGA *x, I. ALDANA *, P. PARRADO *, M. FONT *, and E. FERNANDEZ ALVAREZ ‡

Received December 3, 1981, from the **Facultad de Farmacia, Universidad de Navarra, Pamplona, Spain* and the ‡*Instituto de Química Orgánica del CSIC, Juan de la Cierva, 3 Madrid-6 Spain.* Accepted for publication January 27, 1982.

Abstract □ A series of 4-hydrazino-5H-pyridazino(4,5-b)indoles (VIII) and their potential metabolites (3,4-dihydro-4-oxo-5H-pyridazino(4,5-b)indoles (V) and 11H-1,2,4-triazolo(4,3-b)pyridazino-(4,5-b)indoles (IX) were investigated for antihypertensive activity in spontaneously hypertensive rats. All compounds showed antihypertensive activity at 25 mg/kg ip. Compound VIII was the most active, and the most toxic.

Keyphrases □ Antihypertensive agents—synthesis of pyridazino-(4,5-b)indole derivatives, rats, metabolites □ Metabolites—synthesis of antihypertensive agents, pyridazino(4,5-b)indole derivatives, rats □ Pyridazino(4,5-b)indole—derivatives, synthesis of antihypertensive agents, hypertensive rats

In connection with work related to the preparation and study of new products as potential antihypertensive agents, a series of pyridazino(4,5-b)indole derivatives (1–3) related to the well-known antihypertensive agent hydralazine[1] (I), as well as its metabolites (4, 5) were synthesized. The metabolism of these compounds takes place essentially (5, 6) through N^2-acylation (formyl, acetyl) of the hydrazino group and further cyclization to triazole derivatives (II), as well as the hydrolysis of the hydrazino to give the oxo derivatives (III).

The results of a preliminary evaluation in spontaneously hypertensive rats of Compounds V, VIII, and IX (see Scheme) are reported. All of these compounds are structurally related to hydralazine (I)[1] and its metabolites.

Some preliminary data for Compound VII*a* in normotensive and hypertensive (renal fistula), anesthetized

[1] Apresoline (1-hydrazinophtalazine).

EXPERIMENTAL

Chemistry[2]—Compounds V–IX have been prepared according to Scheme I. The following compounds have been previously reported: V*a* and VIII*a* (3); V*b* (mp 283–285°, and erroneously reported mp 218°) and V*e* (7); IX*a* and IX*b* (2); V*c* (8, 9) and V*d*; VIII*d* and IX*d* (9). Compounds VIII*b*, VIII*e*, and IX*e* were prepared by methods similar to those previously reported (2, 3, 9) but these compounds had not been reported previously.

4-Hydrazino-5-methyl-5H-pyridazino(4,5-b)indole (VIII*b*)—Compound VIII*b* was prepared from Compound V*b* (7) in a similar way to that reported previously (3) for Compound VIII*a*. Yield: 90%; mp = 178–180°; (ethanol), white crystals IR (potassium bromide): ν (cm^{-1}) = 3200 (bs, NH); 1625 (s, C=N); 765 (s, 1,2-aromatic disubstituted) ^{1}H-NMR (dimethyl sulfoxide-d_6): δ = 3.40 (sb, 2H, NH_2); 4.25 (s, 3H, CH_3); 7.10–7.90 (m, 3H, H_{6-8}); 7.85–8.30 (dd, H_9); 8.50 (sb, 1H, NH); 9.95 (s, H_1).

Anal.—Calc. for $C_{10}H_{12}N_5$: C, 61.7; H, 5.62; N, 32.7. Found: C, 61.9; H, 5.61; N, 32.7.

4-Hydrazino-8-benzyloxy-5H-pyridazino(4,5-b)indole (VIII*e*)—Compound VIII*e* was prepared from Compound V*e* (7) in a similar way to that reported previously (3) for Compound VIII*a*. Yield: 80%; mp 340° (*N*,*N*-dimethylformamide–water). Light brown crystals formed. IR (potassium bromide): ν (cm^{-1}) = 3000–3200 (m) and 3280–3399 (m) (NH); 1645 (s, C=N); 830 (m, 1,2,4-aromatic trisubstituted); 700 (s, aromatic monosubstituted) ^{1}H-NMR (dimethyl sulfoxide-d_6): δ = 5.30 (s, 2H, CH_2—O); 6.00–7.00 (bs, 3H, NH_2—NH—); 7.20–7.65 (m, 7H, $H_{6-7}C_6H_5$—); 7.85 (dd, H_9); 9.20 (s, H_1).

Anal.—Calc. for $C_{17}H_{15}N_5O$: C, 66.9; H, 4.91; N, 22.9. Found: C, 66.5; H, 4.75; N, 22.5.

11-H-1,2,4-Triazolo(4,3-b)pyridazino(4,5-b)-8-benzyloxyindole (IX*e*)—Compound IX*e* was synthesized from Compound VIII*e* in a similar way to that previously reported (2, 9) for Compounds IX*a*,*b*,*d*. Yield: 90%; mp 340° (*N*,*N*-dimethylformamide). White crystals formed. IR (potassium bromide) ν (cm^{-1}) = 3080–3120 (m, NH), 1640 (s) and 1625 (s) (C=N): 820 (s, 1,2,4-aromatic trisubstituted) ^{1}H-NMR (dimethyl sulfoxide-d_6): δ = 3.20 (s, 3H, CH_3); 5.40 (s, 2H, CH_2—O); 7.40–7.55 (m, 7H, $H_{6-7}C_6H_5$); 7.85 (dd, H_9); 9.60 (s, H_1).

Anal.—Calc. for $C_{19}H_{15}N_5O$: C, 69.3; H, 4.59; N, 21.3. Found: C, 69.5; H, 4.82; N, 21.4.

Pharmacology—Compounds were evaluated for antihypertensive activity in unanesthetized spontaneously hypertensive, 8-week-old male rats (spontaneously hypertensive)[3], of the Okamoto strain weighing 300–350 g and with systolic blood pressure levels >180 mmHg. Changes in the arterial pressure were measured by mechanical transduction[4] and registered on paper. A dose was given to each of four animals and blood pressures were measured at 3, 5, and 24 hr. The tested compounds were administered (2.5 ml/kg ip) either dissolved or suspended in normal saline containing 0.2% carboxymethylcellulose and 1% polysorbate 80.

The initial dose was 25 mg/kg. The more active compounds were tested at lower concentrations, as shown in Table I. The most active compound

		R	R′	R″
IV–IX:	a)	H	H	H
IV–IX:	b)	H	CH_3	H
IV–V:	c)	OH	H	H
IV–IX:	d)	Cl	H	H
IV–IX:	e)	H	H	C_6H_5—CH_2—O—

[2] All melting points were determined in a Gallenkamp apparatus in glass capillary tubes and were uncorrected. Analysis included microanalysis of samples dried in vacuum on phosphorus pentoxide (2–3 hr, 60–70°). Where a molecular formula is given, analytical results are within 0.4% of the theoretical values. IR spectra were recorded in a Perkin-Elmer model 681 apparatus. The ^{1}H-NMR spectra were recorded in a Perkin-Elmer model R-32 spectrometer (90 MHz) at room temperature, with tetramethylsilane as an internal reference: s, d, t, for singlet, doublet, triplet; bs = broad signal; dd = deformed doublet.

[3] Navarra University Farms.

[4] W+W, BP Recorder 8005.

(VIII*a*) was also similarly tested in desoxycorticosterone–saline rats (intraperitoneally) (10).

Acute toxicities were determined in male mice weighing 20 ±2 g. A dose was given orally to each of five animals and mortalities were recorded 1 week later. The LD_{50} was calculated according to a previous procedure (11).

RESULTS AND DISCUSSION

Table I summarizes the results of the pharmacological assays. All the compounds studied showed appreciable activity in the spontaneously hypertensive rat assay. In decreasing order of activity they are: VIII*a* > VIII*d* > VIII*e* > VIII*b* > V*c* > V*a* > V*b* > V*e* > IX*e* > IX*b* > IX*d* > IX*a*.

The hydrazino group is not essential for activity although it does considerably increase antihypertensive activity and toxicity. Group VIII compounds are thus the most active and the most toxic. Furthermore, the antihypertensive activity of V compounds may be related to that of other non hydrazine antihypertensive compounds (12, 13). It seems that this is the first report of antihypertensive activity in the oxo and triazole metabolites of pyridazino–hydrazine antihypertensives.

Simple Methods for Estimating Percent Disintegrated–Time Data

ADNAN EL-YAZIGI

Received March 9, 1981, from the *Department of Pharmaceutics, College of Pharmacy, University of Riyadh, Riyadh, Saudi Arabia.* Accepted for publication of February 3, 1982. Present Address: Cancer and Radiation Biology Research, Cancer Therapy Institute, King Faisal Specialist Hospital and Research Center, Riyadh, Saudi Arabia.

Abstract □ Two techniques are described for the treatment of dissolution rates to estimate the percent disintegrated–time data for tablets and capsules. The first is an extension of an equation derived previously with the assumption of first-order disintegration and dissolution processes; whereas, the second involves the determination of the rate constant from the terminal segment of the curve and the use of numerical derivatives according to a disintegration kinetics-independent approach. The dissolution data of six commercial tablet and capsule formulations were treated according to the described techniques. Good agreement was found between the percent disintegrated–time data estimated by the second approach for an acetaminophen tablet and those obtained by a well-established model where a Weibull function was employed.

Keyphrases □ Dissolution—tablets, simple methods for estimating percent disintegrated–time data □ Disintegration—tablets, simple methods for estimating percent disintegrated–time data, dissolution

There are few methods available for utilizing dissolution rate data to estimate the fraction disintegrated as a function of time for tablets (1, 2). These techniques, however, lack simplicity and require computer programs which may not be available.

A simple method was described recently for the disintegration–dissolution analysis of percent dissolved–time data (3). The technique is based on a biexponential equation with the assumption of first-order disintegration and dissolution according to a simple dissolution model.

The present report describes two approachs that can be used to estimate the percent disintegrated–time data for tablets and capsules. The first is an extension to the above report (3), whereas the other is based on disintegration kinetics—independent approach. Both techniques are simple and rapid and allow computations to be carried out manually.

THEORETICAL

Estimation of Percent Disintegrated–Time Data (Approach I) —Assuming first-order disintegration and dissolution processes, if A, A_p, and A_s represent the amounts of drug in dosage form, small particles, and solution, respectively, at any given time, and it is assumed that the disintegration and dissolution are first-order processes whose apparent rate constants are k_d and k_s, respectively, or:

$$A \xrightarrow[\text{first-order disintegration}]{k_d} A_p \xrightarrow[\text{first-order dissolution}]{k_s} A_s$$

Scheme I

the following equation can be derived (3):

$$100 - f_s = \frac{100\,k_d}{k_d - k_s} e^{-k_s t} - \frac{100\,k_s}{k_d - k_s} e^{-k_d t} \qquad \text{(Eq. 1)}$$

where f_s is the cumulative percent dissolved at time t.

Based on Scheme I, the following also can be derived:

0022-3549/82/1200-1408$01.00/0

(VIII*a*) was also similarly tested in desoxycorticosterone–saline rats (intraperitoneally) (10).

Acute toxicities were determined in male mice weighing 20 ±2 g. A dose was given orally to each of five animals and mortalities were recorded 1 week later. The LD_{50} was calculated according to a previous procedure (11).

RESULTS AND DISCUSSION

Table I summarizes the results of the pharmacological assays. All the compounds studied showed appreciable activity in the spontaneously hypertensive rat assay. In decreasing order of activity they are: VIII*a* > VIII*d* > VIII*e* > VIII*b* > V*c* > V*a* > V*b* > V*e* > IX*e* > IX*b* > IX*d* > IX*a*.

The hydrazino group is not essential for activity although it does considerably increase antihypertensive activity and toxicity. Group VIII compounds are thus the most active and the most toxic. Furthermore, the antihypertensive activity of V compounds may be related to that of other non hydrazine antihypertensive compounds (12, 13). It seems that this is the first report of antihypertensive activity in the oxo and triazole metabolites of pyridazino–hydrazine antihypertensives.

Simple Methods for Estimating Percent Disintegrated–Time Data

ADNAN EL-YAZIGI

Received March 9, 1981, from the *Department of Pharmaceutics, College of Pharmacy, University of Riyadh, Riyadh, Saudi Arabia.* Accepted for publication of February 3, 1982. Present Address: Cancer and Radiation Biology Research, Cancer Therapy Institute, King Faisal Specialist Hospital and Research Center, Riyadh, Saudi Arabia.

Abstract □ Two techniques are described for the treatment of dissolution rates to estimate the percent disintegrated–time data for tablets and capsules. The first is an extension of an equation derived previously with the assumption of first-order disintegration and dissolution processes; whereas, the second involves the determination of the rate constant from the terminal segment of the curve and the use of numerical derivatives according to a disintegration kinetics-independent approach. The dissolution data of six commercial tablet and capsule formulations were treated according to the described techniques. Good agreement was found between the percent disintegrated–time data estimated by the second approach for an acetaminophen tablet and those obtained by a well-established model where a Weibull function was employed.

Keyphrases □ Dissolution—tablets, simple methods for estimating percent disintegrated–time data □ Disintegration—tablets, simple methods for estimating percent disintegrated–time data, dissolution

There are few methods available for utilizing dissolution rate data to estimate the fraction disintegrated as a function of time for tablets (1, 2). These techniques, however, lack simplicity and require computer programs which may not be available.

A simple method was described recently for the disintegration–dissolution analysis of percent dissolved–time data (3). The technique is based on a biexponential equation with the assumption of first-order disintegration and dissolution according to a simple dissolution model.

The present report describes two approachs that can be used to estimate the percent disintegrated–time data for tablets and capsules. The first is an extension to the above report (3), whereas the other is based on disintegration kinetics—independent approach. Both techniques are simple and rapid and allow computations to be carried out manually.

THEORETICAL

Estimation of Percent Disintegrated–Time Data (Approach I) —Assuming first-order disintegration and dissolution processes, if A, A_p, and A_s represent the amounts of drug in dosage form, small particles, and solution, respectively, at any given time, and it is assumed that the disintegration and dissolution are first-order processes whose apparent rate constants are k_d and k_s, respectively, or:

$$A \xrightarrow[\text{first-order disintegration}]{k_d} A_p \xrightarrow[\text{first-order dissolution}]{k_s} A_s$$

Scheme I

the following equation can be derived (3):

$$100 - f_s = \frac{100\,k_d}{k_d - k_s} e^{-k_s t} - \frac{100\,k_s}{k_d - k_s} e^{-k_d t} \qquad \text{(Eq. 1)}$$

where f_s is the cumulative percent dissolved at time t.

Based on Scheme I, the following also can be derived:

0022-3549/82/1200-1408$01.00/0

[a] Estimated according to *Approach I*. [b] Estimated according to *Approach II*.

$$A_d = A_0 (1 - e^{-k_d t}) \quad \text{(Eq. 2)}$$

where A_d is the amount disintegrated at time t and equal to the amount of drug in dosage form at time 0 (A_0) minus the amount of drug in dosage form at time t (A). Multiplying both sides of Eq. 2 by $100/A_0$ yields:

$$f_d = 100 (1 - e^{-k_d t}) \quad \text{(Eq. 3)}$$

where $f_d = 100A_d/A_0$ and is the cumulative percent disintegrated at time t.

The disintegration profile can be obtained by substituting for k_d in Eq. 3 the values determined graphically according to Eq. 1 where k_s can also be determined (3).

Disintegration Kinetics Independent Approach (Approach II)—If the dissolution process is assumed to follow first-order kinetics while disintegration is taken as a kinetics-independent process, the following can be derived using a simple kinetic approach:

$$f_{d(t)} = \frac{(df_s/dt)_t}{k_s} + f_{s(t)} \quad \text{(Eq. 4)}$$

where $(df_s/dt)_t$ is the dissolution rate at time t, and $f_{d(t)}$, $f_{s(t)}$, and k_s have the same meaning as described earlier. Equation 4 can also be derived using a convolution technique (2). Employing Eq. 4, a direct calculation of the cumulative percent disintegrated–time data can be achieved once $(df_s/dt)_t$ is calculated and k_s determined. The apparent first-order rate constant for dissolution (k_s) can be determined from the terminal straight line segment of $\ln(100 - f_s)$ *versus* time plot.

RESULTS AND DISCUSSION

The dissolution data obtained for six commercial tablets and capsules containing isoniazid, theophylline, ampicillin, tetracycline hydrochloride, and tetracycline hydrochloride–phosphate complex (3) were employed to examine the use of the described techniques to estimate the percent disintegrated–time data.

The apparent first-order disintegration and dissolution rate constants (k_d and k_s, respectively) were determined graphically according to Eq. 1. The values of k_d were substituted in Eq. 3, and the percent disintegrated at various time values were calculated and are presented in Table I.

When *Approach II* was employed for the determination of the percent disintegrated–time data, the dissolution rate $(df_s/dt)_t$ was calculated for each time interval, and the midinterval time was taken as t. The cumulative percent dissolved at midinterval time (t) was estimated by the arithmetic mean of the percent dissolved at the beginning and the end of the interval. Table I presents the percent disintegrated–time data determined by this approach.

As demonstrated in Table I, the data obtained by *Approach I* were generally comparable to those obtained by *Approach II*. Indeed, for formulations C, D, and E, the data produced by both techniques were very close. The disagreement in the results, when existent, generally occurred in the initial data points. This may indicate less than perfect fit of these data points to Eq. 1. More initial data points might have led to better estimates of k_d; however, this would require the automation of the dissolution test. A good fit of the dissolution data to Eq. 1 is essential if the percent disintegrated–time data were to be estimated accurately according to Eq. 3.

To examine the reliability of the described techniques, the dissolution rate data of an acetaminophen tablet were subjected to the described analysis. These data were reported and employed (2) to demonstrate the application of a model to estimate the fraction disintegrated–time data. The data were well represented by a Weibull function (2), and a good estimate of k_d according to Eq. 1 could not be obtained. However, the curve produced by plotting $\ln(100 - f_s)$ *versus* time had a linear terminal segment whose slope was equal to 1.389 min^{-1}. This value was used as k_s in Eq. 4, and the percent disintegrated–time data were determined after the dissolution rate $(df_s/dt)_t$ was calculated for each interval. The percent dissolved at midinterval time $(f_s)_t$ was reported.

In a continuous function approach using convolution techniques, an equation was derived (2) which was employed to analyze these data. The equation was obtained by substituting a Weibull function for f_s in Eq. 3. The two parameters for this Weibull function were determined by a nonlinear regression of the Weibull function to the above tablet data. The first-order dissolution parameter was determined (2) from separate dissolution tests of acetaminophen powder and plotting the data semilogarithmically against time.

As can be seen in Table II, the percent disintegrated–time data by *Approach II* were similar to those obtained previously (2). Therefore, while the existent methods (1, 2) involve either a system of linear equations which require computer programs to solve or continuous functions with three parameters to be determined, the estimation of the percent disintegrated–time data by *Approach II* is simple and requires no separate dissolution testing of drug powder. The estimation of the first-order dissolution rate constant can be performed easily by plotting the tablet dissolution data semilogarithmically against time. The terminal data points most frequently behave in a first-order fashion. This approach for determination of k_s is valid here, because the acetaminophen tablet dissolution was less rapid than disintegration (1, 2), and k_s was smaller than k_d for the other formulations used (Table I).

While the usefulness of Eq. 3 to estimate the percent disintegrated–

Lysine and Polylysine: Correlation of their Effects on Polyphosphoinositides *In Vitro* with Ototoxic Action *In Vivo*

AKIRA TAKADA *, SHAHID LODHI ‡, NORMAN D. WEINER ‡x, and JOCHEN SCHACHT ‡

Received November 19, 1981, from the **Kresge Hearing Research Institute and* ‡*College of Pharmacy, The University of Michigan, Ann Arbor, MI 48109.* Accepted for publication February 3, 1982.

Abstract □ Low concentrations of poly-L-lysine, a polycationic hydrophilic molecule, caused a large expansion of polyphosphoinositide monolayers and produced a significant loss of cochlear microphonic potentials in perilymphatic perfusions in the guinea pig. In contrast, the monomeric L-lysine had only slight effects on polyphosphoinositide monolayers and did not affect cochlear microphonic potentials even at concentrations as high as 10 m*M*. These data substantiate the hypothesis that the expansion of polyphosphoinositide monolayers by a drug is an indicator of its ototoxicity.

Keyphrases □ Polyphosphoinositides—correlation of effects of lysine and polylysine *in vitro* with ototoxic action *in vivo* □ Lysine—correlation of effects on polyphosphoinositides *in vitro* with ototoxic action *in vivo*, polylysine □ Polylysine—correlation of effects on polyphosphoinositides *in vitro* with ototoxic action *in vivo*, lysine

Evidence has previously been provided in *in vivo* and *in vitro* studies for an involvement of polyphosphoinositides in the toxic actions of aminoglycoside antibiotics (1). Monolayer studies have shown that polyphosphoinositides are unique among various anionic phospholipids with respect to both the type and magnitude of the interactions with neomycin and Ca^{2+} (2). The observed increase in surface pressure was indicative of a very strong preference of the polyphosphoinositide film for neomycin over Ca^{2+} and other cations. It was further shown that the degree of interaction of eight aminoglycoside antibiotics and fragments with polyphosphoinositides correlated well with their ototoxicity in the guinea pig (3).

In order to test further the hypothesis that the degree of expansion of polyphosphoinositide monolayers is correlated with ototoxicity, monolayer studies, and ototoxicity tests for two compounds unrelated to aminoglycosides, poly-L-lysine and L-lysine, are reported here. Poly-L-lysine represents a polycationic hydrophilic compound, capable of occupying an area-determining position in lipid films (4), and L-lysine represents the corresponding singly-charged hydrophilic monomer.

EXPERIMENTAL

Materials and Methods—Poly-L-lysine had a molecular weight of 3400 (polymerization grade, 16)[1]. Polyphosphoinositides were purified from ox brain by chromatography on immobilized neomycin (5).

A polytef beaker (8-cm diameter) held 100 ml of subphase containing 50 m*M* sodium *N*-2-hydroxyethylpiperazine-*N'*-2-ethanesulfonate, pH 7.0, 1 m*M* $CaCl_2$, and sufficient sodium chloride to adjust the ionic strength to 0.2. A stationary syringe, with the needle immersed in the subphase throughout the experiment, delivered the additions of lysine and polylysine. The solutions were stirred with a magnetic bar at slow speed without the film being disturbed. The polyphosphoinositide mixtures (phosphatidylinositol phosphate–phosphatidylinositol bisphosphate, 1:2 molar ratio) were spread as a solution in *n*-hexane–ethanol–chloroform (80:5:15, v/v/v). Approximately 0.2 μg of lipid/cm^2 was spread to obtain the desired surface pressure (14–15 dyne/cm) which was read with a balance[2] after the film had stabilized for 10 min. Polylysine or L-lysine was then injected into the subphase for final concentrations of 10^{-7}–10^{-4} *M*. After each addition, the subphase was mixed for 15 min before measurements were taken. Experiments were performed at 25±2° in duplicate, and surface tension readings always agreed within 0.1 dyne/cm.

Perilymphatic Perfusions—Perilymphatic perfusions were carried out in male albino guinea pigs (200–300 g). An animal with a positive Preyer hearing reflex was anesthetized with pentobarbital (20 mg/kg of body weight ip), atropine sulfate (0.05 mg/kg sc), and 0.5 ml/kg of body weight im of a solution containing 0.4 mg of fentanyl and 20.0 mg of droperidol/ml (6). The animal's body temperature was maintained at 37 ±1° with a heating pad and artificial respiration was provided through a tracheal cannula. Surgical and perfusion techniques were similar to that described previously (3).

The perilymphatic spaces of the cochlea were perfused at a rate of ~30 μl/min. Cochlear microphonic potentials were measured in response to a sound stimulus of white noise, 20–4000 Hz, delivered through an earphone. The sound intensity level was adjusted to give an initial microphonic potential of 200–400 μV. After the potential had stabilized for 30 min (control period), ototoxicity was determined as its loss after 30 min of a subsequent perfusion with added drug.

Bar on left indicates range of surface pressure before additions. Key: (○) lysine; (△) neamine; (●) poly-L-lysine; (▲) neomycin.*

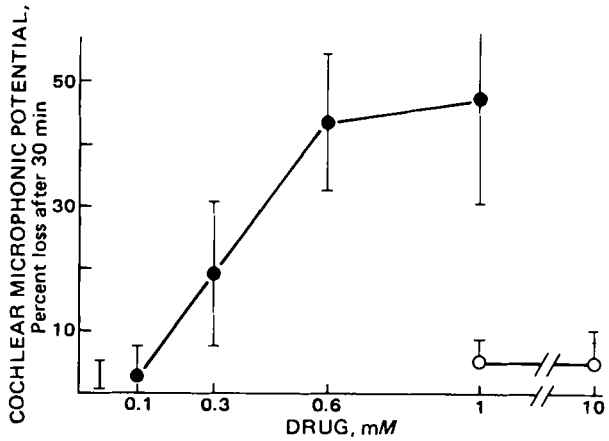

Figure 2—*Effects of cationic agents on cochlear microphonic potentials in the guinea pig. Numbers are means ±SD for five to eight animals at each condition. Bar on left indicates range of microphonic potentials without drug. Toxicity of poly-L-lysine at 0.3, 0.6, and 1 mM is significant at $p < 0.01$. Key: lysine (○); poly-L-lysine (●).*

Perilymphatic perfusions could usually be carried out for up to 2 hr without significant detrimental effect on cochlear microphonic potentials. Animals with an initial potential of <200 μV or with an unstable potential during the control period (loss of >10%) were excluded from the studies.

RESULTS AND DISCUSSION

It has previously been suggested that the specific interaction of a drug with polyphosphoinositides that leads to an expansion of the lipid monolayer in the presence of Ca^{2+} is an indicator of its ototoxicity. This interaction is apparently based on the configuration of the positive charges on the drug and not only on their number. For instance, kanamycin and neamine both have four primary amino groups, yet the first is more interactive with polyphosphoinositide films and also more ototoxic (3).

The cationic polymer, poly-L-lysine, can form complexes with acidic lipids (4) including polyphosphoinositides (7) and induce structural damage in biological membranes (8). Its action on the polyphosphoinositide film was strikingly different from that of the lysine monomer (Fig. 1). While low concentrations of the polymer dramatically increased the surface pressure ($\Delta\pi$ at 10^{-4} M, > 14 dyne/cm) the monomer showed only little effect (~2 dyne/cm). For comparison, the curves for the highly ototoxic compound, neomycin, and the nontoxic compound, neamine, (3) are shown.

In perilymphatic perfusions, effects on the cochlear microphonic potential were seen within 2–8 min after the introduction of polylysine into the perfusion fluid. The rate of loss was dependent on the drug concentrations up to 0.6 mM when an apparent maximum of toxicity was reached (Fig. 2). In contrast to polylysine, lysine did not affect the microphonic potential even at concentrations as high as 10 mM.

It should be noted that the molarity given for the polymer in these experiments refers to lysine equivalents for better comparison to the monomer, *i.e.*, 1 mM poly-L-lysine represents 1 mM lysine residues in the polymer corresponding to an actual concentration of 0.06 mM polymer. This consideration further accentuates the discrepancy between the action of the two compounds.

The correlation between polyphosphoinositide interaction and ototoxicity was demonstrated for a compound unrelated to aminoglycoside antibiotics. This finding further supports the hypothesis that the polyphosphoinositides play a crucial role in drug-induced ototoxicity.

Comparative Estimation of Glycyrrhetinic Acid Content of *Lonchocarpus cyanescens* and Glycyrrhiza Roots

MAURICE M. IWU

Received November 16, 1981, from the *Phytotherapy Research Laboratory, Faculty of Pharmaceutical Sciences, University of Nigeria, Nsukka, Nigeria.* Accepted for publication February 5, 1982.

Abstract □ The glycyrrhetinic acid (enoxolone) content of *Lonchocarpus cyanescens* roots has been determined by colorimetric and GC analysis. This plant gave lower values for both bound and unbound glycyrrhetinic acid when compared with glycyrrhiza (licorice).

Keyphrases □ *Lonchocarpus cyanescens*—comparative estimation of glycyrrhetinic acid content in roots, glycyrrhiza roots, colorimetric and GC analysis □ Glycyrrhetinic acid—comparative estimation of the content of *Lonchocarpus cyanescens* and glycyrrhiza roots, colorimetric and GC analysis □ Colorimetry, analysis—comparative estimation of the glycyrrhetinic acid content in *Lonchocarpus cyanescens* and glycyrrhiza roots □ GC analysis—comparative estimation of the glycyrrhetinic acid content in *Lonchocarpus cyanescens* and glycyrrhiza roots

Lonchocarpus cyanescens Benth (Leguminosae) is used extensively in African ethnomedicine for the treatment of various diseases, including infantile constipation and venereal infections (1). On the west coast of Africa, the root decoction is used by the natives for the treatment of arthritis. The antiphlogistic activity of *L. cyanescens* has been attributed to the oleanane derivatives, 18β-glycyrrhetinic acid (enoxolone), 28-hydroxy-β-glycyrrhetinic acid, and its 18α-isomer, lonchoterpene, isolated from this plant (2).

Other species of *Lonchocarpus* are valued as effective insecticides due to the rotenone content of this genus (3). Some species are cultivated as fish poisons (4), and others are commercial sources of the Yoruba indigo dye (5).

Flavonoids and triterpenoids are the most important secondary metabolites of this plant (2). Previous phytochemical works established the presence of pterocarpans (6), *C*- and *O*-prenylated chalcones (7), and prenylated stilbenes (8). The present report describes the quantitative estimation of the glycyrrhetinic acid present in the root bark of *L. cyanescens*.

A number of analytical methods are available for the qualitative evaluation of glycyrrhetinic acid, including gravimetric, colorimetric, and GC–MS (9–11). Here, the determination was by colorimetry and GC.

EXPERIMENTAL[1]

Methods—*Colorimetric Determination*—One gram each of *L. cyanescens* root bark, powdered glycyrrhiza, and ammoniated extract of glycyrrhizin were processed as described earlier (11). The quantity of glycyrrhetinic acid present in the samples was estimated by measuring the extinction of the complex formed by coupling the acidic genin, glycyrrhetinic acid, with methylene blue. A single-beam spectrophotometer was used for all the measurements[2], and the determinations were carried out at 640 nm. For the hydrolyzed extract, the percent yield of glycyrrhizin was calculated from (11):

$$\text{Percent glycyrrhizin} = \frac{A_t \times 0.5 \times 1.75}{A_s \times W} \qquad \text{(Eq. 1)}$$

where, A_t is the absorbance of the test sample, A_s is the absorbance of the reference, W is the weight of the substance, and 1.75 is the transformation factor.

Gas Liquid Chromatographic Estimation—One gram of powdered root bark of *L. cyanescens* was extracted with chloroform (50 ml) in a soxhlet apparatus for 3 hr. The filtered extract was evaporated to dryness under reduced pressure and the resultant residue was silylated before GLC analysis, as will be described. The air-dried marc was further extracted with (50 ml) 70% ethanol for 3 hr. The filtered alcoholic extract was transferred quantitatively to a 250-ml round-bottom flask and refluxed for 3 hr with 50 ml of 6 *N* HCl. After cooling, the extract was extracted twice with 50 ml of chloroform, and the combined chloroform extracts were evaporated to dryness under reduced pressure. The resultant residue was treated with 0.5 ml each of anhydrous pyridine and *N,O*-bis(trimethylsilyl)trifluoroacetamide. A 5-ml aliquot was analyzed after 30 min by GLC[2] using a chromatograph loaded with Chromosorb (100–120 mesh); the injector and detector were maintained at 320°.

Samples of glycyrrhiza roots and authentic reference glycyrrhetinic acid were similarly treated and analyzed. In each case the glycyrrhetinic acid content was calculated from measurements of the mean peak areas from these replicates.

Table I—Percent Yield of Glycyrrhetinic Acid

Sample	Method of Analysis: Colorimetric	Method of Analysis: GLC
L. cyanescens (unhydrolyzed[a])	0.54	0.55
L. cyanescens (hydrolyzed[b])	0.50	0.52
Glycyrrhiza liquid extract	0.12	0.14
Glycyrrhiza roots (unhydrolyzed[a])	0.67	0.60
Glycyrrhiza roots (hydrolyzed[b])	0.58	0.48

[a] The values obtained for the unhydrolyzed samples are indicative of the free genin content. [b] The total yield of glycyrrhetinic acid is obtained by adding the values obtained both before and after hydrolysis.

RESULTS AND DISCUSSION

The percent yield of glycyrrhetinic acid from both methods of analyses are shown in Table I. Although *L. cyanescens* gave a comparatively lower glycyrrhetinic acid value, the abundance of this plant makes it an attractive source for this agent. The higher yield of the unbound genin is also a positive index for the economic exploitation of this plant.

Paired-Ion High-Performance Liquid Chromatographic Assay for Sulfinpyrazone in Plasma

N. J. PATEL, D. O. KILDSIG, G. S. BANKER, P. R. MAYER, and M. A. GONZALEZ *x

Received July 23, 1979, from the *Department of Industrial and Physical Pharmacy, School of Pharmacy and Pharmacal Sciences, Purdue University, West Lafayette, IN 47907.* Accepted for publication February 18, 1982. *Present address: Key Pharmaceuticals, Inc., Miami, FL 33169.

Abstract □ A specific and sensitive liquid chromatographic method is reported for the assay of sulfinpyrazone in plasma utilizing ion pairing between the tetrabutylammonium cation and the sulfinpyrazone anion. The method is rapid in that conventional extraction procedures are avoided in favor of using disposable cartridges packed with an octadecylsilane bonded phase as a means of separating the drug from plasma. The samples were chromatographed on a C_{18} reversed-phase column using a mobile phase consisting of 0.005 *M* tetrabutylammonium phosphate in methanol–water (56:44). The coefficient of variation obtained was 4.5% and the response was linear over a range of 0.2–80 μg/ml.

Keyphrases □ High-performance liquid chromatography—paired ion, assay for sulfinpyrazone in plasma □ Sulfinpyrazone—paired-ion high-performance liquid chromatographic assay in plasma

Sulfinyprazone has been used as a uricosuric agent for over 20 years. Recently, new interest in this drug has been generated by reports indicating that it may protect patients from sudden death after myocardial infarction (1, 2).

Several methods have been reported in the literature that can be used for the quantitative determination of sulfinpyrazone in biological fluids. A spectrophotometric method reported previously (3) involves a tedious double extraction and lacks sensitivity, since it is based on UV absorption. A high-performance liquid chromatographic (HPLC) method was described (4) using radiolabeled sulfinpyrazone as an internal standard which complicates the routine application of this method. An HPLC method using a microparticulate silica column also was published (5). This method requires that the sample be injected 2 mm inside the column, thus, making it necessary to periodically refill that portion of the column with fresh silica. Another method (6) involves a two-step extraction and lacks adequate sensitivity.

It was considered desirable to develop a simple, rapid, and sensitive method for sulfinpyrazone determination in biological fluids. The reversed-phase HPLC method described here is based on the formation of ion pairs between sulfinpyrazone anions and tetrabutylammonium cations. The reported method has the advantage of not involving any extraction step. The drug is isolated from plasma using disposable cartridges filled with octadecylsilane bonded phase packing (C_{18} cartridge[1]).

EXPERIMENTAL

Materials—All reagents were analytical grade. All solutions were prepared using glass distilled water.

The high-performance liquid chromatographic system included a solvent pump[2] equipped with an injector[3], a fixed wavelength UV detector[4] set at 254 nm (λ_{max} was 260 nm), a recorder[5], and in integrator[6].

The analytical column was 30 cm long with 4-mm i.d. It was packed with octadecylsilane-bonded silica (particle size 10 μm)[7].

Mobile Phase—The mobile phase consisted of 0.005 *M* tetrabutylammonium phosphate[8] (I) in methanol–water (56:44). It was prepared by adding sufficient glass-distilled water to a vial of I to make 440 ml. An aliquot of 560 ml of absolute methanol was added, the solution was stirred for 10 min, and the volume was adjusted to 1 liter with a 56% (v/v) methanol–water solution. The solution was then filtered using a 0.5-μm pore, inert filter[9]. The mobile phase was deoxygenated using a vacuum flask attached to a water aspirator. The flow rate of the mobile phase was 1 ml/min at ambient temperature.

Preparation of Standards—A stock solution of sulfinpyrazone[10] was prepared by dissolving 100 mg of the drug in 100 ml of 50% (v/v) methanol–water. Solutions of varying concentration were prepared by serial dilutions of the stock solution in 50% (v/v) methanol–water. The plasma samples for use in the preparation of calibration curves were prepared by adding 200 μl of the appropriate drug solution to 1.8 ml of rat plasma in a 15-ml conical centrifuge tube. The plasma samples were mixed by agitating for 30 sec on a vortex-type mixer[11], and a 1.0-ml aliquot was taken for analysis.

0022-3549/82/1200-1413$01.00/0

Sample Preparation—Sulfinpyrazone was isolated from plasma using disposable C_{18} cartridges. Plasma samples (1.0 ml) with concentrations ranging from 0.2 to 80 μg/ml were used. The cartridges were conditioned by initially passing 3 ml of absolute methanol and 3 ml of a 0.01 *M* aqueous (I) solution through the cartridge. All solvents and solutions were introduced into the cartridge using disposable 5-ml hypodermic syringes. An equal volume of 0.02 *M* I in 50% (v/v) methanol–water was added to the plasma samples, which were then agitated for 30 sec. Each plasma sample was then passed quantitatively through a cartridge, and the eluate was discarded. The cartridges were washed with 1 ml of a solution containing 0.01 *M* I in methanol–acetonitrile–water (15:15:70). The drug retained on the cartridge was then eluted with 1 ml of absolute methanol. A new cartridge was used for each sample.

Assay—A 20-μl aliquot of the methanol from the last step in the previous section was precisely measured and injected into the chromatograph using a microliter syringe[12].

Reproducibility Study—To study the reproducibility of the procedure, 0.6 ml of a 100-μg/ml solution of sulfinpyrazone was added to 5.4 ml of rat plasma to produce a drug dilution containing 10 μg/ml. Five 1-ml aliquots of this solution were then processed using the procedure described above.

Retention Time and Peak Height Correlation Study—The peak height values obtained from 1-μg/ml plasma samples were used to investigate the correlation between peak heights and retention times. The peak height and retention time values generated during the development and optimization of the assay procedure were used. The latter involved changes in the methanol–water ratio, pH, and concentration of I.

RESULTS AND DISCUSSION

Utilizing disposable C_{18} cartridges adds great flexibility to any assay procedure. It must be kept in mind, however, that these cartridges are in essence miniature reversed-phase columns and must be treated accordingly. In the cartridge-conditioning step, methanol was passed through the cartridge as a cleaning solvent, but it served the dual purpose of also allowing drug diffusion from the serum to the packing material itself. An aqueous solution of I was used to condition the cartridge with the ion-pairing reagent. The tetrabutylammonium cations complex with sulfinpyrazone anions; the ion pair then has a greater affinity for the C_{18} packing material than the sulfinpyrazone anion. This increased affinity allows the ion to be retained in the cartridge while the plasma water and its polar constituents pass through the cartridge.

Not all interfering substances in plasma or other biological fluids will be separated in the first step. Therefore, it is necessary to utilize a washing step to rid the cartridge of additional plasma constituents. This step is critical in that it represents a possible source of sample loss. An optimum recovery of 80% of the sulfinpyrazone with minimal plasma extraneous peaks was obtained by washing the cartridge with 1 ml of a solvent consisting of 0.01 *M* I in methanol–acetonitrile–water (15:15:70). After this washing step, sulfinpyrazone was eluted from the cartridge with 1 ml of absolute methanol. The methanol from this last step was then chromatographed.

The mobile phase used in this procedure also contained I. Sulfinpyrazone is too strong an organic acid (pKa 2.8) to be maintained in an undissociated state, as is desirable when using reversed-phase HPLC. If a mobile phase with a neutral pH is used, sulfinpyrazone will be completely ionized, and its retention volume on the column will rarely exceed the void volume. Therefore, it was advantageous to utilize a mobile phase which contained the tetrabutylammonium cation that could ion pair with sulfinpyrazone and increase its retention time. A typical chromatograph of blank plasma and plasma containing 20 μg/ml of the drug are depicted in Fig. 1. While the blank rat plasma contained a number of peaks which could not be removed by the disposable cartridge, none of these peaks had retention times that would interfere with sulfinpyrazone.

Calibration curves were prepared, and Table I summarizes the results obtained after chromatographing samples from plasma with different concentrations of sulfinpyrazone. Calibration curves could be prepared using either peak heights or areas under the peaks. The data for the 10-μg/ml point represents the mean of five determinations using five different cartridges. The coefficient of variation for this point was 4.5%. The reproducibility between cartridges was satisfactory, and the coefficient of variation could be further improved by utilizing the same cartridge, which is possible by washing the cartridge with three or four 1-ml aliquots of absolute methanol between samples. While in certain applications repeated use of a cartridge may not be desirable, it was found that used cartridges stored in methanol gave reproducible results for several separate assays. This feature greatly diminishes the cost of an assay.

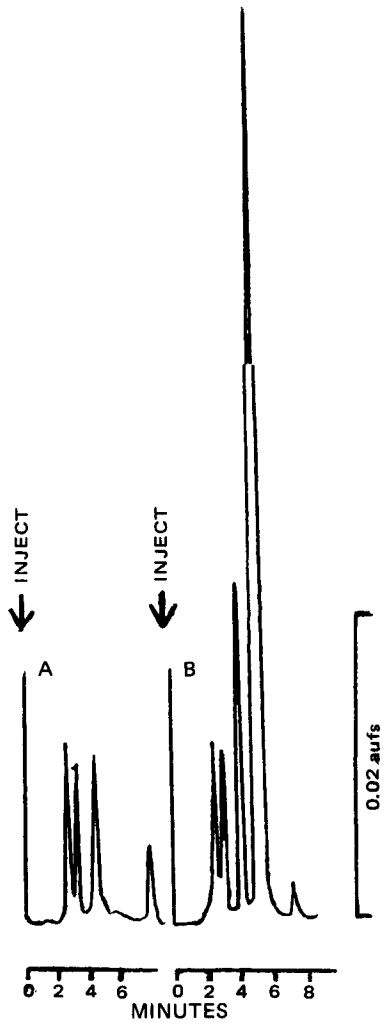

Figure 1—*Recorder tracings of representative chromatograms after 20-μl injections. Key: (A) plasma blank; (B) plasma spiked with sulfinpyrazone (20 μg/ml). Peak I is sulfinpyrazone.*

Since the drug is retained on the C_{18} cartridge as an ion pair, it is conceivable that at high drug concentrations there could be insufficient tetrabutylammonium cations to interact quantitatively with the sulfinpyrazone anions. This would result in a deviation from linearity at the higher concentrations of a standard curve. This was found to be the case if plasma concentrations >80 μg/ml were processed undiluted through the procedure. The linearity, however, was good from 1 to 80 μg/ml resulting in a correlation coefficient of 0.9992 when peak heights were used and 0.9990 for peak areas. The sulfinpyrazone–tetrabutylammonium complex appeared to be very sensitive to methanol concentrations in the

Table I—Values of Plasma Calibration Curve Points

Concentration, μg/ml	Peak Height[a], mm	Peak Area[b], μV sec × 10^{-4}

Table II—Observed and Predicted Values of Slopes

Retention Time, min	Observed Slope	Predicted Slope
5.2	91.81	90.27
7.8	70.47	68.58
8.0	61.69	59.68

mobile phase, such that changes in retention times occurred with slight changes in methanol concentration. Such changes in retention time would influence the peak heights, thus, peak areas were found to be preferable in the preparation of standard curves.

Peak heights can be used without constantly repeating standard curves, if a correction is made for changes in peak height due to changes in retention time. It is well established that an inverse relationship exists between peak heights and retention time. Different retention times were produced by varying pH, methanol concentration, and I concentration to study this relationship. The flow rate of the mobile phase, however, was always the same. There is a good correlation between the peak heights and the reciprocal of the retention time ($r = 0.9954$), and it is independent of the reason for the change in retention time. Because of the linearity of the response, it should be possible to predict a slope for a new standard curve from a single concentration point. This would preclude the necessity of repeating an entire standard curve when the retention time of sulfinpyrazone changes, although a three-point standard curve would reinforce that reliability. Slopes were predicted from peak heights obtained from a 1-μg/ml drug solution run at different retention times. These values are listed in Table II. Entire standard curves were then run at different retention times and slopes were calculated by linear regression analysis. The latter values are also listed in Table II. The maximum difference between the observed and predicted values of the slope was 2.7%.

It is evident from the results that paired-ion reversed-phase HPLC is a good method for assaying sulfinpyrazone in plasma. Using disposable C_{18} cartridges further simplifies the analysis, since the entire separation of drug from plasma can be accomplished in 2 min. This isolation method also has the advantage of not requiring large volumes of expensive organic solvents as do conventional extraction procedures. While the reported calibration curve used 0.2 μg/ml as the lowest concentration, the sensitivity could easily be increased by increasing the injection volume. This sensitivity is adequate for pharmacokinetic studies or therapeutic drug level monitoring.

Protein Binding of Caffeine in Young and Elderly Males

JAMES BLANCHARD

Received January 18, 1982, from the *Department of Pharmaceutical Sciences, College of Pharmacy, University of Arizona, Tucson, AZ 85721.* Accepted for publication February 22, 1982.

Abstract □ The plasma protein binding of caffeine in young and elderly males was evaluated using an ultrafiltration technique. In spite of a significantly lower plasma albumin concentration in the elderly subjects the observed percent bound (~35%) was essentially identical in both subject groups. The binding of caffeine to human plasma albumin (4.5% w/v) *in vitro* was also examined using ultracentrifugation and it was observed to be bound to the extent of 37.8%. In both the plasma and albumin binding studies the free fraction remained constant over the range of concentrations examined. Although there was no apparent correlation between the percent bound and the albumin concentration in the plasma of either subject group the close agreement between the degree of binding of caffeine to albumin and human plasma indicates that albumin is likely the major plasma binding protein for caffeine.

Keyphrases □ Caffeine—protein binding in young and elderly males, ultrafiltration □ Protein binding—caffeine in young and elderly males, ultrafiltration □ Ultrafiltration—protein binding of caffeine in young and elderly males

It is well known that drug–protein interactions can influence drug pharmacokinetics (1). Since plasma albumin concentration decreases and globulin concentration increases with aging (2, 3), and because a great many drugs are bound reversibly to plasma albumin, the potential importance of age-related changes in protein binding is clear. Of the relatively few studies that have examined the effect of age on protein binding, significant reductions in binding with aging have been reported for meperidine, phenylbutazone, phenytoin, and warfarin, while for phenobarbital, benzylpenicillin, diazepam, desmethyldiazepam, salicylate and sulfadiazine, no alterations in the extent of binding were observed (4). While some studies of caffeine binding *in vitro* (5) and *in vivo* (6, 7) have been reported, no specific examination of possible alterations in its binding characteristics with aging has been made. Since the pharmacological effect of caffeine is probably best related to its unbound fraction (as is true for most drugs), knowledge of any age-related binding differences could prove valuable in helping to interpret the pharmacokinetics of this widely consumed agent, which has received increased attention recently due to its possible role in the treatment of premature apnea (8). The goal of this study was, therefore, to compare the plasma protein binding of caffeine in young and elderly subjects.

EXPERIMENTAL

Subject Selection—Ten healthy, young adult male volunteers ranging in age from 18.8 to 30.0 years and eight healthy, active elderly male volunteers aged 66.0–78.2 years were studied. All subjects were given a physical examination, electrocardiogram, and the following laboratory tests: plasma urea, electrolytes, creatinine, bilirubin, aspartate aminotransferase, alkaline phosphatase, total protein, albumin, creatinine clearance, and complete blood count. In addition, all subjects had a normal health history and were not taking any medication at the time of the study.

Table II—Observed and Predicted Values of Slopes

Retention Time, min	Observed Slope	Predicted Slope
5.2	91.81	90.27
7.8	70.47	68.58
8.0	61.69	59.68

mobile phase, such that changes in retention times occurred with slight changes in methanol concentration. Such changes in retention time would influence the peak heights, thus, peak areas were found to be preferable in the preparation of standard curves.

Peak heights can be used without constantly repeating standard curves, if a correction is made for changes in peak height due to changes in retention time. It is well established that an inverse relationship exists between peak heights and retention time. Different retention times were produced by varying pH, methanol concentration, and I concentration to study this relationship. The flow rate of the mobile phase, however, was always the same. There is a good correlation between the peak heights and the reciprocal of the retention time ($r = 0.9954$), and it is independent of the reason for the change in retention time. Because of the linearity of the response, it should be possible to predict a slope for a new standard curve from a single concentration point. This would preclude the necessity of repeating an entire standard curve when the retention time of sulfinpyrazone changes, although a three-point standard curve would reinforce that reliability. Slopes were predicted from peak heights obtained from a 1-μg/ml drug solution run at different retention times. These values are listed in Table II. Entire standard curves were then run at different retention times and slopes were calculated by linear regression analysis. The latter values are also listed in Table II. The maximum difference between the observed and predicted values of the slope was 2.7%.

It is evident from the results that paired-ion reversed-phase HPLC is a good method for assaying sulfinpyrazone in plasma. Using disposable C_{18} cartridges further simplifies the analysis, since the entire separation of drug from plasma can be accomplished in 2 min. This isolation method also has the advantage of not requiring large volumes of expensive organic solvents as do conventional extraction procedures. While the reported calibration curve used 0.2 μg/ml as the lowest concentration, the sensitivity could easily be increased by increasing the injection volume. This sensitivity is adequate for pharmacokinetic studies or therapeutic drug level monitoring.

Protein Binding of Caffeine in Young and Elderly Males

JAMES BLANCHARD

Received January 18, 1982, from the *Department of Pharmaceutical Sciences, College of Pharmacy, University of Arizona, Tucson, AZ 85721.* Accepted for publication February 22, 1982.

Abstract □ The plasma protein binding of caffeine in young and elderly males was evaluated using an ultrafiltration technique. In spite of a significantly lower plasma albumin concentration in the elderly subjects the observed percent bound (~35%) was essentially identical in both subject groups. The binding of caffeine to human plasma albumin (4.5% w/v) *in vitro* was also examined using ultracentrifugation and it was observed to be bound to the extent of 37.8%. In both the plasma and albumin binding studies the free fraction remained constant over the range of concentrations examined. Although there was no apparent correlation between the percent bound and the albumin concentration in the plasma of either subject group the close agreement between the degree of binding of caffeine to albumin and human plasma indicates that albumin is likely the major plasma binding protein for caffeine.

Keyphrases □ Caffeine—protein binding in young and elderly males, ultrafiltration □ Protein binding—caffeine in young and elderly males, ultrafiltration □ Ultrafiltration—protein binding of caffeine in young and elderly males

It is well known that drug–protein interactions can influence drug pharmacokinetics (1). Since plasma albumin concentration decreases and globulin concentration increases with aging (2, 3), and because a great many drugs are bound reversibly to plasma albumin, the potential importance of age-related changes in protein binding is clear. Of the relatively few studies that have examined the effect of age on protein binding, significant reductions in binding with aging have been reported for meperidine, phenylbutazone, phenytoin, and warfarin, while for phenobarbital, benzylpenicillin, diazepam, desmethyldiazepam, salicylate and sulfadiazine, no alterations in the extent of binding were observed (4). While some studies of caffeine binding *in vitro* (5) and *in vivo* (6, 7) have been reported, no specific examination of possible alterations in its binding characteristics with aging has been made. Since the pharmacological effect of caffeine is probably best related to its unbound fraction (as is true for most drugs), knowledge of any age-related binding differences could prove valuable in helping to interpret the pharmacokinetics of this widely consumed agent, which has received increased attention recently due to its possible role in the treatment of premature apnea (8). The goal of this study was, therefore, to compare the plasma protein binding of caffeine in young and elderly subjects.

EXPERIMENTAL

Subject Selection—Ten healthy, young adult male volunteers ranging in age from 18.8 to 30.0 years and eight healthy, active elderly male volunteers aged 66.0–78.2 years were studied. All subjects were given a physical examination, electrocardiogram, and the following laboratory tests: plasma urea, electrolytes, creatinine, bilirubin, aspartate aminotransferase, alkaline phosphatase, total protein, albumin, creatinine clearance, and complete blood count. In addition, all subjects had a normal health history and were not taking any medication at the time of the study.

0022-3549/82/1200-1415$01.00/0

Plasma-Binding Studies—After obtaining informed consent, all subjects were administered a 5-mg/kg dose of caffeine both intravenously[1] and orally[2] on separate occasions ~1 week apart, using a randomized crossover design. The subjects were instructed to abstain from caffeine-containing foods and beverages, tobacco, and alcohol from 72 hr before until 24 hr after each dose of caffeine. Blood samples (10 ml) were collected at 0.25, 1, 4, and 9 hr following the oral dose and at 0.25, 2, 6, and 12 hr following the intravenous dose. Plasma samples were harvested immediately and divided into two aliquots. One aliquot, designated D_t, was stored at −20° until assayed. Three milliliters of the second aliquot was placed in a membrane cone[3], covered[4], and centrifuged at 250×*g* for 30 min, which produced ~1 ml of ultrafiltrate. The ultrafiltrates were tested[5] to ensure that no protein had passed through the cones. If this test indicated that more than a trace of protein was present, another aliquot of plasma was ultrafiltered using a new cone. Previous tests using the Lowry method of assay for protein had indicated that the CF-25 cones removed ~99.8% of the protein from plasma (9). The protein-free ultrafiltrates were then stored at −20°. The ultrafiltrates and D_t samples were assayed in duplicate using a slight modification of a technique described elsewhere (10), the difference being that the protein in plasma samples was precipitated with an equal volume of perchloric acid (12% w/w) in place of the sodium tungstate–sulfuric acid mixture used before, since this precipitant was found to produce a slightly cleaner supernatant (9).

Correction for Membrane Cone Binding—To assess whether significant amounts of caffeine were binding to the membrane cones under the conditions employed in the plasma binding studies, the following experiment was performed. Stock solutions of caffeine at 1, 5, 10, and 20 μg/ml concentrations were prepared in saline phosphate buffer (11). Three-milliliter portions of each stock solution were then placed in membrane cones, which were treated in the usual fashion. The average percent bound over all the cones was then subtracted from each percent bound calculated in the plasma binding experiments to provide a corrected percent bound value.

Albumin Binding Studies—The binding of caffeine to human albumin was studied as follows. A stock solution (5% w/v) of human albumin (essentially fatty acid free)[6] in pH 7.4 saline phosphate buffer was prepared. Sufficient amounts of caffeine in saline phosphate buffer were added to this solution to produce 5 ml of solution containing final concentrations of 1, 5, 10, and 20 μg/ml caffeine in albumin (4.5% w/v). The caffeine–albumin solutions were allowed to equilibrate for 30 min in a 37° water bath. Aliquots (0.5 ml) of these solutions (designated D_t) were then taken and stored at −20°. The remainder of these samples were ultracentrifuged[7] at 4° for 15 hr at 260,000×*g*. Then 0.6 ml of the top layer (designated D_f) was removed, tested[5] to ensure that it was essentially protein free, and stored at −20° until assayed. All samples were assayed in the same manner as the plasma samples.

Calculation of Binding Capacity—The extent of binding was calculated using:

$$\% \text{ Bound } (\beta) = \frac{Db}{Dt} \times 100 = \frac{Dt - Df}{Dt} \times 100 \qquad \text{(Eq. 1)}$$

where Db is the concentration of drug bound to protein, Df is the concentration of free (unbound) drug present in the protein-free ultrafiltrate or upper layer of the ultracentrifuged sample, and Dt is the total concentration of drug (bound plus free) present in the samples prior to ultrafiltration or ultracentrifugation.

Analysis of Data—Differences in the various parameters between the young and elderly groups were assessed using a two-tailed Student's *t* test for unpaired data, with $p < 0.05$ being taken as the minimum level of significance.

RESULTS AND DISCUSSION

The results of the plasma binding studies are summarized in Table I. The values shown have been corrected for the observed degree of binding of caffeine to the membrane cones. It was found that the mean β value for the binding of caffeine to the cones ($n = 18$) was 12.13 ± 0.83% (mean ± *SEM*). The reduction in the total plasma protein concentration observed in the elderly group was not significant ($p > 0.1$), whereas the reduction in the plasma albumin concentration was significant ($p < 0.001$). Both of these observations are consistent with data previously reported (12).

Table I—Comparison of the Plasma Protein Binding of Caffeine in Young and Elderly Males

Parameter	Young Group ($n = 10$) Mean	Young Group ($n = 10$) *SEM*	Elderly Group ($n = 8$) Mean	Elderly Group ($n = 8$) *SEM*	Level of Significance
Age	21.80	1.14	71.20	1.39	$p < 0.001$
Total plasma protein (g/liter)	73.30	1.68	70.00	1.44	NS[a]
Plasma albumin (g/liter)	45.90	0.77	41.13	0.58	$p < 0.001$
Percent bound	35.45	0.73	34.97	0.90	NS[a]
Unbound caffeine concentration (mg/liter)	2.95	0.19	3.06	0.23	NS[a]
Total caffeine concentration (mg/liter)	5.68	0.35	5.78	0.41	NS[a]

[a] Not significant.

In spite of the reduced plasma albumin concentration in the elderly, the observed percentage bound values reported for caffeine did not differ significantly ($p > 0.2$) between the two groups. In addition, the mean percent bound observed here of ~35% correlates well with the value of 31.3% previously reported (6) for 15 healthy male subjects ranging in age from 18 to 71 years. However, both of these values are substantially higher than the value of 15% bound to human plasma previously reported (7).

The following equation (13) illustrates how various factors, including the drug concentration, affect the degree of protein binding:

$$D_t = D_f \left[1 + \frac{nP_t}{\frac{1}{K} + D_f} \right] \qquad \text{(Eq. 2)}$$

where K is the binding association constant (liters per mole), P_t is the total protein concentration, and n is the number of binding sites per protein molecule. When $1/K \gg D_f$ and $n = 1$, Eq. 2 can be simplified to:

$$\alpha = \frac{D_f}{D_t} = \left[\frac{1}{1 + KP_t} \right] \qquad \text{(Eq. 3)}$$

This equation illustrates how the free (unbound) fraction (α) and, therefore, the bound fraction (β) are constants, provided $1/K \gg D_f$. Equation 3 also demonstrates the linear nature of the relationship between the unbound and total drug concentrations. Excellent linear correlations for caffeine binding in the plasma of the young ($r^2 = 0.9393$) and elderly ($r^2 = 0.9088$) subject groups were found (Fig. 1). This figure illustrates the constancy of the degree of binding over the concentration ranged examined, a finding which may also be true for many other drugs over their range of therapeutic concentrations (14). The near-superimposability of the regression lines for the young (slope = 0.5189) and elderly (slope = 0.5337) data is a further demonstration of the similarity in the binding behavior of caffeine in the two groups.

There are at least two plausible explanations for why the observed reduction in plasma albumin in the elderly group did not result in a concomitant reduction in the degree of plasma binding of caffeine. The first possibility is that the amount of drug bound to a given amount of albumin may somehow increase with aging, possibly due to a loss of some endogenous ligand which competes with caffeine for binding sites on albumin. Another possibility is that caffeine may bind to components of plasma other than albumin.

Figure 2 shows a plot of the average percent of caffeine bound to plasma *versus* the measured albumin concentration in each subject and illustrates how there was no apparent correlation between these two parameters. This contrasts with previous findings (6) where a direct linear correlation between the extent of caffeine plasma binding and the serum albumin concentrations was observed in the subject population.

The results of the *in vitro* studies of caffeine binding to plasma albumin are depicted in Fig. 3. These data indicate that caffeine is bound to albumin (4.5% w/v) to the extent of 37.81 ± 1.16% (mean ± *SEM*) with the

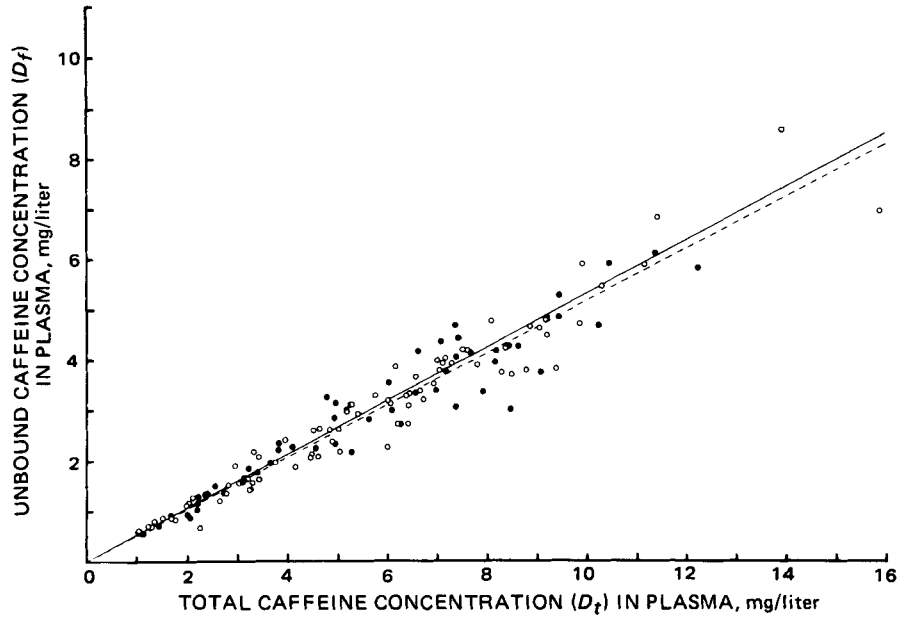

Figure 1—*Relationship between unbound and total caffeine concentrations in plasma of young (○ - - - ○) and elderly (●—●) men.*

percent bound being essentially constant over the concentration range of 1–20 μg/ml, indicating that only a small fraction of the available binding sites is occupied at these concentrations. The close similarity of the mean percent bound values for plasma and albumin implies that albumin is certainly the major plasma binding protein for caffeine, and possibly the only one. The values of the association constant (K) for the respective binding experiments can be calculated by substituting the mean values for β, D_f, and P_t into the rearranged form of Eq. 2 shown below:

$$K = \frac{\beta}{P_t - \beta(P_t + D_f)} \qquad \text{(Eq. 4)}$$

The assumptions involved here are that $n = 1$ and that caffeine only binds to the albumin component of plasma. Under these conditions the value of P_t for plasma in Eq. 4 can be obtained by dividing the average albumin content of plasma by 69,000 (the assumed molecular weight of albumin). The values of K shown in Table II indicate the close agreement of the association constants with one another and with the K value for the

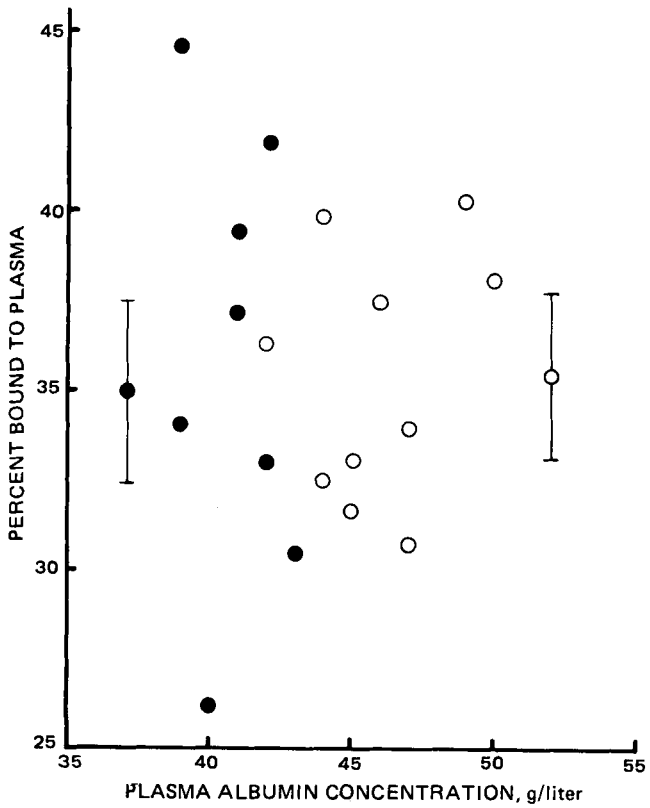

Figure 2—*The effect of plasma albumin concentration on the percentage of caffeine bound to plasma in young (○) and elderly (●) males. Each data point represents the mean of six to eight determinations. The vertical bars represent the means ± 1* SD.

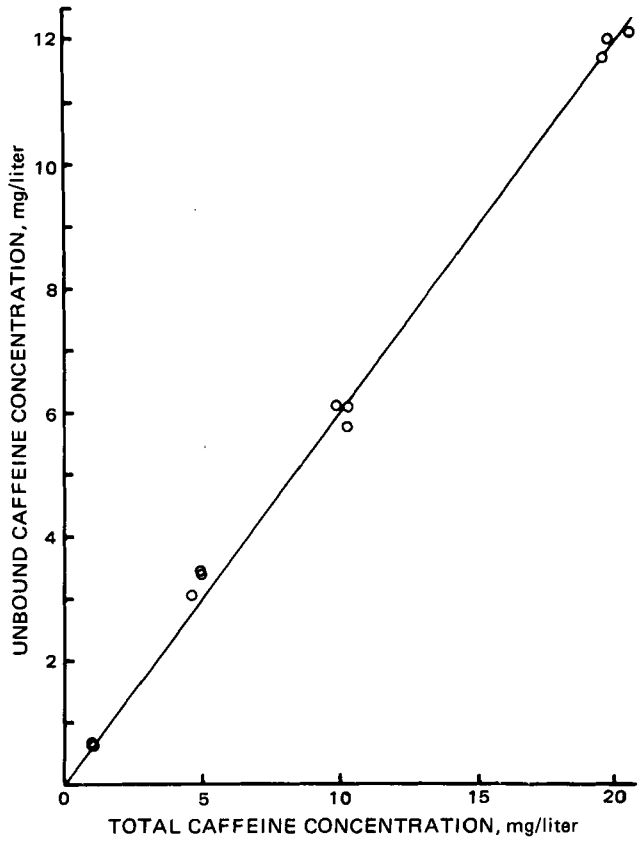

Figure 3—*Relationship between unbound and total concentrations for caffeine binding to human albumin (4.5% w/v)* in vitro. *The regression equation was* $D_f = 0.6012D_t (r^2 = 0.9964)$.

Table II—Calculated Binding Constants for the Interaction of Caffeine with Human Albumin and Human Plasma

Protein-Containing Sample	Binding Association Constant, K (liters/mole)
Human albumin in pH 7.4 buffer	0.958×10^3 (0.932×10^3)[a]
Human plasma from young subjects	0.839×10^3 (0.826×10^3)
Human plasma from elderly subjects	0.918×10^3 (0.902×10^3)

[a] Values in parentheses were calculated using Eq. 3, which assumes that the binding (β) is maximal. The similarity of the respective association constants calculated by each method indicates that drug concentrations are sufficiently low for binding to be nearly maximal.

binding of caffeine to albumin of 1.02×10^3 liters/mole reported previously (16). A 4.5% w/v albumin solution was utilized, since this value represents normal levels in humans and falls within the mean values for plasma albumin found in the two subject groups used in this study. In addition, the plasma binding experiments were performed at 37° using freshly collected (unfrozen) plasma, in view of previous reports (17–19) that the freeze–thaw process may alter drug binding. Thus, the results obtained here should be an accurate indication of the actual binding characteristics of caffeine *in vivo*.

While the binding of caffeine to human plasma is not extensive, and therefore not likely to exert a major influence on its overall pharmacokinetic behavior, a knowledge of the degree of binding over the usual therapeutic range (5–20 μg/ml) could prove useful when monitoring plasma caffeine concentrations in premature infants with apnea (8). These data could also be valuable when studying the effects of various diseases, other drugs, *etc.*, on the clearance of caffeine, since the clearance of unbound drug will be a more accurate indicator of the metabolizing capability of the liver than will the clearance of total (free + bound) drug (20).

Activity of Sodium Ricinoleate Against *In Vitro* Plaque

JOYCE J. MORDENTI *x, **RICHARD E. LINDSTROM**, and **JASON M. TANZER** ‡

Received September 1, 1981, from the *Department of Pharmaceutics, School of Pharmacy, University of Connecticut, Storrs, CT 06268.* Accepted for publication February 26, 1982. *Present address: Department of Medical Research, Hartford Hospital, Hartford, CT 06115. ‡Present address: Department of Oral Diagnosis, School of Dental Medicine, University of Connecticut Health Center, Farmington, CT 06032.

Abstract □ The antiplaque activity of sodium ricinoleate was studied *in vitro* against intact preformed plaques of *Streptococcus mutans*. The data obtained suggest that sodium ricinoleate may not interfere with *in vivo* plaque formation by *S. mutans*; however, there is some evidence that sodium ricinoleate may render these plaques less acidogenic.

Keyphrases □ Sodium ricinoleate—activity against *in vitro* dental plaque, bacterial formation □ Dental plaque—activity of sodium ricinoleate against bacterial formation, *in vitro* □ Bacterial formation—activity of sodium ricinoleate against *in vitro* dental plaque

The relationship between structure and bactericidal properties for numerous straight-chain fatty acids and derivatives has been studied (1, 2). The antimicrobial activity of fatty acids was shown to be a function of chain length, unsaturation, conformation, and functional groups. *Cis* monoenoic and dienoic C_{18} fatty acids were the most inhibitory (1), and unsaturation at the 2, 7, or 8 position gave the greatest biological activity (2). Long-chain fatty acids have limited solubility in water, and they are difficult to manipulate in most test situations; therefore, the aqueous soluble salt of a fatty acid which had several of the desirable antimicrobial features identified previously (1, 2) was examined as a novel antiplaque agent. Sodium ricinoleate [$CH_3(CH_2)_5CH(OH)CH_2CH{=}CH(CH_2)_7COO^-Na^+$], a *cis*-monoenoic C_{18} fatty acid salt, but with unsaturation at the 9 position, has attracted considerable attention due to its detoxifying, bactericidal, and anticalculus properties (3–15). Considering these studies and that sodium ricinoleate is extremely surface active, it was hypothesized that sodium ricinoleate could inhibit plaque formation and retention in the oral cavity through three possible modes of action: (*a*) antiadherent effect (coating the teeth with a repellent monolayer), (b) antibacterial effect (attaining bactericidal concentrations at the tooth surface, in the gingival sulcus, and in the intact plaque), and (*c*) detergent effect (breaking up the plaque for mechanical removal).

Although plaque has a mixed bacterial composition *in vivo*, there is a strong association between heavy infection by *S. mutans* and caries in humans and experimental animals (16–20), between the topographical localization of lesions on the enamel with overlying heavy colonization of *S. mutans* on that tooth site (21, 22), and between that colonization event and the subsequent inception of a lesion below the site of colonization (21, 23). Consequently, sodium ricinoleate's antiplaque activity was tested against *S. mutans*—the organism commonly associated with dental caries.

An *in vitro* assay had to be chosen which would reasonably simulate oral conditions and which would allow determination of dose–response relationships. In addition, the assay had to be reproducible, easily executed, inexpensive, and produce results in a minimum of time. *In vitro* tests have been developed in which model plaque specimens are formed on glass, wire, agar, bovine enamel, ceramic hydroxyapatite, and human teeth (24). After assessing the merits of each technique, the wire method (25–28) was chosen as the *in vitro* assay system to be used in this study. Growth of plaque on wires has received criticism in the past because wire is neither tooth enamel nor is it pellicle-coated (29). However, it has been shown (30) that plaque formation by *S. mutans* on enamel correlates closely (with and without salivary pellicle) with that on nichrome wires at both electron microscopic and biochemical levels. The wire model for bacterial attachment is a good predictor of bacterial–enamel interactions with this organism.

EXPERIMENTAL

Materials and Methods—Sodium ricinoleate[1] and chlorhexidine digluconate[2] were studied. *S. mutans* 6715-13 was studied; its properties with respect to a variety of antiseptics is typical of strains of *S. mutans* (26–28). The organisms were maintained by monthly transfer to fresh fluid thioglycollate medium containing 20% (v/v) meat extract[3] and excess calcium carbonate. Cultures were stored at 4°.

Minimum Inhibitory Concentration and Minimum Bactericidal Concentration for Bacterial Suspension—The minimum inhibitory concentration of sodium ricinoleate against *S. mutans* in complex medium (31) with 5% (w/v) sucrose, 0.005% (w/v) sodium carbonate, and bromocresol purple pH indicator (2 mg/liter) was determined by the macrobroth dilution method (32). (The pH indicator was incorporated into the culture fluid to visually detect acid production: a color change from purple (pH > 6.8) to yellow (pH < 5.2) denoted acid production.) The test was then repeated to measure the minimum bactericidal concentration as a function of time for various concentrations of sodium ricinoleate. At hourly intervals, the color of each solution was noted, and one loopful of each solution was plated on blood agar to detect viable organisms.

Minimum Bactericidal Concentration and Minimum Killing Time for Intact Plaque—Plaque was grown on #20 nichrome wires using a previous method (26). In that method 0.1 ml of an overnight culture of *S. mutans* in fluid thioglycollate was transferred to 150 × 18-mm culture tubes containing 10 ml of sterile complex medium (31) with 5% sucrose and 0.005% sodium carbonate. The nichrome wires, fixed to culture tube closures, were suspended in this bacterial broth for 24 hr at 37°. The wires were transferred daily to fresh medium until the wire-adherent microorganisms (*in vitro* plaques) had grown to a McCabe rating of 4 (25). Then the wires were transferred for 2 hr to fresh broth, rinsed free of broth in sterile distilled water, and immersed for varying times in 10 ml of aqueous sodium ricinoleate (1–10%) or control agents (0.2% chlorhexidine[4] and sterile distilled water). After treatment, the plaque samples were rinsed twice in 15 ml of sterile distilled water and transferred to fresh complex medium containing 5% sucrose, 0.005% sodium carbonate, and bromocresol purple pH indicator. The plaque samples were judged to have been killed when culture acid production

0	Yes	>24	<5.2

[a] Detected as an increase in turbidity. [b] As determined by the bromocresol purple pH indicator that was incorporated in the culture fluid.

stopped [*i.e.*, lack of a color change from purple (pH > 6.8) to yellow (pH < 5.2)], by a lack of increase in culture turbidity, and by the failure of 24-hr posttreatment plaque samples to grow when plated on either blood agar or *mitis salivarius* agar.

Penetration Through the Plaque Barrier—Immature wire-adherent plaques were grown to a McCabe rating of 1. The wires were immersed for 10 min in either 10% sodium ricinoleate or control agents (sterile distilled water and 0.2% chlorhexidine[4]), and the antibacterial effects of the agents were tested as detailed above.

RESULTS AND DISCUSSION

Minimum Inhibitory Concentration and Minimum Bactericidal Concentration for Bacteria in Suspension—*S. mutans* was selected as the test organism because it has been identified as a plaque producer associated with lesions (16–23). The minimum inhibitory concentration against *S. mutans* was determined to be 1% (or 3.12×10^{-2} *M*) sodium ricinoleate. During the minimum inhibitory concentration testing, four distinct concentration-dependent cell growth and acid production phenomena were identified: (*a*) no cell growth, medium pH[5] > 6.8; (*b*) cell growth[6], medium pH > 6.8; (*c*) cell growth, medium pH 5.2–6.8; and (*d*) cell growth, medium pH < 5.2. To better characterize these phenomena and to determine the minimum bactericidal concentration as a function of time, another experiment was conducted in which the pH of each culture and the viability of the organisms were examined over a 24-hr period (Table I).

Minimum Bactericidal Concentration and Minimum Killing Time for Intact Plaque—*S. mutans* formed uniform wire-adherent plaque specimens. When the plaque specimens had reached a McCabe rating of 4, they were placed in treatment solutions for 10 min according to the method described in *Experimental*. Although 0.2% chlorhexidine killed the plaque specimens, the sodium ricinoleate (1–10%) treatments and the distilled water controls were unable to do so. The plaques that had been in the sodium ricinoleate treatment group showed a sizable lag time in detectable acid production when compared with the distilled water control group. This lag time increased with increasing concentrations of sodium ricinoleate.

To test the effects of increased treatment time upon plaque viability, those that had reached a McCabe rating of 4 were submerged for varying times in 1% sodium ricinoleate, 0.2% chlorhexidine, or distilled water. Even after 18 hr of treatment, the plaques remained viable in both the sodium ricinoleate and distilled water groups; however, the 1% sodium ricinoleate group showed a marked delay in reduction of medium pH when compared with the distilled water controls (Table II).

The minimum bactericidal concentration of sodium ricinoleate against *in vitro* plaques of *S. mutans* was not established because concentrations of sodium ricinoleate >10% and treatment times >10 min are beyond the conditions that would be clinically acceptable.

[5] As determined by the bromocresol purple pH indicator incorporated in the culture fluid.

[6] Detected as an increase in culture turbidity.

Table II—Effects of Varying Duration of Treatment Upon the Ability of *Streptococcus mutans* in Intact Plaque to Lower the Culture Fluid pH < 5.2[a]

Length of Treatment, Hr	Hours Between Treatment and Detection of Acid: 1% Sodium Ricinoleate	Distilled Water	0.2% Chlorhexidine
1	24	24	—[b]
7	48	24	—
18	72	36	—

[a] As determined by the bromocresol purple pH indicator that was incorporated in the culture fluid. [b] Chlorhexidine (0.2%) kills the plaque within 10 min; therefore, the plaque specimens were not viable and did not produce acid.

It is possible that agent adsorption to saliva-coated surfaces *in vivo* could play a significant role in the pharmacodynamics of any plaque antiseptic. However, this is of significant interest only if the agent shows appreciable potency. The test conditions used (≤7 hr of direct plaque exposure to 1% ricinoleate being required to evidence any antimicrobial effect) strongly suggest that even substantial adsorption–desorption would only trivially affect potency. Thus, no assessment was made of agent binding *per se*.

When the experiments were completed, the ease of plaque removal was examined in the sodium ricinoleate and distilled water treatment groups; in both groups the plaque remained firmly attached to the wires. A qualitative difference was not evident between the two groups.

Penetration Through the Plaque Barrier—Wires with only minimal plaque accumulation (McCabe rating of 1) were immersed for 10 min in 10% sodium ricinoleate, distilled water, or 0.2% chlorhexidine. At the end of the testing, the plaque specimens treated with 10% sodium ricinoleate or distilled water remained viable. Again, a sizable delay in detectable acid production, in some instances as great as 3 days, was observed following the sodium ricinoleate treatment. These data suggest that the outer layer of cells and glucan matrix of *S. mutans* plaque constitute a diffusion barrier to sodium ricinoleate, allowing a small number of *S. mutans* to survive.

CONCLUSIONS

The recognition of the important role of dental plaque in the pathogenesis of caries, gingivitis, and periodontal disease has prompted many investigators to search for chemical agents capable of either inhibiting or removing dental plaque. Useful antiplaque agents may be ones that quickly inhibit bacterial attachment to the tooth surface, kill intact plaque, and/or assist in the removal of attached plaque and matrix. The ideal agent must be effective at a concentration that is nontoxic to humans and nonirritating to the oral mucosa.

In the preliminary minimum inhibitory concentration and minimum bactericidal concentration experiments, sodium ricinoleate was shown to possess bactericidal activity against the representative *S. mutans* strain 6715-13. In later experiments, wire-adherent plaque specimens were treated with various concentrations of sodium ricinoleate for varying lengths of time. In all tests, the intact plaque samples survived. The ability of sodium ricinoleate to kill bacteria in suspension, but not in intact plaque, clearly demonstrates the lack of a correlation between antibacterial activity against cells in suspension and antiplaque activity (9, 26, 29).

The treatment of intact plaque with sodium ricinoleate brought about a noticeable decrease in detectable acid production; the effect became more pronounced with increasing concentrations of sodium ricinoleate. This reduced acidogenicity can be due to the buffering of acidic bacterial end-products by sodium ricinoleate; the increased bacterial killing with increased concentrations of sodium ricinoleate; and/or the reversible effects such as inhibition of metabolic processes, as has been shown for a number of long-chain fatty acids (34). By reducing the acidogenicity of established plaque, sodium ricinoleate may exert a clinical effect upon the cariogenicity of plaque caused by *S. mutans* even if plaque formation by this organism is not totally prevented.

Use of Continuous Withdrawal Technique to Estimate the Initial Area Under the Curve

Keyphrases □ Continuous withdrawal technique—estimation of the initial area under the plasma concentration–time curve □ Pharmacokinetics—use of the continuous withdrawal technique to estimate the initial area under the plasma concentration–time curve □ Clearance—use of the continuous withdrawal technique to estimate the plasma concentration–time curve

To the Editor:

Recently it was pointed out (1) that the instantaneous input hypothesis of the conventional compartmental models may overestimate the area under the plasma concentration *versus* time curve (*AUC*). It was shown that the *AUC* of furosemide could be overestimated, using extrapolation to time zero, by as much as 20% in the dog. This is consistent with data found for Evans blue when used to measure cardiac output (2). In the first 12 sec after an intravenous bolus injection, no dye could be found in the arterial blood; then, the concentration rose gradually, not reaching a peak for several more seconds. Thereafter, it declined for 10 sec before it rose again to a second, lower peak at ~38 sec.

Based on physiological considerations, the delay could be explained as the time needed to reach the sampling site from the administration site, with the second peak perhaps resulting from recirculation of the dye. This phenomenon is important for drugs with a fast initial decline, particularly where the initial phase potentially contains a significant portion of the *AUC*. It is the purpose of this communication to illustrate an ideal method for determination of the *AUC* in the initial period which reflects accurate values, regardless of distribution and elimination rates and sampling sites. This method is based upon the continuous sampling technique described previously (3) to determine various pharmacokinetic parameters, and has been used in our laboratory for several years with good success (4).

A peripheral vein was cannulated prior to the start of the study to facilitate constant blood withdrawal. The drug was then administered in another vein after initiating the constant withdrawal.

The amount of drug in collected plasma, A_w, withdrawn over time t, when a constant blood withdrawal at rate $\dot{V}$ is carried out, can be obtained from:

$$A_w = (1 - H)\dot{V} \int_0^t C dt \qquad \text{(Eq. 1)}$$

where C is the concentration of drug in the plasma at any time, and H is the hematocrit. The area under the curve, $\int_0^t C dt$, in the time period, t, therefore, can be obtained by the ratio $A_w/[\dot{V}(1 - H)]$. Because the plasma drug amount withdrawn is equal to the total volume withdrawn, V_w, multiplied by the plasma concentration in the withdrawn sample, C_w, and because:

In the first 12 sec after an intravenous bolus injection, no dye could be found in the arterial blood; then, the concentration rose gradually, not reaching a peak for several more seconds. Thereafter, it declined for 10 sec before it rose again to a second, lower peak at ~38 sec.

Based on physiological considerations, the delay could be explained as the time needed to reach the sampling site from the administration site, with the second peak perhaps resulting from recirculation of the dye. This phenomenon is important for drugs with a fast initial decline, particularly where the initial phase potentially contains a significant portion of the *AUC*. It is the purpose of this communication to illustrate an ideal method for determination of the *AUC* in the initial period which reflects accurate values, regardless of distribution and elimination rates and sampling sites. This method is based upon the continuous sampling technique described previously (3) to determine various pharmacokinetic parameters, and has been used in our laboratory for several years with good success (4).

A peripheral vein was cannulated prior to the start of the study to facilitate constant blood withdrawal. The drug was then administered in another vein after initiating the constant withdrawal.

The amount of drug in collected plasma, A_w, withdrawn over time t, when a constant blood withdrawal at rate $\dot{V}$ is carried out, can be obtained from:

$$A_w = (1 - H)\dot{V} \int_0^t C dt \qquad \text{(Eq. 1)}$$

where C is the concentration of drug in the plasma at any time, and H is the hematocrit. The area under the curve, $\int_0^t C dt$, in the time period, t, therefore, can be obtained by the ratio $A_w/[\dot{V}(1 - H)]$. Because the plasma drug amount withdrawn is equal to the total volume withdrawn, V_w, multiplied by the plasma concentration in the withdrawn sample, C_w, and because:

$$(1 - H)V = V_w/t \qquad \text{(Eq. 2)}$$

the following is obtained:

$$\int_0^t Cdt = C_w t \qquad \text{(Eq. 3)}$$

By keeping a constant withdrawal of blood and measuring the concentration of drug in the sample and the time of withdrawal, the *AUC* can readily and accurately be determined without the problems of extrapolation.

This method is especially valuable in the time just after administration of an intravenous bolus dose, because no assumptions regarding the distribution and elimination need to be made. At later time points, when it is more desirable to determine the various rate constants, the continuous withdrawal can be terminated and individual blood samples then can be taken.

We have used this method extensively for indocyanine green clearance in rabbits, where the initial half-life after a 0.1-mg/kg iv. bolus dose is ~0.8 min. Approximately 40–60% of the total area can be estimated to be located between 0 and 1 min if an extrapolation is carried out when the first sample is taken at 1 min. However, when a continuous withdrawal is carried out, only 20–30% of the total area is obtained in the first minute. Therefore, as much as a 1.5- to twofold underestimation of the clearance can be made when using single venous plasma concentration time points with extrapolation, rather than a continuous withdrawal technique for indocyanine green clearance in rabbits.

Schiff Base Formation with Nitrogen of a Sulfonamido Group

Keyphrases □ Benzothiadiazones—Schiff base formation with the nitrogen of a sulfonamido group □ Schiff bases—formation with the nitrogen of a sulfonamido group □ Colored complexes—Schiff base formation with the nitrogen of a sulfonamido group

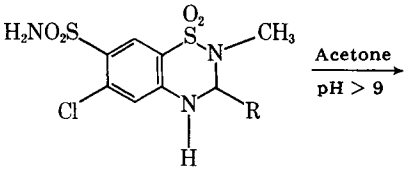
To the Editor:

Recently an unexpected result was reported (1): A violet-colored compound was reported to have formed on TLC plates when benzothiadiazines (I) were sprayed with acidified *p*-dimethylaminobenzaldehyde (II). Hennig *et al.* (1) stated that the type of colored complex formed between I and II was difficult to postulate, since there was no apparent record of Schiff base formation with the nitrogen of a sulfonamido group. We have an explanation that attempts to rationalize the formation of this colored complex.

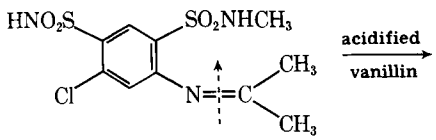
Our studies with polythiazide (I*a*) have shown that II as well as acidified vanillin (II*a*) form a violet-colored compound. We have identified this compound to be a product of a double aldol condensation between acetone, used as the solvent for spotting I, and II or II*a* to form in each case, respectively, substituted distyryl ketone (V).

Bahner and Schultze (2) reported the formation of divanillylidene acetone (V*a*) in a photometric estimation of acetone. Compound V*a* is yellow in alkaline solutions and develops into a pink-violet color when acidified with hydrochloric acid.

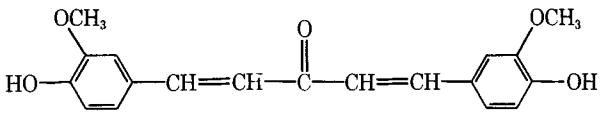
We have noted that at pH 9 polythiazide partially decomposes into 4-amino-2-chloro-5-(methylsulfamyl)-benzenesulfonamide (VI). Compound VI reacts with acetone to form a Schiff base (see Scheme). The ionized form of this Schiff base has an R_f = 0.55 in an ethyl acetate–benzene (8:2) system. When sprayed with acidified vanillin, the Schiff base hydrolyzes and the acetone thus liberated reacts with vanillin to give a violet-colored spot on the chromatograms. A similar reaction takes place with acidified *p*-dimethylaminobenzaldehyde used as a spray reagent.



I



VI schiff base



V*a*

Vanillin is often used as flavoring to mask the unpleasant taste of polythiazide tablets. If the alcohol that is used as a granulating liquid contains acetone as an impurity, the reaction in the Scheme may cause an incompatability problem resulting in colored granules.

Vanillin is often used as flavoring to mask the unpleasant taste of polythiazide tablets. If the alcohol that is used as a granulating liquid contains acetone as an impurity, the reaction in the Scheme may cause an incompatability problem resulting in colored granules.

Calculation of the Nucleophilic Superdelocalizability by the CNDO/2 Method

Keyphrases □ Structure–activity relationships—calculation of the nucleophilic superdelocalizability by the CNDO/2 method, perturbation theory □ Perturbation theory—calculation of the nucleophilic superdelocalizability by the CNDO/2 method, structure–activity relationships □ Nucleophilic superdelocalizability—calculation by the CNDO/2 method, perturbation theory, structure–activity relationships

To the Editor:

In the application of the perturbation theory to the search of structure–activity relationships (1–3), there is an approximation that consists of replacing energies of the virtual molecular orbitals of the receptor by a constant. This replacement, expressed in previous reports (1, 4), leads to the appearance of the nucleophilic superdelocalizability index, S^N, of the atoms of a drug, in the expression relating the equilibrium constant to molecular structure factors. This index is usually calculated with semiempirical methods, like CNDO/2[1] (3) or INDO (2). The S^N index of the atom p is defined as:

$$S_p^N = 2 \sum_n \sum_j^{AO} \frac{C_{jn}^2}{E_n} \qquad \text{(Eq. 1)}$$

where n is the virtual molecular orbitals, E_n is the energy of the nth virtual molecular orbital, the summation on j is over the atomic orbitals (AO) of the atom p that contribute to the basis, and C_{jn} is one Linear Combination of Atomic Orbitals (LCAO) coefficient.

For one N electron system with a basis of t AOs, the CNDO/2 method produces $N/2$ occupied molecular orbitals and $(t - N/2)$ virtual molecular orbitals. These virtual molecular orbitals cannot be regarded as suitable for the description of the excited states of the system.

With the aim of examining the dependence of the CNDO/2 S^N values on the conformation, we have analyzed the value of this index for several rotamers in a group of molecules. Presented here are the results for the amine nitrogen and the carbon atom where the hydroxide group is attached, for six rotamers of the p-hydroxy-β-phenylethylamine in its basic and protonated form (Table I). For comparison, we present also the net charges and the electrophilic superdelocalizabilities of these atoms. The relative positions of the hydroxide group and the amine chain are referred to by *cis* and *trans*; parallel (//) and perpendicular ($\perp$) refer to the position of the substituents in relation to the phenyl ring. The geometry employed is composed of bond angles and bond distances normally found in crystallographic studies.

From Table I it can be seen that the values of Q and S^E do not change significantly between the different rotamers in the basic and protonated forms. The S^N index does not change in the basic rotamers; the protonated rotamers show profound changes, but these do not seem to show any relation with the conformation. Negative S^N values are due to the appearance of virtual molecular orbitals with negative energies.

Table I—Reactivity Indexes of the Nitrogen and Carbon (Hydroxide) Atoms of some Rotamers of the p-Hydroxy-β-Phenylethylamine

Form	Position of the —OH and Ethylamine Groups[a]	Q_c	S_c^E	S_c^N	Q_N	S_N^E	S_N^N
Basic							
	N //, O $\perp$	0.1588	−4.6864	13.2226	−0.2502	−7.0713	7.1340
	cis, N $\perp$, O $\perp$	0.1542	−4.7115	13.0695	−0.2477	−7.0288	7.2308
	trans, N $\perp$, O $\perp$	0.1542	−4.7120	13.0661	−0.2477	−7.0328	7.2234

	trans, N //, O //	0.1655	−4.6549	13.1981	−0.2502	−7.0761	7.1255
	N $\perp$, O //	0.1609	−4.6802	13.0521	−0.2477	−7.0364	7.2158
Protonated							
	N //, O $\perp$	0.1816	−3.9527	84.9492	−0.0275	−3.9295	−81.9167
	cis, N $\perp$, O $\perp$	0.1810	−3.9575	−8.1637	−0.0268	−3.9247	−331.5201
	trans, N $\perp$, O $\perp$	0.1809	−3.9588	−15.6034	−0.0268	−3.9258	−409.2566
	cis, N //, O //	0.1878	−3.9273	54.8285	−0.0275	−3.9299	−371.0407
	trans, N //, O //	0.1877	−3.9281	44.8999	−0.0274	−3.9307	−563.3219
	N $\perp$, O //	0.1877	−3.9330	−32.9728	−0.0268	−3.9265	−621.9106

[a] The symbols // and $\perp$ indicate parallel and perpendicular positions, respectively, in relation to the phenyl ring.

Table II—S^N Value for the Nitrogen Atom in Some β-Phenylethylamines

Substituent	S^N
o—OCH_3	780.0266
m—OCH_3	77.0958
p—OH	−371.0407
p—CH_3	586.3877
—H	−302.6347

In Table II we present the S^N values for the nitrogen atom in a group of protonated β-phenylethylamines. All of the substituents are coplanar with the phenyl ring. Even so, the nitrogen S^N values seem to show no relation with the substitution.

Perhaps this lack of correlation between S^N and molecular structure in protonated molecules could explain why in some quantum chemical studies the S^N indexes do not appear, or, when they do, their t values are low.

This analysis strongly suggests that the S^N values obtained with the CNDO/2 method must be employed with caution in structure–activity studies.

Considering that a great number of molecules act in a protonated form and that the exact position of the substituents at the receptor level is not known, it seems necessary to define an S^N index that shows the same dependence on the conformation as the S^E index and the net charges.

Comments on the USP XX Gas Chromatographic Analysis of Alcohol in Drugs and Drug Formulations

Keyphrases □ GC—USP XX GC analysis of alcohol in drugs and drug formulations □ Alcohol—USP XX GC analysis in drugs and drug formulations

To the Editor:

The analysis of the alcohol content in drug formulations is a part of not only elixir and tincture monographs but also is included as a limit test for residual alcohol from the synthesis of some drug substances.

The performance of a divinylbenzene polymer for the GC analysis of alcohol was described previously (1), and it was concluded that there were definite advantages with the use of porous polymer beads for the analysis of alcohol in pharmaceuticals. In 1975 the 12th edition of the "Official Methods of Analysis of the Association of Official Analytical Chemists" (2) adopted a GC method for the analysis of alcohol in drugs which was based on a collaborated method developed previously (3). This procedure utilized a flame ionization detector and a column packed with a 80–100 mesh copolymer of ethylvinylbenzene and divinylbenzene[1] (I) operated at 130° with a retention time of ~5 min for acetonitrile, the internal standard. The USP XX (4) changed the chromatographic procedure for alcohol to essentially that cited previously (3). The change of the column packing to I was an improvement in the USP method since it eliminated interferences caused by column bleed and the late elution of water experienced with the earlier polyethylene glycol column. Unfortunately, it now appears that a suitable grade of I is no longer commercially available.

Data to support this conclusion was developed during a recent evaluation of the alcohol analysis for dexamethasone elixir.[2] Six lots of I, including both the 80–100 and 100–120 mesh sizes, were evaluated to determine the extent of the problem. These lots represent commercially available materials between 1976 and 1981. Both coiled and U-shaped glass columns were packed and used with three different gas chromatographs[3]. Even though both the temperature and the nitrogen flow rate were adjusted, complete baseline separation of the alcohol and acetonitrile peaks was not achieved with any lot of Compound I. The alcohol peak also exhibited marked tailing, which was not present in the chromatograms published by Falcone (3) or those by Hollis (5) who did some of the first experimental work with porous polymer beads. The acetonitrile peak remained symmetrical regardless of packing pretreatment, column temperature, or whether injected alone or with alcohol. Tailing of the alcohol peak can be reduced by either the chloroform soxhlet extraction of I prior to packing the column or by raising the column temperature. The change in resolution can be attributed to the interaction of alcohol with residual polymerization compounds in I. Tailing and resolution factors calculated during this evaluation are listed in Table I.

During conditioning, current lots of I released vapors suggestive of the drying oils found in paints. This odor can also be detected in the bulk packing container, yet the remainder of a bulk lot which was received in 1968 is odorless. The difference in the odor itself indicates that there has been some change in the polymer synthesis which introduces different residual compounds. IR analysis of the oily residue extracted with chloroform showed that at least three compounds are vaporized during column conditioning. A brochure (6) distributed by the manufacturer of I states that "... any residual chemical in the bead can contribute to spreading of the peak, change in retention time, or loss of resolution." This brochure also recommends conditioning for at least 2 hr at 250°. All columns that were evaluated had been conditioned at 235° for 16 hr. One column that was conditioned for a second 16-hr period did not show any improvement in its performance. Only the 100–200 mesh lot, which was exhaustively extracted with chloroform, showed a reduction in the tailing of the alcohol peak. The observed experimental results substantiate the manufacturer's information about residual chemicals in the polymer beads, in that there has been a deterioration in peak resolution, and there is tailing for hydroxyl compounds which was not observed in the collaborative study (3). There is also great variation in column performance between different batches of I.

It is the opinion of this author that the data in Table I demonstrate that acetonitrile is no longer a suitable internal standard for the GC analysis of alcohol. Either the resolution factor or the alcohol tailing factor requirement of USP XX can be met but not both with the same set of chromatographic conditions and the 100–200 mesh size specified in the Alcohol Determination monograph. Of the lots tested, only one lot of 80–100 mesh met all the requirements, except for mesh size, of the system suitability test. A series of five replicate injections of the alcohol standard preparation onto this column had a relative standard deviation (*RSD*) of 2.98% for the peak height ratios, which is less than the 4.0% required by this system suitability test. The *RSD* for the peak area ratios from these same injections was 0.28%. The average result cal-

Table I—Ranges of Flow, Temperature, Retention Times, Tailing (T), and Resolution (R) for Alcohol and Acetonitrile Chromatographed on a Copolymer of Ethylvinylbenzene and Divinylbenzene [a]

Lot/Year	Temperature	Flow rate, ml/min	R	Alcohol		Acetonitrile	
				T	t_R [b]	T	t_R [b]
			80–100 Mesh				
Pre-1976	125°	61	1.2	1.2	4.78	1.0	6.32
N.D./1976	125°	65	1.6	1.6	3.96	N.D. [c]	5.26
1971/1979	115–130°	39–65	1.2–1.5	1.3	3.19–8.38	N.D.	4.13–10.82
010/1981	110–120°	50–64	2.0–2.4	1.1–1.5	5.76–8.74	1.0–1.1	7.84–12.06
			100–120 Mesh				
1850/1980	110–120°	54–62	1.3–1.4	N.D.	5.55–7.27	N.D.	712–9.33
1850/1980 [d]	160°	60	1.43	6.5	4.71	0.87	6.10
009/1981	115–120°	59	2.6–3.0	3.7–3.8	6.73–7.73	1.0–1.1	9.10–10.47
009/1981 [e]	120–165°	58–61	2.0–2.6	1.6–2.0	2.32–6.61	1.0–1.2	3.01–8.99

[a] USP XX system suitability test for the gas chromatographic analysis of alcohol specifies $R \geq 2$, T for alcohol ≤ 1.5, and a retention time between 5 and 10 min for acetonitrile. [b] Retention time in minutes. [c] Not determined. [d] Column had a 2.6-mm i.d. The difference in the alcohol tailing is attributed to interaction with the column walls. [e] The copolymer was extracted with chloroform for 3 hr and air dried prior to packing the column.

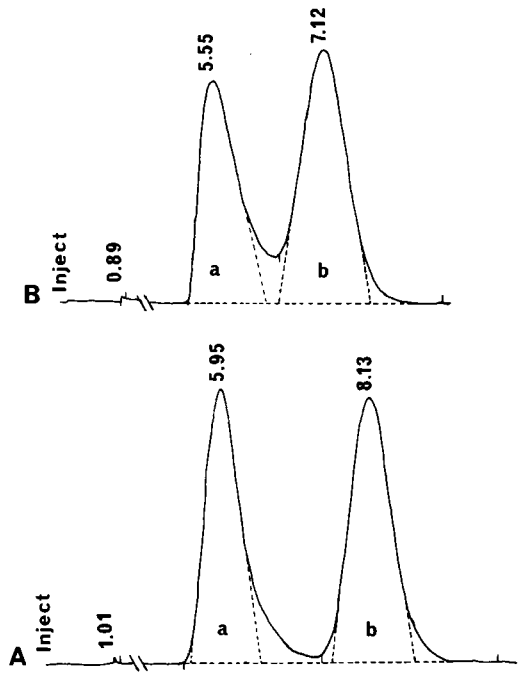

Figure 1—*Typical chromatograms on 80–100 mesh I, 120°, and attenuation of 2^{10} on lot 010 (59 ml/min) (A) and lot 1971 (54 ml/min) (B) for alcohol (a) and acetonitrile (b). Retention times are in minutes.*

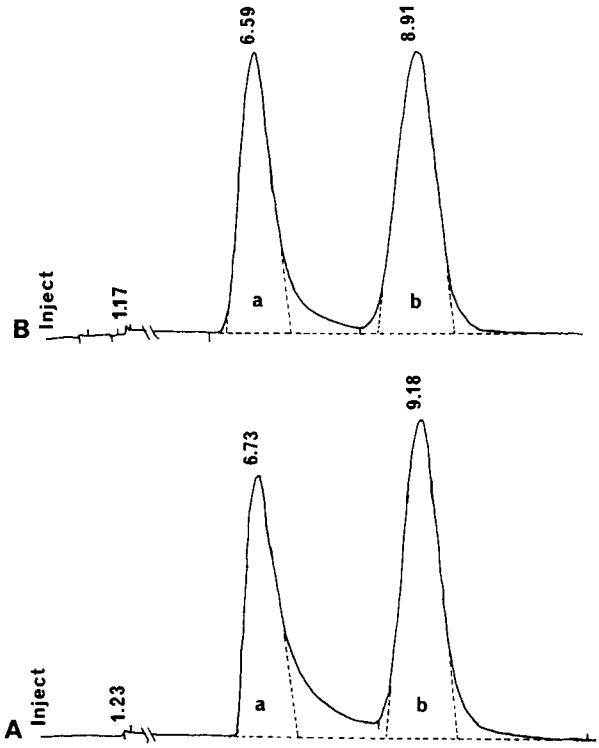

Figure 2—*Typical chromatograms on 100–200 mesh I, 120°, 58 ml/min, and attenuation of 2^{10} on log 009 (A) and lot 009 packed after chloroform extraction (B) for alcohol (a) and acetonitrile (b). Retention times are in minutes.*

culated from the peak height ratios had a 4.5% negative bias compared with a 99.5% recovery for area ratios. A series of 10 standard injections onto the chloroform pretreated 100–200 mesh packing had an *RSD* of 4.32 and 1.66% for the peak height and area ratios, respectively. The negative bias for the average result calculated from peak height ratios was 3.5% compared with a 99.3% recovery for peak areas. Reproducibility studies for the evaluation of each of the three possible internal standards (acetonitrile, methanol, 2-propanol) consistently produced data demonstrating that peak height ratios have larger relative standard deviations than peak area ratios. It was not uncommon to find a factor of 10 difference in the results. Greatest precision and accuracy can be achieved with peak area measurements.

Representative chromatograms for the 80–100 and the 100–120 mesh sizes of I are shown in Figs. 1 and 2, respectively. Inspection of the chromatograms in these figures shows that even when a resolution factor >2 is achieved, there is no baseline separation between the alcohol and the acetonitrile peaks. Clearly, a new internal standard is needed. A suitable internal standard should at least achieve baseline resolution from the sample peak, particularly when the sample peak is the only peak in the chromatogram. Either a new internal standard and a higher column temperature or a different column packing should replace those in the USP XX, in addition to a change to peak area ratios in the calculation formula. An alternative column packing might be the copolymer of styrene–divinylbenzene[4] (II). At 140° and 40 ml/min helium, 80–100 mesh II had retention times of 2.2 and 3.6 min for alcohol and acetonitrile, respectively. Resolution was 2.72. The tailing factor for alcohol was 1.8; that for acetonitrile, 1.3. Reproducibility was not evaluated for this

[4] Chromosorb 101, Johns-Manville, Denver, Colo.

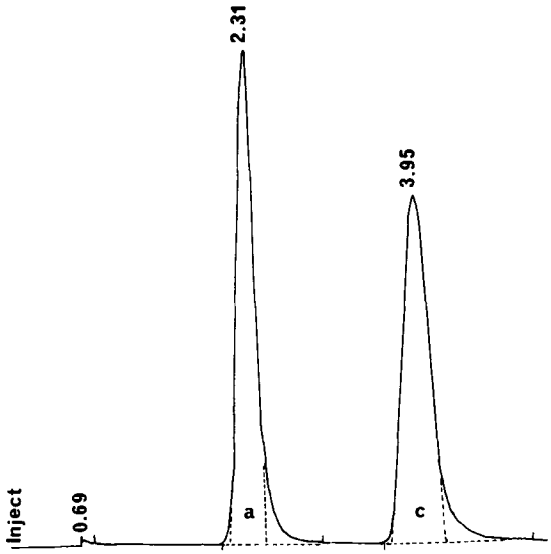

Figure 3—*Typical chromatogram for alcohol (a) and 2-propanol (c) on 100–120 mesh, I, 165°, 59 ml/min, and attenuation of 2^{11} on lot 009 packed after chloroform extraction. Retention times are in minutes.*

packing material. Before any recommendation to change to this polymer could be made, additional investigations would have to be performed to determine if the USP tailing factor for the alcohol peak could be met.

Work in this laboratory has identified 2-propanol as a suitable, readily available internal standard for the analysis of alcohol in drugs and drug formulations. At 165° and 59 ml/min nitrogen, alcohol and 2-propanol had retention times of 2.3 and 4.0 min, respectively, on a column packed with 100–120 mesh I which had been extracted with chloroform. Resolution was 4 with a tailing factor of 1.2 for alcohol and 1.5 for 2-propanol. Two sets of 10 replicate injections of 0.2% solutions of alcohol and 2-propanol had *RSD* values of 0.62 and 0.58% for peak area ratios. Peak height ratios were 4.70 and 7.62%, respectively. A second lot of 100–120 mesh I was tested using the same chromatographic conditions. The RSD for the peak area ratios of 13 standard injections that were interspersed throughout 22 sample injections was 1.42%. A representative chromatogram with a 2-propanol internal standard can be found in Fig. 3.

In the article titled "Spectrofluorometric Determination of Acetylsalicylic Acid, Salicylamide, and Salicylic Acid as an Impurity in Pharmaceutical Preparations" (1), the following correction should be made:

On page 641, the first section under *Background* should appear as shown here:

Methods for Salicylamide—To date, few fluorometric methods have been developed for the determination of salicylamide. Many of the current methods were designed specifically for the analysis of biological specimens and, therefore, contain steps unnecessary for pharmaceutical analysis (1–3). One major problem has been the presence of other salicylates that interfere with the direct determination of salicylamide. Additional steps to eliminate fluorescence interference from salicylic acid are needed for the many preparations containing acetylsalicylic acid and other fluorescent salicylates. Analysis by direct UV (4, 5) and differential UV (6) spectrophotometry are both subject to interferences. One visible spectrophotometric method (7) involves a chromophore-producing reaction with ferric chloride reagent.

In the article titled "Physicochemical Property Modification Strategies Based on Enzyme Substrate Specificities I: Rationale, Synthesis, and Pharmaceutical Properties of Aspirin Derivatives" (1) the following correction should be made:

On page 1302, Table IV, the data under Carboxypeptidase column should read as follows:

Aspirin Phenylalanine ethyl ester (I)	1.84×10^{-4}, 2.8×10^{-3}
Aspirin Phenylalanine amide (II)	1.84×10^{-4}, 2.8×10^{-3}

In the article titled "Physicochemical Property Modification Strategies Based on Enzyme Substrate Specificities III: Carboxypeptidase A Hydrolysis of Aspirin Derivatives" (2) the following correction should be made:

On page 1308, Table I, line 3 should read as follows:

Aspirin Phenylalanine[b] (I) 1.84×10^{-4} 2.8×10^{-3} — 15.2

In the article titled "Noncompartmental Determination of the Steady-State Volume of Distribution for Any Mode of Administration" (1) the following corrections should be made:

On page 373, Table I, the equation for two consecutive infusions should read as follows:

$$V_{ss} = \frac{\text{dose}}{AUC}\left[\frac{AUMC}{AUC}\frac{T_1}{2}\frac{AUC_1}{AUC} - \frac{T_2}{2}\frac{AUC_2}{AUC} - \Delta T\frac{AUC_2}{AUC}\right]$$

where dose is the total dose administered (750 mg), *AUC* is the total area under the concentration–time curve [1500 (μg/ml) hr], *AUMC* is the total area under the first moment of the concentration–time curve [41,000 (μg/ml) hr^2], T_1 and T_2 are the durations of the first and second infusions (2 hr and 6 hr), AUC_1 and AUC_2 are the total areas under the concentration *versus* time curves due to the first and second infusions [1000 and 500 (μg/ml) hr], and ΔT is the time interval between the infusions. This equation can be derived explicitly or obtained from the general relationship presented by Straughn (2).

On page 373, Table II should read as follows:

0022-3549/82/1200-1427$01.00/0

Table II—Calculation of V_{ss} for Various Modes of Administration [a]

Modes of Administration	AUC (μg/ml) hr	$AUMC$ (μg/ml) hr^2	$\frac{AUMC}{AUC}$ hr	$\frac{\Sigma \int_0^\infty X dt^b}{\Sigma \text{ dose}}$ hr	$\bar{t}_b$[c] hr	V_{ss}[d] L
IV bolus, 500 mg	1000.0[e]	25002.5[f]	25.0	0	25.0	12.5
IV infusion, 250 mg/hr over 2 hr	1000.0	26002.5[g]	26.0	1.0	25.0	12.5
First-order administration, 500 mg, $F = 1$, $k_a = 1.4$ hr^{-1}	1000.0	25716.8[h]	25.7	0.7	25.0	12.5
Bolus plus infusion, 500 mg bolus plus 250 mg/hr over 2 hr	2000.0	51005.0[i]	25.5	0.5	25.0	12.5

[a] Calculations based on equation, $C = A_1e^{-\lambda_1 t} + A_2e^{-\lambda_2 t}$, where $A_1 = 60.9545$ μg/ml, $\lambda_1 = 5.0605$ hr^{-1}, $A_2 = 39.0459$ μg/ml, and $\lambda_2 = 0.03952$ hr^{-1} following a 500 mg bolus dose. [b] See Table I. [c] See Eq. 13. [d] See Eq. 9. [e] $AUC = \Sigma_{i=1}^{n} A_i/\lambda_i$. [f] $AUMC = \Sigma_{i=1}^{n} A_i/\lambda_i^2$. [g] $AUMC = \Sigma_{i=1}^{n} A_i/\lambda_i^2 + T\,AUC/2$. [h] $AUMC = N/k_a^2 + k_aA_1/\lambda_1^2(k_a - \lambda_1) + k_aA_2/\lambda_2^2(k_a - \lambda_2)$, where $N = k_a$ dose $(k_{21} - k_a)/V_c(\lambda_1 - k_a)(\lambda_2 - k_a)$. [i] Equals f plus g.

In the article titled "Nitro- *para*- and *meta*-Substituted 2-Phenylindolizines as Potential Antimicrobial Agents" (1), the following corrections should be made:

On page 559 in the *Experimental* section for 1,3-Dinitro-2-phenylindolizine (XVIIIa), it is compound XVIIIa which was obtained in a 14% yield with mp 245–246° and appearing as one spot when analyzed by TLC.

On page 559 in the *Experimental* section for 2-(*p*-Nitrophenyl)indolizine (XIj), it is XIj which was obtained in 50% yield with mp 236–237°.

On page 560 in the *Experimental* section for 1,3-Dinitro-2(*m*-methoxyphenyl)indolizine (XVIIIe), it is compound XVIIIe which appeared as one spot when analyzed by TLC.
